This work is dedicated to my wife and sons, who have been ever patient and considerate in allowing me to pursue my academic interests. It is also dedicated to my mentors who believed in me and gave me the opportunity to grow. It is also dedicated to our patients who place their faith in our hands and who allow us the honor and privilege to continue to learn and better the art of medicine for a better tomorrow.

–Sijo J. Parekattil

To my father Waldemar Esteves (late) for instilling the virtues of integrity, perseverance, and enthusiasm. To my wife, Fabiola, my sons, Alexandre and Catarina, for their devotion, love, and support. To Prof. Nelson Rodrigues Netto Jr. (late) (UNICAMP), Prof. Anthony Thomas (late) (Cleveland Clinic), Prof. Sidney Glina (ABC University), and Prof. Ashok Agarwal (Cleveland Clinic) for their guidance and support and for being giants who take their apprentices by their hands and teach them how to climb; once on their shoulders they show us what to see, helping us to see better and further.

–Sandro C. Esteves

To my father Professor RC Agarwal (late) for instilling the virtues of honesty, dedication, and hard work. To my wonderful wife, Meenu, sons, Rishi and Neil-Yogi, for their unconditional love and support. To Prof. Kevin Loughlin (Harvard Medical School), Prof. Anthony Thomas (late) (Cleveland Clinic), and Prof. Edmund Sabanegh (Cleveland Clinic) for their friendship, guidance, and support and for making an indelible positive impression on my life. To my associates at work, large number of researchers and students, and most importantly the patients who placed their trust in our work.

–Ashok Agarwal

Foreword

I have been eagerly awaiting the release of the second edition of this text, *Male Infertility: Contemporary Clinical Approaches, Andrology, ART and Antioxidants*, which is edited by three luminaries in the field of reproduction, Sijo J. Parekattil, MD; Sandro C. Esteves, MD; and Ashok Agarwal, PhD. The first edition of this text served as an invaluable resource to those of us involved in the clinical care of couples encountering reproductive challenges and also to those of us investigating the pathophysiology underlying disordered fertility. In the same vein, this second edition builds upon the important principles shared in that first edition but also includes new and important insights that have been subsequently reported in both the basic science and clinical literature.

The editors have done a masterful job of assembling a panel of expert authors who are also fantastic writers. Each chapter is rich with important information, yet at the same time very pleasant to read. Additionally, while each chapter is a "stand-alone" piece of academic work, collectively, the chapters build upon one another to provide the reader with a truly 360-degree, state-of-the-art understanding of andrology, ART, and antioxidants.

In an era where the clinical and research focus in reproductive medicine often pivots solely to assisted reproductive techniques, this text does a wonderful job of comprehensively and holistically examining andrology, assisted reproductive techniques, and the role of antioxidants. The "winners" in all of this are the clinicians who will use this book to enhance the integrated and informed care that they are providing their patients, as well as the patients themselves, who are on the receiving end of this optimized care. The editors are to be congratulated for passionately assembling this important group of academic manuscripts. There is no doubt that countless couples will benefit from the collective knowledge and inspiration that this text imparts within reproductive clinicians and scientists alike.

Chicago, IL, USA — Robert E. Brannigan, MD

Preface

The practice of male infertility has dramatically evolved over the past few decades. This has been achieved after the realization of the important contribution the male counterpart holds in the couple's infertility. It is also supported by a number of breakthroughs in the diagnosis and treatment of this medical condition. The field of male infertility truly illustrates the need for a multispecialty approach to the effective diagnosis and management of such conditions. From the initial referral possibly from a reproductive endocrinologist or gynecologist to the male infertility urologist or andrologist, a multidisciplinary team including doctors, nurses, embryologists, technicians, researchers, and alternative medicine specialists needs to work as a cohesive unit to provide our patients with the most effective and highest quality care.

Due to the success of the first edition of this book in 2012, we decided to work on the second edition in 2018 with the goal to bring out a medical textbook that can serve as the most reliable source of accurate information on various aspects of the rapidly developing field of male infertility. This book was an attempt to gather experts from each of these fields and present an integrated management approach with detailed descriptions of topics ranging from the initial clinical diagnosis, management, new treatment options, and scientific rational for the various approaches. The book initially focuses on the clinical aspects of male infertility and then dives into the use of antioxidants as adjunctive therapy and the current state of affairs in antioxidant research. In this second edition, which includes 72 chapters in total across 7 parts, over 20 new chapters were added to enhance the book's appeal by including the most recent advances brought to the male infertility arena. Additionally, this edition has new features including video clips illustrating some of the most fascinating male infertility treatment modalities and a dedicated new part on current guidelines on male infertility and antioxidants to enlighten readers on how to most optimally manage male infertility clinical scenarios. The 129 contributing authors hail from leading institutions in 18 countries across 6 continents in an attempt to capture a wide range of techniques and approaches. New to this edition are dedicated sections within each chapter covering key points and review criteria, carefully bookended by introductory and concluding content that sets the stage for and sums up the state of the art in male infertility. We are hoping that this text may serve as a reference guide for specialists across the male infertility team to further enhance dialogue, discussion, and refinement in our multidisciplinary approach.

We would like to thank the authors for their contributions and our families for their patience in allowing us to put together this project. We wish to acknowledge the Glickman Urological & Kidney Institute at the Cleveland Clinic Foundation, the PUR Clinic with University of Central Florida, and Androfert Fertility Center for institutional support for this endeavor as well. We are grateful to Kristopher Spring, senior editor, for his support and advice, and to Michael D. Sova, developmental editor, for his tireless efforts in reviewing and editing each of the manuscripts. We hope that this book will provide a comprehensive, consolidated reference for a broad range of topics in male infertility.

About the Editors

Sijo J. Parekattil, MD is Co-director of PUR Clinic (Personalized Urology & Robotics) at South Lake Hospital and Orlando Health and Associate Professor of Urology at the University of Central Florida (UCF). He was an Electrical Engineer (University of Michigan) prior to his medical training and thus has interests in surgical techniques incorporating technology, robotics, and microsurgery. He completed his urology residency training at Albany Medical Center and then went on to complete dual fellowship training from the Cleveland Clinic Foundation, Cleveland, in Laparoscopy/Robotic Surgery and Microsurgery/Male Infertility.

Dr. Parekattil has received numerous awards and published several articles in the field of robotic microsurgery. He is an editor of a few textbooks on Male Infertility and a surgical textbook on Robotic Microsurgery. He is a pioneer in robotic microsurgery in urology. He has developed novel treatments for chronic groin and testicular pain. He is one of the founding board members of the Robotic Assisted Microsurgical and Endoscopic Society (RAMSES) and is on the foundation board for Florida Polytechnic University, Lakeland, FL.

Sandro C. Esteves is Medical and Scientific Director of ANDROFERT—Andrology and Human Reproduction Clinic—a referral Fertility Center for Male Reproduction in Brazil.

He earned his MD in 1990 from the University of Campinas (UNICAMP), Brazil, where he did residency training in General Surgery and Urology. He completed his training in the United States (1995–1996) as a Research Fellow at the Cleveland Clinic's Center for Reproductive Medicine. He was awarded a Master's degree in Surgery in 1998, at UNICAMP, and a PhD in Medicine (Urology) in 2001, at the Federal University of São Paulo (UNIFESP). Dr. Esteves is a board-certified Urologist by the Brazilian Society of Urology, and a certified-ART Center Director and IVF Consultant by the Brazilian Society of Assisted Reproduction.

Dr. Esteves is a Collaborating Professor in the Department of Surgery (Division of Urology) at the University of Campinas (Brazil) and Honorary Professor of Reproductive Endocrinology at the Faculty of Health, Aarhus University, Denmark. He is also Research Collaborator at the Cleveland Clinic's Center for Reproductive Medicine (USA). His major contributions in the

field of reproductive medicine have been in the area of male infertility and microsurgery, reproductive endocrinology, assisted reproductive technology, cleanroom technology, and quality management. His center, ANDROFERT, was one of the first centers, both in Brazil and worldwide, to introduce quality management and IVF cleanroom technology, and it is certified according to ISO 9001:2015 and ISO 14644-1 standards.

Prof. Esteves has published approximately 300 peer-reviewed scientific papers, authored over 80 book chapters, and presented over 150 papers at both national and international scientific meetings. His current Hirsch index is 46 (Google Scholar) while his citation count is more than 6000. Sandro is also a Faculty Member of F1000Prime in the area of reproductive endocrinology and infertility since 2016 and is a co-founder of Group POSEIDON (**P**atient-**O**riented **S**trategies **E**ncompassing **I**ndividualize**D** **O**ocyte **N**umber) (www.groupposeidon.com). He is also a member of the Society for Translational Medicine's male infertility cooperative group.

Dr. Esteves has served as an editor of eight textbooks related to male infertility, reproductive medicine, and assisted reproductive technology. He is also the guest editor of six special issues in scientific journals on topics related to reproductive medicine. He currently serves on the editorial board of several journals and is Associate Editor of *International Brazilian Journal of Urology* and *Frontiers in Endocrinology* (Reproduction).

Dr. Esteves is a much-requested international lecturer and gives approximately 50 lectures annually. He has been invited as guest speaker in over 40 countries. He is the recipient of the "Alumni of the Year" Award from the Cleveland Clinic Center for Reproductive Medicine, and consecutive Star Awards from the American Society for Reproductive Medicine for the last 6 years.

Ashok Agarwal, PhD, HCLD(ABB), ELD(ACE) is the Head of Andrology Center and Director of Research at the American Center for Reproductive Medicine since 1993. He holds these positions at The Cleveland Clinic Foundation, where he is Professor of Surgery (Urology) at the Lerner College of Medicine of Case Western Reserve University. Ashok was trained in Male Infertility and Andrology at the Brigham and Women's Hospital and Harvard Medical School and later worked as Assistant Professor of Urology at Harvard from 1988 to 1992. Ashok has over 26 years of experience in directing busy male infertility diagnostic facilities and fertility preservation services. He is very well published with over 730 scientific papers and reviews in peer-reviewed scientific journals and is ranked in Scopus as the #1 author in the world in the fields of Male Infertility/Andrology and Human Assisted Reproduction, based on the number of peer-reviewed publications, citation scores (Scopus: 32,001; Google Scholar: 67,039), and h-index (Scopus: 96; Google Scholar: 125). He is currently an editor of 39 medical text books/manuals related to male

infertility, ART, fertility preservation, DNA damage, and antioxidants and active in basic and clinical research. His laboratory has trained over 1,000 scientists, clinicians, graduate, and undergraduate students from the United States and more than 55 countries. His current research interests include proteomics of male infertility and the molecular markers of oxidative stress and DNA integrity in the pathophysiology of male reproduction.

Part I

Male Infertility Diagnosis and Management

Causes of Male Infertility

1

Graham Luke Machen and Jay I. Sandlow

Key Points

- The majority of the causes of male infertility may be either preventable or treatable.
- Pre-testicular causes of male infertility exert their negative effect via imbalances in the hormonal milieu of sperm production. Sexual function is also negatively impacted with effects seen at the level of erectile function, ejaculatory function, and sexual desire.
- Varicocele is a common modifiable cause of male infertility and negatively affects global testicular function through oxidative stress.
- Severe oligospermia or azoospermia requires genetic screening, given their high associated prevalence of Klinefelter's syndrome, karyotypic abnormalities, and microdeletion of the Y chromosome.
- Many testicular causes of male infertility (radiation, toxins, environmental factors, genital tract inflammation, varicocele, testicular hyperthermia) lead directly to sperm DNA damage.

1.1 Introduction

Of all sexually active couples, 12%–15% are infertile, of which a male component can be identified 50% of the time either in isolation or in combination with a female factor [1, 2]. Previous research in a US male fertility clinic analyzing 1430 patients identified causes of infertility from most to least common: varicocele, idiopathic, obstruction, female factor, cryptorchidism, immunologic, ejaculatory dysfunction, testicular failure, drug effects/radiation, endocrinology, and all others [3]. However, despite recent technologic and diagnostic advances, idiopathic infertility remains a common diagnosis, with approximately 25% of patients not having an identifiable cause of infertility [4, 5]. Regardless, many recognizable causes of male infertility are treatable or preventable; thus, a keen understanding of these conditions remains paramount. This chapter will provide an overview of the causes of male infertility, divided into pre-testicular, testicular, and post-testicular etiologies.

1.2 Causes of Male Infertility

1.2.1 Pre-testicular

1.2.1.1 Hypogonadotropic Hypogonadism

Hypogonadotropic hypogonadism (low or absent gonadotropins) affects fertility at multiple levels. Sperm production is deleteriously affected by a lack of testosterone (from low LH) and a lack of a stimulatory effect of FSH on the Sertoli/germ cell complex. Hypogonadism may also manifest itself through effects on sexual function, including sexual desire as well as erectile and ejaculatory dysfunction. There are many etiologies of hypogonadotropic hypogonadism. The most common include elevated prolactin, medications, illicit drugs, and pituitary damage. Idiopathic hypogonadotropic hypogonadism, including Kallmann syndrome, is another, albeit rare, cause of hypogonadotropic hypogonadism.

1.2.1.2 Elevated Prolactin

Elevated prolactin may cause hypogonadism by suppressing the release of GnRH. Symptoms of hypogonadism, especially erectile dysfunction and loss of libido, are the most common presenting symptoms in males with hyperprolactinemia, though galactorrhea and gynecomastia may also be evident [6].

G. L. Machen · J. I. Sandlow (✉)
Department of Urology, Medical College of Wisconsin, Milwaukee, WI, USA
e-mail: jsandlow@mcw.edu

S. J. Parekattil et al. (eds.), *Male Infertility*, https://doi.org/10.1007/978-3-030-32300-4_1

Elevated prolactin may be secondary to various etiologies. The most common of these is a prolactinoma, which typically arises from the pituitary gland. Because prolactinomas in men are more likely to manifest through mass effect, visual disturbances and headaches may be present [7]. Normal prolactin levels range from 2 to 23 ng/mL. In the setting of prolactinomas, the prolactin level frequently corresponds to tumor size. Specifically, levels typically range from 50 to 300 ng/mL in microadenomas but may be as high as 5000 ng/mL in patients with macroadenomas (greater than 1 cm in greatest dimension) [8, 9].

There are other significant causes for hyperprolactinemia as well. Prolactin elevation may be associated with common medical conditions, such as renal failure, hypothyroidism, and cirrhosis. Prolactin levels may also be elevated in certain systemic diseases such as systemic lupus erythematosus, rheumatoid arthritis, celiac disease, and systemic sclerosis. Many drugs elevate prolactin levels, especially those which block the effects of dopamine, such as antipsychotics [10].

1.2.1.3 Pharmacologic

Various medications may cause hypogonadotropic hypogonadism. Estrogens and progestins may cause a decrease in testosterone levels via negative feedback to the hypothalamic–pituitary–gonadal (HPG) axis. Marijuana is known to decrease testosterone levels by working on the endocannabinoid receptors present at multiple levels of the hypothalamic–pituitary axis [11]. Both ethanol and cannabinoids suppress GnRH secretion at the level of the hypothalamus. Endocannabinoid receptors have been found in the pituitary and so may also affect the hypothalamic–pituitary axis at that level as well [12].

LHRH agonists and antagonists are used for the treatment of prostate cancer, precocious puberty, and gender reassignment surgeries. These medications produce a tonically stimulated state which, unlike the physiologic circadian rhythmicity of normal LHRH stimulation, acts to decrease LH and FSH secretion.

Opioids may also produce profound hypogonadism; these medications bind to mu-receptors in the hypothalamus inhibiting the production and release of GnRH [13]. Of note, opioids may also directly inhibit spermatogenesis in the testis, and chronic opioid users have been shown to have decreased sperm concentration, motility, and increased DNA fragmentation [14, 15].

Another increasingly common medication resulting in infertility is exogenous testosterone replacement for hypogonadism. Testosterone downregulates the HPG axis, leading to a decrease in spermatogenesis [16]. Despite this established effect on fertility, many physicians, including urologists, still prescribe testosterone to hypogonadal men with infertility; in fact a recent survey found that 25% of urologists prescribed testosterone to men in this specific patient cohort [17].

1.2.1.4 Idiopathic Hypogonadotropic Hypogonadism and Kallmann Syndrome

Idiopathic hypogonadotropic hypogonadism (IHH) is a rare disorder caused by defects in gonadotropin-releasing hormone, including its action and/or release, in the setting of an otherwise normal HPG axis [18]. While the age and severity of presentation may vary, most commonly patients present during adolescence with failure to go through puberty. Other presenting symptoms may include anosmia, cleft palate, and hearing loss [19]. In the presence of anosmia, IHH is referred to as Kallmann syndrome, which affects 1 in 8000–10,000 males [20, 21]. The etiology is likely genetic, and multiple genes have been identified as playing a role in pathogenesis including *KAL1* [22, 23]. These most commonly manifest through the same mechanism whereby GnRH-secreting neurons fail to migrate to the hypothalamus. Lack of these neurons in the hypothalamus results in a lack of GnRH secretion and thus hypogonadism.

1.2.1.5 Testicular

Varicocele

A varicocele is a dilation of the pampiniform plexus likely caused by the absence or incompetence of the venous valves of the internal spermatic vein. Varicoceles have long been associated with infertility. The first written description is attributed to Celsius who noticed the association between the varicocele and testicular atrophy [24]. In the 1800s, surgical correction was seen to improve semen quality. It is the most common surgically correctable cause of male infertility. Roughly 12% of all men have a varicocele, but this number jumps to 35%–40% in men with infertility [25, 26].

Varicoceles may affect multiple semen parameters, including total sperm count, sperm motility, and sperm morphology [27, 28]. There are many theories about the underlying pathophysiology of a varicocele, with heat, renal metabolites, and hormonal abnormalities all playing a role. However, most agree that disruption of the countercurrent heat exchange mechanism in the testis, causing hyperthermia, is the most likely mechanism. Numerous studies point to impaired sperm production and a decrease in semen quality when scrotal temperatures are elevated [29–34]. One study showed that men with scrotal skin temperatures above 35 °C for >75% of the day had sperm concentrations of 33 million/mL as compared with densities of 92 million/mL in men with scrotal skin temperatures greater than 35 °C for <50% of the day [33].

The mechanism by which heat causes decreased sperm counts is poorly understood, but one hypothesis is that increased temperature could increase the metabolic rate of testicular and epididymal sperm. Regardless, men with varicoceles demonstrate increased reactive oxygen species and decreased antioxidant capacity, which may alter sperm DNA and can affect sperm maturation [35–37]. Furthermore, data has suggested that larger varicoceles may be associated with more profound oxidative stress [38, 39].

A somewhat controversial area with regard to the management of varicoceles is associated with hormonal abnormalities. It has been hypothesized that the pathophysiology associated with spermatogenesis may be applicable to Leydig cells and testosterone synthesis as well [40, 41]. Accumulating data supports this hypothesis of global testicular dysfunction, and by repair of the varicocele, testosterone may improve [42, 43]. In fact, a meta-analysis in 2012 found a mean improvement in testosterone of 97.5 ng/dL [44]. However, the evidence is somewhat mixed as to the degree of improvement, with several recent prospective studies demonstrating more modest testosterone increases [45–47]. Thus, the clinical implications of varicoceles and their effects on hypogonadism remain somewhat controversial.

Cryptorchidism

Cryptorchidism is well known to affect fertility. The severity of its effect on fertility is directly proportional to the severity of the cryptorchidism, with bilateral cryptorchidism having more severe effects than unilateral and with higher testes having worse function than lower testes [48–51].

Similarly, orchidopexy has been shown to improve fertility, with the best results obtained with fixation at a young age, especially prior to 1 year of age [52]. Fixation after age 10 may not improve fertility, or may improve it only modestly, suggesting that permanent and progressive damage is done to the testis while in an abnormal position, which is supported by histologic studies [53, 54]. Actual paternity rates in men who underwent orchidopexy for unilateral cryptorchidism are 89%, slightly less than the non-cryptorchid group, which had a 94% paternity rate. Bilaterally cryptorchid men post-orchidopexy had markedly lower paternity rates, at 62% [50, 51].

The pathophysiology of cryptorchidism is complex, with heat likely playing a partial but significant role [55, 56]. A number of other factors are likely to come into play, including the underlying genetics, hormonal milieu, and environmental exposures which originally led to the cryptorchidism [57–59].

Testicular Cancer

Testicular cancer is strongly associated with infertility. There are multiple ways in which testicular cancer can contribute to reduced fertility. Both testicular cancer and impaired spermatogenesis may be related in their etiology of embryologic testicular dysgenesis. The testicular dysgenesis syndrome is a spectrum of disease that may involve cryptorchidism, hypospadias, decreased spermatogenesis, and testis cancer. In this syndrome, it is thought that all of these share an origin of abnormal fetal testis development. As a result of this developmental anomaly, any number of these manifestations may be present in a boy [60]. Testicular tumors may also directly contribute to infertility by secreting hormones, which can downregulate sperm production in the contralateral testis [61–64]. This is uncommon but has been seen with Leydig and Sertoli cell tumors as well as seminomas. Tumors may directly disrupt spermatogenesis by mass effect, by alterations of the endocrine cascade, or by the effects of the inflammatory reaction to the tumor [65].

At presentation, roughly 10% of men will be azoospermic, and roughly 50% will be oligospermic. While orchiectomy will result in a rebound in semen parameters in roughly 90% of these men [66], adjuvant treatments with surgery, chemotherapy, or radiation can further decrease fertility.

1.2.1.6 Ionizing Radiation

Excellent data on the effects of ionizing radiation is available from two similar studies, which are unlikely to be repeated. Researchers in these studies prospectively irradiated the testes of prisoners with single or multiple doses of radiation up to 600 cGy [67, 68]. Sperm counts were followed, and serial testicular biopsies were done. These studies showed that sperm counts declined when testes were irradiated and that decline was dose dependent. At low doses of ~7.5 cGy, a mild decline of sperm counts was seen, and this decline increased to severe oligospermia by 30–40 cGy and azoospermia by 78 cGy. The time to recovery was also seen to be dose dependent, with those receiving 20 cGy beginning to have a recovery of sperm counts by 6 months, those with 100 cGy at 7 months, 200 cGy at 11 months, and 600 cGy at 24 months. The percentage of men achieving a complete recovery and time to achieve a complete recovery also declined with increasing radiation doses.

Decline to the nadir of sperm counts was seen at roughly 64 days, corresponding roughly to the time required for sperm cell production from spermatogonia. More rapid declines were seen with higher radiation doses, indicating increased damage to the more highly differentiated cells undergoing spermatogenesis. Biopsy results from these studies showed that spermatogonia numbers nadired at much lower levels with higher doses of radiation and that these nadirs took longer to achieve than those which had received lower doses of radiation.

These studies provide excellent information into the biology of the effects of radiation on spermatogenesis on the

healthy young testis. Clinically, however, the effects seen are often more pronounced given the setting of the radiation, namely, cancer patients undergoing radiotherapy. Fractionated radiation has been shown to be more damaging than single-dose radiation [69]. One report showed that fractionated radiation with a total dose of 200 cGy may cause permanent azoospermia [70].

1.2.1.7 Chemotherapy

Chemotherapy typically targets rapidly dividing cells and thus has profound effects on the germinal epithelium. As such, the expected outcome of acute chemotherapy is a decline in spermatogenesis, and this has been well documented since the late 1940s [71]. The mechanism by which chemotherapeutics decrease fertility and the rates of recovery is both drug and dose dependent [72–75]. Further, it should be noted that it is impossible to predict recovery of spermatogenesis following chemotherapy.

Alkylating agents, such as cyclophosphamide and cisplatin, are perhaps the most cytotoxic classes of medications, possessing the greatest risk of prolonged azoospermia [76]. Decreases in semen parameters typically occur within 1–2 months of beginning treatment, and azoospermia can be seen after 2 months. Of those men who do become azoospermic, the probability of recovery is the highest within 2 years and rarely occurs after 5 years [77].

Furthermore, while not as toxic as the aforementioned chemotherapeutics, certain drugs, such as anthracyclines and microtubule inhibitors, can have an additive effect on gonadotoxicity when paired with higher risk agents. Other chemotherapeutics such as topoisomerase inhibitors and metabolic inhibitors (methotrexate and 5-fluorouracil) are toxic to differentiating spermatogonia, but less so to testicular germ cells. This frequently leads to only transient decreases in sperm counts [77].

1.2.1.8 Genetic Azoospermia/Oligospermia

It is estimated that 2%–8% of infertile men have an underlying genetic abnormality, with this number rising to 15% in azoospermic men [78]. Although the majority of male infertility does not have an identifiable genetic cause, two potential etiologies are Y chromosome microdeletions and karyotypic abnormalities. The two most common karyotypic abnormalities are Klinefelter's (47,XXY) and chromosomal translocations.

Y chromosome microdeletions occur in approximately 10% of men with azoospermia or severe oligospermia [79]. Research has focused on the azoospermia factor (AZF) region on the long arm of the Y chromosome at Yq11. This area itself contains three separate regions, AZFa, AZFb, and AZFc, and microdeletions of these areas lead to slightly different phenotypes [80]. Deletions in the AZFa and AZFb regions both cause azoospermia, but they differ histologically with AZFa deletions resulting in Sertoli cell-only syndrome and AZFb deletions causing an arrest of spermatogenesis at the primary spermatocyte stage [78]. AZFc deletions are the most common of the Y chromosome microdeletions and are found in 5%–7% of oligospermic men [80]. Unlike the AZFa/AZFb deletions, they do not uniformly result in azoospermia; rather, a spectrum of phenotypes are seen with partial deletions being found in normospermic men, from oligospermia to azoospermia in some full deletions [78]. In men undergoing micro-TESE sperm extraction with ACFc deletions, reported success rates have ranged from about 35% to 72% [81–84].

Classic and mosaic Klinefelter's are common karyotypic abnormalities found in infertile men. Klinefelter's has a prevalence of one in 660 males and is found in 15% of men with nonobstructive azoospermia; thus, it is the most common chromosomal cause of male infertility [85–88]. Klinefelter's affects fertility through two routes: direct effects on spermatogenesis and indirect hormonal effects on spermatogenesis [85, 89, 90]. These men uniformly present with very small testicles, increased gonadotropins, and hypogonadism. Interestingly, sex hormone levels are normal until puberty. During puberty, they may rise to low-normal levels, but plateau. By adulthood, serum testosterone levels are typically below normal. Histologic studies demonstrate gradual degeneration of the testes with development, with hyperplasia of poorly functioning Leydig cells [91].

As far as altered spermatogenesis is concerned, many Klinefelter's patients do produce sperm, with micro-TESE recovery rates ranging between 55% and 65% [84, 92]. Additionally, one report found 8% of men with non-mosaic Klinefelter's had sperm in their ejaculate [84]. However, the quantity of sperm produced is typically very low. Biopsy studies of Klinefelter's testes have demonstrated that spermatogenesis is halted pre-pachytene in the vast majority of aneuploid cells and that meiosis was seen mainly in cells with normal karyotypes [90].

Robertsonian translocations are a third significant genetic cause of infertility. They occur in 0.8% of infertile men, and this number rises to 1.6% in oligospermic men [93]. Phenotypes are highly variable given the possibilities of recombination [78].

1.2.1.9 Lifestyle Factors

Hyperthermia is considered to be a major contributor in the pathogenesis of infertility in men with varicocele and cryptorchidism. Subsequently, one may infer that other lifestyle factors, such as underwear type, heated car seats, or occupational exposures, could have a similar effect. However, these cases have not been manifest in existing studies. The role of underwear style in male infertility has

been investigated. One small study of 14 normospermic men, a tight polyester scrotal support, when worn day and night, was shown to make all azoospermic at a mean time of 140 days. After removal of the scrotal support, all men regained function at a mean time of 157 days [94]. However, normal underwear (i.e., boxer or brief style) has not been shown to exert a significant influence on semen parameters [95]. Other types of heat exposure, such as occupational heat exposure in a group of welders, have been shown to decrease semen quality [96]. Sedentary posture, heated car seats, and sauna and hot tub use are all lifestyle factors that increase scrotal temperature as well and may contribute to a decline in fertility [97].

Cell phones have been implicated as possibly playing a role in decreasing male fertility, and several studies show that there may be some basis for this theory. One observational study assessed semen parameters and cell phone usage in 361 men who presented to an infertility clinic. Approximately 60% of the men in this study had greater than 2 h of cell phone use per day, with 30% using their cell phones for more than 4 h per day. They found that sperm counts, motility, viability, and morphology all worsened with increasing cell phone use [98]. The mechanism by which cell phones affect semen parameters has not yet been elucidated, but one hypothesis is that cell phone-generated electromagnetic radiation (CPEMR) alters mitochondrial function and acts to increase reactive oxygen species. This is somewhat corroborated by one study which looked at the effects of CPEMR on semen parameters and found increased levels of reactive oxygen species with decreased viability and motility in the sperm exposed to CPEMR [99].

Tobacco use has been implicated in the pathogenesis of numerous cancers and medical diseases. While the use of tobacco significantly impacts female fertility, its impact on male fertility is less clear. Semen parameters, including sperm density, motility, and morphology, have all been shown to be worsened with tobacco use [100–103]. However, a significant reduction in fertility has not yet been proven.

Another increasingly common condition negatively effecting fertility is obesity. A 2006 study of over 20,000 families found that increasing body mass index was associated with worsening male fertility [104]. This finding has been corroborated by further studies demonstrating worse semen parameters, increased DNA fragmentation, and possibly genetic alterations in obese men [105–108]. The mechanism for this is multifaceted. Obese men are at in increased risk of hypogonadism via both decreased secretion and response to LH and increased peripheral aromatization of testosterone to estradiol [109, 110]. Furthermore, obese men are at an increased risk of developing cardiovascular disease and diabetes, which may exacerbate these negative effects [111].

1.2.1.10 Testicular Injury

Injury to the testicle can be sustained either directly or indirectly. Direct trauma to the testis is typically managed by debridement of devitalized seminiferous tubules and closure of the tunica albuginea [112]. The resultant loss of volume of seminiferous tubules and possible obstruction from scarring is one possible cause of decreased fertility. Reports on testicular salvage after bilateral trauma indicated that preserved volume of testis is the key to preserving fertility [112–117].

Indirect damage to the testis may be sustained by exposure to infection or inflammation of the testis. While rare in developed nations, the classic infectious agent causing infertility is mumps. The mechanism by which mumps causes orchitis is via pressure atrophy. Infection of the testis with the mumps virus causes inflammation and swelling, which is limited by the tunica albuginea; this in turn leads to atrophy [118]. Approximately 1.5% of postpubertal males with mumps may become infertile as a result of the illness [119].

Other bacterial and viral pathogens may also cause infertility at the testicular level, most commonly; this is the result of spread of infection from the epididymis [120, 121]. The mechanism for infertility in these cases may be persistent inflammation which suppresses testicular function or obstruction secondary to resultant sclerosis.

1.2.1.11 Primary Ciliary Dyskinesia

Ultrastructural defects that affect sperm motility are described under the grouping of primary ciliary dyskinesia (PCD). PCD is a rare and heterogeneous genetic disease which affects one in 20,000–60,000 [122]. Many components of cilia and flagella are affected, though the defect is found in the dynein in over 80% of cases [123]. The key clinical finding is chronic respiratory infections leading to bronchiectasis. When situs inversus is present in addition to the other components, it is termed Kartagener's syndrome. Male infertility secondary to sperm dysmotility is related to the dysfunction of the flagellate tail of the sperm. It is a common finding, though not universal, given the phenotypic heterogeneity.

1.2.1.12 Antisperm Antibodies

In the normal male, sperm reside in an immunoprivileged site. The blood–testis barrier prevents proteins from the sperm from interacting with the immune system and setting up an immune reaction against them. Trauma, infection, and inflammation all may disrupt this barrier and result in immunity against the germinal epithelium and spermatozoa.

Antisperm antibodies (ASA) are very common, with 8%–17% of men and 1%–22% women in infertile couples

testing positive for serum ASA [124, 125]. As expected, ASA are heterogeneous in their binding sites and, as such, have wide ranging effects on sperm function. Some ASA will not significantly affect fertility, and 0.9%–2.5% of fertile men will test positive for serum ASA [126, 127]. ASA targeted against proteins on the head region are more likely to affect zona binding and sperm penetration, whereas ASA targeted against the tails of spermatozoa are more likely to decrease motility and cervical mucus penetration and cause sperm agglutination [128]. While ASA clearly may affect fertility in some cases, serum ASA positivity is not a strong predictor of infertility.

1.2.2 Post-testicular

1.2.2.1 Absence of the Vas Deferens

Congenital bilateral absence of the vas deferens (CBAVD) is a condition strongly related to cystic fibrosis (CF), and the same genetic mutation of the CFTR is typically responsible for both disease processes [129]. While men with CF do not necessarily have CBAVD, most men with CBAVD do have a CFTR mutation [130–132]. The pathophysiology of CBAVD thus clearly involves altered chloride transport in the majority of cases, and, similar to the respiratory and pancreatic sequelae seen with CF, there is evidence that the genital abnormalities and pathology seen are a progressive disease. Namely, intentionally aborted CF fetuses demonstrate normal vas deferens, albeit with secretions filling their lumens. This suggests that the mechanism for CBAVD is atresia, and not aplasia, when a CFTR mutation is present [133]. One interesting sequela of this case is that renal agenesis is not associated with CBAVD [134].

Congenital unilateral absence of the vas deferens (CUAVD) is a different entity altogether [135]. While there remains a significant rate of CFTR mutations in men with CUAVD, especially when the obstructive azoospermia is present [129], the majority of CUAVD is the result of an embryologic Wolffian duct aberrancy [136]. As such, renal agenesis is often seen with CUAVD, though CUAVD is not always seen in men with unilateral renal agenesis, as there are many other embryologic missteps that may occur to result in renal agenesis. While there is only a 20% rate of CUAVD seen in those with a unilateral renal agenesis, there is a 79% rate of unilateral renal agenesis seen in men with CUAVD. Since CUAVD not associated with a CFTR mutation is usually a unilateral and isolated phenomenon, fertility is often preserved.

1.2.2.2 Young's Syndrome

Young's syndrome is a rare disorder which presents clinically as obstructive azoospermia and chronic sinopulmonary infections [137]. Thus, it can be difficult to differentiate clinically from cystic fibrosis variants and primary ciliary dyskinesia. Indeed, definitive diagnosis of Young's syndrome requires negative CFTR genetic testing and investigation of ciliary ultrastructure to rule out primary ciliary dyskinesia [138]. Normal spermatogenesis is seen, and the obstructive azoospermia is due to inspissated secretions in the vas deferens.

The etiology of Young's syndrome is unclear with childhood mercury exposure having been postulated to play a role in the past [139]. Interestingly, the incidence of Young's syndrome has plummeted from estimates of one in 500 in the 1980s down to case reports and articles which question the existence of Young's syndrome today [140]. The observation that the reduced incidence over the last 50 years coincides with a decrease in mercury use and poisoning is tempered by the fact that our knowledge of genetics has rapidly advanced. Thus, the decreased incidence of Young's syndrome is more likely due to the increased correct genetic diagnosis of CF spectrum disease.

1.2.2.3 EjDO/Seminal Vesicle Dysfunction

Ejaculatory duct obstruction is a common etiology of male infertility, occurring in 1%–5% of men presenting with infertility [141]. There are many causes of ejaculatory duct obstruction, including cystic fibrosis spectrum disease, Wolffian or Mullerian origin cysts, calcifications, tuberculosis and other GU infections, calculi, and urinary tract instrumentation [142, 143]. Additionally, chronic ejaculatory duct obstruction may affect the seminal vesicle in a manner analogous to the effect of bladder outlet obstruction on the bladder. Namely, with longstanding obstruction, the seminal vesicles may lose contractility, and resolution of the anatomical obstruction may not improve seminal vesicle emptying during ejaculation.

1.2.2.4 Nerve Injury

Nervous injury affecting ejaculation may occur at many levels and have a diverse etiology ranging from spinal cord injury to neural damage during retroperitoneal or pelvic surgery to neuropathy from systemic diseases. Ejaculatory dysfunction is present in 90% of spinal cord injury patients [144]. The type and severity of ejaculatory dysfunction are dependent on the level and extent of the injury. Higher cord lesions, typically at T10 or above, often result in an intact reflex arc which allows for penile vibratory stimulation to induce ejaculation. Men with sacral lesions or lesions of the efferent parasympathetic nerves are typically not responsive to penile vibratory stimulation and may require endorectal electrical stimulation to induce ejaculation [140, 145]. These men may additionally have trouble initiating erections, as injuries at this level can interrupt the arc for reflex erections [146].

While sperm concentration in men with spinal cord injuries characteristically remains normal, many have low motility and viability [147, 148]. The exact reason for this phenomenon remains unclear, but is possibly a result of decreased mobility, voiding dysfunction, accessory gland dysfunction, and/or inflammatory changes [146, 149]. Of note, an interesting physical finding seen in 25%–50% of men with spinal cord injuries likely related to seminal vesicle dysfunction is brown semen [150]. The exact reason for this phenomenon is unclear; brown coloration is not derived from heme and is not related to semen stasis per se.

Retroperitoneal lymph node dissection (RPLND) for testicular cancer resulted in a high rate of ejaculatory dysfunction until the development of methods to spare the sympathetic nerve fibers. Both emission and bladder neck contraction are mediated by the sympathetic nervous system, and damage to the sympathetic chain and the hypogastric plexus overlying the great vessels results in a high degree of ejaculatory dysfunction. In the past, RPLND was associated with a 55%–60% chance of ejaculatory dysfunction [151, 152]. Modified templates have helped to reduce the rates of retrograde ejaculation, with one study demonstrating an 82% rate of antegrade ejaculation with a modified unilateral template [153]. Another study using a modified bilateral template demonstrated an 88% rate of preservation of antegrade ejaculation [154].

Nerve-sparing RPLND, developed in the late 1980s, has reduced the incidence of retrograde ejaculation even further to 0%–7% [155, 156]. Nerve-sparing RPLND may also be done after chemotherapy, though only 136 of 341 men qualified for this method as compared with standard RPLND in one series [157]. Rates of ejaculatory dysfunction were also higher at 21%.

1.2.2.5 Medications

Medications affecting ejaculation do so by altering adrenergic signaling. This scenario is most clearly seen with alpha-1 antagonists. Tamsulosin and silodosin, especially, are known to cause ejaculatory dysfunction [158, 159]. Previously, this case was thought to be retrograde ejaculation. Recent studies have shown that the ejaculatory dysfunction induced by alpha-1 antagonists is actually a failure of emission [160, 161].

Antipsychotics have long been associated with sexual dysfunction, including ejaculatory dysfunction. Antipsychotics have effects on many different neurotransmitters including dopamine, norepinephrine, acetylcholine, and serotonin. Predictably, altered ejaculatory function with antipsychotics use correlates with anti-adrenergic actions of the antipsychotics [162]. Even atypical antipsychotics such as risperidone may affect ejaculation [163, 164].

1.2.2.6 Coital

Abnormal coital practices may play a role in infertility when they interfere with semen deposition in the vagina or affect their timing with the female reproductive cycle. Similarly, erectile dysfunction and penile abnormalities such as hypospadias and chordee may interfere with semen deposition and thus may play a role in infertility.

Lubricants are commonly used by infertile couples, and many vaginal lubricants have been shown to negatively affect fertility. Many synthetic lubricants not only affect sperm motility but have also been shown to increase the DNA fragmentation index. In one study, FemGlide, Replens, and Astroglide all affected sperm motility, and FemGlide and K-Y jelly increased DNA fragmentation. One lubricant that has not been shown to have a significant impact on sperm motility or DNA fragmentation is Pre-Seed [165]. Another study showed similar findings with decreased motility in sperm exposed to K-Y jelly and Touch. Nonviability was seen in sperm exposed to Replens and Astroglide which was comparable to the nonviability seen when sperm were exposed to the spermicide nonoxylnol-9 [166]. In this study, canola oil was not found to affect sperm motility or viability. Yet another study showed that K-Y jelly, saliva, and olive oil all reduced sperm motility, while baby oil did not significantly affect motility [167].

1.3 Conclusion

The etiologies of male infertility are robust and varied. It must be remembered that the majority of the causes of male infertility are either preventable or treatable. This fact, along with a growing body of evidence suggesting infertility may have implications for overall health, highlights the importance of an evaluation for all male partners of couples struggling to conceive. While idiopathic infertility still comprises a large portion of the men evaluated for problems with reproduction, this percentage will likely continue to decrease in the future with scientific advancements, particularly in the field of genetics. It is crucial that reproductive urologists have an understanding of the causes of infertility in men so as to provide the optimal management of couples struggling to conceive (see Table 1.1).

1.4 Review Criteria

MEDLINE was searched for articles published in English from January 1980 to November 2018. Abstracts and papers were reviewed with a focus on the etiologies of male infertility. In addition, the reference sections of these articles, along with relevant chapters of infertility textbooks, were consulted.

Table 1.1 Summary table

Pre-testicular		Pathophysiology
	Hypogonadotropic Hypogonadism	Lack of stimulation of Sertoli/germ cell complex
	Elevated prolactin	Suppression of GnRH
	Pharmacologic	Downregulation of HPG axis
	Idiopathic hypogonadotropic hypogonadism	Defective action or release of GnRH
Testicular	Varicocele	Testicular hyperthermia resulting from a disruption of the countercurrent heat mechanism
	Cryptorchidism	Testicular hyperthermia; possible role of genetic and/or environmental factors
	Testicular cancer	Embryologic testicular dysgenesis, mass effect, inflammation, alteration of endocrine cascade
	Radiation	Direct cytotoxic effect on spermatogenesis
	Chemotherapy	Damage to testicular germ cells, fibrosis of testicular interstitial tissues
	Genetic	YCMD – Sertoli cell only syndrome or arrest in primary spermatocyte stage (AZFa or AZFb deletion), quantitative spermatogenesis impairment (AZFc deletion) Klinefelter's – direct effect on spermatogenesis and indirect hormonal effect on spermatogenesis
	Lifestyle	Testicular hyperthermia, increased DNA fragmentation, and/or genetic alterations
	Injury	Loss of seminiferous tubules, scarring leading to obstruction
	Primary ciliary dyskinesia	Dysfunction of the flagellate tail of the sperm
	Antisperm antibodies	Impairment of sperm motility and/or penetration
Post-testicular	Absence of vas deferens	CFTR mutation resulting in vasal or seminal vesicle atresia; embryological Wolffian duct aberrancy
	Young's syndrome	Inspissated secretions in the vas deferens
	Ejaculator duct obstruction	Obstruction of ejaculatory ducts and/or resultant loss of seminal vesicle contractility
	Nerve injury	Ejaculatory dysfunction
	Medications	Alteration of adrenergic signaling leading to impaired ejaculation
	Coital	Interference with semen deposition in vagina; lubricants may impair semen parameters

Epidemiologic Considerations in Male Infertility

2

Samuel J. Ohlander, Whitney R. Halgrimson, and Mark A. Faasse

Key Points

- There is a 15% lifetime incidence of infertility among couples in Western countries; only 3%–5% of couples are sterile.
- If the timing of sexual intercourse relative to ovulation is deliberately controlled, then the monthly probability of pregnancy may approach 40%; however, the human average for monthly fecundity is 20%.
- The absence of a gold-standard test for male infertility is a fundamental problem, preventing an accurate understanding of its epidemiology and of the predictive value of tests employed for its diagnosis.
- Sperm concentration correlates with the probability of conception up to a density of 40 million/mL, but there is no additional likelihood of pregnancy at higher sperm densities.
- Purported declines in semen quality during the twentieth century may be an artifact of bias from geographical differences in sperm counts.
- Economic analyses suggest that pathology-directed treatment of male infertility is generally more cost-effective than proceeding directly to ART.

2.1 Introduction

This chapter primarily aims to discuss the epidemiologic relationship between infertility and male reproductive potential. It will focus in detail on the accuracy and diagnostic value of semen studies. Controversial reports of declining sperm counts during the twenty-first century will also be addressed, followed by a review of trends in health-care resource utilization and cost analysis models pertinent to the management of male infertility.

Antioxidant therapy for male infertility has an epidemiologic basis in the understanding that reactive oxygen species (ROS) contribute to sperm damage and are present in higher levels in the semen of infertile men [1–4]. However, given the increasing availability and use of assisted reproductive technology (ART), it may be surprising to encounter an epidemiologic approach to male infertility in the modern era [5]. The relative ease of surgical sperm retrieval in cases of azoospermia and severe oligozoospermia has seemingly rendered comprehensive evaluation and treatment of infertile men less relevant. Even though such an evaluation may identify one or more modifiable risk factors for infertility (as well as potentially serious underlying or coexisting illnesses and genetic abnormalities), the outcome of pathology-directed treatment may take longer to realize.

However, risk and uncertainty are also attendant to the use of ART. Cost-effectiveness studies have demonstrated that a straight-to-ART approach is less efficient than pathology-directed treatment in many situations involving male infertility. Therefore, renewed emphasis is being placed on the paradigm of intervention to correct modifiable male risk factors [6].

2.2 Epidemiology of Infertility

It is important to distinguish reproductive potential, or capacity, from actual reproductive performance, or outcomes [7, 8]. Infertility is ultimately defined by a reproductive *outcome* (i.e., childlessness), but "male infertility" is a diagnosis of relative impairment in male reproductive *potential*. Before discussing male infertility in more detail, we will review the epidemiology of infertility in general.

2.2.1 Incidence and Prevalence of Infertility in Developed Countries

Childlessness within long-standing marriage has been observed to occur in roughly 10% of couples in developed countries [9]. This figure represents a measure of reproductive outcomes, but it does not exclude couples who remain voluntarily childless or do not have regular intercourse during the fertile phase of the female's menstrual cycle.

The World Health Organization (WHO) has defined infertility by "the failure to achieve a clinical pregnancy after 12 months or more of regular unprotected sexual intercourse," which captures the concept of impaired reproductive potential [10]. By this criterion, the lifetime *incidence* of unwanted infertility is approximately 15% among couples in Western countries [11]. Two-thirds of these cases are primary, that is, in couples who have never previously conceived, while one-third are secondary [9].

It is not uncommon to see infertility defined by other durations of time, such as 2 or 5 years. Also, while the outcome of interest in the WHO's definition is conception, others prefer to regard infertility as the absence of live birth [7, 8]. This distinction is important, because 10–25% of recognized pregnancies end in miscarriage [12].

The annual *prevalence* of infertility among married US women aged 15–44 years was 6.7% in 2015, down from 11.2% in 1965, 8.5% in 1982, to 7.4% in 2002 [13, 14]. This trend may reflect improvements in reproductive potential, perhaps through better awareness of ideal timing for intercourse, which may be attributable to at-home ovulation tests. However, other factors could also be involved, such as more couples utilizing infertility treatment prior to reaching the 12-month threshold necessary for inclusion in the rate's numerator. Declining marriage rates among lower socioeconomic classes may also be disproportionately removing women at greater risk of infertility from the denominator [13].

A popular misconception is that infertility is synonymous with, or virtually approximates, sterility [8]. In fact, only 3%–5% of couples are sterile [9, 15].

2.2.2 Infertility in the Developing World

In 2002, the WHO estimated that 16%–30% of married women in developing countries were experiencing infertility of at least 5 years duration, with the vast majority being secondary [16]. A more recent study, focused on child-seeking women, lowered these estimates to 9%–20% (Table 2.1) [17]. Interestingly, this study found little difference in the prevalence of infertility between high-income countries and low- or middle-income countries of certain regions. Sexually transmitted infections and postpartum complications have been identified as key factors contributing to secondary infertility in the developing world [18].

Table 2.1 Prevalence of infertility of 5-year duration among child-seeking women in high-income countries and low- or middle-income countries of various regions, 2010

	Primary or secondary infertility (%)	Primary infertility (%)	Secondary infertility (%)
High-income countries	9.9	1.8	8.1
Latin America/ Caribbean	8.8	1.5	7.3
Middle East/North Africa	9.1	2.6	6.5
Sub-Saharan Africa	11.8	2.0	9.8
East Asia/Pacific	12.4	1.6	10.8[a]
South Asia	13.7	2.4	11.3
Central/Eastern Europe and Central Asia	20.2	2.3	17.9

Adapted from Mascarenhas et al. [17]. With permission from Creative Commons

[a]Estimate excludes China

The rate of childlessness in developing countries among sexually experienced women who are beyond childbearing age is approximately 3% [16]. This figure is comparable to the estimated prevalence of sterility in Western societies.

High cost represents an important barrier to the accessibility of most infertility treatment, and specifically ART, in the developing world [18]. Therefore, further identification of avoidable gonadotoxins, as well as clarification of the role of less expensive therapies, would be especially welcome there [19].

2.2.3 Reproduction—a Matter of Chance: The Natural History of Infertility

Reproduction has been described as "a matter of chance depending on the subtle balance between success or failure of complex, mostly poorly understood, sequential processes that may lead to a pregnancy and eventually to the birth of a healthy child" [15]. Failure of a couple to reproduce is a unique medical problem in that it occurs *between* rather than *within* individuals [7].

Individuals' reproductive potential is a continuous, as opposed to dichotomous, variable. It reflects the influence of many factors, including age. Reproductive potential declines in members of both sexes over 30 years old, but female age has the most profound effect on the likelihood of conception [20, 21].

Since a couple's reproductive capacity is the composite of its individual members' reproductive potentials, it, too, is a continuous variable. Impairment of a male's reproductive

potential may be compensated for—or compounded—by that of his female partner and vice versa. This concept is illustrated by the fact that artificial insemination with donor semen is more often successful in partners of azoospermic men than in partners of men with oligozoospermia [22].

Couples' monthly, or cycle-wise, likelihood of conception falls along a spectrum of probability. This is referred to as fecundability or monthly fecundity rate (MFR). The average MFR for human couples having regular, unprotected intercourse is approximately 20%, and the overall distribution of human MFRs is believed to range from 0% to 60% [23, 24]. The variable likelihood of pregnancy at 6, 12, 24, and 60 months has been calculated for couples with different MFRs (Table 2.2). Based on these values, a hypothetical model has been constructed of the proportion of couples with varying degrees of reproductive potential (MFR) among residual nonpregnant couples after specified durations of infertility (Table 2.3) [25].

Table 2.2 demonstrates that couples with average fecundability have a better than 90% chance of conceiving within 12 months. However, 30% of couples who do not conceive within 12 months are still of average reproductive potential (see Table 2.3). Population-based studies have found that couples who are infertile after 12 months retain a roughly 50% likelihood of achieving unassisted pregnancy by 24 months [26]. Thereafter, the odds of conception decline precipitously, as illustrated in Fig. 2.1. The proportion of couples that are sterile increases with the duration of infertility.

An obvious but nevertheless critically important factor in determining reproductive potential is the timing of sexual intercourse relative to ovulation (Fig. 2.2) [27]. In a cohort of 340 German couples who received natural family planning education intended to improve their timing of intercourse, the monthly probability of achieving pregnancy averaged 38%, markedly higher than the average human MFR of 20% [28].

2.3 Diagnostic Accuracy and Utility of Semen Studies

Male infertility is diagnosed in approximately 50% of couples presenting for evaluation of infertility [11]. Basic semen analysis remains the most widely utilized laboratory study for this purpose. However, the limitations of semen analysis should be clearly understood.

The parameters usually assessed by semen analysis include ejaculate volume, sperm concentration (density), sperm motility, and sperm morphology. From the ejaculate volume, concentration, and percentage of motile sperm, the total sperm count and total motile count are calculated. Semen pH, viscosity, white blood cell concentration, and the degree of sperm agglutination may also be reported [29].

More specialized studies that are undertaken on a case-by-case basis include evaluation of sperm viability, antisperm antibodies, and functional assays, such as assessment

Table 2.2 Cumulative spontaneous pregnancy rates of couples in five hypothetical categories of reproductive potential

		Cumulative pregnancy rate (%) after period of months			
	MFR (%)	6 months	12 months	24 months	60 months
Highest fecundability	60	100	–	–	
Average fecundability	20	74	93	100	
Below-average fecundability	5	26	46	71	95
Severely impaired fecundability	1	6	11	21	45

of sperm–cervical mucus interaction, capacitation, and sperm penetration of a zona-free hamster oocyte [30]. Relatively recent developments have included the introduction of tests for seminal ROS levels and sperm DNA fragmentation [31, 32].

Preliminary studies have also suggested that sperm epigenetics may have a future role in the evaluation of male infertility. Gene H19 is a common target for study and was associated with infertile men by a factor of 9.9 in one meta-analysis [33]. Epigenetic research remains exploratory and is limited by the wide number of possible gene targets for study.

Table 2.4 WHO reference values for analysis of semen parameters

	1992	1999	2010
Ejaculate volume (mL)	≥2.0	≥2.0	≥1.5
Sperm concentration (10^6/mL)	≥20	≥20	≥15
Total sperm number (10^6/ejaculate)	≥40	≥40	≥39
Sperm motility (% motile)	≥50 (a + b)[a]	≥50 (a + b)	≥40 (a + b + c)
Sperm morphology (% normal)	≥30	≥14[b]	≥4
Sperm viability/vitality (% live)	≥75	≥75	≥58
White blood cells (10^6/mL)	<1.0	<1.0	<1.0

Reprinted from Menkveld [34]. With permission from Asian Journal of Andrology

[a]Motility is graded as follows: a = rapid progressive motility (>25 μm/s); b = slow/sluggish progressive motility (5–25 μm/s); c = nonprogressive motility; d = immotility

[b]Kruger (Tygerberg) strict criteria were adopted by the WHO in 1999

2.3.1 Relationship Between Semen Parameters and Male Infertility

Semen analysis definitively confirms male factor infertility in men who are found to have semen characteristics at the negative extremes, that is, azoospermia, nonmotile sperm, or the severest cases of teratozoospermia. However, only a small fraction of men who present for evaluation of infertility have such findings [11]. The present section explores the relationship between male infertility and the entire spectrum of semen quality.

Since 1980, the WHO has published reference values for human semen parameters. These values have been changed periodically (Table 2.4) [34]. As of 2010, they represent the fifth percentile in the distribution of semen parameters from a population of men with proven fertility [35]. They provide no information regarding the distribution of semen parameters in men who are infertile.

Although the WHO criteria are commonly used as thresholds for designation of male infertility, the diagnostic picture in a clinical setting is considerably more complex. This scenario is because of substantial overlap between the distributions of semen characteristics in empirically fertile men and those with infertility whose female partners have had a normal fertility evaluation (Fig. 2.3).

Basic performance measures of a test such as semen analysis include calculation of its sensitivity and specificity. These concepts are illustrated in Tables 2.5 and 2.6. If a sperm concentration below 15 million/mL is the criterion for a "positive" result (i.e., diagnosis of male infertility), then men who are

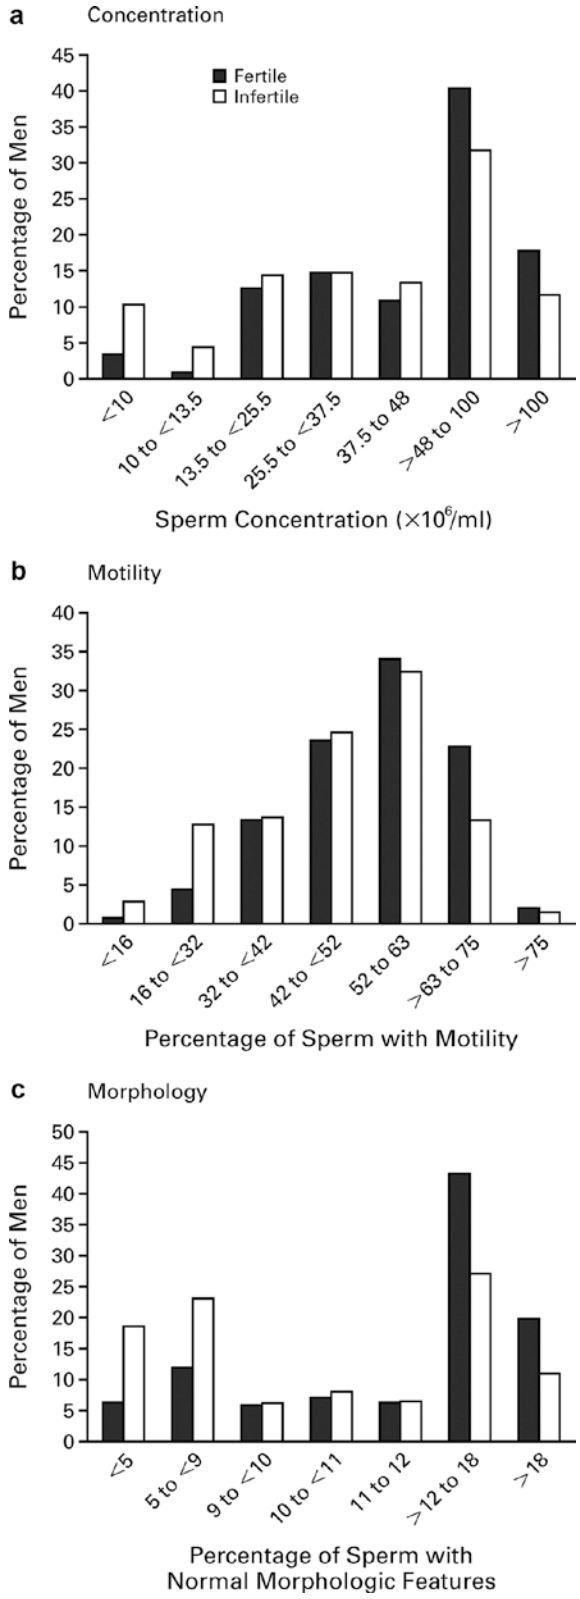

Fig. 2.3 Frequency histograms depicting the percentage of men from fertile (*shaded bars*) and infertile (*unshaded bars*) couples with sperm concentration (**a**) sperm motility (**b**) and sperm morphology (**c**) within specified ranges. Data were obtained from 696 fertile men and 765 men from infertile couples whose female partners had an unrevealing fertility evaluation. (Reprinted from Guzick et al. [36]. Table 2.5 2 × 2 Table depicting actual fertility status vs. test results using the 2010 WHO reference value for sperm concentration as a threshold for diagnosis of male infertility, in a hypothetical population of 200 men presenting for evaluation of infertility

		Actual fertility status	
		Infertile	Fertile
Test results	Abnormal	15 (TP)	5 (FP)
	Normal	85 (FN)	95 (TN)

TP true positives, *FP* false positives, *FN* false negatives, *TN* true negatives

Table 2.6 Accuracy metrics based on Table 2.5, using the 2010 WHO reference value for sperm concentration (15 million/mL) as a threshold for diagnosis of male infertility

Accuracy metric	Formula for calculation	Result (%)
Sensitivity	TP/(TP + FN)	15
Specificity	TN/(TN + FP)	95
Positive predictive value	TP/(TP + FP)	75
Negative predictive value	TN/(TN + FN)	53
Classification accuracy	(TP + TN)/N	55

TP true positives, *FP* false positives, *FN* false negatives, *TN* true negatives, *N* = total number

actually fertile will be correctly classified 95% of the time. In other words, the threshold of 15 million/mL has a specificity of 95%. However, 85% of infertile men also have sperm concentrations above 15 million/mL; thus, the sensitivity of the test at this threshold is only 15% [36]. Many men with impaired reproductive potential will not be recognized as such.

If we assume that 50% of couples presenting for an evaluation of infertility have a contributing male factor, then the predictive value of a positive result (i.e., its likelihood of being correct) would be 75%. The predictive value of a negative, or normal, result would be only 53% (see Table 2.6).

Of course, diagnostic thresholds can be changed. If they are increased, sensitivity improves, but there is a reciprocal decline in specificity, and vice versa. One way to assess the diagnostic accuracy of a test across all thresholds is by a receiver operating characteristic (ROC) curve [28, 34]. ROC curves are constructed by plotting the probability of detecting true positives (sensitivity) against that of detecting false positives (1 − specificity) at each threshold.

The total area under the ROC curve (AUC) for a particular test represents its overall discriminatory capability. A perfect test has an AUC of 1.0, while a test is useless if the likelihood of a true positive matches that of a false positive at every threshold, resulting in the no-discrimination line from (0, 0) to (1, 1) and an AUC of 0.5. The amount by which a test's ROC curve diverges from this line—and by extension, to which its AUC exceeds 0.5—is the degree to which it is diagnostically helpful. An AUC that exceeds 0.9 is considered excellent, while an AUC of less than 0.7 is poor.

Figure 2.4 represents an example of an ROC curve generated from MacLeod's data on sperm concentration in fertile and infertile men [37]. Its AUC is only 0.59, indicating that the overall accuracy of sperm concentration for diagnosis of

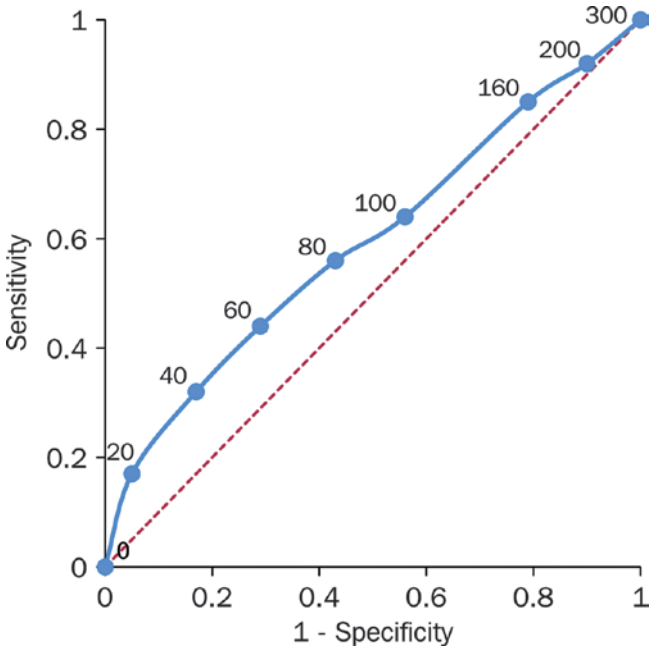

Fig. 2.4 Receiver operating characteristic (ROC) curve for diagnosis of male infertility at specified thresholds of sperm concentration in millions/mL (data from [37]). The no-discrimination line is shown in *red*. (Modified from Niederberger [38]. With permission from Elsevier)

male infertility just narrowly exceeds that of random chance. In Guzick and colleagues' series, which was depicted in Fig. 2.3, the AUC for sperm density, motility, and morphology were 0.60, 0.59, and 0.66, respectively [38].

The ROC curve alone does not provide information regarding the likelihood that a specific patient's positive or negative test result is correct. This probability is dependent both on test performance and the prevalence of disease in the relevant population. As previously illustrated, a diagnosis of male infertility based on sperm concentration below 15 million/mL may be correct 75% of the time in the population of males from infertile couples. False-positive results for infertility are relatively rare in this population. By comparison, if semen analysis were performed on men in the general population (e.g., to assess sperm donors with no prior reproductive history), its positive predictive value would be considerably less, on account of a much lower prevalence of male infertility.

Other studies have reported AUCs for sperm density, motility, and morphology, as described in Table 2.7 [39–43]. In general, motility and morphology demonstrated greater discriminatory capability than sperm concentration. Although the authors of these studies reported "optimal thresholds" for discrimination of fertile and infertile men, some of these thresholds have been criticized for having an unacceptably low positive predictive value in the setting of an infertile population [44].

Guzick and colleagues took a different approach to selecting diagnostic thresholds, using classification and regression tree (CART) analysis to determine *two* thresholds for each parameter that define the upper and lower boundaries of an indeterminate range lying between the fertile and infertile ranges (see Table 2.7). Unfortunately, a large number of men presenting for infertility evaluation fall into the indeterminate range, leaving unanswered the question of whether they warrant intervention for modifiable risk factors. The odds of male infertility multiply if more than one semen parameter is within the infertile range [36], but only 1% of men fail to meet all five WHO reference criteria for ejaculate volume, total sperm number, sperm concentration, motility, and morphology [45].

Table 2.7 Reported areas under the ROC curve for various seminal characteristics

	Population	AUC density	AUC motility	AUC morphology (strict)
MacLeod [37][a]	1000 fertile; 800 infertile[b] (ages NR)	0.59	NR	NR
Guzick et al. [36][a]	696 fertile (avg age, 33.5 ± 5.0); 765 infertile (avg age, 34.7 ± 4.9)	0.60 (13.5, 48)	0.59 (32, 63)	0.66 (9, 11)
Ombelet et al. [42]	144 fertile; 143 infertile (ages NR)	0.69 (34)	0.61 (45)	0.78 (10)
Gunalp et al. [39]	61 fertile (avg age, 29.9); 62 infertile (avg age, 31.3)	0.56 (34)	0.71 (42)	0.70 (12)
Menkveld et al. [41]	107 fertile (avg age, 33.8 ± 4.3); 103 infertile[b] (avg age, 33.7 ± 3.9)	NR	0.79 (45)	0.78 (4)
Jedrzejczak et al. [40]	113 fertile (avg age, 31 ± 4.7); 109 infertile (avg age, 32.2 ± 4.1)	0.80 (45–50)	0.91 (24)	0.82 (11)
Sripada et al. [43][b]	488 fertile (avg age, 30.6 ± 4.8); 938 infertile[b] (avg age, 32 ± 5.4)	NR	0.55 (30)	0.57 (9.5)

Based on data from Ref. [38]

AUC area under the ROC curve, *NR* not reported, ages of study populations are reported as mean ± SD, values in parentheses are the "optimal thresholds" identified by the respective studies for discrimination of fertile from infertile men—see text for additional details

[a]For data from these studies, the ROC curve was plotted and AUC was reported by Niederberger [38]

[b]These reports did not specify female partners as having had a negative fertility evaluation

2.3.2 Do Semen Parameters Prospectively Predict Fertility and Assisted Reproductive Technique Outcomes?

Only a handful of studies have attempted to prospectively identify variables associated with male reproductive poten-

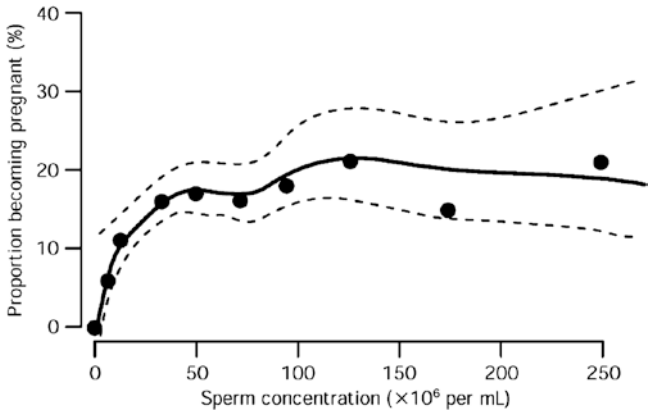

Fig. 2.5 Probability of pregnancy per menstrual cycle relative to sperm concentration. (Reprinted from Bonde et al. [47]. with permission of Elsevier)

tial. One such project included 200 couples, some of whom had had prior pregnancies [46]. After discontinuing contraception, the couples were followed for up to 12 months. Around 78% conceived during the study period, and both sperm motility and morphology were significantly associated with fertility. The difference in sperm concentration between fertile and infertile couples remained statistically insignificant.

Bonde and colleagues investigated 430 Danish couples between 20 and 35 years old who had never previously been or tried to become pregnant, following them for up to six menstrual cycles after discontinuation of contraception [47]. Around 60% of couples became pregnant. The probability of conception increased up to a threshold sperm concentration of 40 million/mL, but there was no additional likelihood of pregnancy at higher sperm densities (Fig. 2.5). This finding has led some reproductive specialists to argue that the appropriate threshold of sperm concentration for diagnosis of male infertility should be 40 instead of 15 million/mL [48]. A change of this sort, however, would also increase the number of false-positive diagnoses, prompting unnecessary evaluation and treatment.

Leushuis and colleagues have published an incisive review of prediction models in reproductive medicine, including several that use one or more semen characteristics to predict conception by infertile couples [49]. One such model, which has been externally validated in a population excluding men with total motile sperm counts of less than three million, takes account of sperm motility and the characteristics of the female partner and the duration of the couple's infertility; it is available online at www.freya.nl/probability.php [50]. Another model utilizes inputs of sperm concentration, motility, morphology, and hypoosmotic swelling to assess the likelihood of pregnancy, with a reported accuracy greater than 85% [40]. Of note, however, the AUCs for each variable in this study substantially exceeded those published in the other reports described in Table 2.7, and the predictive model has yet to be validated.

Sperm quality also affects ART outcomes, at least to some degree. Several investigations have demonstrated a positive correlation between semen characteristics, including ROS levels, and in vitro fertilization/intracytoplasmic sperm injection (IVF/ICSI) success rates; however, there was no apparent association with clinical pregnancy rates [51, 52]. Studies of intrauterine insemination (IUI), by contrast, have shown a correlation between successful outcomes and sperm concentration, motility, and morphology [44, 53–55].

2.3.3 Novel Assays for Diagnosis of Male Infertility

Andrologists often lament the lack of more accurate studies for diagnosis of male infertility. Several tests are currently in various stages of development, including genomic, epigenomic, proteomic, glycomic, lipidomic, and metabolomic analyses [56, 57]. Testing for seminal ROS levels was found to have an AUC of 0.82 in a study of 105 patients [58]. Further evaluation in a larger cohort of patients is necessary.

Sperm DNA fragmentation, or damage, may also have diagnostic value. The etiology of DNA fragmentation appears to be multifactorial, including accumulated defects during spermiogenesis, exposure to oxidative stress, exogenous toxicity (e.g., smoking), and elevated temperature (e.g., secondary to a varicocele) [59].

The degree of DNA fragmentation may have implications for ART success. Evaluation of 1633 IVF and ICSI cycles found the likelihood of a live birth after IVF to be significantly lower at higher levels of fragmentation. Using the sperm chromatin structure assay (SCSA) and DNA fragmentation index (DFI), the odds ratio of live birth after IVF was 0.61 (95% confidence interval 0.38–0.97, p = 0.04) when DFI was >20%. This decrease is believed to be due to impaired fertilization, since DNA fragmentation was not associated with a lower birth rate after ICSI [60].

However, questions remain as to the diagnostic accuracy and predictive value of different DNA fragmentation assays. Cissen and colleagues performed a meta-analysis of various techniques for assessment of DNA fragmentation, finding that only terminal nick-end labeling was able to predict IVF/ICSI outcomes [61].

2.4 Are Sperm Counts Declining?

One of the most controversial issues in reproductive medicine during the past 30 years has been a purported decline in semen quality during the twentieth century. In 1992, a widely publicized meta-analysis of 61 studies by Carlsen and

colleagues appeared to demonstrate a worldwide decrease in average sperm concentration from 113 million/mL in 1940 to 66 million/mL in 1990 [62]. This report was echoed by additional publications, raising the question of whether exposure to environmental toxins, such as estrogenic compounds like diethylstilboestrol (DES), was adversely affecting testicular function [63, 64].

Important methodological shortcomings have since been identified in Carlsen and colleagues' analysis and in the quality of many studies that were included in their review [65, 66]. Geographical differences were found to be the source of much of the variance in sperm density [67]. All studies included in the review from before 1970 were performed in the USA; however, because US studies generally reported higher sperm concentrations than those conducted elsewhere, the review was biased toward an apparent decline in sperm concentration by inclusion of international studies post-1970.

In subsequent investigations, Fisch and colleagues found no evidence of a decline in sperm density in the USA, although they did identify substantial differences between the average sperm counts of men from different states [68, 69]. Fisch and colleagues also concluded that worldwide studies did not reveal a global decline in semen quality, although more limited, locoregional trends could not be excluded [65].

More recently, Levine and colleagues published a large meta-regression analysis of 185 worldwide studies (including almost 43,000 men) that reported on sperm concentration and total sperm count between 1973 and 2011 [70]. They found a 52% decrease in sperm concentration and a 59% decrease in total sperm count among Western countries (North America, Europe, Australia, and New Zealand) but no significant decline of either parameter in non-Western countries. This decline has not been uniformly reported, though. A key study of nearly 5000 Danish men found a slight increase in sperm concentration, total sperm count, and total normal morphology from 1996–2000 to 2006–2010 [71].

2.5 Health-Care Resource Utilization for Male Infertility

Medical intervention for male infertility may take the form of outpatient care, surgical procedures, and ART. The Urologic Diseases in America (UDA) Project, which published its first report in 2007, has facilitated a better understanding of the scope of health-care resource utilization for male infertility in the USA.

2.5.1 Office Visits and Ambulatory Surgery Cases

According to data from the National Ambulatory Medical Care Survey (NAMCS), which are summarized in the UDA Project's report, the average number of physician office visits for male infertility in the United States exceeded 150,000 annually between 1992 and 2000, with little variability [72]. However, there was a 29% decline in hospital outpatient visits and 23% decline in outpatient visits for male infertility from 2002 to 2006 [73]. The reasons for this trend are unclear but may include preferential use of ART.

Age-wise, the greatest utilization of health-care services for male infertility between 2002 and 2006 was among men 35–39 years old. Varicocele was the most commonly identified diagnostic code, accounting for 53% of office visits and 67% of ambulatory surgeries.

Other data from the NAMCS demonstrate substantial regional variation in resource utilization for male infertility. Men living in the Northeast United States had a rate of ambulatory surgery visits associated with a diagnosis of infertility of 227 per 100,000, while those in the Midwest, South, and West had rates of just 110.9, 128.9, and 119.2 per 100,000, respectively. The decline in outpatient visits was disproportionately experienced in the Northeast and West, decreasing by 36% and 32%, respectively, from 2002 to 2006. Visits in the South and Midwest decreased by 17%. The explanation for this variability is probably multifactorial, reflecting a combination of patient demand and availability of services.

2.5.2 Assisted Reproductive Technology

About 231,936 ART cycles were performed in the United States in 2015, an increase from 142,435 in 2007 and 81,438 in 1998 [74]. A total of 60,778 live births resulted from these cycles, representing a cumulative success rate of 26.2%. Approximately 33% of ART cycles were associated with a diagnosis of male factor infertility, and 17% were linked to a combination of male and female factors. The overall likelihood of a live birth per ART cycle was 34.4%.

The percentage of ART procedures involving the use of ICSI has steadily increased, from 71% in 2006 to 79% in 2015 [74]. Although ICSI was originally developed specifically to overcome severe oligozoospermia or azoospermia, nearly 70% of ART cycles now utilize ICSI even when no male factor is identified [74].

2.5.3 Cost of Treatment for Male Infertility

The overall economic burden of health care for male infertility is difficult to estimate precisely. While expenditures for office and ambulatory surgery visits were reported by the NAMCS to be $17 million in 2000, this figure does not account for IVF/ICSI or out-of-pocket expenditures [75]. If the assumed cost per IVF cycle is $15,715, then expenditures on ART alone for male infertility exceeded $1.8B in 2015,

given the percentage of ART procedures involving a diagnosis of male factor infertility [74, 76] .

On an individual basis, the average annual expenditures on health care for a privately insured male with infertility was $11,437 from 2003 to 2006, compared with $6942 for men without infertility. The difference in expenditures increases with patient age, from $2249 for men aged 18–34 to $8127 for men aged 55–64, likely due to increased utilization of more costly IVF technology [73].

There are significant disparities between countries in the cost of utilizing ART. In 2009, the average cost of a standard IVF cycle in the United States was $12,513, compared with $8500 in Canada, $6534 in the United Kingdom, and $3956 in Japan [77].

2.6 Cost Analysis Models for Management of Male Infertility

When a male risk factor for infertility is identified, the couple is often faced with the choice of using ART or having pathology-directed treatment. Evaluating the economic efficiency of these alternatives is the domain of cost analysis.

Cost analysis is only meaningful with respect to treatments that have previously been demonstrated to be effective. Our intention in this chapter is not to review the studies that have established the effectiveness of the interventions discussed here—or, in some cases, the controversies surrounding them. Rather, our focus is limited to a brief introduction to cost analysis studies as they pertain to male infertility.

Two types of cost analysis are utilized in reproductive medicine: cost-minimization analysis and cost-effectiveness analysis. The first, cost-minimization analysis, is also known as cost identification. It involves assessment (and comparison) of the costs associated with particular treatments. Direct and/or indirect costs may be taken into account—direct costs being health-care expenditures and indirect costs being "downstream" burdens such as transportation expenses, lost wages, etc. In well-conducted economic analyses, future costs should be appropriately discounted to present values by a factor of 3%–5% per year.

When the outcomes of alternative interventions are not equivalent, cost-effectiveness analysis is useful to compare them, as it involves not only identifying the costs that accrue but also expressing them relative to the probability of a particular result (e.g., dollars per pregnancy or live birth). Decision analysis, such as Markov modeling, is the most common technique employed for this purpose in the field of male infertility. Details of relevant methodology are covered in *Methods for the Economic Evaluation of Health Care Programmes* [78].

Comparison of cost-effectiveness has been applied to several management options that may be encountered in male reproductive medicine, including varicocele treatment vs. immediate ART (with or without surgical sperm retrieval), vasectomy reversal vs. ART, and hormonal therapy vs. ART for hypogonadotropic hypogonadism. Pathology-directed intervention has almost invariably been found to be more cost-effective than a straight-to-ART approach [79, 80]. One exception is when a varicocele is present in the setting of nonobstructive azoospermia; in this situation, microsurgical testicular sperm extraction (TESE) for ICSI is more cost-effective than varicocelectomy [81].

Every cost-effectiveness analysis in the arena of male infertility is sensitive to assumptions about treatment costs, success and complication rates, and the subsequent management of couples for whom first-line intervention is unsuccessful [82, 83]. Precise characterization of the clinical scenario(s) is very important and should be considered when determining the generalizability of results. For instance, the age of the female partner has a significant influence on the relative cost-effectiveness of vasectomy reversal and ART [75].

2.7 Conclusion

This chapter examined a number of issues that are commonly misunderstood and/or misrepresented with respect to the epidemiology of infertility, in general, and male infertility, in particular. First, infertility should not be confused with sterility—or even below-average fecundability. Approximately 10% of couples with average reproductive potential will not conceive within 12 months of unprotected intercourse and are therefore designated as infertile. Such couples may comprise a substantial proportion of those who present for evaluation of infertility (see Table 2.3). Their odds of spontaneous, unassisted conception remain high.

From a clinical standpoint, it would be ideal to accurately identify men with below-average reproductive potential. However, while semen analysis is the most common test employed for this purpose, its utility is limited by substantial overlap between the distributions of semen characteristics in empirically fertile and infertile men. Using relatively low diagnostic thresholds, such as the 2010 WHO reference values, carries the advantage of high specificity and perhaps a relatively decent positive predictive value in the setting of an infertility clinic; unfortunately, the negative predictive value only narrowly exceeds that of a coin flip.

The diagnostic inaccuracy of semen analysis is a fundamental problem for several additional reasons. From an epidemiologic perspective, the absence of a gold-standard test for male infertility means that we have, at best, an uncertain grasp of its actual prevalence, let alone its association with putative risk factors, such as varicocele, cryptorchidism, sexually transmitted infections, etc. Moreover, if the true prevalence of male infertility is unclear then so, too, is the predictive value of tests employed for its diagnosis.

Finally, there is the question of how to counsel infertile men whose semen parameters exceed diagnostic thresholds. Given the poor predictive value of these "negative" results, should we advise consideration of further evaluation and treatment for modifiable risk factors identified in these individuals? An affirmative response to this query carries the risk of unnecessary treatment and costs, while the alternative may deprive some couples of an improvement in reproductive potential that facilitates natural conception, allows the use of IUI instead of IVF, or increases the odds of successful IVF/ICSI [84]. Well-designed studies to address this question are necessary.

2.8 Review Criteria

An extensive search was performed to identify studies regarding the epidemiology, diagnosis, and treatment of male infertility. Search engines such as MEDLINE (Ovid), PubMed, and Google Scholar were used. For the second edition, emphasis was placed on studies published between 2010 and 2018. Key search terms included male infertility, incidence, epidemiology, sperm count, semen parameters, prediction, cost analysis, DNA fragmentation, IVF, ART, and ICSI. Data were abstracted from publications by the Centers for Disease Control and Prevention (CDC), including the National Ambulatory Medical Care Survey and the CDC's ART National Summary Report, as well as the Urologic Diseases in America report issued by the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK). Articles published in languages other than English were not considered. Websites and book-chapter citations provide conceptual content only.

Acknowledgments The authors thank Kelli M. Mulder and Ranya N. Sweis for critically reviewing an earlier edition of this chapter. Jonathan L. Faasse and Kristin M. Faasse provided valuable assistance with the figures.

Laboratory Evidence for Male Infertility

3

Neel Parekh and Ashok Agarwal

Key Points

- The WHO manual is currently in its fifth edition and updated the reference values. The lower reference values provide a broader range of "normal" parameters.
- Azoospermia is defined as the complete absence of sperm after examination of a centrifuged pellet on two separate occasions obtained more than 2 weeks apart.
- Healthy sperm DNA is bound to protamine and tightly packed to protect from stress and breakage during transport through the female reproductive tract.
- The TUNEL assay identifies "nicks" or free ends of DNA by incorporating fluorescent nucleotides into the site of damage. It is both highly specific and associated with a high positive predictive value to quantify SDF.
- An AZFa or AZFb Y-microdeletion has rarely successful sperm retrieval rates. However, sperm retrieval rates are as high as 80% in patients with an isolated AZFc deletion.

3.1 Introduction

The semen analysis has been the primary biomarker to evaluate male infertility and is a direct reflection of the male's fertility and overall health in the preceding 74 days [1]. Semen analyses first began with the advent of microscopy in 1678, when van Leeuwenhoek first described spermatozoa or "semen animals" in the ejaculate [2]. However, it was not until 1951 that the integral role of semen in reproduction became evident. MacLeod's landmark study compared semen parameters of 1000 men who conceived naturally and 800 men who were presumed infertile and paved the way for modern semen analyses [3]. MacLeod plotted the semen parameters on histograms, and the plots were divided into quartiles for each of the two groups of men. He believed that men in the lowest quartile would be infertile while men above this threshold were likely fertile. The data was instrumental in developing reference ranges for semen parameters used in the first edition of the World Health Organization (WHO) manual in 1980 [4]. Since then, advances in assisted reproductive technologies (ART) have shown considerably more options for subfertile and infertile men to achieve fecundity. Such changes have necessitated a more comprehensive and methodological assessment of infertile men. The aim of this chapter will be to discuss modern laboratory exams and techniques available to successfully evaluate and treat male factor infertility.

3.2 WHO Guidelines for Assessment of Semen Specimen

Since 1980, the WHO has endeavored to standardize how laboratories analyze and report semen parameters globally. The WHO manual is currently in its fifth edition which was published in 2010 [5]. The fifth edition aims to provide evidence-based reference ranges based off of populational studies. The new reference ranges are significantly lower than the previous manuals (Table 3.1) [5, 6]. Cooper et al. analyzed semen samples from more than 4000 men from 14 different countries on four continents, and reference values were calculated from men who naturally conceived with their partner within 12 months [7]. After the data was examined, the 95th percentile for semen volume, concentration, motility, vitality, and morphology was formulated, and the

S. J. Parekattil et al. (eds.), *Male Infertility*, https://doi.org/10.1007/978-3-030-32300-4_3

fifth percentile was set as the lower reference limit. There are, however, several limitations to this study including significant population biases. Specifically, the majority of the cohort was from Europe, and only 10% of the study population was from the southern hemisphere. Furthermore, the data is derived solely from a fertile cohort and was not compared to an infertile one; therefore, a "cutoff" between infertile and fertile men cannot be determined [8]. As a result of the lower reference values, men who would have been categorized as having abnormal parameters using the old reference values are now being classified as having normal parameters. Murray and colleagues determined that roughly 15% of men who had one or more aberrant parameters using the fourth edition values were categorized as having all parameters within the normal fifth edition reference ranges [9]. The fifth edition manual provides clinicians a table which reviews where individual semen parameters lie within the 2.5th to 97.5th percentiles for men who naturally conceived with their partner within 12 months (Table 3.2) [5, 7]. This information can be informative for men when reviewing semen analysis parameters in the office.

Table 3.1 Evaluation of fourth and fifth editions of the WHO manual semen analysis reference values

Parameter (units)	Fourth edition reference value	Fifth edition lower reference limit fifth centile (95% CI)
Semen volume (ml)	2.0	1.5 (1.4–1.7)
Total sperm number (10^6/ejaculate)	40	39 (33–46)
Sperm concentration (10^6/ml)	20	15 (12–16)
Total motility (%)	50	40 (38–42)
Progressive motility (%)	25	32 (31–34)
Sperm morphology normal forms (%)	Not given but suggests possibly 15	4 (3–4)
% Vitality (live spermatozoa)	50	58 (55–63)
Peroxidase-positive leukocytes (10^6/ml)	<1.0	<1.0

3.3 Laboratory Evaluation of Male Factor Infertility

3.3.1 Basic Semen Analysis

The process of natural conception is intricate, culminating in fusion of a healthy sperm to healthy ovum. Semen analyses provide valuable information for clinicians and patients but is only a surrogate for male fertility and does not guarantee paternity. It is unclear why some men with "normal" semen analyses suffer from infertility and those with "abnormal" semen analyses may remain fertile [8]. Reproductive potential is also strongly influenced by female factors in many couples and should be assessed when appropriate. To appropriately assess for male factor infertility, a thorough history and physical exam should be performed. Ideally, two semen analyses should be obtained and performed one month apart. Clinicians should be able to appropriately counsel male patients on the protocol for proper semen collection and ultimately interpret the results [9].

3.3.1.1 Collection

It is generally recommended that a semen specimen be collected at least 3 months after a febrile illness or stressful life event. The WHO recommends providing a semen specimen after 2–7 days abstinence [5]. However, the optimal abstinence interval may be 2–4 days, as studies have shown a relative improvement in total sperm concentration and motility after 4 days [10]. A longer abstinence interval has been associated increased sperm DNA damage [11]. Preferably, the specimen should be obtained in a sterile cup via masturbation either at home or in the laboratory. However, sexual intercourse using a special collection condom that is not detrimental to sperm may also be utilized. Lubricants should be avoided as they may alter sperm motility [12]. The semen specimen should be evaluated within an hour of collection and stored at room or body temperature until then. The Clinical Laboratory Improvement Amendments (CLIA) has specific guidelines by which laboratories should observe to ensure quality and accurate semen analysis results [13]. Once the semen liquefies, typically within 20–60 minutes, a

Table 3.2 Review of semen analysis percentiles for men whose partners had a time to conception of ≤12 months

Percentiles									
Parameters	2.5th	5th	10th	25th	50th	75th	90th	95th	97.5th
Semen volume (ml)	1.2	1.5	2.0	2.7	3.7	4.8	6.0	6.8	7.6
Total sperm (10^6/ejaculate)	23	39	69	142	255	422	647	802	928
Sperm concentration (10^6/ml)	9	15	22	41	73	116	169	213	259
Total motility (%)	34	40	45	53	61	69	75	78	81
Progressive motility (%)	28	32	39	47	55	62	69	72	75
Sperm morphology normal forms (%)	3	4	5.5	9	15	24.5	36	44	48

macroscopic assessment of the semen sample is performed which includes volume, pH, color, and viscosity. Subsequently, microscopic examination is utilized to calculate the concentration, motility, morphology, and vitality [14].

3.3.1.2 Volume

Over 70% of the semen volume is provided by the seminal vesicles, and current WHO criteria for normal semen volume is >1.5 ml [5]. A low semen volume following an appropriate abstinence interval and complete collection may indicate partial retrograde ejaculation, ejaculatory duct obstruction (EDO), congenital absence of the vas deferens, or severe hypogonadism. A high semen volume (>4 ml) may be seen in instances of prolonged sexual abstinence.

3.3.1.3 Liquefaction and Viscosity

Fibrinolysin is a proteolytic enzyme that is secreted by the prostate and facilitates liquefaction of semen from the coagulum state (~30–60 minutes). A defect in liquefaction may be indicative of an EDO or inadequate secretion of fibrinolysin by the prostate. Semen viscosity is related to the fluid nature of the specimen and can be determined by utilizing a 1.5 mm pipette to drop a semen specimen into a cup and examining the length of the thread formed. A thread length >2 cm is considered abnormally viscous. There is a concern that increased viscosity impairs sperm motility and therefore fertility, but this is controversial [8]. "Non-liquefaction" and "hyperviscosity" are two distinct conditions that are commonly interchanged inappropriately. "Non-liquefaction" is a result of the semen remaining in the coagulum state. "Hyperviscosity" is when the semen specimen pours thick as opposed to in drops. This is associated with hypofunction of the prostate or seminal vesicles, infection, or high levels of leukocytospermia [15]. Trypsin can be used to treat hyperviscous semen specimens prior to additional testing.

3.3.1.4 pH [normal > 7.2]

Measurement of pH is primarily determined by the balance of alkaline seminal vesicle fluid and the acidic prostatic secretions. The normal range of semen pH typically lies between 7.2 and 8.0. An acidic pH is associated with obstruction or seminal vesicle hypoplasia seen in men with congenital absence of the vas deferens [12, 13]. An alkaline pH > 8.0 may be associated with an underlying infection [8, 12].

3.3.1.5 Concentration

Normal sperm concentration is defined as >15 million sperm/mL and is determined after careful light microscopic examination of the wet preparation [5]. Typically, a minimum of 200 spermatozoa are counted utilizing counting chambers within a grid pattern for accurate assessment (Fig. 3.1). The concentration is then calculated and reported per milliliter. Alvarez et al. demonstrated that compared to other sperm parameters (count, morphology, motility, and volume), sperm concentration has the highest intra-observer variation [16]. Oligozoospermia is defined as <15 million sperm/mL, but incomplete collection or short abstinence interval should be ruled out prior to making this diagnosis. Azoospermia is defined as the complete absence of sperm after examination of a centrifuged pellet on two separate occasions obtained more than 2 weeks apart. EDO, ejaculatory dysfunction, and abnormal spermatogenesis are potential causes of azoospermia.

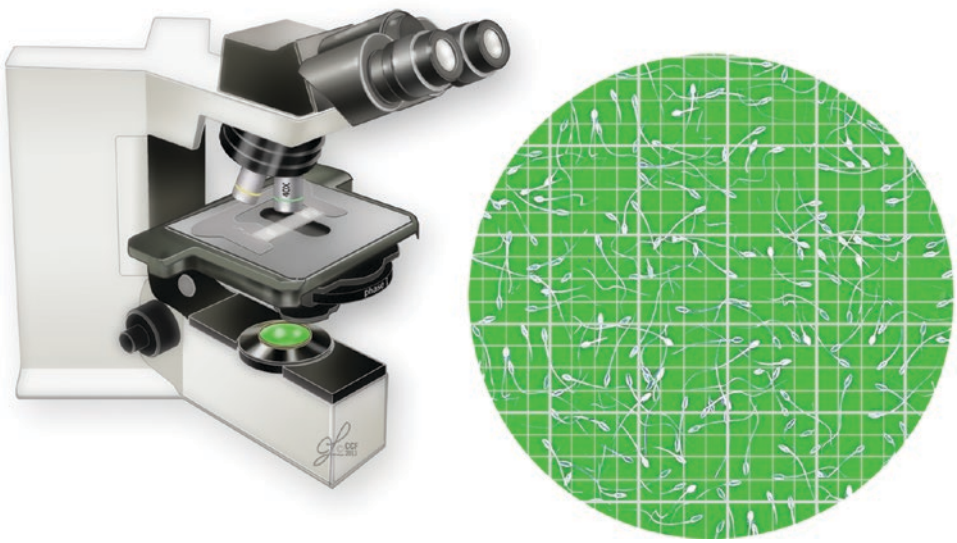

Fig. 3.1 Measurement of sperm concentration and motility by a fixed counting chamber and a phase-contrast microscope. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2013–2019. All Rights Reserved)

Recently, studies have revealed that the total motile sperm count (volume × concentration × % motility) is more predictive of infertility compared to concentration, motility, and volume alone [17, 18]. Compared to infertile men with normal semen parameters, those with total motile sperm count (TMSC) <1 million experienced 83% fewer natural pregnancies, while those with 10–20 million had 55% fewer pregnancies [18]. Surprisingly, among men with TMSC 0–1 million, 23% were able to achieve a natural pregnancy within 3 years, further highlighting the predictive and diagnostic limitations of semen analyses [18]. TMSC was also recently shown to be a better predictor than total sperm count for intracytoplasmic sperm injection (ICSI) outcomes compared with WHO values [19]. Clinically, TMSC facilitates decision-making when counseling couples on appropriate treatment options, including assisted reproductive technologies.

Computer-assisted semen analysis (CASA) is an automated method of determining sperm parameters which offers several advantages over manual semen analyses. Specifically, the basic parameters evaluated manually by an operator (concentration, motility, and morphology) can be measured more precisely by CASA. CASA also provides useful kinematic information. However, CASA systems suffer from other challenges such as costly equipment, more complicated procedure, and poorer performance with low sperm concentrations [20].

3.3.1.6 Motility

Sperm motility is determined by assessing sperm for signs of movement and is a critical indicator of the functionality of spermatozoa. It should be characterized immediately following liquefaction to avoid temperature changes and dehydration. The WHO considers normal total motility to be >40% and is dependent on the ability of the sperm to traverse the epididymis and successfully mature [5]. A motility of <5%–10% can be attributed to ultrastructural defects in the reproductive tract. The previously utilized WHO subclassification of progressive motility into fast and slow has fallen out of favor due to high variability and inaccuracy among laboratory technicians. Currently, motility is simply divided into (1) progressive, space gaining motion; (2) nonprogressive, motion in place or in small circles; and (3) nonmotile or immotile [6].

Asthenozoospermia (sperm motility <40%) can also be a result of a poor specimen collection that may have been exposed to a rubber condom, lubricants, or spermicides. Sporadic clumps of agglutinated sperm are typically not concerning. However, clumping of sperm seen >10%–15% of the time is associated with antisperm antibodies (ASAs). ASAs may impair sperm motility and elicit an unusual "shaking pattern" that can impede transit of sperm through the cervical mucous. Lengthy abstinence intervals, infection, partial EDO, ultrastructural defects, and varicocele have all been implicated as potential causes of asthenozoospermia [12, 16].

3.3.1.7 Morphology

Over time, there have been significant shifts in the classification of sperm morphology which is a source of controversy. Normal morphology reference values have shifted from ≥80.5% in the WHO first edition to ≥4% normal forms in the WHO fifth edition [5, 21]. Stricter approaches and lack of standardization in technician training may have contributed to these changes [21, 22]. To appropriately classify morphology, the sperm should routinely be analyzed in a fixed, air dried, and stained semen smear. Either Shorr, Papanicolaou, or Diff-Quik smear stains are approved by the WHO. This process alone has been implicated in affecting morphologic appearance [23, 24]. Normal sperm are typically comprised of a smooth oval head with a distinct acrosomal region covering 40%–70% of the sperm head. Normal morphology dimensions have been defined as a sperm head of 3–5 μm in length and 2–3 μm in width. Furthermore, the sperm should be devoid of head, midpiece, or tail defects [25].

- *Head defects* include micro- or megalocephalic heads, tapered head, missing acrosome (globozoospermia), heads with irregular forms, and bicephalic or multicephalic heads.
- *Midpiece defects* consist of abnormal or no tail insertions. Distended, thin, bent, or elongated midpieces are abnormal.
- *Tail defects* include coiling (associated with osmotic stress), multiple, short, 90° bending, or broken tails.

Sperm morphology male infertility–laboratory evaluation is reported as the percentage of atypical forms present in the ejaculate and classified according to the WHO criteria or the Kruger's strict criteria. Teratozoospermia is defined as <4% normal morphology by the WHO method. Early studies demonstrated that it is most likely the morphologically normal appearing spermatozoa that are best able to navigate the female reproductive tract and fertilize the egg [26, 27]. More recent data suggests that abnormal morphology should not deter intrauterine insemination (IUI) or require couples to proceed immediately to in vitro male infertility–laboratory evaluation: fertilization/intracytoplasmic sperm injection (IVF/ICSI) [28–30]. The American Urological Association (AUA) recommends against utilizing isolated abnormalities in strict morphology to counsel couples on treatment decisions [31].

3.3.1.8 Agglutination

Microscopic examination may identify sperm agglutination or clumping and is characterized by sperm adhering to one another without other cells or debris. Sperm agglutination may be indictive of ASA. However, if there is clumping of

sperm, cells, and debris, it is most likely a result of aggregation. Aggregates typically only consist of dead sperm while agglutination from ASA consists of a proportion of motile sperm. Clinicians should be aware that a small amount of agglutination may be unremarkable [6]. However, when significant agglutination is present, additional testing with ASA testing and/or semen cultures is recommended [12, 31].

3.3.1.9 Leukocytospermia

Leukocytospermia is defined as >1 × 10^6/ml WBCs in the semen and is commonly associated with idiopathic male infertility [32]. It is important to avoid classifying immature spermatozoa – spermatids and spermatocytes, which appear as round cells – as seminal leukocytes. The primary sources of leukocytes are from the prostate, seminal vesicles, vas deferens, and epididymis. They are unlikely to arise from the testis, secondary to the blood–testis barrier [33]. If there are >5 round cells per high-powered field (HPF), further investigation is recommended. Immunocytochemistry is the gold standard, but due to cost and difficulty standardizing the monoclonal antibodies, it is not commonly performed by most laboratories. Peroxidase staining or the Endtz test is a reliable substitute to properly identify leukocytes and distinguish them from immature spermatozoa [34].

Although leukocytospermia can be indicative of an infectious process (male accessory gland infection), recent investigation has determined that WBCs can exist in the absence of infection or immune response [35]. Furthermore, leukocytospermia has been implicated in negatively affecting sperm functionality through the formation of reactive oxygen species (ROS) [35, 36]. Sharma and colleagues have shown that ROS levels are increased, even with leukocytospermia levels <0.2 million/mL, suggesting leukocyte levels lower than the WHO "cutoff" are detrimental [37].

Athayde et al. demonstrated that men with a normal Endtz test had a 24% chance of natural conception, while men with leukocytospermia levels <1 million/mL lowered natural conception rates to 16% on 12-month follow-up [38]. Unfortunately, identifying leukocytospermia is not standard practice in many andrology laboratories or must be ordered separately from the basic semen analysis. Routine urine and semen cultures should be performed if leukocytospermia is identified. Current therapies to treat leukocytospermia include anti-inflammatory medications, antioxidants, and antihistamines. Antibiotics are used to treat concurrent clinical infections.

3.4 Retrograde or Post-Ejaculatory Urinalysis (PEUA)

Men with retrograde ejaculation (semen is redirected into the urinary bladder), incomplete collection, EDO, congenital bilateral absence of the vas deferens (CBAVD), hypogonadism, or lack of emission may present with low-volume ejaculate on semen analysis. A PEAU is a routine laboratory test used to differentiate retrograde ejaculation from the aforementioned conditions. The AUA Best Practice Statement recommends that clinicians perform PEUA in patients with ejaculate volume <1.0 ml and in the absence of CBAVD or hypogonadism [31]. PEUA is performed by microscopically assessing the pellet at ×400 magnification after approximately 10 minutes of centrifugation at a minimum of 300 *g*. In patients diagnosed with aspermia or azoospermia, identification of any sperm on PEUA is indictive of retrograde ejaculation. However, in patients with low volume oligozoospermia, "significant numbers" of sperm should be identified on PEUA in order to diagnose retrograde ejaculation. There is no expert consensus on "significant numbers" of sperm in PEUA.

3.5 Reactive Oxygen Species (ROS) Testing

There is mounting evidence that elevated ROS levels play an independent role in the etiology of male infertility [39, 40]. ROS are produced by leukocytes and abnormal spermatozoa and are a natural byproduct of metabolic pathways. Small quantities of ROS are actually required to ensure normal spermatogenesis, successful capacitation, and the acrosome reaction [40, 41]. An overabundance of ROS levels compared with antioxidants, however, may result in oxidative stress (OS) which has been observed to impair spermatogenesis as well as sperm kinetics [41]. Mitochondria have been identified as an essential component of seminal ROS production, which is primarily mediated through the formation of superoxide in the electron transport chain [42]. Oxidative stress has been shown to negatively affect sperm physiology and function through several pathways: increased rates of DNA fragmentation [43], decrease in sperm motility [44], and diminished quality of sperm [45]. Elevated seminal ROS levels have been identified in 25%–80% of infertile men, but levels are significantly lower in the fertile population, and it remains unclear if this scenario is predominately a correlative or a causative relationship with infertility [46, 47]. Clinically, measurement of seminal oxidative stress can identify men where oxidative stress is associated with infertility and identifies a patient who may benefit from antioxidant supplementation [46].

The ideal method of testing for ROS is controversial, likely due to a lack of standardization among laboratories regarding reference values, equipment, and technique. Currently, there are a variety of direct and indirect ROS testing modalities utilized to determine seminal OS. However, the most reliable and accurate modality has been luminol-based chemiluminescence assay. This technique accurately measures both intracellular and extracellular ROS. Luminol

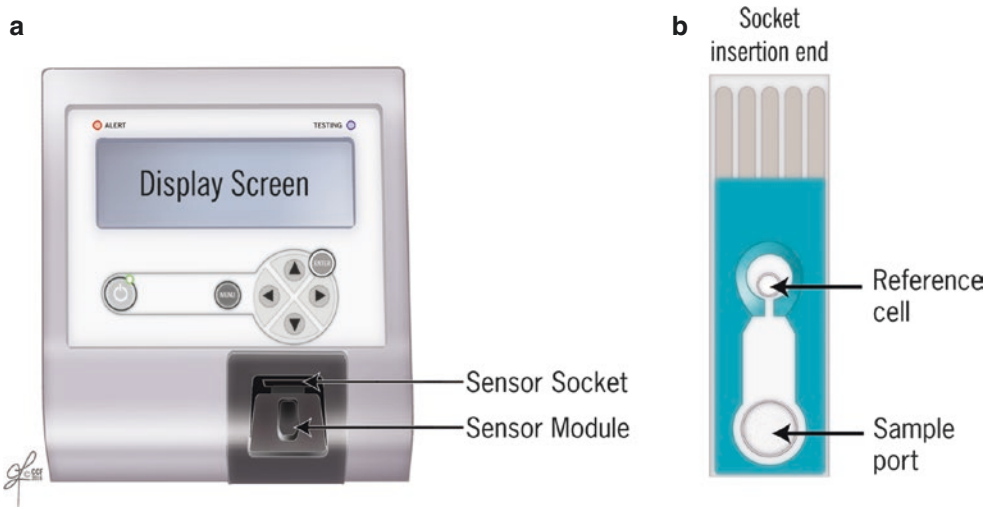

Fig. 3.2 Measurement of ORP using (**a**) MiOXSYS analyzer and the (**b**) sensor. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2013–2019. All Rights Reserved)

is also able to react with various forms of ROS, including hydrogen peroxide, hydroxyl radical, and superoxide anion. An adequate semen specimen is required to perform this test (>1 × 10^6/ml) and analyzed within 1 h of collection. Luminol adheres to the free radicals to produce a light signal that the luminometer converts to an electrical signal. The quantity of free radicals produced is measured as relative light units (RLU)/s 10^6 sperm. Agarwal and colleagues [48] determined that in healthy controls with normal semen parameters, the physiologic ROS level is 102.2 RLU/s/10^6. Men above this threshold value can be considered to be oxidative stress positive and should be counseled appropriately.

The latest advancement in laboratory diagnostics is the Male Infertility Oxidative System (MiOXSYS) (Fig. 3.2). It allows for an easy and accurate measurement of ROS through the oxidation-reduction potential (ORP). ORP, or redox balance, measures for the homeostasis between reductants and oxidants in a variety of biologic specimens. Several studies have validated the reproducibility and reliability of the MiOXSYS in measuring the ORP levels in semen specimens of patients evaluated for male infertility [49, 50]. The MiOXSYS has several advantages over standard chemiluminescence assays which include ease of use, smaller sample volume (30 μL vs. 400 μL), and more forgiving measurement protocol (up to 120 minutes after specimen is produced) [50].

While ROS measurement is not routinely recommended on initial evaluation of male infertility, it is a clinically useful tool to further evaluate patients with varicocele, lifestyle factors (i.e., smoking), and idiopathic infertility [12, 31].

3.6 Acrosome Reaction Testing

The acrosome reaction is an essential step of successful fertilization. The acrosome is a modified Golgi apparatus that encompasses 40%–70% of the sperm head. The primary function of the acrosome reaction is to release the lytic enzymes acrosin and hyaluronidase to digest the zona pellucida which ultimately allows for spermatozoa fusion with the oocyte. Acrosome reaction testing is not routinely performed in many laboratories, but may be considered when substantial irregularities of head morphology exist or the setting of recurrent IVF failure. Acrosomal status can be examined through triple staining with transmission electron microscopy, optic microscopy, flow cytometry, and fluorescently labeled lectins [51–55].

3.7 Antisperm Antibody (ASA) Testing

A number of urologic conditions including testicular cancer, torsion, and traumatic or surgical disruption of the testis can violate the blood–testis barrier [56]. Breakdown of the blood–testis barrier may predispose men to an immune response to sperm in the form of ASA. ASA are deemed an important factor impairing pregnancy rates and are seen in approximately 10% of infertile men as opposed to 2% of fertile men [57, 58]. Extensive sperm agglutination is a result of ASA which can impair the process of fertilization by inhibiting sperm penetration of cervical mucous and preventing fusion of the sperm and oocyte. Sperm concentration and motility have also been shown to be lower with the presence of ASA [12, 56].

The mixed antiglobulin reaction (MAR) and immunobead test are qualitative laboratory tests used to detect IgA and IgM sperm antibodies. If ≥50% of motile sperm are bound by antibodies, then these tests are considered abnormal [5]. The clinical utility of ASA testing is varied, but in men with isolated asthenospermia and normal concentration or with significant sperm agglutination, ASA testing should be considered [12, 31].

3.8 Sperm Viability Testing

Sperm viability testing or a vitality assay is a laboratory test utilized to facilitate identification of living sperm in the setting of low motility (<25%). In ejaculated specimens with low motility or nonmotile surgically derived sperm to be used for IVF/ICSI, it is necessary to differentiate between necrozoospermia (dead sperm) and viable immotile sperm (asthenozoospermia). This is done by evaluating the integrity of the sperm cell membrane which should be intact in living sperm. The fifth edition WHO reference parameter for vitality is ≥58% [5]. Cell membrane integrity can be evaluated through the hypoosmotic swelling test (HOS test) and the dye exclusion test.

The dye exclusion test is dependent on the intact cell membrane of a live sperm resisting absorption of specific dyes. Eosin Y and nigrosin are two of the most commonly utilized dyes. Nigrosin is particularly useful as it will stain the background dark and provide good contrast for sperm assessment. Eosin Y will stain sperm heads red or dark pink if they are dead. It will stain live sperm heads white or light pink. The HOS test is dependent on the ability of the live sperm (intact cell membrane) to swell in hypotonic solutions. The HOS test is favored over the dye exclusion test due to the ability of quickly assessing for necrozoospermia without damaging viable sperm [31]. Therefore, sperm used for a HOS test can still be used for subsequent IVF/ICSI [58, 59].

3.9 Advanced Semen Testing

3.9.1 Sperm DNA Fragmentation (SDF)

Evaluation of sperm DNA fragmentation has evolved into an essential tool for the overall assessment of male infertility. Sperm DNA is bound to protamine and tightly packed to protect from stress and breakage during transport through the female reproductive tract. The cause of DNA damage is likely multifactorial (i.e., smoking, drug use, environmental exposure, malignancy, chemotherapy, and varicocele) [60]. Elevated SDF has been identified in roughly 8% of subfertile men with normal semen parameters [61]. The integrity of sperm DNA has been shown to affect couple's fecundity through its impact on successful fertilization, healthy embryo development, implantation, and pregnancy [62].

Several sperm DNA integrity assays have been introduced to evaluate the degree of SDF. In general, the assays were developed to facilitate clinicians in implementing early and effective management plans for specific clinical scenarios. These scenarios include couples with recurrent pregnancy loss, patients with idiopathic infertility, ART failure, and varicocelectomy candidates. Commonly utilized methods for evaluating SDF are summarized in Table 3.3.

Table 3.3 Methods of evaluating sperm DNA damage

Assay	Measures	Method
Sperm chromatin structure assay (SCSA)	Susceptibility of sperm DNA to denaturation by heat or low pH	Flow cytometry based
Terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL)	Single- and double-stranded DNA breaks	Fluorescence microscopy or flow cytometry based
Single-cell gel electrophoresis assay (Comet)	Single- and double-stranded DNA breaks Altered bases	Objective and quantitative, fluorescence microscopy
Sperm chromatin dispersion (SCD)	Absence of sperm DNA damage - Halo	Flow cytometry based

3.9.2 Sperm Chromatin Structure Assay (SCSA)

The SCSA is dependent on the principle that heat or acid will denature sperm with an abnormal chromatin structure. Specifically, SCSA is a measure of the susceptibility of sperm DNA to acid or heat denaturation utilizing flow cytometry [63]. The metachromatic shift from green to red fluorescence is measured using flow cytometry. The percentage of spermatozoa with red fluorescence (red–red + green fluorescence) is expressed as DNA fragmentation index (DFI). The clinical threshold for DFI is <30%. Couples with >30% DFI have lower conception rates with natural intercourse and ART. It is a very sensitive assay and has been reported as an excellent tool to detect dose–response relationship in men exposed to environmental toxicants [64]. SCSA can evaluate over 10,000 cells rapidly and has a well-standardized protocol, thus minimizing interlaboratory variations. The major drawbacks include expensive instrumentation (flow cytometry) and skilled technicians.

3.9.3 Terminal Deoxynucleotidyl Transferase dUTP Nick End Labeling (TUNEL)

The TUNEL assay identifies "nicks" or free ends of DNA by incorporating fluorescent nucleotides into the site of damage [65]. Single- and double-stranded DNA damage can be examined by either fluorescence microscopy or flow cytometry. Advantages of the TUNEL assay include proven reliability, accuracy, and ease of use with low interlaboratory discrepancies [66]. Furthermore, by utilizing a threshold of 16.8% for SDF, the TUNEL assay is both highly specific and associated with a high positive predictive value and will aid in its clinical utility [67].

3.9.4 Single-Cell Gel Electrophoresis Assay (Comet)

The comet assay provides an objective and quantitative measure of the degree of DNA damage per sperm [68]. Comet is able to detect not only single- and double-strand breaks but also abasic sites. The sperm are subject to electrophoresis at high pH which results in structures resembling comets under fluorescence microscopy. The number of DNA breaks is quantified by the intensity of the comet tail relative to the head. An advantage of this assay is that it requires only 5000 sperm to evaluate SDF and is particularly useful in cases of severe oligozoospermia [69].

3.9.5 Sperm Chromatin Dispersion (SCD)

The SCD test or Halosperm test is unique in that it is a measure of the absence of SDF. The SCD test produces sperm nucleoids with a central core and a peripheral halo of dispersed DNA loops. Sperm with nonfragmented DNA will demonstrate the characteristic halo, but sperm with DNA fragmentation will produce very small or no halo on fluorescent microscopy. While the SCD test is easy to use, high interlaboratory variations has impeded widespread standardized usage [12].

3.9.6 Endocrine Evaluation

Approximately 3% of infertile men will have a hormonal imbalance as a basis of their subfertility [70]. The 2011 AUA Best Practice Statement recommends endocrinologic assessment in men with (1) abnormal semen analysis (sperm concentration < 10 million/ml), (2) diminished sexual function, or (3) clinical findings of a small firm testis or altered masculine features. The hypothalamus secretes gonadotropin-releasing hormone (GnRH) which traverses the hypophyseal portal system to the anterior pituitary and stimulates the release of FSH and LH. These gonadotropins exert their effect on the testicle in a pulsatile fashion. Under normal conditions, LH stimulates the testicular Leydig cells to produce testosterone. Testosterone provides negative feedback onto the hypothalamus by inhibiting GnRH release. FSH stimulates the testicular Sertoli cells to promote spermatogenesis and secrete inhibin B and activin. Inhibin B causes negative feedback by inhibiting the release of FSH from the anterior pituitary, whereas activin stimulates the release of FSH from the anterior pituitary. The relationship between these hormones can help determine an underlying cause of subfertility.

At a minimum, the initial endocrinologic workup should include a measurement of serum follicle-stimulating hormone (FSH) and morning serum testosterone levels. Morning collection of blood for hormone testing is recommended due to a normal physiologic decrease in testosterone levels throughout the day. If the testosterone level is low, then a repeat measurement of total and free testosterone should be obtained. In addition, measuring serum prolactin and luteinizing hormone (LH) is also advised.

While normal serum FSH levels do not guarantee active spermatogenesis, an elevated or "high normal" FSH level is indicative of an abnormality in spermatogenesis such as hypergonadotropic hypogonadism (primary testicular failure). Causes of primary testicular failure include Klinefelter's syndrome, Noonan syndrome, and poorly functioning testes (i.e., cryptorchidism, atrophy, or torsion). Obstructive azoospermia typically presents with normal testosterone and FSH/LH levels. When serum testosterone levels are low and gonadotropins are also either low or "inappropriately normal," hypogonadotropic hypogonadism (secondary testicular failure) may be the cause. Elevated prolactin levels, hemochromatosis, opioid use, pituitary/hypothalamic damage, or genetic conditions (i.e., Kallman's syndrome) are associated with hypogonadotropic hypogonadism.

If hypogonadotropic hypogonadism is diagnosed or symptoms suggest prolactinoma, then obtain a serum prolactin. Due to significant physiologic variability, serum prolactin levels should be repeated if initially abnormal. Slight elevations of serum prolactin (<50 ng/ml) can be associated with stress, kidney disease, certain medications, or be idiopathic in nature. However, if the serum prolactin remains abnormally elevated or is extremely high, then magnetic resonance imaging (MRI) should be performed to assess for a pituitary tumor.

Obese men have increased activity of the hormone aromatase, an enzyme found in adipose that converts testosterone to estrogen. An overabundance of estrogen is associated with diminished libido, gynecomastia erectile dysfunction, and hypogonadism. Evaluation of estrogen should be performed in obese infertile men or those with symptoms suggesting hyperestrogenism.

3.9.7 Genetic Evaluation

Genetic testing is a key component of the male infertility evaluation. It provides necessary information to establish causes of infertility, identify clinically significant medical comorbid conditions, and assess the likelihood of success of certain fertility treatment options (i.e., microdissection testicular sperm extraction or varicocele repair). Furthermore, it allows the clinician to counsel partners on the potential risk of transmitting genetic conditions to future progeny. The most common genetic causes of male infertility are cystic fibrosis transmembrane conductance regulator (CFTR) gene mutations, Y-chromosome microdeletions, and chromosomal

Table 3.4 Frequency of karyotype abnormalities in infertile men

Azoospermia	10%–15%
Oligozoospermia	5%
Normal	<1%
All infertile men	*7%*

anomalies. The CFTR gene is located on chromosome 7 and is associated with cystic fibrosis (CF), CBAVD, and unilateral absences of the vas. Almost all men with CF have a CFTR mutation and CBAVD. However, not all CFTR mutations are currently detected, and it is best to assume that men with CBAVD have a CFTR mutation and may be carriers of CF. It is thus imperative to assess the female partner for CFTR carrier status prior to proceeding with ART.

Karyotype evaluation and Y-chromosome microdeletions are frequently utilized genetic tests to evaluate patients with severe oligozoospermia (<5 million/ml) or nonobstructive azoospermia (NOA). A numeric or structural chromosomal abnormality is identified in roughly 7% of infertile men, and the degree of infertility inversely correlates with the presence of chromosomal abnormalities (see Table 3.4). Klinefelter's syndrome is the most common chromosomal abnormality in infertile men and accounts for over 60% of chromosomal abnormalities identified in workup of infertility. Couples should be counseled regarding the potential for paternal transmission of chromosomal abnormalities as it can result in miscarriage, birth defects, and other genetic syndromes.

Y-chromosome microdeletions are identified in roughly 10%–15% of males with severe oligozoospermia or NOA [71, 72]. Typically, microdeletions occur in the AZF regions (AZFa, AZFb, and AZFc) on the long arm of the Y-chromosome (the site of several genes required for normal spermatogenesis). A deletion within the Y-chromosome does not necessarily result in infertility, but sperm retrieval attempts are rarely successful with an AZFa or AZFb deletion. However, sperm retrieval rates are as high as 80% in patients with an isolated AZFc deletion. It is unclear if there are any medical conditions associated with Y-chromosome microdeletions, but all of the male progeny will inherit the abnormality, and appropriate genetic counseling is recommended.

3.9.8 Conclusion

The laboratory evaluation of male infertility extends far beyond a basic semen analysis. The clinician is tasked in identifying and treating reversible conditions that may improve the male's fertility or even potentially detect harmful underlying conditions. The fertility evaluation must be complemented by a thorough history and physical examination with an understanding of genetic and endocrinological conditions which cause male infertility. Advances in sperm function tests have been developed to provide earlier and more individualized treatment for couples [73, 74]. Ongoing investigation in the field of proteomics will continue to aid in the development of more successful treatment options and provide more answers for couples experiencing infertility.

3.10 Review Criteria

We extensively searched Google Scholar, PubMed, Medline, Clinical Key, and Science Direct for articles focusing on semen analyses, male infertility, advanced sperm testing, hormonal, and genetic assessment. We began our literature search in September 2018 and completed it by November 2018. The following key words were utilized in our search: "semen analysis," "sperm DNA fragmentation," "oxidative stress," "WHO manual," "TUNEL," "oxidative-reduction potential," "computer-assisted semen analysis." We reviewed only English language articles. Tables were created with assistance from Microsoft Excel.

Imaging Modalities in the Management of Male Infertility

4

Marcello Cocuzza, Joao Paulo Cardoso, and Sijo J. Parekattil

Key Points

- Testicular MR spectroscopy is promising for the assessment of metabolic integrity and differentiation between normal and markedly decreased spermatogenesis testicles, with further clinical studies necessary to assess its full diagnostic and therapeutic capability.
- Microsurgical technique remains the gold-standard procedure for the varicocele repair, but the concomitant use of intraoperative Doppler should be seriously considered as a tool to improve surgical outcome and safety.
- Microsurgical organ-sparing resection with micro-TESE and tissue cryopreservation may be considered for patients presenting with azoospermia and incidental testicular lesions, especially for those with solitary testicles and bilateral tumors.
- Annual ultrasound follow-up is recommended for testicular microlithiasis, when accompanied by other potentially premalignant features. Patients with testicular dysgenesis syndrome features, such as infertility, may be in higher risk of intratubular germ cell neoplasia.

4.1 Introduction

Infertility affects approximately 15% of couples desiring conception, and male infertility underlies almost half of the cases. Assisted reproductive technology (ART) is increasingly being used to overcome multiple sperm deficiencies and because of its effectiveness it has been suggested by some to represent the treatment for all cases of male factor infertility regardless of etiology. Although the use of these technologies may allow infertile couples to achieve pregnancy rapidly, associated higher cost, potential safety issues, and the fear of transferring the unnecessary burden of invasive treatment on healthy female partners weigh down this treatment option heavily.

Diagnostic imaging techniques may be indicated as part of the complete male fertility evaluation. Reproductive therapy can be instituted only after completion of a thorough evaluation that begins with a detailed history and physical examination. Due to the introduction and enhancement of newer imaging modalities, reliable adjuncts to clinical examination can be obtained to diagnose a variety of causes of male infertility including varicocele, epididymal blockage, testicular microlithiasis (TM), seminal vesicle (SV) agenesis, and ejaculatory obstruction. Imaging plays a key role in the evaluation of the hypospermia or azoospermic man. It can detect correctable abnormalities, which can lead to a successful conception. It can also reveal potentially life-threatening disorders in the course of an infertility evaluation such as testicular tumors. The goal of this article is to provide the reader with a foundation for a comprehensive evaluation of the male partner and emerging technologies that can improve the treatment of correctable causes of male infertility.

4.2 Testicular Tissue Imaging for Guided Sperm Retrieval

4.2.1 Doppler Duplex Flow Imaging

Testis biopsy with cryopreservation of sperm is a procedure performed in men with possible nonobstructive azoospermia (NOA), and at times, in men with a previous vasectomy (who do not want a reversal) and men with spinal cord injuries (who fail electro-ejaculation or vibratory ejaculation). Recent studies have illustrated that it is likely to find active spermatogenesis in areas with good blood supply within the testicle.

Nowroozi et al. [1] also performed a prospective study in 130 patients with azoospermia, both NOA and obstructive azoospermia (OA). OA patients had previous history of vasectomy and failed vasovasostomy or vasoepididymostomy (21 out of 24 patients), 4 patients had obstruction due to recurrent UTI, 1 patient had a known congenital bilateral absence of vas deferens, and 1 patient had a prostatic cyst with failed surgical treatment. All patients underwent ultrasonography with Doppler before surgery, with location and number of vessels recorded and testicular artery resistive index (RI) registered. Testicular parenchyma was mapped in upper, middle, and lower segments and according to visible vessels at Doppler: grade 1 – no visible vessels, grade 2 – 1 to 3 visible vessels, and grade 3 – more than 3 visible vessels.

All patients with OA had successful fine needle aspiration. Only 4 patients with NOA had successful aspiration, and all of them had grade 3 perfusion. A micro-TESE was performed for all other patients with NOA.

Patients with OA revealed a significantly higher intratesticular perfusion than NOA, and there was a correlation between visible vessels on Doppler and probability of sperm retrieval success. Among patients with grade 3 testicular perfusion, 60% required less than 3 biopsies, while 82% of the patients with grade 1 perfusion required more than 3 biopsies. Differences were statistically significant. No acceptable cutoff value of FSH or testicular artery RI through ROC curve analysis was able to allow discrimination between NOA or OA with these isolated parameters. Doppler-guided sperm retrieval would be suitable for increasing probability of success and decreasing the number of required biopsies in patients with NOA.

Evaluation of handheld Doppler phase shift flow mapping of the testicle at the time of biopsy appears to have promise in detecting areas of spermatogenesis. However, further data analysis on more patients has now shown that the predictive value was not as high as we initially had expected, and so there remains more work that has to be done in this area before conclusions can be made about the use of this technology for this application.

4.2.2 MRI Spectral Imaging

Patients with idiopathic oligozoospermia or azoospermia, especially those with normal serum gonadotrophins and physical examination, always present a diagnostic dilemma. Both situations can represent a ductal obstruction or a testicular failure, but they have completely different prognoses. Testicular functions are currently evaluated in rather indirect ways, by seminal parameters and hormonal assays. Histological analysis, which involves obtaining specimens by biopsies or surgical explorations, can directly evaluate testicular tissue. However, it cannot be widely used in clinical situations due to possible damage to testicular functions and its invasive character.

Eliveld et al. [2] performed a recent meta-analysis of 15 studies regarding TESE-induced hypogonadism. The authors highlight transient, although significantly decreased, total testosterone. Patients usually recover to baseline levels from 18 to 26 months. Unfortunately, in terms of hypogonadism symptoms, available data is limited.

Nevertheless, heterogeneity of testicular tissue also limits broad indications for diagnostic biopsies, because aleatory tissue samples may not reflect the total parenchyma. Chances of sperm retrieval in a following procedure may only be estimated. Ideally, noninvasive techniques for testicular functions in vivo would allow better evaluation without inconvenience of procedures and potentially guide treatments [3].

Ultrasound is the initial radiological method that is used to evaluate the testis. However, the increased availability of magnetic resonance imaging (MRI) has allowed this noninvasive diagnostic tool to further evaluate testicular function. This technique was already used in a number of experimental studies on testis [3, 4]. On humans, there are few magnetic resonance spectroscopy (MRS) reports; one describes its application on a patient with testicular non-Hodgkin's lymphoma to monitor response to irradiation [5], and the other reveals the in vivo tissue characterization of the testis in patients with carcinoma in situ [6]. Also, differentiation between normal healthy testes and those with markedly decreased spermatogenesis presenting with oligozoospermia or azoospermia in whom spermatogenesis is completely absent was achieved [7, 8].

MRI spectroscopy is a noninvasive technique for obtaining metabolic information from living tissue based upon differences in the ratio of peaks of lipid and choline levels [9]. These metabolites may be used to evaluate the state of fertility and to investigate ischemia–reperfusion disorders.

More recently, in vivo hydrogen MR spectroscopy using stimulated echo acquisition mode measurements was performed with a short echo time, improving the detection of signals from low-molecular-weight metabolites including glutamate, choline, creatinine, and glycine not only in the

normal state but also in diseased conditions such as ischemia [10]. In addition to these metabolites, a lactate signal could be observed in the ischemic testis. The presence of a lactate signal in the H spectra could be utilized to distinguish between normal and ischemic testes [10].

Other recent studies describe MRS for spermatogenesis identification. Aaronson et al. [11] observed significantly lower concentrations of phosphocholine in patients with Sertoli-cell only samples in caparison with fertile patients. Phosphocoline is enrolled in membrane synthesis and may be a marker for active cell proliferation.

Storey et al. [12] performed a study with a quantitative ^{1}H-MRS at 3T, a proton spectroscopy, to compare testicular metabolite concentrations between infertile men and fertile controls. The most prominent peak of spectra was the choline compounds, in accordance with previous studies. Researches also observed lower concentrations of creatine and myo-inositol. Creatine and phosphocreatine are involved in cellular energy metabolism, crucial in high energy-demanding cells such as spermatozoa. Myo-inositol is related to sperm motility. Heterogeneity and size of the cohort limits direct clinical application before proper validation. Nevertheless, it represents a potential shift toward non-invasive techniques. Patients with higher metabolites concentration would represent the best candidates for surgical sperm retrieval.

MR spectroscopy is a sensitive tool for assessment of testicular metabolic integrity and differentiation of normal testicles from those with markedly decreased spermatogenesis. MRS may improve sperm retrieval rates by better identifying isolated foci of spermatogenesis during testicular sperm retrieval in men presenting with nonobstructive azoospermia. MR spectroscopy of the testis might be a promising new modality that warrants further clinical studies to assess its diagnostic and therapeutic capability.

4.2.3 Testicular Artery Mapping During Varicocelectomy

Current data supports the statement that varicocele repair does indeed have a beneficial effect in reversing the harmful effects of varicocele upon testicular function in selected patients by improving seminal parameters in the majority of controlled studies [13]. A diversity of open surgical techniques has been used to repair this condition, including retroperitoneal, inguinal, and subinguinal. Recently, open microsurgical inguinal or subinguinal varicocelectomy techniques have been shown to result in higher spontaneous pregnancy rates and fewer recurrences and postoperative complications than conventional varicocelectomy techniques in infertile men [14]. The subinguinal approach has the same principles as the inguinal approach but is performed through an incision below the external inguinal obviating to the need to open the aponeurosis of the external oblique causing less postoperative pain.

The microsurgical subinguinal varicocelectomy is the preferred approach for most experts. On the one hand, the use of an operating microscope allows the preservation of the testicular artery and lymphatics vessels, resulting in lower recurrence rates and hydrocele after the procedure [15]. On the other hand, the spermatic cord at the subinguinal level has a greater number of internal spermatic veins and an increased likelihood of encountering multiple spermatic arteries [16]. Previous studies reported that multiple spermatic arteries are identified in approximately 40% of the spermatic cords during microsurgical varicocelectomy at the subinguinal level [16, 17]. The recognition of the main spermatic artery can be confirmed by visualization of clear pulsatile movement and/or evidence of antegrade, pulsatile blood flow with gentle lifting, and partial occlusion of the vessel. However, the identification of tiny secondary arteries is not at all times apparent, and a sterile intraoperative probe attached to a 9.3-MHz VTI surgical Doppler and a disposable probe flow detector (Vascular Technology Inc., USA) (Fig. 4.1) have been used at this point [18]. Consequently, it is possible that an inadvertent unrecognized ligation of a small internal spermatic artery occurs more frequently than reported [19]. Following are some of the reasons that could explain how the injury occurs. First, the size of the arteries may be so small that

Fig. 4.1 VTI surgical Doppler 9.3 MHz and a disposable probe flow detector (Vascular Technology Int., USA)

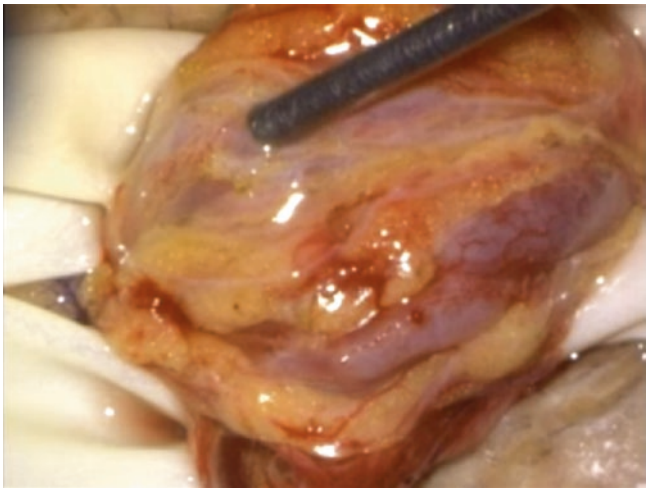

Fig. 4.2 Using a vascular Doppler probe to preserve all testicular arterial branches during varicocele repair

Table 4.1 Intraoperative evaluation of internal spermatic veins ligated, number of lymphatic spared, and arteries preserved and injured in 377 spermatic cord dissections during microsurgical subinguinal varicocele repair with and without vascular Doppler

Variable	With Doppler (no. spermatic cords = 225)	Without Doppler (no. spermatic cords = 152)	*P* value
Number of veins ligated[a]	8.0 (3.1)	7.3 (2.8)	0.02
Number of arteries preserved[a]	1.6 (0.6)	1.3 (0.5)	<0.01
Number of arteries injured[b]	0	2 (1.1%)	0.06
Number of lymphatics spared[a]	2.2 (1.2)	2.0 (1.5)	0.21
Operative time unilateral repair (min)[a]	52.8 ± 17.8	53.0 ± 36.7	0.98
Operative time bilateral repair (min)[a]	101.0 ± 16.2	101.9 ± 16.3	0.37

the pulsation is difficult to identify. Second, aggressive manipulation of the vessels during dissection can lead to spasm, making it difficult to identify arterial pulsation. Third, the arteries tend to be in close proximity to or buried under complex branches of veins [19]. In all these situations, the use of vascular Doppler may help to preserve the arterial branches (Fig. 4.2). Even though there is no agreement about the necessity to preserve all testicular arterial branches during varicocele surgery [20, 21], not doing so might be responsible for suboptimal improvement in seminal parameters in some cases [22].

A recent study showed that concomitant use of intraoperative vascular Doppler during subinguinal varicocelectomy allows a higher number of arterial branches to be identified and therefore preserved [23]. Data concerning surgery using the Doppler vascular device and without it show that a solitary artery is identified in 45.5% and 69.5% of cords, respectively; 2 arteries are identified in 43.5% and 28.5%, respectively; and 3 or more arteries are identified in 11% and 2%, respectively. Also, the authors reported that a higher number of internal spermatic veins were ligated when Doppler was used (Table 4.1). The use of intraoperative Doppler gives the surgeon more confidence during dissection of a dense complex of adherent veins surrounding the artery present in 95% of cases when the subinguinal approach is used [16]. Accidental artery ligation documented by a pulsatile twitching of the ligated vessel stump under magnification is less common when Doppler is applied [23].

The clinical implication of these findings can be supported by recent studies showing that the total number of veins ligated was significantly positive correlated with improvements in total sperm motility and sperm concentration [24, 25]. These results suggest that ligating a larger number of veins should decrease reflux, which in turn would lead to diminished insult to spermatogenesis.

More recently, Guo et al. [26] conducted a prospective randomized study comparing outcomes for microscopic subinguinal varicocelectomy with and without the use of Doppler ultrasound. A total of 172 patients were strictly selected and randomized in two groups, that is, simple microscopic varicocelectomy and intraoperative vascular Doppler ultrasound-assisted microscopic varicocelectomy, and each group was designated to a single surgeon. Procedures were performed in the same hospital and with the same technique, by surgeons trained in microsurgery and male infertility. Groups were different only in the systematic use of intraoperative Doppler to identify all vessels before ligation in the Doppler-assisted group. The Doppler-assisted group had a statistically higher number of internal spermatic veins ligated and higher number of internal spermatic arteries preserved during surgery. Authors attribute the reduction of operative time to rapid and precise identification of vessels with the use of intraoperative Doppler. No testicular atrophy was described. Results showed improvements in semen parameters, from the third month of follow-up, and were durable at 6 and 12 months, with significantly higher sperm motility in the Doppler-assisted group. Probably due to sample size limitation, pregnancy rates were not different between the two groups compared in the study.

4.3 Management of Testicular Lesions in Infertile Patients

4.3.1 Organ-Sparing Microsurgical Resection of Testicular Tumors in Infertile Patients

Epidemiologic studies have given attention to a worldwide possible increase in testicular cancer incidence in the last two decades, particularly in industrialized, developed countries [27]. One of the possible explanations for this augmented detection of testicular lesions is the widespread use of ultrasound as a screening method in all fields of medical practice, including scrotal ultrasonography in urology [28, 29].

In patients presenting with bilateral tumors (Fig. 4.3) or tumors in a solitary testis, the gold-standard procedure is to perform a radical orchiectomy which leads to permanent sterility, lifelong dependence on androgen replacement therapy, and psychological problems of castration at a young age [30]. As a result, organ-sparing surgery has been reported as a safe procedure in selected patients, especially for infertile men desiring to preserve their fertility [31–33]. The German Testicular Cancer Study Group established a guideline for organ-sparing surgery for testis tumors that includes cold ischemia during spermatic cord clamping, restriction of the procedure for organ-confined tumors of less than 20 mm that do not infiltrate the rete testis, performance of multiple biopsies of the tumor bed, and application of adjuvant local radiotherapy to eradicate carcinoma in situ and avoid local recurrence [33].

Testicular germ cell tumors (TGCTs) are the most common type of malignancy during the reproductive age [34, 35]. However, as the majority of incidental testicular nonpalpable lesions with negative markers diagnosed in scrotal ultrasonography performed during andrology investigation show a benign histology, surgical approach must be as conservative as possible for the testicular parenchyma [36]. In such cases, the most important step is the confirmation that frozen section analysis is an oncologically useful method for assessing small incidental testicular tumors when performed by an experienced pathologist [37]. The high degree of oncological efficiency achieved by the frozen section analysis during resection of testicular masses supports organ-sparing approaches that reduce the chances of facing difficult decisions intraoperatively [38].

Due to the advances of microsurgical techniques, partial orchiectomy was appointed as first-line therapy in infertile men even for nonpalpable small testicular lesions [31, 39, 40]. Also, infertile patient presenting with azoospermia and incidental testicular lesions now can experience the chance to father their own genetic offspring [37]. The combination of organ-sparing surgery, microdissection for TESE, cryopreservation, and assisted reproductive technologies represents a powerful tool to preserve fertility even for azoospermic men [41]. The complete procedure was meticulously described by Hallak et al. as follows [39]: During the procedure, the testis can be delivered through the inguinal incision, respecting principles for oncological procedures to avoid any potential spillage of tumor cells. The vas deferens must be carefully isolated from the spermatic cord and blood circulation interrupted by a delicate vascular clamp placed across the spermatic cord (Fig. 4.4). Slugged ice may be used to prevent warm ischemia, and a temperature probe inserted far from the tumor location controls the temperature at 12–15 °C (Figs. 4.5 and 4.6). A linear ultrasound transducer at 15 MHz guides real-time intraoperative placement of a 30-gauge 10-cm-long stereotaxic hook-shaped needle (Guiding-Marker System; Hakko, Tokyo, Japan) adjacent to the tumor to guide microsurgical resection (Figs. 4.7 and 4.8). Using a surgical

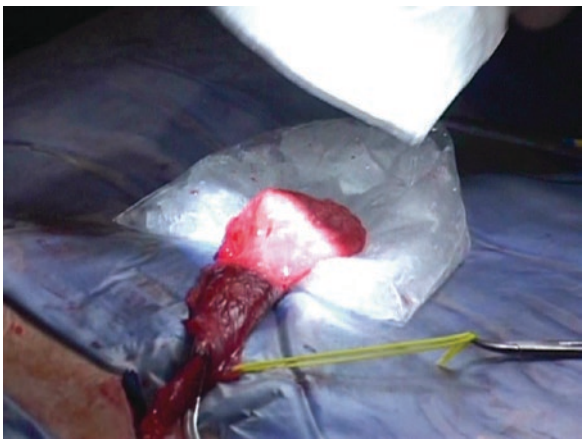

Fig. 4.5 Slugged ice wrapped the testicle, thus preventing from warm ischemia

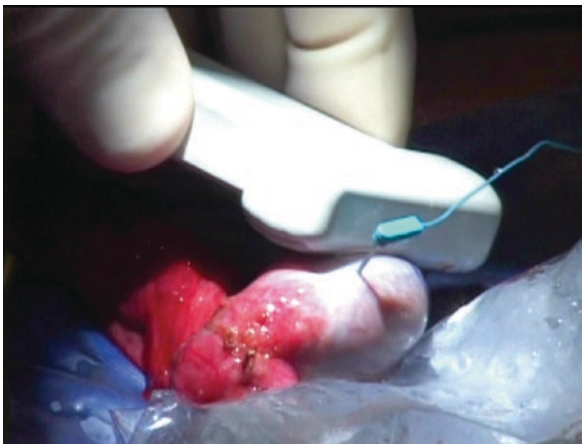

Fig. 4.6 A temperature probe was inserted far from the tumor location in the upper pole of the testicle

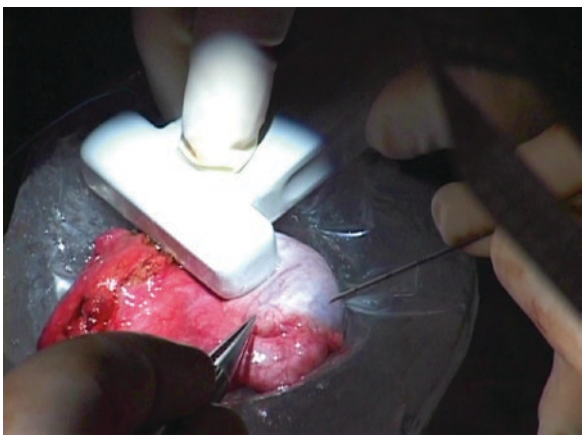

Fig. 4.7 Linear ultrasound transducer at 15-MHz guides real-time intraoperative placement of the stereotaxic hook-shaped needle adjacent to the nodule. The 30-gauge stereotaxic hook-shaped needle that permits the hook to be completely contained in and pass through the needle lumen. The introducing needle can thus be optimally positioned prior to engaging the hook. The hook is ejected and released from the needle tip reforming to the hook and anchoring into the tissue adjacent to the tumor

Fig. 4.8 Intraoperative ultrasound image showing a nonpalpable hypoechoic intratesticular lesion to guide real-time needle placement

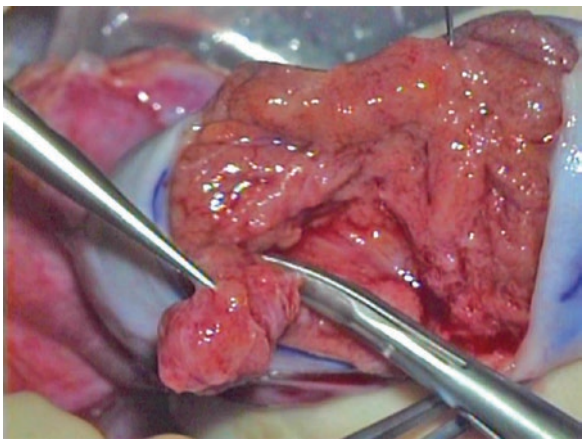

Fig. 4.9 After the tunica albuginea is incised in an avascular region using an operating microscope, dissection respecting testicular lobules and arteries is conducted. Seminiferous tubules were separated carefully by blunt dissection following the needle until the lesion that is excised using micro-instruments is found, leaving 2–3-mm borders as safe margins around the nodule

operating microscope, the tumor can be gently dissected and removed along with the adjoining parenchymal tissue (Fig. 4.9). Frozen section studies must be performed, and if malignancy is confirmed, then biopsies of the tumor cavity margins and the remaining parenchyma must be obtained to ensure the absence of residual tumors. After biopsies are sent for frozen section, the testicular parenchyma must be meticulously microdissected for identification of functioning seminiferous tubules, as reported by Schlegel [41]. After excision of selected enlarged and opaque tubules, viable spermatozoa can be retrieved for cryopreservation in 80% of cases [39]. This procedure integrates modern skills accumulated in the field of male infertility, combining knowledge in testicular vascular anatomy, oncology, microsurgery, organ preservation, tissue preparation, and sperm cryopreservation.

Recently, De Stefani et al. [42] presented a retrospective series of 20 patients submitted to microsurgical testis-sparing surgery for small testicular masses. The authors report the procedures using a similar technique of sperm retrieval for infertility, as previously described, also with the use of a guided needle for tumor identification and frozen section examination. Using the infertility approach to the testis, researchers were able to preserve testicular parenchyma and avoid areas of increased vascularity. Intraoperative ultrasound was used for smaller lesions difficult to locate even with microscopic enhancement. No postoperative clinical hypogonadism was identified, although the series was retrospective. Authors emphasize the importance of an experienced pathologist and a relatively high-volume center for adequate approach.

The possibility of intracytoplasmic sperm injection (ICSI) with cryopreserved testicular sperm has given infertile azoospermic men the chance to have their own genetic offspring [43]. As previously highlighted, it is very important to keep in mind that this approach is only appropriate in centers experienced in managing testicular cancer for patients who want to preserve fertility.

4.3.2 Testicular Microlithiasis

Testicular microlithiasis (TM) is an entity of unknown etiology that results in the formation of intratubular calcifications. TM is detected in 0.6% of adult males with clinical indications for scrotal ultrasonography [44]. Recently, microlithiasis, although uncommon, has been considered a feature of the testicular dysgenesis syndrome. This poorly defined entity is based on the assumption of a testicular dysgenesis during fetal development [45]. A range of testicular and male reproductive problems may arise or be associated with microlithiasis, such as Klinefelter's syndrome, cryptorchidism, varicocele, testicular atrophy, torsion, tumors, and infertility [46–49]. The strength of the association of microlitiasis with any of these entities has been difficult to precisely determine. In terms of infertility, the exact mechanism by which microlithiasis affects spermatogenesis is unknown [49]. Scrotal ultrasound is diagnostic, and typically, there are small echogenic foci (1–3 mm).

The clinical significance of TM is debatable because inconsistencies exist in the literature. Therefore, there are conflicting recommendations regarding the appropriate interval and duration of subsequent surveillance of patients with testicular microlithiasis, or even if there is a definitive association with TM and cancer [50]. Nevertheless, it is a general consensus that patients with microlithiasis and testicular dysgenesis syndrome features, such as infertility, may be in higher risk of intratubular germ cell neoplasia of unclassified type (ITGCNU) [45]. Therefore, follow-up at this time should be dictated based on risk factors for developing testis cancer more than on the presence of TM [46]. Casteren et al. suggested taking a testicular biopsy in a selected patient population with at least one additional risk factor for testicular germ cell tumors [51]. This would be the case for patients in particularly high risk of testicular germ cell tumor (TGCT): gonadal dysgenesis and cryptorchidism. For these patients, an early biopsy at age 18 would be beneficial for early diagnosis [45]. Finally, there is no definitive proof that TM by itself can cause infertility. Probably, decreased seminal function is not directly due to the TM but rather to an underlying testicular abnormality or associated condition such as cryptorchidism [52].

4.3.3 Seminal Vesicle and Ejaculatory Duct Imaging

Seminal vesicles and vas deferens are important and essential urogenital organs. They share close embryological relationship with the kidneys and ureters. Although both agenesia and hypoplasia are rare, unilateral seminal vesicle and vas deferens agenesis, as well as seminal vesicles cysts, may correlate with unilateral kidney agenesis, and bilateral seminal vesicle agenesis may correlate with cystic fibrosis diagnosis. On the one hand, congenital bilateral agenesis of vas deferens is usually associated with seminal vesical aplasia. Ejaculatory duct obstruction (EDO), on the other hand, usually associates with dilated seminal vesicles [53].

Ultrasonography, computed tomography, and magnetic resonance are imaging modalities that have been used to evaluate these structures. Knowledge of embryology and anatomy of these structures is essential for correct interpretation [54].

MRI has the advantage of allowing visualization of the intra-abdominal segment of the vas deferens. A tubular structure of low intensity in both T1 and T2 may be traced from the internal ring towards the ejaculatory duct topography, where a small portion of intraluminal fluid may be detected [55]. Seminal vesicles demonstrate low signal intensity on T1-weighted images and high signal on T2-weighted images, been identified as elongated structures with thin septa and fluid-filled.

Apart from identifying the presence and anatomy elucidation of seminal vesicles, MRI is also useful to identify other entities, such as congenitally acquired cysts (Müllerian cysts, paramedian prostatic – wolffian – cysts), vesiculitis, and primary and secondary neoplasms [54].

Chen et al. [56] performed a prospective study in 30 patients with agenesis or hypoplasia or seminal vesicles, submitted to both TRUS and MRI. Congenital defects of the seminal vesicles were diagnosed in 22/30 patients through both imaging methods, with a concordance rate of 73.3%. The authors suggest that an inconclusive TRUS should motivate an MRI study. In contrast, Chiang et al. [55] also performed a prospective

study with both CUAVD and CBAVD. Sensitivity and specificity values of TRUS compared with MRI were 0.62 and 0.25, respectively. The authors highlight the disagreements of study data with previous publications.

Ejaculatory duct obstruction is usually suspected in patients with low ejaculate volume (<1 ml) and acidic pH semen, when vas deferens is palpable bilaterally. The use of TRUS facilitates the diagnosis, when there is dilation of seminal vesicle (>1.5 cm internal section diameter), dilatation of vassal ampullae, or midline prostatic cysts [53].

Ejaculatory duct has also been studied with the use of MRI. For improvement of anatomy precision, an endorectal coil has been used. Although it allows useful images, MRI carries limitations regarding the presence of patient's hardware or devices. Nevertheless, evidence comparing MRI and TRUS for diagnosis of ejaculatory duct abnormalities shows controversial results [57]. Engin et al. [58], comparing both techniques, reached a similar conclusion of seminal vesicle imaging: TRUS is a cheaper and more accessible tool, with MRI probably more precisely indicated when initial TRUS is inconclusive.

Turek et al. presented a technique of transrectal vasodynamics (pressure-flow study of the seminal vesicle) to assess for partial ejaculatory duct obstruction (EDO). We have been exploring the use of a 3D transrectal ultrasound imaging and needle-targeting system to perform vasodynamics for the treatment of necrospermia with partial EDO (Target Scan Touch, Envisioneering, St. Louis, MO).

A patient with necrospermia (viability staining of sperm) and low ejaculatory volume (<0.5 cc) was evaluated for EDO by vasodynamics performed utilizing a 3D transrectal ultrasound needle guidance system (Target Scan™, Envisioneering) in January 2008. This system was utilized to access and maintain a flexible needle within the seminal vesicle (SV) during vasodynamics. The decision to perform transurethral (TUR) unroofing of the ejaculatory duct would be based on the pressure readings obtained during vasodynamics.

The patient had no visible left SV and a dilated right SV (>1.5 cm). The system provided an easy stable-guided platform to place and maintain a flexible needle within the right SV. A pressure reading of 41 cm H_2O was achieved with delayed emptying of the right SV (on simultaneous cystoscopic examination of the ejaculatory ducts within the urethra). Transurethral (TUR) unroofing of the right ejaculatory duct was performed, and the post-TUR SV pressure reading dropped to 31 cm H_2O. The right SV drained promptly post-TUR on cystoscopic examination. Postoperatively, the patient initially had retrograde ejaculation. At 1 year post-op, the patient now has an ejaculate volume of 1 cc with 70 million sperm/hpf with 64% motility.

The use of a 3D transrectal ultrasound needle guidance system to perform vasodynamics is feasible for the treatment of patients with necrospermia and partial EDO, and it enhances a surgeon's ease in performing vasodynamics. Further testing and evaluation are needed.

4.4 Conclusion

The objective of this chapter was to discuss the potential role of imaging modalities in the management of male infertility. The advanced technologies discussed may not only provide new treatment options but also reduce the number of couples without a definitive diagnosis of the cause of failure to conceive. There is no hesitation that all technical advances such as those explained in this chapter will drive the development of pioneering approaches to the management of the infertile male by andrologists.

On the one hand, imaging may help to diagnose reversible causes of infertility and treat them to achieve seminal improvement and pregnancy. On the other hand, the use of imaging in the field of infertility is no longer just for diagnosis but also as part of the arsenal that provides more precise surgery procedures as described above.

Collaborations with radiologists have provided a rich opportunity to explore and expand imaging techniques for intraoperative use during urologic surgery. Due to the continual improvement of a variety of imaging and tissue characterization modalities, surgeons will have an increasing number of tools at their disposal to improve intraoperative surgical decision-making. Only through the application of evidence-based assessment and evaluation, however, will there be a firm understanding of the true impact of these new technologies on the field of urology. However, further studies will be needed to confirm whether or not these techniques can evolve into widespread clinical practice.

4.5 Review Criteria

The current chapter is based on an electronic search using Pubmed/MEDLINE database and references of the identified articles performed between November 2018 and January 2019. The following key words were used on the search engines: "imaging in male fertility," "Doppler flow imaging," "ultrasound," "ejaculatory duct imaging," "testicular microlithiasis," and "MRI spectral imaging."

Endocrinopathies

5

Sam Haywood, Isaac Lam, Eric L. Laborde, and Robert Brannigan

Key Points

- Hypogonadotropic hypogonadism, characterized by deficient production of gonadotropins (FSH and LH), results in low testosterone levels and can arise due to either congenital or acquired causes.
- Males with Klinefelter syndrome have a 47, XXY karyotype and also commonly have hypergonadotropic hypogonadism with impaired or absent spermatogenesis.
- Androgen excess, which commonly arises through the use of prescription exogenous testosterone therapy or illicit use of anabolic steroids, suppresses intratesticular testosterone production which typically results in partial or complete suppression of spermatogenesis.
- Estrogen excess, which is commonly associated with obesity, results from the conversion of testosterone to estradiol by aromatase in adipose tissue and can lead to low testosterone levels.
- Clomiphene citrate and human chorionic gonadotropin (hCG) are both off-label therapies for testosterone deficiency that can support both intratesticular testosterone production and spermatogenesis.

5.1 Introduction

Spermatogenesis depends on an intricate interplay of hormonal factors both centrally and in the testis. Centrally, the hypothalamus releases gonadotropin-releasing hormone (GnRH), which acts on the anterior pituitary to cause secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). At the level of the testis, FSH acts on Sertoli cells to induce the maturation process in spermatogonia. LH exerts its effect on Leydig cells, stimulating the production of testosterone. Effective spermatogenesis requires local testosterone concentrations to be much higher than serum concentrations. This intratesticular testosterone then acts indirectly to stimulate germ cell maturation through actions on Sertoli cells [1].

Although endocrinopathies only account for a small minority of cases of male infertility, about 1%–2% [2], the treatment of these conditions offers patients a strategy of directed therapy. Broad classification of endocrinopathies involves two main categories, that is, hormonal deficiency and hormonal excess, with specific hormonal abnormalities falling under each of the previously mentioned categorizations.

In this chapter, we provide an overview on diseases in which hormonal imbalance can negatively impact fertility. We discuss the etiology and clinical presentation for each disease. The standard diagnostic process and best management approach will be addressed as well, and future directions for research in this area will be explored.

5.2 Hormonal Deficiency

5.2.1 Hypogonadotropic Hypogonadism

As the name suggests, hypogonadotropic hypogonadism is a state of testosterone deficiency associated with subnormal levels of gonadotropins (FSH and LH). Etiologies of hypogonadotropic hypogonadism can be numerous and are divided into congenital and acquired causes.

S. J. Parekattil et al. (eds.), *Male Infertility*, https://doi.org/10.1007/978-3-030-32300-4_5

Kallmann syndrome is one identified congenital etiology of hypogonadotropic hypogonadism. Inherited in an X-linked recessive fashion, Kallmann syndrome can arise due to a variety of mutations, the most prevalent of which involves the KAL1 gene. Features include hypogonadism as well as anosmia, facial defects, renal agenesis, and neurologic abnormalities [3]. The hypogonadism and associated clinical sequelae (delayed puberty, infertility) result from a failure of migration of GnRH-secreting neurons. This failure of migration leads to the absence of GnRH secretion which in turn leads to the absence of LH and FSH secretion [2].

Hypogonadotropic hypogonadism can also be acquired, as in the case of pituitary insufficiency resulting from pituitary tumors, surgery, infarct, or infiltrative disease. Regardless of the myriad etiologies of hypogonadotropic hypogonadism, the underlying disturbance is low gonadotropin levels, and treatment can be affected through pharmacologic replacement.

Treating hypogonadotropic hypogonadism involves replacement of the deficient hormones through gonadotropin therapy. Agents used in this therapy include human chorionic gonadotropin (hCG), human menopausal gonadotropin (hMG), and recombinant follicle-stimulating hormone (rFSH). Human chorionic gonadotropin use stems from its properties as an LH analogue, acting at the Leydig cell to stimulate androgen secretion. Human menopausal gonadotropin is a product purified from the urine of postmenopausal women that contains both LH and FSH. Regimens of gonadotropin therapy for men with hypogonadotropic hypogonadism typically begin with hCG administration alone for 3–6 months. Dosages range from 1000 to 1500 USP units either IM or SC three times per week. Adequacy of therapy can be assessed by measuring serum testosterone levels, with the goal of achieving sustained normal levels. Although the pertinent goal for spermatogenesis is adequate intratesticular testosterone concentrations, this value is not normally assessed in gonadotropin replacement therapy. However, intratesticular testosterone levels show linear correlation with administered hCG dosage [4]. After titration to sustained normal testosterone levels, usually after 3–6 months of hCG monotherapy, therapy is initiated to replace FSH levels. One method of FSH replacement involves hMG given at doses of 75–150 IU IM/SC three times a week at a separate injection site. Alternatively, rFSH can be used at dosages of 150 IU SC three times a week [5]. Relative efficacy of hMG versus rFSH has been studied to some extent in women undergoing IVF, but comparisons in male patients are lacking. Replacing gonadotropins in this manner has shown promising results as more than 90% of treated males experience spermatogenesis [2]. The time to spermatogenesis can be quite variable, with the average response occurring in about 6–9 months. However, therapy may be required for up to 1–2 years before a response may occur, and some individuals unfortunately never respond to this modality [6]. An Australian study of 38 men with hypogonadotropic hypogonadism found that median time to first sperm in the ejaculate was 7.1 months, while median time to conception was 28.2 months [7].

While spermatogenesis occurs in a strong majority of patients, sperm concentrations achieved through gonadotropin therapy still sometimes fall below goal ranges (<20 million sperm/mL). Despite this, fertility outcomes with gonadotropin therapy are very good. In a study of 24 men with hypogonadotropic hypogonadism treated with gonadotropin therapy, 22 men achieved pregnancy, even though mean sperm concentration was 16.7 million sperm/mL [8]. A retrospective study of Japanese men found sperm production in 71% of men treated with hCG (3000 IU) and hMG (75IU), provided testicular size was greater than prepubertal sizes (>4 mL) [9]. A recently published Saudi Arabian paper studied 87 infertile men with hypogonadotropic hypogonadism treated with IM gonadotropins for a median of 26 months, with the primary outcome of fertility. Overall, 35 of the 87 patients (40%) were able to achieve pregnancy [10].

An important area of newer research focuses on determining predictors of response to gonadotropin therapy. The aforementioned long-term study in Japanese men found a correlation between testicular size pretreatment and response to gonadotropin therapy. Men with testicular size >4 mL had a 71% chance of responding to treatment, whereas men with testicular size <4 mL had only a 36% chance of responding to treatment [9]. In addition, the above Saudi Arabian study found that only pretreatment testicular size was predictive of conception. In particular, responders to treatment had a mean testicular pretreatment volume of 9.0 ± 3.6 mL, while the pretreatment testicular volume of nonresponders was only 5.7 ± 2.0 mL. Interestingly, there was no significant difference in conception rates between men with hypogonadotropic hypogonadism due to congenital or acquired etiologies [10]. Larger baseline testicular size has also been shown as an independent predictor of response time to gonadotropin therapy, and achieving summed testis volume >20 mL after treatment increased the odds of achieving both goal sperm parameters and pregnancy by at least twofold [7]. It is worth noting that the lower sperm concentrations found in these studies, while below traditional goals of infertility management, may allow for pregnancy with adjunctive use of assisted reproductive therapies such as intrauterine insemination or in vitro fertilization. Additionally, such medical treatment may allow increased efficacy of surgical sperm extraction.

Another method of treatment for men with hypogonadotropic hypogonadism involves the use of antiestrogen agents. These agents competitively bind to estrogen receptor sites in the hypothalamus. Normally, estradiol acts via negative feedback at this endocrine center to inhibit gonadotropin secretion.

By binding at these sites, antiestrogen agents block estradiol's feedback inhibition of the hypothalamus and thus increase the hypothalamic secretion of GnRH. The increased secretion of GnRH leads to increased pituitary secretion of gonadotropins, which thereby stimulates an increase in intratesticular testosterone production. The most commonly used agent in this class is clomiphene citrate, but similar agents include tamoxifen, raloxifene, and toremifene. These drugs have been previously studied in the setting of empiric therapy for idiopathic infertility with mixed results [6]. However, the directed use of clomiphene in patients with proven hypogonadotropic hypogonadism has shown to be useful in limited settings. An American study treated four men with hypogonadotropic hypogonadism with clomiphene citrate 50 mg three times a week and found improved testosterone levels and semen parameters in three of these patients. Subsequently, two of these three men achieved documented pregnancy [11]. Similar success at the biochemical level has also been described in case reports, although fertility was not a goal of these treatments [12, 13]. A recent retrospective study of 31 men compared clomiphene citrate with testosterone therapy. Serum testosterone levels were highest in the group injected with testosterone and lower for the groups that received topical testosterone and clomiphene treatment. Despite these findings, the ADAM questionnaire determined that level of satisfaction was similar in all groups [14]. Clomiphene treatment of male infertility can be associated with such side effects as visual disturbances, GI upset, weight gain, hypertension, and insomnia [6].

Although using testosterone therapy to improve spermatogenesis is not recommended, a significant number of providers still utilize this approach. A recent study found that around one fourth of urologists surveyed have prescribed testosterone in an attempt to enhance spermatogenesis [15]. However, exogenous testosterone actually has detrimental effects on spermatogenesis. Increased levels of exogenous testosterone result in negative feedback to the hypothalamus, leading to lower levels of GnRH, gonadotropin, and ultimately intratesticular testosterone. Previous research indicates that suppression of intratesticular testosterone to levels less than 20 ng/mL can substantially impair normal spermatogenesis [16].

It is worth noting that exogenous GnRH treatment represents another avenue of medical therapy for hypogonadotropic hypogonadism. Synthetic analogues of GnRH can be administered to stimulate secretion of gonadotropins. However, the short half-life of these agents combined with the necessary pulsatile release to recreate normal physiology requires a method of frequent administration, such as frequent injections, nasal sprays, or an implantable pump. These methods are obviously less convenient, and further, studies have not shown this treatment to have a strong benefit for hypogonadotropic hypogonadism [1].

5.2.2 Hypergonadotropic Hypogonadism

In hypergonadotropic hypogonadism, the main perturbation is an inadequate or absent function of the testes. Gonadotropins are appropriately elevated secondary to lack of negative feedback from estradiol, testosterone, and inhibin B from the testis. Without appropriate androgen secretion, spermatogenesis is impaired. These men also typically have significant testicular atrophy with fibrosis and markedly reduced germ cell number, also leading to abnormally low levels of spermatogenesis. Hypergonadotropic hypogonadism can occur as a result of genetic etiologies (e.g., Klinefelter syndrome) or from acquired conditions. Acquired etiologies of hypergonadotropic hypogonadism include destruction of normal gonadal tissue from chemotherapy or radiation, trauma, mumps orchitis, or androgen decline in the aging male. Men with hypergonadotropic hypogonadism not desiring fertility can be treated with exogenous testosterone therapy, but men trying to conceive should generally not be given exogenous testosterone. The treatment for men trying to conceive is less well characterized. Aromatase inhibitors have been suggested as treatment for men with Klinefelter syndrome [4]. A small cohort of patients with Klinefelter syndrome treated with aromatase inhibitors showed hormonal improvements with treatment, although the study did not comment on semen parameters in the Klinefelter subset. In particular, for this subset of patients, testolactone therapy was more efficacious with respect to hormonal levels than anastrozole [17].

It is important to mention the additional potential advantage in the setting of surgical sperm extraction after adjuvant medical therapy in men with Klinefelter syndrome. Surgical sperm extraction alone has resulted in successful retrieval in up to 50% of attempts [18]. Ramasamy et al. retrospectively studied 68 azoospermic men with Klinefelter syndrome. Of these 68 men, 56 were treated for low testosterone levels (<300 ng/dL) with a combination of medical therapies (aromatase inhibitors, hCG, clomiphene) before microdissection TESE. Of the 56 men receiving medical therapy before TESE, 28 received testolactone alone, 12 received testolactone and weekly hCG, 9 received anastrozole alone, 1 received anastrozole and hCG, and 4 received hCG alone. Three patients received clomiphene citrate. While there was no difference among specific agents in terms of successful sperm extraction, these medical regimens collectively resulted in improved sperm retrieval when patients responded to medical therapies with posttreatment testosterone >250 ng/dL. More specifically, successful sperm extraction was seen in 77% of men with posttreatment testosterone >250 ng/dL versus 55% of men with posttreatment testosterone <250 ng/dL [18].

Most commonly, androgen supplementation is initiated when luteinizing hormone levels rise above normal during puberty. Despite the paucity of data, studies in progress may

help provide the foundation for producing evidence-based guidelines on the timeline of androgen supplementation. A recent retrospective study found that infants with Klinefelter syndrome who received testosterone treatment had superior cognitive development at 3 and 6 years old, but the generalizability of these findings is questionable due to the lack of randomization and blinding [19]. To date, no randomized controlled trials of testosterone supplementation in Klinefelter syndrome children have been published, but a study is currently in progress at Children's Hospital Colorado. Another randomized controlled trial on Klinefelter syndrome in early adolescence is in the process of enrolling as well, with the purpose of evaluating the psychosocial impact of topical testosterone [20]. Despite the deficit in data, studies in progress may help provide the foundation for producing evidence-based guidelines on the timeline of androgen supplementation.

The rate of diagnosis of Klinefelter syndrome may increase substantially in the coming years as prenatal testing for the disease may be integrated into routine prenatal care in the near future. This change would lead to an estimated increase in rate of diagnosis by up to five times the current rate [21]. As a result, the higher rate of diagnosis may potentially drive the research community to allocate more energy and resources to studying patient-centered Klinefelter syndrome health and treatment outcomes.

5.2.3 Hypothyroidism

Thyroid hormones are essential in organ development and routine metabolism. However, there have been few studies evaluating hypothyroidism and male reproduction in humans. Substantial research has been performed on rats studying the relationship between hypothyroidism and male fertility. Rats with drug-induced hypothyroidism have been shown to have fewer and smaller seminiferous tubules, lighter testes, less testicular germ cells, and impaired sperm parameters in contrast to their control rat counterparts [22–24].

In humans, hypothyroidism has long been associated with diminished libido and erectile dysfunction [25]. Additionally, a recent study by Meeker et al. revealed a correlation between thyroxine (T4) level and sperm concentration, with higher T4 being correlated with better sperm concentrations [26]. Sperm concentration may not be the only parameter affected, as a study by Krassas et al. showed that men with hypothyroidism have a lower than normal percentage of sperm with normal morphology as well as impaired sperm motility and decreased ejaculate volume. Correcting the hypothyroidism resulted in 76% of the patients having a normal morphology [27]. Overall, there is a relative scarcity of data regarding hypothyroidism and semen parameters. Nonetheless, these studies do suggest a link between thyroid function and spermatogenesis.

5.3 Hormonal Excess

5.3.1 Androgen Excess

Within the hypothalamic–pituitary–testis axis, testosterone exerts negative feedback inhibition on the hypothalamic secretion of GnRH. This effect is indirect and thought to occur via aromatization of testosterone to estradiol. Acting in this manner, excess circulating testosterone can suppress this axis and cause inhibition of spermatogenesis.

Testosterone excess can result from exogenous testosterone administration or from endogenous production.

Therapeutic administration can inadvertently result in testosterone excess, but testosterone excess can also result from the illicit use of anabolic steroids. Regardless of the cause, exogenous androgens typically suppress gonadotropin secretion with resultant decreased levels of intratesticular testosterone and decreased spermatogenesis. Diagnosis is suggested by normal to high serum testosterone levels with suppressed gonadotropins. The first step in treating a male with suspected androgen excess is to remove the exogenous source. Return of spermatogenesis usually occurs within 4 months but in some instances can take up to 3 years [28, 29]. If sperm parameters do not improve adequately or are slow to improve, then some evidence suggests beneficial effects of gonadotropin therapy in improving intratesticular testosterone levels [29, 30]. If response to treatment remains suboptimal after a trial of gonadotropin therapy, then limited evidence suggests a possible use of clomiphene in reestablishing the hypothalamic–pituitary–testis axis [31].

Although abuse of anabolic androgenic steroids has not been a focus in mainstream medicine, a recent review has brought to light the toll this issue has had on the health of young men in America. Retrospective analysis of over 6000 patients revealed that steroid abuse was the etiology in over a third of the patients with profound hypogonadism, and perhaps even more worrisomely, about one fifth of men treated for symptomatic hypogonadism reported previous use of anabolic androgenic steroids [32]. Given the rise in incidence of steroid abuse, growing numbers of psychiatrists accept anabolic androgenic steroid dependence as a diagnostic entity [33]. Counseling patients with anabolic steroid-associated hypogonadism and understanding the patients' motivation for use is crucial for both preventing future use and recognizing other diseases the patient may have such as primary hypogonadism that the provider can safely medically manage.

Androgen excess can also result from endogenous androgen production. The most common endogenous source is congenital adrenal hyperplasia, although functional tumors (adrenal or testicular) and androgen insensitivity syndromes could also be responsible [2]. Although congenital adrenal hyperplasia is more commonly discussed in the context of female fertility, there have been multiple studies linking the

disease to decreased fertility in men [34, 35]. In one of these studies, only two thirds of men with congenital adrenal hyperplasia who attempted pregnancy achieved success [36]. In terms of treatment, numerous strategies have been studied and proven efficacious, including hCG with FSH, clomiphene citrate, and intracytoplasmic sperm injection [37–39].

5.3.2 Estrogen Excess

As mentioned earlier, testosterone's ability to inhibit GnRH secretion at the hypothalamus is mediated through conversion to estrogens. A primary excess of estrogens can act similarly to inhibit the hypothalamic–pituitary–testis axis and thus contribute to decreased fertility. While estrogens are produced in the testis along with testosterone, the main source of estrogens in males is peripheral aromatization of testosterone by the enzyme aromatase, found in adipose tissue. The rising prevalence of obesity in our society puts more men at risk for estrogen excess. In particular, the ratio of testosterone to estradiol (T:E2) appears to be an important measure of estrogen excess, with a goal ratio > 10:1 sought by many clinicians. Pavlovich et al. examined a cohort of infertile men and found significantly reduced T:E2 ratios in the infertile men compared with a fertile control group (6.9 vs. 14.5) [40].

Treatment of relative estrogen excess involves inhibitors of the aromatase enzyme. There are two main classes of aromatase inhibitors: steroidal agents (e.g., testolactone) and nonsteroidal agents (e.g., anastrozole). Both have shown utility in treatment of infertile men with low T:E2 ratios. The above Pavlovich study treated 63 men with male factor infertility and low T:E2 ratios with testolactone, 50–100 mg twice daily. Treatment was effective in improving both T:E2 ratio and sperm quality, as defined by concentrations and motility [40]. A more recent study by Raman and Schlegel treated 140 infertile men with abnormal T:E2 ratios with either testolactone (100–200 mg daily) or anastrozole (1 mg daily). Both treatment arms showed improvement in T:E2 ratio and improved sperm concentration and motility. Further, the study did not show any significant difference between the two classes of aromatase inhibitors in terms of hormonal profile or semen analysis, except in the setting of Klinefelter syndrome, where testolactone was superior in treating the abnormal T:E2 ratios [17]. These studies combined show a clear role for aromatase inhibitors in infertile men with abnormal T:E2 ratios. This treatment strategy may be of particular importance in obese patients [41].

5.3.3 Thyroid Excess

As was touched upon earlier, the role of thyroid hormones in spermatogenesis is not entirely clear. However, hyperthyroidism appears to adversely affect semen parameters. Abalovich et al. found that patients with hyperthyroidism have lower bioavailable testosterone, higher sex-hormone-binding globulin, and higher LH levels compared with controls [42]. Hyperthyroid patients were reported to have markedly impaired semen parameters, including low motility, low ejaculate volume, low sperm concentration, and abnormal morphology. The authors noted that 85% of the seminal abnormalities normalized on semen testing conducted 7–19 months after achievement of euthyroid status. A more recent study also found that hyperthyroidism can impair semen parameters [43]. The authors of this study reported that hyperthyroid patients had significantly lower sperm motility than controls. Motility was improved after euthyroid status was achieved with medical thyroid ablation. Just as with hypothyroidism, there is a scarcity of data regarding hyperthyroidism and spermatogenesis. However, the available studies seem to suggest that hyperthyroidism can adversely affect semen parameters.

5.3.4 Prolactin Excess

Hyperprolactinemia, an excess of the hormone prolactin, is another hormonal etiology of male infertility. The diagnosis is relatively straightforward, as hyperprolactinemia can be detected on routine serum testing, but determination of a particular etiology can be more challenging. Hyperprolactinemia can occur in the case of hypothyroidism, liver disease, stress, use of certain medications (i.e., phenothiazines, tricyclic antidepressants), and with functional pituitary adenomas (prolactinomas). Clinical suspicion must be high for excess prolactin, as the manifestations can range from asymptomatic in many patients to galactorrhea or hypoandrogenic states (i.e., low libido, erectile dysfunction) in affected patients. Patients with pituitary adenomas may also present with bilateral temporal visual field defects. This state, known as bitemporal hemianopsia, is the result of the close anatomic proximity of the pituitary gland to the optic chiasm. Growth of the pituitary tumor compresses the optic nerve, leading to visual field deficits.

Hyperprolactinemia can cause male infertility through its inhibitory effects on the hypothalamus. The high levels of prolactin suppress the secretion of GnRH from the hypothalamus, which subsequently impairs the release of gonadotropins, the production of testosterone, and spermatogenesis. The multiple effects on the hypothalamic–pituitary–testicular axis can result in a patient presenting with multiple problems such as decreased libido, inability to achieve erection, and abnormal semen parameters.

Once the diagnosis of hyperprolactinemia is made, the practitioner should obtain an MRI study focusing on the pituitary gland. If a prolactinoma is found, then it can be

characterized based on its size and appearance. The main differentiation is between microadenomas, lesions <10 mm, and macroadenomas, which are lesions >10 mm. If a prolactinoma is discovered, then medical therapy focuses on blocking the secretion of prolactin through the use of dopamine agonists. Examples of these agents include bromocriptine, cabergoline, pergolide, and quinagolide, with the most well-characterized agents being bromocriptine and cabergoline. These agonists make use of the natural inhibition of prolactin secretion by dopamine. This can actually cause regression of the tumor, although the process generally occurs over months. Possible side effects of dopamine agonists include nausea, vomiting, and postural hypotension. While inhibition of excess prolactin secretion prevents the disruption of the hypothalamic–pituitary axis, there have been few studies specifically elucidating the effects of these dopamine agonists on spermatogenesis and fertility. A 1974 study treated men with functional prolactinomas and hypogonadism with bromocriptine and found no increase in sperm motility [44]. However, more recently, DeRosa and colleagues compared bromocriptine and cabergoline in such patients. Both treatments showed overall improvements in sperm number, motility, rapid progression, and morphology within 6 months of therapy [45]. A subsequent study from the same institution compared seminal fluid parameters between men with prolactinomas and control men. After 24 months of treatment with cabergoline (initial dose 0.5 mg weekly, subsequently titrated to PRL levels), two-thirds of men showed restored gonadal function as compared against healthy control men [46].

Comparing cabergoline and bromocriptine, it appears that cabergoline is more efficacious at normalization of prolactin levels and regressing tumor burden [47]. Further, a higher percentage of patients show a clinical response to cabergoline when compared with bromocriptine. Finally, there is a higher overall rate of permanent remission and fewer side effects with cabergoline compared to bromocriptine [47]. Considering all of these findings, cabergoline is often the first therapy utilized in treating men with prolactinomas.

While treatment of prolactinomas with dopamine agonists can be effective in many cases, a significant percentage of men may still remain persistently hypogonadotropic. Recent research suggests that clomiphene citrate may be an effective treatment for these men. Ribiero and Abucham treated 14 persistently hypogonadal men with clomiphene (50 mg/day for 12 weeks) and noted both improved testosterone levels and sperm motility [48].

Ablative therapy for prolactinomas—in the form of radiation therapy or transsphenoidal resection—is also available. Ablative therapy is typically reserved for those who fail medical management. Ablative treatments remove the source of prolactin and thus the inhibition of GnRH secretion. Measurement of the patient's gonadotropin levels posttreatment remains important, as further intervention with exogenous gonadotropins may be necessary to optimize therapeutic benefit.

Medical treatments for male infertility have traditionally centered on empiric approaches to enhance spermatogenesis. Over the past two decades, improved insight has been gained into the pathophysiology of male infertility and the outcomes associated with empiric therapy. With this insight, more targeted and directed use of medical agents has been described. As such, "empiric therapy" is used with less frequency now than was the case 20 years ago. Many available medical therapies for infertile men are used to optimize the hormonal milieu and thus optimize spermatogenesis. This has indeed been the focus of this chapter. However, numerous other medical agents are used routinely to address other specific pathophysiologic conditions leading to male factor infertility. These agents include antimicrobial drugs, anti-inflammatory medications, and sympathetic agonists. Each of these classes of drugs has clear indications for use in specifically targeted subgroups of infertile men, and they are each described in other specific chapters of this text.

One important point clearly delineated in the literature over recent years is this: empiric medical therapy generally has limited utility and benefit in the treatment of infertile men. While randomized, double-blinded, placebo-controlled studies are costly in terms of time and money, they remain the proving ground for effective medical therapies. More than one agent has failed to pass this test in recent years, but this is a good thing. While the armamentarium of available medical agents for the treatment of male infertility is somewhat limited, this fact should push us to strive harder to gain enhanced insight into the pathophysiological mechanisms leading to decreased male reproductive potential. It is with this enhanced insight into the fundamental problems leading to male infertility that we will develop additional, effective medical therapies.

5.4 Conclusion

Male fertility relies on an intricate hormonal balance and thus a deficiency or excess in a number of hormones can result in impaired fertility. This imbalance can impact fertility by affecting the more central hypothalamic–pituitary axis or by causing dysregulation in the testis where LH and FSH act on Sertoli cells and Leydig cells, respectively, to stimulate maturation of spermatogonia. Despite the low percentage of infertility cases involving endocrinopathies, further research on better understanding the etiology of the mechanism behind infertility is essential as it may lead to the development of more tailored therapies for endocrinopathy-induced infertility. As the rates of metabolic diseases continue to rise

in this country, addressing the impact of hormonal imbalance on male fertility will play an increasingly important role in improving patient quality of life.

5.5 Review Criteria

A meticulous search of studies addressing the topic of endocrinopathies related to male infertility was performed using the search engines PubMed and MEDLINE. The start and end dates for these searches were November 2018 and December 2018, respectively. Manuscripts published in academic meeting proceedings were not included. The overall strategy for study identification and data extraction was based on the following key words: male infertility, spermatogenesis, endocrinopathy, hypogonadotropic hypogonadism, hypergonadotropic hypogonadism, hyperprolactinemia, hyperthyroidism, androgen excess, and estrogen excess.

Oxidative Stress and Its Association with Male Infertility

6

Ashok Agarwal and Pallav Sengupta

Key Points

- ROS mediate some essential intracellular signaling cascades needed for normal male reproductive functions.
- Excess ROS production leads to redox imbalance and OS that cause oxidative damage to the sperm.
- ROS can affect male reproductive functions through lipid peroxidation, sperm DNA fragmentation, apoptosis of germ cells, and adversely affecting ART media.
- Laboratory assessment of ROS in male infertility includes both indirect methods via lipid peroxidation markers, TAC and seminal ORP, and direct method through chemiluminescence assay.

6.1 Introduction

Infertility is a major global medical and social concern, and male etiology contributes to half of the overall infertility [1]. The mechanisms, by which multivariate causative factors influence male fecundity, are not yet fully understood. The advances in research in the arena of male reproductive science could potentially recognize some of the most deleterious factors attributing to male factor infertility. These include physiological, environmental, as well as genetic and epigenetic factors. At the molecular level, most of these factors interfere with normal male reproductive functioning via the imbalance in reactive oxygen species (ROS) generation and antioxidant capacity, a condition of oxidative stress (OS) [2].

ROS are the oxygen metabolism derivatives. They present as a set of toxic metabolites, while possessing some vital physiological role in normal male reproductive functions [3]. At normal physiological levels, ROS participate in essential intracellular signaling cascades to ensure proper reproductive functions such as capacitation and hyperactivation of sperms, and acrosome reaction (AR) [3, 4]. On the contrary, the imbalance between ROS and antioxidant levels causes a disparity in the redox balance, which has deleterious effects over the cellular micro- and macromolecules including the carbohydrate components, lipids, proteins, and nucleic acids [5]. Spermatozoa are very vulnerable to OS as they lack proper cell repair machineries and have inadequate antioxidant capacity [6]. These deficiencies in spermatozoa are due to their structural peculiarity possessing diminutive cytoplasmic content. Spermatozoa are highly susceptible to OS-induced lipid peroxidation (LPO) due to high abundance of PUFA in their cell membrane. As a result of LPO, spermatozoa lose their membrane permeability causing efflux of the much-needed ATPs, thereby impairing their own motility with disrupted flagellar movements [7, 8]. OS impairs the structural and functional aspects of sperm including its production, viability, and fertilizing potential [9].

This chapter provides a concise overview by discussing (a) the generation and sources of ROS in the male reproductive tract, (b) physiological role of ROS in male reproductive functions, (c) pathological role of ROS in causing male infertility, and (d) assessment as well as management of OS-induced male infertility. This chapter aims to aid in better understanding of association of ROS with male infertility from physiological and clinical perspectives.

6.2 Biochemistry of Oxidative Stress

Reactive oxygen species (ROS) are generated as a result of physiological cellular metabolism. Biological energy production mostly involves oxidative phosphorylation by the enzymatically regulated reaction of oxygen with other bio-

S. J. Parekattil et al. (eds.), *Male Infertility*, https://doi.org/10.1007/978-3-030-32300-4_6

molecules within the mitochondria [10]. In the course of these enzymatic reductions of molecular oxygen to produce energy, free radicals are formed [11]. A free radical refers to an oxygen molecule that has a single or several unpaired electron(s) in the molecular orbitals. Superoxide anion ($O_2^{\bullet-}$) radical, the primary ROS molecule, is produced by incorporation of an electron to the molecular O_2. This primary product, either by direct or indirect conversions, is then transformed to secondary ROS products, namely, peroxyl radical ($ROO^{\bullet-}$), hydroxyl radical ($OH^{\bullet-}$), or hydrogen peroxide (H_2O_2) [8]. Among these, H_2O_2 cannot be categorized as a free radical as it is devoid of any unpaired electron. Reactive species derived from nitrogen (reactive nitrogen species or RNS) also have vital physiological and pathological importance. RNS include nitrous oxide (N_2O), peroxynitrite ($ONOO^-$), peroxynitrous acid (HOONO), nitrogen dioxide (•NO2), and dinitrogen trioxides (N_2O_3) etc. [10, 12].

Spermatozoa generates ROS via two mechanisms: (a) in sperm plasma membrane, ROS is be produced by the nicotinamide adenine dinucleotide phosphate (NADP) oxidase system and/or (b) in sperm mitochondria, ROS can be generated via the NAD-dependent redox reaction. Spermatozoa are mitochondria-rich cells owing to their constant requirement of energy for their motility [13]. Increased number of dysfunctional spermatozoa triggers higher ROS production in semen which in turn affects sperm mitochondrial function and motility. As discussed earlier, the leading ROS in human spermatozoa is $O_2^{\bullet-}$ that reacts with itself through dismutation reactions to yield H_2O_2. In presence of transition metals (Fe^{2+} and Cu^{2+}), H_2O_2 and $O_2^{\bullet-}$ can generate the most reactive $OH^{\bullet-}$ via the Haber–Weiss reaction which can initiate a LPO cascade disrupting membrane fluidity and impairing sperm functions [14, 15].

6.3 Sources of ROS in Male Reproductive Tract

6.3.1 Endogenous Sources

6.3.1.1 Leukocytes

The significant percentage of semen specimens contain peroxidase-positive leukocytes (polymorphonuclear leukocytes, predominantly neutrophils, 50~60%) and macrophages (20~30%) that originate from prostate gland and seminal vesicles. Leukocytospermia is also a sperm-disrupting disorder characterized by the presence of $>1 \times 10^6$ WBC/mL of semen [16]. Any infection or inflammatory response triggers these cells to produce 100 times more ROS than normal production rate as a defense mechanism and also promote NADPH production through the hexose monophosphate (HMP) shunt [5]. ROS generation is one of the prime mechanisms of leukocytes-induced immune defense with leukocytes being quite potent OS-inducing cells [15]. In addition, the elevation of pro-inflammatory mediators (predominantly IL-6, IL-8, and TNFα) and reduction of antioxidants in inflammatory reactions can induce a respiratory burst resulting in OS (Fig. 6.1) [17].

6.3.1.2 Immature Spermatozoa

In normal conditions, the cytoplasm is extruded from the maturing spermatozoa to prepare itself for fertilization. Any disruption in spermiogenesis may result in retention of excess residual cytoplasm (ERC) around the mid-piece of the spermatozoon, as in immature teratozoospermic sperms (Fig. 6.1). These ERCs have considerable content of enzymes to regulate glucose metabolism, namely, the glucose-6-phosphate dehydrogenase (G6PD). They also mediate intracellular β-nicotinamide adenine dinucleotide phosphate (NADPH) production through the HMP shunt that is the major fuel for ROS production via NADPH oxidase located within the sperm membrane [18]. Thus, teratozoospermic sperms produce more ROS compared with morphologically normal sperm. The calcium-dependent NADPH oxidase (NOX 5) present in the sperm differs from those present in the leukocytes, as the sperm-specific NOX5 activity is not dependent upon protein kinase-C [19]. However, the correlation of overexpression of NOX5 in spermatozoa in OS-induced infertility remains under debate.

6.3.1.3 Infections, Autoimmune/Inflammatory Conditions

Genitourinary Tract Infection

Prostatitis may affect up to 50% of men worldwide, and 10% of them suffer from chronic prostatitis [20]. Bacteria that cause prostate infection are of urinary tract origin and/or transmitted sexually [21, 22]. Some important nonsexually transmitted bacteria are gram-negative bacteria (*E. coli*, *Proteus mirabilis*), Streptococci (*S. viridans* and *S. pyogenes*), atypical mycoplasma strains (*Ureaplasma urealyticum)*, and *Mycoplasma hominis* coagulase-negative Staphylococci (*S. epidermidis*, *S. haemolyticus*). These agents commonly produce acute inflammatory responses by promoting leukocyte influx into the male reproductive tract and, ultimately, triggering ROS production [13]. Viral infections by cytomegalovirus, herpes simplex virus (HSV), Epstein–Barr virus, and others can also initiate oxidative damage to spermatozoa. Herpes simplex DNA has been found in semen of 4–50% of infertile men [23], with a tenfold increase IgM antibodies toward HSV [24].

Systemic Infection

Several chronic systemic infections have been correlated with increased OS in the male genital system. Human immu-

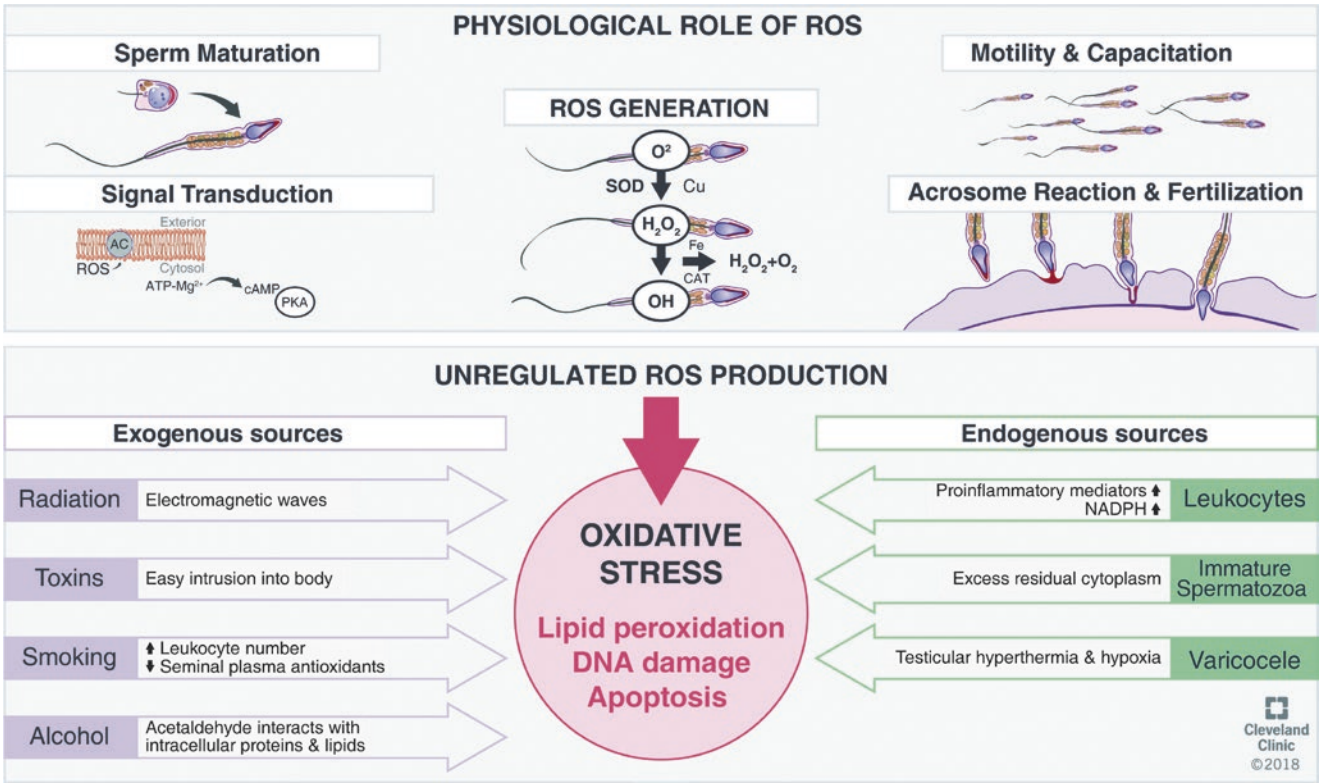

Fig. 6.1 Physiological roles of ROS and generation of excess ROS by exogenous and endogenous sources. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2017. All Rights Reserved)

nodeficiency virus (HIV) infection is associated with an elevation of leukocyte number in semen [25]. Hepatitis B and C infection have also been linked with significant hepatic and seminal OS [26, 27]. Chronic infections such as tuberculosis [28], leprosy [29], malaria [30], and Chagas disease [31] have all been connected with elevated degrees of systemic and male genital OS.

Autoimmune/Inflammatory Condition

Chronic nonbacterial (noninfective) prostatitis is an inflammatory condition of the prostate that has been linked with considerably elevated OS within semen [32]. It accounts for more than 90% of all cases and effects 10% of men [20]. The majority of the cases are reported to have adverse autoimmune responses to seminal or prostate antigens, leading to an elevation in seminal pro-inflammatory mediators and ROS-generating leukocytes [32, 33]. The specific mechanism inducing this response is unidentified, but a probable cause is polymorphism of the T_H-2 cytokine IL-10 [34]. Thus, reduction in IL-10 may shift immune responses to T_H-1 mechanism that induces T-lymphocytes against prostate antigens. The prime cytokines involved in this regulation are IFN-Ð, TNF-α, and IL-1b activating chemotaxis and activation of leukocytes and thereby inducing seminal OS [33]. OS, as discussed earlier, results in a significantly decreased semen quality and sperm membrane integrity [35]. OS also affects infertility after vasectomy reversal, due to disruption of blood–testis barrier. This causes loss of testicular immune privilege and initiation of immune responses against sperm [36], such as elevated seminal leukocytes, inflammatory cytokines, and generation of free radicals [36, 37].

6.3.1.4 Varicocele and Cryptorchidism

Varicocele, a pathogenic condition characterized by an abnormal venous dilation in the pampiniform plexus around the spermatic cord, is detected in about 40% of male partners of all infertile couples and is thought to be the leading cause of male factor infertility [38]. Many mechanisms have been proposed in the pathophysiology of varicocele. Testicular hyperthermia and hypoxia are the most commonly accepted theories resulting in OS-induced testicular dysfunction [38, 39] (Fig. 6.1). Recent studies have confirmed the presence of significantly higher OS parameters such as ROS and lipid peroxidation in semen samples from infertile patients with varicocele compared with normal fertile donors [38, 40]. The increase in varicocele-induced ROS generation is strongly correlated with a reduction in sperm DNA integrity [41]. The seminal ROS levels have been reported to be directly associated with the grade of varicocele [42].

Cryptorchidism is yet another cause of male factor infertility. It involves hypo-spermatogenesis with inability of gonocytes to mature to type-A spermatogonia [43]. Cryptorchidism-affected men may be surgically treated with orchidopexy in early stage of life still, but they will continue to possess an increased sperm ROS generation and DNA fragmentation [40].

Spermatic cord torsions are also associated with male infertility. It is suggested that OS-induced ischemia reperfusion injury results in damage to contralateral testis and with torsions. A prolonged ischemic phase follows either surgical or spontaneous restoration of testicular blood flow. This results in sudden influx of activated leukocytes into the testis [1, 40] that accelerates the generation of free radicals [6].

6.3.1.5 Other Chronic Diseases

Diabetes, one of the most prevalent chronic diseases, impairs male reproductive functions influencing both spermatogenesis and erectile processes. Diabetic men have shown higher sperm DNA fragmentation induced by OS compared with normal men [43]. Chronic inflammation and OS are also found in men with chronic kidney diseases [44]. Men with hemoglobinopathies, such as β-thalassemia, possess systemic OS [45] that can cause oxidative damage to sperm owing to iron overload by multiple blood transfusions [46]. Homocysteines can also lead to reproductive dysfunctions and OS by accumulated toxins [46]. Hyperhomocysteinemia generally occurs via suboptimal homocysteine re-methylation to methionine by methyl tetrahydrofolate reductase (MTHFR). This is caused by dietary folate deficiency or a single nucleotide polymorphism (SNP) in the MTHFR gene [47]. SNPs in the MTHFR gene are more commonly reported in the infertile men [48–50], rendering these men at elevated risk for homocysteine-induced OS.

6.3.2 Exogenous Sources

6.3.2.1 Radiation

Mobile phone radiation magnifies ROS generation in seminal plasma and causes deleterious effects on semen quality. It induces sperm DNA damage affecting sperm motility, count, and vitality [6, 51]. The radiofrequency electromagnetic waves interfere with the intracellular electron transfer along the membranes owing to cytosolically charged molecules, and thus interfering with the normal germ cell functions [52–54]. Radiofrequency waves affect male fertility through both thermal and nonthermal mechanisms (Fig. 6.1). Since testis depends mostly upon surface conduction for its temperature regulation, it is susceptible to damage by electromagnetic energy than any other organs who mainly depend on blood flow for temperature control. Radiation may elevate scrotal temperature, and even if it gets increased by 1 °C, normal spermatogenesis gets affected. The nonthermal effects of radiation include induction of oxidative stress or cell membrane potential alterations which disrupt germ cell proliferation and trigger apoptosis. Radiation may also cause sperm DNA fragmentation and epigenetic modifications. Chronic exposure to radiation severely disrupts steroidogenesis and brings about degeneration of Leydig cells [52–54].

6.3.2.2 Lifestyle Factors

Smoking disrupts the balance of ROS production with adequate antioxidant defense. Smoking has been reported to elevate concentrations of seminal leukocytes by 48% that accounts for the increase in seminal ROS by 107%. This leads to reduction in seminal antioxidants capacity and subsequent rise in 8-OHdG concentrations (a potent oxidative damage biomarker) [52]. Furthermore, smoking elevates cadmium and lead concentrations in blood and semen. This in turn increases ROS generation and damages sperm motility [52]. Germ cell apoptosis and DNA damage are generally identified in smokers, thus compromising male fecundity [55].

Alcohol is another inducing factor leading to uncontrolled seminal ROS generation and deterioration of antioxidant capacity. Acetaldehyde, produced as a by-product through ethanol metabolism, yields ROS via reaction with sperm cellular components. This significantly reduces the percentage of functional spermatozoa [56].

6.3.2.3 Toxins

Industrialization and domestic sophistications have led to the generation of a huge mass of environmental toxins and endocrine disruptors in an individual's immediate environment. These intrude into the body and may potentially induce excessive testicular ROS generation (Fig. 6.1). ROS thereby impairs morphology and functions of sperms. Exposure to environmental toxins leads to ROS-induced germ cell apoptosis [55]. Increased use of plastics have led to rise in exposure to phthalates which in addition to toxic metals such as lead, manganese, cadmium, chromium, and mercury afflict sperm quality, count, and spermatogenesis [52, 57].

6.4 Physiological Role of ROS

ROS, at physiological limits, is crucial for the quintessential phases of sperm development such as their maturation, capacitation, hyperactivation, and finally acrosome reaction (Fig. 6.1). The efficiency of ROS as signaling molecule attributes to its compatible small size, abundant generation in cells, and short half-life [58]. Redox modulation of cysteine residues is the key regulatory step by which ROS influence

the most of the signaling cascades. It is to be mentioned that activity of any specific enzyme is determined by the redox status of its thiol groups. ROS operates through activation of adenyl cyclase (AC), thus increasing intracellular cyclic AMP (cAMP) production. This turns on protein kinase A (PKA) that activates the downstream messengers specific to the spermatozoa maturational state [59].

6.4.1 Capacitation

Capacitation is the process of ultimate functional maturation of spermatozoa, which is essential to fertilize an ovum. Maturation of spermatozoa takes place mostly in the epididymis. It involves cell membrane restructuring, surface protein redistribution, and alterations in nuclear components and enzymes [3, 59]. ROS mediates the spermatozoa maturation by regulating the vital cell signaling cascades [59, 60]. Spermatozoon in human has compactly packed chromosomal DNA with smaller proteins than histone proteins. Chromatin stability is achieved through ROS-aided disulfide bonds between the cysteine residues of protamines. Thus, ROS helps in conferring chromatin stability and in preventing DNA damage. ROS also protects mitochondria from proteolytic dilapidation by participating in the development of "mitochondrial capsule" formed by disulfide bonded proteins [3, 61]. ROS facilitates spermatozoa capacitation by signaling cascades increasing intracellular cAMP levels. This activates protein kinase A followed by subsequent phosphorylation of MEK (extracellular signal regulated kinase)-likeproteins,sheathproteins,andthreonine-glutamate-tyrosine [18, 62]. This cellular pathway ultimately leads to spermatozoa capacitation, which is a prerequisite for acrosome reactions [52, 63].

6.4.2 Hyperactivation

Hyperactivation refers to a state of increased sperm motility with enhanced amplitude and asymmetric sperm flagellar movements. It confers a nonlinear movement of sperm with an increased sideward displacement of the sperm head [64]. This process just follows capacitation or can be considered as a later part of capacitation. It is required to determine proper sperm penetration into the zona pellucida for successful fertilization. The initiation of the process is mediated by calcium ion influx, which together with ROS activates adenylyl cyclase (AC), inducing cAMP production and activation of PKA. This triggers NADPH oxidase to further induce ROS generation [60]. PKA triggers protein tyrosine kinases (PTK) and phosphorylates the tyrosine residues present within the axonemal fibrous sheath and flagellar cytoskeleton. ROS induces the phosphorylation of tyrosine by influencing the activation of PTK and deactivation of phosphotyrosine phosphatase (PTPase) [3, 52].

6.4.3 Acrosome Reaction

The hyperactivated spermatozoon crosses the cumulus oophorous, to get attached to the zona pellucida of the oocyte. This is followed by a pore formation in the extracellular matrix of zona pellucida by spermatozoa exocytotic release of proteolytic enzymes [61]. These reactions enable sperm attachment and entry into ova and together is termed as acrosome reaction. These reactions are initiated by phosphorylation of tyrosine residues of membrane proteins that is aided by ROS-regulated cell signaling pathway. The primary pathway as discussed in the earlier sections involves Ca^{2+} influx, rise in intracellular cAMP, and PKA activation [3, 59].

6.4.4 Fertilization

ROS also assists in the process of fertilization by enhancing the membrane fluidity for sperm–oocyte fusion to occur [52]. ROS inhibits protein tyrosine phosphatase activity and thus prevents phospholipase A2 (PLA2) from getting deactivated. Hence, the activated PLA2 cleaves the secondary fatty acid present in the membrane to effectively enhance membrane fluidity [65].

6.5 Mechanisms of ROS-Mediated Male Infertility

6.5.1 Lipid Peroxidation

Sperm has substantially high lipid content in its plasma membrane. They are mostly present as PUFAs with unconjugated double bonds in methylene groups. This weakens the methyl bond between carbon and hydrogen. Thus, hydrogen is rendered vulnerable to oxidative attack. The uncontrolled rise in intracellular ROS initiates a progressive reaction cascade and triggers LPO [39, 66, 67]. LPO is a self-propagating autocatalytic reaction that destroys almost 60% of the membrane fatty acids affecting its fluidity. It also imparts nonspecific permeability of the membrane and disrupts membrane receptors and enzymes that severely impairs fertilization [52, 66, 68].

Oxidative damage once initiated follows steady propagation until it is terminated. "Initiation" is marked by isolation of hydrogen atoms from the carbon–carbon bonds, followed by generation of free radicals and lipid radicals. This reacts with oxygen to produce peroxyl radicals [66]. These peroxyl radicals further abstract hydrogen atom from the lipids

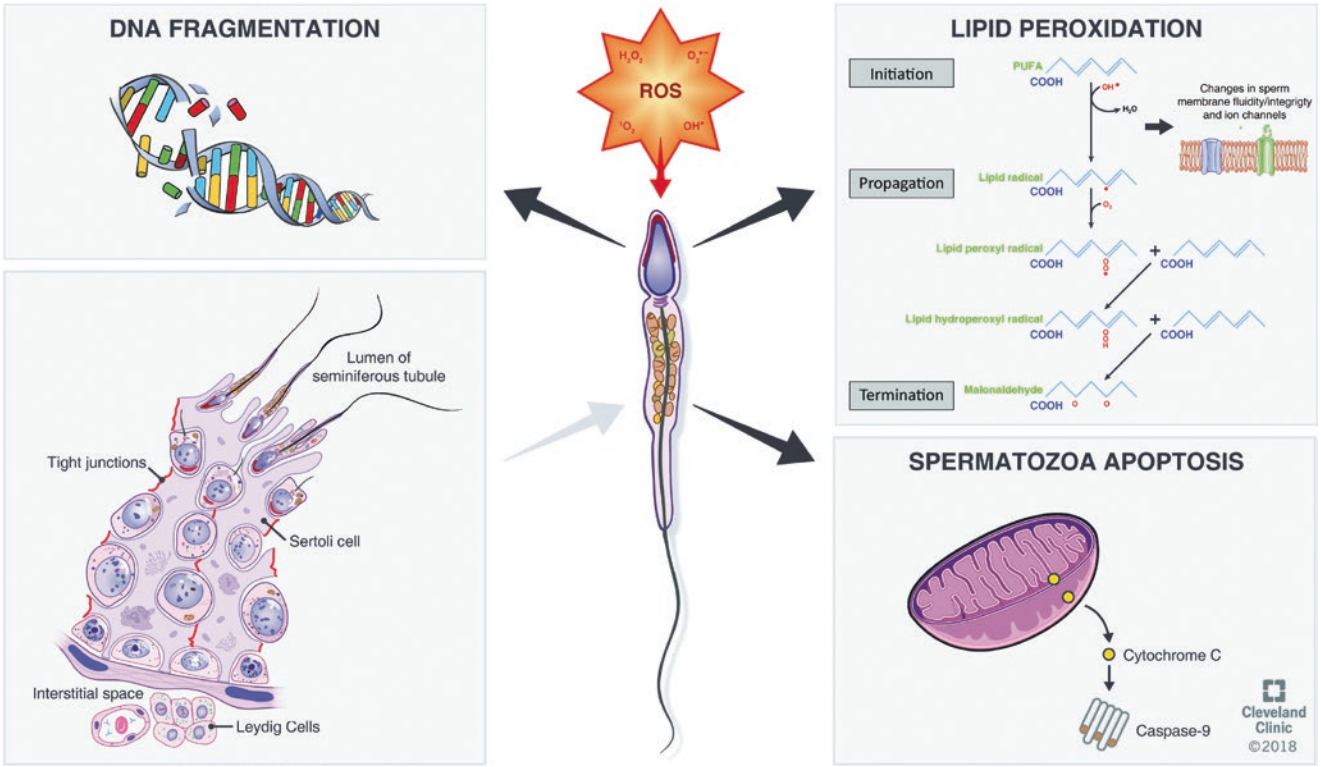

Fig. 6.2 Mechanisms of ROS-induced impairments in sperm functions. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2017. All Rights Reserved)

(action enhanced by the presence of metals such as copper and iron). This triggers the chain of autocatalytic reaction. The "propagation" of oxidative damage refers to continuation of the damaging reaction with the existing radicals reacting with succeeding lipids, giving rise to toxic aldehydes by hydroperoxide degradation (Fig. 6.2) [15, 18, 66]. Cytotoxic peroxyl and alkyl radicals are generated in a cyclical manner until a stable end product, malondialdehyde (MDA), is produced to terminate the reaction [66]. MDA thus bears importance as a marker to predict the level of peroxidative damage caused to spermatozoa. Another deleterious product of LPO is the hydrophilic 4-hydroxynonenal that severely impairs spermatozoa function affecting its proteomics and genomic constitution [52].

6.5.2 Sperm DNA Fragmentation

ROS adversely affects sperm nuclear DNA through sperm DNA fragmentation (SDF), inducing chromatin cross-linking, randomly modifying the base-pairing and chromosomal microdeletions (Fig. 6.2) [52, 66, 69]. ROS also aids adenine and pyridine nucleotides removal by initiating LPO [52, 69]. Numerous intrinsic and extrinsic factors are suggested in the etiopathogenesis of male SDF, including infection, varicocele, advanced male age, lifestyle factors, heat stress, environmental toxins, radiations, defective protamination, and sometimes even remain idiopathic [43, 70]. Several of the mentioned etiologies are mediated by uncontrolled ROS generation leading to increased SDF [71]. Testicular SDF has been characterized by abortive germ cell apoptosis [72] and defective sperm maturation [73]. As a consequence of imbalance between ROS production (via testicular hypoxia, reflux of metabolites, endocrine disruption, and scrotal hyperthermia) and protective antioxidant capacity, a state of OS is established. This induces elevated lipid peroxidation products in infertile men with pathological conditions that serve as etiology for SDF [74]. Moreover, treatment of such pathological state with antioxidants seems to be effective in concurrent decrease in both ROS [75] and SDF [76].

6.5.3 Apoptosis of Spermatozoa

ROS is capable of disrupting the inner and outer mitochondrial membranes releasing cytochrome C. This cytochrome C in turn activates the apoptotic caspases [52, 62]. ROS induces apoptosis of spermatozoa by elevating cytochrome C level, which have been reported by seminal plasma analysis in infertile men (Fig. 6.2). The increased cytochrome C level in seminal plasma is an indicator of severe sperm mitochondrial damage [6, 52]. Besides the defects in sperm chromatin compaction, numerous intrinsic and extrinsic factors have been reported in the etiopathogenesis of SDF, including

varicocele, infection, advanced male age, heat stress, lifestyle factors, environmental toxins, ionizing and nonionizing radiations, defective protamination, and, at times, idiopathic [43, 70]. Many of the above etiologies, but not all, are mediated by ROS leading to high SDF [71]. Abortive apoptosis [72] and defective maturation [73] theories have been proposed to correlate the role of intrinsic factors in testicular SDF. Moreover, evidences showed more DNA fragmentation in epididymal and ejaculated sperm than the testicular sperm, signifying the impact of extrinsic factors in most patients [77]. The presence of a large amount of polyunsaturated fatty acids (PUFA) in the plasma membrane makes sperm susceptible to ROS-induced damage [78].

The close relationship between ROS and SDF is also evident from the etiopathologies of all grades of clinical varicocele. The result of imbalance of ROS (produced by testicular hypoxia, scrotal hyperthermia, reflux of metabolites, and endocrine disruption) and protective antioxidant system was demonstrated by the higher level of ROS and lipid peroxidation products in infertile men with varicocele than infertile men without varicocele [74]. Moreover, treatment of varicocele is effective in decreasing both ROS [75] and SDF [76].

6.6 ROS in Assisted Reproduction

ROS has been shown to possess a significant role in fertilization. Oocyte metabolism produces ROS, but it actually lacks adequate protective antioxidant mechanisms [79], which results in OS. Moreover, preimplantation embryonic development needs a preferred modulation in cellular energetics [80]. Thus, the established OS serves as beneficial state where oxidative phosphorylation is needed as energy source for preimplantation embryo development. This oxidative phosphorylation dependency shifts to glycolysis to increase energy production [80, 81]. Oxygen may oxidatively phosphorylate ADP to ATP, which is utilized in folliculogenesis and oocyte maturation. In case of any alterations in these reactions using oxygen, it results in excess production of ROS which adversely affects embryo development [81].

Sources of ROS differ in case of conventional IVF and for ICSI [82]. The oocytes for ICSI are devoid of cumulus cells, rendering the oocyte and the injected spermatozoa as the only potential ROS sources in the culture media environment [81, 83]. While in IVF, ROS gets generated from the several oocytes per culture dish, a large mass of cumulus cells, and also from the inseminated spermatozoa. Moreover, unlike IVF, in ICSI there is no sperm–oocyte contact, thus limiting the scope of ROS production by faulty spermatozoa [59]. This explains why lesser the concentration of spermatozoa in the in vitro culture media, higher is the possibility of proper fertilization, implantation, and pregnancy [84]. ICSI utilizes a single spermatozoon at a time and therefore a better procedure to minimize OS.

In either IVF or ICSI, both the culture media and external environment influence the ultimate outcomes [8]. The procedures differ mostly in the fact that for ICSI there is shorter incubation time that reduces exposure to modulating external environmental factors [83, 85]. The predicted limit of the incubation time is 1–2 hours which yields better ART outcomes. In both IVF and ICSI, ROS is generated from the gametes, the embryo, or may arise indirectly from external factors, such as cumulus cells, leukocytes, etc. Since fertilization followed by embryo development in vivo takes place under low oxygen tension, a state of OS in the in vitro setting definitely accounts for high failure rate in ARTs. Hence, in order to improve ART outcomes, in vivo conditions should be emulated via minimizing exposure to the factors that promote generation of excess ROS [83, 86].

6.7 Measurement of OS

ROS-induced sperm damage is a major contributing male reproductive pathology (almost 30–80% of idiopathic male infertility) [87]. Assessment of ROS levels in the infertile men thereby is very crucial for its treatment and management. However, the difficulties in ROS assessment arise from the factors such as high cost, screening inconveniences, and scarcity of accepted specific analysis method. With the advent of research and technology, more than 30 different ROS measurement assays have emerged lately that can predict the level of OS in infertile men [52].

6.7.1 Assessment of Sperm OS from Routine Semen Analysis

Routine semen analysis (sperm count, morphology, and motility) provides diagnostic clues to the clinicians with asthenozoospermia being a major OS marker [88, 89]. Seminal plasma hyperviscosity is suggestive of increased MDA and reduced seminal antioxidant levels [88]. In addition, *Ureaplasma urealyticum* infection in the semen can also increase seminal viscosity and can be associated with high seminal ROS production [88]. The presence of round sperm cells may infer leukocytospermia which is again a potent source of ROS. However, it is needed to ascertain that the round cells are actually not immature spermatozoa. For this, several other tests are required, such as peroxidase test, seminal elastase measurement, or staining of CD45 (transmembrane glycoprotein) antibody. OS status is also presumed from disruption in sperm morphology and cytoplasmic droplets featuring anomalous spermatozoa. Poor sperm membrane integrity is diagnosed by hypoosmotic swelling test (HOST), which also associates with a state of OS [52].

6.7.2 Total Antioxidant Capacity (TAC)

Antioxidant capacity testing has been reported to potentially enhance prognostic information for infertile men. Luminol, a chemical exhibiting chemiluminescence when reacted with particular oxidizing agent, is being widely used to measure seminal total antioxidant capacity (TAC). It is quantified in contrast to a vitamin E analog "Trolox," a water-soluble tocopherol. The results signify ROS-TAC score and aid to infer the level of antioxidants produced as a combined efforts of all seminal constituents such as vitamins, lipids, and proteins [89].

6.7.3 Lipid Peroxidation Markers

Spermatozoa often carries accumulated lipid peroxides, produced as end-products. These metabolites, hydroxynonenal, MDA, 2-propenal (acrolein), and isoprostanes, can be used as OS indicators [66]. Thiobarbituric acid (TBA) assay is used for MDA measurement. The principles include combination of MDA with TBA to produce 1:2 adduct. This is a colored substance measured by fluorometry or spectrophotometry [52, 89].

6.7.4 Seminal Oxidation-Reduction Potential (ORP)

Oxidation-reduction potential (ORP) or redox potential measures the potential of electrons transfer between different chemical species [90, 91]. ORP helps to infer the association between oxidants and antioxidants and thereby suggest the level of OS. Recently, a novel method has been developed based on galvanostatic electron measure to assess OS changes in patients in trauma [92, 93].

Seminal ORP is efficiently assessed with the MiOXSYS System (AytuBioScience, USA) which is a standardized, reproducible, and reliable method. It provides greater application for OS analysis in research and clinical settings (Fig. 6.3) [94, 95].

6.7.5 Direct Laboratory Assessments of OS

Seminal ROS can be directly measured the chemiluminescence assays. The procedure involves a luminometer and a chemiluminescent probe such as luminal (5-amino-2,3, -dihydro-1,4-phthalazinedione). Luminol measures both extracellular and intracellular ROS. The free radicals contained in the semen sample produce a light signal reacting with luminal, which is converted by the luminometer to an electric signal (photon). Results are expressed as relative light units/s/10^6 sperm. The range of normal ROS levels in washed sperm suspensions is 0.10–1.03 units/s/10^6 [89].

6.8 Management of OS-Associated Male Infertility

Primary steps in OS management involve unveiling its underlying cause(s) followed by effective treatment.

6.8.1 Lifestyle Management Approach

Stress arises from both personal lifestyle adoptions and competitive professional load. The ill habits, such as substance

abuse, alcoholism, tobacco smoking and chewing, and an unbalanced diet are all major contributors to cause OS. Therefore, minimizing the avoidable lifestyle disorientations may help to prevent OS [52, 96].

Exposure to endocrine and reproductive disruptors which include pollutants, heavy metals, and other toxins greatly account for OS development. Increase in scrotal temperature via rigorous exercise, hot baths, driving for long hours, sedentary office works, etc., induce heat stress that create OS [39, 87, 97].

6.8.2 Vitamin and Antioxidant Supplementation

Antioxidant supplementation may eradicate excess ROS or decrease its production, to halt the damaging oxidative chain reactions. On the one hand, preventive antioxidants such as the metal chelators or binding proteins, for example, transferrin and lactoferrin, prevents OS by restricting ROS generation [98]. On the other hand, the scavenging antioxidants (vitamins C and E) combat OS by mitigating excess ROS [99].

Antioxidants can also be classified as enzymatic and nonenzymatic. Natural antioxidants are mostly enzymatic antioxidants that include superoxide dismutase (SOD), catalase, and glutathione reductase (GSH). Examples of nonenzymatic antioxidants include vitamins B, C, and E, carnitines, carotenoids, cysteines, pentoxifylline, taurine, hypotaurine, albumin, and some metals. They can also be obtained from certain foods and food supplements [52, 100, 101].

Available reports suggest antioxidant supplements are a beneficial treatment option for OS-induced male infertility that may reduce sperm DNA damage and improve semen parameters [102–107]. Specific antioxidants such as vitamin C, vitamin E, N-acetyl-cysteine, selenium, and zinc have been reported to be beneficial in treatment of OS-induced male infertility [108].

6.8.3 Surgery

Surgeries effectively correct the venous abnormality in varicocele patients and decrease seminal ROS, thus preventing further oxidative damage [87]. Surgical repair improves several sperm parameters and has been shown to improve pregnancy rates as well [52, 75]. It has been reported that inflammatory and OS markers such as MDA, H2O2, and nitric oxide (NO) are reduced while antioxidant levels improved following a successful varicocelectomy [109]. This scenario suggests that varicocelectomy decreases seminal ROS levels and increases TAC to restore male reproductive functions in varicocele patients [109, 110].

6.9 Conclusion

OS arises from disrupted balance between ROS production and their elimination. While at physiological levels, ROS contribute in maturation of sperm and normal sperm functions, and excessive seminal ROS induce OS that impairs sperm quality and functions. This deleterious chain of oxidative reactions leads to infertility. With proper assessment and management strategies, along with healthy life style practices, it is possible to improve male reproductive potential in OS-induced infertile men.

6.10 Review Criteria

An extensive literature search has been performed to find the relationship between oxidative stress and male infertility using search engines such as Science Direct, OVID, Google Scholar, PubMed, and MEDLINE. The overall strategy for study identification and data extraction was based on the following key words: “oxidative stress,” “reactive oxygen species,” “infertile men,” “infertility,” “semen parameters,” and “assisted reproduction” and the names of related oxidative-stress markers and specific ROS assessment methods. Articles published languages other than English were also considered. Data that were solely published in conference or meeting proceedings, websites, or books were not included. Websites and book-chapter citations provide conceptual content only.

Oxidative Stress Measurement in Semen and Seminal Plasma

7

Rakesh Sharma and Ashok Agarwal

Key Points

- Abnormal spermatozoa and leukocytes are major producers of reactive oxygen species (ROS).
- Physiological levels of ROS have an important role in sperm function; pathological levels result in oxidative stress.
- Various direct and indirect methods are available to measure oxidative stress. Each method captures only a single dimension of oxidative stress from which the overall oxidative stress status in a given biological system is generalized. These methods fail to provide a complete picture of the true oxidative stress status environment. They only reflect the redox status at a single point.
- Current markers of oxidative stress are antiquated, time-consuming, and time-sensitive.
- Oxidation reduction potential (ORP) is a novel direct marker of oxidative stress. It provides the relative proportion of oxidants (ROS) and reductants (antioxidants) that are present in a given biological system at any given time. ORP can be used as an adjunct tool to basic semen analysis in all patients who present for infertility. It can provide valuable information about sperm function and the fertilizing ability of the man.

7.1 Introduction

Infertility is defined as the inability to achieve a clinical pregnancy after 12 months of unprotected sexual intercourse. While contributing to about 50% of cases overall, males are solely responsible for 20–30% of infertility cases [1]. Approximately 7% of men worldwide are infertile [2]. When encountering male infertility, routine semen analysis is the first step for laboratory evaluations. Almost 15% of infertile men have semen parameters that are within normal reference range [3] and categorized as idiopathic infertility cases. Thus, assessing a man's fertility not only depends on gross physical parameters of spermatozoa but also on their functional capability.

Male infertility is strongly correlated to excess reactive oxygen species (ROS) in human semen [3–6]. The delicate balance in the cellular environment is maintained by the presence of a scavenging system via enzymatic and nonenzymatic antioxidant pathways. Physiological levels of ROS are required for normal cellular metabolism, spermatogenesis, sperm maturation, capacitation, hyperactivation, acrosome reaction, and sperm–oocyte fusion [7]. However, when ROS threshold supersedes the balance between ROS and antioxidants cells undergo oxidative stress (OS), this may lead to cellular dysfunction via lipid peroxidation, changes in protein conformation, and DNA integrity (Fig. 7.1) [8]. Due to its negative effect on cells, OS is associated with numerous pathological conditions in addition to infertility [7, 9–14].

Defective spermatozoa and presence of activated leukocytes are the major sources of ROS in human semen [5]. OS is one of the most common etiologies affecting 30–80% of men with infertility [3, 15], especially those who have unexplained and idiopathic male infertility [16]. OS can also potentially have consequences at a systemic level by decreasing the amount of testosterone or LH [17].

Increased OS is detrimental to sperm DNA and may compromise the paternal genomic contribution to the embryo [18]. Numerous studies have reported that sperm DNA fragmentation (SDF) is linked to reduced fertilization rate [19–23]. Several hypotheses have been proposed to understand the origin of sperm DNA fragmentation [19, 24, 25]. The first hypothesis describes endonuclease-mediated DNA cleavage, also called abortive apoptosis. This occurs when sperm with damaged DNA escape from normal programmed cell death [19]. The second hypothesis involves DNA strand breaks induced by oxidative stress [24]. The third hypothesis is characterized by an increase in torsional stress during spermiogenesis that can in turn increase the activity of endogenous endonucleases, which may stimulate DNA fragmentation [19]. Due to these characteristics, OS in male infertility can lead to serious health risks including cardiovascular and diabetes if not carefully controlled over time [26–29].

7.2 Seminal Reactive Oxygen Species and Antioxidants: Physiological and Pathological Roles

7.2.1 Physiological Roles

ROS are highly reactive free molecules or non-radicals that are generated from oxygen metabolism. Free radicals are molecules that contain at least one unpaired valence electron in their outer shell, making them highly reactive and short-lived [5]. Among all the ROS, superoxide anion ($\bullet O_2^-$), hydrogen peroxide (H_2O_2), and hydroxyl radicals ($\bullet OH$) are the most common examples. Reactive nitrogen species (RNS) are a subclass of ROS that contain nitrogen compound [30]. Examples of reactive nitrogen species are nitric oxide ($\bullet NO$), lipid peroxyl ($\bullet LOO^-$), and thiyl ($\bullet RS$) and peroxynitrite ($ONOO^-$). ROS/RNS are formed during

normal cellular and sperm mitochondrial metabolism and normal levels are essential to perform many physiological processes, including the activation of immune system [31]. They are also generated by sperm mitochondria during normal cellular respiration [32, 33] regulating different intercellular signaling pathways and facilitating normal maturation and fertilization in reproductive systems [16, 34–37].

7.2.2 Pathological ROS and Oxidative Stress

Contributing factors to OS include genito-urinary infections, varicocele, chronic inflammation (inflammatory bowel diseases) metabolic syndrome, cigarette smoking, alcohol abuse, recreational drug abuse, ionizing radiation, mobile phone use, psychological stress, strenuous exercise, spinal cord injury, and environmental pollution [3, 38–42]. Major exogenous sources include lifestyle factors: smoking, alcohol use, nutrition, obesity, stress, medication, environmental; pollutants, pesticides, xenoestrogens, cell phone radiation [27, 43–48]. Whereas primary contributors of endogenous ROS production include immature and morphologically abnormal spermatozoa with excess residual cytoplasm in the mid-piece of the flagellum [49] and infiltrating leukocytes (especially granulocytes) [4, 16, 50] (Fig. 7.1).

The number of leukocytes in seminal plasma increases with genital tract infection and/or inflammation (i.e., epididymitis, prostatitis). Peroxidase-positive leukocytes can produce approximately 1000 times more ROS than spermatozoa by enhancing nicotinamide-adenine dinucleotide phosphate (NADPH) production via the hexose monophosphate shunt [51]. These cells predominantly originate from the prostate and seminal vesicles [52]. A strong association is seen between the seminal ROS levels and presence of male accessory gland infections (MAGI), such as prostatitis, prostato-vesiculitis, and prostato-vesiculo-epididymitis [16].

7.2.3 Oxidative Stress and Male Infertility

High levels of ROS have shown a detrimental effect on parameters such as sperm concentration [53–58], motility [7, 56, 57], sperm morphology [7, 52, 55], as well as increased sperm DNA damage [53, 59], apoptosis [59, 60], and overall decrease in sperm function [6, 18]. Furthermore, oxidative stress disrupts the sperm membrane by altering its permeability, fluidity, and key functions. It also affects both natural and assisted reproduction outcomes, and low pregnancy rates have been reported in men with high ROS levels [61, 62].

Spermatozoa are prone to OS because their plasma membrane contains an unusually high percentage of polyunsaturated fatty acids (PUFAs), which are susceptible to lipid peroxidation [53]. Lipid peroxidation is characterized by the breakdown of PUFAs into lipid peroxides due to oxidative stress [63] as electrons from plasma membrane lipids are stripped away by ROS. This propagates a chain of redox reactions that eventually generates highly mutagenic and genotoxic electrophilic aldehydes such as malondialdehyde (MDA), 4-hydroxynenal (4-HNE), and acrolein [64]. Compared to free radicals, these aldehydic products are relatively stable and are able to move freely and react with molecules like DNA, proteins, and lipids.

Oxidative stress is responsible for single-strand breaks in DNA [52, 65]. Furthermore, apoptosis can also occur as a result of increased oxidative stress and can result in DNA fragmentation. Several studies show that infertile men have high number of single- or double-stranded sperm DNA fragmentation (SDF) [23, 66–71]. Several etiological factors have been implicated including cigarette smoking, irradiation, chemotherapy, leukocytospermia, varicocele, cancer, elevated levels of ROS, abnormalities during chromatin packaging, and advanced age that have demonstrated compromised sperm DNA quality [7, 18, 60, 65, 72–74]. Increased levels of ROS are associated with reduced fertility; impaired embryo development increased miscarriage or pregnancy loss [20–23, 75–80].

For these reasons, measuring the accurate levels of oxidative stress markers specifically ROS is important and can be offered as a diagnostic test or screening test for differentiating fertile population from infertile or men with unexplained/idiopathic infertility [81].

7.2.4 Types of Samples for Oxidative Stress Measurement

The types of semen samples that can be used to measure OS levels include unprocessed seminal ejaculates, simple wash and resuspend samples, and samples processed by swim-up or density gradient centrifugation [52]. An ejaculate comprises not only of spermatozoa but also of all other secretions from prostate and seminal vesicles and other accessory glands and cellular components such as round cells, leukocytes, and epithelial cells. Levels of ROS are reflective of the de novo status of the ROS in the sample. In a simple wash and resuspend sample, the seminal plasma is removed; however, the leukocytes, round cells, and debris remain in the sample. In samples prepared by swim-up the actively motile sperm are separated from the non-motile sperm and the debris, whereas in the density gradient separation, spermatozoa are separated on the basis of their densities and motility, which results in the separation of actively motile and morphologically normal sperm [52].

7.2.5 Markers of Oxidative Stress and their Assessment

Many individual markers have been used to reflect oxidative stress. The rationale for various laboratory techniques used to measure OS are a result of direct measurement of ROS or indirect measurements through oxidized products of ROS production. Direct laboratory techniques measure OS or free radicals such as ROS and reactive nitrogen species. Direct laboratory techniques include chemiluminescence, nitroblue tetrazolium (NBT), cytochrome C reduction test, fluorescein probe, electron spin. Indirect laboratory techniques measure lipid peroxidation, antioxidants, cofactors, or other end products secondary to ROS production. More specifically, indirect measurements could be an accumulative result of oxidized products resulting from sources of ROS such as the oxidized form of nicotinamide adenine dinucleotide (NADPH)-oxidase in the sperm, the reduced form of NAD (NADH)-dependent oxidoreductase in mitochondria, or leukocytospermia [82]. Indirect laboratory techniques include measurement of Endtz test, lipid peroxidation, chemokines, antioxidants/micronutrients/vitamins, ascorbate, total antioxidant capacity (TAC), or DNA damage (Table 7.1).

7.3 Common Methods to Measure Oxidative Stress

7.3.1 Nitroblue Tetrazolium Test

The nitroblue tetrazolium test, or the NBT test, is based on the detection of ROS produced by spermatozoa and leukocytes by using the compound nitroblue tetrazolium. NBT is a yellow water-soluble nitro-substituted aromatic tetrazolium compound that reacts with superoxide ions to form formazan derivative that can be monitored spectrophotometrically [83]. This test is based on the principle that when heterogeneous samples such as ejaculate are stained with NBT, it results in the formation of colored formazan due to reduction of NBT. This has been shown to correlate with impaired sperm function [83]. NBT is an electron acceptor that becomes reduced in the presence of free oxygen radicals to form a blue–black compound, formazan [84]. Spermatozoa containing formazan can be stained histochemically and scored under the microscope. Spermatozoa are scored as follows: formazan occupying 50% or less of the cytoplasm (+) and more than 50% of cytoplasm (++) [84]. Leukocytes are scored as: no detectable formazan (−), scattered or few formazan granules (+), intermediate density (++), and cells filled with formazan (+++). NBT reaction reflects the ROS generating activity in the cytoplasm of cells, and therefore it can help determine the cellular origin of ROS in semen [85]. The advantages of this method include that it is readily available, inexpensive, and has high sensitivity. It provides information about the differential contribution of leukocytes and abnormal spermatozoa in the production of ROS, i.e., the cellular origin of ROS in the sample [84]. The major limitation of this test is that presence of other cellular reductases may also reduce NBT. Furthermore, changes in the cellular content of various oxido-reductases may also alter the rates of NBT reduction [85, 86].

7.3.2 Chemiluminescence Assay

Chemiluminescence is one of the most commonly employed methods used to detect ROS in a semen sample [87–89]. The reaction causes emission of light, which is measured with a luminometer. The two major types of luminometer include the photon-counting luminometer and the direct current luminometer. The photon counting measures the individual photon, whereas the direct counting measures the current passing through a luminometer. These are measured as photons per minute or relative light units, respectively [7].

The basic principle of chemiluminescence is the measurement of emitted light due to a chemical reaction occurring between chemical reagents and the ROS generated. The following equation shows two reactants A and B in presence of an excited intermediate [◊] resulting in emission of light. The decay of this excited state [◊] to a lower energy level causes light emission.

$$[\mathbf{A}]+[\mathbf{B}]\rightarrow[\Diamond]\rightarrow[\text{Products}]+\text{light}$$

There are two major types of probes used in chemiluminescence which include luminol for global measurement of ROS and lucigenin for measurement of superoxide anion [82, 89, 90].

The reagents used for global measurement of ROS are the stock luminol probe (100 mM), the working luminol (5 mM), and the dimethylsulfoxide (DMSO) solution [81, 91]. The test is light sensitive and performed under subdued light. A luminometer is attached to a computer (Fig. 7.2). A total of 11 tubes are used including 3 blank tubes which contain only phosphate buffer saline (PBS), 3 negative controls which contain PBS + luminol (working solution), 2 tubes which have the patient sample and + luminol, and 3 positive controls which contain PBS + hydrogen peroxide (50 µL) + luminol (Fig. 7.3). The tubes are loaded into the luminometer (Berthold, Autolumat Plus LB 953), and a real-time plot of the ROS levels produced in each sample is visualized on the computer monitor and analyzed (Fig. 7.4) [91].

Table 7.1 Advantages and disadvantages of direct and indirect measurement of ROS in semen

Assays	Principle/Probe	Instrument	Type of sample	Advantages	Disadvantages
Direct methods					
Chemiluminescence	Luminol Lucigenin	Luminometer	Extracellular and intracellular Extracellular	1. Robust, high sensitivity, and specificity	1. Time-consuming, large and expensive equipment 2. Interfering variables 3. Requires high sample volume.
Nitro blue tetrazolium (NBT)	NBT reduced to formazan by superoxide ions	Spectrophotometer	Extracellular	1. Cost-effective, user friendly 2. Detect neutrophils at a concentration of 0.5×10^6/mL or higher	1. Subjective interpretation of a positive vs. negative neutrophils
Cytochrome C reduction test	Ferricytochrome C	Spectrophotometer	Extracellular	1. Quantify $O_2^{\bullet-}$ released during the respiratory burst of neutrophils or by isolated enzymes 2. Good for high level of ROS production	1. Relatively insensitive to detect NADPH oxidase activity, if enzymatic activity is low 2. Cannot detect intracellular $O_2^{\bullet-}$
Fluorescein probe	2′-7′-Dichlorodihydrofluorescein diacetate (DCFH-DA)	Flowcytometry	Spermatozoa		2′-7′-Dichlorodihydrofluorescein diacetate (DCFH-DA)
Oxidation induced fluorochrome probe	Dihydroethidium (DHE)	Confocal microscope	Spermatozoa		
Fluorescein isothiocyanate (FITC)-labeled lectins				1. Detect acrosome status	1. Difficult to distinguish true and false acrosomal reactions 2. Impossible to detect sperm viability and acrosomal status in one picture 3. Fluorescent signal fades in times
Electron spin resonance	Paramagnetic species	Electron spin resonance spectroscopy	Extracellular and intracellular	1. Broad usages such as observations of free radicals, analysis of free radical characteristics, quantitative analysis of free radicals, and kinetic analysis 2. Good for high level of ROS production	1. Limitation if a free radical reacts immediately with a molecule other than the spin-trapping agent 2. Inference factors such as possible neutralization

(continued)

Table 7.1 (continued)

Assays	Principle/Probe	Instrument	Type of sample	Advantages	Disadvantages
Indirect methods					
Myeloperoxidase or Endtz test	Peroxidase activity	Colorimeter	Spermatozoa	1. Clearly distinguishes WBCs especially ROS-producing granuloctyes from other immature germ cells in semen	1. Cannot be used to detect ROS generation by spermatozoa
Lipid peroxidation levels	Thiobarbituric acid-reactive substances	Colorimeter	Oxidized components in seminal plasma	1. Malondialdehyde is a colored substance that can be measured by fluorometry or spectrophotometry 2. Low sperm concentration of malondialdehyde can be measured through sensitive high-pressure liquid chromatography equipment or spectrofluorometric measurement of iron-based promoters	1. Not widely used in clinical practice at this time
Chemokines	Specific antibodies ELISA	ELISA reader	Seminal plasma	1. Produced as a result of ROS-induced inflammation	1. Requires a large amount of biological material (>0.5 L of culture supernatants).
Antioxidants, micronutrients, vitamins (vitamin E, vitamin C, ascorbate)	Column chromatography	HPLC	Seminal plasma	1. Cofactor of essential enzymatic reactions of ROS	1. Assess an end state occurring secondary to other unknown pathologic processes
Antioxidants- total antioxidant capacity (TAC)	2,2′ -azinodi-[3-ethylbenzthiazolinesulfonate] (ABTS)	Luminometer	Seminal plasma	1. Rapid colorimetric method 2. Total antioxidants in seminal plasma measured	1. Does not measure enzymatic antioxidants or individual antioxidants. 2. Requires expensive assay kit and microplate reader
DNA damage	TUNEL SCSA Comet SCD	Flow cytometer	Spermatozoa	1. Robust and sensitive method 2. Multiple methods are available to measure DNA fragmentation such as sperm chromatin structure assay (SCSA), sperm chromatin dispersion, TUNEL, comet, sperm chromatin dispersion assay, nuclear protein composition, sperm nuclear maturity test, and 8-OHdG.	1. Accessibility of the DNA (TUNEL) 2. Inter observer, intra observer + inter-assay and intra-assay variability. Lack of standardized reference (Comet, SCD).

Fig. 7.2 Autolumat 953 Plus Luminometer used in the measurement of ROS by chemiluminescence assay. Multiple tubes can be loaded simultaneously for measuring ROS. The luminometer can be connected with a computer and monitor. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2013–2019. All Rights Reserved)

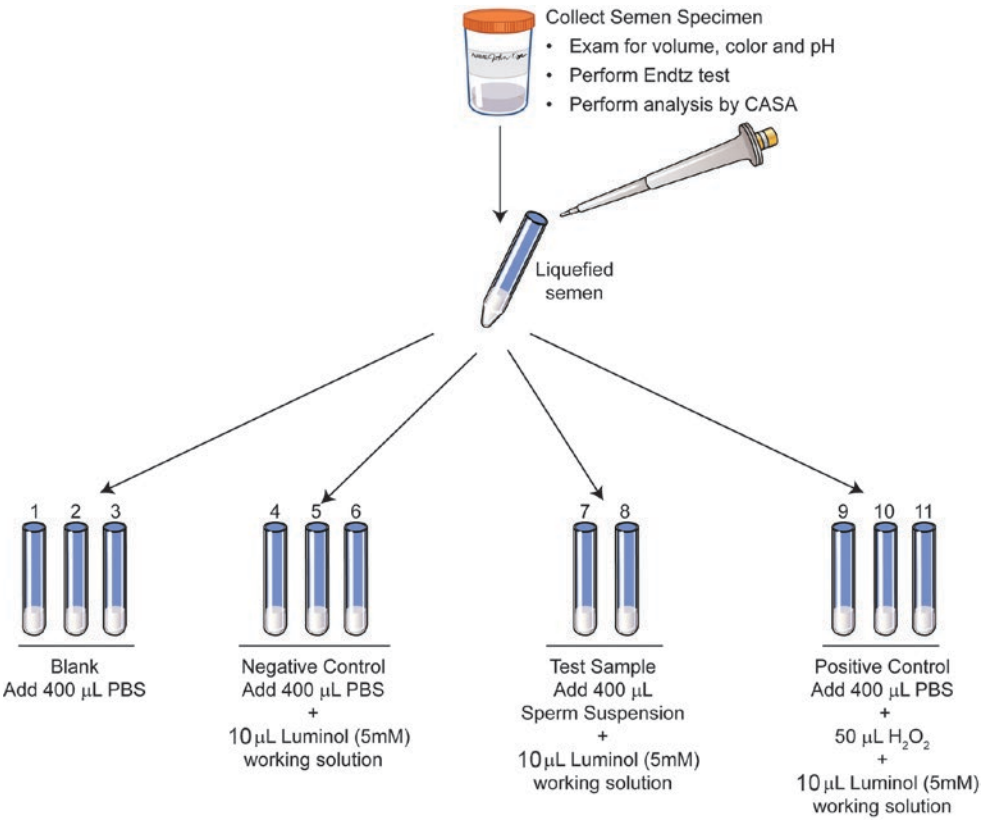

Fig. 7.3 Setup of the tubes for ROS measurement. A total of 11 tubes are labeled from S1-S11: Blank, negative control, test sample and positive control. Luminol is added to all tubes except the blank. Hydrogen peroxide is added only to the positive control. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2013–2019. All Rights Reserved)

7.3.3 Factors Affecting the ROS Measurement

Semen age, viscosity, repeated centrifugation, and the use of media containing albumin that can generate spurious signal spikes and sensitivity of luminol to pH changes are potential variables that influence ROS production. Other factors affecting ROS measurement are: (i) luminometer calibration; (ii) sensitivity and the dynamic range as well as the units used; (iii) concentration and the type of probe used; (iv) concentration and the volume of semen used; and (v) temperature of the instrument at the time of measurement.

This test effectively differentiates between fertile and infertile population using ROS cutoff values. ROS levels >102 RLU/sec/10^6 sperm are considered abnormal. At this cutoff, ROS sensitivity is 76.4%, specificity of 53.3% with a positive predictive value of 82.1% and a negative predictive

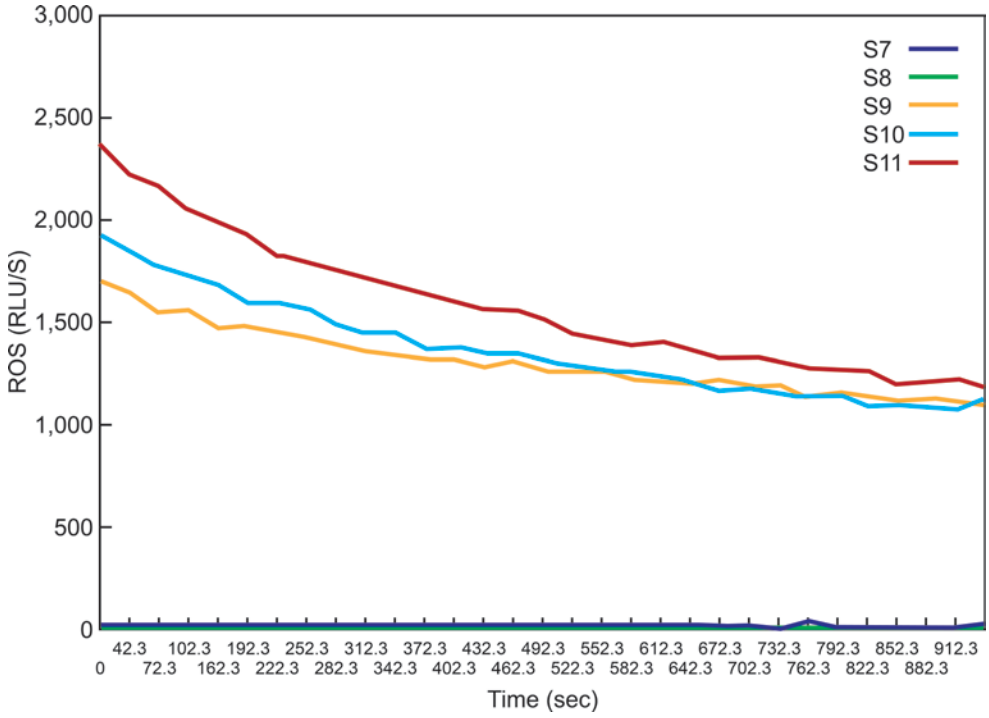

Fig. 7.4 A typical graph showing the ROS levels in the 11 tubes (S1–S11). As seen here, only the positive controls have significantly higher levels of ROS. Those producing low levels (Tubes S1–S8) of ROS are seen very close to the X axis. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2013–2019. All Rights Reserved)

value of 44.5% in differentiating infertile men from controls [81]. When the controls were strictly comprised of individuals who had established pregnancy, the cutoff was slightly lower at <93 RLU/sec/ × 10^6 sperm. The sensitivity increased to 93.8% indicating that the test can differentiate subjects that are fertile from those that are not. Levels of ROS >102 RLU/sec/ × 10^6 sperm must be considered pathological [7].

The major advantages of this approach include high specificity and sensitivity and its ability to measure global ROS, i.e., both intracellular as well as extracellular [81]. The major disadvantages are: (i) it cannot measure multiple markers simultaneously and (ii) highly time sensitive as the levels of ROS decline with the time after ejaculation due to short half-life of ROS.

7.3.4 Measurement of Intracellular ROS

Intracellular levels of ROS can be measured by flow cytometry using dihydrofluorescein diacetate (DCFH) to detect intracellular hydrogen peroxide radicals. This dye is oxidized to the highly fluorescent derivative dichlorofluorescein (DCF), which is detected by the use of a flow cytometer [11, 92, 93]. A counterstain dye for nucleic acid (propidium iodide) is used to exclude apoptotic spermatozoa [72]. Dihydroethidium (DE) can be used to detect intracellular levels of superoxide anions [11, 72, 92, 94]. The results are interpreted as percentage of fluorescent spermatozoa [72].

7.3.5 Measurement of DNA Fragmentation

Several tests have been introduced to measure the sperm DNA damage [7, 19, 20, 66, 95–103]. The methodological approaches by which sperm DNA damage is investigated in these tests are varied. Some tests measure abnormalities in sperm chromatin, whereas others measure direct DNA strand fragmentation. Among such tests, the most commonly used to measure DNA fragmentation are the sperm chromatin structure assay (SCSA) and terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL), comet, and sperm chromatin dispersion assay [71, 73, 97, 99, 104–106]. The advantages and disadvantages of various tests of sperm DNA fragmentation are described in Table 7.2, whereas individual test details are described below.

7.3.6 Sperm Chromatin Structure Assay (SCSA)

Sperm Chromatin Structure Assay (SCSA) detects damaged sperm DNA using flow cytometry of acridine orange stained sperm. It is based on the susceptibility of DNA breaks to acid denaturation [66, 107, 108]. Low pH treatment opens the DNA strands at the sites of breaks. Staining by acridine orange is highly precise, repeatable, and comparable between fresh and frozen samples. The DNA damage is induced by exposing it to denaturing conditions. This

Table 7.2 Tests for measurement of DNA fragmentation

Assay	Advantages	Disadvantages
SCSA		
For single- and double-stranded DNAs 1. Mild acid treatment denatures DNA with single-strand or double-strand breaks 2. Acridine orange binds to DNA double-stranded DNA (nondenatured) fluoresces green, single-stranded DNA (denatured) fluoresces red 3. Flow cytometry counts 10,000 cells. 4. DNA fragmentation index (DFI)—the percentage of sperm with a ratio of red to (red + green) fluorescence greater than the main cell population	1. Direct and objective 2. Established clinical thresholds 3. Many cells rapidly examined 4. High repeatability 5. Fresh or frozen samples 6. Most published studies and is reproducible	1. Proprietary method 2. Not available in commercial kits 3. Expensive equipment 4. Acid-induced denaturation 5. Small variations in lab conditions affect results 6. Calculations involve qualitative decisions 7. Very few labs conduct this assay
COMET		
For single- and double- stranded DNA 1. Electrophoresis of single sperm cells 2. DNA fragments form tail 3. Intact DNA stays in head *Alkaline COMET* 1. Alkaline conditions, denatures all DNA 2. Identifies both single- and double-strand breaks *Neutral COMET* 1. Does not denature DNA 2. Identifies double breaks	1. Indirect assay, subjective 2. Poor repeatability 3. High sensitivity 4. Fresh samples only 5. Correlates with seminal parameters 6. Small number of cells required 7. Versatile (alkaline or neutral)	1. Variable protocols 2. Unclear thresholds 3. Not available in commercial kits 4. Time- and labor-intensive 5. Small number of cells assayed 6. Subjective 7. Lacks correlation with fertility 8. Requires special imaging software
SCD test		
1. Individual cells immersed in agarose 2. Denatured with acid then lysed 3. Normal sperm produce halo	1. Easy 2. Can use bright-field microscopy	1. Thresholds for SCD are not clearly established for men with unexplained infertility 2. Low-density nucleoids are faint and produce less contrasting images 3. Few studies have shown correlation between sperm DNA damage and ART outcome 4. Cannot discriminate the type of DNA fragmentation or quantify the amount of DNA damage at the spermatozoa level
TUNEL		
1. Adds labeled nucleotides to free DNA ends 2. Individual template 3. Labels single- and double-strand breaks 4. Measures percent cells with labeled DNA	1. Direct objective 2. Performed on few sperm (10,000) 3. High repeatability 4. Objective, high sensitivity (flow cytometry) 5. Fresh or frozen samples 6. Indicative of apoptosis 7. Correlates with semen parameters 8. Associated with fertility 9. Available in commercial kits	1. Thresholds not standardized 2. Variable assay protocols 3. Not designed specifically for spermatozoa 4. Need for special equipment (flow cytometer) 5. Template independent 6. Requires proper controls

SCSA sperm chromatin structure assay, *TUNEL* terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL), *SCD* sperm chromatin dispersion

test utilizes the metachromatic properties of acridine orange to distinguish single-stranded/red fluorescence and double-stranded/native DNA/green fluorescence [66, 72, 103]. The results of this test are expressed as DNA fragmentation index (DFI) which is the ratio of percentage of sperms showing red fluorescence/total fluorescence (red + green) [11, 66]. The SCSA also measures sperm with high DNA stainability (%HDS) which is related to the nuclear histones retained in immature sperm and shown to be predictive of pregnancy failure [103]. The current clinical threshold is 25% DFI, which categorizes patients into a statistical probability of the following: (a) longer time to natural pregnancy, (b) low odds of IUI pregnancy, (c) more miscarriages, or (d) no pregnancy [103]. The test is precise and repeatable with an acceptable DNA fragmentation threshold which places a man at risk of infertility.

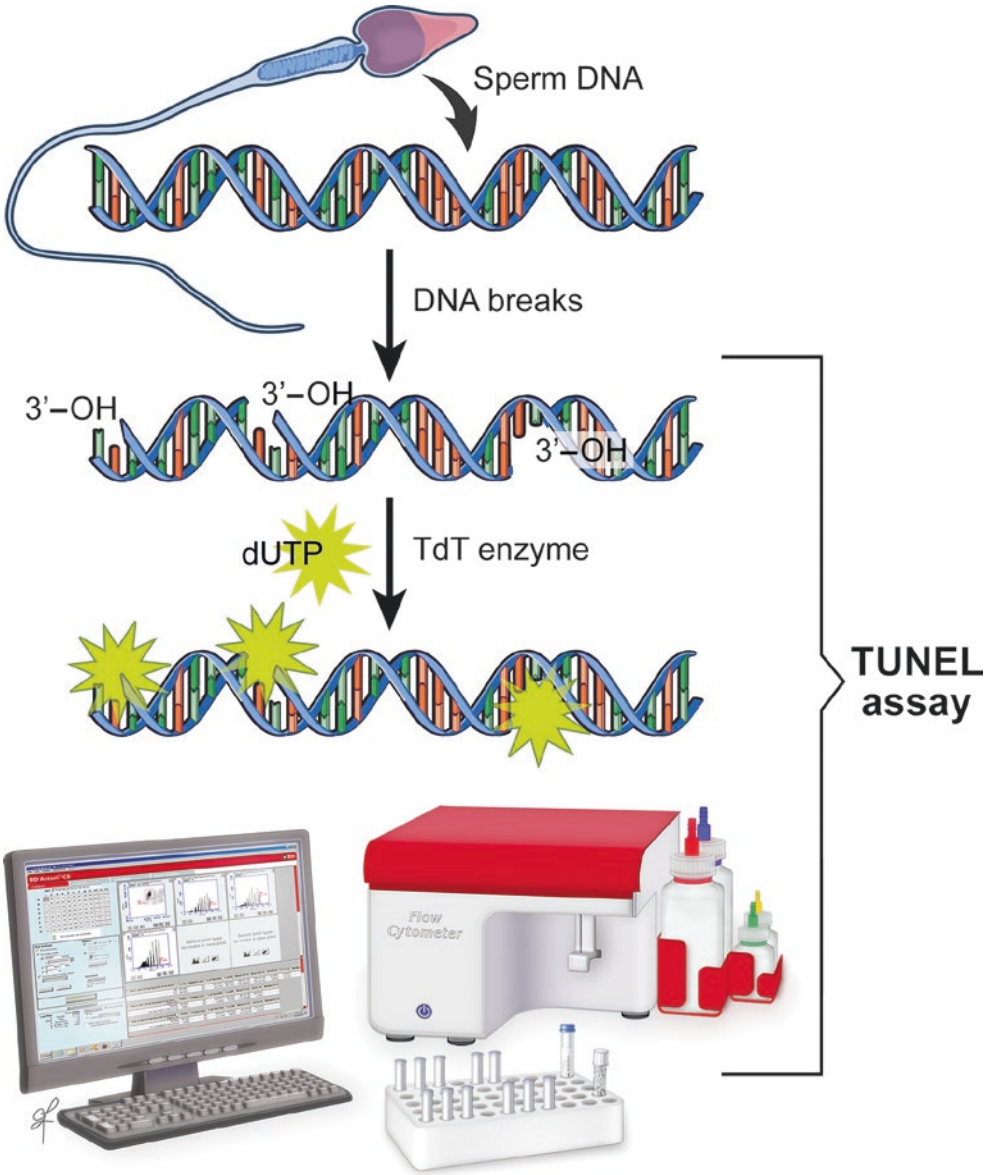

Fig. 7.5 Schematic of the DNA staining principal by the TUNEL assay. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2013–2019. All Rights Reserved)

7.3.7 Terminal Deoxynucleotidyl Transferees dUTP Nick End Labeling (TUNEL) Assay

The TUNEL assay utilizes a template-independent DNA polymerase called terminal deoxynucleotidyl transferase (TdT) that non-preferentially adds deoxyribonucleotides to 3′ hydroxyl (OH) single- and double-stranded DNA. Deoxyuridine triphosphate (dUTP) is the substrate that is added by the TdT enzyme to the free 3′-OH break-ends of DNA (Fig. 7.5) [23, 99, 109].

The more DNA strand breaks sites are present, the more labels are incorporated within a cell. This identifies the in situ DNA breaks. Here, the 3′ hydroxyl-free ends are labeled using a fluorescent label which on passing through a flow cytometer generates fluorescence, which is directly proportional to the number of strand breaks [99, 110]. DNA damage can be detected via TUNEL assay such as fluorescein isothiocyanate labeled dUTP system and Apoptosis detection kit. The reagents used in the assay are shown in Fig. 7.6. DNA fragmentation can be measured by a bench top flow cytometer. About 2.5 × 10^6 sperm are fixed and permeabilized with 3.57% paraformaldehyde. Staining is carried out for 1 h at 37 °C in the dark followed by rinsing and staining with propidium iodide. Both assay kit controls (positive and negative controls), as well as internal controls of known DNA fragmentation are included along with the test samples. TdT is omitted from the negative controls and positive controls are treated with hydrogen peroxide 2% at 50 °C for 1 h. According to the acquisition and alignment strategy, the percentage of DNA fragmentation in each sample is calculated.

Fig. 7.6 Staining reagents for the TUNEL staining using the Apodirect detection kit. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2013–2019. All Rights Reserved)

This test is highly sensitive and specific [99, 110]. It measures a definite end point and is considered to provide better prediction regarding the potential of embryo implantation [23, 70, 71, 79, 104, 111] .

Studies have reported DNA fragmentation measured by TUNEL assay to range from 12% to 36.5% at which no pregnancies were reported by microscopy and flow cytometry [99, 109, 112–118]. A cutoff value of 16.7% has been recently shown to have 91.6% specificity and positive predictive value of 91.4% [99]. The specificities can be further increased by including only men with established pregnancies as controls. The high specificity and positive predictive value is important particularly in cases of idiopathic and unexplained infertility.

7.3.8 Epifluorescence Using Acridine Orange Dye

Acridine orange is a nucleic-acid-specific, fluorescent, cationic dye. It interacts with DNA by intercalation and by electrostatic interaction with RNA or single-stranded DNA. Exposure to acid in a pre-incubation step denatures labile DNA sites with single- or double-stranded breaks, to which acridine orange intercalates leading to either red or green fluorescence, respectively, after excitation with ultraviolet light (Fig. 7.7). Sperm stained green indicate sperm with DNA fragmentation. This method is relatively rapid, simple, and inexpensive. The major disadvantage of this technique is the heterogeneous staining and color fading of the slides.

7.3.9 Comet Assay

The comet assay is a single gel electrophoresis method which measures the breaks in DNA [119]. Electrophoresis is used to mobilize DNA fragments that are produced from nucleoids after being depleted of proteins. The method is based on the general concept that DNA fragments resulting from preexisting DNA breaks have different mobility in the electrophoretic field depending on the relative size of the fragment. This generates morphological differences between nuclei containing fragmented DNA when examined under fluorescent microscopy. The resulting image represents a "comet" that consists of a head and a tail chromatin in the direction of the anode. The larger the size of the comet, the higher the level of DNA fragmentation [95, 119–122].

The assay can be performed in both neutral as well as alkaline environments. In neutral buffer, double-stranded DNA damage is measured, while in alkaline environment, DNA can be denatured; both single- (SS) and double-stranded (DS) DNA damage can be measured due to unwinding of the DNA strands [123, 124]. Under the influence of an electric field, broken DNA strands are separated (SS and DS) [122, 125–128]. Thus, sperm with more DNA breaks showing intense comet tails can be measured using the fluorescence microscope or cytometer [95, 124]. The comet's tail length and fluorescent intensity is directly proportional to the degree of DNA fragmentation [71, 122, 129].

7.3.10 Sperm Chromatin Dispersion (SCD) Assay

The sperm chromatin dispersion (SCD) assay uses the Halosperm kit to differentiate between non-fragmented from fragmented sperm DNA [95]. It is based on a controlled species-specific DNA denaturation to produce single-stranded DNA stretches from any DNA breaks, coupled with controlled DNA depletion [101, 130–133]. This test is usually used in laboratories without access to flow cytometry as it can be evaluated using bright field or fluorescence microscopy. The process involves (1) integration of sperm sample into an inert agarose microgel on pretreated slide, (2) controlled acid denaturation of DNA, and (3) controlled protein depletion.

Normal sperm produce halos of dispersed chromatin around a dense core. Contrary, fragmented DNA does not produce halos of dispersed chromatin [76, 132, 134]. The halos can further be classified according to their morphology, and the results can be expressed for each patient against the established cutoff criteria (Fig. 7.8). The results show a strong correlation when compared with indirect assessments of DNA damage such as the SCSA or the comet assay [95, 135].

7.4 Measurement of Total Antioxidant Capacity

The total antioxidant capacity (TAC) is a parameter that can be measured by evaluating the reducing ability of various antioxidants present in semen against an oxidative reagent, such as hydrogen peroxide, and measuring the effect on the substrate [136, 137]. Clear seminal plasma is used for the assay. The reaction can be measured with a spectrophotometer or colorimeter depending on the substrate. Most techniques employed to estimate TAC measure the low molecular weight, chain-breaking antioxidants and do not include the contribution of antioxidant enzymes (glutathione group of enzymes, catalase, and superoxide dismutase) and metal-binding proteins. TAC can be measured in two ways:

7.4.1 Colorimetric Analysis

The antioxidant assay is based on the principle that aqueous and lipid antioxidants in seminal plasma specimens inhibit the oxidation of the 2,20-Azino-di-[3-ethylbenzthiazoline sulphonate] (ABTS) to $ABTS^{+}$. Under the reaction conditions used, the antioxidants in seminal plasma cause suppression of the absorbance at 750 nm to a degree that is proportional to their concentration to produce a stable blue–green color [136–138]. The capacity of the antioxidants present in the sample to prevent ABTS oxidation is compared with that of standard Trolox (6-hydroxy-2, 5, 7, 8-tetramethylchroman-2-carboxylic acid), a water-soluble tocopherol analogue.

Ten microliters of metmyoglobin and 150 μL of chromogen are added to all standard/sample wells. The reaction is initiated by adding 40 μL of hydrogen peroxide as quickly as possible. The plate is incubated for 5 min at room temperature on a horizontal shaker and absorbance is monitored at 750 nm using a microplate reader. The total antioxidant concentration of each sample can be calculated using the equation obtained from the linear regression of the standard curve by substituting the average absorbance values for each sample into the equation:

$$\text{Antioxidant}\left(\mu M\right) = \frac{\text{Unknown average absorbance} - \text{Y-intercept} \times \text{dilution} \times 1000}{\text{Slope}}$$

Results are reported as micromoles of Trolox equivalent. A diagnostic cutoff value of 1947 mM Trolox in seminal plasma distinguishes infertile patients from healthy men with a sensitivity of 59.5% and specificity of 63.0% [138].

7.4.2 ROS-TAC Score

There is a novel parameter derived from the ROS concentration and seminal TAC values called ROS-TAC score. It is superior than the individual ROS and TAC alone as it is capable of discriminating fertile from infertile men [139]. ROS and TAC values from controls are used to create a scale of these two variables using controls as reference point [14, 140, 141]. Both values are normalized for distribution after converting ROS to the log of ROS +1. Both log ROS +1 and TAC are

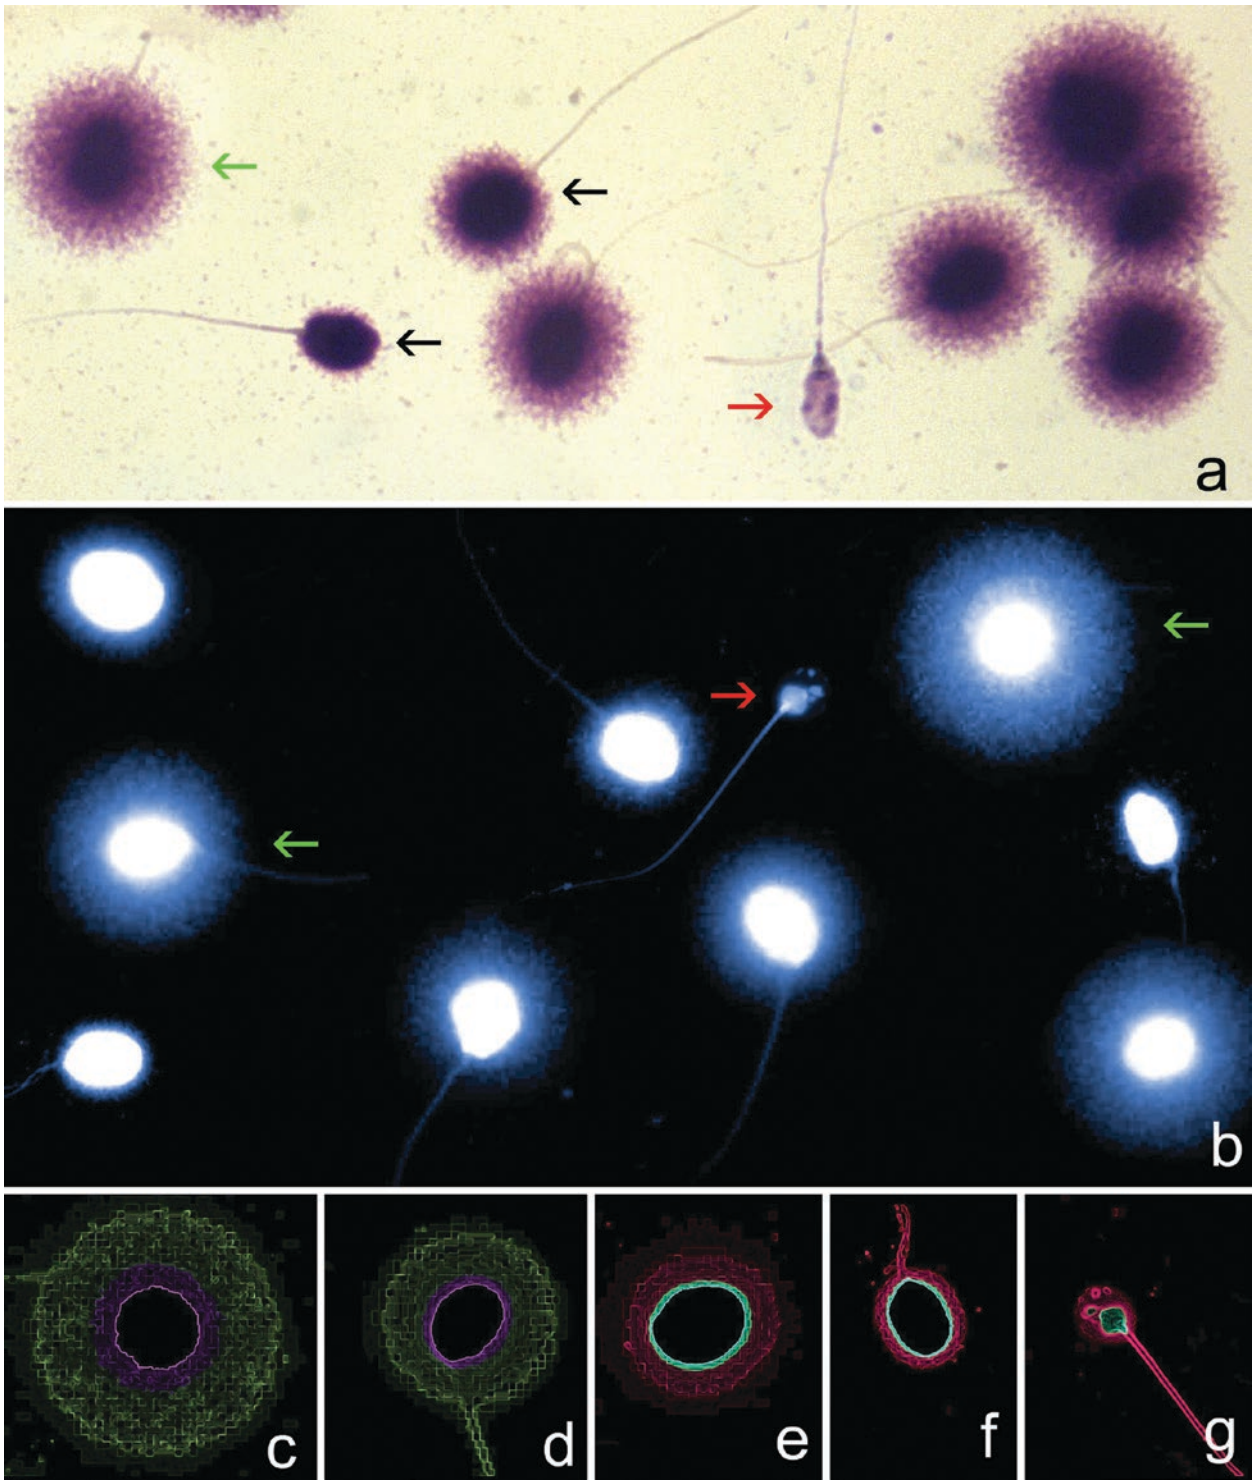

Fig. 7.8 Assessment of sperm DNA fragmentation using the sperm chromatin dispersion (SCD) test. Nucleoids from human spermatozoa obtained with the improved SCD procedure (Halosperm, Halotech DNA, SL, Madrid, Spain) under (**a**) bright field microscopy and Wright's stain (**b**) under fluorescence microscopy and DAPI staining. Green arrows target spermatozoa containing a normal DNA molecule. Red arrows target a highly fragmented spermatozoon (degraded sperm). (**c**–**g**) Electronic filtered images showing a series of nucleoids with different levels of sperm DNA damage. Nucleoids with highlighted core delineation in green correspond to (**c**) large (**d**) and medium halos of dispersed chromatin representing a normal DNA molecule. Nucleoids in red are spermatozoa containing fragmented DNA and are represented by (**e**) small or (**f**) no halos of dispersed chromatin and (**g**) degraded spermatozoa. Bright-field and fluorescence microphotographs were obtained using a motorized fluorescence microscope controlled with software for automatic scanning and image digitization (Leica Microsystems, Barcelona, Spain). The microscope was equipped with a Leica EL6000 metal halide fluorescence light source and Plan-Fluotar 60 × objectives with three independent filter blocks (DAPI-5060B; FITC- 3540B and TRITC-A; Semrock, Rechestern NY, United States). A charge coupled device (Leica DFC350 FX, Leica Microsystems, Barcelona, Spain) was used for image capture. (Courtesy of Prof. Jaime Gonsálvez, Madrid, Spain)

Table 7.3 Various techniques to measure lipid peroxidation

Technique	Principle	Advantage	Disadvantage
Thiobarbituric acid assay (TBARS)	MDA-TBA adduct detection by colorimetry or fluoroscopy	Simple but non-specific	Rigorous controls are required
Isoprostane	EIA/liquid chromatography-tandem mass spectrometry	Specificity, stable compound	Labor-intensive and high expense of equipment
HNE-his adduct ELISA	ELISA	Rapid, helps in quantification	Chances of cross reactivity

MDA malondialdehyde, *TBA* thiobarbituric acid, *HNE-His* hydroxynonenal histidine

standardized to Z scores (mean = 0, SD = 1) so that both will have the same variability. Standardized scores are calculated by subtracting the mean value of the controls from the individuals observed values and dividing by the standard deviation of the control population. The standardized values of ROS and TAC are analyzed with principal component analysis, which provides linear combinations or weighted sums that account for most variability among correlated variables [14]. Infertile men with male factor or idiopathic diagnoses were reported to show low ROS-TAC scores. Infertile men with higher ROS-TAC scores were able to initiate pregnancies compared to those who had low scores and had failed pregnancy [14].

7.5 Measurement of Lipid Peroxidation

Measurement of the end products of lipid peroxidation is a widely accepted marker of oxidative stress. Some of the common methods to measure lipid peroxidation are described below:

7.5.1 TBARS Assay

Malondialdehyde (MDA) is a reactive compound formed as one end product of lipid peroxidation [142]. The thiobarbituric acid (TBA) assay is one of the commonly used tests to assess MDA concentrations. The assay detects TBA-reactive substances (TBARS) via spectrophotometry, high performance liquid chromatography (HPLC), colorimetry, or spectrofluorescence [143]. In this reaction, which is carried out in acidic conditions and under a high temperature (90–100 °C), MDA and TBA react together to form an MDA–TBA adduct. This adduct formation is measured colorimetrically at 530–540 nm or fluorometrically at an excitation wavelength of 530 nm and an emission wavelength of 550 nm [144]. Lipid peroxidation in sperm is expressed as nmol MDA 10^{-7} sperm [145].

7.5.2 4-Hydroxynonenal-Histidine Adduct ELISA Assay

The 4-Hydroxynonenal-Histidine (HNE-his) adduct ELISA assay is a method to detect HNE bound to proteins using ELISA assay. This immunoassay has been developed for quantification and rapid detection of HNE-His protein adducts. 4-HNE can react with lysine, histidine, or cysteine residues in protein to form adducts. A 96-well ELISA titer plate is taken and protein samples (10 μg/mL) or BSA standards 0-200 μg/mL are adsorbed onto it. The HNE-protein adducts present in the standard or sample are probed with a primary antibody (anti-HNE-His antibody). This is followed by addition of a HRP-conjugated secondary antibody. Standard curves prepared from predetermined HNE-BSA standards are used to compare and quantify the HNE-protein adduct content in an unknown sample. Using a primary wavelength of 450 nm, the absorbance of each well is read on a microplate reader. Results are expressed as pmol/mg [146].

7.5.3 Isprostane (IsoP) Method

Another important biomarker of lipid peroxidation is 8-isoprostane (IsoP) measured as ng/mL [147]. It is a specific end product belonging to the family of eicosanoids derived from nonenzymatic peroxidation of polyunsaturated fatty acids [37]. The advantages of using the IsoP marker include the fact that it is not produced by enzymatic pathways like cyclooxygenase and lipoxygenase pathways of arachidonic acid, its stability and ease of quantification in seminal plasma [147]. The advantages and disadvantages of various lipid peroxidation methods are shown in Table 7.3.

7.6 Measurement of ROS-Induced Post-translational Modifications

Reactive oxygen species can modify proteins resulting in altered functions such as activation or inhibition of transcription factors, signal transducers, and enzymes [148, 149]. These result in alterations in structural and functional integrity of specific proteins. Most of the oxidants will react with several amino acids to yield multiple products. Three principal type of post-translational modification of proteins are induced by ROS and consist of S-glutathionylation (GSS-R), carbonylation, and nitrotyrosine modifications (Nitro-Y). Carbonylation, nitration, and thionylation of proteins are

regarded as the most common post-translational modifications leading to dysfunction of proteins [149–151].

Reactive carbonyls are produced by direct protein oxidation (oxidation on Trp, Lys, Arg, Pro, and Thr) with low- or high-molecular weight dicarbonyls (modifications of Lys, Arg, and Cys) generated during lipid peroxidation and glycoxidation, and oxidative degradation of Amadori products. Products of oxidation such as protein carbonyls are useful for detection and in estimation of ROS levels in a semen sample [150]. Protein carbonyls are chemically stable, more reliable, and a frequently used marker for protein oxidation [150, 152].

ELISA can measure both, nitrosylation and carbonylation. For detection or quantification of carbonyl modification of spermatozoa proteins, BSA standards or protein samples (10 µg/mL) are adsorbed onto a 96-well plate for 2 h at 37 °C. The protein carbonyls present in the sample or standard are derivatized to DNP hydrazone and probed with an anti-DNP antibody, followed by an HRP-conjugated secondary antibody. The protein carbonyl content in an unknown sample is determined by comparing with a standard curve prepared from a predetermined reduced and oxidized BSA standard.

Nitrotyrosine is formed by the reaction of peroxynitrite or donors of NO• with tyrosine residues. It can be produced by sperm cell by reaction of superoxide with NO•. The nitrotyrosine protein modification can result in alteration of protein function or structure. Higher amounts of nitrotyrosine were found in patients with impaired motility (asthenozoospermia) or spermatic cord blood in varicocele patients [150–155].

A competitive ELISA kit can be used for nitrotyrosine quantitation. In this assay, the unknown protein nitrotyrosine sample or nitrated BSA standards is first added to a nitrated BSA pre-absorbed EIA plate. After a brief incubation, an anti-nitrotyrosine antibody is added, followed by an HRP-conjugated secondary antibody. The protein nitrotyrosine content in an unknown sample is determined by comparing it with a standard curve prepared from predetermined nitrated BSA standard.

7.7 Measurement of ROS-Induced Protein Alterations: Proteomic Analysis

Proteomics and bioinformatics tools can be utilized to understand alterations in proteins as a result of exposure of spermatozoa to reactive oxygen species or oxidative stress. It also helps in demonstrating how post-translational modifications such as phosphorylation, proteolytic cleavages, glycosylation, and mutations can bring about changes in the physiological functions of spermatozoa. Global change occurs in the proteomic profiles of human spermatozoa and seminal plasma under oxidative stress conditions [12, 156, 157].

Differential regulation of protein expression in infertile patients has been reported with variations in ROS level as evidenced by global proteomic profiling [12]. Both, spermatozoa and seminal plasma proteome influence fertilization and implantation in infertile men with various levels of ROS or oxidative stress [12, 156–158]. Most commonly employed techniques to understand sperm-specific proteins include 2D polyacrylamide gel electrophoresis (2D-PAGE), differential in-gel electrophoresis (DIGE), and liquid chromatography-mass spectrometry, or LC-MS/MS. Global proteomic analysis involves analysis of pooled or individual test samples (either spermatozoa or seminal plasma from semen samples of infertile men exhibiting oxidative stress). Seminal proteome, proteins involved in biomolecule metabolism, protein folding and protein degradation are differentially modulated in infertile patients exposed to low, medium, and high ROS [12]. Similarly, in the seminal plasma proteome, pathways involved in post-translational modification of proteins, protein-folding (heat shock proteins, molecular chaperones), and developmental disorder are overexpressed in the high ROS group compared with fertile control group [155, 158].

7.8 Limitations of Current Oxidative Stress Markers

All markers of oxidative stress such as measurement of ROS by chemiluminescence assay [81, 87, 159], antioxidants by colorimetric assay, [11, 136, 160–162], lipids by measuring oxidized products by thiobarbituric acid assay or 4-hydroxynonenal (4-HNE) [144, 146], apoptotic markers such as annexin V [163, 164], DNA fragmentation by TUNEL, SCSA, comet or SCD, and oxidatively modified protein alterations using proteomic tools [12, 81, 158] described above are individual methods. Each method captures only a single dimension of oxidative stress from which the overall oxidative stress status in a given biological system is generalized. Therefore, these methods fail to provide a complete picture of the true oxidative stress status environment. They only reflect the redox status at a single point. Furthermore, these methods are antiquated, time-consuming, and time-sensitive, requiring large financial investments such as measurement of ROS by chemiluminescence or proteomics. It is therefore important to identify a test that includes all constituents of OS and helps in our understanding of the real-time redox status in a given semen sample and thereby improve the management of these patients. This is accomplished by the redox potential marker called oxidation reduction potential described below.

7.9 What Is Oxidation Reduction Potential?

Measuring oxidation reduction potential (ORP), or redox potential, is the latest addition in the attempt to identify a single direct marker of oxidative stress that has diagnostic value especially in male infertility. ORP, also known as redox balance, provides the relative proportion of oxidants (ROS) and reductants (antioxidants) that are present in a given biological system at any given time. It is a measure of the potential of electrons to move from one chemical species to another. In an attempt to quench the damaging effects of oxidants, antioxidants donate electrons thereby reducing the chances of oxidants to acquire electrons from adjoining cells and cause damage. This test was initially used to measure ORP in water treatment industry to determine if the oxidant activity was sufficiently high to kill bacteria and other microbes [165]. Later, it was used to measure ORP in biological fluids, such as blood plasma of patients with brain injury, trauma, and stroke [166–170]. ORP testing was introduced in the andrology setting as a reliable marker of OS in the human semen in 2016 [171, 172].

7.9.1 Measurement of Oxidation Reduction Potential Using MiOXSYS

The development of the *M*ale *i*nfertility *Ox*idative Stress *Sys*tem, or MiOXSYS, system and the measurement of ORP in semen samples represents an invaluable clinical tool that obviates the need for complicated oxidative stress assays. The MiOXSYS system is an instrument that overcomes the negative aspects of other more complicated and expensive methods to evaluate oxidative stress in semen samples.

ORP in human semen samples can be measured in real time by using the MiOXSYS system, a galvanostat-based technology [173]. The MiOXSYS system is designed to capture the transfer of electrons from reductants to oxidants in the sample and is based on the Nernst equation [174].

$$\mathrm{ORP} = \mathrm{E}^{\circ} - RT / nF \ \ln\left(\left[\mathrm{Red}\right] / \left[\mathrm{Ox}\right]\right)$$

where

E° = standard reduction potential
R = universal gas constant
T = absolute temperature
N = number of moles of electrons exchanged
F = Faradays constant
Red = concentration of reduced species
Ox = concentration of oxidized species

The MiOXSYS system is comprised of the MiOXSYS analyzer and the MiOXSYS sensor (Fig. 7.9a, b). The analyzer uses a constant negligible current and measures the passive exchange of electrons between the oxidants and reductants. This is also called the static or passive or current state of activity between the oxidants and antioxidants. Static ORP (hereafter referred as ORP) represents the actual redox balance in a given sample and is expressed as milliVolts (mV). A higher ORP is indicative of higher oxidative stress reflecting the imbalance in the redox system in favor of the oxidant activity. Monitoring ORP levels in semen may therefore help predict treatment efficacy in such patients. Higher ORP levels are indicative of the progression of infertility.

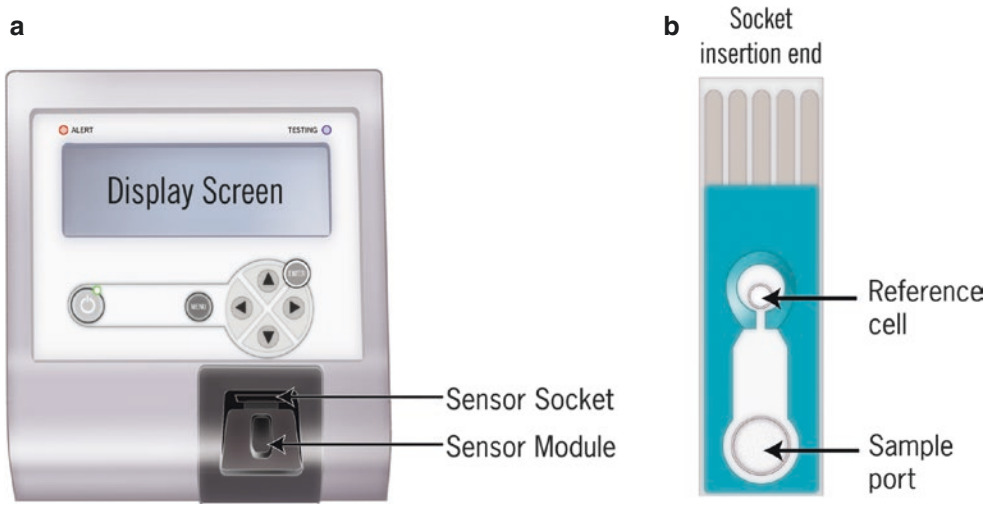

Fig. 7.9 Oxidation reduction potential can be measured by the MiOXSYS system comprised of (**a**) MiOXSYS Analyzer and (**b**) MiOXSYS Sensor. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2013–2019. All Rights Reserved)

7.9.2 Protocol to Measure Oxidation Reduction Potential

To measure ORP in a given semen samples, a MiOXSYS sensor is placed on the MiOXSYS port with the sensor electrodes facing the analyzer (Fig. 7.10). Using a pipette, a small volume (~30 μL) of liquefied neat semen sample is added on the pre-inserted sensor (Figs. 7.11 and 7.12a–c). The results are normalized to express ORP in the sperm by dividing the ORP with the sperm concentration and expressed as milliVolts (mV)/10^6 sperm/mL ORP provides redox balance in real time, is less time consuming, is independent of sperm concentration, and requires less expertise than other laborious methods such as ROS [171, 172]. ORP has demonstrated excellent intra- and inter-observer reliability indicating that the measurements are highly reproducible and samples need not be tested in duplicate or triplicate [175].

7.9.3 Value of ORP in Fresh and Frozen Semen Samples and Seminal Plasma

The MiOXSYS system can measure ORP levels in semen and seminal plasma both in fresh and frozen samples [172, 176] and also not affected by the age of the semen [172]. Semen ORP levels were also correlated with those in the seminal plasma both at time 0 and at time 120 min. ORP levels in semen and seminal plasma showed strong negative correlation with semen parameters, especially concentration. Similar negative correlation was seen between ORP and sperm parameters at time 0 and 120 min. The fact that ORP levels in semen samples were stable and not affected by time up to 2 h makes the ORP technology easy to employ in a clinical setting [172]. ORP measurement can also be made in fresh and frozen semen samples [172].

7.9.4 Assessment of Semen Quality and Fertility Status Using Oxidation Reduction Potential

ORP levels measured in semen from male partners of infertile couples suggest that ORP levels are significantly lower in infertile men that have normal individual semen parameters [177].

Agarwal et al. examined 106 infertile and 51 healthy men who were categorized into normal and abnormal based on the semen parameters according to the 2010 WHO guidelines [178, 179]. A strong negative correlation was seen between ORP and semen parameters both in controls and patients combined especially sperm concentration ($r = -0.823$; $P < 0.001$); total sperm count ($r = -0.728$; $P < 0.001$); and motility ($r = -0.048$; $P < 0.001$) as well as between ORP and controls only for sperm concentration ($r = -0.688$; $P < 0.001$); total sperm count ($r = -0.540$, $P < 0.001$); and motility ($r = -0.255$; $P < 0.001$). Higher ORP levels were seen in patient group and they were inversely correlated with sperm concentration ($r = -0.846$; $P < 0.001$); total sperm count ($r = -0.765$; $P < 0.001$) motility ($r = -0.445$; $P < 0.001$); and morphology ($r = -0.226$; $P < 0.020$) [175].

In a study comprising of 293 infertile men and 15 fertile men, ORP was highly significantly ($P < 0.0001$) and negatively correlated with sperm concentration ($r = -0.840$); motility ($r = -0.429$); and weakly correlated with morphology ($r = -0.288$) [176]. Arafa et al. [180] examined 365 infertile men and 50 fertile men for semen parameters and ORP levels. These authors reported significantly higher ORP levels in infertile men with abnormal semen parameters (total sperm count, motility/morphology) compared with those of normal semen parameters. Furthermore, infertile men had higher ORP values (Mean ± SE; 5.00 ± 0.56 mV/10^6 sperm/mL) compared to fertile donors (1.26 ± 0.15) ($P < 0.001$). ORP was negatively correlated with sperm concentration ($r = -0.909$; $P < 0.001$); total sperm count ($r = -0.799$; $P < 0.001$); and motility ($r = -0.554$; $P < 0.001$) [180].

Furthermore, Agarwal and Wang examined 194 infertile men, including 28 who underwent repeated semen analysis and ORP measurement; they reported that patients with oligozoospermia appeared to have the highest ORP levels compared to those with asthenozoospermia or teratozoospermia [177]. These authors also reported that infertile men ($n = 42$) who had normal semen parameters had significantly lower ORP values [0.74 (0.41, 1.3)] compared to 152 infertile men who exhibited at least abnormal semen parameter [3.76 (1.19, 16.4); $P < 0.001$] [177]. Patients who had significantly poorer sperm parameters and higher ORP levels on the first evaluation showed significant improvement in sperm concentration and motility with a concomitant decrease in ORP after a repeat semen test was done 16.8 ± 7.7 weeks later [177].

In a recent study, Majzoub et al. examined semen parameters and ORP levels in 1168 infertile men and 100 fertile men [181]. They reported significantly poor sperm parameters in infertile men including count ($P < 0.001$); total motility ($P < 0.001$); total morphology ($P < 0.001$) compared to fertile men. Furthermore, the ORP levels were significantly higher in infertile men [mean ± standard error, (5.44 ± 0.34) compared with fertile men (1.18 ± 0.94) ($P < 0.001$). Similarly, when various cutoff values for normal morphology (0% to >4%) were examined, ORP levels were highest (13.12 ± 1.84 mV/10^6 sperm/mL) in samples with 0% normal morphology compared to those with >4% normal morphology (1.99 ± 0.26 mV/10^6 sperm/mL) [181].

7.9.5 Oxidative Reduction Potential: Establishing Reference Values

Higher ORP values indicate a higher state of oxidative stress. Data from ORP studies conducted in healthy men and in infertile men [172, 177] reinforce the impression that oxidative stress is related to poor semen quality [7, 13, 54, 61, 141, 182, 183].

In the study reporting the reference values of ORP for the first time in semen and seminal plasma [172], a cutoff of 1.48 mV/10^6 sperm/mL and 2.09 mV/10^6 sperm/mL in seminal plasma was reported (Fig. 7.13a, b). At these cutoffs, ORP was also able to distinguish semen quality based on good (≥40%) and poor (≤40%) motility in semen and seminal plasma (Fig. 7.13c, d).

In a later study comprising of 106 infertile men and 51 healthy men with normal semen parameters, a cutoff of 1.36 mV/10^6 sperm/mL was able to distinguish normal

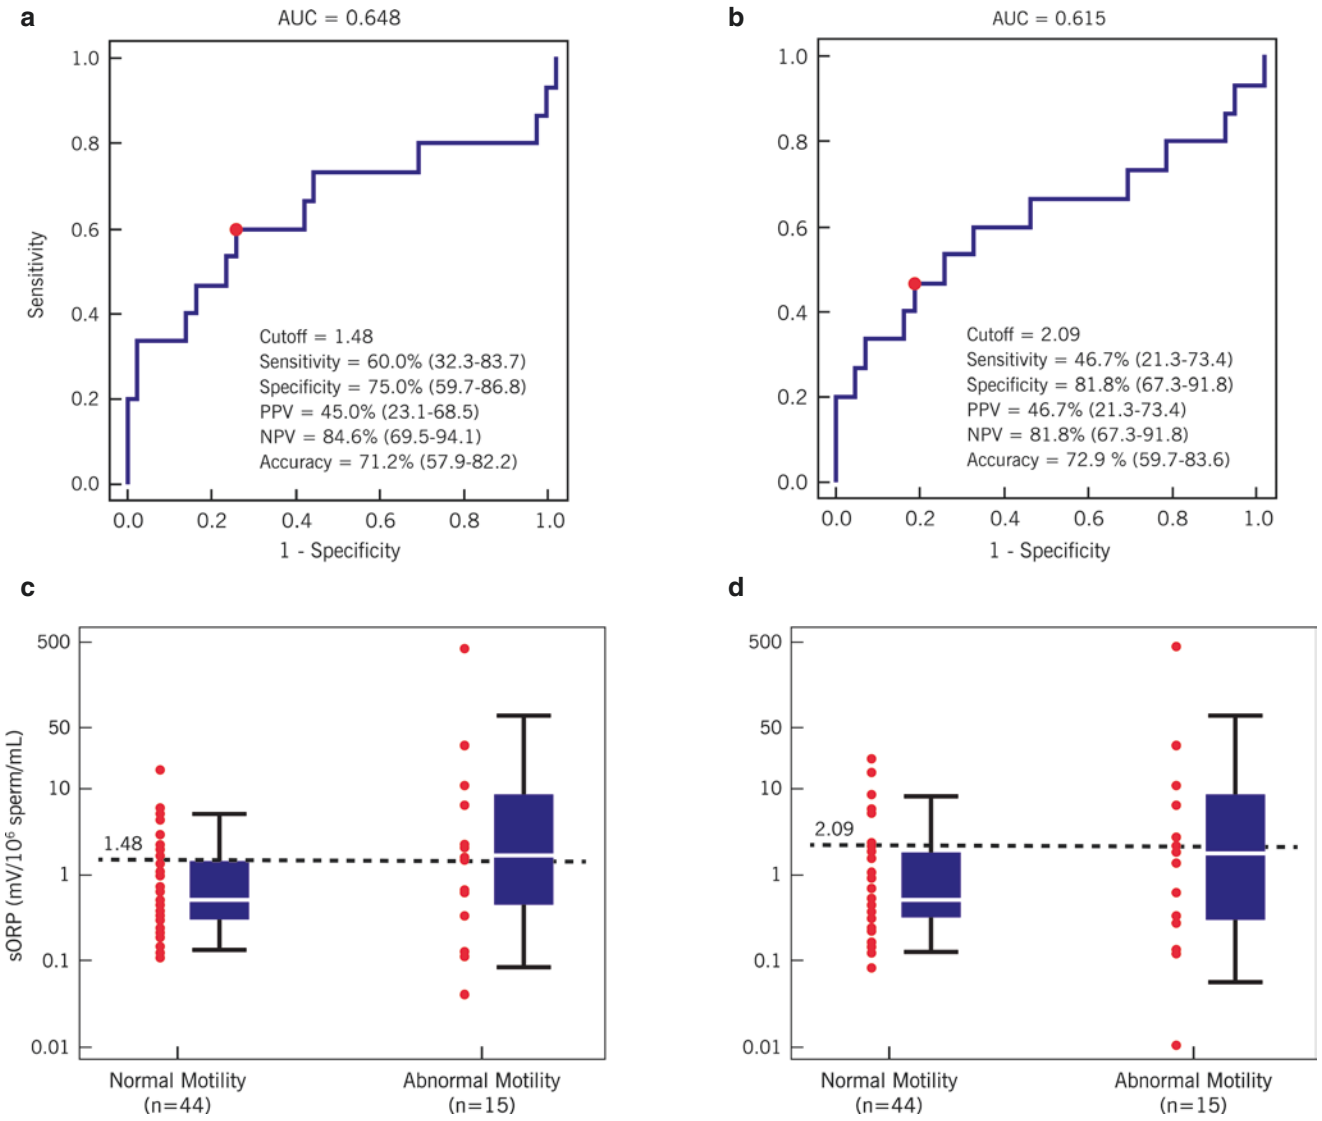

Fig. 7.13 ROC curve showing ORP cutoff in (**a**) semen and (**b**) seminal plasma. Distribution of ORP in subjects with normal and abnormal motility based on good (≥40%) and poor motility (≤40%) motility in (**c**) semen and (**d**) seminal plasma. healthy men from infertile men with a sensitivity of 69.6% and specificity of 83.1% (Fig. 7.14) [175].

In a study by Agarwal et al. [176], ORP was measured in 293 patients and 15 controls and categorized according to WHO criteria as normo-, oligo-, astheno-, terato-, and oligoasthenoteratozoospermic. When subjects were grouped based on concentration, motility, morphology, or a combination of these, the area under curve for ROC curve, sensitivity and specificity, positive predictive value, and ORP cutoffs were significantly different. The ROC curves generated were able to differentiate between fertile controls and infertile men and other categories. The ORP cutoffs were also able to differentiate between subjects and any two semen parameters between various categories (Fig. 7.15).

In another study by [177], ORP at a cutoff of 1.57 (mV/10^6 sperm) was able to detect at least 1 abnormal sperm parameter with a sensitivity of 70.4% and specificity of 88.1% (Fig. 7.16a, b). Similarly, ORP at a cutoff of 2.59 (mV/10^6 sperm) had the highest predictive values in detecting oligozoospermia with 88% sensitivity and 91.2% specificity [177]. In another study by Majzoub et al. [181], comprising of 1168 infertile men and 100 men with confirmed fertility, using a cutoff of 4% normal morphology to determine the presence of teratozoospermia, Majzoub et al. showed that ORP cutoff of 1.73 mV/10^6 sperm/ mL had a sensitivity of 76%, specificity 72%, positive predictive value of 69.32%, and a negative predictive value of 78.6% with an accuracy of 73.9% [181].

Arafa et al. [184] reported a cutoff of 1.38 mV/10^6 sperm/mL; sensitivity of 63.3%, specificity 87.8%, PPV 97.6% and NPV 23.2%, and accuracy of 66%. This cutoff was able to distinguish and identify semen samples with abnormal quality such as sperm motility, various morphological abnormalities, ORP, and sperm DNA fragmentation. The odds ratio that a semen sample with a sORP value greater than 1.38 mV/10^6/ml was abnormal in quality was 10.05 ($P < 0.001$) [184].

7.9.6 Update on Research on Oxidative Reduction Potential: Multicenter Findings

In a multicenter study [175] conducted in Cleveland Clinic, the United States, and the other in Doha, Qatar, semen analysis and ORP measurements were compared between the two laboratories. The U.S. dataset comprised of 194 patients and 51 fertile donors, while the Qatar dataset comprised of 400 patients and 50 fertile donors. In both individual datasets and combined datasets, infertile men had significantly lower sperm concentration, total and progressive motility and morphology. Furthermore, ORP levels were higher when compared to the fertile men ($P < 0.05$). The dataset from the United States identified ORP cutoff of 2.26 mV/10^6 sperm/mL and 1.42 mV/10^6 sperm/mL for the Doha data. The combined dataset showed a cutoff of 1.42 mV/10^6 sperm/mL in distinguishing infertile patients from healthy controls (Fig. 7.17a–c). The overall ROC characteristics with cutoff, sensitivity, specificity, area under curve, accuracy, positive predictive value, negative predictive value examined for all studies published on ORP is shown in Table 7.4. The findings show that although semen parameters showed significant differences between the two centers, ORP levels were consistent in both datasets individually or combined showing reproducibility and reliability of ORP [175].

7.9.7 Clinical Utility of Oxidation Reduction Potential in Male Infertility

Application of ORP measurement in clinical practice can benefit infertile men with varicocele, infection, inflammation, spinal cord injury, and severe oligozoospermia [178, 180, 181]. The ability to measure ORP in cryopreserved semen samples as a single marker for oxidants and the available antioxidant reserves is important as it can help in predicting the success of assisted reproductive techniques [185]. Combining sperm parameters with advanced tests, such as DNA fragmentation, can help recognize sperm with greater reproductive potential despite having abnormal morphology [181, 186]. This can further provide knowledge for developing novel sperm selection techniques that can be used during ART. ORP can also be used as a screening tool to identify patients who are more likely to benefit from various sophisticated tests and treatment [172, 181, 187].

7.9.8 Oxidation Reduction Potential: A Test Replacement or a Test in Conjunction with Semen Analysis?

All reported studies demonstrate that individual semen parameters are poor predictors of sperm infertility [188, 189]. It would be useful to use ORP in conjunction with sperm parameters to support the interpretation of standard semen analysis rather than as an independent marker. A significant overlap was reported in individual sperm parameters in infertile and fertile men [3]. Assessment of progressive motility is subjective, and its reliability as a fertility marker is questionable and both total and progressive motility were lower in proven fertile donors [190], suggesting a more complex relationship between motility and infertility.

ORP is a measure of oxidative stress, and oxidative stress affects sperm numbers, motility, and morphology [7, 54, 183, 191]; ORP is not influenced by semen age or BMI [184]. Changes in ORP reflect site-specific changes in oxidative stress as the testis is an immune privileged site [183, 192]. Therefore, elevation in oxidative stress at the site of spermatogenesis and maturation is more likely to translate into changes in semen and sperm quality. These changes may not be reflected in systemic alterations. Therefore, by focusing on the ability to measure small site-specific alterations in semen, ORP can help focus on the relationship between oxidative stress, semen quality, and male infertility.

7.9.9 Clinical Relevance of Combination of OS Markers and Other Sperm Function Tests

We have highlighted several recent studies that have measured ORP in relevance to sperm functional parameters. The findings point out the relationship between oxidative stress and semen parameters, specifically sperm count, motility, and morphology. Using receiver-operating characteristic curves, various ORP cutoffs have been reported that can help distinguish infertile from healthy men. Negative association of ORP with SDF has also been reported in high SDF groups (4.03 ± 0.61 mV/10^6 sperm/mL) versus low SDF groups (2.14 ± 0.14 mV/10^6 sperm/mL, respectively, $p < 0.001$) [180, 184]. A five-fold higher ORP was seen in the semen of infertile men when compared with the fertile controls ($P < 0.0001$). Head defects were significantly higher amongst infertile patients (54%) than fertile controls (48%)

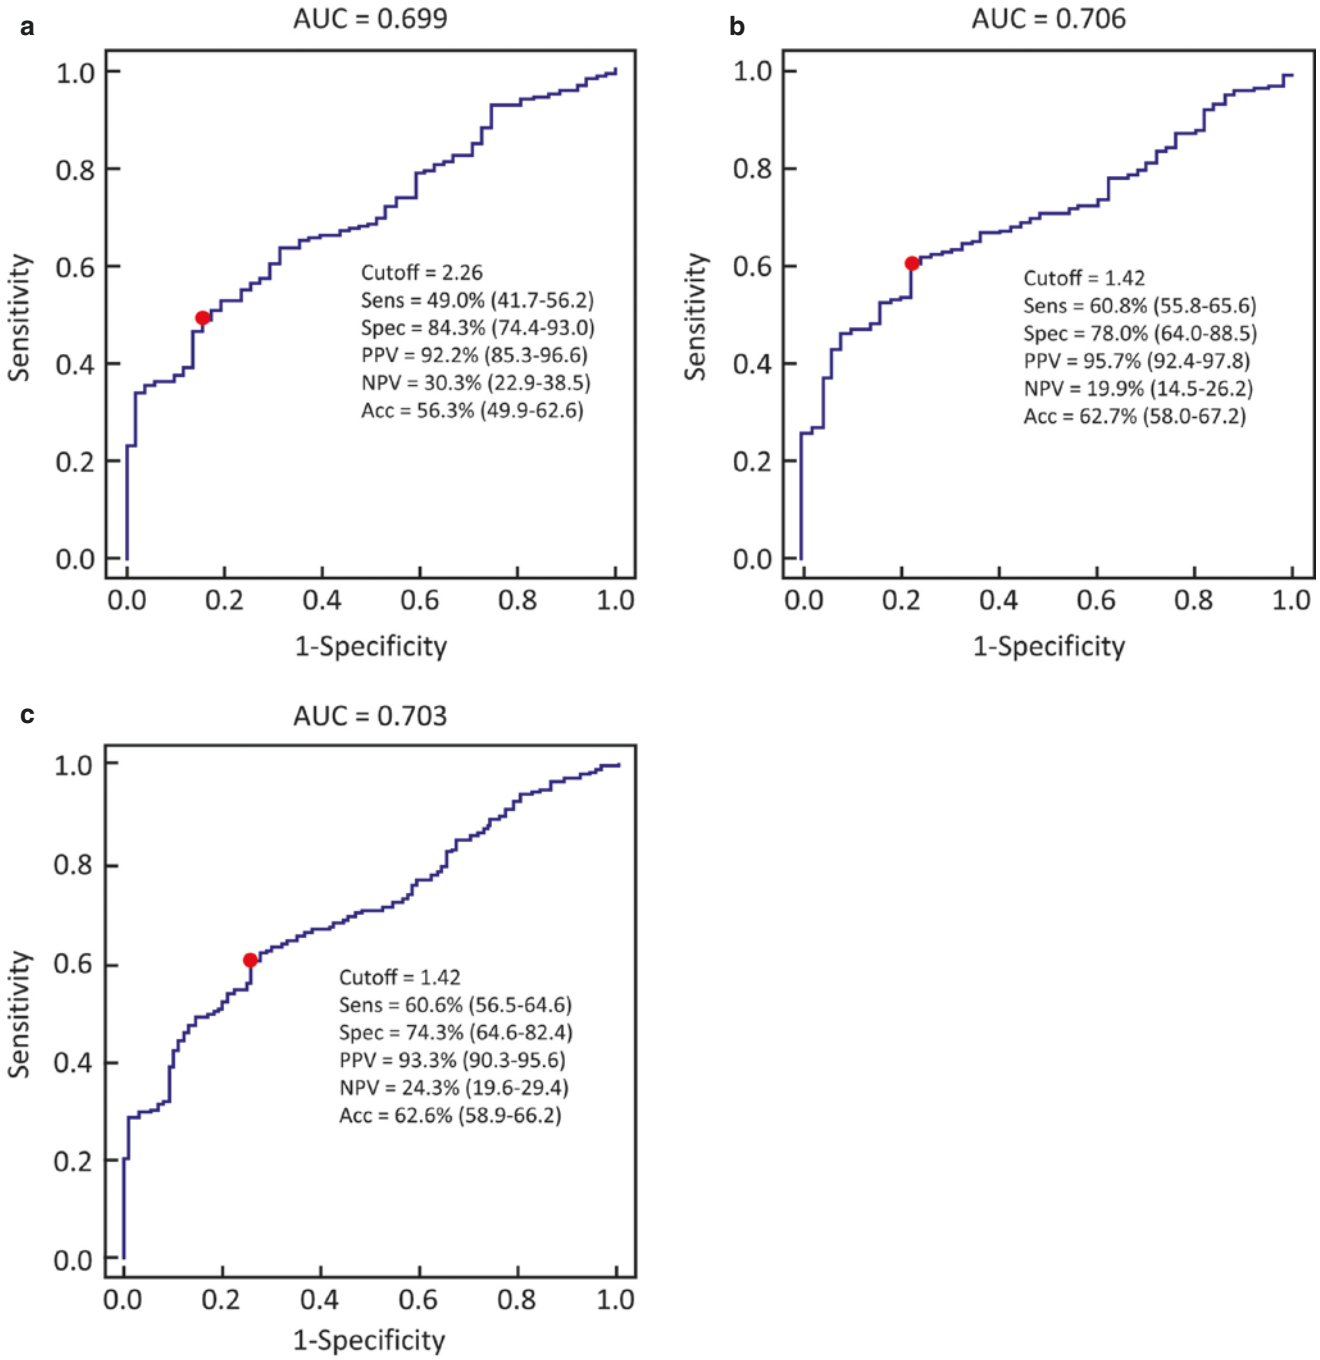

Fig. 7.17 Receiver operating characteristic of the oxidation-reduction potential in distinguishing infertile patients from healthy controls in (**a**) Cleveland Clinic, U.S. dataset, (**b**) Doha, Qatar dataset, and (**c**) combined dataset. AUC area under the curve, NPV negative predictive value, PPV positive predictive value, Sens sensitivity, Spec specificity, and Acc accuracy. ($P < 0.001$). Majzoub et al. [187] also reported the positive association of ORP with abnormal morphology, especially abnormal sperm heads ($P < 0.001$) [180, 181, 184]. Ayaz et al. [193] reported higher pregnancy rates in patients with low ORP (<1.36 mV/10^6 sperm/mL) than in those in a high ORP group (>1.36 mV/10^6 sperm/mL) ($p = 0.006$) [193]. In ART monitoring, ORP allows for better preparation and selection of sperm as it detects not only oxidative stress associated damage but also provides important clues on prognosis and an individual's clinical health. Higher ORP levels have also been reported in infertile men with varicocele that exhibited poor sperm parameters ($P < 0.001$) [175, 184,

Table 7.4 Review of studies examining the receiver operation characteristic curves to identify the ORP criteria that best predicts the normal and abnormal semen parameters as well as differentiates normal healthy controls from male factor infertility patients

No.	Reference	Study population	Cutoff	Sensitivity% (95% CI)	Specificity% (95% CI)	PPV% (95% CI)	NPV% (95% CI)	Accuracy% (95% CI)	AUC

194]. When compared to infertile men with idiopathic infertility, varicocele patients had significantly lower sperm concentration, fewer morphologically normal sperm, and higher ORP levels ($P < 0.005$) [194]. Lastly, genitourinary infections are a major contributor of oxidative stress-induced male infertility. Sikka et al. [195] proposed monitoring of ORP as an indicator of oxidative stress in leukocytospermia as ORP levels were also shown to be similar to certain active inflammation biomarkers such as Toll-like receptor-4 and cyclooxygenase [195].

7.10 Future Directions

The current literature is convincing to recommend the use of ORP as an adjunct tool to basic semen analysis in all patients who present for infertility, as ORP can provide valuable information about sperm function and the fertilizing ability of the man. ORP can also be used as an important ancillary tool for male infertility evaluation and assessment of a patient's initial oxidative stress status. Additional studies, however, from other centers and increasing use of ORP in the evaluation of basic semen analysis will further help establish the clinical utility of ORP in the infertility evaluation. This can be beneficial in guiding clinicians with appropriate therapeutic interventions. The utility of ORP in monitoring patients before and after varicocelectomy, idiopathic infertility and after life style modifications needs to be investigated. Future studies should also aim to examine the value of ORP in longitudinal studies to monitor the progress in patients with specific clinical conditions.

7.11 Conclusions

Oxidative stress is recognized as an important factor in male infertility. Accurate assessment is therefore critical in the laboratory evaluation of male infertility attributed to oxidative stress. In this chapter, we have described various techniques that can be used to measure reactive oxygen species or their end-products using simple techniques such as the nitroblue tetrazolium test to ROS measurement by chemiluminescence assay, measuring antioxidants or end products of oxidative stress such as lipid peroxidation, DNA damage, or protein modifications. We have highlighted the value of the newer tools such as proteomics in identifying oxidatively modified proteins and validating these proteins. The ultimate goal is to identify potential markers of oxidative stress to assist in elucidating the underlying mechanism of oxidative stress-related sperm dysfunction that ultimately results in male infertility and assists the clinicians in the management of these patients.

We described novel approach (ORP analysis by MiOXSYS system) to measure oxidative stress in semen and seminal plasma supported by contemporary literature evidence. ORP provides a comprehensive measure of oxidative stress with a high sensitivity and specificity. Measuring ORP using a portable MiOXSYS system can assess seminal oxidative stress quickly and in small volume samples both in fresh and frozen semen and seminal plasma. It offers the wider application of oxidative stress measurements both in clinical and research settings. MiOXSYS system provides a novel diagnostic method that may be used in conjunction with routine semen analysis. It is a valuable tool to identify patients who will potentially benefit from treatment. It is an advanced and independent test of semen quality that can fit in the algorithm of the male infertility workup and help the clinicians in the management of their patients. Appropriate treatment strategies can be recommended in patients presenting with high oxidative stress.

7.12 Review Criteria

An extensive search of studies examining the relationship between oxidative stress and male infertility was performed using search engines such as Google Scholar and PubMed. The start and end dates for these searches were September 1996 and September 2018, respectively. The overall strategy for study identification and data extraction was based on the following key words: "male infertility", "oxidative stress", "reactive oxygen species", "infertile men", "antioxidants", "DNA fragmentation", "oxidation reduction potential", and "pregnancy rate" as well as the names of specific oxidative-stress markers. Articles published in languages other than English were excluded. Data published in conference or meeting proceedings, websites, or books were also included.

Sperm Chromatin Integrity Tests and Indications

8

Rakesh Sharma, Marlon P. Martinez, and Ashok Agarwal

Key Points

- Assessment of sperm chromatin integrity is important. It provides useful information in cases of male idiopathic infertility, post-chemo/radio therapy, and in couples pursuing assisted reproduction.
- Pathologically increased sperm DNA fragmentation (SDF) is a paternal-derived cause of repeated ART failures.
- Assessment of SDF is important for evaluating semen samples prior to their use in assisted reproduction particularly in men with multiple sperm defects.
- There are multiple assays that can be used to evaluate sperm chromatin and SDF.
- It is important to evaluate the real cause of DNA damage and provide proper therapeutic strategies.
- Several studies have correlated sperm DNA fragmentation with pregnancy outcome in IVF.
- The predictive value of SDF testing in regards to IVF/ICSI outcomes is controversial.
- There is a strong recommendation that sperm DNA fragmentation be included in the evaluation of infertile men.

8.1 Introduction

Laboratory-based semen analysis is the cornerstone assessment for male factor infertility [1]. However, impaired semen parameter cannot predict the fertility [2]. As a result, this laboratory test cannot differentiate fertile from infertile men. Earlier studies have shown that male infertility did not only include abnormal conventional semen parameters but also showed a correlation between compromised efficiency of DNA integrity and reduced fertility potential [3]. Human sperm DNA is a complex configuration which is very susceptible to damage resulting in defective chromatin structure and quality leading to infertility. One of the main causes of sperm DNA damage is reactive oxygen species (ROS) [4]. ROS are known to induce lipid peroxidation of the plasma membrane of the sperm which is the primary cause of sperm DNA fragmentation (SDF). High levels of SDF have been shown to have a negative impact on semen parameters and reproductive potential. This abnormality cannot be detected in routine semen analysis.

Many tests have been developed to measure SDF. The most commonly used SDF tests are the terminal deoxynucleotidyl transferase deoxyuridine triphosphate (dUTP) nick end labeling (TUNEL) assay, sperm chromatin structure assay (SCSA), and sperm chromatin dispersion (SCD) assay [5]. A panel composed of fertility experts worldwide extensively studied the utility of sperm DNA fragmentation test as part of the evaluation of infertile men [6]. Their practice recommendations are based on clinical scenarios, and recommend SDF testing for men with varicocele (high grade varicocele with normal semen parameters or low grade varicocele with abnormal semen parameters), unexplained infertility, recurrent pregnancy loss, recurrent intrauterine insemination (IUI) failures, exposure to environmental pollutants, drugs, radiation, smoking, febrile illness, varicocele, advanced age, and obesity can increase SDF fertilization (IVF) and intracytoplasmic sperm injection (ICSI) failures and men with lifestyle risk factors such as exposure to environmental pollutants, drugs, radiation, smoking, febrile

illness, varicocele, advanced age, and obesity can increase SDF smoking [6]. Despite the impact of SDF testing to evaluate infertile men, many reproductive societies such as the American Society for Reproductive Medicine (ASRM), European Association of Urology (EAU), American Urological Association (AUA), and National Institute of Clinical Excellence (NICE) do not recommend its use as part of the routine assessment of male infertility. Good methodological studies should be conducted to determine chromatin packaging defects as well as the clinical utility of SDF testing in the evaluation of infertile men. In this chapter, we describe the sperm chromatin structure, factors associated with abnormal chromatin structure, and discuss the methods available to analyze sperm DNA chromatin and DNA integrity.

8.2 Limitation of Semen Analysis

Routine semen analysis continues to be the cornerstone of laboratory evaluation of male infertility. However, its ability to diagnose male fertility is limited. Semen analysis provides important information about spermatogenesis, sperm production, formation of spermatozoa, and the individual components of semen and their function; however, there is a significant overlap in the semen parameters such as concentration, motility, and morphology between fertile and infertile [7]. Although sperm motility, concentration, and morphology are parameters that collectively provide important information about the efficiency of spermatogenesis, it is important to look for tests beyond traditional semen analysis [8].

The latest edition of the WHO 2010 laboratory manual provides statistically derived 5th centile lower reference limits. The traditional semen analysis has limited ability to identify the underlying alterations in the molecular and cellular mechanisms that play a critical role in fertilization and fertility. Standard measurements of semen parameters do not provide information about the subtle sperm defects that can affect fertility. The head must contain DNA that has been correctly assembled during spermatogenesis and disassembled during spermiogenesis and finally correctly reassembled to partner with the female DNA to ultimately form the new genome. Similarly, the midpiece must contain mitochondria to provide energy, and the flagellum must be present to transfer the energy to provide the motility. Thus, the outcome can help alleviate the emotional and financial burden to the patient [9, 10]. The introduction of improved automated semen analyzers, smart phone semen testing, microfluidics, and proteomics are all platforms that may potentially provide useful information [11–14], but the technology is still far away from predicting the correct diagnosis with 100% accuracy.

Therefore, there is a need to combine other diagnostic tools to better discriminate infertile men from fertile men, predict pregnancy outcome in female partners, and calculate the risks associated with adverse reproductive events. Perhaps the candidate test with the greatest potential for inclusion is DNA integrity assessment.

8.3 Sperm DNA Integrity

Sperm chromatin abnormalities have been extensively studied as a cause of male infertility. With the increasing use of assisted reproductive technologies (ART), especially ICSI, attention has focused on the genomic integrity of the male gamete and concerns about the transmission of damaged DNA. The ability of the oocyte to repair DNA damage is limited, and excessive DNA damage raises concerns about potential chromosomal abnormalities, congenital malformations, and developmental abnormalities in ICSI-born children [15–18]. Disturbances in the male genomic content are negatively associated with fertility potential of spermatozoa, both in vivo and in vitro [19–27]. Sperm DNA damage is indicative of male subfertility regardless of the normal semen parameters [28, 29]. High sperm DNA fragmentation can compromise embryo quality and result in pregnancy loss following ART [23]. With increasing reports in the literature regarding the association of sperm DNA fragmentation with pregnancy outcome, there is a strong recommendation for inclusion of sperm DNA fragmentation in the evaluation of male infertility [30].

Sperm chromatin is different from that of somatic cells in terms of the chromatin packaging [31, 32]. The histones are replaced by protamines, which make the sperm nuclei highly compacted [33]. While in the mice, 95% of nucleoproteins are comprised of protamines which confers 40% less nuclear volume than that of normal somatic nuclei [34], human sperm nuclei retains about 15% of the histones and contains considerably fewer protamines (85%) when compared to the sperm nuclei of other species such as bull, stallion, hamster, and mouse [35, 36]. The distinct mammalian sperm chromatin packaging called toroids is comprised of 50–60 kb that are cross-linked by disulfide bonds [37, 38]. This condensed, insoluble, and highly organized structure confers genetic integrity during transport of the paternal genome through the male and female reproductive tracts, ensuring proper fusion of the male and female genome and correctly expressing the genetic information in the developing embryo [30, 39, 40].

In contrast to other species which contain only one type of protamine (P1), human and mice spermatozoa contain a second protamine called P2 which is deficient in cysteine residues [31]. P2 diminishes the disulphide cross-linking which is responsible for stable packaging and makes the sperm nuclei less compacted and more susceptible to DNA strand

breaks [41]. Furthermore, the alterations in P1/P2 ratio and absence of P2 are associated with male fertility problems [42–46]. Distinct differences in P1/P2 ratio are reported between fertile and infertile men and P1/P2 ratio has been shown to correlate with sperm DNA fragmentation [47]. Alterations in P1/P2 ratio have been shown to be a good indicator of disturbances in spermatogenesis and lead to male infertility [48].

8.4 Indications and Importance of Sperm DNA Integrity in Male Infertility

Evaluation of sperm chromatin integrity can be challenging; it is difficult to link it with the known physiological mechanisms. Furthermore, its role in clinical practice especially ART is still controversial [49–51]. Evaluating sperm chromatin structure is complex and different methods are necessary to assess this structure. Several confounding factors such as lack of standardized protocols, validated reference ranges, and the assay principles of various sperm DNA testing assays complicate the interpretation of the results. Not all DNA damage is lethal and the oocyte has the ability to repair sperm DNA damage. Although a sperm with damaged DNA can fertilize an egg, it can result in compromised embryonic growth, miscarriage, or childhood deformities [52–56]. Numerous studies have demonstrated significant differences in sperm DNA damage levels between infertile and fertile men [49, 57–61]. Several etiological factors have been implicated in damaging sperm DNA including environmental and lifestyle factors, varicocele, male accessory gland infections, advanced paternal age, and systemic diseases [5, 52, 62–66].

Varicocele has been shown to have an adverse effect on SDF [67]. Higher SDF has been shown in men with varicocele compared to fertile men [68]. Another study reported higher SDF in infertile men with varicocele compared to infertile men without varicocele [69]. Similarly, the same study reported higher SDF rates in men with varicocele and no history of infertility compared with fertile men without varicocele [69]. In a study by Esteves et al., using SCD, varicocele was identified with 94% accuracy based on the rates of degraded sperm determined by the proportion of degraded sperm in the population of spermatozoa with fragmented DNA which was eight-fold higher in men with varicocele than in donors [62]. SDF is also increased in the presence of oxidative stress in these men [70–72]. Varicocelectomy has been shown to be beneficial in select cases [73]. Varicocele repair has been shown to lower SDF and increase the chances of a natural pregnancy [67]. A meta-analysis comprised of six studies that evaluated the effect of varicocelectomy on SDF and found an overall reduction in SDF with a mean difference of −3.37% (95% CI: −4.09 to −2.65; $p < 0.00001$) [68]. Another study evaluated 92 patients with clinical varicocele and examined semen parameters and SDF before and after subinguinal microsurgical varicocele repair [74]. Significant improvement in SDF was reported from a preoperative mean of 42.6–20.5% post-operative ($p < 0.001$). Similarly, Smit et al. [75] evaluated 49 men with varicocele, oligozoospermia, and primary infertility. Following varicocele repair, SDF was significantly reduced post-operatively, and higher pregnancy rates through natural conception with ART were reported. Other reasons for testing DNA fragmentation are recurrent pregnancy loss, unexplained infertility, ART, and cancer patients undergoing chemotherapy or radiotherapy [6].

8.5 Clinical Relevance of DNA Integrity with ART Outcomes

Sperm chromatin integrity is important for effective transmission of genetic information. Abnormal sperm chromatin affects both natural fertility and ART outcomes [70, 73, 76–80]. High SDF as determined by SCSA was shown to result in natural pregnancy failure with high odds ratio of 7.01 (95% CI: 3.68–13.36) [81]. High SDF was also shown to result in increased time to pregnancy in first-time couples without any history of infertility [82, 83]. Both, SCD and TUNEL were able to predict natural pregnancy with over 80% sensitivity and specificity [84, 85]. High levels of SDF have also been associated with poor IUI outcomes [86, 87]. A significant adverse effect of high SDF on clinical pregnancy in both IVF and ICSI was also demonstrated in a meta-analysis comprised of 8068 treatment cycles [86]. Another meta-analysis comprising of 2969 couples demonstrated a 2.2 fold risk of miscarriage when semen specimens with high SDF were used for ICSI (95% CI: 1.54–03.03; $p < 0.00001$) [88]. Similarly, another meta-analysis study comprising of pooled data from 14 studies, abnormally high SDF was associated with higher miscarriage rates in ICSI cycles (OR: 2.68; 95CVI: 1.40–5.14; $p = 0.003$) [89]. Furthermore, SDF was higher in couples experiencing recurrent pregnancy loss compared to fertile controls (18.8% ± 7.0% vs 12.8% ±5.3%; $p < -0.9001$) [90]. All these studies elucidate that higher SDF plays a role in both natural pregnancy and in ART outcomes.

8.6 Contemporary Sperm Chromatin Integrity Tests

Different methods such as aniline blue staining, acridine orange staining, SCSA, 8-hydroxy-2-deoxyguanosine (8-OHdG) assay, Comet assay, sperm chromatin dispersion (SCD) assay and TUNEL assay are available to evaluate sperm chromatin and DNA integrity. These are described below.

8.6.1 Aniline Blue Staining

The acidic dye aniline blue has a strong affinity for binding with loose or decondensed proteins due to residual histones. Aniline blue does not measure SDF. It does not even measure DNA features. It is only a measure for chromatin condensation. Aniline blue staining differentiates lysine-rich histones and arginine/cysteine-rich protamine nuclei. Immature sperm nuclei are rich in lysine-rich histones and sperm are stained blue, whereas protamines are rich arginine and cysteine and therefore do not pick up the stain, thus remain unstained. Therefore, this technique is able to differentiate immature and mature sperm in ejaculated spermatozoa [91].

The technique involves air-dried smears of ejaculated or washed spermatozoa fixed in 3% glutaraldehyde in phosphate buffered saline (PBS) for 30 min. The fixed slides are stained in acidic (pH 3.5) 5% aqueous aniline blue solution for 5 min. A total of 200 spermatozoa are counted under bright field microscopy. Percentage sperm stained with aniline blue is counted and should not exceed 25% [92]. Immature, decondensed sperm nuclei are stained light blue (Fig. 8.1a–c). A modified method combines aniline blue counterstained with 0.5% Eosin Y for 1 min [93].

The advantage of this technique is that it is simple and inexpensive and requires only a simple bright field microscope. The disadvantage is that the staining is not homogenous. A high percentage of sperm with nuclear instability is reported with aniline blue staining in patients with varicocele, idiopathic infertility, and unilateral cryptorchidism [94]. While its correlation with other sperm parameters is controversial, aniline blue-stained spermatozoa showed normal sperm count, motility, and morphology [95, 96]. While immature sperm chromatin may or may not correlate with abnormal morphology patterns in asthenozoospermic samples [91, 97], chromatin condensation observed by aniline blue staining was reported to be a good predictor of IVF outcome [93, 94]. The aniline blue test could be considered as one of the complimentary tests of semen analysis for assessment of male infertility [96, 98].

8.6.2 Toluidine Blue Staining

Toluidine blue is a basic thiazine metachromatic dye that binds selectively with acidic components of the tissue. It has a high affinity to bind with the phosphate residues present in sperm DNA of immature nuclei [6, 99, 100]. Air-dried sperm smears are fixed in ethanol-acetone (1:1) at 4°C for 30 min and hydrolyzed in 0.1 N HCl at 4°C for 5 min, followed by rinsing thrice in distilled water. Smears are stained for 5 min with Toluidine blue (0.05%) prepared in 30% citrate phosphates or McIlvain buffer, pH 3.5. Permanent preparations are prepared after dehydrating in tertiary butanol twice for 3 min each followed by xylene twice for 3 min each. Staining is observed using light microscopy. Normal sperm heads stain light blue, whereas sperm heads with abnormal DNA stain purple–violet due to the metachromatic shift [101, 102]. It is therefore a sensitive probe for DNA structure and packaging. Toluidine blue staining has demonstrated application in assessment of male fertility potential with 95% specificity and a sensitivity of 42% when the threshold is set at 45% [103, 104]. It is a simple and inexpensive stain that has been used for morphological assessment by light microscopy. It has also been shown to correlate with other advanced tests of sperm DNA fragmentation, i.e., SCSA and TUNEL [102, 105].

8.6.3 CMA 3 Assay

Chromomycin A3 (CMA3) is an indirect assay to measure protamine deficiency in sperm DNA. It is only a measure for chromatin condensation. Poor chromatin packaging is revealed by CMA3 a guanine-cytosine-specific fluorochrome which competes with protamine for binding to the minor grooves of DNA [106]. Spermatozoa exhibiting low protamination show high CMA3 binding [107]. The technique involves air drying of methanol-glacial acetic acid (3:1) fixed sperm at 4°C for 20 min. The slides are treated for 20 min with CMA3 solution prepared in McIvlain's buffer supplemented with 10 mmol/l $MgCl_2$. Slides are rinsed in buffer and mounted with PBS-glycerol (1:1 vol./vol.) and kept overnight at 4°C.

Staining is observed under fluorescence microscope and 200 spermatozoa are counted on each slide. CMA3-positive spermatozoa indicative of poor protamination stain bright

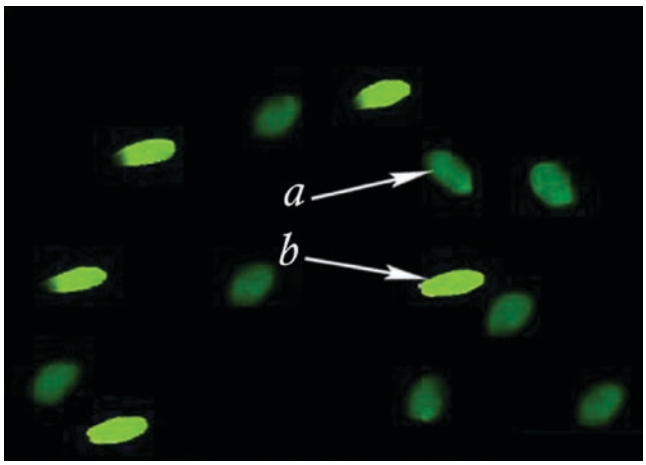

Fig. 8.2 Chromomycin A3 (CMA3) staining of sperm chromatin in a man with (**a**) spontaneous recurrent abortion showing normal spermatozoa versus (**b**) spermatozoa with protamine deficiency. (Reprinted from Kazerooni et al. [96]. With permission from Springer Nature)

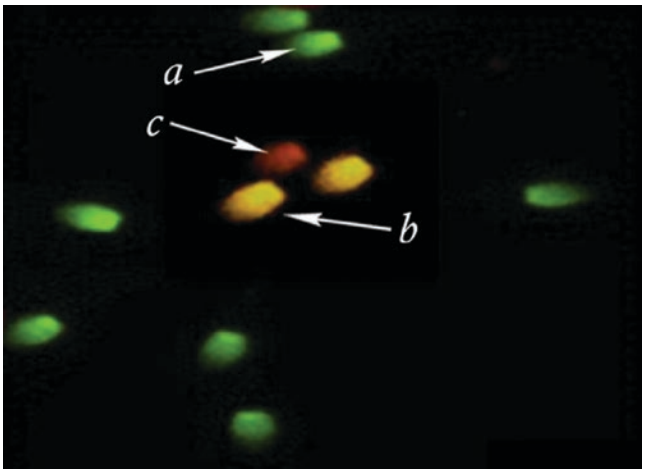

Fig. 8.3 Acridine orange (AO) staining of sperm chromatin of a man with spontaneous recurrent abortion showing (**a**) normal, (**b**) moderately denaturated, and (**c**) completely denaturated spermatozoa. (Reprinted from Kazerooni et al. [96]. With permission from Springer Nature)

yellow or bright green, whereas CMA3-negative spermatozoa (high protamination) stain faint yellow or dull green [96, 108, 109]. (Figure 8.2a–b). CMA3 staining has demonstrated a sensitivity of 73% and a specificity of 75% and reported to be a good discriminator of IVF success [110, 111]. CMA3 results have shown an inverse correlation with sperm concentration, motility especially morphology. Men with poor sperm morphology exhibited a greater degree of protamine deficiency and DNA damage [112, 113]. Furthermore, significantly higher CMA3 staining has been demonstrated in globozoospermic patients [114]. The sensitivity and specificity of CMA3 staining is strongly correlated with that of aniline blue staining [108]. However, this assay is limited due to inter-observer subjectivity.

8.6.4 Acridine Orange

Acridine orange is a flurochrome dye used to measure the susceptibility of the sperm nuclear DNA to acid-induced denaturation. It intercalates into double-stranded DNA as a monomer and binds to a single-stranded DNA as aggregate. Acridine orange fluoresces green when bound to native DNA and green the relaxed acridine orange fluoresces red in denatured DNA [115, 116]. Acridine orange is used both in fluorescence microscopy and in flow cytometry. For fluorescence microscopy, thick semen smears are fixed in Carnoy's fixative (methanol: acetic acid; 1:3) for 2 hours and stained in acridine orange for 5 min. After rinsing in deionized water, about 200 spermatozoa are examined for the intact (green) and damaged DNA (yellow–orange to red) [96] (Figure 8.3a-c). The DNA fragmentation index is calculated by measuring the ratio of yellow to red/green + yellow to red florescence [115].

For flow cytometry, 25–100 μL of sample containing about 1×10^6 spermatozoa are suspended in ice cold PBS at pH 7.4 and centrifuged at 600 × g for 5 min. The pellet is resuspended in ice-cold TNE (0.01 mmol/l of tris-HCl, 0.15 mol/l NaCl, and 1 mmol/l EDTA, pH 7.4) and centrifuged at 600 × g for 5 min. After removing the supernatant, the pellet is again resuspended in TNE containing 10% glycerol and fixed in 70% ethanol for 30 min. The fixed samples are treated with triton-X 100 solution (0.15 mol/l NaCl and 0.08 N HCl; pH 1.2) for 30 seconds. Acridine orange (6 μg/mL, 37 mmol/l citric acid, 126 mmol/l Na_2HPO_4, 1 mmol/L disodium EDTA and 0.15 mol/l NaCl, pH 6.0) is added. A minimum of 5000 cells are examined by flow cytometery using a light source with excitation at 488 nm light source. The ratio of acridine bound to intact double-stranded DNA fluorescing green at 513–530-nm and acridine orange bound to damaged single-stranded DNA fluorescing red is calculated (630 nm) [117].

Acridine orange positive cells are more likely to have structural abnormalities compared to acridine-orange-negative spermatozoa [118]. In infertile men, acridine orange technique demonstrated significantly higher DNA damage in infertile men compared to controls in men with varicocele. This was significantly reduced after varicocele repair demonstrating the clinical utility of this technique [104, 119]. The acridine orange assay shows low intra-assay variability, and the technique is highly reproducible. A strong positive correlation has been demonstrated between acridine orange assay and other techniques that are used to measure single-stranded DNA, such as TUNEL assay [120]. The cutoff to differentiate between fertile and infertile men varies between 20% and 50% [109, 121, 122]. Single-stranded DNA staining has also shown to negatively correlate with the classical IVF and lower pregnancy rates [116, 122–125].

8.6.5 Sperm Chromatin Structure Assay

The sperm chromatin structure assay (SCSA) measures in situ DNA susceptibility to the acid-induced conformational helix-coil transition by acridine orange (AO) fluorescence staining. The extent of conformational transition in situ following acid or heat treatment is determined by measuring the metachromatic shift of AO fluorescence from green (native DNA) to red (denatured or relaxed DNA) (Fig. 8.4). The SCSA acid method is much easier to use than the heat treatment. DNA damage that is SCSA-defined is manifested by the DNA Fragmentation Index (DFI) [121].

An aliquot of unprocessed semen (about 13–70 μl) is diluted to a concentration of 1–2 × 10^6 sperm/ml with TNE buffer (0.01 M Tris-HCl, 0.15 M NaCl, and 1 mM EDTA, pH 7.4). This cell suspension is treated with an acid detergent solution (pH = 1.2) containing 0.1% Triton X-100, 0.15 mol/l NaCl, and 0.08 N HCl for 30 seconds, and then stained with 6 mg/l purified AO in a phosphate-citrate buffer, pH 6.0. The stained sample is placed into the flow cytometer sample chamber [121]. The extent of DNA fragmentation is measured as % of sperm with fragmented DNA termed as DNA fragmentation Index, or DFI. It is the ratio of red fluorescence to total (red + green fluorescence). Native (double-stranded) or intact spermatozoa fluoresce green and fragmented DNA (single-stranded DNA) fluoresce red (Fig. 8.4). Since the SCSA is more constant over prolonged periods of time than routine World Health Organization (WHO) semen parameters, it may be used effectively in epidemiological studies of male infertility [126]. No significant male age-related increase in DFI was demonstrated [127]. SCSA has clearly established clinical thresholds for utility in the human infertility clinic [128]. In clinical applications, the SCSA parameters can distinguish fertile and infertile men. In addition, these parameters are also able to classify men according to the level of *in vivo* fertility, i.e., high fertility (pregnancy initiated in less than 3 months), moderate fertility (pregnancy initiated within 4–12 months), and no proven fertility (no pregnancy by 12 months). Furthermore, a DFI threshold of <30% can identify samples compatible with in vivo pregnancy (<30%) [25, 86, 129–131].

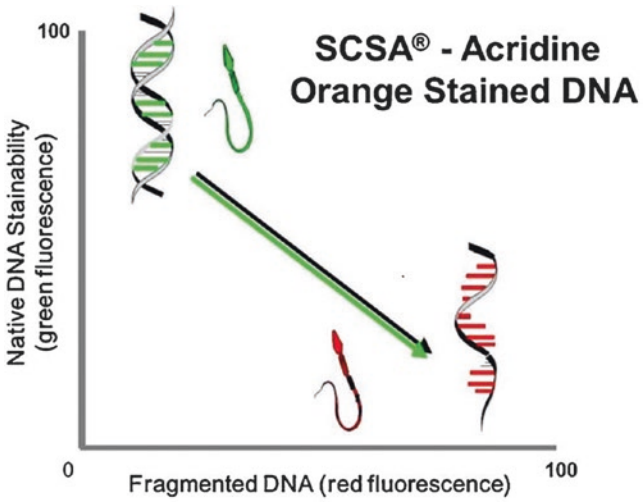

Fig. 8.4 Schematic of SCSA test showing fluorescence color shift from normal double-stranded (Normal or Native DNA) (green) to fragmented single-stranded DNA (red). (Reprinted from Evenson [221]. With permission from Elsevier)

SCSA can predict the various outcomes of ART. However, this is true only for neat semen [132] including the fertilization and implantation rates [22, 86, 133, 134], but this finding was not supported by a study by Lin et al. [135] who reported increased abortion rate in the high DFI (>27%) group. Reports suggest that DFI can be used as an independent predictor of fertility in couples undergoing IUI [22], but an association between SCSA results and IVF and ICSI outcomes are not strong enough [136]. It is also proposed that all infertile men should be tested with SCSA as a supplement to the standard semen analysis [137]. Recent data suggests that ICSI should be the method of choice when DFI exceeds 30% [86].

The SCSA accurately estimates the percentage of DNA-damaged sperm and has a cut-off point (30% DFI) to differentiate between fertile and infertile samples [22, 129]. However, it requires the presence of expensive instrumentation (flow cytometer) and highly skilled technicians. SCSA DFI shows significant association with TUNEL assay results when Spearman's rank correlation was used, however, regression and concordance correlation results showed that these methods are not comparable. SCSA rather measures DNA damage in terms of susceptibility to DNA denaturation, while TUNEL measures "real" DNA damage [138].

8.6.6 Measurement of 8-Hydroxy-2-Deoxyguanosine (8-OHdG)

This assay measures levels of 8-hydroxy-2-deoxyguanosine (8-OHdG), which is a byproduct of oxidative DNA damage in spermatozoa. It is the most commonly studied biomarker for oxidative DNA damage. Among various oxidative DNA adducts, 8-OHdG is representative of oxidative DNA damage owning to its high specificity, potent mutagenicity, and relative abundance in DNA [139].

The technique involves three steps: in step 1, DNA extraction is performed with chloroform-isoamyl alcohol (12:1 v/v) after the sperm cells are washed with sperm wash buffer (10 mmol/l Tris-HCl, 10 mmol/l EDTA, 1 mol/l NaCl, pH 7.0) and lysed at 55 °C for 1 hour with 0.9% SDS, 0.5 mg/ml proteinase *K*, and 0.04 mol/l dithiothreitol (DTT). After ribonuclease A treatment to remove RNA residue, the

extracted DNA is dissolved in 10 mmol/l Tris-HCl (pH 7.0) for DNA digestion. Step II involves the enzymatic DNA digestion that is performed with three enzymes: DNAase I, nuclease P1, and alkaline phosphatase. The final solution is dried under reduced temperature and pressure and is redissolved in distilled and deionized water for HPLC. The third step uses HPLC analysis and consists of a pump, a partisphere 5 C18 column, an electrochemical detector, an ultraviolet detector, an autosampler, and an integrator. The mobile phase consists of 20 mmol/l $NH4H_2PO_4$, 1 mmol/l EDTA, and 4% methanol (pH 4.7). The calibration curves for 8-OHdG are established with standard 8-OHdG, and the results are expressed as 8-OHdG/10^4 dG [97]. 8-oxoG can also be determined using a specific fluorescent probe (8-oxoG) from the OxiDNA assay kit.

8-OHdG provides the most direct evidence suggesting that oxidative sperm DNA damage is involved in male infertility, based on the finding that levels of 8-OHdG in sperm are significantly higher in infertile patients than in fertile controls and have an inverse relationship with sperm concentration [97]. 8-OHdG formation and DNA fragmentation assessed by TUNEL are highly correlated with each other [140]. 8-OHdG levels also are highly correlated with the disruption of chromatin remodeling [141]. Levels of 8-OHdG in sperm DNA have been reported to be increased in smokers, and they inversely correlate with the intake and seminal plasma concentration of vitamin C. It is demonstrated that infertile patients with varicocele have increased 8-OHdG expression in the testis which is associated with deficient spermatogenesis [142]. If not repaired, 8-OHdG modifications in DNA are mutagenic and may cause embryo loss, fetal malformations, or childhood cancer. Moreover, this modification could be a marker of OS in sperm, which may have negative effects on sperm function [143, 144].

8.6.7 Comet Assay

The comet assay or the single-cell gel electrophoresis is based on the principle of permeabilization and electrophoretic migration of cleaved fragments of DNA. In the neutral comet assay, the migration of the double-stranded DNA loops from a damaged cell comes in the form of a tail unwinding from the relaxed supercoiled nucleus. This unwinding is proportional to the damage that the cell is subjected to. This gives rise to the characteristic appearance of a comet with the tail when seen under fluorescence microscope using DNA stains.

This assay was later modified by Singh et al. [145] using alkaline electrophoresis buffers to expose the alkali-labile sites on the DNA and increase to the sensitivity of the assay to detect both single- and double-stranded DNA. The single- and double-stranded DNA breaks can also be evaluated by the modified two-tailed comet assay [146, 147]. Poor quality chromatin is closely associated with, and highly indicative of, some fertility problems. Many methodologies to assess DNA fragmentation in spermatozoa are available, but they are all unable to differentiate between single-stranded DNA breaks (SSB) and double-stranded DNA breaks (DSB) in the same sperm cell.

The two-tailed Comet assay (2 T-Comet) protocol overcomes this limitation. A modification of the original Comet assay was developed for the simultaneous evaluation of DNA SSB and DSB in human spermatozoa. In this assay, the DNA damage is quantified by measuring the displacement between the genetic material of the nucleus or the comet head and the resulting tail. The tail length is used as an index of the damage. In addition, the "tail moment" is a product of tail length and the intensity or the fraction of the total DNA in the tails. It can also be defined as similar to the torsional moment of the tail [148].

The comet assay is a simple, versatile, sensitive, and rapid assay and has demonstrated some correlation with other assays such as SCSA and TUNEL [149]. The assay requires expertise in result interpretation as it is based on the fluorescence microscopy. The 2 T-Comet assay is a fast, sensitive, and reliable procedure for the quantification and characterization of DNA damage in spermatozoa [150] (Figs. 8.5a–b and 8.6a–c).

The comet assay has been used to evaluate the DNA damage after cryopreservation [151]. It has been used to predict embryo development after IVF and ICSI, especially in couples with unexplained infertility [152, 153]. Although the clinical thresholds have been established for diagnosing infertility and predicting IVF outcome [154–157], not all studies have demonstrated such an association [158].

8.6.8 Sperm Chromatin Dispersion Test (Halosperm Assay)

The sperm chromatin dispersion (SCD) test produces sperm nucleoids consisting of a central or core and peripheral halo caused by release of DNA loops, signifying the absence of DNA fragmentation. When sperm are treated with an acid solution prior to lysis buffer, a complete absence or a minimal halo is produced in spermatozoa with fragmented DNA. A distinct halo is seen in spermatozoa with intact DNA integrity [159]. When spermatozoa with non-fragmented DNA are immersed in an agarose matrix and directly exposed to lysing solutions, the resulting deproteinized nuclei (nucleoids) show extended halos of DNA dispersion, which can be observed either by bright field microscopy or fluorescent microscopy. The presence of DNA breaks promotes the expansion of the halo of the nucleoid [80, 160–165].

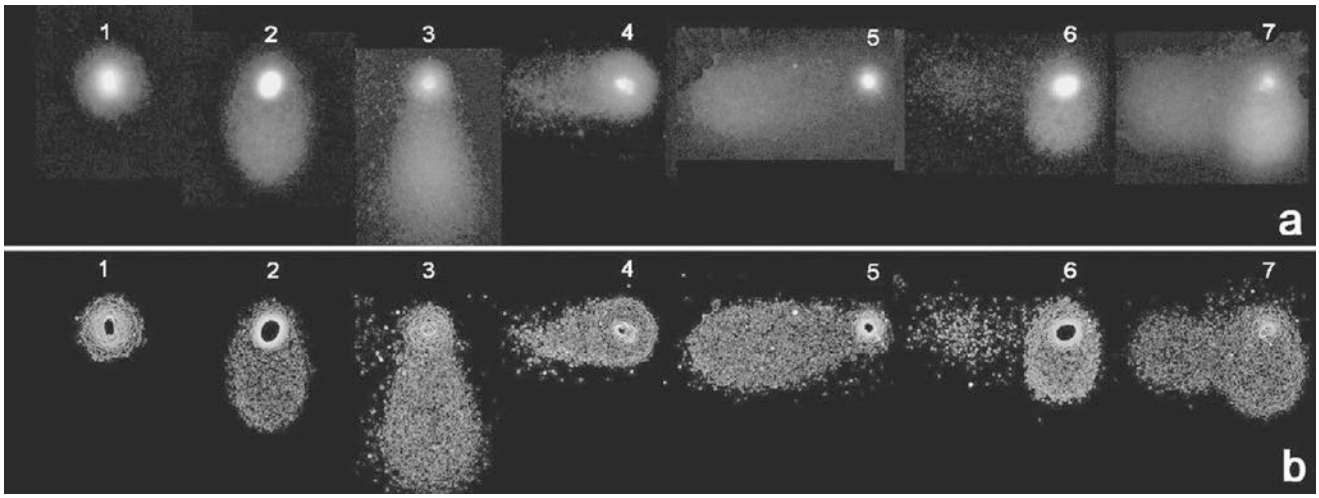

Fig. 8.5 Two-tailed (2 T) comet assay protocol detects seven comet types: (1) undamaged; (2) low level of single-stranded DNA breaks (SSB); (3) high level of SSB; (4) low level of double-stranded DNA breaks (DSB); (5) high level of DSB; (6) low level of SSB and low level of DSB; (7) high level of SSB and high level of DSB. Scale bar: 10 μm. (Reprinted from Enciso et al. [150]. With permission from Elsevier)

In this assay, aliquots of sperm at a concentration of 5–10 million/ml are prepared by diluting in PBS. The samples are mixed with 1% low-melting-point aqueous agarose (to obtain a 0.7% final agarose concentration) at 37 °C. Aliquots of 50 μl of the mixture are pipetted onto a glass slide precoated with 0.65% standard agarose dried at 80 °C, covered with a coverslip, and left to solidify at 4 °C for 4 min. The coverslips are then carefully removed, and the slides are immediately immersed horizontally in a tray of freshly prepared acid denaturation solution (0.08 N HCl) for 7 min at 22 °C in the dark, which generates restricted single-stranded DNA (ssDNA) motifs from DNA breaks. Denaturation is then stopped, and the proteins are removed by transferring the slides to a tray with neutralizing and lysing solution 1 (0.4 mol/l Tris, 0.8 mol/l DTT, 1% SDS, and 50 mmol/l EDTA, pH 7.5) for 10 min at room temperature. The slides are then incubated in neutralizing and lysing solution 2 (0.4 mol/l Tris, 2 mol/l NaCl, and 1% SDS, pH 7.5) for 5 min at room temperature. The slides are thoroughly washed in Tris-borate EDTA buffer (0.09 mol/l Tris-borate and 0.002 mol/l EDTA, pH 7.5) for 2 min, dehydrated in sequential 70%, 90%, and 100% ethanol baths (2 min each), and air-dried. For bright-field microscopy in the improved SCD test (Halosperm® kit), slides were horizontally covered with a mix of Wright's staining solution (Figs. 8.7a–i and 8.8). Cells can also be stained with DAPI (4′,6-diamidino-2-phenylindole) (2 μg/ml) for fluorescence microscopy [109, 159].

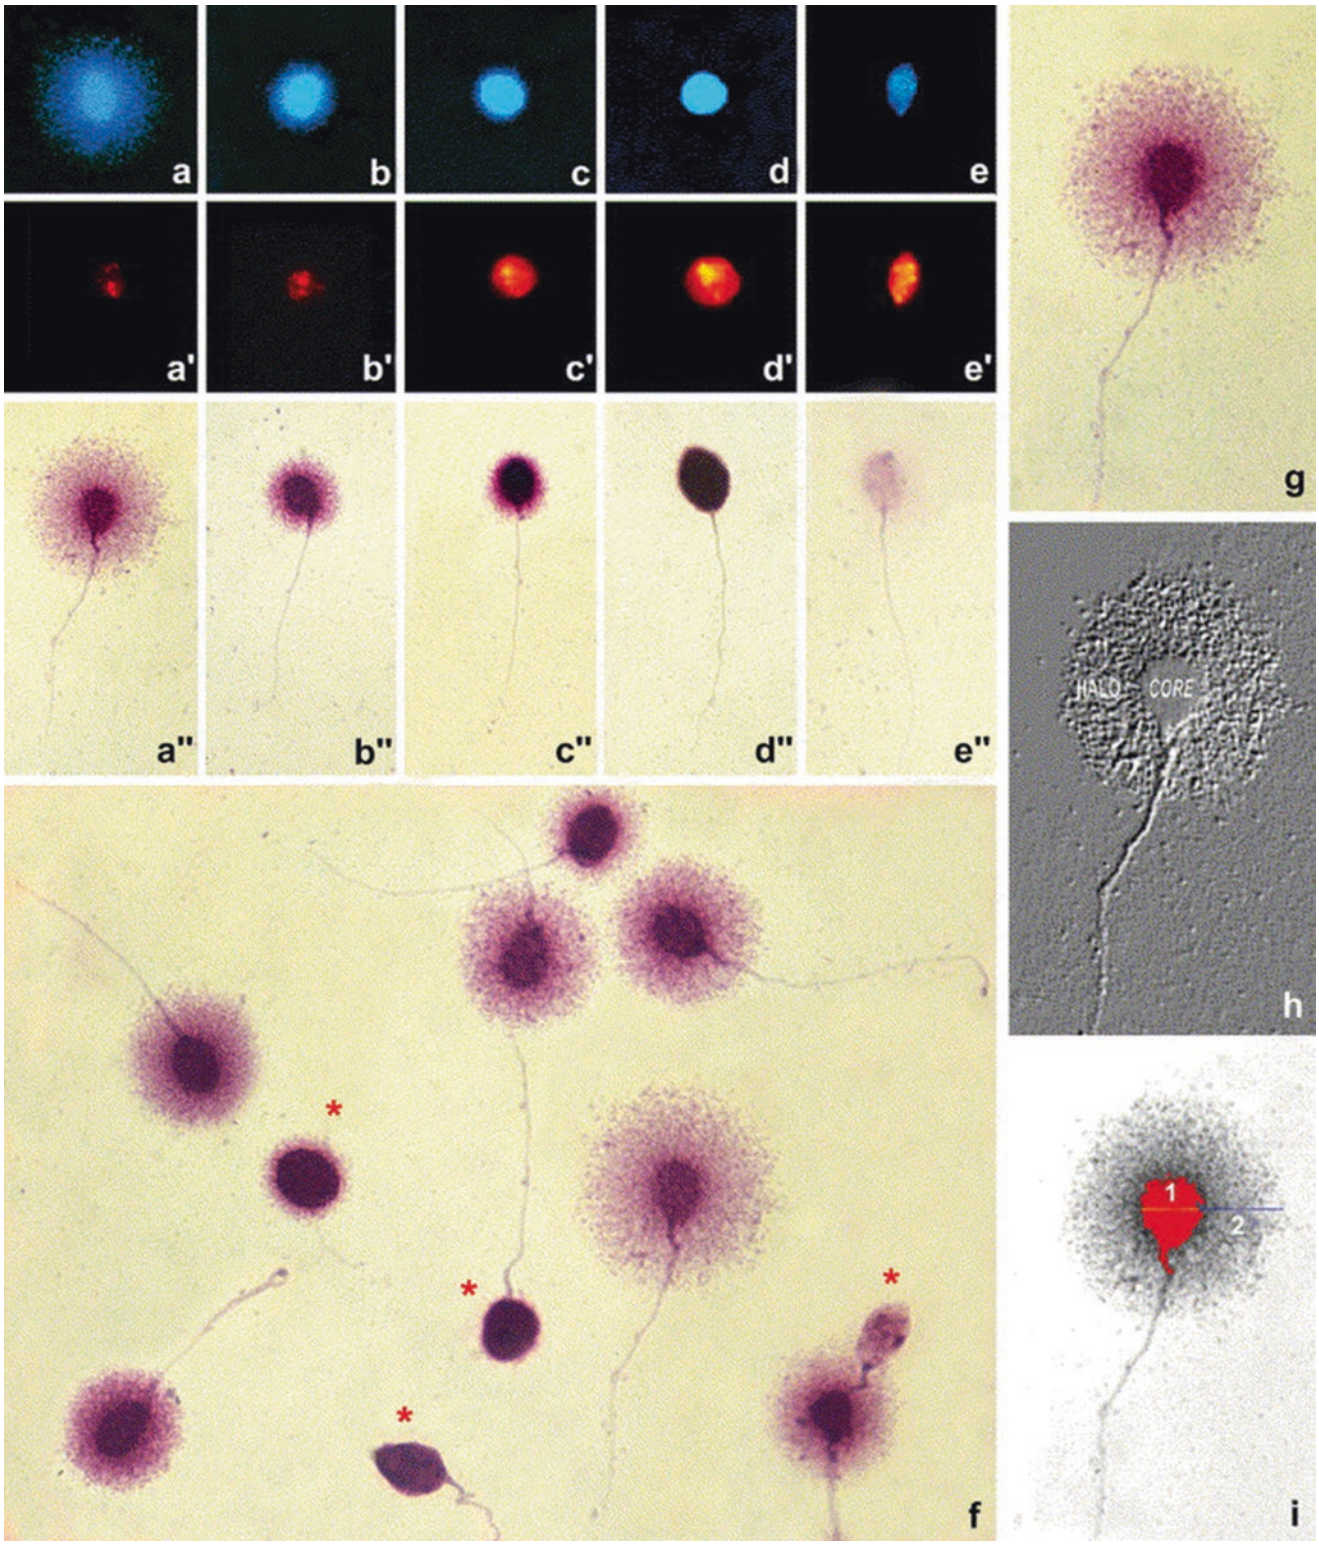

Fig. 8.7 Nucleoids from human sperm cells obtained with the improved SCD procedure. (**a**–**e**) DAPI staining for fluorescence microscopy. (**a′–e′**) Sequential DBD-FISH with a whole genome probe to demonstrate DNA breakage. (**a″–e″**) Wright staining for bright-field microscopy. (**a**, **a′**, **a″**) Nucleoids with big halo of DNA dispersion. (**b**, **b′**, **b″**) Nucleoids with medium-sized halo. (**c**, **c′**, **c″**) Nucleoids with small halo size. (**d**, **d′**, **d″**) Nucleoids without halo. (**e**, **e′**, **e″**) Nucleoids without halo and degraded. According to the DBD-FISH signal, those nucleoids with small halo, without halo, and without halo and degraded contain fragmented DNA. (**f**) Microscopic field visualized after Wright staining. Those sperm cells with fragmented DNA are indicated by an asterisk. (**g–i**) Besides the preservation of the tails, the improved SCD protocol allows for a better chromatin staining, obtaining highly contrasting images for bright-field microscopy (**g**), where the core and the periphery of the halo are well delimitated (**h**). (**i**) The estimation of the halo size was established by comparison of the halo width (2) with the minor diameter of the core (1). (Reprinted from Fernández et al. [222]. Fig. 8.8 The SCD test in an individual with varicocele. The frequency of sperm cells without halo and degraded (asterisks) is high, reflective of a very high degree of nuclear damage. (Reprinted from Fernández et al. [222]. With permission from Elsevier)

The SCD test is simple, fast, and reproducible with comparable results to those of the SCSA [162, 164] and TUNEL [166]. The currently available protocol is suitable for bright field microscopy as it significantly reduces equipment cost. The test is successfully used in clinical studies to detect sperm DNA damage [167] and can be simultaneously combined with the FISH (SCD-FISH) assay for detection of aneuploidy in sperm cells [168]. This is the only test allowing sperm DNA fragmentation and chromosomal aneuploidy by FISH in the same cell. Oxidative DNA damage can also be simultaneously determined in the same sperm cell by combining SCD and incubation with an 8-oxoguanine DNA probe [169]. A commercially available Halosperm kit is available to perform this test [170]. Reports suggest that sperm DNA fragmentation as reported by the SCD test is negatively correlated with fertilization rates and embryo quality in IVF/ICSI but not with clinical pregnancy rates or births [162, 171].

8.6.9 Terminal Deoxynucleotidyl Transferase dUTP Nick End Labeling (TUNEL) Assay

This single step staining method labels DNA breaks with FITC-dUTP followed by flow cytometric analysis. TUNEL utilizes a template-independent DNA polymerase called Terminal Deoxynucleotidyl Transferase (TdT), which non-preferentially adds deoxyribonucleotides to 3′ hydroxyl (OH) single- and double-stranded DNA. Deoxyuridine triphosphate (dUTP) is the substrate that is added by the TdT enzyme to the free 3'-OH break-ends of DNA [172–174]. DNA fragmentation can be quantified with conventional or the bench top flow cytometry [172] (Fig. 8.9).

TUNEL utilizes a template-independent DNA polymerase called terminal deoxynucleotidyl transferase (TdT) that non-preferentially adds deoxyribonucleotides to 3′ hydroxyl (OH) single and double-stranded DNA. Deoxyuridine triphosphate (dUTP) is the substrate that is added by the TdT enzyme to the free 3'-OH break-ends of DNA. To assess the DNA fragmentation by TUNEL, an APO-DIRECT Kit (BD Pharmingen, CA) is used. It contains the reaction buffer, TdT, FITC-dUTP, and propidium iodide/ RNase stain. The assay kit also contains negative and the positive controls, which are not sperm cells. About 2.5×10^6 sperm are fixed with 3.7% paraformaldehyde for a minimum of 30 min at 4 °C. The sample is centrifuged at 300 × g for 7 min.

Paraformaldehyde is removed by centrifuging the samples at 300 × g for 7 min. Supernatants are discarded and the pellets resuspended with 1 mL of ice-cold ethanol (70% vol./vol.). The tubes are kept at −20 °C for at least 30 min. To create negative sperm controls, the enzyme terminal transferase is omitted from the reaction mixture. To create positive sperm controls, the samples are pretreated with 2% (v/v) hydrogen peroxide and incubation for 1 h at 50 °C. A 50 µL of the stain is added and incubated for 1 h. Following two washes with 1 mL of the "Rinse buffer," PI /RNase stain is added and incubated for 30 min. For flow cytometry, the laser excitation is provided at 2 wavelengths of 488 nm supplied by a solid blue laser at 20 mW and 640 nm powered by 14.7 mW diode red laser. Green fluorescence (480–530 nm) is measured in the FL-1 channel and red fluorescence (640 nm) in the FL-2 channel. The percentage of positive cells (TUNEL-positive) is calculated on a 1023-channel scale from the flow cytometer software (Fig. 8.10a–e). The analysis is conducted with a similar strategy on both the C6 and the C6 Plus flow cytometer, and dot plots are generated by the BD Accuri software (BD Biosciences, Ann Arbor, MI, United States) [173]. TUNEL results of SDF obtained from a standard (C6) flow cytometer have been compared with a newer version of the same instrument (C6 Plus), and the cut-off, sensitivity, specificity without calibration (adjustment), and after adjustment have been examined. Using identical sperm preparation, matched acquisition settings, the performance of two flow cytometers and two observers has been examined to assess the strength of agreement of the results [175]. After adjustment of the settings, overall concordance was high and the two cytometers showed 100% positive and negative predictive value with 100% area under the curve. The overall correlation coefficient observed between C6 and C6 plus was highly significant ($p < 0.0001$; $r = 0.992$; 95% CI 0.982–0.997). After adjustment, the two cytometers showed very high precision of 98% and accuracy of >99%. The inter-observer agreement on C6 flow cytometer for the two observers was 0.801 ± 0.062 and 0.746 ± 0.044 for C6 Plus. A strong agreement was demonstrated between the samples tested on the two flow cytometers after calibration and established the robustness of both instruments [175].

The standard TUNEL assay can be improved to become more sensitive to DNA fragmentation by incubating sperm cells in 2 mm dithiothreitol (DTT) solution for 45 min prior to fixation with formaldehyde. This modified version of the TUNEL assay was shown to significantly enhance its sensitivity. Mitchell et al. modified the TUNEL methodology by incubating spermatozoa for 30 min at 37 °C with LIVE / DEAD Fixable Dead Cell Stain (far red) (Molecular Probes, Eugene, OR, United States). The cells were then washed three times with culture medium before incubation with DTT allowing both DNA integrity and vitality to be simultaneously assessed [176].

The TUNEL assay has been widely used in male infertility research related to sperm DNA fragmentation. A negative correlation was found between the percentage of DNA-fragmented sperm and motility, morphology, and concentration in the ejaculate [120, 177]. It also appears to be potentially useful as a predictor for IUI pregnancy rates, IVF embryo cleavage rates, and ICSI fertilization rates [19]. In addition, it provides an explanation for recurrent pregnancy loss [149, 177–179]. A predictive threshold of 19.2% has been shown significant differentiation between fertile and infertile men with a sensitivity of 64.9% and a specificity of 100% [57, 149]. This is higher than that demonstrated for IUI procedures (12%) [179]. A very high specificity (91.6%) and positive predictive value (90%) was reported at a cutoff point of 16.8% (Fig. 8.11a, b). The high specificity of the TUNEL assay is helpful in correctly identifying infertile patients who do not have sperm DNA fragmentation as a contributory factor [172, 180]. Due to its high positive predictive value, the assay is able to confirm that a man who tests positive is likely to be infertile due to elevated sperm

DNA fragmentation. A similar specificity (91%) of TUNEL was reported [181]. The calculated cutoff would be ideal as any value above this threshold will be strongly associated with infertility.

The TUNEL assay is relatively expensive and time- and labor-consuming. Also, a number of factors can significantly affect assay results including the type and concentration of fixative, fixed sample storage time, the fluorochrome used to

label DNA breaks, and the method used to analyze flow cytometric data [182]. The flow cytometric method of assessment is generally more accurate and reliable than fluorescent microscopy, but it is also more sophisticated and expensive and it presents limitations in the accuracy and reproducibility of the measures of sperm DNA fragmentation [182]. Fairly good quality control parameters with minimal inter- and intra-observer variation (<8%) have been demonstrated for the fluorescent TUNEL assay using the bench top flow cytometer [180, 183].

8.7 Limitations of Current Protocols

One of the criticisms on SDF testing is lack of standardization [184]. While it is true that some of the methods for SDF suffer from high inter-laboratory variation, other tests have been studied extensively to standardize the methods. To achieve this, it is recommended that the testing for SDF should be done in a facility equipped with appropriate instrumentation, qualified technicians, and with both internal and external quality control measures [185]. For example, in a blinded study, two experienced observers carried out inter- and intra-observer variation of TUNEL assay using bench top flow cytometer [183]. The mean TUNEL assay measurement from one observer was confined to the average measurement of the two observers combined with an absolute difference of 1.73% and percent difference of 6.68% in 80% of cases. On the other hand, one TUNEL assay measurement from one observer was likewise limited to the average measurement of the two observers with an absolute difference of 3% in 90% of the cases, while the percentage difference was 9.68% in 80% of the cases. In another study, standardization of the method on SDF testing was assessed in two reference laboratories [183]. No significant differences were detected between the duplicate results. The mean difference between the duplicate readings within each testing centers was 0.5%, while the correlation showed exemplary results ($r = 0.75–0.95$).

There are three categories in which SDF can be measured directly or indirectly [184]. These include the tests that measure the degree of compaction of the chromatin, tests that measure the DNA breaks before and after DNA denaturation and tests that measure SDF by inserting DNA probes or modified nucleotides at the site of damage. Due to these categories, the results measured from one SDF testing do not imperatively correlate with those obtained by the other tests [186]. In a prospective comparative experimental study on 20 sub-fertile men with unexplained infertility, SCD test measured significantly higher SDF compared to TUNEL assay (20.6 ± 14.0% vs 11.5 ± 7.3%, $p < 0.05$) [165]. However, these two tests were poorly correlated ($r = 0.29$) due to the fact that they implemented two distinct methods of SDF detection [165].

As it stands, there are still no clear cutoff values for SDF testing. Sharma et al. [172] provided a detailed protocol and quality control steps on SDF measurement using the TUNEL assay on 95 semen specimens from controls and 261 from infertile men. The positive predictive value was 91.4%, while the negative predictive value was 33.1%. Based on these findings, men with elevated SDF levels are most likely to present a challenge in their reproductive potential. Wewak et al. [84] determined the sperm deoxyribonucleic acid fragmentation index (DFI) of 26.1% as a cutoff point to differentiate infertile men and fertile men using the SCD assay. At this threshold, the prevalence ratio of 2.84 demonstrated the onset of male infertility. In another test using SCD, Lopez et al. [28] reported that the predictive cutoff value of 25.5% DFI could distinguish between successful and unsuccessful IVF or ICSI outcome from 152 infertile couples. SCSA was used to examine the relationship of DNA fragmentation with ART outcomes [59]. The chance of pregnancy in IUI was significantly higher if the value of DFI was 27%. On the other hand, IVF and ICSI outcomes were non-significant in groups with DFI less than 27%. In another study examining the effect of sperm DFI on pregnancy outcome and pregnancy loss in 531 couples after autologous ICSI ($n = 416$), donor egg procedure ($n = 39$), and IUI ($n = 76$), a cutoff of DFI 27% correlated with reproductive outcomes [187].

The current SDF testing methods cannot identify the nature of DNA damage and the location of DNA breaks [188]. Not all SDF tests measure the same damage. Aniline blue and toluidine blue determine the degree of chromatin decondensation while TUNEL, SCD, and SCSA measure DNA breaks [184]. Unlike the semen sample used in ART, SDF measurement is carried out using unprocessed semen [189]. Bungum et al. [132] assessed the effect of SCSA measurement in semen sample from 510 ART cycles prepared by density gradient centrifugation (DGC). No significant difference was seen in clinical pregnancy outcomes between SCSA performed in a neat semen compared to post DGC. In another prospective, observational study comprising of 44 non-azoospermic infertile men and nine fertile men, DFI measured by SCSA increased significantly in infertile men following DGC (25% vs. 15%, $p < 0.01$) [190]. This may reflect a potential deleterious effect of sperm processing on the integrity of sperm DNA. Similar results were demonstrated in 223 couples undergoing IVF where SDF measurements were analyzed by SCSA after swim-up preparation [191]. Although an abnormal DFI (> 27%) had a lower healthy embryo rate (13.2% vs 27.5%, $p < 0.05$), there was no noticeable significant differences in fertilization rate, clinical pregnancy rate, and delivery rate. Zini et al. [192] compared the effects of the two sperm processing methods on sperm DNA integrity in 22 semen samples collected from

non-azoospermic infertile men. SDF was significantly higher in Percoll-treated spermatozoa compared to samples processed by swim up (10.1% vs 4.8%, $p < 0.0001$). Mean sperm motility was significantly improved with the two methods ($p < 0.005$) [192].

8.8 Controversies of Sperm DNA Fragmentation

Varicocelectomy is recommended in men with a palpable varicocele and abnormal semen parameters [1]. In recent guidelines proposed by Agarwal et al. [193], elevated SDF testing levels may significantly shift the way fertility specialists are discussing varicocelectomy in men with normal semen parameters. Varicocele repair can be considered in infertile men with high grade varicoceles and normal conventional semen parameters or low grade varicoceles with abnormal conventional semen parameters. Multiple studies have determined that elevated SDF can be observed in men with varicoceles even in those with normal conventional semen parameters [63, 194]. Significant reduction in SDF is observed after varicocelectomy [195]. In a prospective study of 60 men with varicocele and abnormal semen parameters, DFI was significantly improved 3–6 months after varicocelectomy (from 29.49% to 18.78%, $p < 0.001$) [196]. There was a concomitant reduction in ROS ($p < 0.001$) and significant increase in total non-enzymatic antioxidant capacity (TAC) ($p < 0.001$) post varicocelectomy. In another prospective study of 72 infertile men with varicocele and oligozoospermia, a significant reduction in DFI was observed after varicocelectomy (from 34.5% to 28.2%, $p = 0.024$) [197]. Also, other semen parameters such as total sperm count, sperm concentration, percent progressive motility, percent normal morphology were also significantly improved. In recent study of 157 semen samples with varicocele, elevated sperm DFI measured by SCSA of more than 30% was significantly associated with poor motility and viability ($p < 0.01$). Likewise, abnormal sperm concentration was observed in men with high DFI (24.5% vs. 33.5%, $p < 0.05$) [198]. SDF testing can help physicians prognosticate infertile men with varicocele. Despite the improvement of SDF after varicocelectomy, there are a number of confounding variables [199]. Further research is warranted to understand fully the exact mechanism(s) of SDF in infertile men with varicocele.

Limited data is available to recommend the benefit of screening for SDF in unexplained infertility, recurrent pregnancy loss, and IUI failure [184]. Couples with unexplained infertility usually demonstrate DNA damage. Vandekerckhove et al. [200] examined the incidence of SDF in couples with previously unexplained infertility who underwent IUI. Using SCD test with a DFI of 20%, the incidence of SDF was 42.9%.

There is still an existing controversy regarding the predictive value of SDF testing the outcomes of IVF and ICSI procedures. SDF alone cannot predict the pregnancy outcomes due to a wide list of factors influencing the ART outcomes [184]. Although the negative impact of elevated SDF on the reproductive outcome in conventional IVF is well studied, its poor association with ICSI is not clearly demonstrated [6]. Lin et al. [135] investigated the relationship of SDF on the outcomes of IVF and ICSI. In 233 couples undergoing ART (IVF = 137; ICSI =86), no significant differences were observed in fertilization rate, good embryo rate and pregnancy rate between the two procedures even in low to high DFI (>27%). On the other hand, total and progressive sperm motility was negatively correlated with high DFI [201, 202]. The quality of post-implantation embryo and spontaneous abortion should be a concern with high DFI affecting the pregnancy outcomes [88, 203]. Cissen et al. [204] performed a systematic review and meta-analysis of 30 extractable data on SDF and clinical outcomes of medically assisted reproduction. TUNEL assay, SCD test, and Comet assay showed no predictive values between IVF and ICSI outcomes. Due to the significant limitations of the evidence available, further research is needed to determine the effect of SDF in reproductive outcome after medically assisted reproduction. In contrast to the recent systematic review and meta-analysis, Simon et al. [205] provided sufficient evidence that SDF has negative impact on reproductive outcome following ART procedures. SDF significantly affects the clinical pregnancy after IVF (OR = 1.65; 95% CI: 1.34–2.04; $p < 0.0001$) and ICSI (OR = 1.31; 95% CI: 1.08–1.59; $p = 0.0068$).

Numerous factors can affect the reproductive abilities not only of men but also of women. This is the reason why both partners in an infertile couple should be evaluated at the same time during the assessment of their fertility status. The role of female factors should be addressed in the management of men with SDF [206]. Jin et al. [207] investigated the impact of SDF in 2865 women with different ovarian reserves who underwent ART procedures. Live-birth rate and implantation rate were significantly reduced in women with reduced ovarian reserves when DFI is above 27.3%. In contrast, women with normal ovarian reserves did not demonstrate significance in clinical pregnancy, live-birth rate, and implantation rate with the same values of DFI. Carlini et al. [90] conducted a study on the male factor in 114 Italian infertile men whose wives had recurrent pregnancy loss following natural conception. SDF values were significantly higher in infertile men compared to the controls (18.8% vs 12.8%, $p < 0.001$).

Based on the results of SDF testing, clinicians may advise the infertile men to take measures to decrease SDF. Yet, there is a lack of evidence to demonstrate that lifestyle changes will improve SDF in men with borderline abnormal or normal conventional semen analysis [184]. Improvement in

dietary patterns was able to reduce the DFI ($p = 0.05$) in 336 men with normal sperm concentration or slight oligozoospermia. In addition, higher sperm concentration and higher level of serum testosterone were observed. The use of antioxidants has also shown a beneficial impact on basic semen parameters, advanced function, outcomes of ART procedures, and live-birth rate [208].

In a placebo-controlled, double-blind, randomized study of 77 infertile men with DFI more than 25%, there was no statistically significant difference observed in those men taking antioxidants for 6 months. Although sperm concentration was significantly improved after the treatment period of 3 months ($p = 0.028$) and 6 months ($p = 0.053$) [209]. Intake of antioxidants (vitamins with zinc and selenium) resulted in significant reduction of SDF (−19.1%, $p < 0.0004$) after 90 days of treatment. In another study, Greco et al. [210] evaluated 38 men with DFI more than 15% and whose wives had one failed ICSI attempt. After 2 months of treatment with antioxidants (vitamin C 1 g/day, vitamin E 1 g/day), significant improvement in clinical pregnancy (48.2% vs 6.9%) and implantation rates (19.6% vs 2.2%) were observed. Despite these findings, further studies with appropriate methodological designs are warranted to determine the benefit of antioxidant therapy to resolve SDF. Despite these findings, antioxidant therapy is a reasonable option for the management of infertile men [211].

8.9 Common Laboratory Protocols for Measuring DNA Fragmentation by TUNEL and Flow Cytometry (Direct and Indirect Methods)

Sperm DNA integrity is fundamental in sustaining the reproductive potential of a man. This is relevant because of the popularity of ART procedures, which bypass natural selection barriers unlike in the natural process, which only selects sperm with intact DNA to undergo fertilization. The endonucleases which are activated during programmed cell death degrade the sperm chromatin initially into fragments (30 kb) and then into much smaller fragments (50 kb) [180]. DNA fragments being produced during this process can be detected by TUNEL assay. Flow cytometry and fluorescent microscopy can identify the DNA strand breaks using TUNEL assay [28, 212].

The TUNEL assay is one of the most promising methods to measure SDF. This measures both single and double DNA strand breaks. It directly quantifies DNA damage while other tests assess the DNA integrity indirectly by examining its susceptibility to acid or alkaline denaturation. It is detected by flow cytometry making it a robust evaluation for SDF [173, 183, 213]. The modified dUTP can be labeled either directly with fluorescein-dUTP or indirectly through labeled antibodies or streptavidin. Flow cytometry is used in quantification with TUNEL assay which make rapid evaluation of more than 10,000 spermatozoa per sample. This is combined with staining of the nucleus with propidium iodide (PI) to factor out apoptotic bodies in the semen sample which allows additional diagnostic power in two distinct intensities of the spermatozoa. Spermatozoa with normal DNA integrity will only demonstrate background staining. On the other hand, those fragmented DNA with multiple chromatin 3'OH ends will fluoresce brightly [117].

The protocols must be standardized and validated before it can be used in clinical practice. Sharma et al. [180] reported an earlier detailed standardization of the TUNEL assay with less than 10% on both inter- and intra-observer variability and inter assay variability. With a sensitivity of 64.9% and specificity of 100%, a threshold value of 19.25% can differentiate infertile men with SDF from fertile men. In a more recent study on the standardization of TUNEL assay, the cut-off value of 16.8% showed a specificity of 91.6% and sensitivity of 32.6 with a positive predictive value of 91.4% and a negative predictive value of 33.1%. At this threshold, abnormal SDF level are strongly indicative that SDF may be the cause of reproductive incapacity of a man [172].

8.10 Challenges Using Indirect Assays to Measure DNA Integrity by TUNEL Assay

Ribeiro et al. [214] compared the efficacy between the indirect antibody-based labeling system (BrdUTP/fluorescein-anti-BrdUTP) and the direct labeling system (fluorescein-dUTP). Both labelling systems showed similar staining functions in live spermatozoa. When compared to direct labeling system, the TUNEL indirect labeling system underestimates the SDF with the differences ranging from 19.2% to 85.3% ($p < 0.05$). These differences were more pronounced in semen samples with total motility less than 40% or weak propidium iodide stained spermatozoa (PI dimmer spermatozoa) higher than 14%. In addition, a major difference was observed when dead spermatozoa were stained (40.1% vs 65.7%, $p < 0.05$). There was a correlation between the number of immotile spermatozoa and the intensity of difference between the two labeling systems. Indirect TUNEL labeled to lesser extent the PI dimmer population. Compared to direct labeling, indirect labeling only stained a small number from the PI – dimmer population (90.6% vs 17.9%). Overall, only 30–100% of the total number of spermatozoa stained with direct TUNEL labeling system was stained with indirect method. In this study, the most probable reason in the different staining efficiency of both the labeling system was due to the steric hindrance of the antibody during its binding to the BrdUTP. In addition, condensed chromatin

architecture in dead spermatozoa contributed to the staining differences.

In earlier studies, measurement of TUNEL assay was highly correlated with sperm vitality [176, 215]. There was a significant difference on the staining efficiency of the dead population of indirect labeling compared to direct labeling (40.1% vs 65.7%, $p < 0.05$). On the other hand, no significant difference was found on staining the number of live spermatozoa using both TUNEL labeling methods 8.9% vs 8.3%, $p > 0.05$) [214]. TUNEL assay should be standardized in all laboratory centers performing this specialized test. This will help clinicians to further assess these infertile men whose treatment options may highly depend in the results of SDF testing.

8.11 Common Direct Methods to Measure DNA Integrity

Apart from the TUNEL assay, the comet assay is likewise a direct method to measure SDF. This quantifies the amount of DNA damage per spermatozoon. The degree of SDF is proportional to the intensity and length of the DNA fragments that stream out of the sperm head. This represents the amount of migrated DNA which looks like a comet with a tail when viewed under the fluorescent microscope and DNA stains. This assay is beneficial for men with severe oligozoospermia as low as 5000 sperm [216]. Comet assay can detect alterations in DNA bases aside from its identification of the usual DNA strand breaks. However, this is not a rapid test, as it demands highly specialized personnel to run the assay.

8.12 Current Challenges in Sperm Chromatin Integrity Tests

Well-known professional specialty societies do not recommend the routine use of SDF testing in the evaluation of men presenting with problematic reproductive potential [217]. This is due to unavailability of good quality methodological studies in support of the application of this laboratory test in the clinical scenarios. On the other hand, there is a wide list of evidences including systematic reviews and meta-analyses demonstrating the beneficial impact of SDF testing to reproductive outcome. Despite these findings, different professional societies still do not recommend the routine use of SDF testing in the evaluation of infertile men [1, 217, 218]. In a strengths-weaknesses-opportunities-threats (SWOT) analysis by Esteves et al. on the clinical utility of SDF testing, 51 out of 58 fertility expert participants were supportive of the recommendation set by the clinical practice guideline. Thirty participants expressed their concerns regarding the technical weak points of the SDF testing [184].

Cost of the SDF testing is one of the drawbacks of requesting this procedure. It was reported that SDF testing costs roughly $170.4 ± 122.9 (range $0–450). In a survey, 46.9% of clinicians expressed their unwillingness to utilize these test due to cost to the patients [219]. Majzoub et al. [219] developed a questionnaire to survey fertility specialists on major aspects of SDF testing. Forty-nine invited scholars from 19 different countries mostly composed of urologists (44.9%) completed the questionnaires. The majority (79.6%) of the participants commonly requested SDF testing as part of the evaluation of infertile men. TUNEL (30.6%) and SCSA (30.6%) were frequently utilized to analyze SDF. DFI of 30% was used as a threshold value by 61.2% of the participants. The most common indication to request for SDF testing was recurrent conventional IVF failure or pregnancy loss following conventional IVF (91.8%). The least common reason was to assess patients with low grade varicocele and subnormal semen parameters (46.9%). Cost (46.9%) and lack of validation (36.7%) were major factors for not requesting for SDF testing.

8.13 Future Direction

With support from the Society for Translational Medicine in endorsing the clinical practice guidelines for SDF testing in the evaluation of infertile men, other specialty societies may re-review their recommendations on the potential benefit of this specialized test [193]. There should be an expanded list of indications on who will benefit from this testing and not only be limited to practice recommendations. Good methodological studies should be conducted to determine the positive impact on the clinical utility of SDF testing in the evaluation of infertile men [220]. With more research, a solid evidence-based foundation for future utilization of SDF testing will benefit those men with reduced reproductive potentials as this might be their only hope to father a child.

8.14 Conclusion

In this chapter, we have emphasized the importance of assessing sperm chromatin integrity. Results of sperm assessment provide useful information in cases of male idiopathic infertility and in couples pursuing assisted reproduction. There are multiple assays that can be used to evaluate sperm chromatin. Each assay has advantages and limitations. Choosing the right assay is important and depends on factors such as equipment cost, availability of an andrology laboratory, and the presence of experienced technicians. It is important to determine the underlying cause of DNA damage and provide proper therapeutic treatment before attempting ART to minimize downstream potential side effects of offspring.

It is important to design methods for selecting sperm with undamaged DNA in ART, especially in ICSI. Assessment of sperm DNA damage can be a potential tool for evaluating semen samples prior to their use in assisted reproduction. It allows for the chance to select spermatozoa with intact DNA or with the least amount of DNA damage for use in assisted conception. It provides better diagnostic and prognostic capabilities than standard sperm parameters for assessing male fertility potential. There is a strong data supporting the inclusion of sperm DNA fragmentation in the evaluation of the infertile male.

8.15 Review Criteria

An extensive search of studies examining the relationship between sperm chromatin and sperm DNA fragmentation and male infertility and ART outcome was performed using search engines such as Google Scholar and PubMed. The start and end dates for these searches were September 1996 and September 2018, respectively. The overall strategy for study identification and data extraction was based on the following key words: "male infertility," "sperm chromatin," "reactive oxygen species," "infertile men," "DNA fragmentation," "marks of sperm chromatin assessment," "direct and indirect markers of sperm DNA fragmentation," "sperm DNA fragmentation and male infertility," and "sperm DNA fragmentation and ART failure." Articles published in languages other than English were excluded. Data published in conference or meeting proceedings, websites, or books was also excluded.

Proteomic and Metabolomic Fingerprinting in Male Infertility

9

Manesh Kumar Panner Selvam,
Damayanthi Durairajanayagam, and Ashok Agarwal

Key Points

- Semen proteomics is able to provide valuable information about the patho-physiological state of the spermatozoa.
- Integration of proteomics as a component of male infertility diagnosis in the clinical lab can help explain the underlying molecular etiology associated with specific infertility conditions.
- Metabolomics strategies could potentially be used to differentiate between fertile males and infertile patients or between two different infertility-related disorders.
- Male infertility-related disorders may each have specific metabolic profiles which could contribute toward the noninvasive diagnosis of infertility in males.
- Specific proteins or metabolites identified using the omics strategies may serve as potential biomarkers of a specific male infertility disorder and in the development of new therapeutic modalities.

9.1 Introduction

In the current scenario, infertility is a major concern among couples in the reproductive age group with a global prevalence of 9%. Infertility in 27% of these couples is due to both male and female factors while 38% is contributed by the female alone and 20% is attributed to the male factor. The remaining 15% of infertility problems are idiopathic [1]. An overall 50% of cases are contributed by male factor infertility [2]. Male infertility is a multifactorial disorder and it is evaluated based on the results of semen analysis tests. Conventional semen analysis is considered as the corner stone for the diagnosis of male infertility. It provides information about semen parameters such as sperm concentration, motility, morphology, and vitality. The World Health Organization (WHO) has provided well-established reference values for semen parameters to distinguish fertile men from infertile men [3]. Additionally, advanced tests are carried out along with basic semen analysis to determine the levels of oxidative stress and sperm DNA damage, which are a major cause of fertilization failure or male infertility [4, 5]. However, there are still other underlying mechanisms at a subcellular level of the spermatozoa that cannot be explained merely from the results of a conventional semen analysis.

On the other hand, omics studies are able to explain the molecular mechanisms underpinning male infertility using different approaches. The four main branches of omics include genomics, transcriptomics, proteomics, and metabolomics (Fig. 9.1). Among these omic studies, proteomics and metabolomics are being widely used in the field of male infertility. Semen proteomics and metabolomics are undertaken to understand the cellular pathways and metabolic pathways associated with normal gametogenesis and the role of proteins and metabolites in the fertilization process. Furthermore, proteomics and metabolomics analysis, with bioinformatic tools and metabolomic analysis along with chemometrics, serves as a promising tool in the identification of potential diagnostic and therapeutic biomarkers for the management of male infertility.

In recent years, the availability of advanced proteomic and metabolomic tools has increased the knowledge and understanding of the causes of male infertility. This chapter provides a brief overview of advanced proteomic and metabolomic techniques used in studies involving the sperm and seminal plasma of infertile males. It highlights the general steps involved in these omics approaches, including bioinformatic analysis of the proteomic data. Furthermore, pro-

teomic- and metabolomic-based studies in sperm and seminal plasma are discussed in detail, along with the potential role of biomarkers in the prognosis and diagnosis of male infertility.

9.2 Proteomics in Male Infertility

Proteomics is defined as the complete profiling of proteins extracted from a tissue or cell. The most commonly used proteomic approaches, such as shotgun or bottom-up, can identify more than 1000 proteins in a short period of time. Semen is considered as the biological fluid used for the diagnosis of male infertility. Cellular component of semen is made up of sperm (5%) and seminal plasma (95%). Sperm are transcriptionally and translationally inert gametes and rely on proteins for their functional activity. Currently, proteomics is being widely used in the field of male infertility to study the protein profiles in spermatozoa and seminal plasma [6–8]. High throughput platforms such as matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) and mass spectrometry coupled with liquid chromatography (LC-MS/MS) are used to profile a maximum number of proteins in the sperm and seminal plasma [9].

Advanced proteomic tools were used to identify more than 6000 sperm proteins. Using the data mining approach, 30 proteomic studies were analyzed and a total of 6198 proteins were identified in the spermatozoa [10]. A similar approach was used by Jodar et al., to identify 2064 proteins in the seminal plasma [7]. Any alteration in the sperm or seminal plasma proteome may have an adverse effect on the normal physiological function of the spermatozoa. Several proteomic studies have identified alterations in the sperm and seminal plasma proteome associated with male infertility conditions such as varicocele [11–16], idiopathic infertility [17–19], unexplained infertility [20–23], elevated oxidative stress [24–26], and testicular cancer [27, 28]. Moreover, the key proteins associated with vital sperm functions such as capacitation, hyperactivation, acrosome reaction, and fertilization process, are identified as potential noninvasive biomarkers to differentiate infertile men from normal healthy fertile men.

9.2.1 General Approach to Proteomics

Different proteomic techniques were used in the detection and identification of sperm proteins. The conventional approach includes the use of a two-dimensional (2D) gel electrophoresis of the extracted sperm or seminal plasma proteins. The proteins present in the sample are separated out based on the isoelectric focusing property and molecular weight of the peptides. Martinez-Heredia et al. identified a total of 98 distinct proteins in the human spermatozoa using 2D gel electrophoresis coupled with MALDI-TOF technique. The majority of these proteins were mainly involved in energy production, protein synthesis, and transcription process [29]. A modified version of the 2D gel electrophoresis technique, known as difference gel electrophoresis (DIGE), is used to identify differentially expressed proteins (DEPs) with a minimum error of <10% [30]. Based on the intensity of the different staining dyes (Cy3 and Cy5), the expression of the DEPs are determined on the same gel using automated image analysis software.

Conventional proteomic techniques have several limitations, such as decreased sensitivity, detection of a fewer number of proteins in a given sample, and the missing out in the detection of less abundant proteins. Investigators were able to overcome these limitations by using sophisticated and complex instruments such as MALDI-TOF and LC-MS/MS. These instruments can detect the maximum number of proteins even in samples that are of lesser concentration. Using the in-gel digestion-based LC-MS/MS approach, Johnston et al. identified 1760 sperm proteins and also reported the abundance of 26S proteasome complex [31]. Later on, several other studies also employed the LC-MS/MS-based proteomic profiling of spermatozoa in men with infertility disorders [22, 28, 32–34].

9.2.2 Assessment of Sperm and Seminal Plasma: Methods and Tools, Analysis, Bioinformatics

Proteomic analysis starts with the extraction of proteins either from the spermatozoa or seminal plasma. Seminal plasma are rich in proteins and are readily available for proteomic experiments without undergoing any purification process. However, prior to the extraction of proteins, sperm are subjected to several purification and processing steps. First, sperm are separated from the seminal plasma by the centrifugation technique. Apart from the sperm, semen also contains other cells such as round cells and immature germ cells. The round cells include both spermatogenic as well as non-spermatogenic cells. Investigators proposed that the use of sperm with round cells may contaminate the sperm proteome. Therefore, the density gradient centrifugation step was recommended and performed to isolate a pure fraction of the spermatozoa for proteomic analysis [35–39]. Recently, Paneer Selvam et al., conducted two proteomic studies to understand the role of contamination by round cell proteins in the proteome of sperm and their effect on biological pathways associated with sperm function [40, 41]. The presence of round cell proteins were masked by the sperm proteome, and the influence of non-spermatogenic round cell proteins was found to be very negligible or insignificant [40]. Moreover, the presence of these round cells and leukocyte proteins failed to show any effect on the molecular pathways associated with sperm function [41] (Fig. 9.2).

The isolated sperm are routinely washed for a minimum of three to four times with phosphate buffer saline to remove the remnants of seminal plasma. The sperm pellet, free from any contamination, is mixed with radioimmunoprecipitation assay (RIPA) buffer and left overnight. This results in the complete lysis of spermatozoa. Sonication of the spermatozoa suspended in an isotonic medium is also carried out to extract the sperm proteins. Extracted sperm proteins are checked for their purity and concentration, and then subjected to one-dimensional SDS-PAGE. Proteins separated by electrophoresis are subjected to in-gel digestion using trypsin. Digested proteins and peptides are eluted and injected into the mass spectrometry (MS) system. MS detects the peptides and proteins with an unbiased approach [42]. The proteins are identified with a very low false discovery rate based on their mass/charge ratio (m/z). To identify the post-translational modification such as acetylation, methylation, and phosphorylation in the sperm proteome, enrichment protocols are recommended. In addition, MS coupled with high performance liquid chromatography (HPLC) can simplify the detection of the complex proteins. Other techniques such as MALDI-TOF and SELDI-TOF (surface-enhanced laser desorption/ionization time-of-flight) are also successfully used to detect the sperm proteins [43, 44].

Initially, the complete scan of peptides detected by the MS is compared with the global database consisting of previously annotated and sequenced proteins. Computational software such as SEQUEST, Mascot and X! Tandem operating with different algorithms displays the complete list of proteins [45]. Furthermore, the proteins are categorized as DEPs based on spectral counts and abundance of each protein. These DEPs are used in the downstream bioinformatic analysis to understand the role of proteins in the molecular pathways [46]. Gene ontology (GO) analysis provides additional information such as localization and distribution of the proteins. Freely available bioinformatic tools such as STRING (Search Tool for the Retrieval of Interacting Genes/Proteins) are used to understand the interaction between proteins [47]. In addition, commercially available sophisticated software such as Ingenuity Pathway Analysis (IPA) and Metacore™ are used to obtain a complete picture of the

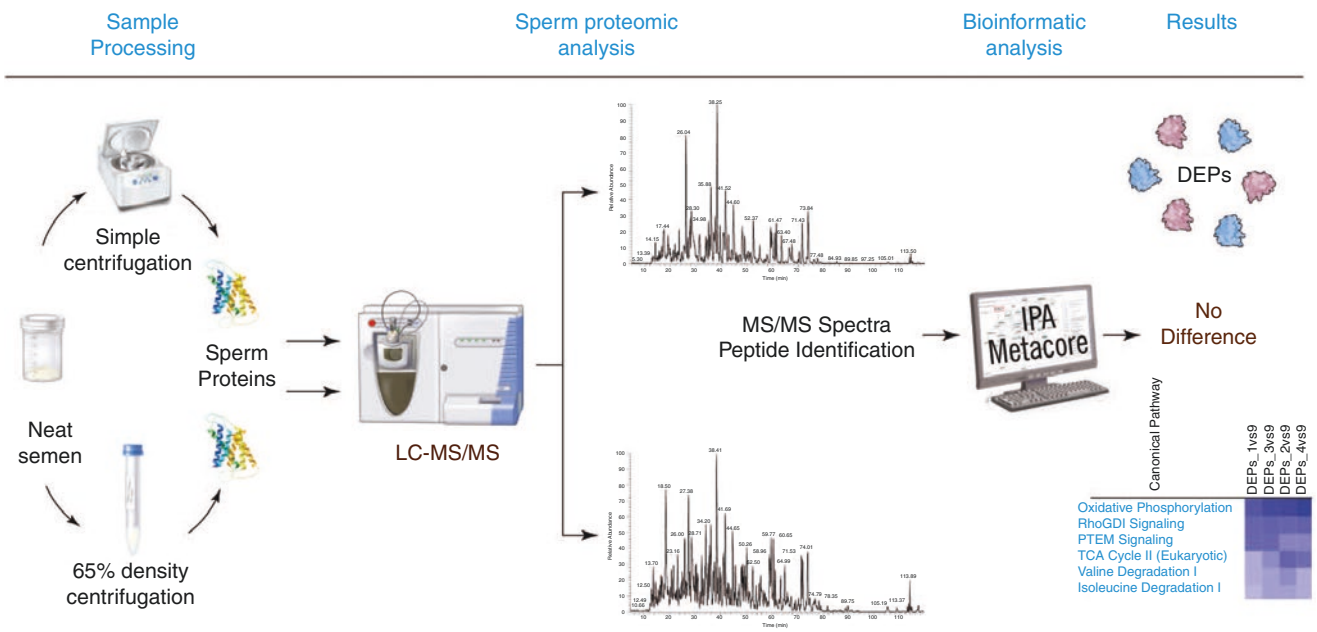

Fig. 9.2 LC-MS/MS analysis of sperm demonstrates the use of neat semen samples in proteomic/bioinformatic analysis. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2018–2019. All Rights Reserved)

interactions between the proteins and the transcriptional factors regulating their expression [47].

9.2.3 Sperm Proteomics

Any pathological state will alter the homeostasis and have a direct effect on the proteome of the tissue or cell. Changes in the proteome content of the spermatozoa may have deleterious effects on the fertilizing ability of spermatozoa. Several studies have identified the changes in the expression of the proteins associated with male infertility.

Proteomic profiling of sperm was performed on asthenozoospermic infertile men [48]. A total of 667 sperm proteins were identified in the asthenozoospermic men. These proteins were found to affect cellular pathways such as glycolysis, gluconeogenesis, and axoneme activation and nucleosome assembly [48]. Cao et al., demonstrated that proteins such as cytochrome c oxidase subunit 6B (COX6B), outer dense fiber 2 (ODF), and tubulin beta 2B (TUBB2B) involved in sperm motility were differentially expressed [32]. Similarly in another study on asthenozoospermic samples, Siva et al., identified that the proteins related to energy and metabolism, movement, and organization and protein turnover, folding, and stress response were significantly altered in their expression levels [49]. In addition to the proteins associated with sperm motility, the other protein components of proteasome complex were also differentially expressed [50, 51]. Moreover, phosphoproteome analysis of the asthenozoospermic samples showed that the dysregulation of these group of proteins were associated with cytoskeleton, fibrous sheath, and energy metabolism [52].

Globozoospermia is an abnormality of the spermatozoa that is associated with male infertility. Proteomic analysis of spermatozoa associated with globozoospermia revealed a total of 35 DEPs that play a vital role in spermatogenesis, cell skeleton, metabolism, and spermatozoa motility [53]. Also, perinuclear theca (PT) proteins were underexpressed and these were involved in acrosomal biogenesis, thus affecting the acrosome function in globozoospermic patients [54].

Proteomic analysis of sperm samples has identified the underlying changes or molecular pathology associated with varicocele condition. LC-MS/MS analysis of the sperm proteins in unilateral varicocele patients showed overexpression of 114 proteins and underexpression of 97 proteins. These DEPs were involved in sperm maturation, motility, capacitation, acrosome reaction, and fertilization [11]. Bioinformatics analysis demonstrated that small molecule biochemistry and post-translation modification proteins pathways were affected in infertile men with unilateral varicocele [11]. Agarwal et al. conducted a prospective study using the sperm samples from bilateral varicocele patients. A total of 73 DEPs were identified and the majority of these DEPs were involved in the regulation of functions such as metabolic processes, stress responses, and oxidoreductase activity. The remaining proteins were involved in sperm functions such as capacitation, motility, and sperm-zona binding [34]. Another proteomic study by the same researchers showed that the dysregulation of the mitochondrial proteins is a cause of male infertility in varicocele patients [16, 34]. The key DEPs

identified as biomarkers in different varicocele studies are presented in Table 9.1.

Testicular cancer has a deleterious effect on semen parameters and the fertilization potential of spermatozoa. The American Cancer Society estimated that there will be 9310 new cases and 400 deaths related to testicular cancer [55]. Several proteomic studies have been conducted for the diagnosis of testicular cancer [56–58]. These studies, however, did not examine the proteome of spermatozoa from testicular cancer patients prior to cancer treatment. Recently, Dias et al., profiled the sperm proteome in men with non-seminoma testicular cancer (NSTC) using the LC-MS/MS platform. They had identified a total of 189 DEPs in their study. Among the DEPs identified, NADH:Ubiquinone Oxidoreductase Core Subunit S1 (NDUFS1), ubiquinol-cytochrome C reductase core protein 2 (UQCRC2), and the testis-specific sodium/potassium-transporting ATPase subunit alpha-4 (ATP1A4) were proposed as the potential biomarker for NSTC patients. Furthermore, mitochondrial dysfunction is identified as the primary cause for the decrease in sperm concentration and motility [28].

9.2.4 Seminal Plasma Proteomics

Apart from sperm proteins, seminal plasma proteins are essential for sperm protection, maturation, and fertilization process. Male infertility conditions such as azoospermia, oligoasthenozoospermia (OAT), and varicocele showed alteration in the seminal plasma proteins [59].

Azoospermia may be either obstructive or non-obstructive. The seminal plasma proteome of azoospermic subjects revealed extracellular matrix protein 1 (ECM1) as a biomarker to differentiate obstructive azoospermia (OA) from non-obstructive azoospermia (NOA) and a differential expression of testis-expressed protein 101 (TEX101) in distinct NOA subtypes [60, 61]. A proteomic study by Yamakawa et al., proposed a total of 4 and 1 biomarker for NOA and

OA, respectively. The NPC2 protein was suggested as a potential biomarker for OA patients [62].

OAT is a semen abnormality condition associated with male infertility. Proteomic analysis of seminal plasma exposed a total of 2489 proteins in subjects with OAT [19]. Twenty-four proteins, primarily involved in metabolism and inflammation, defense, and stress responses, were highly expressed in idiopathic OAT (iOAT). A comparative proteomic analysis of oligoasthenozoospermic and normozoospermic seminal plasma revealed epididymal secretory protein E1 (NPC2) and galectin-3-binding protein (M2BP) to be underexpressed, while lipocalin-1 and a form of prolactin-inducible protein to be overexpressed in iOAT [33]. A recent comparative proteomic analysis identified DEPs involved in multiple biological functions such as binding activity (lactotransferrin, LTF; Prolactin-induced protein, PIP; extracellular matrix protein 1, ECM1), transporter activity (human epididymis-specific *protein* 1, HE1; Prostaglandin D_2 synthase, PTGDS), immune activity (CD177), and hydrolase activity (prostate-specific antigen) were differentially expressed in the seminal plasma of OAT subjects [63].

Seminal plasma proteins were also studied in varicocele patients. The first report on seminal plasma proteins identified 95 DEPs in cigarette smoking, adult varicocele patients. Seminal plasma proteins involved in sperm maturation and sperm–oocyte fusion were dysregulated in these varicocele patients [64]. Whereas, the expression of proteins associated with sperm motility and capacitation were altered in seminal plasma of adolescents with varicocele [65]. A study by Belardin et al. reported that insulin-like growth factor-binding protein 7 (IGFBP7) and deoxyribonuclease-1 (DNASE1) were involved in the regulation of apoptosis as seminal plasma biomarkers in adolescents with varicocele [15]. The seminal plasma proteomic signature also varied from before and after varicocelectomy. Cellular pathways such as oxidative stress and protein stabilization were enriched in patients after varicocelectomy. Proteins related to homeostasis function such as DJ-1, S100-A9, SOD, ANXA1, G3P, and MDH were upregulated and proteins associated with oxidative stress (such as NELFE) were downregulated after varicocelectomy [65].

Proteomic studies identifying DEPs associated with various male infertility conditions are listed in Table 9.1.

9.3 Metabolomics in Male Infertility

Metabolomics is the latest of the omics technologies that has been gaining traction in male infertility research over the last decade. Metabolomics involves the unbiased identification and quantification of all low molecular weight metabolites (< 1 kDa) within a biological system. The resulting metabolome consists of a complete set of these metabolites, which include secondary metabolites as well as hormones and other signaling molecules present in a biological sample [66]. Metabolomics may be applied on various biological samples, including that of bodily fluids (e.g. urine, blood plasma or serum, seminal fluid, follicular, or endometrial fluid) and various tissues in the body [67, 68]. As intracellular metabolites are in a state of dynamic balance with the metabolites in the biological fluids that perfuse these cells, the composition of biological fluids could therefore provide useful insights into the present metabolic state of the body [69].

Moreover, the study of the metabolome is comparatively less complex, provides more real-time information, and could give direct impact of a certain condition/stimuli on the body. For example, while genes and mRNA transcripts may run up to hundreds of thousands in numbers, and proteins to millions, the downstream products of metabolism (i.e., metabolites) only amount to a few thousand within the human metabolome [44]. These metabolites resemble the current phenotypic state of the cell more closely than the transcriptome and proteome do. This is because following gene expression, post-transcriptional and post-translational modifications take place, and these changes are relatively augmented in the metabolome compared to the transcriptome or proteome [70]. As such, metabolomic profiling of a particular biofluid or tissue could thus reveal the current health status of the individual [71].

9.3.1 General Approach to Metabolomics

There are several approaches that could be utilized when applying the metabolomics strategy to biological samples. Metabolomic fingerprinting provides a high-throughput, global and rapid biochemical analysis, which serves as a screening tool to differentiate between samples from healthy controls and that of diseased patients [66]. Changes detected in patient samples from that of normal samples are then correlated with the severity status of the disease or used to assess how an intervention is faring. On the other hand, metabolomic profiling involves the identification and quantification of a selected number of pre-defined metabolites that are involved in a particular metabolic pathway [66], while untargeted metabolic profiling is commonly done as a comparative analysis between the control and treatment groups. Both metabolomic fingerprinting and profiling have been applied to studies dealing with infertile males. Yet another approach is metabonomics, which deals with the quantitative analysis of metabolites in response to either disease or therapeutic treatment or to genetic modification. No matter the approach utilized, all metabolomics strategies include the identification and quantitation of metabolites [72].

The detection of metabolites in human metabolomics studies may be approached as either targeted or untargeted (global) (reviewed in Agin et al. [73]). Studies that employ the targeted approach have a specific hypothesis which warrants the investigation of certain biochemical pathways. Therefore, pre-determined metabolite-specific signals and analytical standards are employed to quantify the concentrations of a specific number of known metabolites in a precise and accurate manner. On the other hand, the global approach aims to measure and compare as many signals as possible without knowing the nature and identity of the metabolites beforehand. Thus, complex datasets are generated along with metabolites that are yet to be characterized. Global metabolomics studies provide only qualitative and semi-quantitative data, however, these studies help identify unknown metabolites, new pathways and generate hypotheses [74–77]. The study of the metabolome is multi-disciplinary and involves disciplines such as analytical chemistry, chemometrics, and biology. Analytical chemistry is useful during sample preparation, generation of metabolic profiles, and elucidation of metabolic structure. Chemometrics is required to extract the most pertinent information from the large datasets generated, for example, in studies using the metabolic fingerprinting strategy. Biology is necessary for understanding the observations, underlying mechanisms of action, and metabolomics pathways of interest [78].

9.3.2 Analysis of the Metabolome

Analysis of the metabolome is generally performed in four main stages: (1) collection of samples (sampling, quenching, and storage), (2) preparation of samples (extraction of metabolites, dilution, and clean up), (3) acquisition of data, and (4) analysis of data to generate a metabolic profile [78, 79].

Samples used in studies pertaining to male infertility include testicular tissue, seminal plasma, spermatozoa, blood serum and plasma, and urine (Table 9.2). The sample chosen for a particular study is influenced by the type of sample that can provide the most information for the intended study, its feasibility, as well as ease of collection [80]. Moreover, each of these biofluids could provide different types of information. For example, urine has the highest amount of water-soluble molecules, whereas blood composition is less variable than urine [81].

Following sample collection, the sample has to be stabilized so that it represents the actual metabolome composition at the time of sample collection. This is done via a metabolism-quenching step in order to halt further metabolic reactions that could either generate or degrade metabolites. Samples are snap frozen in liquid nitrogen for this purpose and stored at −80 °C [82]. Next, the sample is prepared according to protocol. For example, solid matrices undergo an extraction step to transfer the metabolome compound into a liquid phase, whereas low volatile analytes that will be analyzed via gas chromatography (GC) will undergo a derivatization reaction step (e.g., alkylation, acylation, silylation) to increase its volatility and reduce its polarity [83, 84].

Analysis of the metabolome can be approached through several techniques including nuclear magnetic resonance spectroscopy (NMR), Fourier transform infrared spectroscopy (FTIR), near-infrared (NIR), Raman spectroscopy, liquid chromatography, or gas chromatography coupled with mass spectrometry (LC-MS or GC-MS, respectively). Each of these techniques has its own advantages and shortcomings that have been previously reviewed elsewhere [66, 68]. The data acquired are processed using software tools and analyzed using suitable statistical techniques to segregate fewer, relevant metabolites (i.e., potential biomarkers/differential metabolites) that could possibly differentiate the compared sub-groups. Experiments that follow would then focus on the potential biomarker metabolites and explanations of the changes observed [78].

9.3.3 Sperm Metabolomics

Back in 2009, Huser's group had used the micro-Raman spectroscopy technique on individual sperm cells of healthy males to examine if the Raman spectra of sperm chromatin packed within the heads of normal or abnormally shaped sperm cells showed any correlation with its protein content and DNA conformation [85]. While the efficiency of DNA packaging and relative protein content per cell differed between the morphologically normal and abnormal sperm, the study also highlighted the significant variation that existed in protein content and DNA packaging within sperm cells with normally shaped heads [85].

Some years later, Paiva and colleagues were the first to obtain a comprehensive metabolomic profile of mature human spermatozoa through the use of two complementary untargeted metabolomics strategies: proton nuclear magnetic resonance (^{1}H-NMR) spectroscopy and GC-MS in normozoospermic and asthenozoospermic samples [86] (Table 9.2). The NMR and GC-MS techniques identified 42 and 27 endogenous metabolites, respectively, with an overlap of four metabolites. The bulk of the identified metabolites belonged to the super classes of amino acids, peptides, analogues, organic acids, and lipids [86]. NMR and MS strategies provide complementary results that may be applied toward completing the metabolome of the mature human sperm cell.

Using the proton magnetic resonance spectroscopy (^{1}H-MRS) technique, Reynolds et al. determined the molecular composition of a live human spermatozoon from healthy vol-

Study population	Human body fluid/tissue	Analytical technique	Main study outcomes	Reference
Spermatogenic failure; obstructive azoospermia; oligoasthenozoospermic infertility	Seminal plasma	^{1}H-NMR spectroscopy	^{1}H-NMR spectroscopy could potentially be used to differentiate OA from NOA Peak areas for GPC, citrate and lactate in seminal plasma were smaller in azoospermic men Peak area ratios for citrate:lactate and GPC:lactate were altered in control vs. (i) spermatogenic failure, (ii) OA Peak intensity ratio for GPE:GPC was different between spermatogenic failure and OA subjects	Hamamah et al. (1993) [89]
Non-obstructive azoospermia	Seminal plasma	GC–MS	Proposed a novel diagnostic method for NOA patients using the TIC data of metabolites in seminal plasma 36 metabolites were identified as potential discriminatory biomarkers for different groups in NOA	Gilany et al. (2017) [91]
Non-obstructive azoospermia	Seminal plasma	Raman spectroscopy	The seminal plasma metabolome could be used to detect spermatogenesis in NOA patients This metabolomics technique can be applied to detect major metabolomic alterations in seminal plasma of NOA from TESE(+) vs. TESE(−) cases TESE(−) patients had severe oxidative imbalance compared to TESE(+)	Gilany et al. (2018) [92]
Non-obstructive azoospermia (maturation arrest or Sertoli-cell only); normozoospermia (vasectomy reversal)	Testicular tissue	^{1}H-NMR spectroscopy	Testicular concentrations of phosphocholine and taurine were significantly different between normal, and SCO tissue Phosphocholine concentrations were significantly higher in testes with spermatogenesis ^{1}H-NMR spectroscopy could be used to discern a distinct metabolic signature for spermatogenesis, thus contributing to the non-invasive diagnosis of sperm in men with NOA	Aaronson et al. (2010) [96]
Non-obstructive azoospermia and obstructive azoospermia	Testicular tissue	Raman spectroscopy; GC/TOF-MS	Raman spectroscopy could be used to discriminate between samples of NOA and OA testicular tissue Raman spectroscopy could be used to non-invasively differentiate seminiferous tubules with complete and incomplete spermatogenesis. Levels of 12 metabolites were altered between NOA and OA testes (increased: cis-Phytol, glutamine; decreased: S-carboxymethylcysteine, fructose, arachidonic acid, etc.)	Liu et al. (2014) [97]
Non-obstructive azoospermia	Blood serum	HPLC-MS/MS	Serum metabolomic profile could be used to differentiate NOA patients from fertile males 24 metabolites were identified as potential markers, many of which were involved in energy production, oxidative stress, and cell apoptosis in spermatogenesis Metabolic pathways of glycometabolism, lipid metabolism, and amino acid metabolism were disrupted in NOA males Serum metabolic disorders may contribute to the etiology of NOA	Zhang et al. (2017) [115]
Oligozoospermia; normozoospermic infertility	Seminal plasma	^{1}H-NMR spectroscopy	^{1}H-NMR spectroscopy could potentially be used to differentiate normozoospermia from oligozoospermia 10 biomarkers were detected Alanine, citrate, GPC, tyrosine, phenylalanine could be used to screen for MI	Gupta et al. (2011) [102]

Table 9.2 (continued)

Study population	Human body fluid/tissue	Analytical technique	Main study outcomes	Reference
Oligozoospermia	Urine	LC/QTOF–MS	Oligozoospermic infertile men could be differentiated from fertile controls based on altered urinary metabolomic profiles Oligozoospermia seems to be associated with energy consumption and antioxidant defenses in spermatogenesis The combined pattern of acetylcarnitine, carnitine C3:1, and aspartic acid provided moderate diagnostic power for oligozoospermic infertility	Zhang et al. (2014) [95]
Asthenozoospermia	Seminal plasma	Raman spectroscopy	Metabolomic fingerprinting could be used to discriminate between asthenozoospermic and normozoospermic males	Gilany et al. (2014) [90]
Asthenozoospermia	Seminal plasma	^{1}H-NMR spectroscopy	Nineteen metabolites were either up- or down-regulated Asthenozoospermia-related changes of metabolites in lipid, phospholipid (choline), cholesterol, nucleoside, Krebs cycle, and energy metabolic pathways were detected Oxysterols (5α-cholesterol and 7-ketocholesterol) were raised in seminal plasma of patients with asthenozoospermia Oxidative stress is an underlying mechanism in the development of asthenozoospermia	Zhang et al. (2015) [93]
Asthenozoospermia	Seminal plasma	GC–MS	Of the 25 metabolites identified, 7 were significantly different in asthenozoospermic samples compared to controls Levels of oleic acid and palmitic acid were higher in seminal plasma of asthenozoospermic men, which may signify a metabolic disorder of the sperm membrane Deficiency of valine in seminal plasma of asthenozoospermic males may contribute to poor sperm motility	Tang et al. (2017) [116]
Asthenozoospermia	Spermatozoa	^{1}H-NMR spectroscopy and/or GC-TOF/MS	69 metabolites were identified in human sperm extracts: (i) 42 using NMR, (ii) 27 using GC-MS, (iii) 4 by both techniques (carnitine, L-threonine, gamma-aminobutyric acid, oxoglutaric acid) The majority of metabolites identified belonged to the amino acids, peptides, and analogues super class	Paiva et al. (2015) [86]
Idiopathic asthenozoospermia	Spermatozoa	GC-MS	33 metabolites were identified in spermatozoa 27 metabolites (e.g., 3-phosphoglycerate, lactic acid, glutamic acid, tryptophan, leucine, cysteine, guanosine, cytidine) were decreased in IAS group compared to controls 6 metabolites (zymosterol, dithioerythritol, orotic acid, 2-deoxyerythritol, benzoic acid, ethanolamine) were increased in IAS group compared to controls Pathways for nucleoside, amino acid and energy metabolism, and the Krebs cycle were either up- or downregulated) in IAS	Zhao et al. (2018) [88]
Idiopathic infertility, oligozoospermia, asthenozoospermia, teratozoospermia and azoospermia	Seminal plasma	NMR spectroscopy	Seminal plasma metabolomic profile of infertile males differed significantly from that of fertile males The metabolomic profile of idiopathic infertile men were clearly segregated from that of (i) fertile controls and (ii) other infertile groups The biomarker profile of idiopathic infertile patients differed from that of the other groups due to either up- or down-regulation of lysine, fructose, arginine, tyrosine, citrate, and proline	Jayaraman et al. (2014) [109]

(continued)

Table 9.2 (continued)

Study population	Human body fluid/tissue	Analytical technique	Main study outcomes	Reference
Unexplained male infertility	Seminal plasma	Raman spectroscopy	Metabolomic fingerprinting could be used as (i) a screening tool to diagnose male infertility and (ii) to study oxidative stress Men with unexplained infertility have (i) an imbalance of oxidative stress, (ii) increased biomarkers of oxidative stress, and (iii) absence of a functional antioxidant	Jafarzadeh et al. (2015) [94]
Unexplained male infertility	Seminal plasma	GC–MS	153 metabolites were identified in the seminal plasma of UMI subjects, of which 44 metabolites were differentially expressed in UMI compared to fertile controls Tryptophan, phenylalanine, glycine, serine, threonine, isoleucine, proline, and valine were decreased significantly; while urea and glutamine were increased significantly in UMI seminal plasma The major metabolic signature of UMI seminal plasma is the increased catabolism of various amino acids 4-Hydroxyphenylacetic acid is a key metabolite in differentiating between UMI and controls, and its seminal plasma concentration related positively to sperm counts	Qiao et al. (2017) [108]
Idiopathic normozoospermic infertility	Urine	LC/MicrOTOF–Q II MS	The urinary metabolomic profile could be used to differentiate normozoospermic infertile males from fertile controls 37 potential biomarkers were identified with functional roles in energy production, antioxidation, and hormone regulation in spermatogenesis A combination of the top 5 negative biomarkers (i.e. xanthosine, leukotriene E4, methoxytryptophan, 3-hydroxypalmitoylcarnitine, and aspartate) had the best diagnostic ability for detecting normozoospermic infertility	Zhang et al. (2014) [95]
Spinal cord injury-derived infertility	Seminal plasma	MALDI-TOF MS	85 ions were differentially present in seminal plasma of fertile and infertile men The lipids identified were mostly glycerolipids and were related to pathways for biosynthesis of CTP, UTP, and GTP Other metabolic pathways involved were sterol biosynthesis, arachidonic acid metabolism, and response to (i) hydrogen peroxide, (ii) steroid hormone, and (iii) vitamin Men with SCI-related infertility are likely to have altered signal transduction	Da Silva et al. (2011) [117]
Kidney yang deficiency syndrome-associated infertility (erectile dysfunction/premature ejaculation, weak ejaculation/orgasm disorder, oligozoospermia, asthenozoospermia)	Seminal plasma	LC/QTOF–MS	41 metabolites were differentially present in the seminal plasma of fertile men and infertile males with KYDS 7 metabolites were related to the 5 potential metabolic pathways Changes in metabolic pathways of biosynthesis and metabolism of aromatic amino acids, citric acid cycle, and sphingolipid metabolism may contribute to the development of KYDS-associated infertility	Chen et al. (2015) [118]

Table 9.2 (continued)

Study population	Human body fluid/tissue	Analytical technique	Main study outcomes	Reference
Kidney yang deficiency syndrome-associated infertility (erectile dysfunction/premature ejaculation, oligozoospermia, asthenozoospermia, azoospermia, teratozoospermia)	Blood plasma	GC–MS	Metabolomics profiles of infertile males with KYDS were identified 10 potential biomarkers (e.g., 1,5-anhydroglucitol, hydroxyvaleric acid) and 6 metabolic pathways (galactose glucitol, phenylalanine, glutamic acid, L-isoleucine, ornithine, lysine) could be used to discriminate between infertile males with KYDS and healthy controls Infertility in males with KYDS is probably associated with energy consumption and antioxidant defenses	Zheng et al. (2017) [119]
Erectile dysfunction; demen abnormalities	Blood plasma	GC–MS	Males with ED and semen abnormalities could be differentiated from fertile controls based on altered plasma metabolomic profiles 1,5-anhydro-sorbitol and α-hydroxyisovaleric acid are potential biomarkers to differentiate between infertile and fertile males Lactate, glutamate, and cholesterol could be used to discern between subjects with ED or semen abnormalities	Zhou et al. (2016) [120]
Young Danish men presenting with different sperm concentrations: (i) low (>0–20 × 10^6/mL), (ii) intermediate (45–75 × 10^6/mL), or (iii) high (>100 × 10^6/mL)	Blood serum	LC-MS	The serum metabolic profiles differed significantly between males presenting with different sperm concentrations Metabolites identified were mainly amino acids and carboxylic acids Peptides related to protein complement C3f (involved in innate immunity) were down regulated in men with low sperm concentrations and may serve as potential markers of fertility	Courant et al. (2013) [78]

unteers [87]. Sperm were obtained from fresh ejaculates using simple centrifugation or density gradient centrifuge (DGC) with either one or two washes. The DGC yielded sperm populations of 40% or 80%, which was then used to obtain the ^{1}H-MRS spectra. The lactate, lipid, and choline/glycerophosphocholine (GPC) peaks differed significantly between the ^{1}H spectrum of 40% and 80% sperm populations with greater differences evident in the 40% sperm population, which was more likely to possess greater structural defects [87].

Zhao and colleagues were the first to perform an untargeted metabolomics study utilizing GC-MS spectroscopy to compare the metabolic profile of spermatozoa from idiopathic asthenozoospermic and normozoospermic males [88] (Table 9.2). Results of this exploratory study showed dysregulation in amino acid and nucleotide metabolism pathways as well as disruption of glycolysis, Krebs cycle, and energy metabolism in patients with idiopathic asthenozoospermia compared to that of healthy males. Not only were the levels of amino acids (e.g., cysteine, leucine, tryptophan, and glutamic acid) found to be downregulated, guanosine and cytidine levels were also significantly lower in asthenozoospermic patients [88].

9.3.4 Seminal Plasma Metabolomics

A biochemical exploratory study of human seminal plasma in infertile males has been reported as far back as 25 years ago. Utilizing the ^{1}H-NMR method, the study measured the peak areas for glycerylphosphorylcholine (GPC), glycerylphosphorylethanolamine (GPE), citrate, and lactate in human seminal plasma to determine if these metabolites could act as biomarkers to differentiate between azoospermic and normozoospermic males [89] (Table 9.2). The study showed that azoospermic patients had significantly smaller peak areas for GPC, citrate, and lactate in seminal plasma compared to controls, while patients with spermatogenic failure and obstructive azoospermia differed significantly in their GPE to GPC peak intensity ratio [89].

Gilany et al. applied Raman spectroscopy in combination with chemometrics to differentiate between the seminal plasma metabolomic profile of asthenozoospermic and normozoospermic patients [90] (Table 9.2). Based on the Raman spectra obtained from the two groups, the researchers came up with a diagquadratic model that was able to predict between normal and asthenozoospermic samples with a validity of 83% [90]. Gilany's group went on to

examine the seminal plasma metabolome in patients with NOA using two different strategies: untargeted metabolomic profiling using GC-MS and advanced chemometrics [91] as well as metabolic fingerprinting via the Raman spectroscopy approach [92] (Table 9.2). Commonly, males with NOA undergo the invasive testicular sperm extraction (TESE) procedure for detection of sperm in their testes. However, in the untargeted metabolic profiling study, the researchers proposed the use of multivariate models as a new noninvasive diagnostic method to differentiate between fertile and NOA men who were either TESE positive or TESE negative [91]. Their 2018 study also proposed the use of the seminal plasma metabolome as a noninvasive method to detect spermatogenesis in NOA males who were either TESE positive or TESE negative. They also found that patients who were TESE negative had higher reactive oxygen species (ROS) levels compared to TESE positive males [92].

Similarly, Zhang's group conducted an untargeted metabolomic profiling study of seminal plasma using the H^1-NMR spectroscopy approach in asthenozoospermic males. They found that these patients had raised levels of oxysterols (i.e., 5α-cholesterol, 7-ketocholesterol), which suggests that oxidative stress is an underlying mechanism in their asthenozoospermic condition [93]. The role of oxidative stress in unexplained male infertility was also evident when Jafarzadeh and colleagues reported an increase in the –CH functional group (an oxidative stress biomarker) coupled with the absence of the –SH group (a functional antioxidant) that was detected in the Raman spectra of seminal plasma metabolome of these men [94] (Table 9.2).

9.3.5 Urine Metabolomics

In other studies, urine samples have been used to conduct a differential diagnosis between healthy men and diseased patients. For example, the urinary metabolome of normozoospermic infertile patients has been used to discern between normozoospermic infertile men and fertile controls [95] (Table 9.2). The group proposed that the potential negative changes in the citric acid cycle and hormonal activity during spermatogenesis, as well as oxidative stress are among the underlying events that could lead up to normozoospermic infertility [95].

In another study, Zhang's group showed that the urinary metabolomic profile of oligozoospermic patients (sperm concentration <20 M/mL) differed significantly from that of normozoospermic males [95] (Table 9.2). A stronger risk of oligozoospermia seemed to be indicated when biomarkers related to sperm concentration and amplitude of lateral head displacement was altered. Moreover oligozoospermia, a common indication in most male subfertility cases, was potentially associated with disruptions in fatty acid metabolism and antioxidant defenses in spermatogenesis [95].

9.3.6 Testicular Tissue Metabolomics

Metabolomics studies on testicular tissue have proposed noninvasive methods to diagnose either the presence of spermatogenesis in NOA men [96] or to differentiate between seminiferous tubules with complete or incomplete spermatogenesis cycles [97] (Table 9.2). In the latter, testicular tissue from azoospermic males (maturation arrest or Sertoli cell only) was snap frozen and subjected to ^{1}H-MRS. This method is potentially an alternative to testis biopsy as a diagnostic test to detect normal or abnormal spermatogenesis in azoospermic males [96]. In the former study, Raman spectroscopy was used to scan the seminiferous tubules within fresh testicular tissues retrieved from OA and NOA patients with a sensitivity of 90% and specificity of 85.71% in order to discern between seminiferous tubules that had complete spermatogenesis cycles and those that did not [97].

9.4 Potential Biomarkers of Male Infertility

By definition, a biomarker is identified as a characteristic biological marker that represents a condition, event, or process that can be quantitatively assessed, measured, and studied [98]. The biomarker should be highly sensitive, specific, and ideally be easily accessible in order to minimize the need for invasive and often inconvenient tests in the infertile male. In addition, such a biological molecule should facilitate a more detailed and precise classification of the infertile male [99]. Research studies that are evolving in the areas of genomics, proteomics, and metabolomics could potentially lead to the development of novel male infertility biomarkers [100].

The most commonly used biomarker to gauge the male fertility potential is semen analysis, which despite providing critical fundamental information, is highly variable and thereby a poor predictor of fertility [101]. In fact, some infertile males present with normal semen parameters in spite of their poor fertility potential [102]. As semen analysis alone is clearly inadequate to diagnose the infertile male, proteomic and metabolomic technologies are fast becoming potentially vital tools in identifying appropriate biomarkers for use in diagnosis, prognosis, and treatment of male infertility [103, 104]. Moreover, advances in bioinformatics and analytical technologies in the omics have helped further develop protein and metabolite profiling as a useful tool in biomarker discovery [59, 105].

Seminal fluid is made up mainly of seminal plasma and only a small volume of spermatozoa. Seminal plasma has a varied molecular composition and contains a high concentration of tissue-specific proteins which acts as an abundant source of potential biomarkers in the assessment of male fertility [61, 100]. Proteins such as the testis-specific TKTL1 (transketolase-like protein 1), LDHC (lactate dehydrogenase C), and PGK2 (phosphoglycerate kinase 2) seem to be able to serve as a biomarker to distinguish semen from fertile and infertile men [106]. TEX101, a cell membrane protein expressed specifically by testicular germ cells, is among the most promising biomarkers of male infertility [107]. TEX101 (testis-expressed protein 101) could act as a biomarker to predict TESE outcome and to differentiate between Sertoli cell-only syndrome and the other NOA subtypes (maturation arrest, hypospermatogenesis). In addition, the epididymis-expressed protein ECM1 (extracellular matrix protein 1) appears to be able to differentiate between NOA and OA [60]. Other examples of DEPs that could serve as potential biomarkers in the infertile male are shown in Table 9.1.

Metabolomics too shows great promise as a useful tool in disease diagnosis among infertile males [108]. Metabonomic profiling has been proposed as a tool to detect idiopathic infertility, as lysine concentration in the seminal plasma detected using ^{1}H-NMR was found to give a good indication of idiopathic infertility [109]. Qiao's group reported that patients with unexplained male infertility have increased catabolism of several amino acids that could impact male reproduction. Using a GC-MS-based metabolite profiling platform, the study had identified 4-hydroxyphenylacetic acid as a significant metabolite in seminal plasma that could help differentiate between males with unexplained infertility from those who were healthy [108]. Among asthenozoospermic males, deficiency in valine along with high levels of oleic and palmitic acids detected via GM-MS in their seminal plasma may serve as potential biomarkers of asthenozoospermia [108]. While 37 potential biomarkers were identified when comparing the urinary metabolome of infertile normozoospermic and fertile men, it seemed that the best diagnostic ability for the detection of normozoospermic infertility was obtained when a combination of the top five negative biomarkers (i.e., xanthosine, leukotriene E4, methoxytryptophan, 3-hydroxypalmitoylcarnitine, and aspartate) was applied [95].

9.5 Current Challenges and Future Outlook

Proteomics and metabolomics studies in the infertile male have to date identified a number of putative biomarkers for a variety of conditions related to male infertility, which can be used to distinguish between healthy fertile men and patients with a specific infertility disorder [6, 68]. Biomarkers that are identified using an omics approach may be associated with disease pathogenesis and could therefore offer novel therapeutic targets for the management of disease [110]. It is hoped that these omics studies would eventually pave the way for the development of biomarker molecules or panels of natural fertility in the diagnosis and treatment of male infertility [100]. In fact, a combination of biomarkers has the potential to deliver a higher predicative power than would a single biomarker [95, 111].

While differential proteomic and metabolomics studies have identified an extensive set of sperm proteins and metabolites that are present either in varied quantity or state in infertile males, further research is required before it can actually be utilized in a clinical setting [7, 68, 112]. An inherent challenge from all the datasets obtained is in developing clinically relevant biomarkers [112]. Discovery of potential biomarkers must be followed by analytical validation and evaluation of clinical utility, before it can actually be utilized clinically [113]. Despite the increase in the number of studies and the rapid advances in the strategies and analytics for biomarker discovery, translation of these biomarkers from bench to bedside remains at a slow pace [114]. However, as technology and analytics of omics studies improves, it is hoped that the cost of performing wider-scale omics studies also becomes concurrently more affordable in order to facilitate greater advancements in biological knowledge of human fertility.

9.6 Conclusion

There are a multitude of causes underlying male infertility which remain undiscovered. Greater understanding of the molecular and genetic mechanisms underpinning the male fertility potential is needed to determine possible intervention strategies for the management of the subfertile male. In addition to the advanced tests that aid in the determination of oxidative stress and DNA fragmentation in infertile patients, biomarker discovery promises of a viable alternative for the noninvasive diagnosis of male infertility-related pathologies. Proteomics and metabolomics strategies are rapidly growing analytical tools that complement each other in the goal to discover the biomarkers of infertility in the male. These biomarkers may aid in the evaluation of the male fertility potential, and to differentiate between the various etiologies of infertility, and perhaps even help predict successful outcomes of assisted reproduction technologies. Outcomes of studies utilizing omics approaches and bioinformatics would eventually yield in greater understanding of the spermatogenesis process, sperm function, as well as the events that follow fertilization. Awareness of the molecular and genetic basis of male infertility would immensely aid the clinician in the management of the infertile male.

9.7 Review Criteria

An extensive search of studies examining the relationship between proteomics and male infertility along with metabolomics and male infertility was performed using search engines such as PubMed, MEDLINE, OVID, Science Direct, and Google Scholar. The start and end dates for these searches were July 2018 and Dec 2018, respectively. The overall strategy for study identification and data extraction was based on the following key words: "omics", "proteomics", "proteins", "metabolomics", "metabolites", "male infertility", "infertility", "spermatozoa", "spermatogenesis", "seminal plasma", "semen", "seminal fluid", "urine", "serum", "blood", "testicular tissue", "biomarkers", "bioinformatics". Articles published in languages other than English were also considered, provided the abstract was in English. Data that were solely published in conference or meeting proceedings, websites, or books were not included.

Epigenetics and Male Infertility

10

Timothy G. Jenkins and Paul J. Turek

Key Points

- Epigenetics, the study of changes in DNA expression without alterations in the DNA sequence, is now thought to underlie much of human disease, including infertility.
- All four known epigenetic mechanisms, DNA methylation, histone modification and imprinting, non-coding RNAs, and chromatin remodeling, are thought to be active in spermatogenesis.
- Sperm epigenetics has the potential to provide a root cause for much of what is now termed "unexplained" infertility as well as oligospermia and sperm reproductive competence.
- Epigenetic changes that occur in sperm with paternal age appear to be non-random and may involve increased risk of neurodevelopmental diseases in offspring.
- As sperm epigenetic patterns are heritable, their significance to future generations extends to far more than simply infertility and includes familial and *de novo* disease transmission

10.1 Introduction

10.1.1 Definition of Epigenetics

Epigenetics is the study of heritable changes in gene expression that do not alter the underlying DNA sequence. By altering the way in which genes are read, changes in phenotype can occur without changes in genotype. Although every cell in an individual is genotypically identical, epigenetically, each cell's epigenetic signature is distinct, thus facilitating organ-specific differentiation. That is why a nose is not an eye and vice versa, despite having identical copies of DNA. Epigenetic changes are both natural and common occurrences and are influenced by age, environment, lifestyle, and illness. Epigenetic modifications underlie both normal development and also pathologic diseases such as cancer and autoimmunity (Table 10.1) [17].

10.1.2 History of Epigenetics

The term "epigenetics" was first coined by Waddington in 1942 from his work with *Drosophila* fruit flies [18]. He used the word epigenetics to describe the molecular process whereby environmental stress resulted in genetic "assimilation" of phenotypic characteristics. Although conceptually distilled by Waddington, the idea that the environment can influence genetics, that nurture can alter nature, is actually much older with origins ascribed to the eighteenth-century French naturalist Jean Baptiste Lamarck. His concept of "soft inheritance" preceded Darwin's evolutionary theory by 50 years. Whereas Darwin pictured evolution as occurring in rather large, generational "steps," Lamarck had earlier proposed that offspring inherit smaller, environmentally induced changes acquired by parents over their lives. In essence, Lamarck outlined a pathway for evolution that involved passing along traits that were gained from simply living and surviving or the "inheritance of acquired characteristics," an apt description of what we now call epigenetics. Ironically, while Lamarck has historically been considered the one who "got it wrong" in describing the mechanics of evolution, we now believe that certain inheritance patterns are best described by Lamarck's theory.

Our knowledge of epigenetics has exploded over the last quarter century. As outlined in Table 10.1, we now know that epigenetics underlies much of normal cell and tissue function as well as cancer biology, autoimmunity, psychiatric disorders, and intellectual disorders [1, 19]. However, its role as

a cause or consequence of infertility is only beginning to be understood. There is a strong sense in the field, though, that epigenetics is critically important to normal human fertility. Factors that complicate the study of epigenetic infertility are the largely continuous nature of the variables involved, the fact that epigenetics can change with age, a serious lack of a defined "normal" cell signatures and the wide variety of epigenetics marks and measures that exist.

10.2 Epigenetics Mechanisms

Four general types of epigenetic modification have been described. All of these are thought to be active in sperm.

10.2.1 DNA Methylation

DNA methylation is one of the oldest and best-characterized epigenetic mechanisms, first described in 1969 [20]. DNA methylation refers to the addition of a methyl (CH_3) group to the DNA strand, typically to a carbon atom of a cytosine ring. It fixes genes in the "off" position and is important for cellular processes like embryonic development, X-chromosome inactivation, genomic imprinting, gene suppression, carcinogenesis, and chromosome stability. Abnormal DNA methylation has been linked to several human diseases including lupus, cancer, muscular dystrophy, and congenital defects [19]. As an example, cancer cell genomes tend to show overall hypomethylation (i.e., are activated) relative to healthy cells which partly explains their malignant behavior.

10.2.2 Chromatin Remodeling

Chromatin is term used to describe the DNA and its associated proteins that are packed within the nucleus of cells. DNA forms chromatin when it is tightly condensed and wrapped around nuclear proteins called histones. The DNA–histone complex is called a nucleosome. When packed tightly in a nucleosome, DNA is relatively inaccessible to transcription factors and therefore unavailable for transcription. In this state, the DNA is called "heterochromatin." When more loosely packed, and accessible for transcription, it is called "euchromatin."

10.2.3 Histone Modification

Epigenetic modifications to histone proteins, also termed histone modification, commonly occur through methylation, phosphorylation, acetylation, ubiquitylation, and sumoylation. These modifications can alter gene expression by grossly or slightly modifying histone structure and are known to underlie biological processes such as transcriptional activation, chromosome packaging, and repair of DNA damage. This process provides another modifiable layer of gene regulation with the potential for heritability.

10.2.4 Non-coding RNA

A non-coding RNA is a functional RNA that is transcribed from DNA but not translated into protein. Non-coding RNAs thought to have epigenetic functions include microRNA (miRNA,) short-interfering RNA (siRNA), piwi-interacting RNA (piRNA), and long-non-coding RNA (lncRNA). In general, non-coding RNAs regulate gene expression at both the transcriptional and post-transcriptional levels and are known to play a role in heterochromatin formation, chromatin and histone modification, DNA methylation targeting, and gene silencing.

10.2.5 Genomic Imprinting

Genomic imprinting is an epigenetic process that involves DNA methylation and histone methylation within the germline (sperm or egg cells) of an organism. After fertilization, these marks are maintained in the early embryo despite the extensive epigenetic reprogramming that takes place early in development. This generates regions in the genome that have DNA methylation present on one parental allele but absent on the other allele. Imprinted areas are then maintained through mitotic cell divisions in the somatic cells of the individual during its lifetime in a parent-of-origin-specific manner. The precise number of genes known to be imprinted is

debated with some studies claiming to have identified over 1000 imprinted genes [21]. The lack of congruence in the data is largely a result of different tissues and species being screened. What is known is that inappropriate imprinting of certain genes has been implicated in several diseases to date, including defective spermatogenesis.

10.3 Sperm Epigenetics

The sperm epigenetic program is uniquely customized to meet the needs of this highly specialized cell. Sperm chromatin structure is one of the most complex structures in the eukaryotic genome, for good reason. Sperm must transport its genome through the male and female reproductive tracts, which necessitates a chromatin structure that is between six and twenty times more dense and robust than somatic cell nucleosome-bound DNA [22, 23]. The extreme compaction of the sperm head is also thought to enhance sperm motility and to protect the DNA from damage in a cellular environment that lacks robust DNA repair abilities [24]. To achieve this uniquely compact chromatin structure, canonical histones are first replaced with transition proteins. Subsequently, two forms of protamines (P1 and P2) take the place of transition proteins in DNA compaction in humans. This process of protamination essentially "blocks" the DNA from any epigenetic change or gene transcription, which make sense given the need to preserve the sperm genome during transport through both the male and female reproductive tract. In fact, the ratio of P1:P2 is tightly regulated at 1:1 in mature sperm and aberrations in this ratio have been correlated with infertility and poor egg fertilization [25–28].

Even more interesting is the fact that the replacement of sperm histones with protamines is typically incomplete, with between 5% and 15% of chromatin remaining histone-nucleosome-bound. Furthermore, the incomplete replacement appears not to reflect random inefficiency but rather a purposeful and programmatic process occurring in deliberate locations [29, 30]. As such, it is thought that histone retention allows for epigenetic modification of genes important for the embryo, including developmental gene promoters, microRNAs, and imprinted loci [29]. These recent findings now suggest that the sperm epigenome, previously considered silent and inaccessible, is actually critical for regulation of early embryo development [31].

10.3.1 Current Technology Used to Evaluate Sperm Epigenetics

The evaluation of sperm DNA methylation profiles is typically based on bisulfite conversion of extracted sperm DNA. This is most commonly assessed in three ways: using arrays, whole genome bisulfite sequencing, and targeted bisulfite sequencing. Among the most popular techniques to screen DNA methylation signatures in humans is the 850K (EPIC) methylation array (Illumina, San Diego, CA, USA). This array assesses the amount of methylation, or lack thereof, at over 850,000 CpGs and reports these methylation signatures as intensity values. Since intensity values reflect a sperm population average, the value effectively represents a "fraction methylation" at each CpG site. Informatic analysis of these data typically includes regional assessments (such as "sliding window" analyses) and point data analyses (assessment of a single genomic site of DNA methylation). This relatively simple format allows for rapid and reliable screening of most known, well-annotated gene promoters, CpG islands, multiple enhancers, and gene body methylation sites with impressive single base pair resolution. The most comprehensive assessment of DNA methylation comes in the form of whole genome bisulfite sequencing. This technology is quite reliable and can cover the entire genome, but has drawbacks including a high cost per sample and the potential loss of sensitivity to identify small methylation changes. One innovative variation on this technology is termed reduced representation bisulfite sequencing (RRBS) that provides similarly high-quality data but with more targeted coverage and at a lower cost. In addition, RRBS can be tailored to cover specific genomic regions of interest depending on the research goals. In addition to the assessment of DNA methylation, newer technologies show great promise in the assessment of sperm RNAs. Because sperm are transcriptionally quiescent, evaluating RNA can be difficult due to very low transcript numbers. However, RNA sequencing methods developed and modified from somatic cell protocols can effectively be used to assess sperm RNAs. These technologies including DropSeq (McCarroll Lab, Harvard Medical School) and the 10× Genomics (San Francisco, CA) platform have shown excellent performance in the evaluation of somatic cell RNAs. Hopefully, they will soon allow for the assessment of single sperm RNA as well.

Sperm chromatin, protamines, and histone modifications have been investigated using several techniques, including simple staining. More advanced techniques including ATAC-Seq or ChIP-Seq allow for the determination of not only the amount of an individual histone present but also the precise genomic location.

10.3.2 Value of Sperm Epigenetics to the Male Infertility Evaluation

The well-recognized inability of the standard semen analysis to predict male reproductive potential [32] needs no emphasis. The fact is that a semen analysis can inform us regarding a potential fertility problem but does not constitute a formal diagnosis. Its ability to predict pregnancy outcomes or to guide clinical decisions is limited. The wide variability in

quality between ejaculates further complicates the potential of the semen analysis to predict "fertility." On the contrary, an understanding of the sperm epigenome has the ability to not only improve the prediction of fertility but also to provide clues to the root cause of the underlying spermatogenetic disorder. Add to this the fact that DNA methylation signatures in mature sperm remain remarkably stable throughout spermatogenesis provides a foundation for a more reliable and relevant diagnostic test for sperm. Limitations in the evaluation of sperm epigenetics include data contamination with somatic cells, which is technically possible to overcome, and the fact the infertility is inherently a couple phenomenon, which makes isolation of male and female factors difficult in most cases.

10.3.3 Sperm Epigenetic–Fertility Phenotypes

The increasing ability of technology to reliably and relatively inexpensively screen the epigenome with high resolution has helped our understanding of the relationship between the sperm epigenome and fertility phenotypes. For example, RNA sequencing has allowed for the assessment of non-coding RNAs, miRNAs, and mRNAs in sperm [33, 34]. While we know that overall RNA content is very low in sperm and that much of the RNA appears to be "remnant" leftovers from spermatogenesis, there appear to be forms of RNA present that may play a role not only in sperm development but also in embryogenesis [34–37]. To date, published research has correlated sperm RNA content to the following fertility phenotypes: decreased IVF success rates [34] and decreased IUI success rates [38]. Similarly, there appear to be signatures in mature sperm methylation patterns that predict the likelihood that an individual will need IVF to conceive or if less invasive therapeutic interventions may be effective [39].

10.3.3.1 Abnormal Semen Analysis

The earliest research on the relationship between epigenetics and semen parameters focused on imprinted loci and measured methylation of sequences in one or only a few genes [40] Marques et al., (2004) examined the *H19* imprinted locus of men with various sperm concentrations and observed abnormal methylation in 0.13% of normozoospermic men, 17% of those with moderate oligospermia, and in 30% of men with severe oligozoospermia. In a study of men with teratozoospermia or abnormal sperm morphology, 11 of 19 patients displayed a loss of methylation at either *IGF2* or both *IGF2* and *H19* genomic sites [40]. Moreover, several studies have confirmed that the abnormal methylation patterns occurring in men with low sperm counts occur at both paternal (hypomethylated) and maternal (hypermethylated) genomic sites [40–43]. Kobayashi et al. (2007) examined the methylation status of seven imprinted genes in the sperm DNA of infertile men and found that when *both* maternal and paternal DNA was abnormally methylated, the finding of severe oligospermia was more common. Thus, abnormal methylation patterns associated with several imprinted genes of both maternal and paternal origin appear to correlate with low sperm concentration and abnormal sperm morphology. At this time, it is unclear whether abnormal DNA methylation among imprinted genes arises from de novo methylation or improper erasure of pre-existing methylation, although the latter seems to be a simpler mechanism [44].

Subsequently, as measures of DNA methylation improved with the advent of methylation arrays, the possibility of examining hundreds or thousands of different methylation markers across the genome was now realizable. In the first study to use a more extensive array of methylation measures, elevated methylation was found at numerous sequences in the DNA of poor-quality sperm from infertile men [44]. The high-throughput analysis addressed hundreds of DNA methylation targets and revealed significant correlations between methylation levels in 35 gene sequences and sperm concentration, motility or morphology. In four gene sequences, *NTF3, MT1A, PAX8, and PLAGL1*, there were striking correlations between methylation levels and abnormalities involving all three semen parameters. Notably, this study was the first to demonstrate that methylation abnormalities in non-imprinted genes are also associated with abnormal semen parameters.

10.3.3.2 Unexplained Infertility

Analyses of DNA methylation patterns in sperm have also identified candidate genetic loci associated with decreased fecundity. In a paired analysis of semen samples from men who had conceived within 2 months of attempting and men unable to achieve a pregnancy within 12 months, two genomic regions were identified as having significantly different methylation patterns between the cohorts [45]. Interestingly, there were no differences in semen volume, sperm concentration or morphology on routine semen analysis testing between the groups. The two sites in which methylation was associated with reduced fecundity are closely related genes that are known to be expressed in sperm: *HSPA1L* and *HSPA1B*. These observations suggest that abnormal epigenetic patterns in sperm might be linked to sperm function, egg fertilization, or embryo development in addition to their previously described association with semen parameters.

A more recent study expanded on the notion that sperm epigenetic patterns correlate with natural fertility and IVF success. Aston et al. [39] studied whether genome-wide sperm DNA methylation patterns can be used to predict male fertility and IVF success. As illustrated in Fig. 10.1, semen samples from a control group of $n = 54$ men with

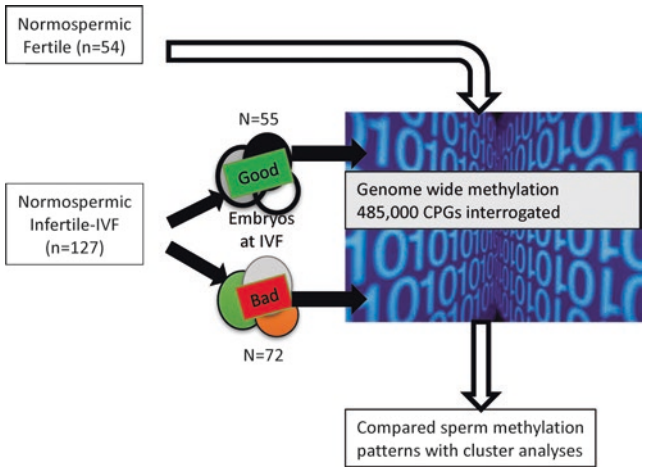

Fig. 10.1 Schematic of study design of genome-wide sperm DNA methylation patterns to predict male fertility and IVF success. Semen samples from a control group ($n = 54$ men) with normal semen quality and proven fertility were compared to infertile men ($n = 127$) with normal semen parameters with none-to-mild female factor infertility undergoing IVF. Genome-wide sperm DNA methylation analysis was performed to measure methylation at >485,000 sites across the genome

normal semen quality and proven fertility were compared to $n = 127$ infertile men with normal semen parameters whose partners were judged to have none to mild female factor infertility and were undergoing IVF. The infertile men were further divided into two groups: men whose partners produced high quality embryos at IVF along with many confirmed pregnancies ($n = 55$ men) and those whose partners produced generally poor-quality embryos ($n = 72$ men) with far fewer pregnancies. Genome-wide sperm DNA methylation analysis was performed to measure methylation at >485,000 sites across the genome. Notably, the sperm DNA methylation patterns were observed to be very stable across semen samples from each individual and maintained consistent difference in methylation patterns across individuals. They observed specific sperm methylation patterns that were highly predictive of fertility status, and somewhat predictive of IVF embryo quality. Predictive models generated based on cluster analysis were capable of correctly classifying male fertility status (fertile or infertile) with 82% sensitivity and 99% positive predictive value. In addition, modeling of the cluster analysis of sperm methylation patterns from infertile couples generating poor quality embryos achieved a positive predictive value of 94%. Finally, a comparison of sperm methylomes of fertile men vs. infertile men revealed >8500 CpGs that had differed significantly. When studying the specific genes with discrepant methylation, several gene classes were involved, including cellular adhesion, cellular morphogenesis and differentiation, and imprinted genes. This study was the first to use large array-based examination of sperm DNA methylation patterns and the first to build predictive models of fertility status using sperm methylation data. It also served as the basis for a commercially available mail in, sperm-based test of male fertility potential (Episona Seed® Assay) that was marketed in the United States from 2016 until 2018 and discontinued due to high testing costs.

10.3.3.3 Embryo Development and Miscarriage

If the sperm epigenome truly influences IVF success, might it act by altering embryo development and effecting miscarriage rates? A study by Denomme et al. [46] has provided early evidence to support the concept that the integrity of the sperm methylome correlates to embryo competence. The study involved comparing the blastocyst methylomes and transcriptomes of 128 couples undergoing IVF for male factor issues characterized by oligoasthenozoospermia to that of 72 surplus banked blastocysts derived from non-male factor patients. Sperm methylomes were not examined. Importantly, all blastocyst were biopsy-euploid to eliminate the influence of maternal or paternal chromosomal disorders on embryo development and pregnancy rates. Although the clinical pregnancy rates were similar after euploid embryo transfer in both male factor and non-male factor embryo transfers, the subsequent miscarriage rate was seven times higher in male factor cases (14.7% vs 2.2%, $p < 0.05$). In addition, there were significant differences in the embryonic methylomes (at 1111 Cpgs) and transcriptome (in 469 transcripts) analyses of embryos between the two cohorts. While the data do not show clear proof of inherited epigenetic dysregulation in blastocysts derived from severe male factor sperm, it does suggest an epigenetic consequence of male factor infertility on embryogenesis and miscarriage rates. The basis for a relationship between sperm DNA methylation patterns and IVF outcomes including miscarriages has now been realized and merits further study.

10.3.4 Sperm Epigenetics and Paternal Age

The relationship between advanced maternal age and pregnancy outcomes is undisputed [47]. Since the advent of epigenetics research, there is now increasing concern that paternal age is associated with non-random alterations in the sperm epigenome that may have implications not only for paternal fertility potential but also on offspring health. Several epigenetic alterations in sperm, particularly DNA methylation defects, have recently been correlated with advanced paternal age [48]. Sperm appear to accumulate hundreds of DNA methylation defects with paternal age that are localized to specific genomic sites, such as CpG regions [48–50]. Strikingly, many of these are found in regulatory or promoter regions and govern neurological, psychiatric, and behavioral disorders, including schizophrenia, bipolar disease, autism, and mood disorders [48–50].

A recent study analyzed age-associated sperm DNA methylation patterns in sperm [48, 51]. In addition to characterizing the type and magnitude of DNA methylation changes, the analysis examined if any specific genomic regions were consistently affected with age. As illustrated in Fig. 10.2, semen samples from men with known fertility were examined at two points in their lives: When they were "younger" (mean age 37.7 years) and "older" (mean age 50.3 years). Global methylation patterns were determined by pyrosequencing, and high-level CpG level array analysis and targeted bisulfite sequencing were performed. Overall, there was a significant global hypermethylation in sperm with paternal age along with localized regions of hypomethylation, which contrasts sharply with patterns of DNA methylation found in somatic tissues with age (i.e., global hypomethylation and localized hypermethylation) [52]. The authors calculated that the average fractional methylation change in sperm was 0.3% per year in hypermethylated regions and 0.28% in hypomethylated regions, both of which appear much higher than the 0.15% annual change in DNA methylation estimated to occur in somatic cells with age [52].

Equally or more intriguing were the study findings that consistently linked altered regions of sperm DNA methylation to genes associated with specific diseases (Fig. 10.1). In a 2014 study, Jenkins et al. found that the genomic loci exhibiting age-associated hyper- or hypomethylation appeared to be enriched at genes associated with bipolar disorder and schizophrenia. This finding suggests that sperm DNA methylation changes observed with paternal age are not randomly distributed within the genome, but could occur more frequently in neurodevelopmental gene sets. This observation is particularly striking when taken in the context of the increased incidence of neuropsychiatric disorders seen in the offspring of older fathers.

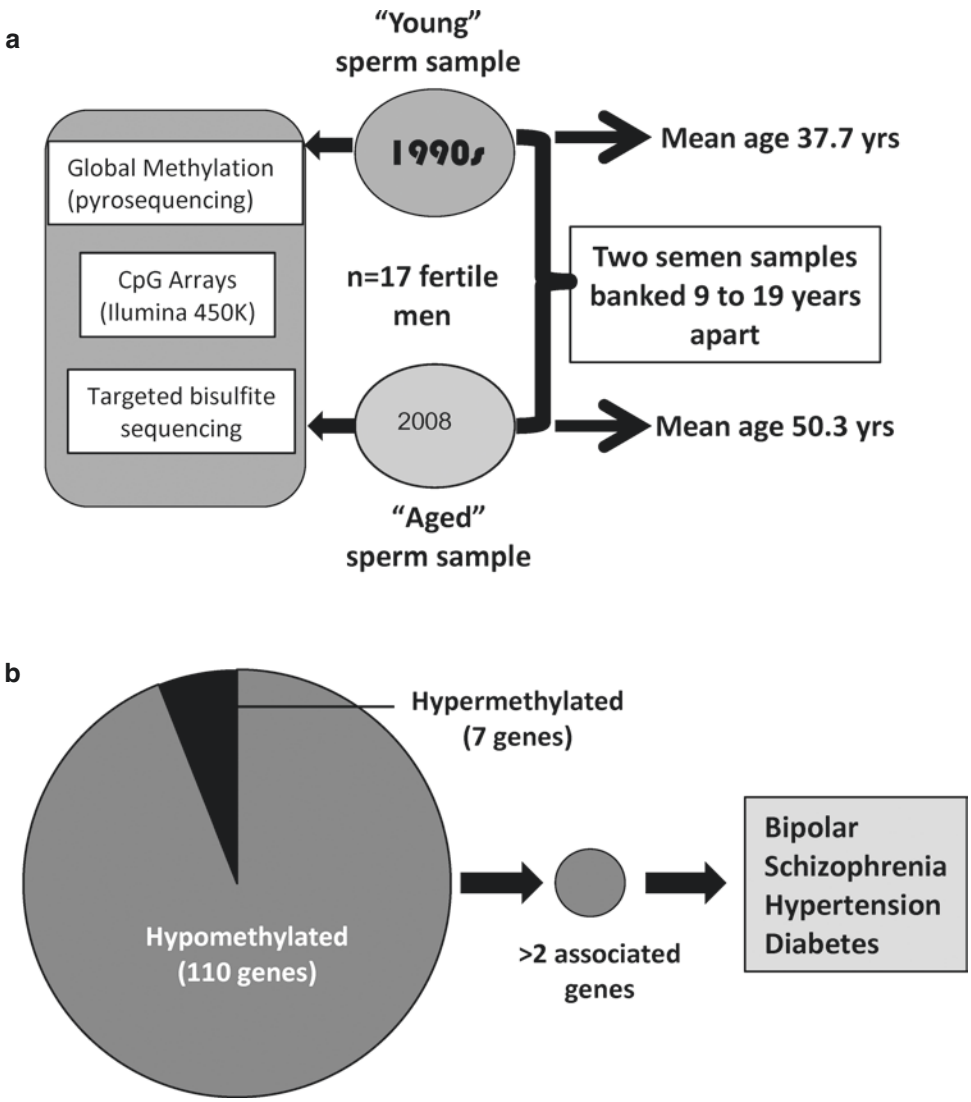

Fig. 10.2 Study of human sperm DNA methylation with age. (**a**) Schematic of study design and epigenetic investigations on sperm. The average difference in subject age between sperm samples was 12.6 years. (**b**) Schematic of study findings. Among the diseased associations with paternal age-related DNA methylation changes, only bipolar disorder reached statistical significance. (Reprinted from Yatsenko and Turek [59]. with permission from Springer Nature)

10.3.5 Lifestyle and Environmental Influences on Sperm Epigenetics

Not only paternal age but nutritional status (obesity) and physical activity levels have also been linked with dynamic epigenetic changes in human sperm [53, 54]. Although potential scientific confounders abound in the examination of environmental influences on sperm epigenetics, including the timing and type of environmental stimulus, the methylation methodology and choice of genomic sites, the type of bioinformatic analysis, somatic cell contamination and the source, purification and fractionation of sperm [55], studies to date are highly suggestive that lifestyle factors significantly modulate the epigenetic health of sperm.

10.3.6 The Hereditability of Sperm Epigenetics

The inheritance of epigenetic alterations in sperm is a plausible way to explain how phenotypic plasticity is transmitted across generations without involving formal genetic mutations [55]. It also lends a molecular mechanism to the mode of inheritance of acquired characteristics postulated by Lamarck more than 200 years ago. Animal models of paternal inheritance have shown that parental dietary factors can affect the metabolism of offspring through epigenetic inheritance [56, 57]. There is also burgeoning evidence from human epidemiological studies that the lifestyle of one generation can modify the risk of chronic disease in offspring through what is now termed "parental effects"[58]. Such modifications have to be transmitted through either sperm or eggs. Currently, the best evidence is that much of human epigenetic inheritance is paternal in nature [57], but this claim may be premature because the investigation of the oocyte epigenome (at least in humans) is ethically and technically far more challenging than studying the sperm epigenome.

10.4 Conclusion

The modern study of epigenetics is based on an old idea that recently found a molecular basis. Sperm epigenetics is a rapidly evolving field that is extremely pertinent to normal and aberrant human reproduction. Abnormal sperm epigenetic profiles appear to correlate not only with semen analysis parameters but also with reproductive competence as defined by embryo quality and miscarriage rates. Sperm epigenetic profiles also change with paternal age and are influenced by paternal lifestyle choices. As sperm epigenetic patterns are uniquely heritable, its significance takes center stage in the study of transgenerational transmission of disease to offspring.

10.5 Review Criteria

In order of importance, randomized controlled trials, scientific studies, meta-analyses, case-controlled cohort studies, and published reviews from 1942 to 2018 were used in this work. Articles published in languages other than English were considered. Data from conference or meeting proceedings, websites, or books were not included.

Genetic Aspects of Male Infertility

11

David Prokai and Orhan Bukulmez

Key Points

- There are a myriad of genes involved in the development and maturation of the male reproductive systems, and perturbations in any of these pathways may manifest in male infertility.
- Chromosomal abnormalities are more common in infertile men; thus, a standard karyotype is recommended in men with severe oligospermia. Additionally, Y chromosome microdeletion testing may be informative regarding the possibility of successful sperm retrieval via microsurgical extraction techniques.
- Cystic fibrosis transmembrane conductance regulator (CFTR) gene mutation testing is recommended in cases of CBAVD in addition to testing for the intended partner as well. Commercial CFTR tests may miss novel mutations in these patients.
- Male infertility is associated with increased risk of testicular germ cell tumors.
- Advances into the genetic origin of male infertility are evolving at a rapid pace. Mitochondrial DNA mutations, epigenetic alterations, copy number variants, and artificial gamete production are emerging areas of interest in male infertility but have not yet reached the level of clinical practice.

11.1 Introduction

Despite advances in our knowledge regarding the causes of male factor infertility, most cases still remain idiopathic [1]. As the genes and genomic regulation involved in male genital tract development, gonadal development, and spermatogenesis become better understood and delineated, new insights into male reproductive health will be gained. It has been estimated that genetic abnormalities may account for 15–30% of male factor infertility [1]. As genetic causes of infertility are clinically significant not just for the patient themselves but potentially for their future children, it is essential to appraise the current information on genetic basis of male reproductive system disorders and to be aware of the future developments in the field.

11.2 Genomic Regulation of Male Sexual Development

As it is essential for the evolutionary success of an organism to be able to reproduce, male sexual development is under very precise and often redundant genetic control. Perturbations in any of the sequences governing the development and maturation of the male gonad can have profound effects on the ultimate reproductive potential of the patient. From the fourth to the sixth week of gestation, gender-specific development relies on the migration of primitive germ cells along the yolk sac to an area consisting mainly of mesenchyme and underlying cells of mesonephric origin known as the gonadal ridges. Male developmental pathways depend on the presence and correct function of a male-determining gene located on the Y chromosome, aptly named *Sry* (sex determining region Y). The principal protein product of this gene acts on a specific set of gonadal ridge cells to stimulate differentiation into Sertoli cells, which are the cells that interact with and nurture the germ cells. Sertoli cells play a role in orchestrating the differentiation of other cell types required for testis formation such as germ cells and steroid hormone producing cells [2]. Importantly, Sertoli cells are the source of anti-Müllerian hormone (AMH), which is responsible for Müllerian duct regression. In the absence of *Sry* function, the developmental pathway proceeds to female differentiation, although in reality, sexual

S. J. Parekattil et al. (eds.), *Male Infertility*, https://doi.org/10.1007/978-3-030-32300-4_11

development is more complex involving multiple networks of molecular signals and the fragility of these pathways are reflected to the fact that disorders of sexual development are among the most common birth defects. These disorders can range from hypospadias to complete sexual ambiguity and sex reversal, which are often associated with infertility.

11.2.1 Testicular Development

Early formation of indifferent genital ridges is a requirement before testicular development. Studies in mice have shown that several transcription factor genes are required for this process. These genes include empty spiracles homologue 2 (Emx2), GATA-binding protein-4 (GATA4), LIM homeobox protein 9 (Lhx9), steroidogenic factor-1 (SF-1/NR5A1), dosage-sensitive sex reversal, adrenal hypoplasia critical region, on X chromosome, gene 1 (DAX-1/Nr0b1), and Wilms' tumor 1 (WT-1) [3–8]. WT-1 and SF-1 are crucial for formation of genital ridges in humans. Furthermore, they are both important in sex-specific gonadal development [9, 10]. DAX-1 levels and expression thresholds on the other hand are important for male versus female functional development [8].

Timely expression of *Sry* is essential for testicular development [11]. Spatially dynamic *Sry* expression begins in waves within the gonadal ridge, peaks for a short time, and then declines as demonstrated in mice [12, 13]. The mechanism of this specific and tight regulation of *Sry* regulation remains elusive. Decreased expression of *Sry* was noted in the presence of splice variant mutants of WT-1, GATA4, Friend of GATA (FOG2), and the insulin receptor family [2, 14]. Delayed expression of *Sry* has been implicated in XY sex reversals, unilateral or bilateral ovotestes, and delayed testis formation [13, 15]. It is thought that *Sry* expression must reach a certain threshold within a specific temporal window of competence in the precursors of supporting cells for proper testicular development. *Sry* encodes for a nuclear high-mobility group (HMG) domain protein that binds and bends DNA.

Downstream of *Sry*, other factors such as SRY-box containing gene 9 (SOX9), SOX8, DAX-1, and fibroblast growth factor 9 (FGF9) have important roles in Sertoli cell differentiation and function [16]. SOX9 is considered an early acting and essential component of male development pathway.

Peritubular myoid cells of the testis are necessary for testicular cord development and integrity. Differentiation of these cells correlates with Sertoli cell specific secretion of desert hedgehog (DHH). DHH receptor patched (PTC) is expressed on peritubular myoid cells and Leydig cells, and it has been demonstrated that null mutation of DHH in mice leads to impaired differentiation of peritubular myoid cells and Leydig cells leading to feminized males [16, 17]. DHH mutations in humans lead to partial or pure XY gonadal dysgenesis accompanied by impaired cord formation and decreased testosterone levels [17, 18].

Fetal Leydig cell development is essential for male sexual differentiation. The candidate genes important in Leydig cell differentiation include aristaless-related homeobox gene (ARX), α-thalassemia/mental retardation syndrome, X-linked (ATRX) and platelet-derived growth factors (PDGFs), and their receptor PDGFRA [19, 20].

Primordial germ cells migrate from their origin at the posterior part of the embryo through hindgut to populate genital ridges where they interact with somatic cells to form primitive sex cords. Germ-cell migration is facilitated by interferon-induced transmembrane proteins 1 and 3 (IFITM1 and IFITM3) [21]. Stromal cell-derived factor 1 (SDF1) and its receptor CXCR4 function in the colonization of genital ridges [22]. New genes of interests continue to emerge in the literature regarding testicular development, and only time will tell if they rise to the level of clinical significance.

11.2.2 Testicular Descent

Testicular descent occurs in two phases. The transabdominal phase of testicular descent happens between 8 and 15 weeks of gestation in humans and is controlled by insulin-like 3 (INSL3) hormone produced by Leydig cells, acting via its receptor LGR8 (also known as GREAT) [23]. The inguinoscrotal phase is usually completed by the 35th week of gestation and is facilitated by the neurotransmitter calcitonin gene-related peptide (CGRP or CALCA) released by genitofemoral nerve under the influence of androgens. Mutations in genes involved with androgen signaling and those that encode transcription factors homeobox A10 (HOXA10), HOXA11, and developmentally and sexually retarded with transient immune abnormalities (DESRT) lead to second stage arrest in testicular descent [24].

11.2.3 Spermatogenesis

More than 2300 genes have been estimated to play a role in spermatogenesis [25]. For example, the number of sperm-specific membrane proteins alone has been estimated to be greater than 200 [26]. One study showed that of 1652 genes whose expression increased with onset of meiosis, 351 of them were expressed only in the male germline [27], and there are many genes involved in DNA condensation, sperm maturation, adhesion, and motility as well. In patients with azoospermia, deleted regions on Yq have attracted clinical attention. Deletions in the azoospermia (DAZ) gene on Y chromosome belongs to a family of three members: DAZ, BOULE, DAZ-like. Their proteins contain a highly conserved RNA-binding motif [28]. DAZ proteins bind to RNAs and may be involved in posttranscriptional regulation of

mRNA expression [29]. The DAZ gene family is expressed exclusively in germ cells.

Many forms of partial deletions occur on Y chromosome in some male infertility cases [30]. These infertility related deletions are not considered to be inherited [31], and most infertile males do not show any mutations or deletions on the Yq. The majority of genes involved with spermatogenesis are located on autosomal chromosomes [32, 33]. For instance, mutations in protamine (PRM) and transition protein (TPN) genes involved with histone to protamine replacement which are located on autosomes have been found in 1/200–1/300 of male infertility cases in Japan [33].

As shown in mice, the X chromosome is enriched for spermatogenic genes functioning both in pre-meiotic and post-meiotic germ cells [34]. In humans, the examples of genes on the X chromosome important in spermatogenesis include structural maintenance of chromosomes 1A (component of meiotic cohesion complex, SMC1A) on Xp11.22-p11.21 and testis expressed 11 (binding protein expressed only in male germ cells, TEX11) on Xq13.1. The X chromosome seems to play more important role in the pre-meiotic stages of mammalian spermatogenesis.

11.2.4 Male Genital Tract Development

Full differentiation of the Wolffian (mesonephric) ducts (WDs) leads to the mature male genital tract. Urogenital sinus contributes to the genital tract by developing prostate. In XY embryos, Müllerian ducts degenerate in an active process facilitated by anti-Müllerian hormone (AMH) which is secreted by Sertoli cells. AMH binds to its receptor AMHR2 on the surface of Müllerian duct mesenchymal cells inducing secretion of matrix metalloproteinase 2 (MMP2), leading to apoptosis of Müllerian duct epithelial cells [35]. Failure of this process in humans results in persistent Müllerian duct syndrome (PMDS), an autosomal recessive condition, which can lead to male infertility [36, 37].

Wolffian ducts differentiate under the vital influence of high local concentrations of testosterone into the epididymis, vas deferens, and seminal vesicles [38]. Mice lacking androgen receptor (AR) show agenesis of the Wolffian duct structures. Bone morphogenetic protein 4 (BMP4), BMP7, BMP8, HOXA10, and HOXA11 genes play important roles in epididymis development. Additionally, fibroblast growth factor 10 (FGF10) and growth and differentiation factor 7 (GDF7) are essential in proper development of seminal vesicles [2, 33].

11.2.5 Male External Genitalia Development

Phenotypically male external genitalia largely depends on the expression of 5α-reductase in the genital tubercle mesenchyme converting testosterone to 5α-dihydrotestosterone (DHT) which is the most potent ligand for AR. Mutations of 5α-reductase result in abnormalities in male external genitalia and prostate development.

Complete androgen insensitivity syndrome due to X-linked AR gene mutation can lead to a full external female phenotype, but partial forms may present with various phenotypes ranging from ambiguous genitalia to male infertility. Other mediators important in male external genitalia include cell surface molecules like ephrins and their receptors (Ephs), Wnts, FGFs, BMPs, Noggin, and Hox genes [2, 39].

Urethral fusion defects can lead to hypospadias. HOXA13 and HOXD13 gene mutations reported in hand-foot-genital syndrome suggest that these genes are important in pathogenesis of hypospadias [40].

11.3 Genetic Defects Associated with Male Infertility

11.3.1 Numerical and Structural Chromosomal Abnormalities

Infertile men have an eight- to tenfold higher prevalence of chromosomal abnormalities than fertile men [41]. Chromosomal abnormalities can be detected in about 5% of infertile men and rise to approximately 15% in azoospermic men [1]. In a review of studies involving 9766 azoospermic and severely oligospermic men, sex and autosomal chromosomal anomalies were found in 4.2% and 1.5% of infertile men, as compared with 0.14% and 0.25%, respectively, in control population [42]. It should also be noted that 0.37% of sperm donors with normal sperm parameters have been reported to have chromosomal translocations [43].

Aneuploidy is the most common error resulting from chromosomal anomalies in infertile men [44]. Although many autosomal and sex chromosomes can be involved, the most common are Klinefelter syndrome, XYY syndrome, XX male syndrome, mixed gonadal dysgenesis, autosomal translocations, and Y chromosome microdeletions. Men with non-obstructive azoospermia present with the highest incidence of aneuploidy of up to 13.7% (predominantly numerical or structural defects) [45]. In men with oligospermia, a 4.6% prevalence of autosomal translocations and inversions was reported [46]. Sex chromosomal aneuploidy may account for approximately two-thirds of chromosomal abnormalities observed in infertile men [47].

11.4 Klinefelter Syndrome

Klinefelter syndrome is seen in about 1 in 500 male live deliveries and is the most common known genetic cause of azoospermia accounting for up to 14% of all cases [1]. It

results from X chromosomal aneuploidy in which 90% of cases carry an extra X chromosome (47, XXY) and 10% are mosaics as 47XXY/46XY. In about half of the Klinefelter syndrome cases, the extra X chromosome is paternally derived. The classic triad associated with the syndrome includes small and firm testes, azoospermia, and gynecomastia. It is also associated with eunuchoid body habitus with increased height, low intelligence quotation scores, varicosities, obesity, diabetes, increased incidence of extragonadal germ cell tumors, leukemia, and breast cancer. There is high phenotypic variation and many patients may not demonstrate these classic findings. The only invariant finding of non-mosaic form is that of small testes volume of 2–4 ml. The laboratory findings include severe oligospermia or azoospermia and low testosterone levels with increased LH and FSH. Testicular histopathology is consistent with seminiferous tubular sclerosis and hyalinization and sometimes Sertoli cell only. In some cases, remarkable small islands of spermatogenesis can be observed creating opportunity to obtain testicular sperm [48, 49].

Mosaic forms of the syndrome are associated with spontaneous fertility. Testicular sperm extraction (TESE) with intracytoplasmic sperm injection (ICSI) has been successful in achieving successful pregnancies in non-mosaic forms. The success with TESE in those cases ranges from 27% to 69% [49, 50]. Interestingly 80–100% of mature sperm obtained from 47XXY patients show normal haploid sex chromosome with either X or Y [51, 52]. This may be either due to somatic-germline mosaicism or abnormal germ cells simply do not develop due to meiotic arrest. Nevertheless, the rates of aneuploid sperm, although low in absolute terms, are increased in men with Klinefelter syndrome as is the prevalence of aneuploid embryos (both sex and autosomal) making genetic and preimplantation genetic testing (PGT) counseling an important component of management [53–55].

11.5 XYY Syndrome

This syndrome is seen in 1/1000 live male births. Phenotypic characteristics include increased height, decreased intelligence, higher risk of some malignancies like leukemia, and aggressive or anti-social behavior [1]. XYY syndrome is associated with severe oligospermia or azoospermia with elevated FSH but normal testosterone and LH levels. Testis biopsies were found consistent with maturation arrest or Sertoli cell only. Similar to Klinefelter syndrome, the majority of the sperm obtained from these patients show normal haploid sex chromosomes, but higher rates of both sex and autosomal chromosomal imbalances have been reported in 47, XYY men [56, 57].

11.6 XX Male Syndrome

Its main characteristics are gynecomastia at puberty and azoospermia. It is less frequent than Klinefelter or XYY syndromes with a frequency of 1 in 20,000 live male births. Patients usually show elevated FSH and LH levels with low testosterone. Testicular histology shows absent spermatogenesis with hyalinization of seminiferous tubules, fibrosis, and Leydig cell clumping [1]. It is thought that the translocation of *Sry* to X chromosome results in testes development; however, there is no spermatogenesis since Yq is totally lacking [58]. Since there is no spermatogenesis, any surgical or medical treatment will not be successful for fertility purposes. These patients may require testosterone treatment for hypogonadism.

11.7 Mixed Gonadal Dysgenesis

This is another rare condition with male or female phenotype usually with a unilateral testis and a contralateral streak gonad. Patients may have ambiguous genitalia and abdominal testes showing Sertoli cell only. The gonads are predisposed to malignant germ cell tumors and need to be removed prior to puberty. The karyotype may be 45X/46XY or 46XY. The mutations of Sry have not been detected in the majority of cases with some suspect genes downstream to *Sry* [1].

11.8 Translocations and Inversions

Translocations or inversions of autosomal chromosomes can be detected in 1 in 600 to 1 in 1000 live deliveries. Exchanges between chromosomes may interrupt important genes at the break point or may interfere with normal chromosomal pairing during meiosis. Robertsonian translocations involving chromosomes 13, 14, 15, 21, and 22 and reciprocal translocations are at least eightfold more common in infertile men [1].

Robertsonian translocations occur when two acrocentric chromosomes fuse with loss of the short arm material; hence, the chromosome number will be 45. They are the most common chromosomal abnormalities in humans seen in 0.1% of newborns. Most commonly they involve chromosomes 13;14 and 14;21 (Fig. 11.1). Robertsonian translocations may be seen in 1.5% of oligospermic and 0.2% of azoospermic men [1, 59, 60]. Furthermore, carriers of Robertsonian translocations are at risk of pregnancies with miscarriages or birth defects. Interestingly, within some families, fertility is unaffected despite the same apparent translocation of t(13;14)(q10;q10) [43]. Of those sperm produced, most have a normal balanced chromosomal comple-

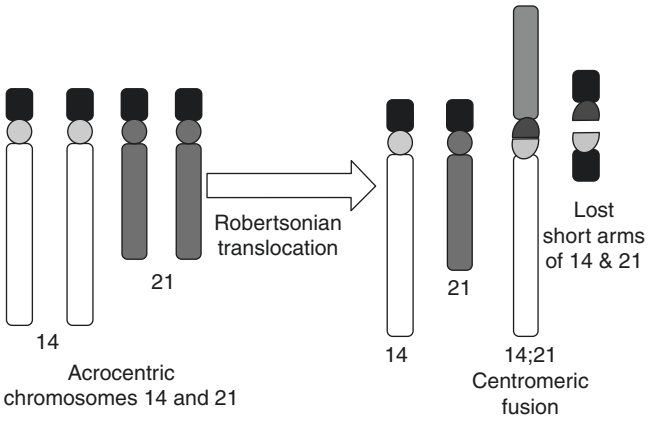

Fig. 11.1 A Robertsonian translocation involves centromeric fusion of the long arms of the acrocentric chromosomes, while the short arms are lost

ment, but an unbalanced karyotype can be present in 4–40% of sperm [61, 62]. Therefore, there is increased risk of trisomies or uniparental disomy. Since the carriers of Robertsonian translocations may pass translocation of imbalanced chromosomal abnormalities to the offspring, genetic counseling and PGT is recommended if sperm from ejaculate or testis is used for ICSI.

Reciprocal translocations are due to the exchange of material between autosomes or between the X or Y chromosome and an autosome and occur in 0.7% of severely oligospermic or azoospermic men [63]. The chromosomal number is normal, and the chromosomes and the break points may be unique to that particular family involved. Depending on the chromosomal material lost, the phenotype may vary. When the sperm is produced, more than 50% are chromosomally unbalanced [61, 64], making genetic counseling even more important.

Chromosomal inversions may involve the centromere (pericentric) or a peripheral segment of the chromosome (paracentric). Although many inversions may be clinically harmless, they may have pathological implications according to the chromosome and the site involved. For example, inversions of chromosome 9 are more frequently observed in infertile men. Due to formation of abnormal loops during chromosomal pairing, chromosomal unbalance can occur, which can effect spermatogenesis or the resulting embryo [61, 65].

11.9 Y Chromosome

The human Y chromosome is 60 megabases (Mb) in length with the least number of genes but the highest copy number of the repetitive sequences as compared to autosomal chromosomes [66]. Approximately 104 coding genes encode about 48 proteins. Among these proteins, 16 proteins have been discovered in the azoospermia factor (AZF) region [67]. The much smaller pseudoautosomal regions (PAR1 2.6 Mb and PAR2 320 bp) (Fig. 11.2), which pair with X chromosome during meiosis, are located at both ends of the Y chromosome. The region outside of the PARs, previously known as the non-recombining region of Y chromosome (NRY), is now called the male specific Y (MSY), which comprises 95% of the chromosome's length. It has also been shown that the MSY may also be somewhat involved in X-Y crossing over during male meiosis while the MSY is flanked on both sides by PARs [68]. But again, the vast majority of the Y chromosome, including the MSY, is less recombining and transmitted as a single block from generation to generation with functional variants and neutral polymorphisms being linked [67].

The MSY is made up of a combination of three classes of gene-rich euchromatic (X-transposed, X-degenerate, and ampliconic) and heterochromatic sequences (Fig. 11.2). The MSY encodes about 27 proteins, and within the MSY, the X-transposed sequences which only encode for two genes (3.4 Mb) are 99% identical to the DNA sequences in Xq21 [67]. X-degenerate sequences are surviving relics of ancient autosomes and encode 16 proteins of the

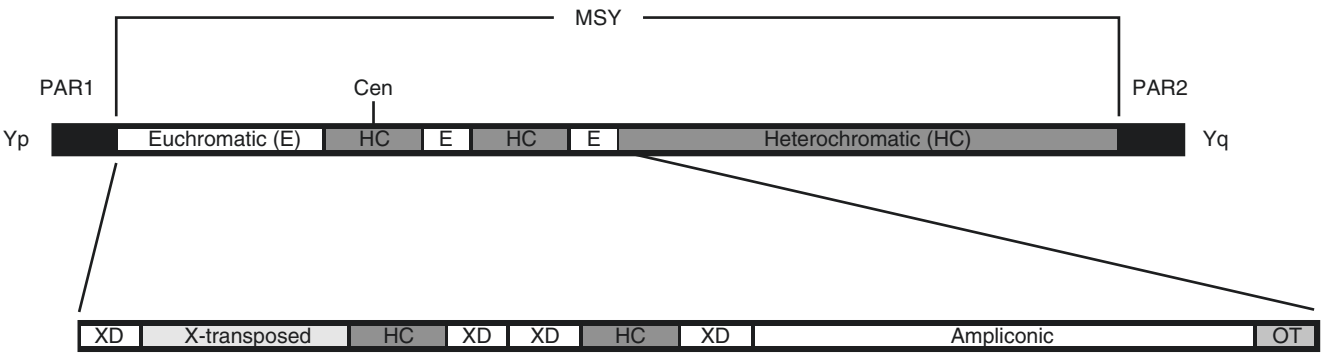

Fig. 11.2 Y chromosome: MSY, Yq, Yp, centromere (Cen), pseudoautosomal (PAR1 and PAR2), and heterochromatic (HC) regions followed by the enlarged view of euchromatic (E) region extending from boundary between PAR1 and Yp to the heterochromatic region of Yq. MSY. Amplicons which encode nine proteins are sequence of nucleotides that are nearly identical large repeats reading in the same (direct) or opposite (inverted) directions. Genes in ampliconic segments may be replicated by recombination between the repetitive sequences. Most Y chromosome genes expressed in the testes are in the ampliconic regions. The Yp (Yp11) and the proximal part of the Yq (Yq11 subdivided into Yq11.1, 11.21, 11.22, 11.23) consist of euchromatin, while the distal part of Yq is made up of heterochromatin which is one-half to two-thirds of the Yq (Yq12) [68, 69] (Fig. 11.1). Loci identified in Y chromosome are thought to be involved in the production and differentiation of the sperm since microdeletions of these loci are associated with severe oligospermia or non-obstructive azoospermia. Accordingly seven deletion intervals were described both on Yp and Yq [70].

Male infertility affects one in 20 men, and primary spermatogenic failure accounts for about 50% of the cases [70]. Yq microdeletions were detected in 5–15% of males with spermatogenic failure. More specifically, these deletions occur in 6–8% of severely azoospermic men and in 3–15% of azoospermic men [70]. These deletions include the total Yq12 heterochromatin block and the part of Yq at Yq11.23. Consequently, it was suggested that at least one genetic Y factor essential for spermatogenesis is located in the distal Yq11 called as azoospermia factor (AZF). Of note, about 6% of severe oligospermia cases occur with deletions outside the AZF region [69].

11.10 AZF Region

The AZF region on Yq is the most thoroughly studied male fertility locus in humans [29]. The AZF region is further divided into three regions defined as AZFa, AZFb, and AZFc [71] (Fig. 11.2). While the AZFa region is truly separate and distinct, the AZFb and AZFc regions actually overlap one another and are simply different stretches of Yq within one much longer, encompassing expanse [28]. It is thought that AZF microdeletions result from intrachromosomal recombination events between homologous repetitive sequence blocks in Yq11 [28]. As there is no counterpart in the genome for mitotic pairing and meiotic recombination of the MSY, this repetitive palindromic sequence structure might have evolved to protect the long-term genetic integrity of Y chromosome by allowing MSY to pair with and to repair itself. However, on rare occasions, this non-allelic homologous recombination may go wrong when two spatially separate ampliconic regions permanently stick together during Y chromosome replication, resulting in loss of all chromosomal material in the intervening portion. In some cases, this may occur due to the deficiency of enzymes necessary for DNA repair. P8-P1 represents eight palindromes ordered nearest to farthest from the centromere within the euchromatic region of Yq. P5-P1 region is statistically more prone to non-allelic homologous recombination due to its unique molecular structure [72].

11.10.1 AZFa

AZFa microdeletions are responsible for azoospermia in 1% of males with non-obstructive azoospermia. The AZFa region is not palindromic, is 792 kb in length, and is located in proximal Yq. AZFa region's candidate genes include USP9Y (ubiquitin-specific protease 9, Y chromosome), or DFFRY (Drosophila fat facets-related Y), DBY (DEAD box on the Y), and UTY (ubiquitous TPR motif on the Y) [68, 71, 73–75]. In AZFa deletions, the most frequent presentation is Sertoli cell-only syndrome (SCO). Two subtypes of SCO have been described. In SCO I cases, there are no germ cells in the seminiferous tubules. In SCO II, associated with partial AZFa deletions, some germ cells with incomplete differentiation and maturation and degeneration can be seen.

11.10.2 AZFb

AZFb microdeletions are 6.2 Mb long and begin in the P5 palindrome and end in the proximal portion of P1, hence the name P5/proximal P1 microdeletion. The so-called AZFb/AZFc microdeletion is also named as P5/distal P1 microdeletion since it also starts in P5 but spans a larger area of 7.7 Mb and ends in distal P1. AZFb or AZFb/AZFc microdeletions are observed in 1–2% of males with non-obstructive azoospermia. AZFb candidate genes include EIF1AY (eukaryotic translation-initiation factor 1A, Y isoforms) and RBMY (RNA binding motif on the Y). For the former, no deletion specifically removing EIF1AY has been reported. Complete AZFb deletions are associated with maturation arrest at the primary spermatocyte or spermatid stages.

11.10.3 AZFc

The AZFc region stretches from the distal portion of the P3 palindrome to the distal portion of P1 and is 3.5 Mb in length (Fig. 11.3). Initially it was believed that the AZFb and AZFc were non-overlapping areas, but subsequent studies demonstrated that both the AZFb and AZFb/AZFc regions overlap the AZFc region. AZFc microdeletions (3.5 Mb) are also called b2/b4 (Fig. 11.3) since it occurs when non-allelic homologous recombination happens between the b2 and b4 amplicons in P3-P1 with loss of all intervening material [29]. AZFc microdeletions are the most common microdeletions found in men with non-obstructive azoospermia, occurring

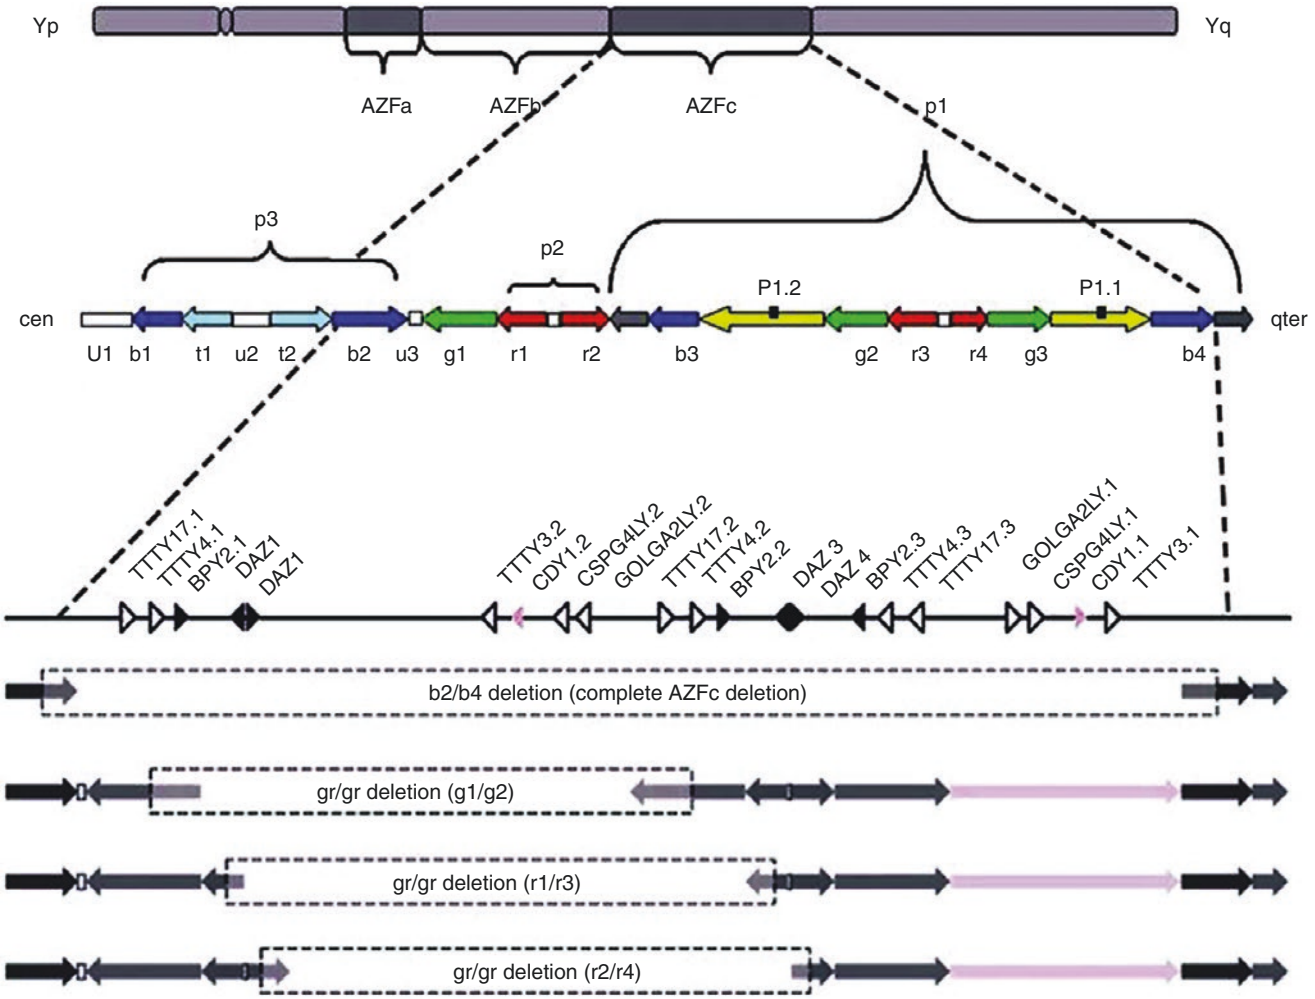

Fig. 11.3 AZFc is comprised of distinct families of nearly identical amplicons. Amplicons b, g, u, r, and t have 4, 3, 3, 4, and 2 repeats, respectively, in the haplotype. Palindromes are indicated as P1, P2, P3. Repetitive sequences are either direct repeats or inverted repeats based on the direction of the arrows. AZFc contains 12 families of transcription units which are all expressed in testis such as BPY2, DAZ, CDY1, and others. AZFc microdeletion subtypes include complete deletion b2/b4, partial deletion g1/g2, r1/r3, and r2/r4. (Reprinted from Li et al. [67]. With permission from Elsevier)

in up to 13% of cases with azoospermia and 6% of men with severe oligospermia. The so-called "Deleted in azoospermia" (DAZ) cluster is the primary candidate gene in the AZFc region. Several other genes in addition to DAZ were mapped in this region including CDY1 (chromodomain Y 1), BPY2 (basic protein Y2), PRY (PTA-BL related Y), and TTY2 (testis transcript Y 2). AZFc deletions are associated with a wide range of conditions from azoospermia to mild to severe oligospermia. This is reflected in testicular histology being consistent with hypospermatogenesis or SCO II in which there is a better chance of finding focal areas of spermatogenesis.

Among all cases with Yq microdeletions, deletions involving DAZ seem to be the most frequent one. Some reports suggest that DAZ deletions may be encountered in up to 13% of cases of male infertility [28]. DAZ was thought to be acquired by Y chromosome from an autosomal homologue DAZL (DAZ-Like) on chromosome 3p24 which shows a single DAZ repeat. The DAZ gene cluster on Y chromosome consists of seven copies of DAZ of which four copies are located relatively close together within a deletion interval on Yq11. DAZ encodes an RNA-binding protein exclusively expressed in early germ cells and is thought to be responsible for activation of silent mRNAs during pre-meiosis stages. It was reported that AZFc may not be critical for meiotic recombination, whereas absence of AZFc regions results in extension of the zygotene stage and reduction of chromosomal condensation [69]. Although most deletions involve all four DAZ genes, an absence of only two is also associated with defective spermatogenesis [28].

Some other partial microdeletions detected in AZFc region such as b2/b3, b1/b3, and gr/gr do not seem to have

any clinical significance, although race specific various phenotypic outcomes were reported [76, 77]. Notably, microdeletions of the AZFc may present with spermatogenic failure in Dutch, Spanish, Chinese, and Italians. However, the presence of AZFc deletion in healthy French, Germans, and Han Chinese questions its importance in male infertility [78, 79]. A partial AZFc microdeletion such as gr/gr can be passed from father to son, but again its clinical significance is still debated [80]. Whereas frequent deletion of DAZ gene cluster in male infertility cases suggests its importance in spermatogenesis, the variable penetration of AZFc deletions in general suggests some redundancies in its function. Perhaps the microdeletion is not an independent event but is compensated by the activation of other genes by gene replication or dosage compensation [67].

11.11 Yq Microdeletions in Clinical Practice

In infertile men with non-obstructive azoospermia or severe oligospermia, it is critical that the patients know the results of Y chromosomal microdeletion analysis before testicular sperm extraction (TESE) and ICSI. Briefly, complete AZFa, AZFb, and AZFb/AZFc microdeletions predict that TESE will be unsuccessful since sperm will not be found and presently there is no available treatment [1]. Men with Y chromosomal microdeletions rarely have a sperm density above five million per milliliter. Although a vast majority of AZFc microdeletions are de novo which means that the father of the patient is not affected, rare cases of natural transmission were also reported [28].

As noted above, it is thought that finding of ejaculated sperm in complete AZFa and AZFb deletions is highly unusual [30]. Combined deletions of two or more regions that include AZFb are associated with SCO or maturation arrest histology. Patients with AZFc deletions have the best prognosis for finding testicular sperm during TESE. Many reports suggest that 50% to 60% of azoospermic AZFc-deleted men will have testicular sperm enough for ICSI [30]. In patients with complete AZFa or AZFb microdeletions, the probability of finding sperm during TESE attempts is extremely low if not impossible. Successful TESE is often not possible in cases with deletions involving one or more regions that include AZFa or AZFb as well.

Small studies are not clear regarding the outcome of ICSI when testicular sperm is used in men with AZF deletions. Some have reported normal fertilization rates but poorer embryo quality as compared to those without AZF deletion and other demonstrated comparable fertilization and pregnancy rates [1]. There is also evidence that men harboring AZFc microdeletions may show time-dependent decline in sperm production. Therefore, counseling patients for sperm cryopreservation for future use is essential.

Men with AZF deletions who conceive via assisted reproduction are likely to pass on the Yq deletion to male offspring [81]. However, the children conceived by testicular sperm seem to be somatically healthy, and their AZFc deletions have not been shown to be altered, although it is expected that male offspring will suffer from similar deficiencies of spermatogenesis.

Since microdeletions cannot be detected by conventional cytogenetic methods, Yq analysis is performed on peripheral blood lymphocytes via polymerase chain reaction (PCR) where various center specific primers were used to amplify sequence tagged sites (STSs) of DNA, which makes evaluation of data challenging. By PCR amplification of STSs, which are specific to each of the AZF regions under review, deletions are identified by the absence of one or more ampliconic products.

11.12 Other Y Chromosome Conditions

Massive palindromes in the human Y chromosome harbor mirror-image gene pairs essential for spermatogenesis. These gene pairs have been maintained by intrapalindromic arm-to-arm recombination. Isodicentric Y (idicY) chromosomes may be formed by homologous crossing over between the opposing arms of palindromes in sister chromatids. This event is usually associated in mosaic event with 45X cell line giving a karyotype of 45X/46XidicY. These patients retain two Yps and two SRYs although the latter may not be functional due to mitotic instability leading to a female phenotype. In cases with male phenotype, the end result would be azoospermia possibly due to Yq segment loss at break points [82]. It remains elusive if successful TESE and ICSI with PGD can be performed in these cases.

The short arm of the Y chromosome also harbors genes related to spermatogenesis. TSPY gene is one of these genes with copies on Yq as well [83]. A study of copy number variation of TSPY demonstrated that more copies were found in infertile men [84].

11.13 X Chromosome

Many X chromosome genes influence male infertility. From rodent studies, it was suggested that the X chromosome may play an important role in pre-meiotic stages of mammalian spermatogenesis [34]. Deletions, translocations, and inversions of X chromosome may result in severe infertility and azoospermia [85–87]. For example, paracentric inversions involving Xq12–25 or deletion of a portion of Xp may result in a phenotype consistent with Klinefelter syndrome. Several X-linked gene mutations were reported in infertile men with oligospermia or azoospermia.

The androgen receptor (AR) gene is located on Xq11–12. Knockout mice studies have suggested that AR signaling in Sertoli cells plays an important role in meiosis I during spermatogenesis [88]. Lack of AR in Leydig cells may lead to spermatogenic arrest at the round spermatid stage [89]. The functional AR in germ cells however was not found to be essential in spermatogenesis [90]. Therefore, androgens control spermatogenesis, but germ cells themselves do not express a functional AR. Androgen regulation is thought to be mediated by Sertoli and peritubular myoid cells [91]. While complete AR gene mutations are associated with androgen insensitivity syndrome with a female phenotype, incomplete forms of AR gene mutations were detected more frequently in infertile men [92].

X-linked spinal and bulbar muscular atrophy or Kennedy's disease is caused by expansion of a CAG repeat in the first exon of AR gene. The CAG repeat encodes a polyglutamine tract in AR protein. The greater the expansion of the CAG repeat, the greater the polyglutamine repeat expansion and the earlier the disease onset and more severe the disease manifestations [93]. Glutamine repeat motifs in the first exon of AR gene (polyQ region) are polymorphic in the general population numbering 10 to 36 repeats. In Kennedy's disease, the polyQ region is expanded between 40 and 62 repeats [93].

The CAG repeat expansion mutations in the AR gene do not affect sexual differentiation. The repeat expansion likely causes a toxic accumulation of mutated AR in nuclei and cytoplasm of motor neurons, resulting in their degeneration and loss [94]. An important point regarding this issue relates to patients with complete androgen insensitivity syndrome. Like patients with Kennedy's disease, there is no androgen receptor function, but there are no neurologic issues in patients with androgen insensitivity as there are no issues with toxic damage to neurons. Patients present with amyotrophic, proximal, or distal weakness and wasting of the facial, bulbar (dysphagia, dysarthria), and limb muscles, occasionally sensory disturbances, and endocrinologic disturbances, such as androgen resistance, gynecomastia, elevated testosterone, and reduced fertility due to defects in spermatogenesis and testicular atrophy. The onset of neurological symptoms is between the ages of 30 and 50 years. In parallel to those observations, CAG repeat polymorphism has been investigated as a possible cause for male infertility [95]. However, it is still controversial if longer or shorter CAG repeats are associated with higher or lower sperm quality [96–98].

The X-linked form of Kallmann syndrome is related to the deletions in KAL-1 gene located in the short arm of X chromosome (Xp22.32). This gene codes for a cell adhesion protein, anosmin-1, which is involved in the migration of gonadotropin-releasing hormone (GnRH) neurons during embryonic development. The condition is associated with hypogonadotropic hypogonadism with sexual infantilism due to the deficiency of GnRH, anosmia or hyposmia due to the absence or hypoplasia of olfactory bulbs and tracts, cognitive and ocular abnormalities, and even with midfacial clefts and renal agenesis [99]. While X-linked KAL-1 mutations are responsible from 30% to 70% of the condition, the remaining cases are related to the deletions in fibroblast growth factor receptor 1 (FGFR1) gene on chromosome 8 which shows autosomal dominant inheritance [100]. With treatment, favorable reproductive outcomes can be attained in addition to maturation of secondary sex characteristics.

11.13.1 Congenital Bilateral Absence of the Vas Deferens (CBAVD) and Cystic Fibrosis

CBAVD is estimated to occur in 1/1000 to 1/10,000 and may be encountered in 1–2% of cases with male infertility. It is detected in 9.6% of cases with obstructive azoospermia [101], and it is thought to result from abnormal development of WD although it is not clear if absence of vas deferens is always congenital [101]. Absence of distal WD derivatives may be related to the early obstruction of these ducts by viscous secretions rather than an embryonic developmental defect. Approximately 80% of CBAVD cases are caused by mutations on both alleles of the cystic fibrosis transmembrane conductance regulator (CFTR) gene. CBAVD is usually associated with absence of the body and tail of the epididymis, vas deferens, and seminal vesicles, but the head of the epididymis is intact (Table 11.1).

Given the fact that almost all CF male patients are infertile due to CBAVD, it was investigated if CFTR was also involved in infertility because of CBAVD alone. In an earlier small study, it was reported that 41% of azoospermic men with CBAVD were found to be heterozygous for F508del CFTR mutation as compared to the population risk of 2.8% [102]. Later, R117H mutations were also found at a higher

Table 11.1 Clinical detection of CFTR mutation-related CBAVD

Azoospermia
Low seminal fluid volume (<2.0 ml)
Biochemical features of the semen: pH <7.2, absent or decreased fructose, and α1–4 glucosidase (markers of properly functioning seminal vesicles and epididymis, respectively)
Absence of palpable vas deferens
On transrectal ultrasound: absence of the intra-abdominal tract of the vas deferens, globus major, and different degrees of hypoplasia of the seminal vesicles
Normal plasma follicle-stimulating hormone (FSH), luteinizing hormone (LH), and testosterone levels
Normal karyotype
Normal testicular size

Based on data from Ref. [108]

frequency in CBAVD cases [103]. In a more recent large study, analysis of 7420 alleles of CFTR gene showed that a CFTR mutation can be identified in 78.9% of patients with CBAVD. In French men with CBAVD, about 71% of the CBAVD patients had a mutation on both CFTR genes and about 16% had a mutation on one CFTR gene, and the remaining 13% of CBAVD patients had no mutation [104].

In 20% of CBAVD patients, the absence of vas deferens is associated with renal malformations [105]. Although a minority of CBAVD patients may have a mild lung disease or a positive sweat test, most CBAVD patients do not have lung disease. It is possible that a mild mutant of CFTR protein with partial chloride channel activity can sustain a normal non-diseased phenotype except for proper functioning and maintenance of vas deferens after its development [106].

The CFTR gene spans about 190 kb and contains 27 exons (chromosome 7q31). The CFTR protein is a glycosylated transmembrane protein, which functions as a chloride channel. In the CFTR gene, currently, 2061 sequence variations have been reported in populations with various geographic locations and ethnicities (http://www.genet.sickkids.on.ca/cftr/StatisticsPage.html) [107]. These are found in both CF and related phenotypes called CFTR-related disorders (CFTR-RD). These are clinical disorders with CFTR dysfunction where the diagnosis of CF cannot be established. These entities include CBAVD, disseminated bronchiectasis, chronic pancreatitis, and chronic rhinosinusitis [108]. As CF is inherited in a recessive manner, CF will develop when deleterious mutations are found on both CFTR alleles. If the mutation is only on one allele, the individual is a CF carrier. One in 2500 newborns has CF and 1 in 25 Caucasians is a CF carrier [106] (Table 11.2).

More than 1200 CF causing CFTR mutations have been identified. A CF patient may carry two identical or different mutations, with the latter condition being called a compound heterozygote for two CFTR mutations. Most mutations are point mutations and the distribution of these mutations varies according to ethnicity. The most common mutation F508del is seen in 70% of Northern European populations, but it is seen in lower frequencies in Southern Europeans [106]. About 1–5% of mutations remain undetermined in CF patients and even more in patients with atypical presentations as undetected mutations may lie within the introns or regulatory regions, which are not routinely analyzed. Additionally, the frequency of undetected mutations increases from Northern to Southern European populations [108]. Besides F508del, other mutations exist in most populations, each reaching frequencies of about 1–2% such as G5542X, G551D, R553X, W1282X, and N1303K. Therefore, in most populations, these mutations and some ethnic specific mutations comprise 85% to 95% of all CFTR mutations. The remaining mutations are rare and sometimes can be found in a single family or population. Depending on the effect at protein level which predicts the severity of the clinical condition, CF mutations are divided in several arbitrary classes [106]. One large study reported that CF patients had two severe mutations (88%) or one severe and one mild/variable mutation (12%), whereas CBAVD men had either a severe and a mild/variable (88%) mutation or two mild/variable (12%) mutations [104].

Most commercial genetic tests for CFTR mutations screen only for the most frequent CF-causing mutations and not the milder mutations, therefore resulting in a CFTR mutation detection rate of only about 60% in CBAVD patients [104]. The most common CFTR mutation presenting with a mild phenotype found in CBAVD patients is the 5T polymorphism (variant) [101].

The 5T splicing variant of the intron 8 acceptor splice site is not considered a CF-causing mutation, but it may be associated with CFTR-RD [108]. At the polypyrimidine tract of intron 8 acceptor splice site, the variants are named according to the number of thymidines as 5T, 7T, and 9T. The lower the number, the lower the efficiency of exon 9 splicing. The extent of splicing is further related to the number of adjacent TG repeats; the higher the number of TGs, the lower the efficiency of splicing. Patients with (TG)13/5T in *trans* with a CF-causing mutation may have mild CF. R117H CFTR-RD mutation can be found in *cis* with 5T or 7T. R117H/5T is considered a mild CF mutation, but R117H/7T is considered as a CFTR-RD mutation. If R117H/5T is trans with a F508del severe CF mutation, the signs of CF may be present. The presence of R117H/7T in the same configuration has been shown to be symptom free [109].

When 5T is found in compound heterozygosity with a severe CFTR mutation, or even with another 5T, CBAVD can be observed. However, not all men who are compound heterozygous for a severe CFTR mutation and 5T develop CBAVD, such as fathers of some CF children [109].Therefore 5T polymorphism is a mutation with partial penetrance. Again, the R117H mutation can either result in CF or CBAVD by being associated by either 5T or 7T allele [109]. Its association with 7T allele may result in CBAVD, and

Table 11.2 Cystic fibrosis detection and carrier rates before and after testing[a]

Ethnic group	Detection rate	Carrier rate before testing	Carrier risk after negative test result
Ashkenazi Jewish	94%	1/24	1/400
Non-Hispanic Caucasian	88%	1/25	1/208
Hispanic American	72%	1/46	1/164
African American	65%	1/65	1/186
Asian American	49%	1/94	1/184

[a]Modified from ACOG Committee Opinion No.691 [110]

R117H/5T may result in CF. F508del mutation is found at a higher frequency in CF patients as compared with those with CBAVD, while R117H is more frequently observed in patients with CBAVD.

Initial CF screening guidelines included 25 pan-ethnic mutations that were present in at least 0.1% of patients with CF. The commercially automated methodology uses PCR with allele-specific oligonucleotide primers [110]. Some screening panels may identify 5T, 7T, and 9T variants, although they are not offered in routine CF carrier screening. As detailed above, the presence of 5T allele may decrease mRNA stability affecting exon 9 [65]. Since CF may occur when 5T is on the same chromosome (*cis*) with R117H missense mutation along with a CFTR mutation on the other chromosome, reflex 5T testing is done if R117H is detected in the screening panel. Since males with 5T allele on both chromosomes are at increased risk for CBAVD, 5T testing should be ordered in CBAVD cases. CBAVD patients with two 5T variants and female with an R117H mutation with 5T variant in *cis* position need genetic counseling to discuss the risk of having an offspring with CF. It should always be remembered that the primary goal of universal CF screening test is to detect CF and not CBAVD, with a reasonable sensitivity. Therefore, at times, complete analysis of CFTR gene by DNA sequencing may be necessary in patients with CF and in patients with CBAVD who tested negative with commercial CFTR screening test results.

Spermatozoa of CBAVD patients used in an ICSI program may transmit CFTR mutation to the offspring. Most CBAVD patients may carry a severe CF-causing CFTR mutation with 50% chance of transmitting that mutation. If the carrier risk of a Caucasian female is 1/25 (0.04), with herself having a 50% chance of transmitting the gene to the offspring, the risk of having a child with CF would be 1 in 100 ($0.5 \times 0.04 \times 0.5 = 0.01$) as compared with a risk of 1/2500 in general population. Therefore, partner testing with genetic counseling is of the utmost importance. Since the commercial genetic tests have about 90% of sensitivity (Table 11.1) when no mutation is found in the test, the partner still has a risk of 1/250 being a carrier of an untested mutation; therefore, the CBAVD couple may still run a risk of 1/1000 of having a child with CF [106].

11.13.2 Genes Involved in Meiotic Recombination

Although the incidence of chromosome abnormalities is about 10 times higher in infertile males than in the general population, most infertile men have normal karyotype. However, these patients may show an increased incidence of aneuploid sperm and diploid sperm in their ejaculate or in sperm obtained from testes [111, 112]. It has also been shown that the risk of aneuploidy or diploidy in sperm correlates with decreasing numbers of sperm and total progressive motility [113]. Many times, meiotic disturbances are the culprits in these cases.

Meiotic recombination in germ cell occurs in prophase of meiosis and involves the induction of double-strand DNA breaks, the pairing of parental homologous chromosomes, followed by the repair of double-strand breaks using the intact homologous chromosome as a template. Several studies have suggested significantly lower rates of meiotic recombination and impaired synapsis in infertile men [114–117]. Faulty meiotic recombination can also cause fertility problems especially if the meiotic errors cannot be corrected (i.e., as in the case of meiotic checkpoint molecules activating apoptotic pathways leading to testicular failure). Furthermore, it was estimated that 5–10% of cases of non-obstructive azoospermia may be due to meiotic arrest [117]. There are many genes involved in meiotic recombination, investigation of which has been mostly relevant to etiology of many cancers [118].

11.13.3 Gene Mutations Associated with Sperm Functional Defects

Primary ciliary dyskinesia presents with immotile but viable sperm along with varying degrees of respiratory tract dysfunction, situs inversus totalis (Kartagener's syndrome), and hydrocephalus. Its frequency is 1 in 20,000 to 60,000 live births [119]. Most of the genetically characterized primary ciliary dyskinesia variants exhibit mutations in the genes dynein, axonemal, heavy chain 5 [DNAH5, 5p15.2], dynein, axonemal, heavy chain 11 [DNAH11, 7p21], dynein, axonemal, intermediate chain 1 [DNAI1, 9p13.3], and dynein, axonemal, intermediate chain 2 [DNAI2,17q25] that encode axonemal dynein-arm components responsible for ciliary beat generation and sperm-specific thioredoxin domain containing 3 [TXNDC3, 7p14.1] encoding a thioredoxin [120]. Some cases may have mutations in retinitis pigmentosa GTPase regulator (RPGR) gene on Xp11.4 which is also associated with retinitis pigmentosa [121]. The patient initially may present with severe asthenospermia, and in these cases, other clinical signs of primary ciliary dyskinesia should be sought. The majority of patients have sperm in the ejaculate, and ICSI has been successfully used in those cases [120].

11.13.4 Copy Number Variations (CNVs)

CNVs are pieces of 1 kb or longer DNA segments that vary in number between individuals, which are considered as submicroscopic duplications and/or deletions of the genome

[31]. CNVs can be detectable by higher-resolution genome-wide microarray comparative genomic hybridization assays and can be further confirmed by PCR-based methods. The complexity about CNVs lies on the facts that their presence can cause overt disease and a predisposition to a disease or may have no effects at all. In general, CNVs may affect up to 20% of the human genome [65]. CNVs have been investigated in many medical disorders; however, the data on male infertility are scarce and more investigation is still needed.

11.14 Mitochondrial Genetics

Mitochondrial DNA is a double-stranded circular DNA molecule coding for 2 rRNAs, 22 tRNAs, and 13 polypeptides essential for respiratory enzyme complexes involved in oxidative phosphorylation [122]. Mitochondrial DNA has no introns, and it mutates at 10 to 20 times higher rates than nuclear DNA due to its unique structure and replication system [123]. Mid-piece of mammalian sperm contains about 80 mitochondria with a single copy of DNA in each organelle. Spermatozoa are dependent on mitochondria for energy needed for rapid progressive motility. Mitochondrial DNA mutations caused by the oxidative damage induced by reactive oxygen species or free radicals may lead to male infertility [124]. In general, about 85% of sperm samples may contain various mitochondrial DNA deletions, which may partly explain the age-related decline in fertility in males.

The presence of multiple mitochondrial mutations has been reported to be associated with oligoasthenoteratospermia [125, 126].The key nuclear enzyme involved in the elongation and repair of mitochondrial DNA strands is DNA polymerase gamma (POLG). The catalytic subunit of POLG is encoded by POLG gene on chromosome 15q24 which includes a CAG repeat region [127]. POLG mutations are associated with mutations in mitochondrial genome, which subsequently affects ATP production and sperm function. Expanded CAG repeats in the region of POLG gene are also associated with several neuromuscular disorders, which may be associated with male factor infertility as well. Many of these disorders like Huntington's disease are transmitted in an autosomal dominant fashion and can show genetic anticipation.

11.15 Epigenetic Alterations

Epigenetics refers to the alterations of the gene expression without any change in DNA nucleotide sequence. Epigenetic mechanisms are associated with the way in which the genome is packed, thus affecting the ability of genes to be activated. It is involved mostly with regulation of transcription or translation.

The most established epigenetic mechanism that is heritable through the germline is DNA methylation. This is a post-replicative modification in which a methyl group is covalently added to CpG (cytosine-guanine) dinucleotide residues of DNA by DNA methyltransferases [128]. Other well-known epigenetic mechanisms include chromatin condensation and histone modifications. The regions of chromatin can be transiently condensed or uncondensed leading to variation in gene expression through transcriptional suppressors, functional RNAs, or interaction with various proteins [129]. Histones are subjected to modifications like phosphorylation, acetylation, methylation, ubiquitination, carbonylation, and such affecting gene expression [130]. Small non-coding RNAs like micro (mi) RNAs or Piwi-interacting (pi) RNAs are additional epigenetic mechanisms acting through transcriptional or translational regulation [131, 132].

Reprogramming of methylation patterns in mammals occurs usually after fertilization (pre-implantation stage) and during fetal development of the germline (gametogenesis) especially during germline differentiation [133]. Allelic differences in methylation which is characteristic of imprinted genes are also delineated during the germ cell line establishment [134]. Imprinted genes conserve their methylation patterns through generations. Therefore, if methylation changes are induced in imprinted genes or new methylation sites are established during germ cell differentiation or after fertilization, heritable factors can either diminish or persist affecting the ultimate phenotype in the offspring [135]. Most endocrine disruptors or environmental factors do not promote DNA sequence mutation but induce modifications of DNA without altering nucleotide composition, i.e., epigenetic changes [128, 136].

Imprinting abnormalities associated with Angelman, Prader-Willi, Beckwith-Wiedemann, and Silver-Russell syndromes have been associated with assisted reproductive technologies (ART), whereas correlations have been found to be weak. It seems these imprinting syndromes may be associated with infertility factors associated with pre-existing methylation aberrations rather than ART itself [137]. Favoring this assumption, it has been reported that epigenetic abnormalities are common in sperm of men with severe oligospermia [138, 139]. Rodent studies also revealed that perturbation of DNA methyltransferases or DNA methylation in male germ cells can affect fertility and sperm function [140]. Abnormal sperm chromatin packaging may have a role in proper establishment of methylation patterns, and abnormal protamine 1 and protamine 2 ratios (P1:P2 equals roughly 1 in fertile men), which were detected in infertile men [141–143], may lead to changes in imprinted genes [144]. Many studies have implicated altered P1:P2 ratios (both greater than and less than 1) with negative impacts on embryo quality, development, and overall IVF outcomes [44]. It is proposed that the erasure and resetting of DNA methylation that

takes place in primordial germ cells is an important stage to prevent DNA methylation defects; however, the effectors and modulators of these steps need further investigation before the applicability of this information to clinical practice [145].

11.16 Malignancy Risks Associated with Genetic Perturbations in Infertile Men

Multiple studies have suggested an association between male infertility and testicular germ cell tumor which is the most common malignancy in men aged 15–35 years [118, 146]. Infertility probably precedes the development of occult testicular cancer, and this association suggests common genetic and environmental factors in both infertility and testicular germ cell tumors. Increased risk of these cancers has been associated with factors related to genetics and epigenetics which include cryptorchidism, chromosome 12 aneuploidy, DNA mismatch repair gene defects, Y chromosome instability, and stem cell dysregulation via abnormal RNA interference [146–148]. Cryptorchidism itself may be associated with mutations in HOXA10, INSL3 and INSL3 receptor LGR8/GREAT, AR, estrogen receptor (ER)α, and SF-1 gene mutations [149]. While elucidation of all these factors and pathways is required, all men evaluated for infertility need to be adequately assessed and screened for testicular tumors.

11.17 Male Genetic Testing in Clinical Practice

Many potential genetic causes of both spermatogenic failure and obstructive azoospermia have been demonstrated, but despite much progress in animal data [150], the validation of the proposed genetic tests has been slow [151]. Therefore, only a limited number of tests are currently recommended in the evaluation of infertile men. Arbitrarily defining severe oligospermia as sperm concentration less than five million/ml and azoospermia as the sperm density below the detection limit, infertile men with those two conditions are recommended to undergo genetic testing.

Men with congenital unilateral or bilateral absence of vas deferens should be tested for a CFTR mutation, which also includes 5T variants. Almost all men with clinical CF have CBAVD. At least two-thirds of men with CBAVD have mutations of the CFTR gene. However, failure to identify a CFTR mutation by commercial tests in a man with CBAVD does not rule out a mutation, since they may still harbor a mutation undetectable with the currently recommended screening panel. It has even been recommended that patients with CBAVD should be assumed to have some sort of CFTR mutation [47]. Although most men with CBAVD have normal spermatogenesis, coexisting spermatogenesis defects should always be ruled out before harvesting sperm for ICSI [47]. Furthermore, since about 25% of men with unilateral absence of vas deferens and 10% of men with CBAVD may have unilateral renal agenesis, an abdominal ultrasound is also required [152].

A karyotype is recommended for infertile men with persistent or severe oligospermia (<10 million depending on the male phenotype or <5 million per ml for all) or non-obstructive azoospermia [61] (Fig. 11.3). Yq deletions are more frequent in azoospermia cases than men with severe oligospermia. Nevertheless, routine Yq microdeletion STS-PCR testing is required before testicular sperm harvesting or before ART in men with non-obstructive azoospermia or severe oligospermia. Chromosomal abnormalities may result in impaired testicular function, while Y chromosome microdeletions result in isolated spermatogenic failure.

At present, testing sperm for aneuploidies or inversions in men with abnormal sperm analysis or men with abnormal karyotype is not recommended since the exact data set establishing threshold levels for the percentage of sperm with abnormal karyotype to assist in clinical and PGT decision making is lacking [65]. Currently, routine assessment of CNVs and epigenetic assessment of infertile men or their sperm do not find any support in the clinical practice.

11.18 Gene Therapy for Male Infertility

Around 15% of the male infertility patients are azoospermic, and normal sperm production with obstructive cause accounts for 40% of these cases. In the remaining 60% of the cases with spermatogenesis defects, approximately half of them may have low levels of sperm, which may be obtained through TESE techniques to be used for ICSI [131, 153]. Only for cases without any viable sperm in the testes, gene therapy may be considered.

There are many challenges to gene therapy for male infertility. Karyotypic abnormalities like Klinefelter syndrome and Y chromosome deletions involve additions or deletions of large amounts of DNA. Currently, there is no technology to manipulate large amounts of DNA for gene therapy. Furthermore, although we mentioned some genetic causes of male infertility in this article, many men with severe infertility do not have any identifiable genetic defects even if the genetic cause is likely. Knowledge of the exact gene(s) involved is essential to proceeding with any gene therapy [154, 155].

Another obstacle in gene therapy for male infertility may involve both somatic (Sertoli, Leydig cells) and germ cells needing more complex approaches. Serious ethical and safety concerns exist regarding inducing genetic alterations

in the germline, and currently, germline genetic therapy is prohibited [156]. In somatic cells, using viral vectors to integrate wild type of gene carries the risk of insertional mutagenesis or carcinogenesis since technology does not allow selected site insertion [157]. With the introduction of CRISPR/Cas9 (clustered regularly interspaced short palindromic repeats/Cas9 nuclease) system, genome editing can now more efficient and more precise. This has opened the door to possible safe germline genome editing in the future, though ethical questions still remain [158].

Other suggested approaches in dealing with gene therapy obstacles include the use of embryonic stem cells, transplantation, and the production of artificial gametes [159–162]. Enucleated oocyte can be combined with patient's somatic cell nucleus, the nucleus can be reprogrammed, and the oocyte is stimulated to become a blastocyst since it contains diploid chromosomes. Then stem cells can be differentiated into germ cell lineage, and these cells can be transplanted back to patient's seminiferous tubules, or further development of germ cells can be achieved in vitro to be used for ICSI. In animals, artificial oocytes and artificial sperm have been created from germline stems cells, induced pluripotent stems cells, and embryonic stem cells [163]. These artificial gametes have been combined to produce viable animal offspring. In humans, various routes of creating "artificial sperm" have been proposed [164]. In males with spermatogonial maturation arrest, in vivo or in vitro induction of maturation of these arrested cells and subsequent reimplantation may allow for the re-establishment of ongoing sperm production [164]. For pre-pubertal patients or those facing gonadotoxic therapies, the harvesting of testicular tissue followed by in vitro maturation and later self-transplantation offers a path to comprehensive fertility preservation. Lastly, somatic cells could be induced into pluripotent stem cells followed by differentiation into mature sperm cells which could allow for reproduction in men with a complete absence of sperm cells. As always, safety and ethical concerns about these procedures remain.

11.19 Conclusion

The continued refinements of approaches such as microarray profiling, comparative genomic hybridization, and mutagenesis screening will open up new avenues in the efforts to understand genetic origins of male infertility [165–168]. As always, new technologies provide a vast amount of data with plenty of background "noise" at times. Therefore, the results from advanced genomic, proteomic, and metabolomic techniques should be confirmed by PCR, Western blot, flow cytometry, mass spectroscopy and chromatography, and protein function assays. These approaches will lead to better preconception counseling and more directed approaches for PGT. Future directions should involve continued research into artificial gamete creation as well as the identification of single gene defects associated with male infertility which may be amenable to gene editing.

11.20 Review Criteria

An extensive search of studies examining genetic aspects of male infertility was performed using search engines such as ScienceDirect, Ovid, Google Scholar, PubMed, and MEDLINE. The start and end dates for these searches were November 2018 and February 2019, respectively. The overall strategy for study identification and data extraction was based on the following keywords: "male infertility," "genetics of male infertility," "genomic regulation of male development," "testicular development," "spermatogenesis," "Y chromosome," "AZF deletions," "genetic testing for male infertility," "CBAVD and male infertility," "copy number variations," "mitochondrial genetics and male infertility," "epigenetics and male infertility," "malignancy risk and male infertility," and "future treatment of male infertility." Articles published in languages other than English were not considered. Data that were solely published in conference or meeting proceedings, websites, or books were not included.

Surgical Treatment for Male Infertility

12

Ricardo Miyaoka and Sandro C. Esteves

Key Points

- Varicocele treatment is recommended for infertile men with clinically palpable varicocele and abnormal semen parameters or sperm functional tests. Overall, open microsurgical inguinal or subinguinal techniques are considered the best treatment modalities due to the higher pregnancy rates, fewer recurrences, and fewer postoperative complications than laparoscopic, radiologic embolization and macroscopic inguinal or retroperitoneal varicocelectomy techniques.
- There are no absolute predictive factors for successful varicocele repair. However, existing evidence does not support the recommendation for treating infertile men with subclinical varicocele.
- Surgical repair of varicocele improves semen parameters and functional markers of oxidative stress and DNA integrity. The chance for either natural or assisted conception is increased after repair of clinical varicoceles.
- Recovery of spermatogenesis can be achieved after repair of clinical varicocele in selected infertile men with non-obstructive azoospermia. Testicular histopathology is predictive of success, and men with maturation arrest and hypospermatogenesis are more likely to ejaculate motile spermatozoa after surgery. Also, the chance of retrieving testicular sperm for ICSI is optimized in non-obstructed azoospermic men with treated clinical varicocele.
- Men with obstructive azoospermia may father children either by surgical correction of the obstruction, which may allow the couple to conceive naturally, or retrieval of sperm directly from the epididymis or testis, followed by intracytoplasmic sperm injection.
- Best results with reconstructive surgery of the male reproductive tract are achieved by surgeons who have necessary microsurgical training and continuous hands-on experience with the procedures. Ideally, procedures should be performed by surgeons who can perform both vasovasostomy and vasoepididymostomy since, in many cases, the need of the latter cannot be anticipated.
- In experienced hands, microsurgical vasectomy reversal is highly successful. Sperm return to the ejaculate after surgery in 70–95% of patients, and 30–75% of couples can be expected to achieve unassisted pregnancy. Patency and pregnancy after microsurgical vasectomy reversal are inversely related to the interval of obstruction since vasectomy. Other factors that affect success rates include the intraoperative appearance of vasal fluid, the presence or absence of sperm in the vasal fluid and their quality, the length of the remaining segment adjacent to the epididymis, the age of the female partner, and the experience of the microsurgeon.
- Vasoepididymostomy should be performed only by those having the requisite training and experience in reproductive microsurgery. When treatment requires an elaborate reconstruction of the male reproductive tract, cryopreservation of retrieved sperm should be considered because surgery may not be successful.
- Ejaculatory duct obstruction is a potentially treatable cause of male infertility. Transurethral resection of the ejaculatory ducts (TURED) is the

treatment of choice, but minimally invasive vesiculoscopy has been applied with promising results. After TURED, sperm return to the ejaculate in approximately 50% to 75% of men, and approximately 20% of couples achieve pregnancy. However, results are highly variable and depend on the etiology (acquired or congenital) and type (partial or complete) of obstruction. Complications of TURED occur in approximately 20% of men, including hematuria, hematospermia, urinary tract infection, epididymitis, and a watery ejaculate due to reflux of urine.

Table 12.1 Distribution of diagnostic categories in a group of infertile men who attended a male infertility clinic

Category	N	Percentage
Varicocele	629	26.4
Infectious	72	3.0
Hormonal	54	2.3
Ejaculatory dysfunction	28	1.2
Systemic diseases	11	0.4
Idiopathic	289	12.1
Immunologic	54	2.3
Obstruction	359	15.1
Cancer	11	0.5
Cryptorchidism	342	14.3
Genetic	189	7.9
Testicular failure	345	14.5
TOTAL	2383	100.0

12.1 Introduction

Infertility complaint is common in the urologic office [1]. According to recent estimates, at least 30 million men worldwide are infertile with the highest rates in Africa and Eastern Europe [2]. Thus, regardless of having formal training in male infertility, urologists should be able to diagnose, counsel, provide treatment, or refer the affected patient for assisted reproductive technology (ART). Urologists with formal training in male infertility may also join the multiprofessional reproductive team in an assisted reproduction unit, being responsible for the above-cited tasks as well as for surgical sperm retrieval whenever needed.

In a group of 2385 infertile couples attending our tertiary center for male reproduction, we identified potentially correctable surgical conditions in 48.4% of the male partners [3] (Table 12.1). In our series, clinical varicocele and obstructive azoospermia (OA) were the most common conditions that could be treated by surgical interventions. Notably, about 1/3 of the patients evaluated in the series mentioned above had azoospermia. While reconstructive surgery might be possible in about 30% of the azoospermic men, the majority would require the use of sperm retrieval techniques once enrolled in ART. Thus, the surgical management can be offered to over 50% of the male infertility population seen in daily practice.

At least two breakthroughs occurred in the area of male infertility concerning treatment. One was the development of microsurgery which increased success rates for reconstruction of the reproductive tract. The second was the development of intracytoplasmic sperm injection (ICSI) and the demonstration that spermatozoa retrieved from either the epididymis or the testis were capable of fertilization and pregnancy [4, 5]. As a result of the latter, several sperm retrieval methods were developed to collect either epididymal or testicular sperm, or both, for ICSI. Microsurgery was also incorporated into this armamentarium, either for harvesting sperm from the epididymis in men with obstructive azoospermia (OA) or from the seminiferous tubules in those with non-obstructive azoospermia (NOA) [4, 6].

This chapter focuses on the most common surgical treatments to overcome male infertility. It includes reparative and reconstructive interventions for the male reproductive system. Sperm retrieval techniques are out of the scope of this chapter as they will be addressed later in Chap. 50.

12.2 Surgical Treatment

12.2.1 Varicocele Repair

12.2.1.1 Indications

About 15% of the general male population and up to 35% of the male population with infertility complaints have a varicocele [1]. The etiology of varicocele is likely to be multifactorial. Several theories tried to explain the impact of varicoceles on testicular function, but none of them fully elucidates the variable effect of varicocele on human spermatogenesis and male fertility [7–9]. Recently, several investigators have highlighted the critical role of reactive oxygen species and oxidative stress in the pathophysiology of varicocele-related infertility. Detailed reviews on varicocele pathophysiology can be found elsewhere [10–12].

According to the ASRM Practice Committee report [13], varicocele treatment should be considered in male partners of infertile couples when the following conditions are met: (1) varicocele is palpable on physical exam in standing position in a warm room; (2) the couple has known infertility; (3) the female partner has normal fertility or a potentially treatable cause of infertility (and is willing to treat it) and time to conception is not a concern; and (4) at least one seminal parameter or functional sperm test is altered [13]. According

to the ASRM, varicocele repair is not recommended in cases of isolated teratozoospermia [13] as improvement is modest in this situation [14]. The European Association of Urology (EAU) has somewhat similar recommendations. The EAU states that varicocelectomy is indicated in the presence of a clinically palpable varicocele, oligozoospermia, infertility duration of more than 2 years, and otherwise unexplained infertility in the couple [15].

Other possible indications for varicocele repair include the following: (i) men presenting with palpable varicocele and altered seminal parameters desiring future fertility but not attempting to have children [16]; (ii) young men with semen parameters within normal ranges but at increased risk of ipsilateral testicular dysfunction, such as coincident varicocele and hypotrophic testis; (iii) varicocele-associated pain; (iv) men with large varicoceles and symptomatic testosterone deficiency [15]; (v) prevention or reversal of testicular hypotrophy in adolescent males; (vi) infertile men with palpable varicoceles, semen parameters within normal ranges, and high sperm DNA fragmentation [17–19]; and (vii) infertile men with palpable varicoceles and non-obstructive azoospermia [20].

The recommendations for varicocele treatment relate to the reported association between varicocele and infertility [21], as well as with both reduced semen parameters and testicular size [22]. Furthermore, surgical treatment of clinical varicoceles can improve semen quality and increases the likelihood of pregnancy [23–25]. Despite that, it is still unclear why most men with varicocele retain fertility and why treatment does not always improve the fertility status [11, 26, 27].

12.2.1.2 Preoperative Planning

Patient Evaluation

Treatment of varicocele in the context of infertility aims at restoring or improving the testicular function. A detailed medical history must be taken, and the prognostic factors identified. Physical examination with the patient standing in a warm room is the preferred diagnostic method. Varicoceles identified by this method are termed "clinical" and are graded according to size. Large varicoceles (grade III) are varicose veins seen through the scrotal skin. Moderate (grade II) and small-sized varicoceles (grade I) are dilated veins palpable without and with the aid of the Valsalva maneuver, respectively [28]. In the presence of a bilateral palpable varicocele, it is recommended to perform surgery on both sides at the same operative time [29].

Physical examination may be inconclusive or equivocal in cases of low-grade varicocele and men with a history of previous scrotal surgery, concomitant hydroceles, or obesity. Imaging studies may be useful when the physical examination is inconclusive. The presence of retrograde blood flow to the pampiniform plexus in men with non-palpable varicoceles, identified by other diagnostic modalities such as venography, Doppler ultrasonography, scintigraphy, or thermography, might indicate the presence of subclinical varicocele [30, 31]. The role of subclinical varicocele as a cause of male infertility remains debatable, and current evidence does not support the recommendation for treating infertile men with only subclinical varicocele [32–34].

Notwithstanding, recent evidence suggests that in patients with left clinical varicocele and right subclinical varicocele, bilateral varicocelectomy is superior to unilateral varicocelectomy [35]. In a 2018 randomized controlled trial involving 358 infertile men with varicocele, the bilateral group showed significantly higher improvements than the unilateral group in sperm concentration, normal sperm morphology, and progressive motility. Moreover, the pregnancy rate was statistically higher in the bilateral group after the surgery (42.5% vs. 26.0%, bilateral vs. unilateral group).

A preoperative hormonal profile including serum levels of follicle-stimulating hormone (FSH) and testosterone might add prognostic information. Testicular volume should be assessed using a measurement instrument such as the Prader orchidometer or a pachymeter. At least two semen analyses must be obtained and evaluated according to the World Health Organization (WHO) guidelines [15, 36, 37]. It seems that infertile men either with higher preoperative semen parameters or undergoing varicocele repair for large varicoceles are more likely to show postoperative semen parameters improvement [38]. On the other hand, reduced preoperative testicular volume, elevated serum FSH levels, diminished testosterone concentrations, and subclinical varicocele are negative predictors for fertility improvement after surgery [32, 39–44].

Men with clinical varicoceles presenting with azoospermia might be candidates for varicocele repair. In such cases, the genetic evaluation including Giemsa karyotyping and polymerase chain Yq microdeletion screening for AZFa, AZFb, and AZFc regions is recommended. The reason is varicocelectomy in azoospermic men with genetic abnormalities is doubtful and should be carefully balanced. In azoospermic men with varicocele, testis biopsy (open or percutaneous) might be informative since testicular histology results seem to be the only valid prognostic factor for sperm return to the ejaculate among treated men [36, 45]. Caution should also be applied to recommend varicocele repair in men with hypotrophic testes, history of cryptorchidism, testicular trauma, orchitis, and systemic or hormonal dysfunction since varicocele in such cases might be coincidental rather than contributory to infertility [45]. Any recommendation for varicocele repair should be established rapport with the patient. Moreover, as for all surgical reconstructive procedures, the evaluation of the female partner's reproductive potential is recommended before any intervention, and the alternatives to varicocele repair should be fully discussed.

12.2.1.3 Operative Aspects

Anesthesia

Varicocele repair may be carried out using local, regional, or general anesthesia, according to surgeons and patient's preferences. In our Clinic, we routinely perform microsurgical subinguinal varicocele repair on an outpatient basis using intravenous anesthesia with propofol delivered by an infusion pump, associated with the blockage of the spermatic cord using 10 mL of a 2% lidocaine hydrochloride [36].

Techniques

Varicoceles are surgically treated either by open (with or without magnification) or laparoscopic approaches. Regardless of the technique, the ultimate goal is the occlusion of the dilated veins of the pampiniform plexus. The high retroperitoneal and laparoscopic approaches aim for the ligation of the internal spermatic vein, whereas the inguinal and subinguinal methods enable the ligation of the internal and external spermatic and cremasteric veins that contribute to the varicocele.

Retroperitoneal Techniques High retroperitoneal open varicocele repair involves incision medial to the anterior superior iliac spine at the level of the internal inguinal ring (Fig. 12.1). The external oblique muscle is split, the internal oblique muscle is retracted, and the peritoneum is teased away. Exposure of the internal spermatic artery and vein is carried out retroperitoneally near the ureter. At this level, only one or two internal spermatic veins are present, but the internal spermatic artery might not be easy to identify. The veins are ligated near to the point of drainage into the left renal vein. Neither the parallel inguinal and retroperitoneal collateral veins that usually exit the testis and bypass the retroperitoneal area of ligation nor can the cremasteric veins be identified in the retroperitoneal approach. Some evidence indicates that these collaterals cause the high recurrence rate seen in high retroperitoneal varicocelectomy [46]. The surgical approach on the right side may be more difficult because the right gonadal vein drains in the inferior vena cava.

A laparoscopic varicocelectomy is a retroperitoneal approach using high magnification. The spermatic artery and the lymphatics are easily identified and spared; collateral veins can also be clipped or coagulated. However, external spermatic veins, the second cause of varicocele recurrence, cannot be treated, leading to a recurrence rate of approximately 5% [47]. Furthermore, it has been argued that laparoscopy varicocele repair is more invasive, costly, and associated with higher complication rates than open procedures [47–49]. A discussion about laparoscopic varicocelectomy is out of the scope of this chapter, but more details can be found elsewhere [50].

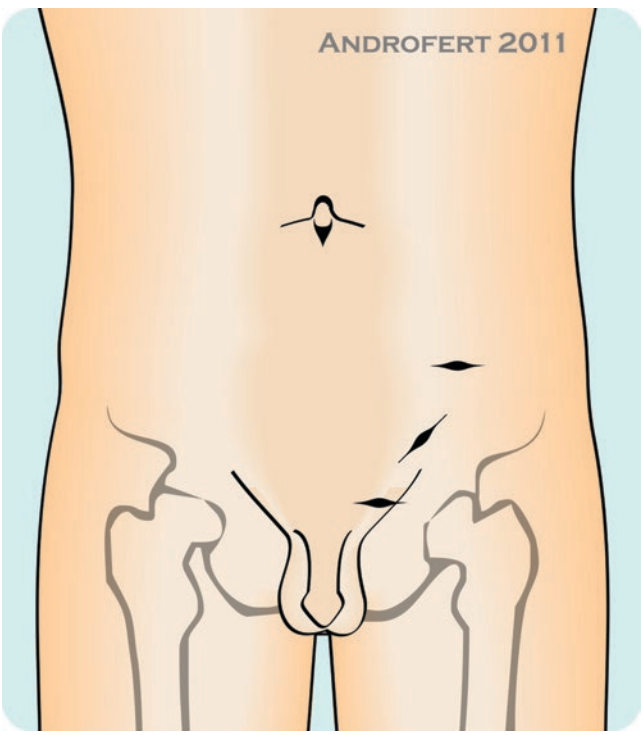

Fig. 12.1 Incision sites commonly used for subinguinal, inguinal, and retroperitoneal varicocele repair. (Reprinted with permission, ANDROFERT© 2011. All Rights Reserved)

Inguinal and Subinguinal Techniques The classic approach to the inguinal varicocelectomy involves a 5- to 10-cm incision over the inguinal canal, an opening of the external oblique aponeurosis, and isolation of the spermatic cord (Fig. 12.1). The internal spermatic veins are dissected and ligated. An attempt is made to identify and spare the testicular artery and the lymphatics. External spermatic veins running parallel to the spermatic cord or perforating the floor of the inguinal canal should be identified and ligated. Although internal and external spermatic veins can be identified macroscopically, the use of magnification facilitates identification and preservation of internal spermatic artery and lymphatics, which may prevent testicular atrophy and hydrocele formation, respectively [51].

Microsurgical varicocelectomy can be performed either by an inguinal or subinguinal approach. The main advantage of the subinguinal over the inguinal approach is that the former obviates the need to open the aponeurosis of the external oblique, which usually results in more postoperative pain and a longer time before the patient return to work. In our practice, varicoceles are treated using a testicular artery and lymphatic-sparing subinguinal microsurgical repair (Marmar's technique) [24, 36, 50]. Briefly, we first make a 2.5-cm skin incision below the external inguinal ring (Figs. 12.2a). Then, we dissect the subcutaneous tissue until the spermatic cord is exposed. The cord is elevated with a Babcock clamp, and the

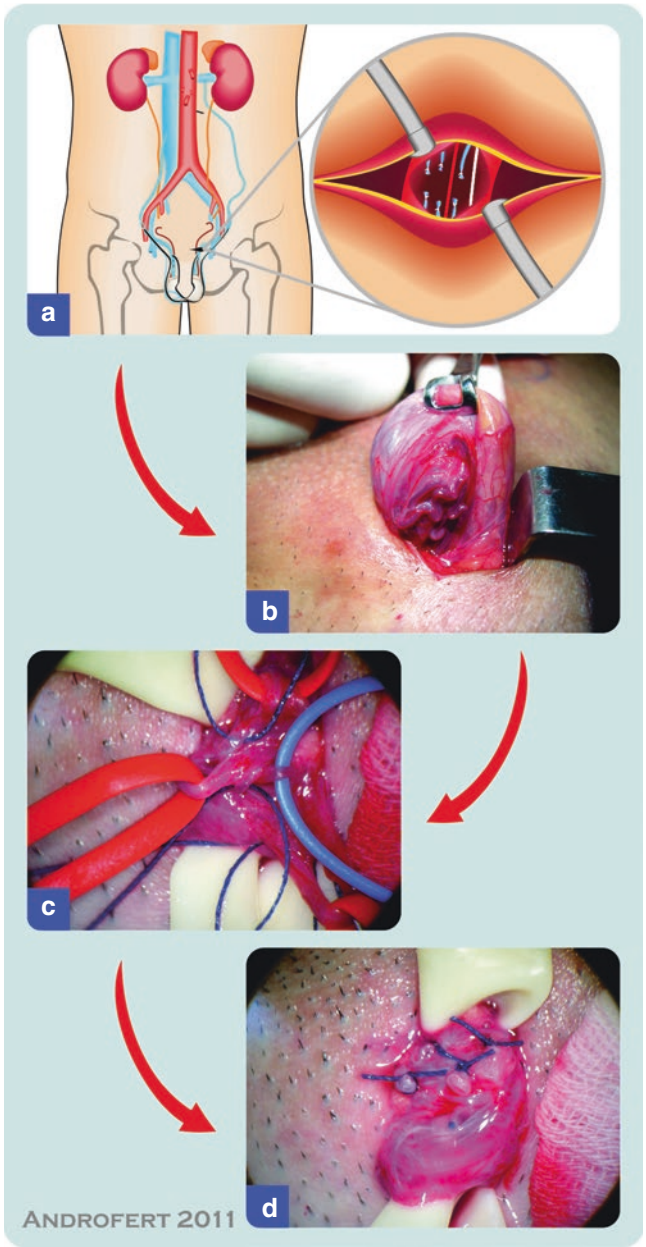

Fig. 12.2 Microsurgical subinguinal varicocele repair. (**a**) In the subinguinal approach, a transverse incision is made just below the level of the external inguinal ring. (**b**) The cord is easily identified and secured, and dilated cremasteric veins are identified by elevating the spermatic cord with a Babcock clamp. (**c**) Testicular artery (blue vessel loop), lymphatics (blue cotton suture), and dilated varicose veins (red vessel loops) are demonstrated. (**d**) Final surgical aspect of varicose veins transected and ligated with non-absorbable sutures. (Reprinted with permission, ANDROFERT© 2011. All Rights Reserved)

posterior cremasteric veins are ligated and transected (Fig. 12.2b). We place a Penrose drain behind the cord without tension. Then, the cremasteric fascia is opened to expose the cord structures, and the dissection proceeds using the operating microscope with magnification ranging from 6× to 16×. We ligate and transect the dilated cremasteric veins within the fascia. The lymphatics and arteries are visually identified and preserved (Fig. 12.2c). Identification of the spermatic artery(ies) can be confirmed by visualization of clear pulsatile movement and/or evidence of antegrade, pulsatile blood flow after gentle lifting and partial occlusion of the vessel. Although papaverine hydrochloride solution might be used on the cord structures to increase the arterial beat, we prefer to use the intraoperative microvascular Doppler (20 MHz) ultrasound to identify and spare small secondary arteries. All dilated veins of the spermatic cord are identified, isolated and tagged with vessel loops, then ligated using non-absorbable sutures, and transected (Fig. 12.2d). We only ligate vasal veins if they exceed 2 mm in diameter and do not use sclerotic agents to occlude small veins.

This subinguinal technique may also be carried out using the da Vinci TM (Intuitive Surgical) robot assistance, but results are still preliminary. In a study involving 258 procedures, persistent varicocele could be detected by Doppler examination in 9.6% of patients at 3 months postoperatively [52]. Improvement in semen parameters occurred only for sperm concentration with a median increase of 37.3% (p <0.03). The treatment did not affect motility and morphology. In this study, the authors did not assess ICSI outcomes, pregnancy rates, and cost-effectiveness [52]. Detailed information about robotic-assisted varicocelectomy is provided in Chap. 21.

Current evidence supported by prospective studies shows that subinguinal microsurgical varicocele repair offers better results regarding fewer complications and lower recurrence rates than the other techniques described above [15, 53].

12.2.1.4 Postoperative Care

We recommend the use of local dressing and scrotal supporter for 48–72 hours and 1 week, respectively. Also, we always recommend scrotal ice packing to decrease the local edema for the first 48 postoperative hours. We counsel our patients to restrain from physical activity and sexual intercourse for 2–3 weeks. Oral analgesics usually suffice to control postoperative pain. Postoperative follow-up aims to evaluate improvement in semen parameters, complications, and natural or assisted conception. Semen analysis should be performed every 3 months until the semen parameters stabilize, or pregnancy occurs.

Semen Improvement Results

Varicocelectomy studies report significant improvements in one or more semen parameters in approximately 65% of men [54]. The mean time for semen improvement and natural pregnancy after surgery is approximately 5 and 7 months, respectively [25, 55].

A 2007 study analyzed seminal improvement following varicocele correction using a new meta-analytic method. The authors reviewed 17 studies where patients with at least one

abnormal seminal parameter and unilateral or bilateral clinically detected varicocele had undergone high ligation or inguinal microsurgical varicocelectomy correction [10]. After microsurgical repair, the combined analysis demonstrated an improvement in sperm count of 9.7 M/mL (95% CI 7.3–12.1, p <0.00001) and 9.9% (95% CI 4.9–14.9, p = 0.0001) in motility. After high ligation, sperm count increased by 12.0 M/mL (95% CI 5.7–18.3, p = 0.0002) and motility increased by 11.7% (95% CI 4.3–19.1, p = 0.002). Morphology in both techniques showed an improvement of 3.2% (95% CI 0.7–5.6, p = 0.001) [10]. The comparisons were made against baseline values.

Along the same lines, Samplaski et al. evaluated the sperm count improvement rate following varicocele repair in men with oligozoospermia. The authors reported an improvement in about 60% of the treated individuals. The baseline total motile sperm count (TMSC), which was below five million, increased to >5 million, thus allowing the use of intrauterine insemination (IUI) or even natural pregnancy [56].

In a 2017 prospective study, 92 subjects with either primary (n = 57) or secondary (n = 35) infertility and varicocele were compared according to semen parameters after microsurgical repair. Baseline parameters were not significantly different between groups. The mean semen parameters improved significantly in both groups and did not differ between primary and secondary infertility patients [57].

Abdel-Meguid et al. conducted a prospective RCT to compare microsurgical varicocele repair versus no intervention. The results at 1-year follow-up did show significant improvement in sperm count, motility, and morphology, both in a within-arm analysis for treatment group and also against the control group [58]. Another study by Bryniarski et al. compared the improvement in semen parameters after varicocele repair with either microsurgery or laparoscopic approaches. Both groups showed improvement in all parameters at 1 year follow-up [59]. Nasr et al. comparing microsurgical varicocele repair and percutaneous embolization at 1-year of follow-up also showed improvement of sperm count and motility. In their study, there was no significant difference between the procedures regarding sperm quality [60]. Tables 12.2 and 12.3 synthetize published RCTs and meta-analyses on varicocelectomy and its effect on spontaneous pregnancy rates, respectively [61–71].

Another study by Baazeem et al. that corroborated these findings [53] showed not only improvement in sperm count and total and progressive motility and ultramorphology but

Table 12.2 Randomized controlled trials of varicocelectomy and its effect on natural pregnancy rates

First author and reference	Year	Population	Interventions and follow-up	Treated	Controls	*P* values
Madgar [60]	1995	45 infertile men with abnormal semen parameters and clinical varicocele (any grade); female partners with no demonstrable infertility factor	High ligation of the internal spermatic vein and observation; 3 years	PR[c]: 60.0%	PR[c]: 10.0%	0.001
Yamamoto [61]	1996	85 infertile men with subclinical left varicocele	High ligation of the internal spermatic vein and observation; 2–5 years	PR[c]: 6.7%	PR[c]: 10.0%	0.96
Nieschlag [62]	1998	125 infertile men with at least one abnormal semen parameter[a] and left clinical varicocele (any grade)	Embolization or surgical repair and counseling; 12 months	PR[c]: 29.0%	PR[c]: 25.4%	NS
Unal [63]	2001	42 men with subclinical varicocele; all couples with primary infertility	Surgical vein ligation and clomiphene citrate; 15 months	PR[c]: 12.5%	PR[c]: 6.7%	0.589
Krause [64]	2002	67 infertile men with at least one abnormal semen parameter[a] and clinical varicocele (any grade)	Antegrade of retrograde sclerotherapy and observation; 12 months	CPR[d]: 30%	CPR[d]: 16.2%	0.189
Abdel-Meguid [58]	2011	145 men with at least one abnormal semen parameter[b] and clinical varicocele (any grade); all couples with primary infertility	Subinguinal microsurgical varicocelectomy and observation; 12 months	PR[c]: 32.9%	PR[c]: 13.9%	0.010
Mansour Ghanaie [65]	2012	136 men with normal semen parameters[b] and clinical varicocele (any grade); all couples with secondary infertility (recurrent pregnancy loss)	Loupe-assisted inguinal varicocelectomy and observation; 12 months	CPR [1]: 44.1%; miscarriage [2]: 13.3%; LBR [3]: 38.2%	CPR [1]: 19.0%; miscarriage [2]: 69.2%; LBR [3]: 5.9%	0.003 [1]; 0.002 [2]; 0.003 [3]

Table 12.3 Meta-analyses of varicocelectomy and its effect on natural pregnancy rates

Author, year, and reference	Population	Included studies	Interventions	Natural pregnancy after varicocelectomy	Remarks
Evers, 2008 [38]	607 couples and male partners with varicocele	8 RCTs reporting pregnancy rates as an outcome measure	Surgical ligation or radiological embolization of the internal spermatic vein and untreated groups	Observed odds ratio (OR) of the eight studies was 1.10 (95% CI 0.73 to 1.68), indicating no benefit of varicocele treatment over expectant management in subfertile couples in whom varicocele is the only abnormal finding	Two trials involving clinical varicocele included some men with normal semen analysis. Three studies specifically addressed only men with subclinical varicoceles
Ficarra, 2006 [39]	Infertile men with abnormal results on semen analyses and a palpable varicocele. Group 1: 120 infertile men with varicocele subjected to surgical repair; Group 2: 117 men with untreated varicocele	3 RCTs reporting pregnancy rates as an outcome measure	Surgical ligation or radiological embolization of the internal spermatic vein and untreated groups	Significant increase in pregnancy rate (PR) in patients who underwent varicocele treatment (36.4%) compared with the control group (20%) ($p = 0.009$)	This study is a revaluation of the Cochrane meta-analysis (Evers et al., 2008) excluding men with normal semen analysis and subclinical varicocele
Marmar, 2007 [40]	Infertile men with abnormal results on semen analyses and a palpable varicocele. Group 1: 396 men subjected to varicocele repair; Group 2: 174 infertile men with untreated varicocele	2 RCTs and 3 observational studies	Surgical varicocelectomy compared with no or medical treatment for palpable varicocele and at least one abnormal semen parameter	Significant increase in pregnancy rate (PR) in patients who underwent varicocele treatment (33.3%) compared with the control group (15%), OR of natural pregnancy after surgical varicocelectomy, compared with no or medical treatment was 2.87 (95% confidence interval [CI], 1.33–6.20) with use of REM and 2.63 (95% CI 1.60–4.33) with use of FEM	The number needed to treat was 5.7 (95% CI 4.4–9.5)
Baazeem, 2011 [12]	380 infertile men with oligozoospermia and a palpable varicocele	4 RCTs reporting on pregnancy outcome after repair of clinical varicoceles in oligozoospermic men	Surgical ligation and untreated groups	Using the random-effects model, the combined OR was 2.23 (95% confidence interval [CI], 0.86–5.78; $p = 0.091$), indicating that varicocelectomy is moderately superior to observation, but the effect is not statistically significant	22, 17, and 5 prospective studies reporting on sperm concentration, total motility, and progressive motility, respectively, before and after repair of clinical varicocele were evaluated. The REM indicated improvement in sperm concentration by 12.32 million sperm per milliliter (95% CI, 9.45–15.19; $p < 0.0001$) and by 10.86% (95% CI 7.07–14.65; $p < 0.0001$) and 9.69% (95% CI 4.86–14.52; $p = 0.003$) total and progressive motility, respectively
Kroese, 2012 [41]	894 couples and male partners with varicocele	10 RCTs reporting natural pregnancy rates as an outcome measure	Surgical ligation or radiological embolization of the internal spermatic vein and untreated groups	The combined fixed-effect OR was 1.47 (95% CI: 1.05–2.05, very low-quality evidence), favoring the intervention. The number needed to treat for an additional beneficial outcome was 17, suggesting benefit of varicocele treatment over expectant management for pregnancy rate in subfertile couples in whom varicocele in the man was the only abnormal finding	Subgroup analysis after exclusion of the studies including men with normal semen analysis and subclinical varicocele (five studies) revealed favorable effect of treatment (combined OR: 2.39; 95% CI: 1.56–3.66; high statistical heterogeneity $I^2 = 67\%$). The number needed to treat for an additional beneficial outcome was 7

(continued)

Table 12.3 (continued)

Author, year, and reference	Population	Included studies	Interventions	Natural pregnancy after varicocelectomy	Remarks
Kim, 2013 [42]	610 infertile men from couples with otherwise unexplained subfertility	7 RCTs reporting natural pregnancy rates as an outcome measure	Surgical ligation and no treatment	The random-effects model showed an odds ratio (OR) of 1.90 (95% confidence interval [CI], 0.77 to 4.66; $p = 0.1621$). However, for subanalysis of three studies that included patients with clinical varicocele and abnormal semen parameters, the fixed-effects pooled OR was significant (OR, 4.15; 95% CI, 2.31 to 7.45; $p < 0.001$), favoring varicocelectomy	There were differences in enrollment criteria among the studies. Four studies included patients with clinical varicocele, but three studies enrolled patients with subclinical varicocele. Meanwhile, four trials enrolled patients with impaired semen quality only, but the other three trials did not

OR odds ratio, *REM* random-effects model, *FEM* fixed effects model

also reduction in sperm oxidative stress and sperm DNA fragmentation (SDF) [53]. Accordingly, Roque and Esteves [72] reviewed the effect of varicocele repair in DNA fragmentation and reinforced this idea after reviewing over 20 studies accounting for more than 1200 treated subjects. Despite using different SDF assays, various designs, and variable sample size, all studies reported significant decreases in SDF rates following varicocele repair in a follow-up period ranging from 3 to 12 months. The exact percentage of men who benefit from surgery is still poorly reported but is estimated to be around 78–90% by some authors [72].

Hence, even if traditional seminal parameters do not show a definite improvement after varicocele microsurgical repair, a positive effect has been demonstrated on other functional sperm tests, mainly among patients presenting varicocele of higher grades [73].

As for the effect of varicocele repair before assisted reproductive technology (ART), our previous observations indicate that treatment of clinical varicoceles can improve the outcomes of ICSI in couples with varicocele-related infertility [24]. In this study, the chances of achieving a live birth were significantly increased by 1.9-fold, while the chance of miscarriage was reduced by 2.3-fold when the varicocele was treated before ICSI [24].

Concerning the role of varicocele repair in men with NOA, a recent review with meta-analysis indicated that sperm return to the ejaculates was achieved in 44% (151/344) of the treated individuals [20]. This benefit is most notorious among men with testicular histopathology revealing hypospermatogenesis when compared with maturation arrest (OR 2.35; 95% CI: 1.04–5.29, $p = 0.04$) and Sertoli-cell only (OR 12.0; 95% CI 4.34–33.17, $p < 0.001$), and the procedure might avoid the need of surgical sperm extraction [20, 74].

Fertility Results

Current evidence indicates that varicocele repair may positively affect pregnancy rates. However, the literature still lacks powered randomized controlled trials with homogeneous populations to clarify the existent debate definitively.

A randomized clinical trial published in 2011 reported natural pregnancy rates of 32.9% in treated men versus 13.9% in the observation group (OR 3.04; 95% CI 1.33–6.95) [58]. Likewise, Marmar et al. in a meta-analysis including studies of various designs showed that the likelihood of natural pregnancy favored the varicocele repair group (odds ratio: 2.97; 95% CI 1.60–4.33) [75].

Another study showed that the type of infertility being either primary or secondary does not seem to impact fertility results at 1-year follow-up after microsurgical varicocele repair (42.1% vs. 31.4%, respectively) [57].

The most recent Cochrane compilation dates back to 2012 and included ten RCTs involving 894 men treated for infertility [76]. In this review, the authors included two trials involving men with normal semen analysis and three in men with subclinical varicoceles. The combined fixed-effect OR for the outcome of pregnancy was 1.47 (95% CI 1.05 to 2.05, very low-quality evidence), favoring the intervention. The number needed to treat (NNT) for an additional pregnancy was 17, suggesting a benefit of varicocele treatment over expectant management in infertile couples in whom varicocele was the only abnormal finding. A subgroup analysis excluding men with normal semen analysis and subclinical varicocele (five studies) also favored treatment (combined OR 2.39; 95% CI 1.56 to 3.66). In this case, the NNT for an additional beneficial outcome was 7. No studies reported live birth.

As for the surgical techniques, a 2009 meta-analysis that analyzed 4473 subjects who underwent microsurgery reported better natural pregnancy rates (41.9%, $p = 0.001$),

lowest recurrence (1.0% $p = 0.001$), and hydrocele formation (0.4%, $p = 0.001$) [77]. Pregnancy following either laparoscopic or microsurgery at 12-month follow-up has also been reported to be similar (29.7% vs. 40.5%, respectively) ($p = 0.34$) [59]. A more recent systematic review and meta-analysis published in 2018 compiled 23 studies with 1178 patients in the group of microsurgery and 1069 patients in the group of laparoscopic surgery [78]. The authors showed that microsurgical varicocele repair decreased complication rates (RR: 0.40, 95% CI: 0.21–0.75), recurrence rates (RR: 0.35, 95% CI: 0.22–0.55), and hospital stay (WMD: −0.53, 95% CI: −0.85 to −0.21), whereas it increased sperm concentration (WMD: 3.00, 95% CI: 1.23–4.76). No effects on operation time (SMD: 1.61, 95% CI: 0.71–2.51) and sperm motility (WMD: 2.38, 95% CI: 0.39–4.37) were observed, and no data was available concerning pregnancy outcomes.

Lastly, a 2019 prospective randomized study including 302 infertile patients with severe oligozoospermia and clinical (grade II/III) varicocele evaluated the role of preserving the testicular artery [79]. The authors showed that there was a statistically significant improvement in sperm density and motility at 3 and 6 months postoperatively, regardless of whether or not the artery was preserved. However, the greater seminal improvement occurred in patients who had the internal spermatic artery preserved. At 1-year follow-up, this group achieved significantly higher natural pregnancy rates (40% vs. 30%, $p = 0.03$). An artery-ligating varicocelectomy was an independent predictor of reduced natural pregnancy rates (hazard risk [HR] = 3.2, 95% CI 1.4–7.1, $p = 0.003$) [79].

12.2.2 Reconstructive Surgery of the Vas Deferens and Epididymis

12.2.2.1 Indications

Vasovasostomy and vasoepididymostomy are surgical procedures developed to bypass obstructions affecting either the vas deferens or the epididymis. In the United States, approximately 13% of married men aged 15–44 years report having had a vasectomy [80]. The number of men seeking a vasectomy reversal due to changes in marital status or reproductive goals is estimated to range from 2% to 6% [81]. In Brazil, approximately 200,000 vasectomies and 7000 reversals are performed annually [82] The vast majority of vasovasostomies and vasoepididymostomies is carried out to overcome obstructions secondary to vasectomy; however, other indications include correction of epididymal or vasal obstructions due to genital infections, iatrogenic injuries related to inguinal or scrotal surgery, especially during the early childhood years, and postvasectomy pain syndrome [83].

12.2.2.2 Preoperative Planning

Patient Evaluation

A detailed medical history must be taken and prognostic factors identified. The obstruction interval from vasectomy to reversal is critical for surgery outcomes. Patency and pregnancy rates for intervals up to 15 years are approximately 74% and 40%, respectively [84], whereas intervals longer than 15 years relate to lower patency and pregnancy rates. Furthermore, long-interval obstructions relate to higher incidence of epididymal obstruction; as a result, vasoepididymostomy (VE) is likely to be required.

A history of a previous vasectomy reversal attempt does not preclude a new one. Patency and pregnancy rates of 79% and 31%, respectively, are reported for repeated reversals [85]. Apparently, the history of conception with the current partner is the only significant predictor for a successful pregnancy. However, a history of genital/inguinal surgery should raise the concern about the possibility of iatrogenic inadvertent surgical obstruction. Repair of obstruction in the inguinal canal or retroperitoneum can be technically challenging.

A detailed physical examination should also be carried out. Small and soft testes might indicate impaired spermatogenesis. Indurate, irregular epididymis and the presence of hydrocele are often associated with obstruction and might suggest the need for vasoepididymostomy. Palpation of a granuloma in the vas deferens should be interpreted as a favorable prognostic sign. Its presence means that sperm has leaked at the vasectomy site preventing overpressure within the epididymis tubules and rupture [81, 84, 86]. If a vasal gap is detected, we advise our patients that a larger incision into the inguinal region might be needed to allow a tension-free anastomosis. Specific laboratory tests are not necessary before reconstructive surgeries. However, serum FSH might be informative concerning testicular reserve if testicular damage is suspected on physical examination. The clinical utility of antisperm antibody testing remains controversial; evidence suggests that late failures following reversals are likely to be technical rather than immunological [87, 88]. Besides, overall conception rates are acceptably high, and the presence of antisperm antibodies does not correlate closely with postsurgical fecundability [89].

We evaluate the female partner fertility carefully before any recommendation for reconstruction. For instance, the ovary reserve and the patency of the fallopian tubes must be evaluated and accounted for since they affect the chances of pregnancy. Also, we discuss the alternatives to vasectomy reversal with the couple. It has been shown that reversal outcomes in men with the same partners are significantly better than those with new partners. The proven fecundity of the couple, a shorter obstruction interval, and the firm decision to achieving conception are

critical factors for the higher success rate [81, 90]. By contrast, the female age greater than 40 years seems to be a negative predictor for success [91, 92].

12.2.2.3 Operative Aspects

Anesthesia

Vasovasostomy and vasoepididymostomy can be performed using local, regional, or general anesthesia. In the authors' practice, procedures are carried out on an outpatient basis. Total intravenous anesthesia with propofol (2,6-diisopropylphenol) coupled with the blockage of the spermatic cord using lidocaine hydrochloride solution is our preferred anesthetic method. A propofol induction dose of 3–4 $mg \cdot kg^{-1}$, followed by infusion of 60–100 $\mu g \cdot kg^{-1} \cdot min^{-1}$, is used under spontaneous or assisted ventilation with 2 $L \cdot min^{-1}$ of 100% O_2 on a face mask. An opioid such as fentanyl (1–2 $\mu g \cdot kg^{-1}$) or alfentanil (7–15 $\mu g \cdot kg^{-1}$) is given before the surgeon performs skin and subcutaneous infiltration with 1% lidocaine without epinephrine. Propofol is advantageous as it has antiemetic effects and allows patients to wake up with a sense of well-being and a clear mental state.

Incision

We make a 2-cm longitudinal scrotal incision in the anterior aspect of the scrotum on each side. The incision is made onto the palpable granuloma or the identified vasal gap. Only the vas ends are delivered through the skin incision. The incision might be extended to the inguinal region when (i) the vasectomy was performed high in the scrotum, (ii) a large segment was removed, or (iii) in repeat reconstructions with difficult vasal mobilization. The testis is only delivered if a vasoepididymostomy or a robotic-assisted anastomosis is to be performed.

Approaching the Vas

Microsurgical dissection is carried out at the region of the prior vasectomy site to free the vas and its vascular pedicle from surrounding scar tissue. Hemostasis is obtained with great care using either bipolar or hand-held thermal cautery units. After the vas has been mobilized and its scarred ends have been excised, patency of the abdominal vas end is confirmed with the introduction of a 24-gauge blunt tipped angiocatheter into the lumen and the injection of 20-mL sterile saline through the catheter. The ends of the vas must be adequately mobilized in order to allow a complete tension-free anastomosis. Either a microsurgical clamp or holding sutures can be used according to the surgeon's preference.

Vasal Fluid Examination

We examine the fluid from the testicular vas end both macroscopically and under the optical microscope for the presence of sperm. The presence of copious, clear, watery, or cloudy fluid and motile sperm is associated with excellent patency rates of 94%, opposed to only 60% when no sperm is found in the vasal fluid [81]. Thick toothpaste-like vasal fluid is suggestive of epididymal obstruction [81, 93]. The quality of sperm found in the intravasal fluid and the surgeon's microsurgical skills are the most critical factors to determine the type of reconstructive technique. Typically, the presence of sperm or sperm parts, and even a "dry" vas, is associated with adequate patency rates of about 70–80% following vasovasostomies [94, 95]. The vasoepididymostomy is a challenging surgical procedure that should only be attempted by experienced microsurgeons. A precise anastomosis of the vas (luminal diameter of 300–400 micrometers) to the epididymal tubule (150–250 micrometers) requires meticulous microsurgical technique and high magnification. Intraoperative sperm harvesting and cryopreservation can be offered during vasoepididymostomy [96].

Vasovasostomy Techniques

Attention to surgical details directly affects the success of reconstructive microsurgeries. These include the accurate mucosa-to-mucosa approximation, a water-tight tension-free anastomosis, preservation of the vasal blood supply and healthy tissue (mucosa and muscularis), and an adequate microscopic atraumatic technique.

Modified One-Layer Technique The modified one-layer technique described by Sharlip is the authors' choice for vasectomy reversal [97]. Our preference is to perform the anastomosis using a 9-0 nylon suture mounted on a taper-pointed needle and with the aid of a vas clamp (ASSI, catalog# MSPK-3678). The operation is performed entirely with the surgeon located on the patient's right side. The first suture is placed on the medial surface of the right vas (zero-degree position) (Fig. 12.3a). This suture is placed through the full thickness of the vas wall on the testicular side first taking a generous bite of adventitia and muscularis and a tiny portion of the mucosa. The suture is then passed into the corresponding zero-degree position of the abdominal side again taking a bite at the edge of the mucosa and a large portion of the muscularis/adventitia layer. This suture is tied and cut long, so it is easily identified as the procedure continues. The second suture is placed 180 degrees opposite to the first, again taking the full aspect of the vas wall, firstly on the testicular side and then on the abdominal one. This suture is also tied and cut long. A third full thickness suture is placed at the 60-degree position, one-third of the distance from the first to the second sutures. Before it is tied, a fourth suture is placed at the 120-degree position, two-thirds of the distance from the first to the second sutures. Third and fourth sutures are then tied after careful inspection of their

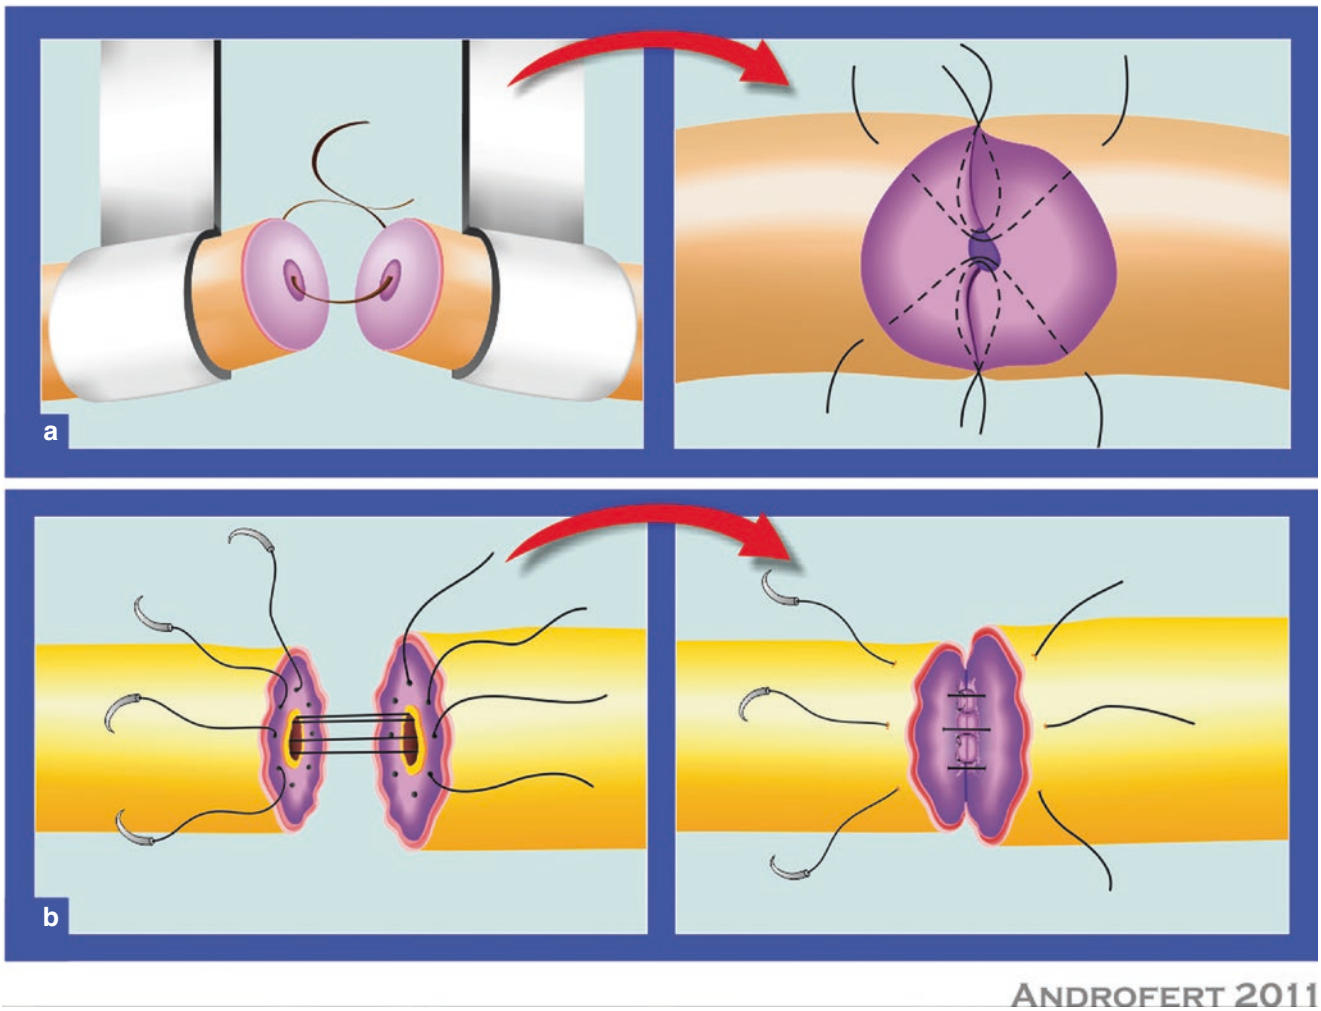

Fig. 12.3 Microsurgical vasovasostomy techniques. Illustration of the modified one-layer (**a**) and the modified two-layer (**b**) techniques. (Reprinted with permission, ANDROFERT© 2011. All Rights Reserved)

proper placement (Fig. 12.3a). A fifth suture is placed between these two at the 90-degree position, but only superficially through the muscularis. This completes the anastomosis of the anterior portion of the vas. At this point, four full thickness stitches and one muscular suture have been placed, and half of the total circumference of the vas wall is closed. The vas clamp is then rotated 180 degrees, and accidental back-walling and proper position of full thickness sutures are checked. After rotation of the vas, two full-thickness sutures are then placed at the 240-degree and 300-degree positions. These sutures are inserted and inspected before being tied. A final suture is placed in the muscularis at the 270-degree position. These complete the anastomosis, summing up eight sutures in total instead of twelve as described by Sharlip [97]. Upon anastomosis completion, the surrounding loose fibrous tissue is sutured over the anastomotic site alleviating tension. The scrotal incision is closed in the usual conventional manner.

Two-Layer Technique This technique, described by Belker, involves placing five to eight interrupted 10-0 nylon sutures in the inner mucosal layer and eight to ten 9-0 nylon sutures in the outer muscular and adventitial layer [98]. The use of an approximating clamp and a holding suture is recommended to stabilize vas ends for the anastomosis. Before the suturing begins, the surgeon looks straight down into the lumen of each end of the vas situated parallel to each other. As suturing proceeds, the transected ends of the vas bend toward each other, bringing the suture together without tension. Firstly, three posterior muscular layer sutures are placed in a row so that the knots are outside. Only 90 degrees of the circumference is approximated, leaving full access to the mucosa. Then, after three posterior mucosal sutures have been placed and tied, the far-corner and near-corner sutures are placed and tied until space remains for only two or three sutures in the anterior aspect of the anastomosis. These remaining stitches are then placed and left long and untied until back-walling can be safely ruled out. The sutures are

finally tied, and the closing muscular layer is sutured with caution to visualize the underlying mucosal layer sutures to prevent penetration of the lumen by the outer-layer ones. Placement of these sutures is more comfortable to perform from the assistant side toward the surgeon's side. Closure of scrotal incision is performed in the usual manner. A recent video shows in detail how the technique is performed by Hakki et al. [99].

Multilayer Microdot Technique This method, originally described by Goldstein, is preferred to treat markedly discrepant diameters in straight or convoluted vas [100]. Vasal ends are prepared with a 90-degree right angle cut, and methylene blue stain can be used to visualize the mucosal rings better. Planned needle exit points can be marked with microtip marking (Fig. 12.3b). Polypropylene monofilament 10-0 double-armed sutures with 70-micrometer-diameter taper-pointed needles are used for the anastomosis. Sutures are placed in an inside-out fashion eliminating the possibility for accidental back-walling. The mucosa and about one-third thickness of the muscularis should be included in each bite, symmetrically on each side of vas ends. Four initial sutures are placed in the anterior aspect of the vas and tied up (Fig. 12.2b). Three 9-0 sutures are then placed precisely in between the previously placed mucosal sutures, just above but not through the mucosa, sealing the gap between the mucosal sutures. The vas is then rotated 180 degrees, and four additional 10-0 sutures are placed completing the mucosal part of the anastomosis. Just before tying the last mucosal knot, vas lumen is irrigated with heparinized saline solution to prevent formation of clots. After completion of mucosal layer, 9-0 sutures are placed in between each mucosal suture again avoiding penetrating the mucosa itself (Fig. 12.2b). The sutures are placed but not tied until two or three more have been placed. Superficial additional adventitia 9-0 sutures should be placed if necessary. The procedure is completed by approximating the vas sheath with four to six 6-0 sutures.

Robot-Assisted Technique In recent years, some authors have shown the possibility to perform the classic above described techniques using robotic assistance. The robot can offer additional benefits of enhanced imaging (up to 100× magnification) and control of physiologic tremor [101, 102]. The use of robot-assisted reconstructive surgery for male infertility is out of the scope of this chapter (please refer to Chaps. 19 and 20 for more information).

Vasoepididymostomy Techniques

The procedure starts with the placement of a longitudinal incision in the upper scrotum. The testis is delivered through the incision, and the testis and epididymis are thoroughly inspected. The obstruction site may be often grossly visible as an area where the epididymis transitions from a firm, full caliber structure to a smaller and softer one. The distal end of the vas deferens is mobilized similarly as described for the vasovasostomy, but often a longer length is required to perform an epididymal anastomosis. At this point, the microscope is brought into the operating field. Currently, three variations of the technique have been used to connect the vas deferens lumen to a single epididymal tubule: end-to-end, end-to-side, and end-to-side intussusception techniques. Before the anastomosis, a dilated epididymal tubule must be identified immediately above the level of obstruction. The tubule is opened and the fluid inspected for the presence of motile sperm. If no sperm are identified, a more proximal site of the epididymis will be required for the anastomosis.

End-to-End Technique First described by Silber, the end-to-end VE is the most challenging anastomosis to perform [103, 104]. It involves dissection of a single epididymal tubule, complete transection, and anastomosis to the vas lumen. The epididymis is dissected off the testis for 3 to 5 cm to provide an adequate length to achieve a tension-free anastomosis. Initially, two 9-0 nylon sutures are placed at the 5 and 7 o'clock positions of the seromuscular surface of the vas, to secure the cut end of the distal vas to the epididymal tunica. Next, four double-armed 10-0 nylon sutures mounted in double-armed 70-micrometer fishhook-shape taper-pointed needle are placed in a quadrant fashion between the vas mucosa and the epididymal tubule (Fig. 12.4a). These sutures are not tied until all have been positioned. The anastomosis is completed by placing several interrupted 9-0 nylon sutures to approximate the seromuscular layer of the vas to the epididymal tunic layer.

End-to-Side Technique The end-to-side VE, popularized by Thomas, is performed by creating a small window in a loop of the epididymal tubule proximal to the obstruction and by suturing the end of the vas lumen to the open window [104]. The advantages over the end-to-end anastomosis include less dissection and bleeding during the anastomosis because hemostasis can be secured before opening the tubule. Moreover, only one tubule is opened making the identification of the patent tubule more precise and easier. With the tubule opened and sperm presence confirmed, three or four double-armed 10-0 nylon sutures are placed in a quadrant fashion through the edge of the epididymal tubule (Fig. 12.4b). The sutures are placed in the corresponding quadrant of the vasal mucosa and tied. The anastomosis is completed with additional 9-0 nylon sutures between the epididymal tunic and the seromuscular layer of the vas deferens. Finally, several 9-0 nylon sutures are used to anchor the vas

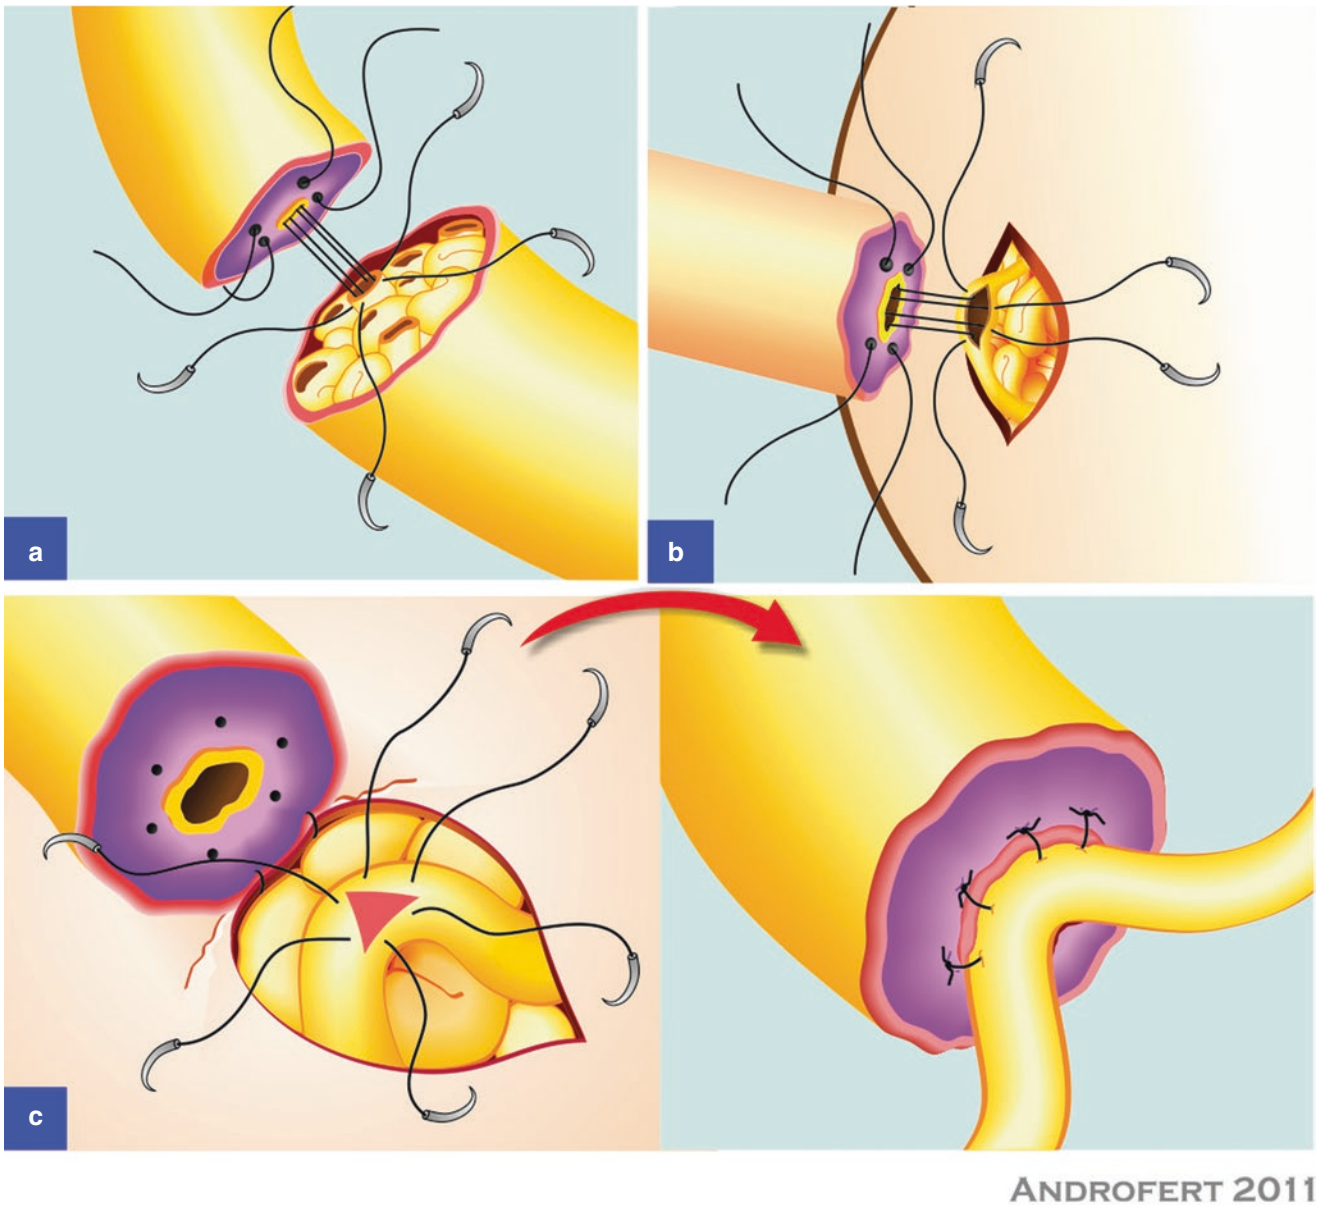

Fig. 12.4 Microsurgical vasoepididymostomy techniques. Illustration of the end-to-end (**a**), end-to-side (**b**), and triangulation end-to-side (**c**) anastomoses (see text for detailed description). (Reprinted with permission, ANDROFERT© 2011. All Rights Reserved)

deferens to the parietal layer of the tunica vaginalis. These final sutures are designed to prevent tension on the anastomosis and are placed well away from the vasoepididymostomy site.

Triangulation End-to-Side Vasoepididymostomy This technique was introduced by Berger [105] (with subsequent modifications by others [106, 107]). It is the simplest and fastest among the three techniques described in this chapter and the authors' choice for vasoepididymostomy. The intention is to combine the precision of the conventional end-to-side anastomosis with a simplified microsuture placement. Rather than a direct approximation of the epididymal tubule to the vas, this method involves pulling the epididymal tubule into the vas lumen. An opening window is made in the epididymal tunic corresponding to the vas diameter. Two 9-0 sutures are used to secure the muscular layer of the vas to the epididymal tunic to avoid tension on the anastomosis site. Three double-armed 10-0 nylon sutures are placed equidistantly in a triangular configuration in the desired epididymal tubule (Fig. 12.4c). Then, the epididymal tubule is carefully opened with microscissors or microknife between the positioned sutures. Once sperm are confirmed in the epididymal fluid, the needles are passed through the lumen of the vas in an inside-out fashion. The sutures are then tied, creating an

invagination of the epididymal tubule into the vasal lumen (Fig. 12.4c). Finally, additional 9-0 nylon sutures are placed to approximate the seromuscular layer of the vas to the epididymal tunic.

Marmar described a modification of the triangulation end-to-side VE [106]. In this technique, a single epididymal tubule is exposed, and two 10-0 nylon sutures mounted on double-armed 70-micrometer bi-curve needles are placed on the field. A needle from each suture is mounted on a styrofoam block and positioned parallel to the other with sufficient room for passage of the tip of a microblade between them. A microneedle holder is used to grasp both needles simultaneously and move them from the block to the field while maintaining the parallel arrangement. The tips of both needles are passed through a selected tubule at once. Both sutures are retracted laterally, and a tubulotomy is cut between them with a microknife. Then, all four needles from the epididymal sutures are individually placed into the mucosal lumen of the vas and out through the muscularis on the cut end. Needles are placed at the 8 and 10 o'clock positions on the left side and the 2 and 4 o'clock positions on the right side. Sutures are tied allowing the epididymal tubule to invaginate into the vas lumen. The anastomosis is completed with 3 to 4 additional 9-0 nylon sutures through the muscularis of the vas and epididymal tunic.

More recently, in 2014, two sutures of 10-0 nylon single-armed needles were used for longitudinal intussusception technique with satisfactory results [108, 109]. The first suture (5 cm long) is placed in an outside-in fashion through the mucosal layer of the vas deferens. Then, the needle is used to pierce the lateral aspect of the epididymal tubule and is placed longitudinally. The second suture (5 cm long) is placed identically and parallel to the first suture on the contralateral side of the epididymal tubule. The tubule is opened between the two parallel needles, and the fluid is examined for the presence of spermatozoa; the needles are pulled out and placed inside-out through the mucosal layer of the vas deferens, and the sutures were tied down making four-point fixation. In a series involving 22 patients, the mean operating time for unilateral and bilateral procedures is about 145 and 214 min, respectively. The reported patency rate was 59% (50% and 70% for unilateral and bilateral procedures, respectively); the overall paternity rate in a series was 36% [109].

12.2.2.4 Postoperative Care

Local dressing and scrotal supporter are kept for 48–72 hours and 2 weeks, respectively. Scrotal ice packing is always recommended to control local edema for the first 72 postoperative hours. Patients are counseled to restrain from physical activity and sexual intercourse for 1 or 2 months in cases of vasovasostomy and vasoepididymostomy, respectively. Oral analgesics usually suffice to control postoperative pain. Postoperative follow-up is aimed at evaluating improvement in semen parameters, complications, and natural or assisted conception. Patients are asked to provide semen specimens for analysis every 2 months after surgery until the semen parameters stabilize or pregnancy occurs.

Results

Microsurgical reconstruction of the vas remains a cost-effective, reliable, and effective means of restoring fertility in most men who have undergone vasectomy [110–114]. However, data comparing surgical reconstruction versus sperm retrieval/ICSI are neither randomized nor homogenous. Therefore, a proper understanding of the factors that can affect outcomes, overall cost, and the morbidity associated with each treatment modality, respective of the institution providing the treatment, is recommended. In experienced hands, reconstructive surgery of the male reproductive tract can be highly successful. Microsurgical techniques are superior to macrosurgical or loupe-assisted anastomoses [81, 115]. After microsurgery, 50–95% of the patients will have the return of sperm to the ejaculate, whereas 30–75% of couples achieve pregnancy without the need for ART.

Overall, historical patency/pregnancy rates following microsurgical vasovasostomy and vasoepididymostomy are 92%/55% and 78%/40%, respectively [75, 81, 84, 90, 93, 95, 103, 104–107, 116–126] (Tables 12.4 and 12.5). More recently, Majzoub et al. reported on their pregnancy data involving 171 consecutive patients after VR [125]. Overall patency rate (presence of any sperm in the ejaculate) was 91.8%, and spontaneous pregnancy occurred in 49.6% of couples with a mean duration of 1.3 ± 0.08 years. Most pregnancies occur within 24 months after surgery. Pregnancy rates are related to the time elapsed from vasectomy and reversal and female age. The likelihood of initiating a pregnancy after vasovasostomy is inversely proportional to the obstruction interval and is estimated to be less than 50% after 8 years according to EAU Guidelines on Male Infertility [15]. Other authors report that 30–40% of couples achieve a pregnancy after reconstructions performed in patients with obstruction intervals greater than 15 years as compared to >50% in shorter intervals [86, 93]. Although female partner's age does not affect patency rates after vasectomy reversal (VR), it does affect pregnancy rates (14% in women aged >40 years vs. 56% in those aged <39 years) [92]. Vasectomy reversal was shown to be feasible even in patients who failed percutaneous epididymal sperm aspiration (PESA). Marmar et al. reported limited epididymis trauma after PESA and up to 50% pregnancy rates after VR in this scenario among couples whose female partner was 37 years old or less [140].

Other factors that affect success rates include the gross appearance of vas fluid at the time of surgery, the presence or absence of sperm in the vas fluid and their quality, and the

length of the remaining segment adjacent to the epididymis. Recently, Scovell et al. performed a systematic review with meta-analysis comprising 1293 subjects with a mean obstruction interval of 7.1 years evaluating the prognostic value of finding sperm in the vasal fluid during vasectomy reversal. The unadjusted OR of postoperative patency was 4.1 times higher (95% CI 2.3–7.3) when intravasal sperm or sperm parts were found. Other vasal fluid characteristics such as consistency were not analyzed because of inconsistent reporting [142]. Mazjoub et al. also noted the presence of sperm or sperm parts during intraoperative vasal fluid analysis to be the only variable to significantly influence pregnancy rate [125]. As patency and pregnancy rates after the existing surgical procedures do not reach 100% and are technically demanding, efforts continue to be made to widen the options for reconstructive repair. Besides the intussusception vasoepididymostomy anastomotic techniques, the use of novel biomaterials/sealants and absorbable and non-absorbable stents and the use of robotics have been attempted [93, 102, 141–145].

The modifications to the conventional vasoepididymostomy techniques simplified and fastened the anastomoses. In a prospective study, Chan et al. reported overall patency and pregnancy rates of 84% and 40% using the intussusception technique [142]. These findings were confirmed by Schiff et al. who reported patency and pregnancy rates of approximately 82% and 45%, respectively, using simplified intussusception techniques [93]. It is suggested that anastomoses are more water-tight by using intussusception techniques; therefore, granuloma formation is decreased. Since pregnancy rates following vasoepididymostomy are below 50%

[a]p <0.05 comparing patency and pregnancy rates between the surgical approaches

and late failures occur in approximately 20% of the cases, it may be useful to retrieve sperm intraoperatively for cryopreservation, particularly in cases of difficult reconstruction. Sperm quality may deteriorate to the level of azoospermia or extreme oligozoospermia in approximately 20% of subjects after vasovasostomy at 1-year follow-up, thus making sperm cryopreservation advisable according to the EAU Guidelines on Male Infertility [15]. By contrast, a cost-analysis study demonstrated that sperm harvesting and cryopreservation during vasectomy reversal are not cost-effective [96].

The rationale of using sealants around the anastomotic site is to decrease operative time and to simplify the procedure without compromising success rates. Fibrin sealant stimulates the coagulation cascade producing a fibrin seal around the anastomosis. When mixed with thrombin and calcium, fibrinogen is converted to fibrin monomer, which in turn is converted to a stable cross-linked fibrin polymer [143]. Ho et al. achieved 85% patency rates and 23% pregnancy rates using three transmural 9-0 sutures and fibrin glue in a mean follow-up of 6.2 months [143]. There are concerns, however, about the potential contact of the glue with the vas lumen, which may result in possible obstruction, and also about the transmission of viral disease because fibrin glue is derived from pooled plasma [141]. The use of non-absorbable polymeric stent has been reported in the animal model. Preliminary results showed 100% patency rates in a follow-up of 39 to 47 weeks, and the total sperm count was significantly higher in the stented group [144].

The use of robotics is also novel. The rationale to add this technology to the already existing armamentarium relies on the possibility of physiologic static tremor correction, visual magnification (up to 100× when using a digital microscopic camera) and ergonomics [145]. Animal studies suggest that robotically assisted vasectomy reversal are easier to perform and yields better pregnancy rates than microsurgical reversal [146]. In a preliminary experience in humans, Parekattil et al. reported shorter operative time and higher postoperative sperm count for robot-assisted vasectomy reversal as compared to the microsurgical technique [145]. However, the advantages of the robot over an experienced microsurgeon are yet to be proven in larger series.

12.2.3 Transurethral Resection of the Ejaculatory Duct

12.2.3.1 Indications

Ejaculatory duct obstruction (EDO) is a potential surgically correctable cause of male infertility. Congenital obstructions are caused by atresia or stenosis of the ejaculatory ducts and utricular, Müllerian, and Wolffian duct cysts. Acquired obstructions can be secondary to trauma or infectious/inflammatory etiologies. Traumatic damage to the ejaculatory ducts might occur after removal of seminal vesicle cysts, pull-through operations for the imperforate anus, and even prolonged catheterization or instrumentation. Genital or urinary infection and prostatic abscess may also cause stenosis or complete obstruction of the ducts [147]. Prostatic infection may result in calculus formation and secondary obstruction, while tuberculosis produces genital devastation.

12.2.3.2 Preoperative Planning

Patient Evaluation

The diagnosis of EDO is usually made by combining the results of medical history, physical examination, semen analyses, and transrectal ultrasound. The clinical presentation may be highly variable; in addition to a history of infertility, complaints such as painful ejaculation, hemospermia, and perineal and/or testicular pain might be present. Nevertheless, some patients are entirely asymptomatic.

On physical examination, enlarged seminal vesicles or a mass might be palpable on rectal examination. Prostatic tenderness and/or epididymal enlargement might also exist. The serum levels of FSH and testosterone are usually normal.

Semen analyses reveal oligozoospermia or azoospermia, decreased motility, and decreased ejaculate volume. An acidic (pH <7.2) and low-volume (<1.5 mL) azoospermic ejaculate, associated with no detectable fructose, palpable vasa, and epididymal thickening, is virtually pathognomonic. However, the typical clinical picture might be complicated as unilateral, partial, and functional obstructions exist [147]. Post-ejaculate urinalyses are often performed to exclude retrograde ejaculation in patients with low-volume ejaculates.

High-resolution transrectal ultrasound (TRUS) evaluation using a 5–7 MHz biplanar transducer is recommended in all cases of suspected EDO. The exact definition of obstruction on TRUS, however, is still a matter of debate due to marked variability in the size and shape of the vas deferens, seminal vesicles, and ejaculatory ducts in fertile and infertile men. Common ultrasound findings include dilation of the seminal vesicles (defined as a cross-sectional width of greater than 1.5 cm) or ejaculatory ducts (defined as an internal duct diameter of greater than 2.0 mm), calcifications or calculi in the region of the ejaculatory duct or verumontanum, and midline or eccentrically located prostatic cysts [148–150]. Transrectal ultrasound-guided seminal vesiculography has been shown to provide excellent radiographic visualization of the ejaculatory ducts [151]. Also, TRUS-guided seminal vesicle aspiration and the presence of motile sperm in the aspirates can be used for diagnosis; since the seminal vesicles are not sperm reservoirs, the presence of sperm is sug-

gestive of obstruction [152]. A testicular biopsy can be done to document the presence of normal spermatogenesis. The authors' preference is to perform a "wet prep" using the percutaneous testicular sperm aspiration technique either before or at the time of surgery. The presence of motile sperm is highly indicative of ductal obstruction.

12.2.3.3 Operative Aspects

Anesthesia

Transurethral resection of the ejaculatory ducts (TURED) is performed using regional or general anesthesia.

Technique

Our choice is to perform the transurethral resection of the ejaculatory ducts (TURED), as described originally by Farley and Barnes [153], with minor modifications [147]. First, the obstruction is documented using intraoperative vasotomy and vasography. The vas is delivered using a small scrotal incision and dissected free of the associated perivasal vessels. A mixture of injectable saline and radiographic contrast material in a 1:1 ratio is injected into the abdominal end of the vas, together with methylene blue dye, by direct vas puncture with a 30-gauge lymphangiogram needle [147]. Vasography confirms obstruction, whereas dye injection confirms patency by visualization of the effluxing dye mixture during TURED. A 9-0 nylon suture is placed at the muscular layer of the vas to close the vasotomy site. Alternatively, transrectal ultrasound-guided seminal vesicle puncture and instillation of contrast can be used to confirm the obstruction.

TURED is performed with the patient in the dorsal lithotomy position. A resectoscope with a 24-French loop is used to remove a strip of tissue on the floor of the prostate just proximal to and including a portion of the verumontanum (Fig. 12.5). The ducts are considered adequately opened by visualizing its dilated portion and the dye efflux. An 18-F Foley catheter is left in place for 24 hours, and the patient is discharged the next day.

Notably, resection of the ejaculatory ducts is a hazardous procedure. The typical EDO patient is young and has a small prostate. Thus, TURED is carried out very close to the bladder neck, rectum, and sphincter. If a midline cyst is present, resection is performed to unroof the cyst completely. If not, the prostatic side of the verumontanum is resected until a dilated portion of the ejaculatory duct is seen. Resection is performed with pure cutting to avoid thermal injury to the proximal ejaculatory duct. We feel more comfortable placing a finger in the patient rectum to prevent rectal injury during resection and having methylene blue injected through the vasotomy site. Resection is completed by identification of free dye efflux into the urethra.

A movie illustrating the technical details of TURED using transrectal ultrasound-guided seminal vesicle puncture and instillation of methylene blue can be found at https://youtu.be/IoD7ssKOLhI [154].

12.2.3.4 Postoperative Care

An indwelling catheter is kept in place for 24–48 h, and patients are discharged the following day. Oral quinolone antibiotics and anti-inflammatory medication are pre-

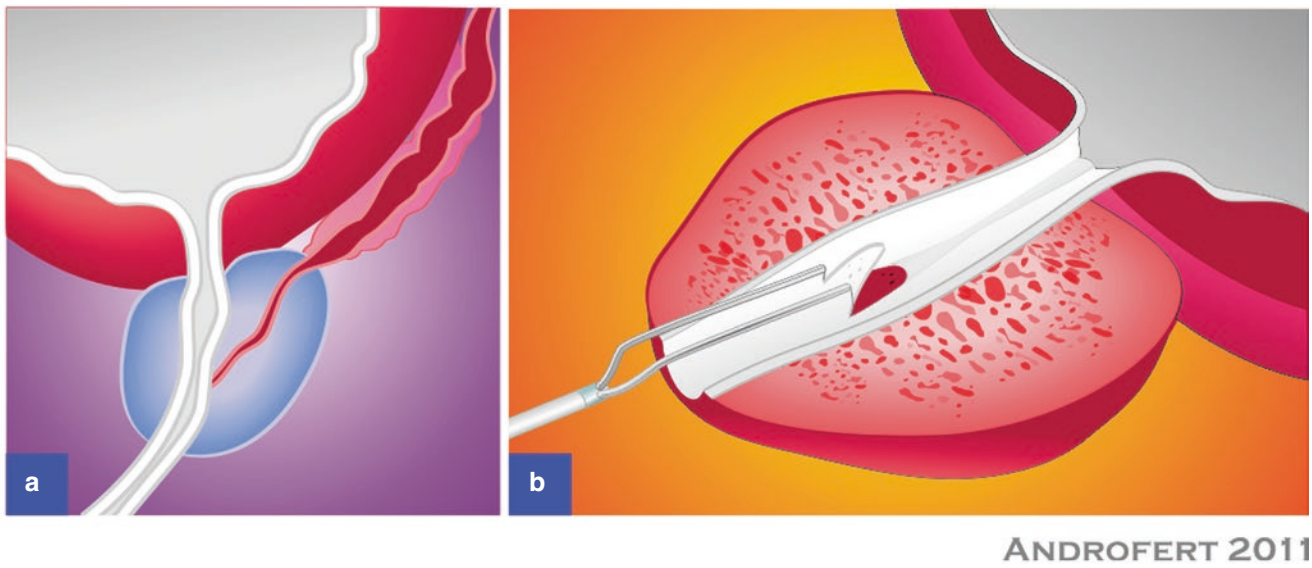

Fig. 12.5 Transurethral resection of the ejaculatory duct. Schematic representation of the ejaculatory duct entering into the prostatic urethra (**a**). A resectoscope loop is used to remove a strip of tissue on the floor of the prostate just proximal to and including a portion of the verumontanum (**b**). (Reprinted with permission, ANDROFERT© 2011. All Rights Reserved)

scribed for 5 days. A scrotal supporter is recommended for 1 week to avoid scrotal edema due to vasotomy. We ask our patients to have frequent ejaculation 3–4 weeks postoperatively, and patients are monitored with monthly semen analyses.

Results

Ejaculatory duct obstruction is a treatable cause of male infertility, but the diagnosis might be difficult to make, particularly in cases of partial obstruction. Transrectal ultrasound is valuable but not specific. Adjunctive procedures such as magnetic resonance imaging, chromotubation, seminal vesicle aspiration, seminal vesicle scintigraphy, and ejaculatory duct manometry might be used to confirm the diagnosis of EDO [155–157]. Transurethral resection of the ejaculatory ducts (TURED) remains the treatment of choice, but due to the risks and the possibility of urinary reflux into the seminal vesicle, less invasive approaches using balloon dilation coupled or not with transurethral incision of the ejaculatory ducts have been proposed with similar results and fewer complications [158, 159].

Furthermore, minimally invasive vesiculoscopy procedures have been introduced for treatment of EDO. Wang et al. used a ureteroscope to inspect the seminal vesicle cavity and remove calculi. In this procedure, the ejaculatory duct might be cleared without damaging the verumontanum [160].

In our earlier reported series of 14 patients with complete or partial obstructions, TURED results varied according to the etiology of obstruction, congenital or acquired. Semen quality improvement (ejaculate volume, sperm count, and motility) was observed in 83% of the patients in the congenital group. Natural pregnancy was obtained in 66% of these patients at an average of 5.7 months postoperatively. In the group of patients with secondary EDO, the seminal improvement was detected in only 30% of the individuals, and only one natural pregnancy was achieved. Two individuals (one in each group) conceived via assisted reproduction techniques. Complication rates were similar in both groups (33%) and included reflux of urine to the unroofed cyst cavity with consequent impairment of the semen parameters, retrograde ejaculation, and one case of epididymitis with obstruction. Rectal injury or incontinence was not reported in our case series [147].

El-Assmy et al. reported on a retrospective cohort of 23 infertile men with either partial or complete EDO secondary to midline cyst or post-inflammatory obstruction. The seminal improvement was seen in all patients with partial EDO and 23.5% of those with complete EDO. Natural pregnancy occurred in 13% of cases. Data suggests that men with complete EDO due to midline cysts do better after TURED compared with those with an inflammatory cause. On the other hand, seminal results do not seem to be affected by the cause of obstruction in partial EDO [161].

12.3 Conclusions

Surgical interventions to treat male infertility are within the scope of urologists with training in microsurgery and endourology. Varicocele repair is recommended to selected infertile men with clinical varicocele as a means to improve fertility and reproductive outcomes, both natural and assisted. Microsurgical reconstruction of the vas deferens is highly successful when properly indicated. However, surgeon's experience is a critical factor for successful outcomes. Vasoepididymoanastomosis is a challenging microsurgical procedure which has to be conducted only by urologists with optimal microsurgical skills. Ejaculatory duct obstruction treatment by transurethral resection of the ejaculatory duct or vesiculoscopy may yield satisfactory results fertility wise, in particular in cases of congenital obstruction.

12.4 Review Criteria

A search of studies examining the use of surgical techniques for varicocele repair, vasovasostomy, vasoepididymostomy, and ejaculatory duct obstruction in the context of male infertility was performed using search engines such as ScienceDirect, Ovid, Google Scholar, PubMed, and MEDLINE. The start date for the search was not specified, and the end date was January 2019. The overall strategy for study identification and data extraction was based on the following keywords: "varicocele," "DNA fragmentation," "semen analysis," "vasovasostomy," "vasoepididymostomy," "vasal reconstruction," "infertile men," "varicocelectomy," "infertility," "semen parameters," "pregnancy rate," "surgical treatment," and "ejaculatory duct obstruction." Articles published in languages other than English were not considered. Data that were solely published in conference or meeting proceedings, websites, or books were not included. Websites and book-chapter citations provide conceptual content only.

Acknowledgments The authors are indebted to Mrs. Fabiola Bento for her editorial assistance and to Dr. José Eduardo Orosz for providing his personal observations concerning anesthesia techniques for varicocele repair and reconstructive surgery.

Microsurgery for Male Infertility

13

Rajeev Kumar and Manoj Kumar

Keys Points

- Obstructive azoospermia is an important diagnostic category since a number of these cases can be treated surgically.
- Evaluation of infertile men aims at identifying the etiology, reversibility, and potential underlying medical conditions that may have manifest as infertility.
- Microsurgery is offered for bypassing an obstruction in the epididymis or the vas deferens and for correction of a varicocele. The evaluation and investigations are tailored to diagnose suitability for microsurgery and maximize successful outcomes.
- Two-suture intussusception vasoepididymostomy using 10-0 polyamide sutures is a quick and highly effective technique. Longitudinal suture placements allow better results than transverse placement.
- Two-layer anastomosis for vasovasostomy with a simplified 4-6 suture technique has excellent outcomes.
- Patient selection is key to success in microsurgical varicocelectomy.

13.1 Introduction

Obstructive azoospermia (OA) is one of the correctable causes of male infertility and is thus an important diagnostic category [1–3]. Microsurgery for infertility involves vasoepididymal anastomosis (VEA), vasovasal anastomosis, and microsurgical varicocelectomy. Reconstruction was first reported by Martin in 1902 when he described his side-to-side technique by bringing together the cut edge of tunica vaginalis of epididymis to the incised seromuscular layer of vas deferens, relying upon the creation of fistula between the open epididymal tubule and vas deferens, and demonstrated patency rates of 43% [4]. In 1936, Hagner reported his surgical outcomes using this technique with 60% patency rate [5]. In 1978, with improvement in magnification, Silber described his microsurgical approach for end-to-end epididymovasostomy and directly anastomosing the mucosa of the end of vas deferens to the end of single epididymal tubule [6]. In 1983, Fogdestam and Fall and Thomas described the end-to-side epididymovasostomy by anastomosing the end of the vas deferens to the side of an epididymal tubule with a patency rate of 64% [7, 8]. In 1998, Berger described the triangulation end-to-side intussusception technique by placing three double-armed 10-0 nylon sutures into the unopened epididymal tubule which reduced the operating time and produced a patency rate of 92% [9]. In 2000, Marmar modified the procedure by passing two needles simultaneously and transversely through the unopened epididymal tubule, with a small transverse tubulotomy placed between them with a microblade (transverse incision vasoepididymostomy [TIVE]) [10]. In 2003, Chan et al. [11] published a comparative report on three different intussusception techniques in rats and concluded longitudinal placement of sutures in the epididymal tubule (longitudinal intussusception vasoepididymostomy [LIVE]) resulted in higher patency rates.

13.2 Etiology and Evaluation

Microsurgery is currently offered for bypassing an obstruction in the epididymis or the vas deferens and for correction of a varicocele. The evaluation and investigations are tailored to diagnose suitability for microsurgery and maximize successful outcomes. The diagnosis of the obstruction is based on the two facts: first, the absence of sperm in the ejaculate (azoospermia), and second, the demonstration of normal production of sperm in the testis (on testicular histology) with normal FSH. Microsurgical reconstruction for obstruc-

S. J. Parekattil et al. (eds.), *Male Infertility*, https://doi.org/10.1007/978-3-030-32300-4_13

tive azoospermia may be offered to patients with vasal injury and vaso-epididymal junction obstruction.

1. *Vasectomy/vasal injury*: Vasectomy, as a cause of infertility, is easily diagnosed from history and examination, which reveals palpable nodules in both the vasa at site of the vasectomy. A semen analysis is obtained to confirm azoospermia, and additional testing is usually not required. Iatrogenic trauma during a hydrocele or hernia repair or retroperitoneal surgeries may cause OA. In such cases, formal vasography with injection of radiographic contrast into the vas deferens may be required to identify the site of the obstruction. This test should be done along with the actual surgical reconstructive procedure. Isolated diagnostic vasograms should not be performed as they may result in vasal scarring and injury.
2. *Vaso-epididymal junction obstruction (VEJO)*: The junction of the vas and the epididymis is susceptible to obstruction following infections and for unknown causes. It is a diagnosis of exclusion in men with normal sperm production, normal ejaculate volume, normal vas deferens, but with absence of sperms in the ejaculate. In a majority of patients, the etiology of VEJO cannot be determined, and the diagnosis is idiopathic obstruction (iVEJO). Fifteen percent of men with OA have intratesticular obstruction that is not amenable to reconstruction but cannot be diagnosed preoperatively. Acquired forms (post-inflammatory or post-traumatic) are more common than congenital forms. Its diagnosis is important because VEJO is one of the surgically correctable causes of azoospermia [12].

13.2.1 Reconstruction Versus Sperm Retrieval and In Vitro Fertilization/ Intracytoplasmic Sperm Injection (IVF/ ICSI)

As in other men with OA, men with iVEJO have the option of surgical sperm retrieval and IVF with ICSI. Treatment should thus be individualized to each couple. Microsurgical reconstruction is more cost-effective than sperm retrieval and IVF, which requires intervention in both partners [13]. A successful surgery allows subsequent pregnancies without further intervention and avoids the risks of complications of IVF including ovarian hyperstimulation, birth defects, multiple gestations, prematurity, and low birth weight [14].

On the other hand, considering the limited success with reconstruction, it should be offered cautiously in couples with advanced age of the spouse as female fertility declines significantly with age [15]. Long duration of obstruction, particularly when reconstruction is being considered post-vasectomy, is associated with poor outcomes [16]. Concomitant female factor abnormalities that require intervention such as tubal blocks would also be an indication for primary sperm retrieval and IVF instead of reconstruction (Table 13.1).

The overall fertilization rates with per injected oocyte after IVF/ICSI is 45–75%, and pregnancy rates range from 26% to 57%, when surgically retrieved epididymal or testicular sperms are used [18–24].

Table 13.1 Comparison of microsurgical reconstruction (vasectomy reversal and vaso-epididymal anastomosis) and in vitro fertilization/intracytoplasmic sperm injection (IVF/ICSI)

	Advantages	Disadvantages
Microsurgical reconstruction (vasectomy reversal and vaso-epididymal anastomosis)	1. Allows natural selection of best sperm during fertilization through natural intercourse. 2. If microsurgery is successful, it allows future conception without additional medical treatment. 3. Less cost – One-time procedure is less than the 20% cost of single cycle of IVF/ICSI [17]. 4. If microsurgery results in patency and not pregnancy, patients have options of IUI and IVF-ICSI using ejaculated sperm instead of other surgical sperm retrieval techniques.	1. This is the most challenging technique in urology; thus, results may depend on the microsurgical skills, experience, and training of the surgeon. 2. Surgical techniques may change over time which will influence the patency and pregnancy rate. 3. May not be available at many centers
In vitro fertilization/ intracytoplasmic sperm injection (IVF/ICSI)	1. It is the only treatment option in intratesticular obstruction, obstruction at multiple sites, and congenital bilateral agenesis of vas deferens (CBAVD). 2. It is preferred in advanced maternal age as fertility potential in female decreases after 35 years and limited after 40 year of age. 3. Females with tubal disease/tubal ligation, it is preferred as it avoids microsurgery in both the partners. 4. Previously failed microsurgical reconstruction in male	1. Risk for the female partner like ovarian hyperstimulation syndrome (OHSS) [14] 2. Risk for the fetus – prematurity, genetic abnormalities, and multiple gestations [14] 3. Complications during oocyte and sperm retrieval 4. Possibility of carrying or transmitting genetic defect to offspring related to male factor infertility 5. Increased cost of the treatment, and intervention in both male and female partners is required

13.3 Microsurgical Procedures

Microsurgical reconstruction is performed as day-care surgery under regional or light general anesthesia. An operating microscope with face-to-face attachments for surgeon and assistant along with an offset arm with facility for camera attachment and transmission is used. There has been a steady evolution in case selection and techniques over the years, and this has been accompanied by an improvement in outcomes.

13.4 Vaso-epididymal Anastomosis

Scrotal explorations for vaso-epididymal anastomosis form the most common microsurgical procedure performed at our institution. Nearly all such procedures are performed for men with idiopathic obstruction. An obstruction is suspected in men with normal volume azoospermia with palpable vas deferens and normal spermatogenesis on testicular FNAC (fine needle aspiration cytology). These men are counselled about the options of scrotal exploration and IVF. A presumptive prognosis for success of reconstruction is provided based on age, testicular size, serum FSH, and presence of scrotal pathology.

Two publications toward the end of the last century on techniques form the basis of our surgical approach (Table 13.2). Berger's [9] paper on the triangulation intussusception technique of end-to-side vasoepididymostomy was the first of these publications. The use of three double-armed sutures instead of multiple independent sutures for the inner layer, coupled with our increasing familiarity with an operating microscope, allowed us to attempt this technique in a number of patients with some success. A major problem that we faced with this approach was with the size of needles for the 10-0 suture. The 10-0 double-armed polyamide suture available to us was swaged on 200-μm needles. Placing three such needles in the small epididymal tubule proved difficult, and we would often manage to get only two sutures in place.

Marmar's [10] article in 2000 on the two-suture technique of vasoepididymostomy proved to be the turning point in our approach to this procedure. It was simpler to perform and afforded excellent results. We began using this technique in 2002 and have been using our modifications of it since then.

In 2003, Chan et al. [11] published a comparative report on three different intussusception techniques in rats and concluded that longitudinal placement of sutures in the epididymal tubule resulted in higher patency rates. Difficulty in placing our thicker needles transversely in the tubules had led us to this modification in our patients at about the same time, and we commented on our findings in a reply to their publication [25].

Table 13.2 Evolution in vasoepididymostomy technique at our center

Early 1990s: 6-0/7-0 sutures, non-mucosal anastomosis
Poor expertise in microsurgery
Limited equipment
Late 1990s: Berger's technique [9] of three suture intussusceptions
Thicker needles, inadequate space for three needles
Early 2000s: Marmar's technique [10] of two suture intussusceptions
Thicker needles
Thin tubules
Current: Modified, longitudinal technique of two suture intussusceptions [27]

13.5 Our Surgical Technique

Our initial microscope had a relatively high minimal height, and the height of the operating table and the eyepiece of the microscope made it impossible to sit and operate. Thus, all our microsurgeries were performed with the surgeon standing up. This initial practice has been continued, and we still perform all such surgeries standing up even after changing our microscope in 2009 to a Zeiss Opmi Vario® (*Carl Zeiss Micro Imaging GmbH, Germany*) with an S-88 stand. Our basic microsurgical instruments set consists of curved and straight micro-needle holders without ratchet, curved micro-scissors, straight iris scissors, Jeweler's toothed and non-toothed microforceps with a platform to assist suture tying, and Adson's toothed and non-toothed forceps. We do not use clamps for holding the epididymis or the vas deferens.

With the patient supine, a longitudinal incision is made in the scrotum at its anterolateral edge toward the upper end of the testis. The incision is deepened to expose the tunica vaginalis, which is incised to deliver the testis. Any adhesions within the tunical layer are divided to expose the anterior surface of the epididymis. The surface is inspected for calcifications/nodules and visibly dilated tubules. In patients with a previous hydrocelectomy, the tunical layer is obliterated, and an attempt is made, by feel, to identify the epididymis and incise layers of tissue above it to expose the epididymal tunic. The spermatic cord is palpated posterior-lateral to the testis to confirm the presence of the vas deferens and get a visual impression of its diameter. Occasionally, in men with a more distal obstruction, the vas may feel dilated and thick fluid in the lumen may be visible through its wall.

Before dividing the vas deferens, we inspect the epididymis through its tunica to identify dilated tubules. In men with clearly dilated tubules, we proceed to preparing the vas. However, if the epididymis does not show any dilated tubules and feels flabby in its entire length, we make an incision in the epididymal tunic and observe the individual tubules under the microscope (Fig. 13.1a). If there still appears to be a doubt about the presence of obstruction, one of the distal

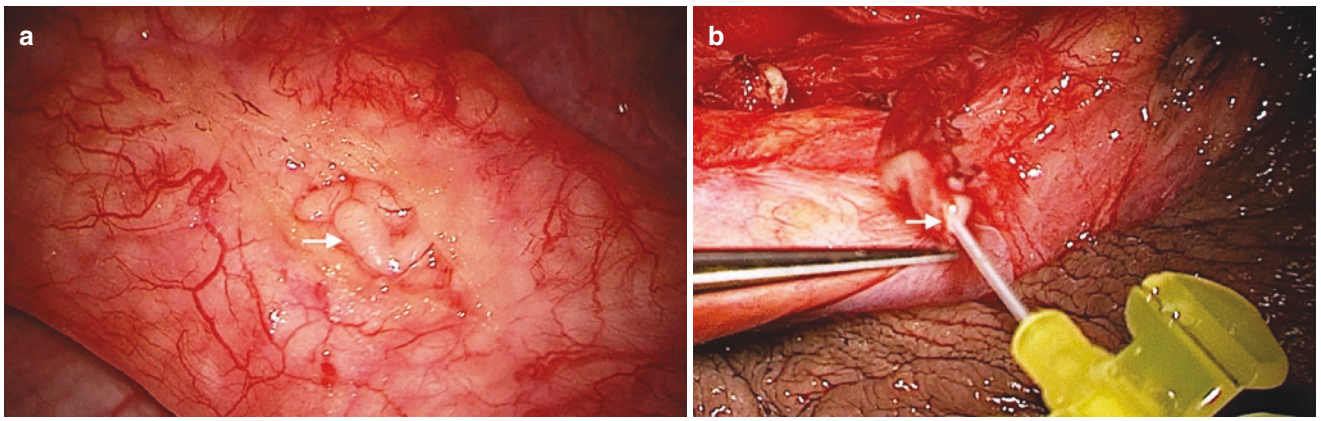

Fig. 13.1 (**a**) Intraoperative photograph of dilated epididymal tubule after opening the tunical layer of epididymis. (**b**) Vas deferens is isolated from the cord structures and transected, and a 24 G angiocatheter is inserted and flushed with saline to look for distal patency

loops of the tubule is incised, and the fluid is examined for sperms. If sperms are confirmed, a more proximal site is selected for the anastomosis.

The vas is isolated from the remaining cord structures with blunt dissection, maintaining a mesentery of blood vessels to the vas in its entire length. The junction of the convoluted and straight vas is identified, and a small segment of the vas at this site is elevated from its mesentery on a small hemostat. Using a sharp straight knife, the vas is hemisectioned at this level and inspected for any fluid that may suggest a more distal block. A 24 G angiocatheter is carefully inserted into the lumen of the distal vas and flushed slowly with up to 20 cm [3] of saline. Free flow of saline with no regurgitation is used as an indicator of distal patency, and the section of the vas is completed (Fig. 13.1b. If there is resistance to flow of saline, a 3-0 polyamide suture is threaded into the lumen to determine the level of block. If the block is at a short distance, the vas is exposed to the expected site of block, and a fresh vasotomy is made at that site and the procedure repeated. For more distant blocks, a formal vasography is performed.

Once distal patency of the vas is confirmed, further mobilization of the mesentery is performed, keeping a good amount of tissue and blood vessels around the vas. The periadventitial tissue is held gently with a hemostat until the first seromuscular sutures are placed.

The epididymis is reinspected and its tunica incised over the most visibly dilated tubules. Individual loops of the tubule are gently separated from their surrounding alveolar tissue until the selected tubule bulges above the rest. In our earlier cases, the sutures were placed transversally (Fig. 13.2a) [26] in the loop in a manner that they could be tied without crossing over of the sutures [27]. In our more recent cases, we place the sutures longitudinally (Fig. 13.2b) [26], again in a manner such that they can be tied to each other without crossing over.

The end of the vas is maneuvered to the site of the tunical incision. An 8-0 polyamide suture is placed from outside-in at the 5 o'clock position in the seromuscular layer of the vas. The needle is then passed through the epididymal tunic from inside out and tied. The procedure is repeated with another suture at the 7 o'clock position. The direction of placement of these sutures is important in that placing the suture along the direction of the vas helps provide traction to the needle as it enters the thick vas. Placement inside out on the epididymal tunic allows the needle to lift the tunic from the underlying tubules, preventing inadvertent injury to the tubules (Fig. 13.3a).

Once the vas is secured to the epididymis, the needle of a 10-0 polyamide double-armed suture is placed in the loop of the epididymal tubule. The needle is inserted at the end closer to the vas and exits at the opposite end. This needle may be placed transversally or longitudinally in the loop depending on the selected procedure. A second similar suture is placed, parallel to the first (Fig. 13.3b). The tubule between the two needles is incised using a microknife. It is important to ensure that the length of this incision does not extend beyond the entry and exit points of the two sutures. Fluid from the tubules is directly collected on a sterile microslide for examination under a light microscope. The procedure is continued if sperms are seen in the fluid. The needles are pulled through and kept separate from each other. The other ends of the sutures with their needles are now closer to the vas and are placed first into the vas lumen. These needles are placed at the 5 o'clock and 7 o'clock positions in the vas from inside the lumen, out through the muscular layer but not the full thickness of the vas. The two needles away from the vas are now placed similarly into the vas lumen at the 1 o'clock and 11 o'clock positions ensuring that the sutures are not entangled. The needles exiting at 7 o'clock and 11 o'clock in the vas belong to the same suture as do the 5 o'clock and 1 o'clock needles. The two

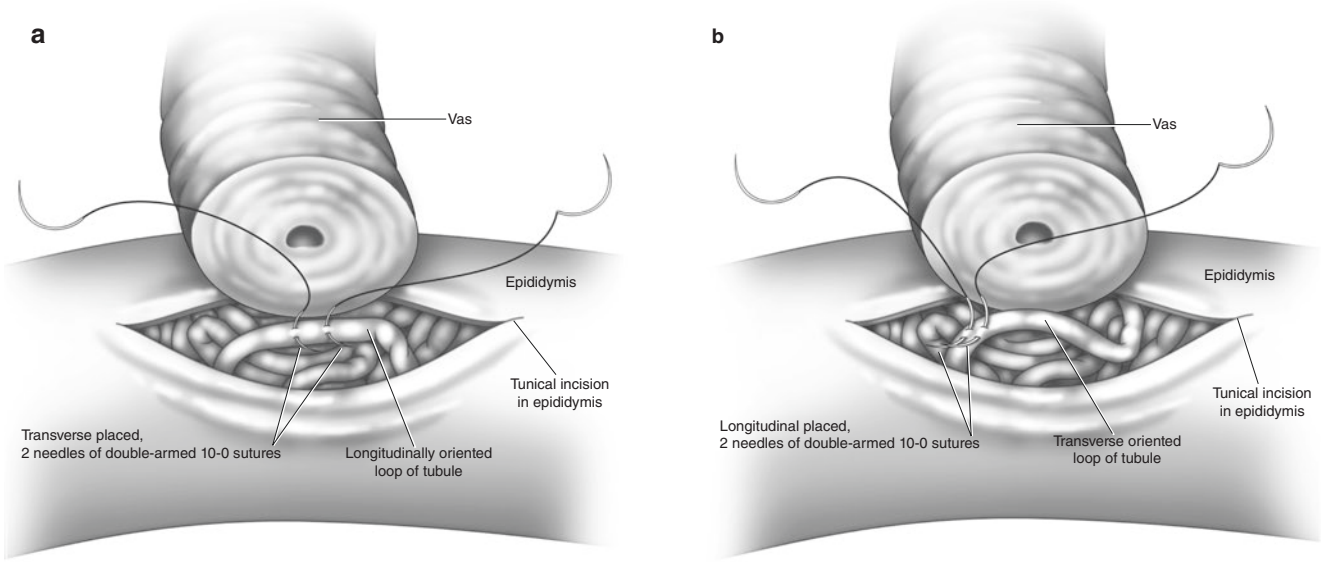

Fig. 13.2 (**a**, **b**) Transverse and longitudinal suture placement in the epididymal tubule for a vasoepididymostomy. Reproduced with permission by Kumar R [26]

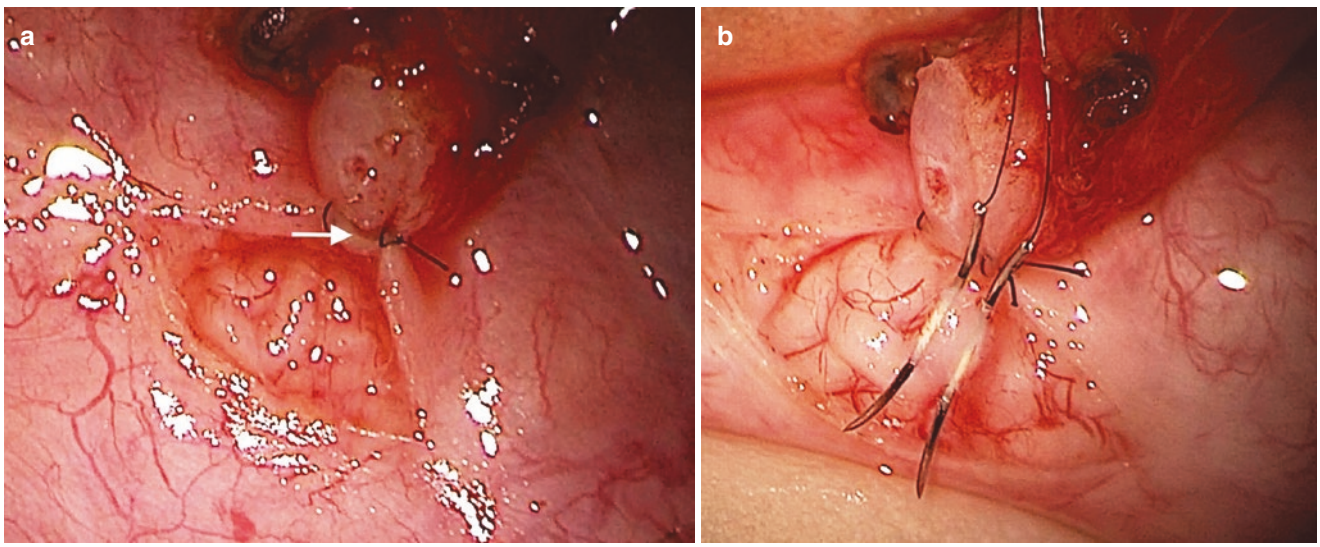

Fig. 13.3 (**a**) End of the vas is fixed with epididymal tunic using 8-0 polyamide suture. (**b**) Longitudinal placement of needles of two 10-0 polyamide sutures over the epididymal tubule and tubule incised in between using microknife

needles of each suture are held together and pulled to "hitch" up the tubule into the vas lumen (Fig. 13.4a). Both ends of the same suture are then tied to each other, intussuscepting the loop into the vas lumen. Additional 8-0 polyamide sutures are placed in the anterior layer of the vas and the epididymal tunic to secure the anastomosis. Two to three 8-0 polyamide sutures are also placed proximally in the serosal layer of the vas and the epididymal tissue to protect the anastomosis from cremasteric contractions (Fig. 13.4b). In case there are no sperms in the epididymal fluid, the sutures are removed and the procedure is repeated at a more proximal site.

All patients receive 3–5 days of antibiotics and are reviewed for suture removal after a week. A semen analysis is performed at 6 weeks and repeated every 3 months until patency is demonstrated. Patients who do not have a patent anastomosis by 1 year are advised to begin evaluation for IVF though they are counseled that delayed patency may occur even at 18 months. The modifications in our technique are described in Table 13.3.

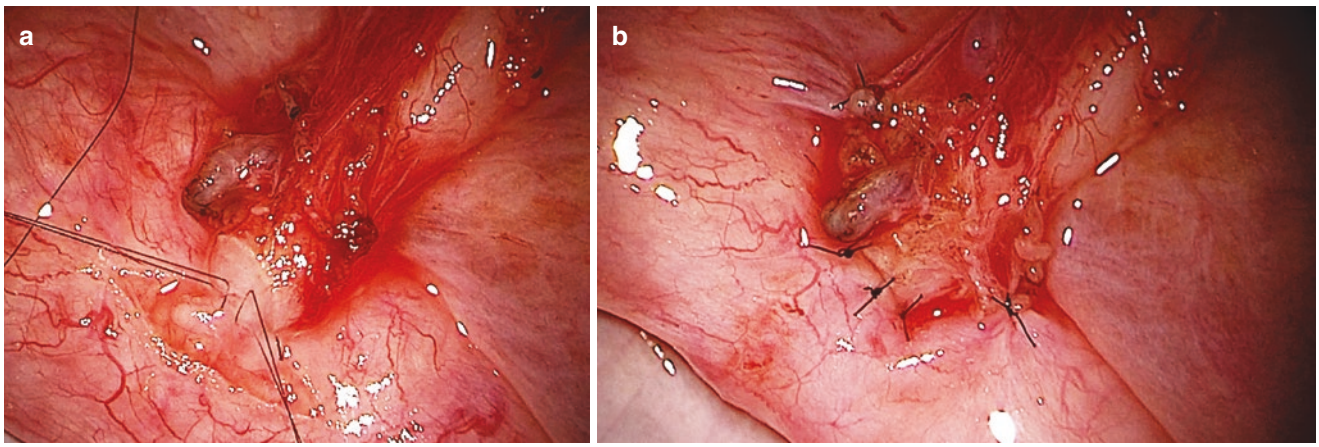

Fig. 13.4 (**a**) Two needles of each suture pulled together and tied to each other, thus intussuscepting the tubule into the vas lumen. (**b**) Final surgical aspect of vaso-epididymal anastomosis. Sutures are placed in the anterior layer of vas and epididymal tunic with 8-0 to secure the anastomosis

Table 13.3 Modifications to the vasoepididymostomy technique

1.Vas fixed to epididymal tunic prior to tubular sutures
Advantage: Limited manipulations required once the mucosal sutures are in place
Disadvantage: Vas sutures need to be taken down if there are no sperms in the epididymal fluid
2.Mucosal sutures placed sequentially, not simultaneously
Difficult to hold both 200-μm needles together in the micro-needle holder
3.Use of 200-μm needles on 10-0 suture instead of 70-μm needles
Cost and availability
4.Incision of tubule with needles in situ
Avoids inadvertent division of the suture material

13.6 Outcomes

Despite our stringent inclusion criteria for a VEA, we are able to perform an anastomosis in only about 60% of all explorations. Even among men where we are able to find sperms within the epididymis, in some, the tubules are extremely thin with minimal dilatation. In such cases, particularly where the sperms are found only in tubules in the head, a single tubule mucosal anastomosis is not feasible, and a non-mucosal anastomosis between the vas lumen and epididymal tunic with an incision in the tubules needs to be performed.

Among cases where a single tubule anastomosis is feasible, our success rates, on average, have been 50% in the form of a patent anastomosis, documented by return of sperms in the ejaculate. These rates have been higher at around 80% when the surgery has been performed bilaterally using the longitudinal suture placement technique and in men with motile sperms in the epididymal fluid. Further, technical satisfaction with the procedure was associated with higher patency rates [28].

Yoon et al. in recent meta-analysis of vasoepididymostomy reported that the mean patency rate was 64.1% and the mean pregnancy rate was 31.1% [29]. There are a number of reasons why our outcomes differ from those reported by other centers (Table 13.4) [30, 31]. The most important among these is an unclear etiology of obstruction. Most of our patients have primary infertility, and the diagnosis of obstruction at the vaso-epididymal junction is one of exclusion. Another potential reason is the use of thicker needles on the sutures. The 200-μm needles that we use are five times less expensive than the standard 70-μm needles, and this difference is often a major concern for our patients. Our attempts at preserving one side and operating unilaterally may also be causative since our outcomes among bilateral

Table 13.4 Operative results of vasoepididymostomy

procedures have been much better. Finally, short follow-up of patients is a problem that plagues all our procedures. It is well known that patency may become apparent many months after a procedure, but most of our patients provide only one or at most two semen samples after the surgery. This may also be related to the previously discussed issues of social pressure and need for early outcomes. A number of these men possibly opt for assisted reproduction soon after the surgery, not willing to wait for a successful surgery [32].

13.7 Vasovasal Anastomosis

Vasectomy is an uncommon form of contraception in India, accounting for fewer than 5% of all contraceptive methods. A decision to undergo a vasectomy is usually taken after careful thought and requests for reversal are rare. The most frequent reason for seeking a reversal is the loss of a child [33]. This statistic has two important implications. First, the stress on success is likely to be greater in this group of patients than in those who already have living children, and second, most patients are interested in early patency during which they may father a child without significant concern about delayed closures. The low volumes of procedures also mean that there is inadequate training of surgeons. These factors have been instrumental in our attempts at simplifying the surgical technique of vasectomy reversal [34].

13.8 Our Surgical Technique

A semen analysis is obtained in all men seeking vasectomy reversal to confirm azoospermia. No additional investigations are requested if the testicular size is normal and both vas are palpable. A longitudinal incision is placed in the scrotal skin, as for the VEA procedure. The testis and the spermatic cord are delivered out of the scrotum, and the site of vasectomy is identified. Babcock forceps are used to hold the vas deferens above and below the site of vasectomy, and a short segment of the vas is stripped of its adventitial tissue. The distal vas is sharply divided and flushed with saline to test for patency, similar to the procedure previously described for a vasoepididymostomy. The proximal end of the vas is then divided and the fluid examined for sperms. In the absence of any fluid, a gentle barbotage of the proximal vas is performed with saline and this fluid is then examined. If no fluid or sperms are demonstrable, the epididymis is examined to look for a secondary block and a vasoepididymostomy is considered.

The adventitial tissue of the two ends of the vas is held with the tip of small hemostats to appose them to each other. Two 8-0 polyamide sutures are placed at the 5 and 7 o'clock positions in the seromuscular layers of the two ends and tied. The suture ends are left long and held in rubber shod hemostat clamps. The hemostats applied to the adventitia are removed. A double-armed 10-0 polyamide suture is placed, inside out at 6 o'clock in the mucosa of the distal vas, and the second needle is placed at the corresponding position of the proximal vas. The suture is tied. Three additional 10-0 polyamide sutures are placed at the 3, 9, and 12 o'clock positions in the mucosa of both ends of the vas. These three sutures are tied sequentially once all have been placed [35]. Two additional 8-0 polyamide sutures are placed in the seromuscular layer (Fig. 13.5a, b). Additional sutures may be placed in the seromuscular layer or the adventitia to stabilize the anastomosis. The postoperative advice and follow-up are as described for the vasoepididymostomy procedure.

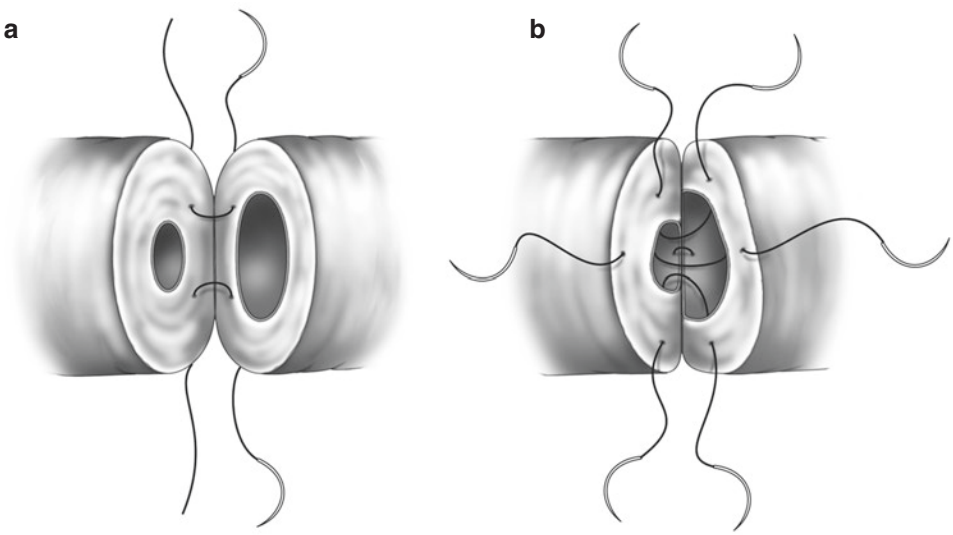

Fig. 13.5 (**a**, **b**) Suture placement technique for a 4 × 4 vasovasostomy. Reproduced with permission by Kumar R [26]

13.9 Outcomes

Vasectomy reversals have traditionally been a very satisfying procedure with excellent patency rates, usually above 90% [16]. The operative results of vasovasostomy are described in Table 13.5 [36–43]. Namekawa et al. in a recent review reported the overall patency rate of 87% and overall mean pregnancy rate of 49% following microscopic vasovasostomy and vasoepididymostomy for vasectomy reversal [44]. Our own practice of vasectomy reversals has been sporadic with fewer than 8–10 cases per year. The results were felt to be good, but a detailed record is not available. Since 2008, we began using the 4 × 4 technique described above exclusively following a study protocol. We have found this technique simple to perform with excellent outcomes. All eight patients described in our recent report have a patent anastomosis. Cases performed after the last accrual in this report are also patent. One of the potential problems with this technique is the possibility of sperm leakage and delayed closure. While this is certainly a theoretical possibility, as we stated earlier, most of our patients are keen on an immediate patency with little interest in delayed results. This procedure is simple and may be performed by a greater number of surgeons than the more difficult microdot technique. We feel the simplicity of the procedure with excellent early results, but unknown long-term outcomes may be an acceptable trade-off with the more difficult techniques that have proven long-term outcomes.

13.10 Microsurgical Varicocelectomy

We maintain a high threshold for case selection for varicocelectomy. Only men with clinically palpable varicoceles are accepted. This policy began even before the AUA and ASRM guidelines were published but were reinforced by these guidelines [45]. Surgery is performed for the side where the varicocele is palpable, and a Doppler of the scrotum is requested only where a clinical examination is doubtful.

13.11 Our Surgical Technique

The external inguinal ring is identified by insinuating a finger through the scrotal skin into the inguinal region. A 2-cm transverse incision is made in the skin overlying the external ring. Under magnification, this incision is deepened to expose the spermatic cord. The tissue around the cord and over the external ring is separated, and a small incision is made in the external ring to make it wider. This incision is directed along the inguinal canal. The cord is held with Babcock forceps and, under the microscope, is freed from the bed and surrounding tissues. The cord is then brought out onto the surface. The fossa is examined for any visibly dilated veins that are ligated and divided. The cord is held on the surface over a hemostat. The superficial layers of the spermatic fascia are divided longitudinally, closer to the cranial end of the cord. The artery is identified and isolated. All visible veins are individually identified and ligated and divided. The cord is then taken onto the surgeon's nondominant hand and scanned inside and outside the spermatic fascia to confirm that all major veins have been divided. We do not deliver the testis into the wound or ligate the gubernacular vessels.

13.12 Outcomes

We have previously reported our outcomes for subinguinal varicocelectomy [46]. Briefly, one-third of patients are able to father a child through natural conception after the surgery, and a majority will show improvements in seminal parameters. The procedure has resulted in downgrading the ART techniques required in a number of patients who have undergone this procedure [47].

13.13 Training and Credentials

Andrology and microsurgery procedures are performed as a part of the standard urological services available to all patients. Urology residents, during their 3 years of training,

Table 13.5 Operative results of vasovasostomy

are posted to assist in these surgical procedures. There are no fellowship programs in male infertility or andrology, and few would return for dedicated specialized training in microsurgery. This results in very little postresidency acquisition of skills or even skills maintenance because the number of procedures performed in urologic practice in the community is very limited.

13.14 Conclusions

The diseases responsible for male infertility and for cases undergoing exploration for microsurgical reconstruction at our center possibly differ from those reported in most Western literature. The largest majority of cases explored are for primary infertility with obstruction of unknown etiology. This has resulted in lower percentage of patients with a successful outcome. However, the socioeconomic factors around infertility management in our country dictate an attempt at reconstruction even when the expected outcomes are poor. In patients with favorable prognostic factors, the outcomes are generally good.

13.15 Review Criteria

An extensive search of studies on "microsurgery for male infertility" was performed using search engines such as PubMed, Google Scholar, ScienceDirect, and Ovid. The overall strategy for data extraction was based on the following keywords: "microsurgery for male infertility," "azoospermia," "varicocele," "vaso-epididymal anastomosis," "microsurgical-varicocelectomy," "vasovasal anastomosis," and "congenital bilateral absence of the vas deferens." Articles published only in English language were considered. The previous version of this chapter was revised.

Advanced Techniques of Vasoepididymostomy

14

Wayland Hsiao and Marc Goldstein

Key Points

- Good anastomoses rely on healthy tissue and an accurate watertight mucosa-to-mucosa opposition in a tension-free anastomosis; setup is key.
- Anastomotic techniques include end-to-end, end-to-side, and end-to-side intussusception.
- Vasal length can be increased on the epididymal end or the vasal end or both. If these two maneuvers prove insufficient, orchiopexy should be considered as well as a crossed septal vasoepididymostomy in cases of unilateral testicular atrophy or absence.
- Our preferred anastomosis is the two-suture longitudinal, end-to-side intussuscepted technique.
- We have developed a single-arm version of vasoepididymostomy, which is useful when double-arm sutures are difficult to obtain.
- Vasoepididymostomy is the most challenging of all microsurgery and should only be performed by surgeons with sufficient training and adequate volume of microsurgery.

14.1 Introduction

The first vasoepididymostomy (VE) was reported in 1902 by Dr. Edward Martin at the University of Pennsylvania. His technique involved slashing across multiple epididymal tubules and anastomosis of the vas to the epididymal tunic in a side-to-side manner with four fine silver wires [1, 2]. Patency depended on the formation of a fistula. In 1909, Martin reported in a series of 11 patients with epididymal obstruction a patency rate of 64% and a pregnancy rate of 27% [3]. He proved that vasoepididymostomy was technically feasible and his approach is the foundation on which subsequent work was based.

With advances in surgical technique and the development of microsurgical techniques, modern vasoepididymostomy allows us to accurately approximate the mucosa of a single epididymal tubule to the mucosa of the vasal lumen [4]. With this increased precision, we have been able to achieve even higher patency and pregnancy rates [5, 6]. Microsurgical vasoepididymostomy, however, remains the most technically demanding procedure in all of microsurgery. In virtually no other operation are results so dependent upon technical perfection. Thus, microsurgical vasoepididymostomy should only be attempted by an experienced microsurgeon who performs a sufficient volume of microsurgery.

14.2 Vasoepididymostomy

Vasoepididymostomy is indicated in patients with obstructive azoospermia, and the decision to perform a vasoepididymostomy rather than a vasovasostomy is made intraoperatively. During vasectomy reversal, the testicular end of the vas is cut until a patent lumen is seen and the intravasal fluid is evaluated both grossly and with the aid of a 400× bench microscope. The presence of thick toothpaste-like fluid devoid of sperm, scant fluid in a patient without a sperm granuloma, or scant fluid with no spermatozoa seen on barbotage constitutes indications for vasoepididymostomy. For non-vasectomy-related obstruction, vasoepididymostomy is indicated when a testis biopsy reveals complete spermatogenesis and transection of the testicular end of the vas reveals no sperm even with barbotage.

The evolution of modern single tubule vasoepididymostomy techniques has progressed from the original end-to-end anastomoses described by Silber, end-to-side anastomoses

described by Wagenknecht and Fogdestam, and end-to-side intussusception anastomoses first described by Berger. In all of these, the initial exposure and setup are similar. A high vertical scrotal incision is made about 3–4 cm in length aimed toward the external ring of the inguinal canal. In cases with inadequate length of the vas, the incision can be extended to the external ring if necessary and the external oblique aponeurosis can be incised and an inguinal dissection of the vas performed. After incision through the skin and dartos fascia, the testicle is delivered with the tunica vaginalis intact. Using a Babcock clamp, the vas is isolated and surrounded with a Penrose drain. The operating microscope is brought into the field. The junction of the straight and convoluted vas is identified and isolated. The vas is then dissected free of its investing sheath and blood vessels under the operating microscope to expose a clean segment of bare vas. The bare segment of vas is hemitransected with a 15° ultrasharp knife until the lumen is visualized. The vasal fluid is then sampled, placed on a slide mixed with media, covered with a coverslip, and examined using a bench microscope at 400× magnification. If no spermatozoa are seen, then an additional 0.1–0.2 ml of fluid is injected into the testicular end and that fluid is expressed back out by squeezing the testis and epididymis and the fluid examined under the bench microscope. Absence of vasal sperm on microscopic exam in a man with either a normal testis biopsy or a positive antisperm antibody assay [7] confirms the diagnosis of epididymal obstruction.

At this point, the abdominal end of the vas is checked for patency by cannulating the abdominal end of the vas with a 24-gauge angiocatheter and injecting 1 ml of lactated ringers. Smooth injection without resistance or backflow confirms patency of the abdominal end of the vas. If further confirmation is desired, then a Foley catheter can be inserted after injecting indigo carmine and the color of the urine inspected. Green or blue urine confirms the patency of the abdominal vas as well as the ejaculatory ducts.

Once epididymal obstruction is confirmed and the need for a vasoepididymostomy verified, the abdominal end of the vas is prepared for anastomosis by completing the transection using an ultrasharp knife drawn through a slotted 2, 2.5, or 3 mm nerve-holding clamp. The vas is cut until healthy vasal tissue is seen. The cut surface of the testicular end of the vas deferens is inspected using 15–25 power magnification and should look like a bullseye with the three vasal layers distinctly visible. A healthy white mucosal ring should be seen which springs back immediately after gentle dilation. This layer is surrounded by muscularis which should appear smooth and homogeneous. A gritty-looking muscularis layer may indicate the presence of scar/fibrosis. Healthy bleeding should be noted from both the cut edge of the mucosa and the surface of the muscularis. If the blood supply is poor or the muscularis is gritty, the vas is recut until healthy tissue is found. The vasal artery and vein are ligated with 6-0 Vicryl. Small bleeders are controlled with a microbipolar forceps set at low power. At this point, the tunica vaginalis is opened and the epididymis is inspected.

In patients with previous vasectomy, there are some minor variations, but the overall approach is similar. In these patients, the testicular and abdominal ends of the vas are identified and dissected free. The abdominal end is transected and checked for patency. After confirmation of abdominal end patency, the testicular end is then inspected and sectioned and intravasal fluid microscopically inspected. If examination of the fluid reveals no spermatozoa, even with barbotage, the need for vasoepididymostomy is confirmed. The tunica vaginalis is opened and the epididymis is inspected under the operating microscope. At this point, it is time to determine the site of anastomosis.

14.3 End-to-End Anastomosis

This is the original microsurgical technique introduced by Silber and it is the first technique to allow the anastomosis of a specific epididymal tubule to the vas. At its introduction, it was far superior to any method previously described. In this technique, the epididymis is dissected down to its junction with the convoluted vas. The epididymis is then serially sectioned until a large rush of fluid is noted (Fig. 14.1), indicating that the area of obstruction has been bypassed. The single tubule with gushing fluid is identified and anastomosed to

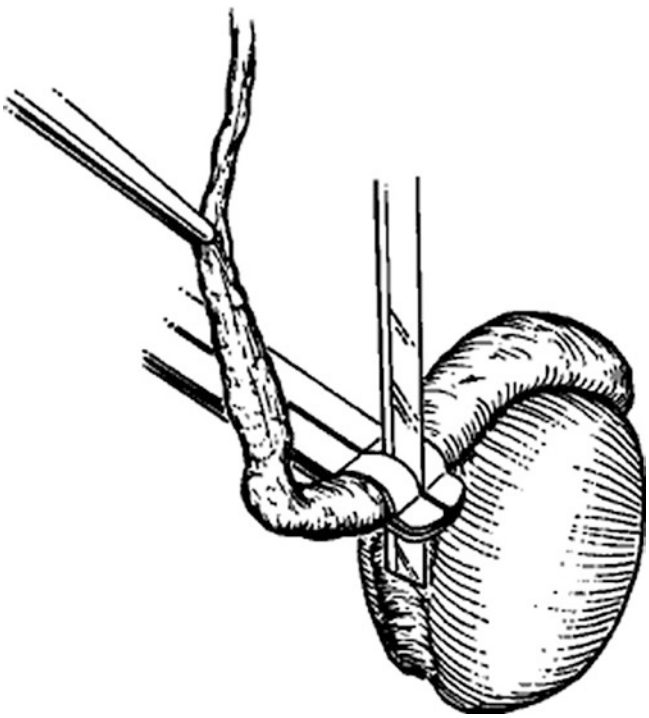

Fig. 14.1 Sectioning method employed in the end-to-end technique. (Reprinted from Goldstein [25], with permission of Elsevier)

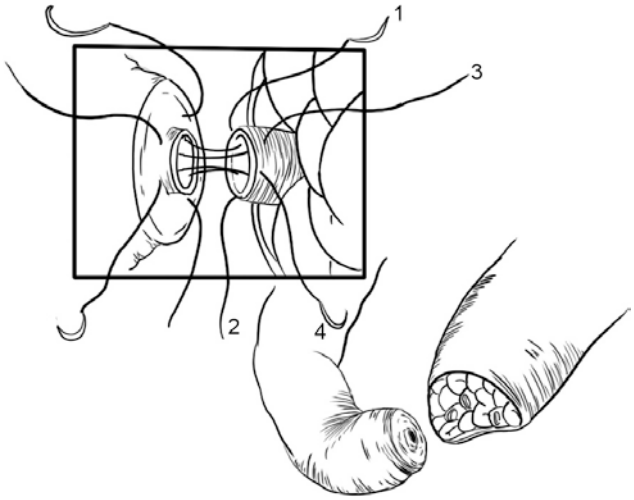

Fig. 14.2 End-to-end anastomosis showing anastomosis of a single epididymal tubule to the vasal lumen. Note that the outer vasal layers are then anastomosed to the tunica of the epididymis. (Reprinted from Goldstein [26]. With permission from Elsevier)

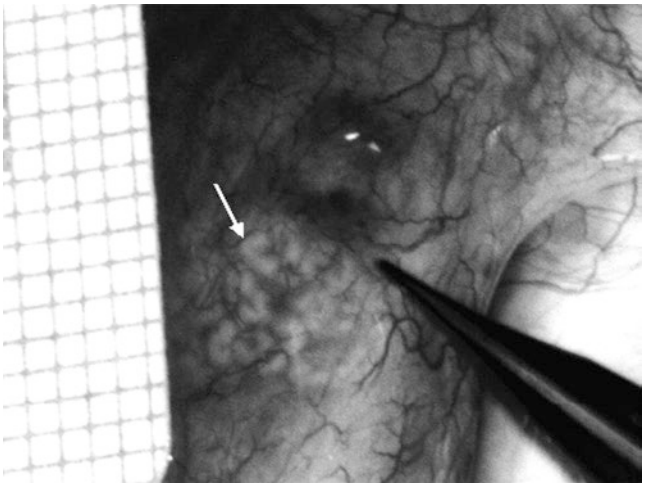

Fig. 14.3 Example of dilated epididymal tubules seen under the operating microscope

the vas with 3–5 interrupted 10-0 nylon sutures. The outer layer of the vas is anastomosed to the tunica of the epididymis with 9-0 nylon sutures (Fig. 14.2).

The advantages of this technique include the ability to dissect off the epididymis and rotate it to gain additional length if there are issues with short vasal length. A major disadvantage of this technique is that the outer diameter of the epididymal tunica is far larger than the outer diameter of the vas deferens, making a watertight closure exceedingly difficult. Also, the epididymal blood supply is invariably affected during transection. It also is more difficult to obtain clean, blood-free sperm for cryopreservation than it is with the end-to-side technique.

14.4 End-to-Side Techniques

End-to-side techniques of vasoepididymostomy improved on the end-to-end technique and have the advantage of being relatively bloodless and less traumatic to the delicate epididymis [8–11]. It requires minimal dissection of the tubule and allows the surgeon to easily tailor the size of the opening in the epididymal tubule. Also, this method allows for the preservation of all the epididymal branches of the testicular artery. Thereby, if another vasovasostomy is required, the blood supply to the intervening segment of vas can be preserved. In cases where the integrity of the testicular artery is in doubt (previous orchiopexy, previous non-microscopic varicocelectomy, or hernia repair), preservation of the deferential artery may be required for the maintenance of testicular blood supply.

The selection of an anastomotic site is a bit more involved with the end-to-side technique when compared with the end-to-end technique. After the vas has been prepared, the tunica vaginalis is opened and the testis delivered. Inspection of the epididymis under the operating microscope may reveal a clearly delineated demarcation above which epididymal tubules are markedly dilated and below which the tubules are collapsed. Often, a discrete yellow sperm granuloma is noted, above which the epididymis is indurated and the tubules dilated and below which the epididymis is soft and the tubules collapsed (Fig. 14.3). If the level of obstruction is not clearly delineated, a 70-μm tapered needle from the 10-0 nylon microsuture is used to puncture the epididymal tubule beginning as distal as possible and fluid sampled from the puncture site until sperm are found. At that level, the puncture is sealed with microbipolar forceps and the anastomosis is performed proximal to the puncture site.

An anastomotic site is selected where the epididymal tubules are clearly dilated. An avascular area is grasped with jeweler's forceps and the epididymal tunica tented upward. A 3–4-mm buttonhole is made in the tunica with microscissors to match the outer diameter of the vas. The epididymal tubules are then gently dissected until dilated loops of tubules are clearly exposed.

At this point an opening is made in the tunica vaginalis and the vas deferens end is brought through and secured to the tunic with two to three interrupted 6-0 prolene sutures to ensure that the vasal lumen reaches the opening in the epididymal tunica without tension and with some length to spare. The posterior edge of the epididymal tunica is then approximated to the posterior edge of the vas muscularis and adventitia with two to three interrupted sutures of double-armed 9-0 nylon. At the end of this step, the vasal lumen should be in close approximation to the epididymal tubule selected as the site for anastomosis. Proper positioning of the vasal segment and

proper setup are critical to the creation of a long-lasting tension-free anastomosis.

14.5 Anastomotic Technique

Once setup for the anastomosis is complete, the surgeon has a choice of anastomotic techniques which vary by the number of sutures placed, the order of suture placement, and intussusception of the tubule. We will discuss the classic end-to-side anastomosis as well as the various intussusception techniques.

14.6 Original End-to-Side

The classic end-to-side approach involves creation of a longitudinal incision along the selected epididymal tubule. This is done under 25–32× magnification. The intratubular fluid is microscopically inspected with the bench microscope. If no sperm are seen on microscopic exam, then the tubule is closed with a 10-0 suture and the overlying tunica closed with 9-0 nylon. A more proximal location is then identified and the setup for anastomosis is repeated. If sperm are found on microscopic inspection, it is safe to continue with the procedure. The extruded epididymal fluid is aspirated into glass capillary tubes and flushed into media for cryopreservation [12]. Diluted indigo carmine is applied to the field to highlight the edges of the epididymal tubule as well as the mucosal edges of the vas segment. Of note, we have previously shown that methylene blue and radiographic contrast are toxic to spermatozoa, while diluted indigo carmine is not [13]. Thus, it is our preference to use indigo carmine diluted 50% with lactate ringers for all vasograms and for emphasis of the mucosal edges.

Constant irrigation with saline or lactated ringers is required to keep the delicate epididymal tubule open and to visualize the edges. The posterior mucosal edge of the cut epididymal tubule is approximated to the posterior edge of the vasal mucosa with two interrupted sutures of 10-0 nylon double-arm sutures with 70-μm diameter tapered needles. After these mucosal sutures are tied, the anterior mucosal anastomosis is completed with two to four additional 10-0 interrupted sutures. The outer muscularis and adventitia of the vas are then approximated to the cut edge of the epididymal tunica with six to ten additional interrupted sutures of 9-0 nylon double armed with 100-μm diameter needles. The vasal sheath is secured to the epididymal tunica with three to five sutures of 9-0 nylon allowing for a straight course without kinks. The tunica vaginalis is then closed with 5-0 Vicryl and the dartos reapproximated with absorbable suture. The skin is closed in a subcuticular fashion.

14.7 End-to-Side Intussusception Technique

The next advance in vasoepididymostomy techniques came with the development of intussusception techniques. This method was first introduced by Berger in 1998 [14]. The setup is identical to that for the classic procedure. After the vas is fixed to the opening in the epididymal tunica, six microdots are placed on the cut surface of the vas to mark the sites of needle exit. The microdot technique ensures precise suture placement by exact mapping of each planned suture. The microdot method separates the planning from the placement of sutures [15]. Much as a civil engineer is consulted before workmen commence construction on a bridge, the microdot method allows the surgeon to completely focus on each individual task at hand. This results in substantially improved accuracy in suture placement as well as better suture spacing. Next, the epididymal tubule selected for anastomosis is dissected until it is free of surrounding tissue and displays prominently. Indigo carmine is applied to highlight the tubule. Using double-arm 10-0 nylon sutures with 70-μm tapered needles, three sutures are placed in the epididymal tubule in a triangular configuration. The needles are left in situ, creating a triangle of needles (Fig. 14.4). It must be remembered that the needle of the 10-0 suture is 70 μm in diameter while the suture material itself is only 17 μm. Thus, if the needles are pulled through prematurely, epididymal fluid and sperm would immediately leak through the suture hole causing the tubules to collapse, making placement of subsequent sutures and opening the tubules more difficult. Leaving the needles in situ also prevents accidentally cutting sutures when making the opening in the epididymal tubule.

After all three needles are properly placed, Berger originally described using a 9-0 cutting needle to lift the tubule and tear an opening in it. We prefer a 15° microknife to make an opening in the epididymal tubule in the center of the triangle. The three needles are then pulled through. The six needles are now

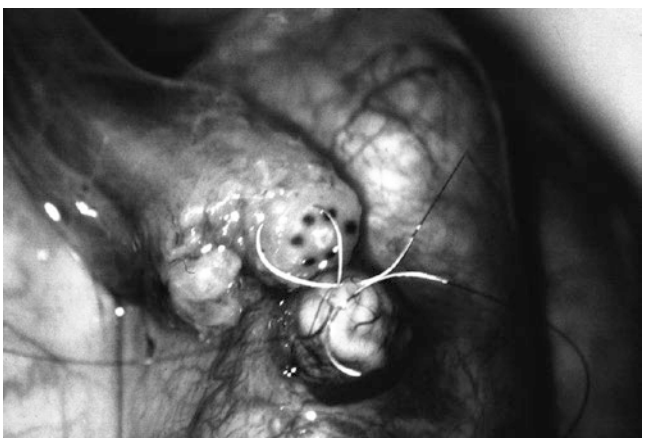

Fig. 14.4 Triangle of needles formed during the triangulation end-to-side intussusception technique introduced by Berger

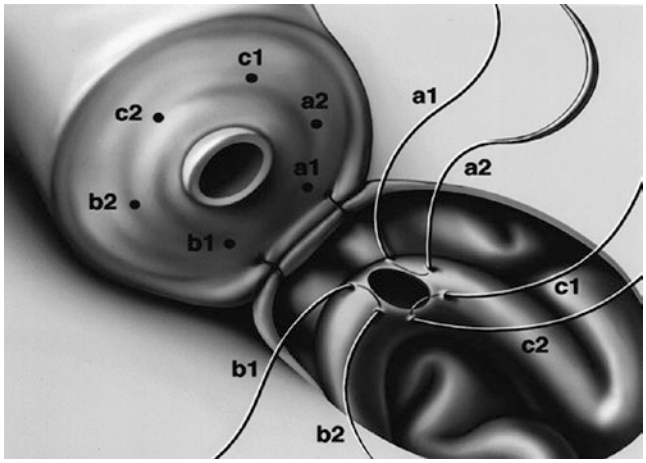

Fig. 14.5 End-to-side triangulation intussusception technique introduced by Berger. (Reprinted from Goldstein [25], with permission of Elsevier)

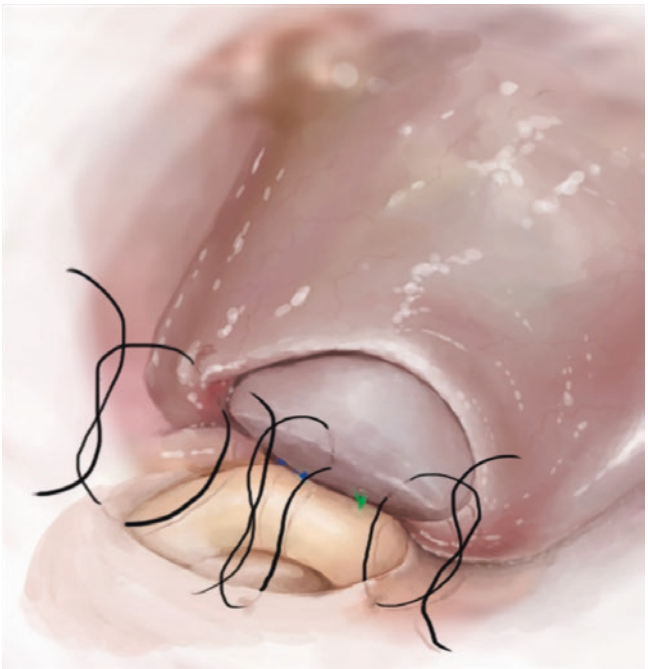

Fig. 14.6 Closure of the epididymal tunica should be done with 9-0 nylon sutures with particular attention paid to avoid incorporating any underlying tubules into the closure. (Reprinted from Goldstein [26]. With permission from Elsevier)

laid out to avoid tangling. The extruded fluid is inspected under the microscope for sperm. If sperm are seen, then the six needles are passed inside out the vas deferens exiting through the six previously placed microdots (Fig. 14.5). The sutures are then tied, intussuscepting the epididymal tubule into the vas lumen and thereby creating a watertight closure. Intussusception also allows the flow of fluid from the epididymal tubule into the vas to push the edges of the epididymal tubule against the vasal mucosa, further reinforcing the watertight nature of this anastomosis. The edges of the vas are then closed with interrupted 9-0 nylon sutures (Fig. 14.6). Limitations of the triangulation technique include the need for a relatively large tubule for the three needles to fit. Thus, this technique is not suitable for anastomosis to the efferent ductules or the proximal caput epididymis where the tubule is smaller.

14.8 Two-Stitch Longitudinal Vasoepididymostomy (LIVE Technique)

This is our currently preferred method of VE which allows for a two-stitch intussuscepted anastomosis. In this technique, four microdots are made on the vasal end. Two needles from two separate 10-0 double-arm sutures are then placed longitudinally in the tubule with care not to pull the needles completely through. The opening in the epididymal tubule is then made with a 15° microknife between the needles. After microscopic confirmation of the presence of spermatozoa, the needles are passed. The four needles are then passed through the vasal lumen and exiting the microdots (inside to outside). A 9-0 suture is placed to pull the anterior vas and adventitia toward the opening in the epididymal tubule bringing the vas mucosa into close approximation to the opening in the epididymal tubule. The lumen is irrigated with heparinized saline just prior to tying the mucosal sutures. Finally, the mucosal sutures are tied down (Fig. 14.7), allowing for the intussusception of the epididymal tubule. The outer layer is closed with interrupted 9-0 nylon sutures careful to not inadvertently incorporate any epididymal tubules when placing these sutures (Fig. 14.8). Again, by not pulling the needles completely through the tubule until the tubule has been incised, the tubule remains distended, which makes suture placement and incision of the tubule more accurate and reliable. Variations in this technique include

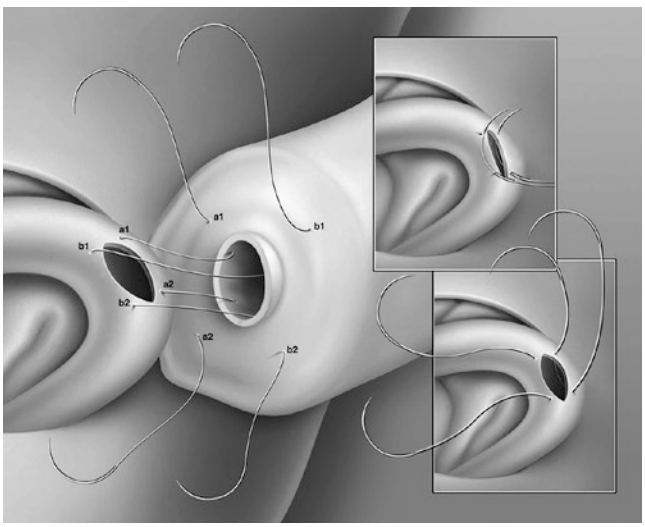

Fig. 14.7 Longitudinal intussuscepted vasoepididymostomy technique. Mucosal suture placement. (Reprinted from Goldstein [26]. With permission from Elsevier)

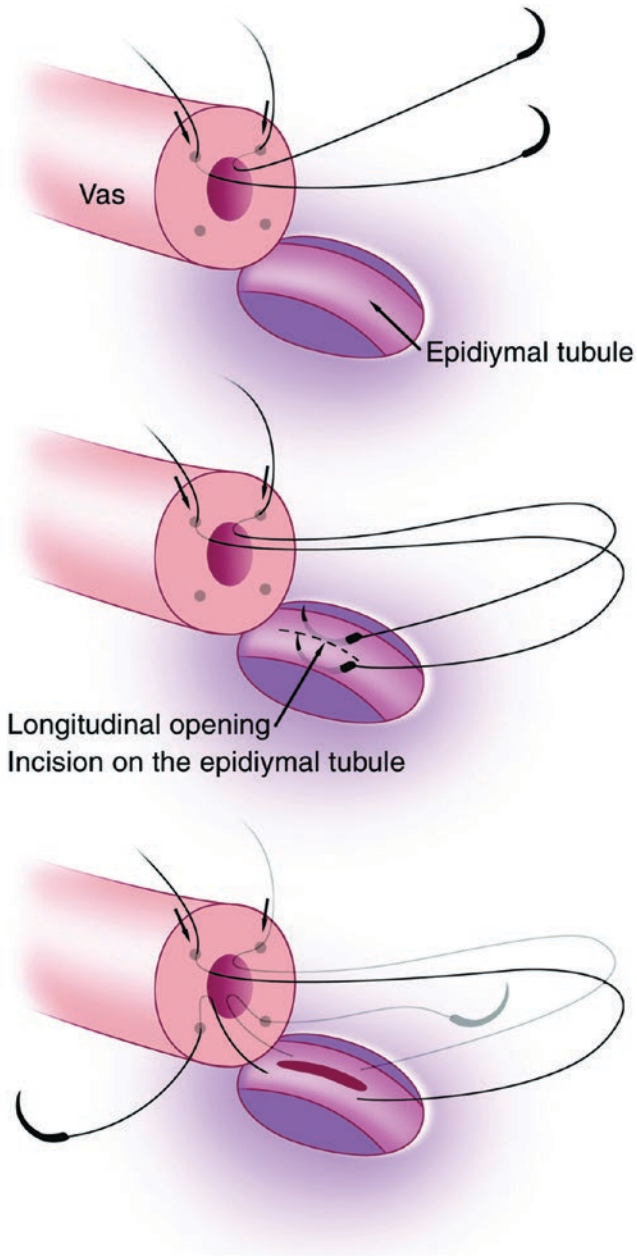

Fig. 14.9 Technique of single-arm vasoepididymostomy technique. Needles are passed outside in on the vas deferens. The needles are then passed longitudinally in the selected epididymal tubule and the cut made in the epididymal tubule. The needles are then passed and then placed inside out in the vas deferens. (Reprinted from Goldstein [26]. With permission from Elsevier)

mounting two needles in a single needle holder and placing them simultaneously transversely in the tubule as suggested by Marmar.

Of note, the cost of double-arm sutures can be high. In response to this, we have developed a single-arm technique of VE which we have found to be almost as effective as its double-arm counterpart [16]. It begins with the standard setup for VE. We then place four microdots in the vasal end. Two 10-0 single-arm nylon sutures are then passed through the microdots and exiting the vasal lumen (outside to inside). After this, the same two sutures are placed longitudinally in the selected tubule and the needles are not completely passed. After opening the tubule and confirming the presence of spermatozoa, the needles are pulled through and the needles passed through the vasal lumen and exiting the microdot (inside to outside) (Fig. 14.9). The sutures are then tied allowing the intussusception of the epididymal tubule. The outer sheath of the vas deferens is then approximated to the tunic of the epididymis with two to four interrupted 9-0 nylon sutures, removing all tension from the anastomosis.

14.9 Techniques When Vasal Length Is Severely Compromised

One of the most common problems that arise during vasoepididymostomy is inadequate vasal length, often due to a very destructive vasectomy. When there is inadequate length of the vas deferens to reach the dilated epididymal tubule without tension, a number of surgical techniques may be employed involving any of the following: freeing up the epididymis, increasing vasal length, fixation of the testis higher in the scrotum, or use of the contralateral vas deferens.

To gain length on the epididymis, the cauda and corpus epididymis can be dissected down to the vasoepidid-

ymal junction and then dissected off the testes as in the end-to-end operation. The epididymis is encircled with a small Penrose drain at the level of obstruction and dissected off of the testis up to the level of obstruction, yielding sufficient length to perform the anastomosis. Usually an avascular plane can be found between the tunica albuginea of the testis and the epididymis, and injury to the epididymal blood supply can be avoided. The inferior and, if necessary, middle epididymal branches of the testicular artery are ligated and divided to free up an adequate length of epididymis. The superior-epididymal branches entering the epididymis at the caput are always preserved, and this is adequate blood supply for the entire epididymis.

If the epididymis is indurated and dilated throughout its length, the epididymis is dissected all the way past the vasoepididymal junction. This dissection is often facilitated by first dissecting the convoluted vas to the vasoepididymal junction from below, and then, after encircling the epididymis with a Penrose drain, dissecting the epididymis to the vasoepididymal junction from above. In this way, the entire vasoepididymal junction can be freed up. This will allow preservation of maximal epididymal length in cases of obstruction near the vasoepididymal junction. After the epididymis is dissected off of the testis and flipped-up, a two-stitch longitudinal end-to-side intussusception anastomosis can be performed as described previously (Fig. 14.10).

Increasing vasal length can be done with extensive blunt dissection of the vas deferens off the spermatic cord toward the inguinal ring. If necessary, the external oblique aponeurosis is incised toward the internal inguinal ring and dissected with a finger sweeping motion. In extreme situations, the vas deferens can be rerouted medial to the vessels similar to the Prentiss maneuver employed during difficult orchiopexies [17]. An opening in the floor of the inguinal canal is made and the vas rerouted medially under the floor of the canal and right over the pubis.

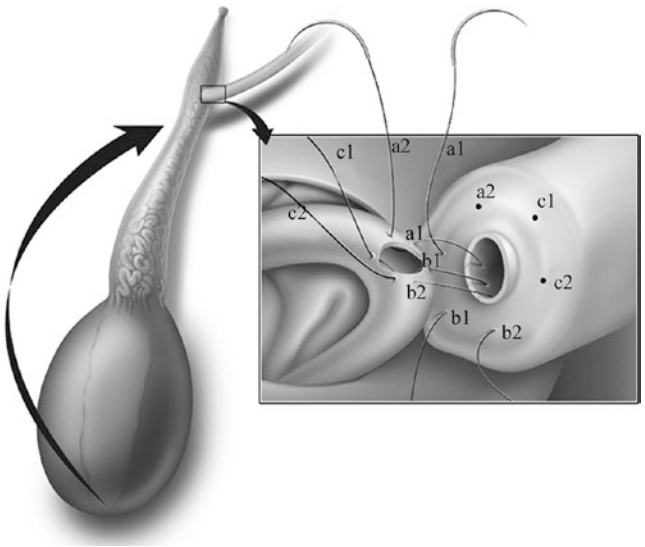

Fig. 14.10 Technique of dissecting the corpus and cauda epididymis to gain further length in cases of short vasal length. This is most helpful when the entire epididymis is dilated. (Reprinted from Goldstein [26]. With permission from Elsevier)

It is also possible to perform an orchiopexy positioning the testicle in a horizontal or even upside-down configuration to decrease the length needed. One must be careful to make sure the cord has no kinks in it and that the stitches do not damage the blood supply to the testis.

In cases where there is a unilateral atrophic testis or the contralateral testis is missing, it is possible to perform a crossed transseptal vasoepididymostomy. This is even more attractive if there is an ipsilateral hernia repair or where there is a second obstruction in the inguinal or abdominal vas. In this procedure, the contralateral vas is harvested as close to the vasoepididymal junction as possible. If vasal length is still inadequate, then the testicle can be pexed in the contralateral scrotal compartment to facilitate a tension-free anastomosis.

14.10 Long-Term Follow-Up Evaluation and Results

Microsurgical vasoepididymostomy in the hands of experienced skilled microsurgeon will result in the appearance of sperm in the ejaculate in 50–85% of men. Classic end-to-side or older end-to-end methods result in patency rates about 70% with a 43% pregnancy rate with a follow-up of 2 years [5, 18]. With intussusception techniques, patency rates are 70–90% with pregnancy rates of 40–45% [6, 14, 19–22]. Regardless of technique, pregnancy rates are higher the more distal the anastomosis is performed [23]. Therefore, one should always strive to make the anastomosis as distal as possible on the epididymis. The advantages and disadvantages of the main techniques we discussed are summarized (Table 14.1).

Another vexing problem is that of late anastomotic failure. With the older end-to-end or end-to-side methods, at 14 months after surgery, 25% of initially patent anastomoses have shut down [12]. With intussusception techniques, the late shutdown rates appear to be less than 10%, but long-term follow-up with these techniques has not yet been reported. Nevertheless, we recommend banking sperm both intraoperatively [24] and as soon as motile sperm appear in the ejaculate postoperatively after vasoepididymostomy, regardless of technique employed. In men with very low counts or poor sperm quality postoperatively and men who remain azoospermic, the sperm intraoperatively cryopreserved can

Table 14.1 Advantages and disadvantages of three main vasoepididymostomy techniques

Techniques	Advantages	Disadvantages
Intussusception (longitudinal intussusception vasoepididymostomy)	Virtually bloodless anastomosis Easier technique with dilated epididymal tubule	Unable to assess for sperm presence before anastomotic setup
End-to-side vasoepididymostomy	Able to assess for sperm presence prior to anastomotic setup No disruption of epididymal blood supply	Difficult to suture to collapsed epididymal tubule
End-to-end vasoepididymostomy	Technically easier inner layer anastomosis Able to assess for sperm presence prior to anastomotic setup Able to assess for sperm presence prior to anastomotic setup Able to mobility the epididymis off the testis for large gaps	Disruption of epididymal blood supply from inferior epididymal artery Difficult outer layer closure Can be difficult to identify proper tubule for anastomosis

be used for IVF with intracytoplasmic sperm injection. Persistently azoospermic men without cryopreserved sperm can opt for either a redo-vasoepididymostomy or microscopic epididymal sperm aspiration combined with IVF and intracytoplasmic sperm injection.

14.11 Conclusion

The modern evolution of vasoepididymostomy has been a remarkable journey. Since Martin's first attempts over 100 years ago, we have continued to make significant strides in the refinement of this surgical technique. Most recently, adoption of microsurgical techniques and intussusception methods of vasoepididymostomy have made this surgery progressively more effective. With the introduction of the two-stitch longitudinal intussusception method, anastomoses have become simpler and easier to teach with a decreasing risk of technical error.

Modern IVF–ICSI has opened up reproductive options for those couples desiring fertility. This has caused some to question the need for advanced reconstructive reproductive tract surgery. However, in the hands of experienced microsurgeons, vasoepididymostomy is a safe, effective method of reconstruction for patients, especially for those who do not want to undergo IVF or desire multiple children. In addition, vasoepididymostomy skills are crucial to have because of the possibility of finding secondary epididymal obstruction at the time of vasectomy reversal. It is of our opinion that any reproductive surgeon who performs vasal reconstruction must be capable of performing a vasoepididymostomy.

While vasoepididymostomy is already associated with good outcomes, we look forward to the future. Further technical refinements will most likely focus on the simplification of the vasoepididymostomy procedure, decreasing operative times and making the procedure more accessible to more surgeons. These developments will come from microsurgical models and animal models. Additionally, collaborative multi-institutional datasets may allow us to find better intraoperative or perioperative predictors of anastomotic patency and pregnancy. Intraoperative factor to evaluate and consider further research into would be factors at the anastomotic site: analysis of the gross fluid quality of epididymal fluid, the effect of microscopic motility, and sperm viability testing during reconstruction.

14.12 Review Criteria

An extensive search of studies examining the vasoepididymostomy outcomes in humans was performed using PubMed in December 2018. The overall strategy for study identification and data extraction was based on the following keywords: "vasoepididymostomy," "epididymovasostomy," and "infertility." Articles published in English were considered. Data that were solely published in conference or meeting proceedings, websites, or books were not included.

Grafting Techniques for Vasectomy Reversal

15

Henry M. Rosevear and Moshe Wald

Key Points

- Microsurgical two-layered anastomosis to correct vasal obstruction remains the gold standard.
- The role of vasal stenting in the era of microsurgical two-layered anastomosis is limited.
- Biodegradable conduits to bridge segments of obstructed vas deferens where a primary microsurgical two-layered anastomosis is impossible remain investigational but hold significant long-term promise.

15.1 Introduction

Surgical reconstruction of the vas deferens is performed to remove an obstructive lesion that is present along its course. Obstruction can exist at various parts of the vas deferens and can be the result of a prior vasectomy, congenital anomaly, inflammation secondary to a urogenital tract infection, trauma, or a surgical misadventure during prior inguinal, pelvic, or scrotal surgery. While no official reporting system exists in the United States to monitor the number of vasectomies performed each year, a survey in 2002 estimated this to be 526,501, which is approximately consistent with data reported in 1991 and 1995 [1, 2]. An estimated 2–6% of all men, and up to 11% of men aged 20–24 at the time of vasectomy, request a vasectomy reversal [3]. It has been estimated that between 30,000 and 80,000 vasectomy reversals are performed annually in the United States, though as with vasectomies, reporting requirements are not standardized so the exact number is unknown [4].

Congenital anomalies which can lead to obstruction of the vas deferens include congenital absence of the vas deferens, which is commonly associated with cystic fibrosis [5]. Partial vasal agenesis and congenital prostatic cysts can also lead to obstruction of the vas deferens [6, 7]. One example of a genetic disorder which can lead to obstructive azoospermia is Young's syndrome, which is characterized by chronic sinusitis and bronchiectasis as well as obstructive azoospermia [8]. In Young's syndrome, the obstruction usually occurs at the junction of the caput to corpus epididymis due to inspissated secretions. Inflammatory causes of obstruction are rare in the antibiotic era but include tuberculous epididymitis, gonorrheal urethritis progressing to obstructive epididymitis, and chlamydial epididymitis [9].

The success of a vasectomy reversal depends on several factors, only some of which can be controlled at the time of surgery. Factors which are independent of the method of reversal but which may influence subsequent conception include age and fertility potential of the patient's partner, length of obstructive interval, presence of antisperm antibodies, and high intravasal and epididymal pressure after the original obstruction [10–13]. Some factors which influence the success of the reversal are directly related to the technique chosen and include rate of stricture or scar development and granuloma formation [14]. The most commonly cited reason for these specific complications is an anastomosis made under tension, devascularization of the wall of the vas deferens, or a technical problem with the anastomosis leading to sperm leakage [15].

The current gold standard to surgically correct an obstructed vas deferens is a microscope-assisted two-layered vasovasostomy, but this has not always been so [16, 17]. Given the complex and time-consuming nature of this operation, new surgical techniques including robotics, modifications, and tools are continuously being explored. Some of these techniques include the use of fibrin glue, laser soldering, absorbable and nonabsorbable stents, and artificial conduits with or without specific growth factors added [18]. This chapter highlights the development of surgical grafting tech-

niques for vasectomy reversal, including the use of stents and grafts, as well as the current clinical application of these devices and areas where further research is required.

15.2 Grafting Techniques in Reconstruction of the Male Reproductive Tract

15.2.1 Stents

As previously stated, several factors related to the success of a vasectomy reversal can be controlled at the time of surgery. From the 1950s to the mid-1970s, macrosurgical techniques for vasovasostomy were common and accepted as the gold standard. This technique allowed a primary anastomosis of the vas deferens to be created but was plagued with, by today's standards, low patency and pregnancy rates. According to a survey of the American Urological Association (AUA) members published in 1973, members at that time practicing vasovasostomy reported a 38% patency rate and a 19.5% pregnancy rate [19]. It should be remembered that the microsurgical techniques which are common today were not developed until the mid-1970s, and as such, stricture resulting in either partial or complete vasal obstruction was the most pressing technical complication of that period. To address this common complication, approximately 90% of urologists performing vasovasostomies at that time employed stents, with either silver wire or nylon suture being the most commonly reported [19]. The reason for the widespread use of stents can also be found in the 1973 AUA survey. Members reported that the pregnancy rate for non-stented reversals was significantly lower, at 10.9% compared to 19.9–26% for stented procedures, depending on the stent used. Numerous techniques had been developed in 1973 which maximized both patency and pregnancy rates. The main variation between these techniques was the use of loupes for magnification and/or the use of stent [20].

In the lexicon of the modern urologist, a stent most commonly refers to the hollow silicon tube that is used in the ureter for treatment of either intrinsic or extrinsic ureteral obstruction. A vasovasostomy stent, as it was originally used, was quite different. A stent in that sense was any foreign body, usually a piece of suture, the purpose of which was to maintain patency of the lumen of the vas deferens during and immediately after a macrosurgical (either with or without the supplemental use of loupes) primary anastomosis of the vas deferens. The simple goal of the stent was to prevent obstruction at the anastomosis site either because of a poorly placed suture at the time of surgery or as prevention of stricture or scar formation in the immediate postoperative period. In one example of this technique, a short section of 2-0 nylon suture is used as a stent to bridge the anastomosis, while 6-0 Prolene is used to actually complete the anastomosis [21]. In this technique, the nylon suture is removed before the operation is completed, and its purpose is to ensure that the vas deferens lumen remains patent during the procedure. In another variation on this theme, described by Dorsey, a zero monofilament suture is fed through a hollow needle introduced approximately 1 cm proximal to the site of the intended anastomosis [22]. This suture is then fed into the distal vas deferens. The anastomosis is then completed using 6–0 Ethiflex, and the proximal end of the stenting suture is brought through the scrotal skin and removed in 12–14 days. The goal of this stent in this technique is to ensure patency of the anastomotic site both during the procedure and in the immediate postoperative healing period. The success rates of these procedures were reported to be over 80% patency, which contrasts with the success rates reported in the 1973 AUA survey.

Even with the improvement in both patency and pregnancy rates reported by clinicians using stents during vasovasostomy, there were numerous known disadvantages of stents, especially with the use of exteriorized stents such as described by Dorsey [20]. The point of exit for the stent is a theoretical source of infection as well as a location where sperm can leave the lumen of the vas [20, 23]. Additionally, the location where the exteriorized stent left the lumen of the vas was identified in a publication by Fernandes as a common site of subsequent luminal obstruction (often instead of the primary anastomosis itself) [24]. To avoid the problem of an exteriorized stent, some groups have experimented with absorbable intravasal suture as a stent to bridge the anastomosis—the theoretical advantage being that these stents would slowly dissolve, maintaining the patency of the anastomosis both during the procedure itself and the postoperative healing period without need to be removed. In one experiment in a canine model, Montie et al. compared three groups: no stent, a Dexon intravasal stent, and a chromic intravasal stent [23]. Three to six months after the vasectomy reversal procedure, retrograde vasography was used to identify patency rates. Both absorbable stent groups had higher patency rates than the control (no stent) group, with the chromic group having the highest overall patency at 70% vs. 60% for the Dexon group and 50% for the no stent group. This concept was tested in a human clinical model by Rowland and colleagues a few years later, who found that intravasal absorbable stents (using 3-0 chromic) had higher patency rates than a group using exteriorized silkworm gut stents (86% vs. 67%, respectively) [25].

In 1975, Silber reported the first use of microsurgical vasovasostomy in humans [26]. His work, along with independent work by Owen, led the way to the modern microsurgical two-layered anastomosis [26, 27]. From a historical standpoint, it should be noted that it was Silber and his group who found through histologic and electron microscopic work

that stricture was more common than originally thought with macrosurgical anastomosis techniques [28]. Silber also popularized the two-layered closure based on his observation that this technique provided a better watertight mucosal approximation given the common discrepancies between proximal and distal luminal diameters of the vas deferens [29]. The techniques developed by these investigators have allowed the microsurgical two-layered vasovasostomy anastomosis to become the gold standard for vasectomy reversal, with success rates dependent on time since obstruction. These success rates may be as high as 97% patency and 76% pregnancy when the obstructive interval is less than 3 years and 71% patency and 30% pregnancy after 15 years of obstruction [13].

The reproducible success of this new technique resulted in a dearth of research into alternative techniques for many years. Even with its success, Silber's microsurgical technique was not perfect. The downside was that microsurgical anastomosis was a time-consuming operation best done by surgeons with specialized training using expensive operating microscopes. This prompted research into new techniques that would simplify the technique while maintaining the high patency and pregnancy rates. In 1989, Flam et al. reported work in a rat model on a hollow, absorbable polyglycolic acid tube [30]. In their experiment, they inserted a 10-mm-long by 0.5-mm outer diameter hollow stent into the lumen of the vas at the site of anastomosis on one side and completed the anastomosis with a single layer of suture (Fig. 15.1). On the contralateral side, they performed standard microsurgical anastomosis. They showed a trend toward improved patency in the stented vas deferens. Flam emphasized in his paper that sperm leakage at the site of the anastomosis could lead to secondary stricture and should be avoided. This work led to a clinical trial using absorbable intravasal stents conducted by Rothman and colleagues in 1996 [31]. This randomized study compared conventional two-layered microsurgical anastomosis to a modified approach using an absorbable polyglycolic acid stent without intraluminal sutures (Fig. 15.2). While the operative time was significantly reduced in the stented group (118 min vs. 137 min), both the patency and the pregnancy rates were lower in the stented groups (81% vs. 89% and 22% vs. 51%, respectively), and the authors concluded that intravasal stents should not be used.

More recently, Vrijhof et al. reported on a nonabsorbable stent in a rabbit model [14]. They theorized that the absorbable nature of the previously reported stents allowed strictures to develop at the site of the anastomosis once the stent had dissolved and that a nonreactive nonabsorbable stent would bypass this problem while simplifying the operation. Their stent was made of a biocompatible material designed to have both hydrophilic and hydrophobic characteristics. The stent also had a transverse ridge which was designed to minimize migration from the anastomotic site (Fig. 15.3). This group reported that all vasa were patent at the end of their study (39–47 weeks) and that total sperm count was higher in the stented group. No human data is available on this type of stent.

In the era of cost-conscious medicine, especially when many patients must pay out of pocket for vasectomy reversals, further research into efforts that simplify the present gold standard is appropriate with the caveat that patency and pregnancy rates should not be compromised. It is important to note that all of the absorbable and nonabsorbable stents which have been used to date in human studies have been well tolerated with no side effects and little to no inflammatory response.

In summary, stents were investigated as a method to improve patency rates in the era of macrosurgical vasovasostomy but were eclipsed by the application of the operating microscope to the field and the introduction of microsurgical two-layered vasovasostomy. Efforts to improve and simplify the microsurgical operation using absorbable stents have not improved overall patency or pregnancy rates. Recent efforts using nonabsorbable stents show promise in animal models but have not been tested in humans so their utility remains unproven. The ideal stent would, at a minimum, maintain the patency and pregnancy rates achieved through a conventional two-layered microsurgical anastomosis while decreasing the operative time, training, and cost required to achieve these results.

15.2.2 Conduits

The preferred method to bypass an obstructed portion of the vas deferens, regardless of the etiology of the obstruction, is surgical excision or exclusion of the obstructed segment and reanastomosis of the vas deferens using a microsurgical two-layered anastomosis. The goal of the operation is a watertight, tension-free, widely patent anastomosis. As described previously, numerous techniques have been suggested in an attempt to simplify this procedure while preserving its patency and pregnancy rates. The assumption in all of the previously described techniques is that the vas deferens could be sufficiently mobilized to allow a tension-free anastomosis. Unfortunately, cases exist where, due to the physical length of the obstruction, the vas deferens cannot be reconstructed in a watertight, tension-free manner. These cases present a clinical challenge because the resulting obstructive azoospermia is theoretically amenable to surgical correction. Presently, the only reproductive option available for these patients is surgical sperm retrieval. The technique of retrieving sperm from either the testicle or epididymis has been successfully reported in cases of obstructive azoospermia that is not surgically correctable but must be coupled with in vitro fertilization [32]. The hormonal manipulation, surgical interventions, risk of multiple gestations, and increased financial cost of in vitro fertilization make this solution less than ideal and create an intriguing field of research into reconstruction of the male reproductive tract.

Grafting of the male reproductive tract theoretically can take one of three forms. The first option is to use transplanted vas deferens with all of the complications, both technical and immunological, associated with such a procedure. The second option is to replace the obstructed segment of vas deferens with a tubular structure, the sole purpose of which is to simply allow passage of sperm in a distal direction. An analogous clinical problem can be found in vascular surgery where surgeons often replace diseased segments of vessels with either endogenous grafts such as the long saphenous vein or exogenous grafts such as a Teflon-coated endovascular stent. The third option involves tissue engineering. Tissue engineering as it applies to reconstruction of the male reproductive system involves the concept of creating an artificial conduit which serves as a scaffolding for the regrowth of the vas deferens itself. In a different biological system, polymer scaffoldings have been shown to facilitate peripheral nerve regeneration in segments as long as 1 cm [33]. Regardless of the method chosen to graft over the obstructed segment of vas deferens, the goal is to reestablish continuity of the male reproductive tract, allowing sperm to be present in the ejaculate and eliminating the need for assisted reproductive techniques (ART). It should be noted that even small amounts of ejaculated sperm could be a significant improvement, as this may allow for less invasive forms of ART [34].

The first reported experiment on the use of grafts in reconstruction of the male reproductive tract was by Romero-Maroto and colleagues in 1989 [35]. This group reported successfully autotransplanting a pediculated segment of vas deferens from one side to the contralateral in

rabbits. They reported good patency rates, but no data on pregnancies was noted. The clinical use of this technique is likely limited, as these subjects would likely be candidates for crossover vasovasostomies, a rare procedure with a high reported success rate [36], and given the questionable feasibility of harvesting a long vasal segment for reconstruction of the contralateral side.

Regarding the second option for grafting the male reproductive tract, Carringer et al. in 1995 reported patency rates in rats after either a vasal or vascular graft obtained from either the contralateral side of the same animal or from female rats, respectively [37]. In this study, three different lengths of grafts were used (0.5, 1.0, and 1.5 cm), corresponding to approximately 10%, 20%, and 30% of the entire vas deferens length. Patency was confirmed by direct examination of the graft 4 weeks postoperatively. The authors found an overall patency rate of approximately 40% in both surgical groups (vasal and vascular graft) with higher rates in the shorter segments. Pregnancy rates were not evaluated. No human clinical trials have been reported using either of these techniques. Questions on long-term patency of extensive artificial grafts remain unanswered, even in animal models, and should be further investigated.

The lack of a suitable allograft in humans for vasal reconstruction has led to research on the potential for biocompatible degradable polymer scaffolding for tissue engineering. As mentioned earlier, this model has been successfully applied to the clinical problem of peripheral nerve regeneration [33]. Additions to this technology, including micropatterned (grooved) inner lumens as well as target-specific growth factors, can increase the efficacy of this technology [38, 39]. The vas deferens is a good target for investigation because it has been shown to undergo spontaneous recanalization at the site of vasectomy [40].

Further evidence that may support tissue engineering of the vas deferens is the demonstration of elevated levels of selected growth factors at the vasectomy site in an animal model. Previous examination of vasectomy sites in rats using real-time polymerase chain reaction, enzyme-linked immunosorbent assay, and histopathological analysis demonstrated a 12-fold increase in platelet-derived growth factor beta and a ninefold increase in transforming growth factor beta [41].

Using the peripheral nerve regeneration model as a guide, biodegradable conduits made of d,l-lactide were studied for reconstruction of the reproductive tract in a rat model [42]. Biodegradable conduits with micro-patterned grooves on the inner surface were implanted in 47 rats following vasectomy (Fig. 15.4, scanning electron microscopy image). At 8 weeks postimplantation of the conduits, no evidence of recanalization was found. However, at 12 weeks, evidence of recanalization was noted in three of the remaining rats, with one showing a microcanal spanning the entire 0.5-cm conduit and the other two showing distinct epithelialized vas deferens microcanals at the conduit edges (Fig. 15.5) [42].

Following the demonstration of microrecanalization of the vas deferens in this biodegradable graft model, attempts were made to identify ways to maximize this response (unpublished data). Based on the identification of elevated growth factor levels at the site of vasectomy, the effect of local microparticle-delivered growth factors on the rate of vasal recanalization in a biodegradable conduit model was examined. Delivering growth factors to a specific location in the body over a sustained period of time is not a simple task. Effective supplementation of growth factors selectively at the site of the grafted vas deferens may be compromised by the fact that the ability of growth factors to perform their function depends on their tertiary structure, which is susceptible to degradation if it is not protected from the local environment. Thus, delivery of a locally sustained concentration of growth factors requires the use of microspheres. The goal of a microsphere is to sequester the biologically active molecule and allow a controlled, sustained release of the molecule. The exact timing of the sustained release is a function of the characteristics of the microsphere into which it is placed. With these considerations in mind, a poly-(d,l-lactide) material was chosen for construction of the microspheres. As the biodegradable conduits used in this study were constructed of the identical material, noncovalent binding was assumed to keep the microspheres near the conduit. Reconstruction of surgically induced vasal gaps using biodegradable conduits soaked in microspheres containing TGF-beta and PDGF revealed an increase in the number of new microcanals in the graft but not in their length at 12 weeks postoperatively.

In an effort to further optimize the conditions for vasal recanalization, methods to increase the vascularity of the reconstructed vas deferens were investigated, based on an observation suggesting that neovascularization increased with time at the conduit to vasal border (unpublished data). To bolster this neovascularization and potentially increase the rate of recanalization, the effect of oral sildenafil citrate on recanalization in the biodegradable graft model was examined. Sildenafil citrate is a type 5 phosphodiesterase inhibitor that has been shown to promote neovascularization in other systems [43]. Rats received a daily dose of 5 mg/kg of oral sildenafil citrate following reconstruction of the vas deferens with a biodegradable graft. At 16 weeks, the rats on sildenafil citrate had a significantly increased number of microcanals (29 vs. 4) though the average length of the canals was constant at 2 mm. This observation was confirmed by an increase in staining for CD31, an endothelial marker. An ongoing study involves combining both oral sildenafil citrate with increasing the local concentration of TGF-beta and platelet-derived growth factors via microspheres. Areas of future research into this field include examining different substrates of which the conduit itself is composed and embedding the growth factors directly into the conduit to maximize local concentration.

15.2.3 Autografts

In addition to the earlier studies of allografts, vascular autografts, and vascularized (pediculated) vasal autografts for vasal reconstruction, more recent research has been conducted on the possible utilization of non-vascularized vas deferens autografts.

Kadioglu et al. [44] evaluated the possible utilization of a non-vascularized vas deferens autograft in a rat model. In this study, segments of isolated vas deferens, 2.5 cm in length, were used as bilateral autografts in 15 rats. Each autograft was implanted between the two transected ends of vas deferens using end-to-end anastomosis. Unlike the earlier study by Carringer [37], this study also assessed pregnancy outcomes. Fertility, sperm motility, and graft survival were evaluated and compared with a control group. After 3 months, 9 of the 15 (60%) rats were able to breed successfully and 24 (80%) vas grafts were patent and viable. Large granulomata were reported to be present at the proximal anastomosis sites in six (20%) autografts that failed. Unilateral minimal fluid leakage was reported in six (20%) of the proximal (testicular end) anastomosis sites in those rats that were able to breed. On semen analysis, forward motility was noted in 76% of sperm in the experimental group, compared to 78% in the control group ($p > 0.05$). The authors of this study concluded that vas deferens autograft can be successfully performed in a rat model with subsequent breeding capability [44].

However, these results were contradicted by a study by Nasir et al. that compared different autogenous graft materials for reconstruction of large segment vas deferens defect in a rat model. In this study, vas deferens, artery, and vein grafts were used to reconstruct 30% and 50% defects of the total vas deferens length. No patency was found in any of the grafts [45].

In addition to avoiding immunological difficulties, the utilization of isolated, non-vascularized vas deferens autografts may also allow more flexibility in the possible location of the implantation site along the reproductive tract, which might be limited when vascularized (pediculated) vasal grafts are used. More research would be required regarding the possible implementation of this technique for the reconstruction of long vas deferens defects.

15.3 Conclusions

Grafting of the male reproductive tract is an exciting new area of tissue engineering which may allow natural conception for patients with significant lengths of obstructed vas deferens. While stents had a significant and important role in increasing patency and pregnancy rates in the pre-microsurgical era, their role in the modern era of microsurgi-

cal two-layered anastomosis remains to be defined. To date, if the vasal obstruction is amenable to a primary watertight, tension-free anastomosis, microsurgical non-stented techniques remain the gold standard. Cases where a tension-free anastomosis is not possible because of the physical length of the obstruction remain problematic, but further research into autografts and tissue engineering in the form of implantable conduits holds much promise.

15.4 Review Criteria

An extensive search of studies examining grafting techniques for vasectomy reversal was performed using search engines such as ScienceDirect, OVID, Google Scholar, PubMed, and MEDLINE. The start and end dates for these searches were 1973 and January 2019, respectively. The overall strategy for study identification and data extraction was based on the following keywords: "grafting techniques," "obstruction of vas deferens," "vasectomy reversal," "epididymal obstruction," "partial vasal agenesis," and "vas deferens autograft." Articles published in languages other than English were also considered. Data that were solely published in conference or meeting proceedings, websites, or books were not included. Websites and book chapter citations provide conceptual content only.

Acknowledgment We would like to thank Kris Greiner for her editorial assistance in preparing this chapter.

Mini-incision Vasectomy Reversal Using the No-Scalpel Vasectomy Instruments and Principles

16

Judith Dockray, Keith Jarvi, Ethan D. Grober, and Kirk C. Lo

Key Points

- Vasectomy reversal is a safe and established option for achieving pregnancy post-vasectomy.
- Microsurgical techniques are preferred to increase luminal patency rates.
- Mini-incision vasectomy reversal, as described below, has demonstrated decreased postoperative pain and faster return to normal activity with no compromise to outcome.
- Single mini-incision vasectomy reversal is a newer modification that is suitable for a subset of well-selected patients.

16.1 Introduction

Vasectomy reversal has a variety of described techniques, and these continue to evolve in current surgical practice. At the University of Toronto, we developed the "mini-incision" for vasectomy reversal using the principles and instruments used for the no-scalpel vasectomy. This has now evolved, in selected cases, to "single mini-incision."

By taking advantage of the compliance of the scrotal wall, a substantial length of vas deferens can be delivered through a mini-incision. By avoiding a longer incision, delivery of the testicle, and more extensive tissue dissection, we have shown a reduction in postoperative pain and a faster return to daily activities. This is achieved without compromising patient outcomes.

16.2 History

Vasectomy remains the most commonly performed urological procedure in North America, with over 500,000 vasectomies performed annually in the United States alone [1–3]. In 1974, the no-scalpel vasectomy was introduced and provided surgeons with a technique that minimized discomfort and post-procedural morbidity without compromising patient outcomes [4–6]. However, between 2% and 11% of vasectomized men will ultimately request a reversal of their vasectomy for a variety of reasons such as a new partner or death of a child [3].

As with most surgical procedures, vasectomy reversal techniques are in constant evolution. The origin of the techniques used for vasectomy reversal dates back to 1902, when Martin performed the first documented vasoepididymostomy for a man with obstructive azoospermia secondary to gonorrhea [1]. In 1909 he published a series of 11 azoospermic men who underwent vasoepididymostomies with a patency rate of 64% and pregnancy rate of 27%. Martin's publication and the demonstrated effectiveness of his vasoepididymostomy technique helped to dispel the then widely held belief that such anastomoses were not worth pursuing given their technical difficulty and expected low success rates. Hagner subsequently reproduced these outcomes, in his series of 33 patients with reported patency and pregnancy rates of 64% and 48%, respectively. This solidified vasoepididymostomy as an effective technique in the management of obstructive azoospermia [1].

Quinby reported the first successful vasovasostomy in 1919 on a man who underwent vasectomy 8 years earlier [1]. O'Connor, Quinby's former assistant, subsequently published a series of 14 vasectomy reversals using Quinby's technique in 14 men, with an overall patency rate of 64% [1].

As the interest in family planning evolved over the ensuing decades, the rates of vasectomy increased substantially, as did the inevitable subsequent demand for vasectomy reversal.

16.3 Vasectomy Reversal Techniques

The original descriptions for vasectomy reversal were open surgical techniques sometimes aided by optical magnification. The earliest described techniques used thin silver wire for the vasal anastomosis, which ultimately evolved into the use of nonabsorbable 4-0 to 6-0 sutures during the 1970s [2]. The reported patency rates for these techniques ranged from 79% to 88% with pregnancy rates of 34–50%. These techniques were largely abandoned when the operating microscope became widely available in most centers.

Silber and Owen are both credited with the first description of a microsurgical vasovasostomy in humans in 1977, although several authors had previously described this technique using animal models [2]. The anastomoses were performed with an operating microscope using 16–25 times magnification and 9-0 nylon sutures in a one- or two-layer closure.

Further evolution and refinements of the original techniques occurred, and by the 1980s, the two-layer closure techniques described the use 10-0 nylon for the mucosal anastomosis and 8-0 or 9-0 nylon for the seromuscular layer. Goldstein invented and introduced the microspike vas approximator clamp and microdot suture placement technique. This allowed for greater stabilization of the vasal ends and more precise placement of the 10-0 anastomotic sutures, particularly useful when the vasal lumens are of disparate caliber [1, 7].

The technique for vasovasostomy, described by Lipshultz et al., is probably the most commonly used among modern microsurgeons [2]. With this technique, the testicles and spermatic cords are delivered via a single 4–6-cm midline or bilateral 4–6-cm paramedian scrotal incision(s). The vasectomy site is identified, and the healthy testicular and abdominal ends of the vas are mobilized. Care is taken to preserve as much perivasal adventitia and vasal blood supply as possible. 5-0 absorbable stay sutures are placed superficially on both the testicular and abdominal vas 1–2 cm from the intended transection sites. The testicular vas is then transected and the expressed fluid is examined immediately with light microscopy at 100–400 times magnification. This serves to confirm patency by identifying the presence of sperm or sperm parts in the fluid. The abdominal vas is transected in an identical fashion and its patency confirmed with saline vasogram (or methylene blue vasography with temporary insertion of a Foley catheter). Hemostasis is managed with bipolar electrocautery to minimize vasal injury.

If the intraoperative findings are suitable for vasovasostomy (copious thin fluid, presence of sperm or sperm parts, and normal vasography), the two vasal ends are approximated and stabilized either by placement within a vas approximator or microvascular clamp or by placing 1–2 adventitial holding stitches at the 6 o'clock position. The operating microscope is now brought into the field, and a two-layer anastomosis is begun. A double-armed 10-0 nylon mucosal suture is tied at the 6 o'clock position. Three to five additional 10-0 mucosal sutures are placed around the circumference of the vasal lumen and tied. Interrupted single-armed 9-0 nylon sutures are circumferentially placed in the seromuscular tissue to complete the second layer.

A common modification to this technique eliminates the delivery of the testicle in an effort to minimize postoperative morbidity [7]. With this technique, a 4–6-cm incision is made in the upper scrotum angled toward the external inguinal ring along the path of the vas deferens. This allows for the easy identification of the vasectomy site and mobilization of the testicular and abdominal vasal ends. The anastomosis is then performed in an identical fashion to the previous description.

The patency and pregnancy rates reported in the literature are widely variable and dependent on a number of preoperative, operative, and postoperative factors that may or may not have been controlled. It is universally accepted that the microsurgical approach yields superior patency and pregnancy rates compared to traditional anastomoses given the ability to more precisely place significantly smaller and less obstructive sutures [3]. Unpublished data also demonstrates that surgeons with microsurgery training experience superior outcomes, with an average patency rate of 89% compared to 53% in inexperienced hands [3]. The Vasovasostomy Study Group reviewed the outcomes of 1469 contemporary microsurgical vasovasostomies [3, 8]. They demonstrated a 97% patency rate and 76% pregnancy rate in men less than 3 years from their vasectomy. As the interval from vasectomy increases, the rates decline with a 71% patency rate and 30% pregnancy rate when 15 years or more have elapsed since the vasectomy. The Vasovasostomy Study Group also determined that there was no statistically significant difference in patency or pregnancy rates between one-layer and two-layer anastomosis, with the decision based on surgeon preference and experience [1, 8].

The morbidity of vasovasostomy has been poorly examined with no published studies comparing the various techniques. Postoperative pain, swelling, bruising, and subsequent limitation of activity are all commonly seen after vasectomy reversal, especially if the testicle and tunica vaginalis are delivered. Most men are counseled to wear supportive briefs for 2 weeks, to take 1–2 weeks off work, and to limit themselves to light physical exertion for 3–4 weeks.

We have already discussed many technical modifications that have been developed in an attempt to improve surgical outcomes, but none specifically developed to help reduce the morbidity of the procedure.

16.4 Mini-incision Vasectomy Reversal (MIVR)

The mini-incision and no-scalpel techniques for performing vasectomy are familiar to most urologists and have been shown to reduce complication rates and decrease recovery

times without compromising vasectomy outcomes. In an effort to maintain the established effectiveness of microsurgical vasovasostomy, and to reduce postoperative morbidity, Jarvi et al. at the University of Toronto applied these principles to vasovasostomy [4, 9].

16.5 Technique of Mini-incision Vasectomy Reversal

The instruments required are a combination of those used for no-scalpel vasectomy and for traditional vasectomy reversal. The key additions are the inclusion of two ring vasectomy clamps and one sharp dissecting forceps, along with the normal microsurgical instruments required for the procedure.

Identical to the no-scalpel vasectomy, the vas deferens is palpated, manipulated, and stabilized through the scrotal skin in the mid to upper scrotum, using the three-finger technique previously described (Fig. 16.1). It is important to bring the vas deferens at least 1 cm lateral to the midline to be situated in the more pliable portion of the scrotal skin. The no-scalpel vasectomy ring clamp is then used to grasp the vas deferens either approximately 5 mm from the previous vasectomy site or directly onto the site of vasectomy occlusion (if possible) in an effort to minimize vasal injury (Fig. 16.2). Using the ring forceps, the abdominal vas is gently elevated to just below the scrotal skin, and a 15-blade scalpel is used to make a 1 cm skin incision directly over the vas (Fig. 16.3). This incision is deepened through the skin and dartos muscle layer using the combination of dissecting forceps plus diathermy, being careful not to injure the underlying vas. Once the vas is exposed, the second ring clamp is used to re-grasp the exposed vas within the incision and elevate it gently out of wound (Figs. 16.4 and 16.5). The vas is then carefully mobilized.

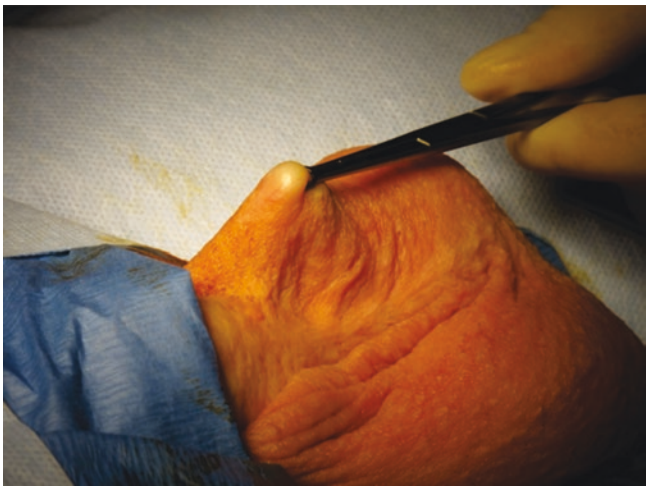

Fig. 16.2 Abdominal end of the vas deferens is grasped with a ring vasectomy clamp approximately 5 mm away from vasectomy defect. Clamp is then elevated

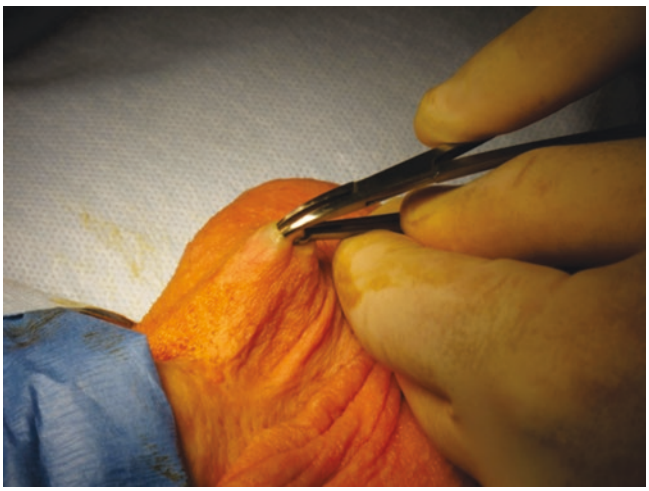

Fig. 16.3 Using a scalpel, the skin and dartos is opened directly over the vas deferens for a length of 8–10 mm

Fig. 16.1 The vas deferens is identified and secured using the three-finger technique

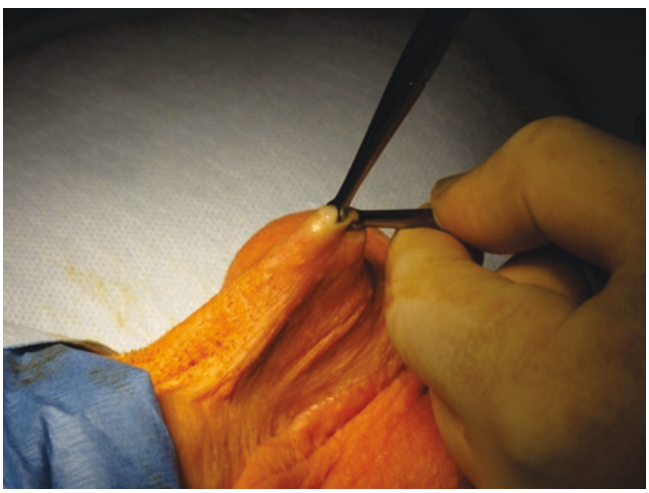

Fig. 16.4 A second vasectomy ring clamp is used to grasp the vas within the incision

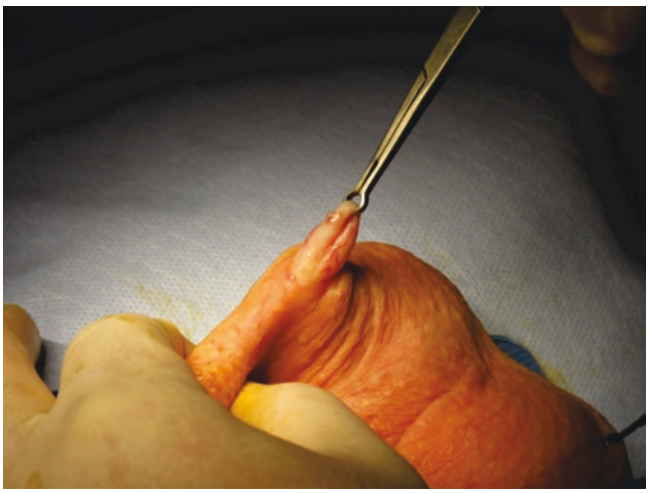

Fig. 16.5 The abdominal end of the vas is gently delivered through the incision

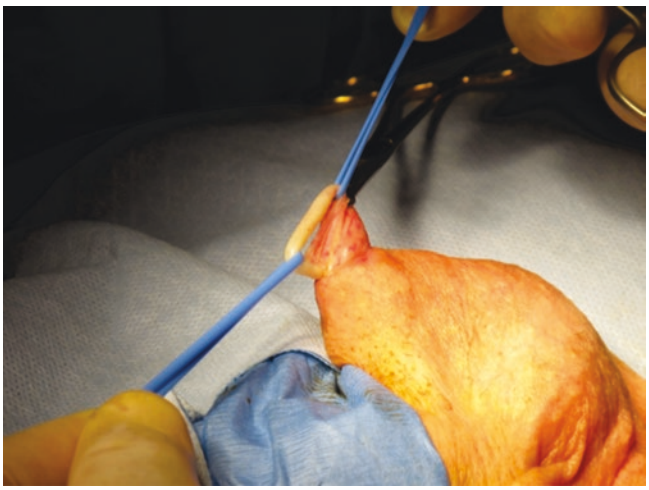

Fig. 16.7 The abdominal end of the vas is secured with vessel loops

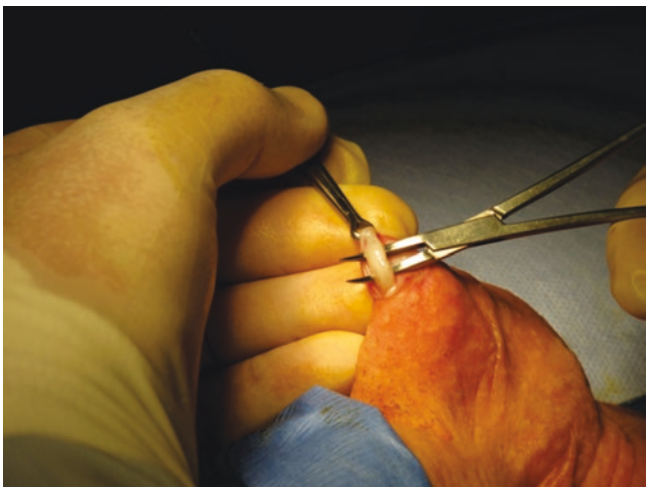

Fig. 16.6 A sharp dissecting forcep is used to isolate a small 1–1.5 cm perivasal window

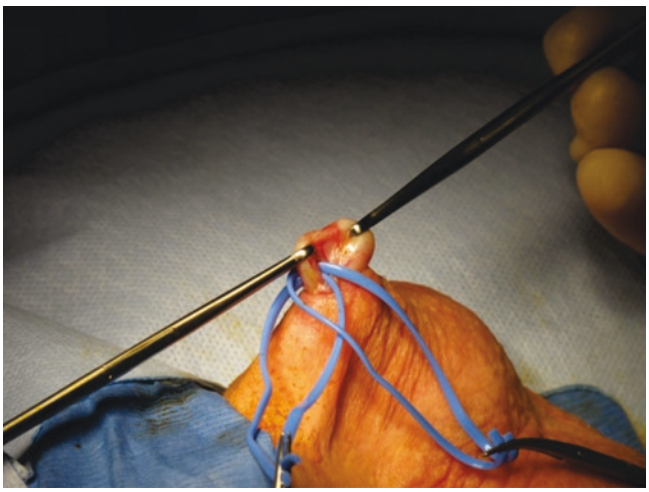

Fig. 16.8 With the abdominal end of the vas secured, the testicular end of the vas is delivered through the same incision and mobilized in an identical fashion to the abdominal end (note the vasectomy defect between the clamps)

A perivasal window is created with a combination of blunt and sharp dissection for a length of approximately 1 cm. Care is taken to preserve the vasculature within the perivasal adventitia. The vas is finally secured with a vessel loop (Figs. 16.6 and 16.7). At every step, meticulous hemostasis, with the judicious use of microscopic bipolar cautery, is essential as vessels in the dartos and subcutaneous layer may be difficult to control after they retract into the scrotum.

With the abdominal end of the vas mobilized and secured, the testicular end of the vas is palpated through the incision beyond the identified vasectomy site and is re-grasped with the ring forceps through the same mini-incision in the scrotal skin. The vas is gently delivered via the incision, mobilized, and secured in a manner identical to the abdominal vas (Fig. 16.8). Using this technique, a substantial portion of the vas can be delivered through the mini-incision given the inherent compliance of the scrotal skin (Fig. 16.9). Care must be taken during the mobilization of the testicular vas as the convoluted portion is often encountered and is very easily injured. Stay sutures of 5-0 Biosyn or PDS are placed through the superficial seromuscular layer of the vas approximately 5–10 mm away from the anticipated transection site on both the abdominal and testicular vas. These stay sutures have a dual function. They allow control of the vasal ends; aiding in positioning of the vas approximator and preventing retraction into the incision but can also can be tied after the anastomosis is complete, relieving tension on the repair.

With both vasal ends secured, each vas is then transected, stabilizing the vas over the forceps, as shown, which acts as

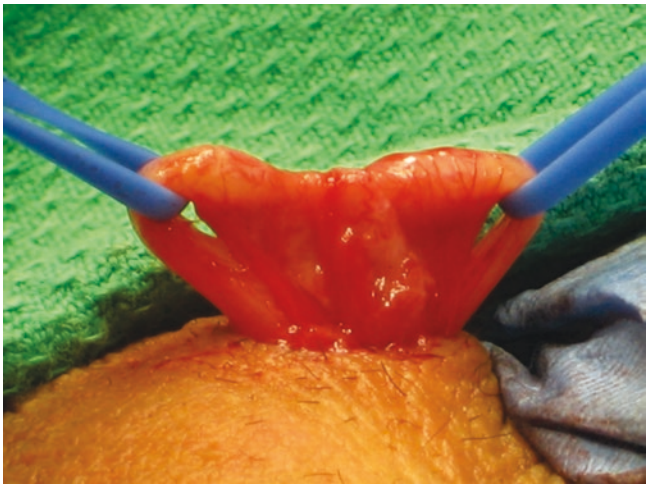

Fig. 16.9 Both vasal ends can be easily delivered through the mini-incision

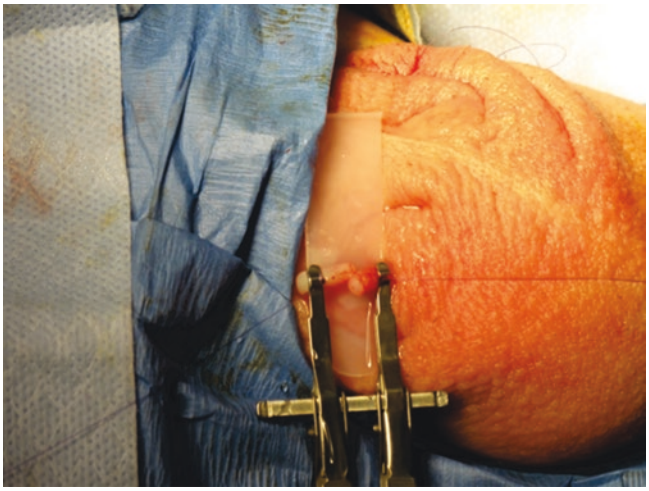

Fig. 16.11 The vasal ends are secured in place in a vas approximator clamp. A pre-cut plastic backboard is placed under the vasa and clamp to stabilize prior to anastomosis

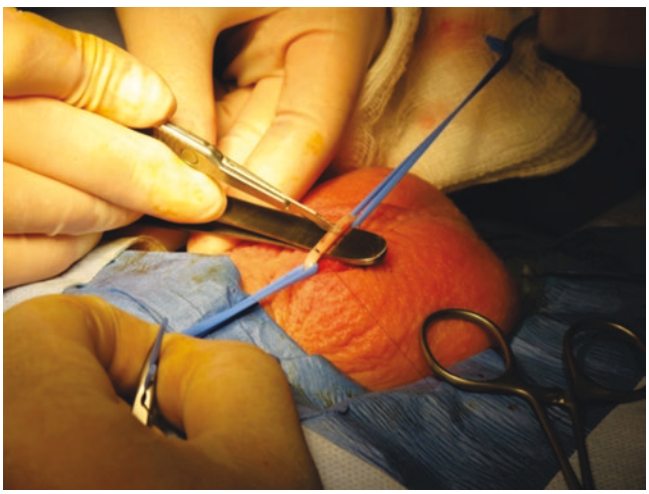

Fig. 16.10 Stay sutures of 5-0 Biosyn or PDS are placed superficially into the seromuscular layer of the vasal ends approximately 1 cm from the intended transection site. The ends are then transected with a scalpel

a backboard for cutting (Fig. 16.10). We recommend the use of a fresh 15-blade scalpel each time. A commercially available vas approximator clamp or small vascular clamp is then used to control the vasal ends and bring them into close proximity to each other just outside the incision. Finally, a solid, high-contrast backing is placed beneath both the vasal ends and the vas approximator clamp to improve visualization of the sutures and provide support during the microscopic anastomosis (Fig. 16.11). This can be easily fashioned from plastic available in the OR, e.g., light handle or diathermy holster.

The anastomosis is then performed under operating microscope magnification in a standard fashion. We begin by placing 4 × 10-0 double-armed nylon sutures through the mucosal and smooth muscle layer anteriorly in an inside out fashion on both vasa. Once all four anterior sutures are placed, they are tied. The second anterior layer is then completed by placing 3 × 9-0 single-armed nylon sutures between the tied 10-0 sutures incorporating the seromuscular layers only. Once the 9-0 sutures are tied, the vas approximator is rotated to expose the posterior wall of the vasa. The patency of the two vasal lumens is easy to assess visually under magnification and can also be confirmed by gentle probing with a jeweler forceps. Two to three additional 10-0 nylon sutures are then placed through the posterior mucosal layer depending on luminal size disparity between the two ends. Once they are tied, three additional 9-0 nylon seromuscular sutures are placed between the 10-0 sutures to complete the two-layer anastomosis. As previously mentioned, the 5-0 stay sutures can be tied loosely together to prevent tension on the anastomosis, or they can be removed at this point.

The vas is then returned to the scrotum and the operating microscope removed from the operative field. Hemostasis of the skin edges and dartos muscle is managed with electrocautery. Typically, only one stitch is needed for closure. The opening in the skin is typically 8–10 mm in length (Fig. 16.12). Postoperatively, a local incision block is performed using 5 cm^3 of 0.25% bupivacaine on each side. All patients are discharged home the same day with a prescription for 20 tablets of mild analgesia and are counseled to use a scrotal support for 7 days, refrain from sexual intercourse for 2 weeks, and avoid strenuous exercise and heavy lifting for 3 weeks. Office follow-up is arranged for 4 weeks postoperatively and semen analysis is arranged for around 3 months postoperatively and then every 3 months until pregnancy is achieved.

For primary or redo vasectomy reversals, the mini-incision approach is technically feasible in the majority of

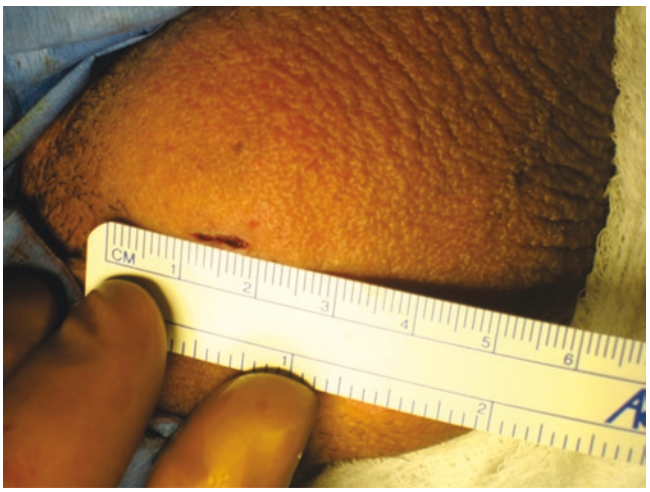

Fig. 16.12 Final incision length of <1 cm

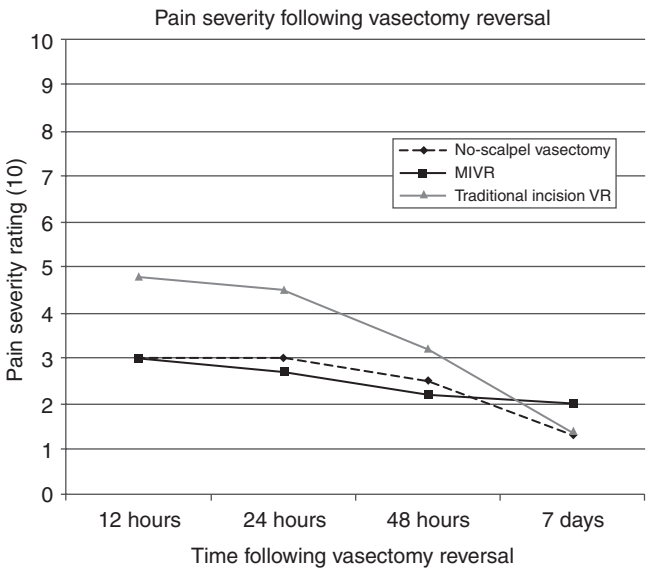

Fig. 16.13 Pain severity during the first 48 h following surgery was less among patients who received a bilateral MIVR compared to patients who received a traditional incision VR

men. Rarely, extensive scarring or very distal defects may preclude the use of the mini-incision technique.

16.6 Outcome of Mini-incision Vasectomy Reversal

Using a single surgeon's data, 164 consecutive vasectomy reversals from 2004 to 2010 were reviewed [9]. All patients were followed up 4 weeks after surgery. Patients were asked to quantify the number of days required for return of work and resumption of daily activities after surgery. Postoperative complications were recorded. Pain scores were documented using a validated post-vasectomy pain scale subsequently adapted to vasectomy reversals [10]. Semen analysis was also carried out at 2 and 4 months postoperatively and evaluated according to WHO 1992 criteria [11].

Of the 164 men, 139 underwent bilateral vasectomy reversal with 55% having a mini-incision technique. The patency rate for the mini-incision technique was 96% and was not statistically different from the patency rate of men who had undergone the traditional incision vasectomy reversal. Mean semen parameters also did not differ between the two incisions.

Fifty-three men completed the pain and recovery assessment including 20 men who underwent mini-incision vasectomy reversal. Reported pain severity in the mini-incision group was significantly less during the first 48 hours after surgery, compared to men who underwent vasectomy reversal using the traditional incision. By 1 week, there was no statistically significant difference in pain scores (Fig. 16.13).

Following the mini-incision vasectomy reversal, patients returned to self-reported "normal everyday activities" 2 days earlier compared to men following traditional incision vasectomy reversal. Time to return to work however was not different between the two groups and averaged 5 days for both.

To date over 3000 mini-incision vasectomy reversals have been performed by three different surgeons at the University of Toronto and is the preferred technique (>98%) for vasovasostomy.

16.7 Single Mini-incision Vasectomy Reversal (SMIVR)

Our newer modification of the above technique. For certain patients with a compliant scrotum and a short, favorably sited vasectomy defect, the vasa can be manipulated centrally allowing both VVs to be performed through a single midline incision (Fig. 16.14).

In a single surgeon's series of 320 patients [12, 13], the outcomes were comparable to bilateral MIVR. When comparing postoperative pain, 120 patients with SMIVR were compared to 200 with BMIVR. SMIVR patients reported significantly less pain immediately post-surgery and up to 1 week post-surgery. SMIVR patients reported quicker complete pain resolution, shorter duration of analgesic usage, and a faster return to work [13] (Fig. 16.15).

Fig. 16.14 Single mini-incision vasectomy reversal

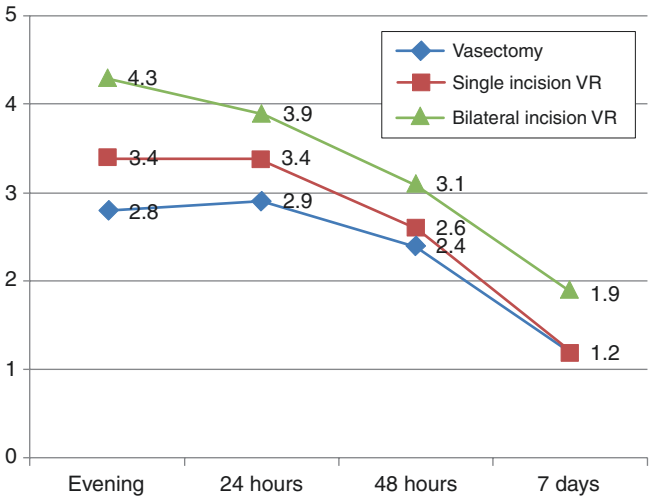

Fig. 16.15 Pain scores and functional recovery

16.8 Conclusion

Surgical techniques remain in constant evolution and vasectomy reversal is no exception. Mini-incision vasectomy reversal (MIVR) takes advantage of scrotal wall compliance and readily available surgical instruments. By avoiding delivery of the testicle and the associated tissue dissection, there are significant gains in reduction of postoperative pain and early return to normal activity. This is achieved without compromising outcome. Single mini-incision vasectomy reversal may be a viable alternative in certain patients with favorable anatomy.

Office-Based Microsurgery Under Local Anesthesia for Male Infertility

17

Amir Toussi and Landon W. Trost

Key Points

- Male infertility procedures can safely be performed in the office setting without compromising outcomes and offer many advantages over general and monitored anesthesia such as reduced costs, faster recovery, convenience, real-time communication with the patient, and avoidance of complications from general anesthesia.
- MESA, TESE, and varicocelectomy can improve or provide sperm with better DNA fragmentation rates, resulting in overall enhanced outcomes with assisted reproductive techniques.
- Several modifications to practice are required to adequately perform procedures such as MESA/TESE, varicocelectomy, and vasectomy reversal in the office.
- The learning curve toward having an office-based male infertility surgical practice may be overcome via a slow transition from the OR to the office setting.
- The significant cost reduction in office-based vasectomy reversal reopens the debate and provides further support for cost-effectiveness over in vitro fertilization.

17.1 Introduction

The majority of urologic procedures involve intra-abdominal organs and require general anesthesia. However, infertility procedures are a unique subset of urologic procedures revolving around the external genitalia where pain can be fully controlled with local anesthesia and thus offer the ability to perform these procedures in the office.

Office-based procedures offer many potential advantages over general or monitored sedation, including elimination of risk of pulmonary or cardiac complications, absence of postoperative extended recovery, ability to communicate with the patient during the procedure, improved cost-effectiveness, greater efficiency, avoidance of side effects from general anesthetic medications, and improved convenience for patients and surgeons, among others.

In the office, cost is significantly reduced where the added expense of an anesthesiologist, ancillary staff, and facility fees are eliminated. As our healthcare transitions to value-based care, cost efficiency has become an important consideration in clinical practice, particularly in the setting of declining insurance reimbursements. This is especially the case with male infertility surgery, where the decision to proceed is often based on deductibles and insurance coverage rather than medical necessity alone. Cost reduction is also important in male infertility as most procedures are cash pay and couples are sometimes left choosing less effective options to limit costs.

Despite rapid development and significant improvements in assisted reproductive technology (ART), live-birth rates are suboptimal in many settings [1]. In order to improve treatment outcomes, recent research delving into molecular pathophysiology of male factors has identified sperm DNA fragmentation index (SDFi) as a critical contributing factor to successful live-births. SDFi represents the degree of DNA breaks present in sperm and varies from one sperm to another. Several intrinsic and extrinsic factors such as defective maturation, oxidative stress (varicoceles), lifestyle factors, prolonged stasis during epididymal transit, and systemic insults (diabetes, infection, cancer) have been linked to pathogenesis of increased SDFi [2, 3]. Clinically, high SDFi (>30%) is

A. Toussi · L. W. Trost (✉)

S. J. Parekattil et al. (eds.), *Male Infertility*, https://doi.org/10.1007/978-3-030-32300-4_17

associated with longer time to achieve natural pregnancy, lower fertility potential, decreased pregnancy and delivery rates after intrauterine insemination (IUI), and decreased pregnancy rates with in vitro fertilization (IVF) [4–6]. Many treatment options have been proposed for high SDFi, and two relevant ones include varicocelectomy to reduce oxidative stress and retrieval of sperm directly from the testicles (testicular sperm extraction [TESE]) for use with ART. A recent meta-analysis revealed a 3.4% reduction in SDFi after varicocelectomy, which translated to higher natural and ART pregnancies [7]. In addition, SDFi is three- to fivefold lower in testicular sperm compared to ejaculated sperm, and a higher live-birth rate has been reported with testicular sperm over ejaculated sperm [8, 9]. Offering both of these procedures in the office can significant reduce the financial and time burden from couples undergoing ART.

Despite these advantages, there are limited data available on office-based male infertility procedures. The procedures described in these articles include hydrocelectomy, malleable penile prosthesis, microepididymal and testicular sperm aspiration (MESA/TESE), orchiectomy, spermatocelectomy, and varicocelectomy [1–15]. However, many of these were done with IV sedation or monitored anesthesia care and/or limited to underdeveloped countries [10–18].

This chapter is intended to describe our technique for commonly utilized infertility procedures in the clinic setting with a detailed focus on clinical setup, anesthetic application, description of the procedures including the complex vasoepididymostomy (VE), pitfalls, and troubleshooting.

17.2 Clinical Setup

17.2.1 Procedure Suite

The office procedure room is equipped with an operating microscope and a standard OR table. Two nurses were available during the majority of the procedure; one nurse handles and transfers the sterile instruments and assists during the procedure and the other nurse charts and handles any nonsterile equipment. No anesthesiologists are involved. The instruments, sutures, and equipment are identical between the office-based procedure room and the OR for all cases. With the patient's consent, the partners of the patient were allowed to be present and observe.

17.2.2 Pain Control

Prior to beginning the procedure, the patients are offered an oral pain medication (oxycodone 5 mg and acetaminophen 500 mg) and midazolam (5–15 mg depending on age and body habitus). This type of oral sedation is considered to be light anesthesia and is considered safe without need for anesthesia monitoring. In contrast, IV sedation with midazolam is considered moderate sedation, with most institutions requiring greater oversight for administration.

Patients receiving any form of sedation are required to have a driver prior to medication administration. For longer cases such as vasectomy reversal (VR), the patients are offered an additional 5–10 mg of midazolam 90 minutes into the procedure if the effects of the first dose had resolved or if desired. In general, the purpose of these medications is to help alleviate the anxiety and minimize bother associated with lying flat for extended periods rather than to enhance pain control.

Liposomal bupivacaine is the preferred medication for achieving optimal local pain control in our experience for several reasons. It is commercially available in 20 mL vials, and it can be diluted with normal saline to achieve a final volume of 80 mL without compromising efficacy. In addition, there is no period of delay required after its application, and it has a lasting analgesic effect for up to 72 hours (although most commonly <36 hours in our experience). In cases of MESA and TESE, it is applied to the incision (5–10 mL) and testicular cord (10 mL) on one or both sides. Varicoceles receive an additional 5–10 mL in the cord and external inguinal canal directly. For VR, 5 mL is used on the incision, 5–10 mL on each vas, and 5–10 mL on each testicular cord. The location and volumes of anesthetic administered are shown in Fig. 17.1. Judicious use is important and

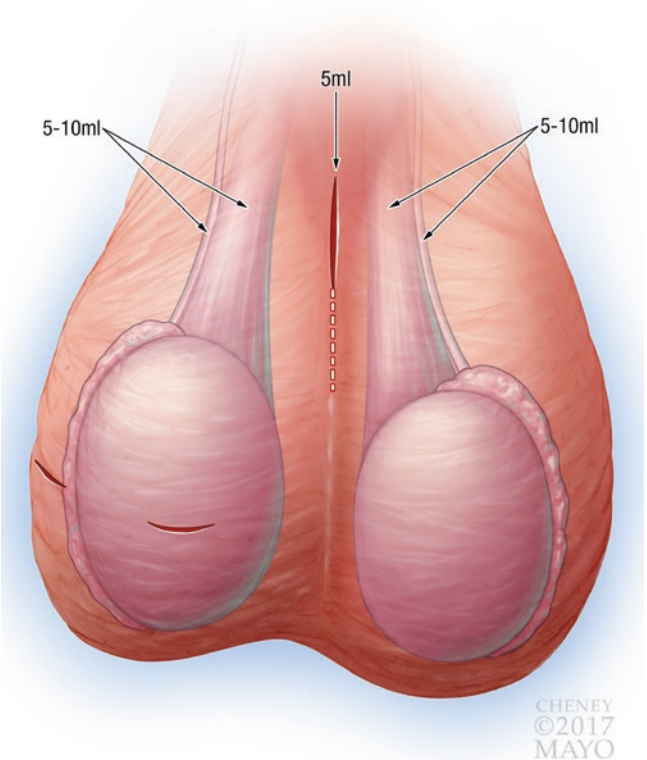

Fig. 17.1 Location and volumes of anesthetic administered. (Reprinted from Alom et al. [29] . With permission from AME Publishing Company)

Table 17.1 Medication and recommended dosing

	Dosing	Comments
Systemic[a]		
Antibiotics	Ciprofloxacin 500 mg	Prior to start of procedure. If allergic, replace with Bactrim or Cefdinir At the start of procedure
Pain control	Acetaminophen 500 mg Oxycodone 5 mg	At the start of procedure
Anxiolytic	Midazolam 5–15 mg	At the start of procedure. Age > 50 = 10 mg; age > 65 = 5 mg
Local[b]		
TESE/MESA	5–10 mL to the incision 10 mL to the cord	–
Varicocelectomy	5–10 mL to the incision 10 mL to the cord 5–10 mL to the external inguinal canal	–
VR	5–10 mL to the incision 5–10 mL to each vas 5–10 mL to each cord	–

[a]Patients without a driver are not offered oxycodone or midazolam
[b]Liposomal bupivacaine is diluted to a final volume of 80 mL using normal saline

it is preferred to have ≥20 mL remaining after all initial blocks are performed in case additional application is needed. The medication dosing and administration are summarized in Table 17.1.

17.3 Technical Description of Procedures

These procedures have previously been described in detail in the surgical literature, and our focus in this section entails modifications to enable performance in office setting under local anesthesia. See Fig. 17.2 for graphical depiction of suggested location of incisions.

17.3.1 TESE

After local anesthetic, a midline or transverse scrotal incision is made and extended for 1–2 cm. The testicle is grasped and rotated to position the epididymis posteriorly. The tunica vaginalis is incised and stay sutures are placed on each side of the incision to provide retraction. Two horizontal, parallel stay sutures are placed into the tunica albuginea of the testicle to elevate the testicle to the wound surface, and a 1 cm incision is made between the two sutures

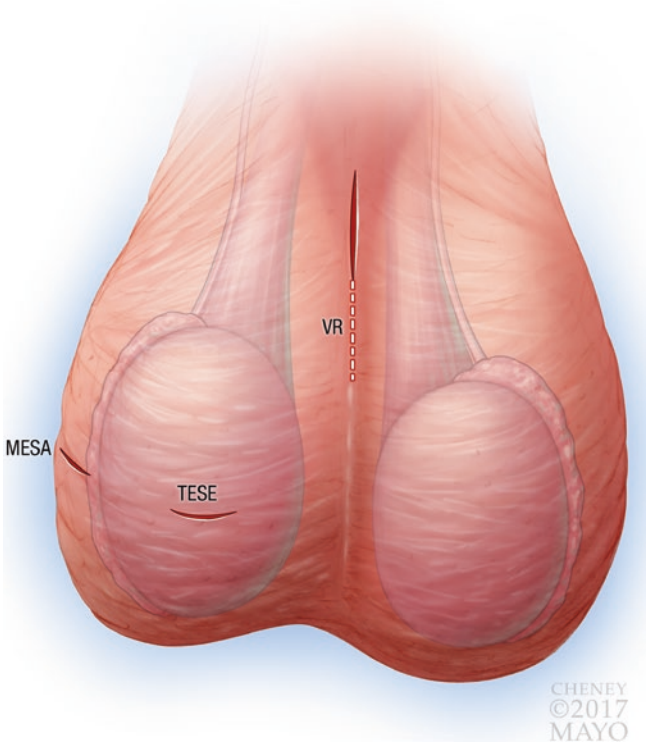

Fig. 17.2 Graphical depiction of suggested location of incisions. (Reprinted from Alom et al. [29]. With permission from AME Publishing Company)

(Fig. 17.3). The tunica is undermined using sharp scissors for 1 cm beyond the incision radially in all directions, and seminiferous tubules are expressed and excised. The tunica albuginea and vaginalis are sequentially closed by tying down the pre-placed sutures. We prefer this approach as opposed to the traditional approach of delivering the testicle to avoid the discomfort and pressure during replacement of the testicle back into its normal anatomic position within the scrotum.

17.3.2 MESA

Although traditionally MESA is performed where the testicle is delivered, we have elected to utilize a more minimally invasive approach without the need to deliver the testicle.

Following administration of the local anesthetic, a transverse scrotal incision is made on the lateral aspect of the scrotum. Once the epididymis is visualized, parallel stay sutures are placed on each side of the epididymis (Fig. 17.3). An eyelid retractor can be placed into the wound to allow better visibility. Alternatively, the pre-placed sutures can be pulled up to secure and bring the selected portion of the epididymis into view. The remainder of the procedure is performed in usual fashion.

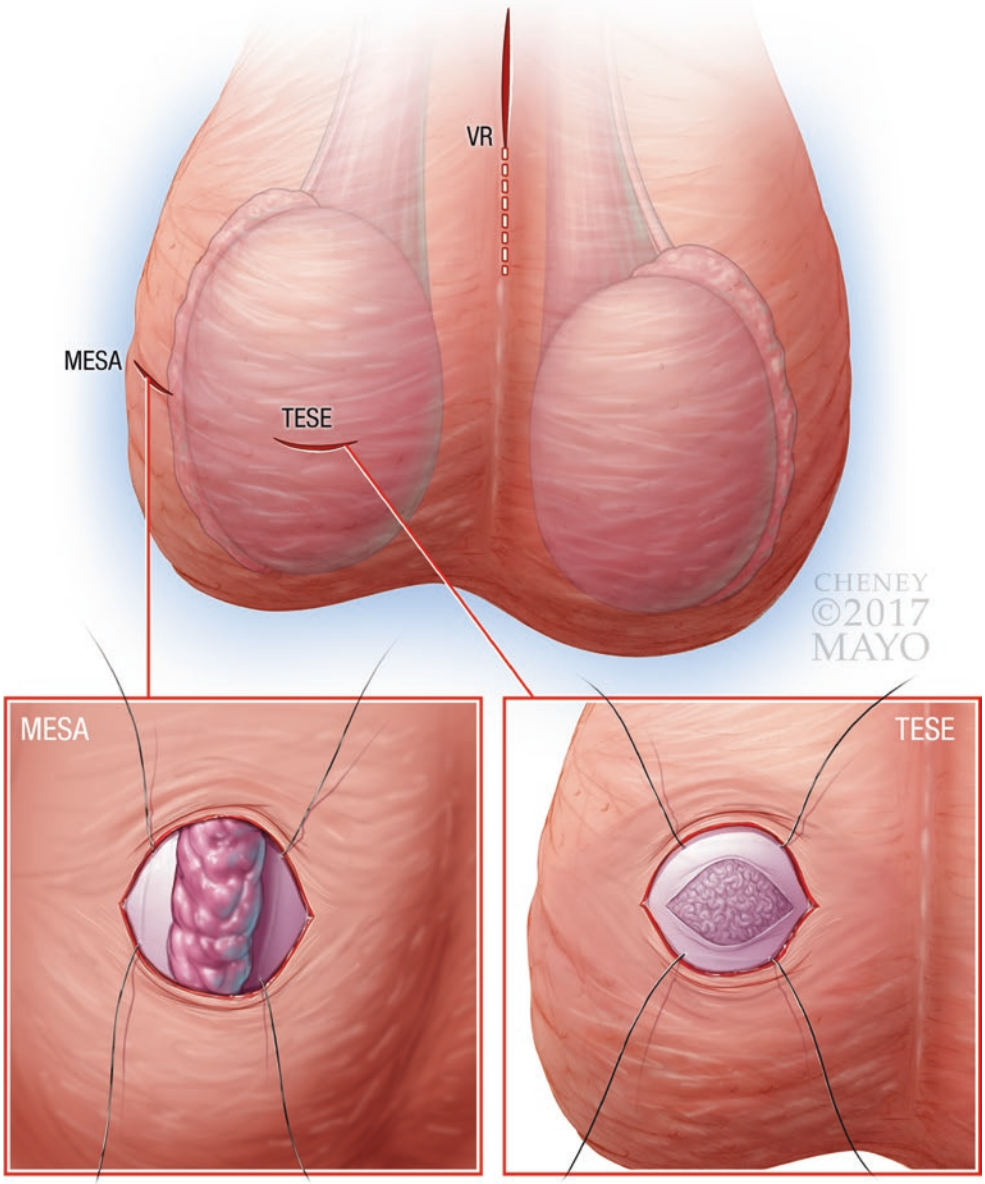

Fig. 17.3 Placement of stay sutures during TESE and MESA to facilitate exposure and closure. (Reprinted from Alom et al. [29]. With permission from AME Publishing Company)

17.3.3 Varicocelectomy

Although other approaches are feasible, we have preferred a microscopic subinguinal technique due to improved outcomes in regard to semen analysis parameters, recurrence rates, and hydrocele and hernia formation [19–24]. More importantly for an office-based setting under local anesthesia, it is associated with less intraoperative pain and faster recovery compared to the inguinal approach [25].

After application of local anesthesia, a standard transverse 2 cm skin incision overlying the external inguinal ring is made. The incision is carried through Camper's and Scarpa's fascia without incising the external oblique fascia. The spermatic cord is isolated near the pubic tubercle and gently elevated through the incision. A tongue depressor is placed under the cord as a backboard to secure it above the wound surface. The external and internal spermatic fascia are incised and opened. Using the surgical microscope, the veins are separated, doubly clipped, and divided. Care is taken to preserve the artery, and intraoperative micro-Doppler is used to confirm the artery prior to division of any structures. The cord is then returned to its bed and the incision is closed in two layers.

17.3.4 Vasectomy Reversal

Similar to TESE, after application of local anesthesia, a midline high scrotal incision is made (2–3 cm) after which

the vasa are brought through the wound. Once the vasa are isolated, the peri-vasal fascia is directly infiltrated with local anesthesia. Care must be taken to avoid extensive traction on the abdominal portion of the vas to limit sensations of flank, lower back, or inguinal pain from this maneuver. It is important, as this sensation cannot be addressed even with directed application of local anesthesia. No significant modifications are required during the dissection of the proximal and distal segments of the vasa, with the exception of granulomas, which often require additional direct administration of local numbing medication surrounding the granuloma.

Once the vasa are dissected, the testicular end of the vas is sampled to assess for presence of sperm. Fluid is also injected into the abdominal portion using a 24-gauge angiocatheter to assess patency. The volume of fluid instilled should be limited, as it may result in a burning sensation with volumes >1 mL.

If the decision is made to proceed with a vasovasostomy (VV), this is performed in the usual fashion. In our practice, we perform a double-layered anastomosis using 8-0 (outer) and 10-0 (inner) interrupted sutures without specific modifications. If a vasoepididymostomy (VE) is required, the scrotal incision is extended and the testicle is delivered. If a VE is required on both sides, it has been our preference to only deliver one testicle at a time. This limits the extent of the incision, amount of traction placed on the abdominal portion of the vas, time spent with testicle outside the body, and likelihood of venous congestion (facilitates pain control). Once the testicle is delivered, it should be kept moist by frequently dripping saline over the surface with a syringe. In our experience, the drying of the tunica sensitizes the testicle to sensations of testicular pressure, which are not easily managed with local numbing medicine. Similarly, care should be taken to avoid compressing the testicle during microsurgery, and gentle manipulation should be used to return it to the scrotum after completion of the VE. The VE is otherwise performed in usual fashion using an intussuscepted technique with parallel 10-0 sutures and 8-0 interrupted second layer. See Fig. 17.4 for graphical depiction of vasectomy reversal (vasovasostomy on the right and vasoepididymostomy on the left).

17.4 Tips and Tricks to Overcoming the Learning Curve

There is a clear learning curve in performing office-based surgical cases without monitored or general anesthesia. The critical learning points are centered on appropriate tissue handling and targeted application of local anesthetic. It is advisable that providers interested in transitioning their practice to an office-based setting consider performing these procedures in the operating room (OR) with anesthesia on standby if needed. The providers may also elect to slowly transition from general anesthesia to monitored care and finally to oral medications alone. In this setting, if deeper anesthesia is required, it can be done without rescheduling or disrupting the procedure. Similarly, providers may wish to step-wise transition from simpler procedures (vasectomy) to progressively more complex ones: MESA/TESE, varicocelectomies, and ultimately VR.

The following represents a list of several key factors that have been identified during our learning curve in the office setting. A summary of these key factors along with troubleshooting measures is shown in Table 17.2.

- Liposomal bupivacaine acts without a period of delay following administration and, as such, immediate feedback is available from patients if numbing is adequate or if additional infiltration is required.
- In general, we prefer liposomal bupivacaine as its duration of action is required for VR over other formulations such as lidocaine that wear off too rapidly.
- Liposomal bupivacaine cannot be diluted much beyond 60–80 mL without losing efficacy in the scrotum and penis.
- The numbing technique is critical to ensure judicious use of the local anesthetic to avoid reaching toxicity limits. Therefore, we recommend utilizing a smaller volume spread over larger area rather than inserting the needle into one location and depositing a large volume. Particularly for the spermatic cord where the nerves are in a wide distribution, a fan-like infiltration with repeated advancing and withdrawing of the needle can better achieve desired numbing effects.
- The adequate numbing of the vas requires direct instillation immediately adjacent to the vas. This technique can be practiced with vasectomy procedures before transitioning to VR.
- Adequate numbing of the testicle can only control the pain with dissection of the tunica vaginalis, vas deferens, and epididymis and not the sensation with excessive pressure. To reduce this pain and sensation, gentle handling of the testicle and periodic moistening are important.
- Patients with baseline addictions to high-dose narcotics and poorly controlled anxiety are better suited for procedures under general anesthesia. Also, patients with multiple previous surgeries in the location of interest (repeated vasectomies/VR, hernia repairs) may have altered nerve distribution and dysesthesias which pose difficulties to adequate local numbing.
- For longer cases such as VR, an iPad with games or movies can be used to entertain patients. Also, allowing their partner to be present in the room can provide some distraction for the patients.

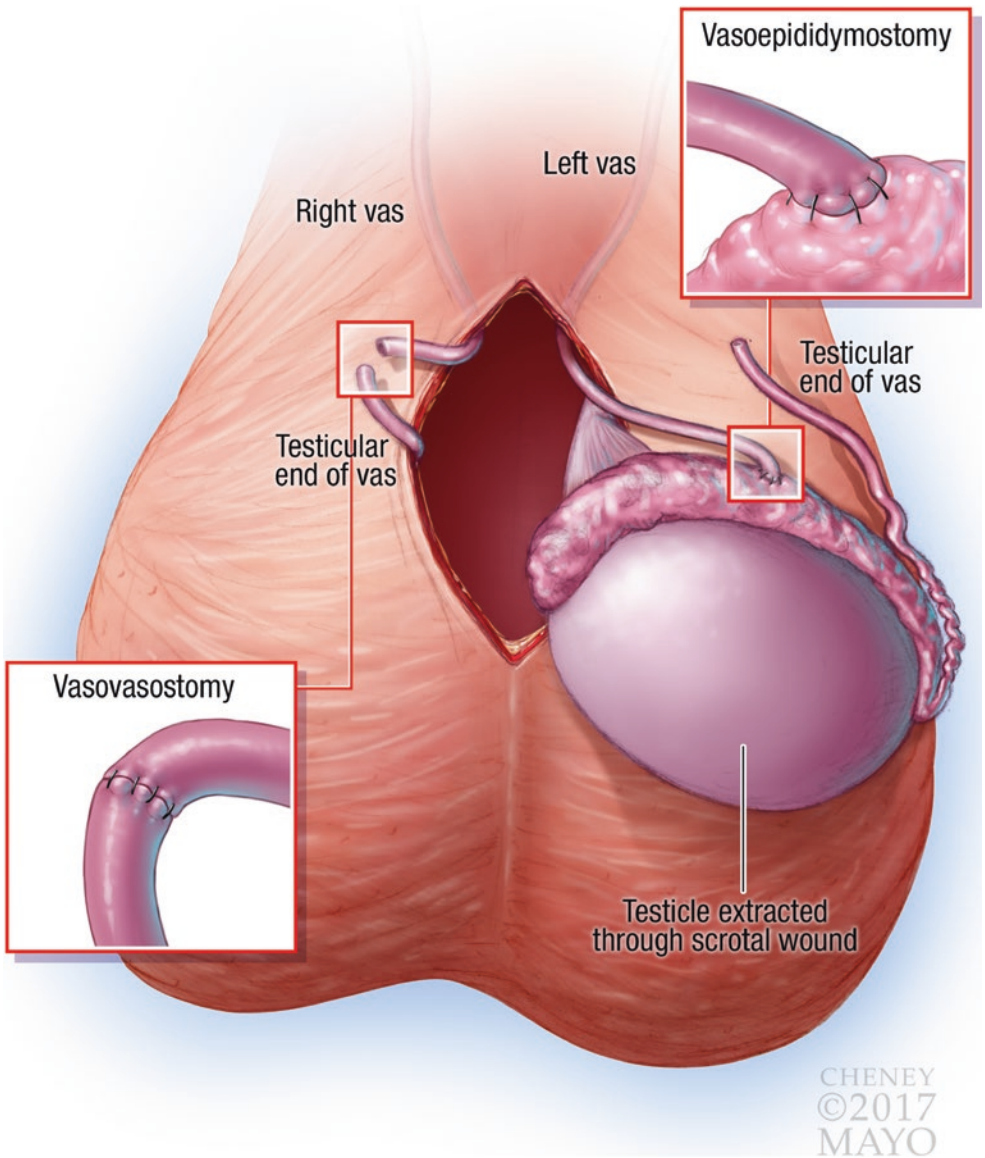

Fig. 17.4 Graphical depiction of vasectomy reversal (vasovasostomy on the right and vasoepididymostomy on the left). (Reprinted from Alom et al. [29]. With permission from AME Publishing Company)

Table 17.2 Key factors to achieving pain control and troubleshooting measures

Issue	Cause(s)	How to prevent	How to treat
Pain with grasping skin	Numbing is too deep	Visualize a "wheal" with numbing	Re-administer numbing medication more superficially
Pain with initial dissection or with grasping dartos muscle or septum	Numbing is not sufficient, is too superficial or deep, or needs to be re-applied	–	For unclear reasons, in some cases after a 3–4 hour procedure, the numbing must be re-applied to the skin prior to closure
Pain with dissecting the testicular tunica vaginalis	Cord block is inadequate (specifically, of the cremasteric fibers of the cord)	Perform a cord block[a]	Re-administer a cord block. If still insufficient, directly apply a small volume to the location where dissection will occur
Testicular (sharp) pain	Cord block is inadequate (specifically of the inner cremasteric sheath contents)	Perform cord block[a]	Re-administer a cord block. If still insufficient, directly apply a small volume (1 mL) inside the testicle
Testicular pressure	Drying of the testicle, compression of the testicle, grasping the tunica albuginea, vascular congestion	Limit pressure on the testicle, keep testicle moist throughout case, limit crushing of tunica with pickup instruments, assure adequate incision size to limit vascular congestion	Eliminate contributing factor(s)

Reprinted from Alom et al. [29]. With permission from AME Publishing Company

[a]Cord block is performed by injecting the testicular cord using a fan-like, and in-and-out motion, with small amounts of medication administered to a larger number of locations. The vas deferens should be included within the cord to assure that the entirety of the cord has been adequately treated

- Prior to any significant portions of the case, patients should be adequately warned about notable sensations that will be upcoming such as application of the numbing medication, grasping of the scrotum, pulling on the abdominal portion of the vas, and replacing the testicle back in the scrotum.

17.5 Financial Considerations

In our practice, the introduction of office-based procedures has permitted same-day surgeries, reduced costs for patients (office-based VR offered for $4550), and most importantly has not compromised technique or outcomes. The issue of cost saving is particularly relevant in the field of infertility, as many therapies are not covered by insurance and couples are often left making decisions based on cost rather than success of treatment modalities. Thus, transitioning infertility procedures to the office may increase access for a subset of patients who may have otherwise been excluded.

Although cost reductions are evident with all office-based procedures, the most significant one clinically is likely VR. Multiple publications have addressed the cost-effectiveness of VR versus IVF, and the preferred decision is complex and relies on factors such as indirect vs. direct costs, age of female partner, duration since vasectomy, success rates of specific VR surgeon and IVF clinic, duration of follow-up used to define success, rates of multiple gestations, potential for increased chromosomal abnormalities and subsequent care required, issues of diminished ovarian reserve, and couple preferences [26–28]. We have previously reported a 62% reduction with an office-based VR at our institution, which reopens the debate and provides further support for cost-effectiveness of VR over IVF in many scenarios [29].

17.6 Conclusions

Office-based surgical procedures performed under local anesthesia are a viable, safe, and cost-effective option for men seeking infertility procedures. We have offered technical modifications and key points to overcome the learning curve that may allow a smoother transition for surgeons interested in utilizing male infertility procedures to the office setting. This transition offers patients convenience, reduced risk with general/monitored anesthesia, increased availability, and allows for a faster recovery. Furthermore, the improved cost-effectiveness and emerging data on SDFi reopens debates on VR versus IVF as well as MESA/TESE and argues for a new debate on optimal cost-based treatment algorithms.

17.7 Review Criteria

An extensive search of studies examining office-based infertility procedures was performed using search engines such as PubMed, Google, and MEDLINE. The overall strategy for study identification and data extraction was based on the following keywords: “male infertility,” “cost-effectiveness,” “MESA,” “TESE,” “varicocelectomy,” “DNA fragmentation,” “office,” and “local anesthesia.” Only articles published in the English language were considered.

Robotic Microsurgery for Male Infertility and Chronic Orchialgia

18

Jamin V. Brahmbhatt and Sijo J. Parekattil

Key Points

- Robotic assistance during microsurgery provides microsurgeons with many advantages: improved operative efficiency, elimination of tremor, scaling of motion, and enhanced imaging.
- Improved clinical efficiency appears likely with robotic assistance, and preliminary studies appear to support this concept.
- Novel treatment options for men with chronic testicular or groin pain are now available with this technology.
- Structured evidence-based platforms for the scientific development of this technology are necessary to protect patient safety. Groups such as RAMSES may provide guidance.

18.1 Introduction

Since the use of the operating microscope for microsurgery in 1975 [1], there has been a steady increase in the use of such technology in the operative management of male infertility and chronic testicular or groin pain [1–11]. Added to the reports relating to greater patency rates and fertility rates of vasovasostomy performed with the operating microscope [12], the concepts of magnification have been successfully applied to vasoepididymostomy and varicocele ligation. More recently, microscopic spermatic cord neurolysis has demonstrated applicability to the treatment of groin and testicular discomfort [13, 14]. These techniques require varying degrees of microsurgical skills and an array of supporting technology, neither of which may be part of many urologists' personal or technical armamentarium. The melding of improved visualization with magnification to an ergonomic platform that can be operated remotely has a significant application to testicular and reproductive surgery. Robotic assistance during surgical procedures has been utilized in a wide array of surgical fields with the abovementioned benefits [15–19]. This chapter covers the latest developments in the robotic microsurgical platform, robotic microsurgical tools, and current evaluations of various robotic microsurgical applications for male infertility and patients with chronic testicular or groin pain.

18.2 Novel Equipment

With any new field, the development of novel tools or instruments that can enable surgeons to create new solutions for existing clinical needs is of paramount importance. Below are some new products that enhance the ability to perform robotic-assisted microsurgery.

18.3 New Robotic Surgical Platform

Intuitive Surgical (Sunnyvale, CA) now offers an enhanced four-arm da Vinci-type Si robotic system with high-definition digital visual magnification that allows for greater magnification than the standard robotic system (up to 10–15×). The enhanced magnification capability allows the surgeon to position the camera 6–7 cm away from the operative field to avoid any local tissue effects from the heat emitted from the camera lighting (this was a problem with the older system, where the camera had to be placed within 2–3 cm of the operative field for microsurgery). This new system allows greater range of motion and better microsurgical instrument handling. The additional fourth arm has improved range of motion and positioning capabilities to provide the microsurgeon with one additional tool during procedures. The robot is positioned from the right side of the patient for microsurgical cases as illustrated in Fig. 18.1.

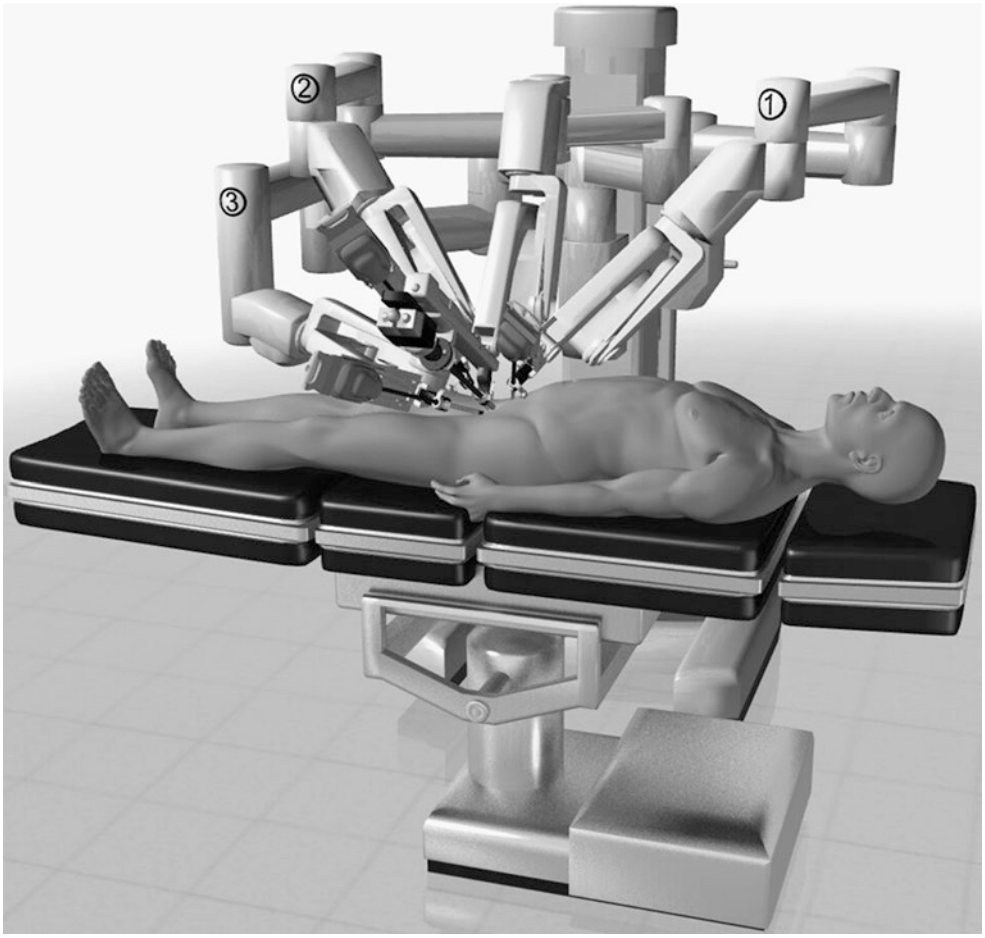

Fig. 18.1 Robotic platform positioning for microsurgical cases

18.4 Refined Robotic Doppler Flow Probe

Cocuzza et al. [20] have shown that the systematic use of intraoperative vascular Doppler ultrasound during microsurgical subinguinal varicocelectomy improves precise identification and preservation of testicular blood supply. During robotic microsurgical cases, the standard Doppler probe has to be held by a surgical assistant and cannot be manipulated readily with the robotic graspers. A new revised micro-Doppler flow probe (MDP) has been developed by Vascular Technology Inc. (Nashua, NH) that is designed specifically for use with the robotic platform (Fig. 18.2). This new probe allows for easy manipulation of the probe with the fourth arm and allows the surgeon to perform real-time Doppler monitoring of the testicular artery during cases such as robotic-assisted microscopic varicocelectomy (RAVx) and robotic-assisted microscopic denervation of the spermatic cord (RMDSC). This allows the surgeon to hear the testicular artery flow while dissecting out the veins and nerves with the other two robotic arms.

A recent prospective randomized controlled trial of the MDP was performed in 273 robotic microsurgical cases from July 2009 to September 2010: 67 robotic subinguinal varicocelectomies (RVx) and 206 robotic spermatic cord denervation procedures (RMDSC). The use of the MDP was randomized to 5 RVx and 20 RMDSC procedures. The primary endpoint was operative time, and secondary endpoint was surgeon ease in testicular artery localization and robotic grasper maneuverability. Operative duration was not affected

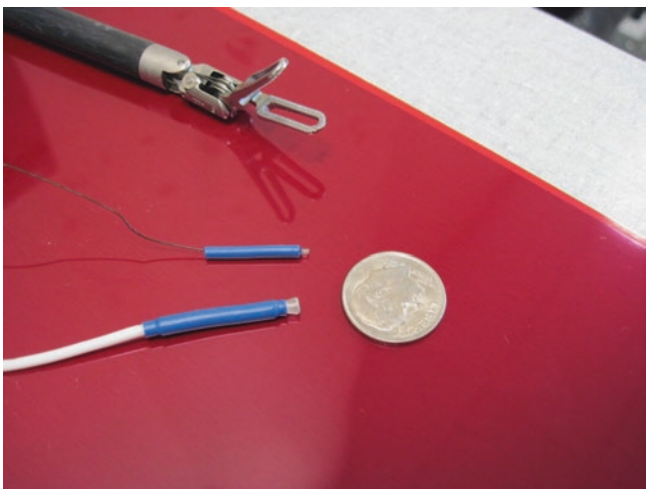

Fig. 18.2 Robotic micro-Doppler probe

by utilization of the MPD ($p=0.5$). The MDP was effective in identifying all testicular arteries within the spermatic cord in all cases. Due to the compact size of the MDP, maneuverability using the robotic grasper was significantly improved over the standard handheld Doppler probe. MDP allowed for full range of motion of the robotic arms allowing the surgeon to easily scan vessels from a wide range of angles. No complications from use of the MDP occurred. The new micro-Doppler probe for robotic microsurgical procedures appears to have performed effectively in this study.

Vascular Technology Inc. (Nashua, NH) has recently developed an even smaller microprobe that can detect flow through vessels at about 0.5-mm diameter (Fig. 18.2). This just expands further potential applications for this technology.

18.5 Enhanced Digital Visual Magnification

The miniaturization and development of advanced digital microscopic cameras (100–250×) allow even greater magnification than the standard robotic (10–15×) and microscopic (10–20×) magnification in use at this time. Our group is currently involved in clinical trials of a 100× digital camera (Digital Inc., China) that can be utilized via the TilePro™ da Vinci Si robotic system (Intuitive Surgical, Sunnyvale, CA) to allow the surgeon to toggle or use simultaneous 100× and 10–15× visualization. This provides the surgeon with unparalleled visual acuity for complex microsurgical procedures.

Karl Storz (El Segundo, CA) also offers a robotic arm platform to hold an optical mini-scope that offers 16–20× magnification that can then be used during the da Vinci robotic cases to provide an additional enhanced magnification view (routed through the da Vinci console).

18.6 Robotic Microsurgical Procedures

18.6.1 Robotic-Assisted Microscopic Vasectomy Reversal

A number of groups have developed robotic-assisted techniques to perform robotic-assisted microscopic vasectomy reversal (RAVV) in animal and ex vivo human models [21–25]. Some studies suggest that robotic-assisted reversal may have advantages over microsurgical reversal in terms of ease of performing the procedure and improved patency rates [23, 24]. A few groups have performed human robotic-assisted vasovasostomies using the initial da Vinci robotic system [26] (Intuitive Surgical, Sunnyvale, CA).

These efforts have been confirmed in human RAVV cases performed using the new da Vinci Si system [27, 28]. Our group performed a prospective control study comparing RAVV and robotic-assisted vasoepididymostomy (RAVE) to standard microsurgical vasovasostomy (MVV) and vasoepididymostomy (MVE) [29, 30]. Between August 2007 and February 2012, 155 vasectomy reversal cases were performed by a single fellowship-trained microsurgeon. The primary endpoint was operative duration. The secondary endpoint was total motile sperm count at 2, 5, 9, and 12 months postoperatively [30]. Case breakdown was as follows: 110 with robotic assistance, 45 pure microsurgical, 66 bilateral RAVV, 44 RAVE on at least one side, 28 bilateral MVV, and 17 MVE on at least one side. Selection of approach (robotic vs. pure microscopic) was based on patient choice. Preoperative patient characteristics were similar in both groups. The same suture materials and suturing techniques (two-layer 10-0 and 9-0 nylon anastomosis for RAVV; 10-0 nylon double-armed longitudinal intussusception technique for RAVE) were used in both approaches.

Ninety-six percent patency was achieved in the RAVV cases and 80% in MVV (>1 million sperm/ejaculate). There was a statistically significant difference in patency rates between the two groups ($p = 0.02$). Pregnancy rates (within 1 year post-op) did not differ significantly for the two groups: 65% for the RAVV and 55% for the MVV. Operative duration (skin to skin) started at 150–180 min initially for the first 10 cases for RAVV, but median operative duration was significantly decreased in RAVV at 97 min (40–180) compared to MVV at 120 min (60–180), $p = 0.0003$. RAVE at 120 min (60–180) was significantly faster than MVE at 150 min (120–240), $p = 0.0008$. Suture breakage and needle bending reduced significantly after the first 10 RAVV cases. Mean postoperative total motile sperm counts were not significantly higher in RAVV/RAVE versus MVV/MVE, but the rate of postoperative sperm count recovery was significantly greater in RAVV/RAVE. Similar outcomes have been reported by other groups as well [31, 32].

Further evaluation and longer follow-up are needed to assess its clinical potential and the true cost–benefit ratio.

18.6.2 Robotic-Assisted Microscopic Varicocelectomy

Although reports of robotic-assisted laparoscopic intra-abdominal varicocelectomy have been published [33], there are a number of publications that suggest that microscopic subinguinal varicocelectomy (MVx) may provide superior outcomes compared to intra-abdominal varicocelectomy [34–37]. Shu et al. were the first to publish on robotic-assisted microsurgical subinguinal varicocelectomy (RAVx) [38]. They compared standard microsurgical to robotic-assisted varicocelectomy and found that the robotic approach provided advantages in terms of slightly decreasing operative duration and complete elimination of surgeon tremor.

To further explore these findings, we performed a prospective randomized controlled trial of MVx to RAVx in a canine varicocele model by a fellowship-trained microsurgeon. The surgeon performed cord dissection and ligation of three veins with 3-0 silk ties. Twelve canine varicocelectomies were randomized into two arms of six: MVV versus RAVx. Procedure duration, vessel injury, and knot failures were recorded. The RAVx mean duration (9.5 min) was significantly faster than MVV (12 min), $p=0.04$. The duration for robot setup and microscope setup was not significantly different. There were no vessel injuries or knot failures in either group.

A review of our prospective clinical database of 97 RAVx cases from June 2008 to September 2010 (median follow-up of 11 months: range 1–27) is as follows. The median duration per side was 30 min (10–80). Indications for the procedure were the presence of a grade 2 or 3 varicocele and the following conditions: 10 with azoospermia, 42 with oligozoospermia, and 49 with testicular pain (with or without oligozoospermia, and failed all other conservative treatment options). Three-month follow-up was available for 81 patients: 75% with oligozoospermia had a significant improvement in sperm count or motility; one with azoospermia was converted to oligospermia. For testicular pain, 92% had complete resolution of pain (targeted neurolysis of the spermatic cord had been performed in addition to varicocelectomy). One recurrence or persistence of a varicocele occurred (by physical and ultrasound exam), one patient developed a small postoperative hydrocele, and two patients had small postoperative scrotal hematomas (treated conservatively). The fourth robotic arm allowed the surgeon to control one additional instrument during the cases decreasing reliance on the microsurgical assistant. The fourth arm also enabled the surgeon to perform real-time intraoperative Doppler mapping of the testicular arteries while dissecting the veins with the other arms if needed.

McCullough et al. [39] recently published at large series review of 258 cases with similar outcomes to the pure microsurgical technique. Robotic-assisted microsurgical subinguinal varicocelectomy appears to be safe, feasible, and efficient. The preliminary human results appear promising. Further evaluation and comparative effectiveness studies are warranted.

18.6.3 Robotic-Assisted Microscopic Denervation of the Spermatic Cord

Recent studies by Levine [13] and Oliveira et al. [14] have shown that microscopic denervation of the spermatic cord is an effective treatment option for men with chronic testicular pain. Our group has been developing a robotic-assisted microsurgical approach for the denervation of the spermatic cord (RMDSC) to assess if there may be any potential benefit over the standard microscopic technique.

Our group recently published a retrospective review of 872 cases (772 patients) who underwent RMDSC from October 2007 to July 2016 [40]. Selection criteria were as follows: chronic testicular pain (>3 months), failed conservative treatments, negative neurologic and urologic workup, and temporary resolution of pain with local anesthetic spermatic cord block. RMDSC was performed. Pain was assessed preoperatively and postoperatively using the subjective visual analog scale (VAS) and objectively with the standardized validated pain score (PIQ-6 by RAND). Follow-up data was available in 860 cases. Over a median follow-up of 24 months (1–70), 83% (718 cases) had a significant reduction in pain and 17% (142 cases) had no change in pain by subjective VAS scoring. Within the patients who had significant reduction in pain, 49% (426 cases) had complete resolution and 34% (292 cases) had a ≥50% reduction in pain. Objective PIQ-6 analysis showed a significant reduction in pain: 67% at 6 months, 68% at 1 year, 77% at 2 years, 86% at 3 years, and 83% at 4 years post-op.

RMDSC is an effective, minimally invasive approach with potential long-term durability for patients with refractory chronic orchialgia.

18.7 Single Port and Abdominal Robotic Microsurgical Neurolysis

Chronic groin pain can be debilitating for patients. Microsurgical subinguinal denervation of the spermatic cord (MDSC) is a treatment option for this pain. However, there are limited further options for patients who fail this treatment or who have phantom pain after orchiectomy. Our goal was to develop a single port and abdominal robotic microsurgical neurolysis technique to ligate the genitofemoral and inferior hypogastric nerve fibers within the abdomen above the internal inguinal ring.

We performed a prospective study of patients with chronic groin pain who either had failed previous MDSC or had phantom pain after orchiectomy. Primary endpoint was impact of pain on quality of life (PIQ-6 pain impact questionnaire from RAND) and secondary endpoint was operative robotic duration. PIQ-6 scores were collected pre-op and at 1, 3, 6, and 12 months post-op.

We completed 30 cases (five single ports) from June 2009 to September 2010. Elimination of pain occurred in 60% (18 cases), and a greater than 50% reduction in pain occurred in an additional 13% (4 cases) within 1 month post-op. Two of the failures were patients that had pain elimination for 6 months, but then pain returned thereafter. Median OR duration was 10 min (5–30). There were three complica-

tions: (i) one post-op scrotal hematoma that resolved with conservative measures, (ii) one patient had pain at one of the port sites, and (iii) one patient had pain that shifted from the groin to the leg. Single port and abdominal robotic microsurgical neurolysis appears to be an option for treatment in this difficult patient population. Further follow-up and evaluation are warranted.

18.8 Conclusion

The use of robotic assistance during microsurgical procedures is expanding. The application of this technology in other microsurgery fields apart from urology is also expanding, such as ophthalmology, hand surgery, and plastic and reconstructive microsurgery. The advantages of a stable microsurgical platform, ergonomic surgeon instrument controls, elimination of tremor, and magnified immersive 3D vision are all intuitively apparent. Further comparative effectiveness studies are ongoing and will be forthcoming on the true applicability of this new surgical platform. However, the preliminary results so far are quite impressive.

18.9 Review Criteria

A search of studies on robotic-assisted microsurgery in andrology was performed using search engines such as ScienceDirect, OVID, Google Scholar, PubMed, and MEDLINE. The overall strategy for study identification and data extraction was based on the following keywords: "robotic vasectomy reversal," "robotic varicocelectomy," "robotic denervation," "infertile men," "varicocelectomy," "vasectomy reversal," and "infertility." Articles published in languages other than English were also considered. Data that were solely published in conference or meeting proceedings, websites, or books were not included.

Key Points

- Regardless of microsurgical or robot-assisted microsurgical approach to vasectomy reversal, it is paramount to have an in-depth knowledge of the surgical anatomy for acceptable outcomes.
- The anastomosis should be performed with a minimal touch, watertight, tension-free manner for optimal patency rates.
- Advantages to robot assistance: elimination of tremor, improved stability, seven degrees of freedom instrumentation, scalability of motion, 3D/HD visualization, manipulating three instruments and camera simultaneously, and faster times after learning curve met.
- Data show comparable outcomes with robotic vasectomy reversal compared to microsurgical vasectomy reversal with improved anastomosis and operative times once the learning curve is met and advantages including ergonomics and decreased fatigue.
- The learning curve for robot-assisted vasovasostomy reveals high-percentage patency rates very early across wide intervals of obstructive intervals, and 75 cases were required to optimize and plateau in anastomosis times and operative times.

19.1 Introduction

Approximately half a million men in the United States undergo vasectomy annually. Approximately 6% of men in the United States who have undergone vasectomy will choose to undergo vasectomy reversal (VR) [1] sometime in their lifetime, which is contributed to by the 50% divorce rate [2, 3]. VR was initially described in the 1930s and a significant improvement in patency rates was achieved with the use of the operative microscope for magnification to assist in the anastomosis, which was applied in the 1970s [4–6].

Americans have been dreaming of robots for decades. Regardless of if robots were dreamed up for science fiction or for practical purposes, the idea of robots mechanically assisting us with tasks has been a goal. Society has imagined robots performing different tasks to assist humans, and the idea that someday robots would do surgery for us was one of these tasks with great interest. That has not necessarily come to fruition; however, the use of robotics has advanced in assisting surgeons with procedures. The da Vinci® system was initially developed for use for gross surgical procedures and has advanced its use to the microsurgical platform. In male fertility surgery, this particularly lends itself to VR. VR was initially attempted without any technology and simply

with the use of the naked eye and then evolved through numerous levels of technology starting with optical loupes, advancing to the use of operative microscopes, and now has progressed to the use of the robotic platform. The gain of seven degrees of freedom from the robotic endowrists allows for movements beyond those that the hand and wrist of a human being can make, scalability of motion, a less fatiguing ergonomic design for the surgeon which may enhance performance, and high-definition three-dimensional optimal visualization of a microsurgical field. After mastering the learning curve for robotic microsurgery, operative times improve as well.

19.2 History of Robotics in Surgery

Since 1942, when Isaac Asimov initially used the word "robotics" in his short story "Runaround," the ideas and imaginations of what robots may be able to do have captivated our society. This is especially true in the field of medicine in which robots have been portrayed in every form and medium including science fiction and cinematic films. The reality of robotics in medicine was developed in the mid-1980s when the PUMA system was developed in the United Kingdom for computed tomography (CT)-guided brain biopsy and for transurethral resection of the prostate (TURP) [7]. In 1992 the PROBOT was developed in London for TURP, with the ability to be programmed to resect based on specific prostate volumes [8]. In 1992 the ROBODOC utilized CT imaging programmed for the individual orthopedic patient to mill out precise fittings in the femur for hip replacements, which was developed in Germany [9]. The PAKY (Percutaneous Access to the Kidney) robotic arm system was developed at Johns Hopkins in 1997 [10–12]. In the 1990s in Germany, the ARTEMIS (Advanced Robotic Telemanipulator for Minimally Invasive Surgery) was engineered, which was the first master-slave manipulator system with instrumentation with six degrees of freedom. It was designed for cardiac surgery but was discontinued due to lack of funding [13]. In 1994 the AESOP (Automated Endoscopic System for Optimal Positioning) was developed in the United States which maneuvered laparoscopic trocars by surgeon voice commands. HERMES was the integrated operating room control system that allowed the complete integration of the robotic system, and in 2001, the ZEUS robotic system was introduced which combined the AESOP and HERMES systems as a master-slave device with a surgeon in a console controlling a separate robotic device [14, 15]. These robotic devices led up to the advent of the standard of care robotic device currently used in clinical surgical practice, the da Vinci® system developed by Intuitive Surgical.

19.3 Da Vinci® Robotic System

In the mid-1990s, the founders of Intuitive Surgical developed the da Vinci® robot system. The device included three primary components: a master-slave software driven system which controlled robotic instruments with seven degrees of freedom, a visualization system with three dimensions, and a safety monitoring system (Fig. 19.1) which is sensor-based to continuously reassess the performance of the device to optimize patient safety [16]. In 1997 the first robot-assisted surgery, a cholecystectomy, was performed by Jacques Himpens and Guy Cardiere in Brussels [17]. The Food and Drug Administration (FDA) approved the da Vinci® robotic system in 2000 with the components including a surgeon's console, a patient-side robotic cart with four arms manipulated by the surgeon, and the visualization system. The current da Vinci® robotic system offers three-dimensional, high-definition digital visual magnification up to 10–15× with instrumentation with seven degrees of freedom and scalability of motion.

19.4 Technology Hype (Gartner-Palmer Tech Hype Curve)

When a new technology is introduced in any field, especially surgery, the technology must be assessed and proven. Along with any technology, whether it is a smart phone, an electric vehicle, or a robotic surgical device, there tends to be a great deal of initial hype, a period of underachievement of expectations, and then a realization of what the technology can actually offer. The Gartner-Palmer tech hype curve can be applied to the da Vinci® robotic system. The hype cycle involves a technology trigger which gains media coverage and publicity. This is followed by a peak of inflated expectations, i.e., this device can do everything! This is followed by the trough of disillusion when the technology fails to deliver on certain expectations. This is followed by the slope of enlightenment as the benefit of the technology becomes more widely understood. Finally, the plateau of productivity is reached as there is more mainstream adoption of the technology and the applicability and relevance become clear (Fig. 19.2). This hype cycle was clearly evident with the advent of the da Vinci® robotic platform as the original design was for telesurgery for battlefield and remote environments and then became honed to be more useful for minimally invasive surgery. It may be argued that we are in a similar hype cycle with the application of robotics to microsurgery, especially with use for robot-assisted microsurgical vasectomy reversal (RAVR) [18].

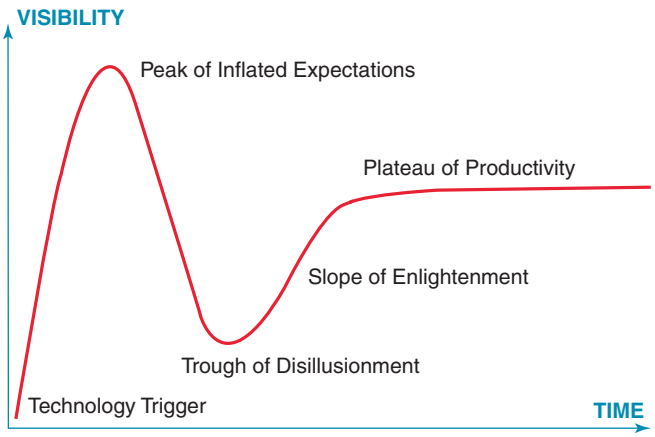

Fig. 19.2 The Gartner-Palmer tech hype curve demonstrating the technology trigger, the peak of inflated expectations, the trough of disillusionment, the slope of enlightenment, and the plateau of productivity

19.5 Anatomy

For successful outcomes of VR, regardless of whether it is performed as a RAVR, or with a pure microsurgical technique, the surgeons' understanding of the anatomy of the vas deferens and epididymis is paramount. The vas deferens extends from the distal end of the cauda of the epididymis. The mesonephric (Wolffian) duct is the embryological origin of the vas deferens. The vas deferens is a tubular hollow structure. The convoluted vas deferens is the tortuous segment exiting the epididymis for the first two to three centimeters of the vas deferens. From the cauda epididymis to the ejaculatory duct, where the vas deferens terminates, it measures between 30 and 35 cm in length. The vas deferens travels posterior to the spermatic cord vessels. The diameter of the lumen of the vas deferens varies between 0.2 and

0.7 mm depending on the segment of the vas deferens [19]. The primary arterial supply of the vas deferens is a branch off of the superior vesical artery known as the deferential artery [20]. The deferential vein is the venous drainage for the scrotal vas deferens which drains into the pampiniform plexus. The pelvic vas deferens' venous drainage is via the pelvic venous plexus. The lymphatic drainage of the vas deferens travels to the internal and external iliac lymph nodes.

Sperm reach the vas deferens by traveling through the epididymis from the testis. If the tightly coiled tubular epididymis was stretched out, the length would reach 12–15 feet. Three regions compose the epididymis including the caput (head), the corpus (body), and the cauda (tail). The caput epididymis is made up of 8–12 ductuli efferentes from the testis. The vas deferens is continuous with the most distal portion of the cauda epididymis. The caput and corpus epididymis receive their arterial supply from a branch of the testicular artery, which divides distally to supply the superior and inferior epididymal branches [21]. Arterial supply to the cauda epididymis is from branches from the deferential artery. Both cauda and corpus epididymis' venous drainage is through the vena marginalis of Haberer, which by means of the vena marginalis of the testis or through cremasteric or deferential veins drains into the pampiniform plexus [21]. The caput and corpus epididymis' lymphatic drainage are through channels that travel with the internal spermatic vein, draining to the preaortic nodes. The cauda epididymis' lymphatic channels join those leaving the vas deferens to drain into the external iliac nodes.

19.6 Preoperative Evaluation/Physical Examination

The level of spermatogenesis in the patient should be assessed prior to proceeding with RAVR. A proven history of fertility from before to the vasectomy is considered adequate. Prior to RAVR a complete physical examination with special attention to the genital examination should be performed. Testicular volumes and consistency should be assessed. Testicles with normal volume and firm consistency are indicators of good spermatogenesis, whereas small or soft testes may indicate spermatogenic dysfunction. The epididymis will commonly feel dilated on examination in men who have undergone vasectomy. Epididymal induration may indicate a level of epididymal obstruction and the need for robot-assisted vasoepididymostomy (RAVE). Counseling for a more extensive dissection to perform a tension-free anastomosis should be considered when a large vasectomy defect or gap is palpated on exam. When a sperm granuloma can be palpated at the testicular end of the vas deferens, it is associated with improved outcomes with VR. The sperm granuloma forms from leakage of sperm as a result of a pop-off valve-like mechanism decreasing intra-epididymal luminal pressures to protect the ductal system [22]. The surgeon should be prepared for a nonstandard incision approach when the scrotal exam reveals a very long vasectomy defect [23]. As hypogonadism has become a very common diagnosis, even in men during their fertility years, testosterone replacement therapy is being utilized to treat these men with an adverse impact on spermatogenesis. Men who plan on VR need an alternate medical regimen for treatment of hypogonadism in a manner that does not suppress spermatogenesis. Discontinuation of testosterone replacement with the addition of testicular salvage medical therapy with Clomiphene Citrate or human chorionic gonadotropin (hCG) should be administered for at least 3 months prior to RAVR for acceptable outcomes [24].

The timeframe since the vasectomy, known as the obstructive interval, plays a significant role on the type of RAVR required, robot-assisted vasovasostomy (RAVV) versus RAVE. Patency rates have been demonstrated to be impacted by the obstructive interval in many studies on VR, and generally the longer the interval since vasectomy, the more challenging the candidate is considered to be for VR [25, 26]. However, an experienced surgeon proficient in both RAVV and RAVE should still be able to offer RAVR to men with longer obstructive intervals. Patency rates remain high regardless of the type of VR performed in men with obstructive intervals over 10 years in technically skilled hands [27]. Several nomograms have attempted to predict the complexity of the VR required and patency success rates. These outcomes were assessed by factors including age of the men, the volume of the testicles, the presence or absence of a sperm granuloma, and the time interval since the vasectomy was performed [28, 29]. Inconsistent data has raised questions about the accuracy of the nomograms and their true predictive ability [30, 31]. Therefore, the recommendation is that VR only be performed by surgeons skilled in both VV and VE, as it is not typically possible to predict preoperatively if VE will be required [32, 33].

The patient's female partner should undergo a fertility evaluation with counseling on age-related impact on female fertility and ovarian reserve impact on the couple's fertility potential, prior to proceeding with VR [23, 34].

19.7 Preoperative Laboratory Testing

Although it is not considered to be common clinical practice, prior to VR, a semen analysis including an evaluation of the centrifuged pellet may be performed. Whole sperm is found in the centrifuged pellet 10% of the time, indicating improved outcomes suggesting that sperm will be encountered in the vas deferens at least unilaterally at the time of VR [35]. Transrectal ultrasound should be performed to assess the

possibility of a concomitant ejaculatory duct obstruction if a low semen volume is found during the semen analysis.

A serum follicle-stimulating hormone (FSH) should be obtained when there are indicators of a potential deficiency in spermatogenesis on physical examination, such as small, soft testicles. As an elevated FSH is a marker of spermatogenic dysfunction and a potentially poor outcome with VR, higher levels of assisted reproductive care may be warranted [36]. Serum antisperm antibody (ASA) testing is not recommended as a part of the routine preoperative evaluation prior to VR. Circulating ASAs are detectable in approximately 60% of men after bilateral vasectomy [37]. There is no proven value in testing ASAs preoperatively, and the impact of circulating ASAs on fecundability is at the very least questionable considering the high conception rate in couples following VR [1, 38–44].

19.8 Anesthesia

Local, regional, or general anesthesia may be administered for RAVR [23]. General anesthesia is the anesthesia of choice to minimize patient movement and to optimize patient comfort considering the level of meticulous tissue handling with RAVR for optimal results. Although it is possible to perform RAVR with local anesthesia with sedation, this results in more difficulty achieving optimal outcomes due to more patient motion. Local anesthesia or sedation poses even more of a challenge when a difficult anastomosis or a RAVE must be performed with longer operative times.

19.9 Positioning the Patient and the Robot

The patient is positioned supine on the operative table. After general endotracheal anesthesia is induced, all pressure points are padded, and a timeout is performed. The scrotum is shaved, prepared, and draped in a sterile fashion. After the vasa are prepared for the anastomosis, the operative robot is positioned from the patient's right side at a 90-degree angle with the zero degree camera placed directly over the operative field, perpendicular to the floor, once the vasa have been prepared and approximated for the anastomosis (Fig. 19.3).

19.10 Incision Approaches

The most direct access to the vasectomy defect is through a scrotal incision to isolate the ends of the vasa deferentia for anastomoses. In cases with high vasectomy defects or lengthy stretches of unusable vas or lengthy vas defects, the incision may be carried in the direction of the external inguinal ring. The testes may be delivered from the scrotum in cases where the vasectomy defect is in the proximal convoluted vas or adjacent to the epididymal cauda or when it is necessary to perform a RAVE. Mini-incision VR using no-scalpel vasectomy principles has been shown to have comparable patency rates with less postoperative pain and faster functional recovery [45, 46]. The author's approach of choice is performing RAVR through a mini-incision, using one longitudinal incision for bilateral anastomoses which is less than 1 cm in its entirety.

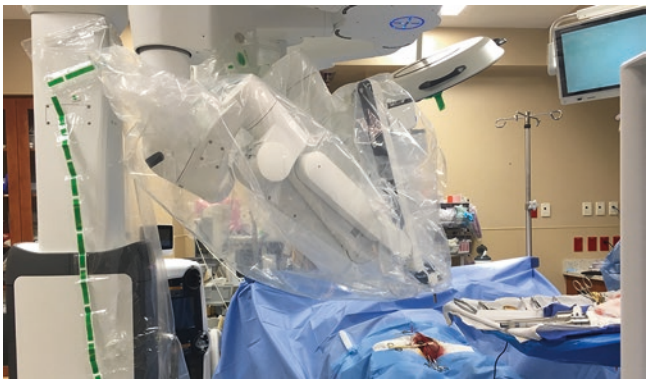

Fig. 19.3 Positioning of the robotic system at a 90° angle to the patient with the camera positioned directly above the operative field (view from console)

The surgical approach to RAVR will vary in men who have previously undergone varicocele repair or inguinal hernia repair. In men who have had a varicocele repair for hypogonadism or orchialgia with a vasectomy simultaneously, access through the previous incision after confirming that the vasectomy was performed subinguinally by previous operative report should be used for a subinguinal RAVR. When there is suspicion for a vas deferens obstruction from previous inguinal herniorrhaphy, performing the RAVR through the scar from the herniorrhaphy will lead to the vasal obstruction. Successful intra-abdominal RAVR has been reported following herniorrhaphy. This demonstrates an optimal example of the utilization of the robotic platforms ability to improve access to a difficult vas deferens reconstruction [47, 48].

19.11 Vas Deferens Preparation

Through a scrotal incision, the vasectomy defect is palpated and isolated, and the testicular and abdominal ends of bilateral vasa are isolated with vessel loops, through one small incision. The microvasculature supply to the vas deferens should be preserved, so care should be taken to not strip the vas deferens of the perivasal adventitia (Fig. 19.4). Mobilization is performed of the testicular and abdominal ends of the vas deferens, while keeping the vasal adventitia intact, in a manner to perform a tension-free anastomosis. The vasectomy defect site where the obstruction from the

Fig. 19.4 The transected end of the vas deferens with the perivasal adventitia intact

original vasectomy is located may be excised or excluded. The deferential artery is preserved during this maneuver. Following isolation of the testicular and abdominal ends of the vas deferens, an exact 90-degree sharp division of the testicular end of the vas deferens is performed. The muscularis and the mucosa of the divided vas deferens should be inspected for a healthy anastomotic surface to minimize selecting an anastomosis site with fibrosis, scar, or an irregular edge. Vasal fluid obtained from the lumen of the testicular end of the vas deferens is applied to a glass microscope slide; the fluid is then diluted with a small amount of saline and is visualized with an inverted light microscope. The microscopic findings and the fluid quality obtained from the testicular lumen of the vas deferens indicate the need to perform a RAVV versus a RAVE. When whole sperm cells with tails are visualized microscopically (Fig. 19.5) or when copious, clear fluid from the lumen of the testicular end of the vas deferens without sperm microscopically are the findings, RAVV is the option of choice. When no fluid is present, barbotage is performed with 0.1 ml of saline injected through a 24-gauge angiocatheter sheath which is cannulated into the lumen of the testicular end of the vas deferens, and the barbotaged fluid is examined under the microscope for presence of sperm. RAVE should be performed when no

Fig. 19.5 Whole sperm visualized under the light microscope in the vasal fluid from the testicular end of the vase deferens

significant amount of vasal fluid or sperm are identified with barbotage. RAVE is also indicated when the vasal fluid appears toothpaste-like and thick and sperm are typically not found on examination of the fluid under the microscope. A patency rate of greater than 90% can be expected when fragments of sperm including sperm heads and/or short tails are visualized in the vasal fluid intraoperatively despite whether the fluid quality is good or bad. This 90% success rate exceeds that expected with VE and is the procedure of choice in this scenario [49, 50]. Vasal fluid sperm quality has been categorized in five grades. Grade 1 is categorized by visualization of motile normal sperm, grade 2 is mostly normal non-motile sperm, grade 3 is categorized by the majority of the findings being sperm heads, grade 4 is sperm heads only, and grade 5 is the complete absence of sperm or sperm fragments [51, 52].

Sharp division of the abdominal end of the vas deferens is performed at an exact 90 degrees. The lumen of the vas deferens is carefully cannulated with a 24-gauge angiocatheter sheath, and saline is injected through the lumen to demonstrate patency. Once abdominal vasal patency has been demonstrated, a Microspike approximating clamp is used to approximate the testicular and abdominal ends of the vas deferens, or they may be approximated with meticulously placed 6-0 polypropylene sutures in the adventitia of the two ends of the divided vasa to approximate the ends with an assistant's help. A metal ruler or tongue blade with a Penrose drain covering it is then positioned under the approximated ends as a template to perform the anastomosis. In instances when an attempt is made to inject saline through the lumen of the abdominal end of the vas deferens and there is high pressure or the saline does not easily flow, this indicates another site of obstruction further away in the abdominal end

of the vas deferens. By passing a 2-0 polypropylene suture gently through the lumen of the abdominal vas deferens, the site of distal obstruction can be isolated. If the obstruction is encountered within 5 cm of the initial site of obstruction where the initial vasectomy defect was found, dissection may be performed to the obstruction site which can be excised to perform a single anastomosis after adequate mobilization of both ends allows for an anastomosis which is tension-free. This often requires extending the incision. It is not recommended to perform multiple anastomoses on the vas deferens due to the increased risk for devascularization of the vas deferens resulting in failure.

19.12 Technical Aspects of Anastomosis

Robotic microsurgical skill is required for acceptable RAVR results. Improvements in outcomes are achieved by strictly adhering to microsurgical principles to perform the anastomosis. The luminal mucosa of the testicular and abdominal ends of the vasa must be perfectly approximated. A watertight anastomosis is necessary due to the inflammatory response antigenic sperm can induce with the potential to result in fibrosis and obstruction at the anastomotic site with sperm cells leaking out of the lumen in the general tissue of the scrotum [53]. Long-term success is dependent on a tension-free anastomosis. Abdominal and testicular vasa segment mobilization and placement of muscularis sutures for reinforcement can optimize long-term patency rates by minimizing tension on the anastomosis (Fig. 19.6). As little manipulation of the vasal ends with a minimal touch technique is crucial for a successful anastomosis, by not compromising microvascular supply by stripping the vas deferens of its adventitia with risk of devascularization of the vas deferens and increased chance of stricture.

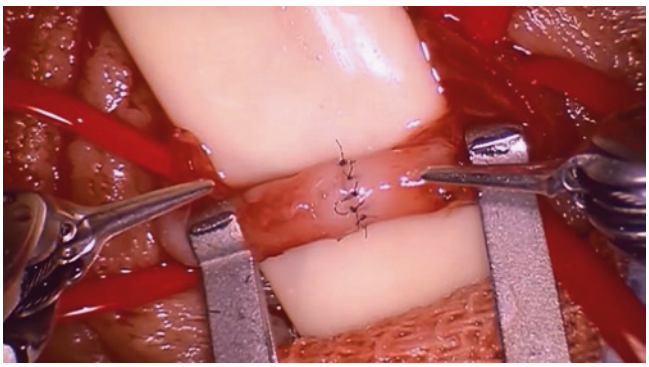

Fig. 19.6 The appearance of a watertight, tension-free anastomosis with the vasal adventitia intact upon completion of a robot-assisted vasovasostomy

19.13 The Da Vinci® Robotic Platform to Assist with Microsurgical Vasectomy Reversal

The robotic platform including a surgeon's console, a patient-side robotic cart with four arms manipulated by the surgeon, and the visualization system offers potential advantages over traditional microsurgery. These include elimination of tremor, improved stability, instrumentation with seven degrees of freedom, scalability of motion, three-dimensional/high-definition visualization, the ability for the surgeon to manipulate three surgical instruments and a camera simultaneously allowing less emphasis on a skilled microsurgical assistant, and faster anastomosis and operative times once the learning curve is met. Most notably the robotic platform has the ability to improve surgeon ergonomics and decrease surgeon fatigue. Replacing the surgical microscope with the robotic platform allows for more throughput with multiple microsurgical cases consecutively with lesser surgeon fatigue subjectively reported. This may ultimately extend the microsurgeon's longevity.

Optimal settings for the robotic platform include a 4× digital zoom, haptic zoom, a close-up working distance setting, and a three-dimensional viewer mode (Fig. 19.7).

19.14 Robot-Assisted Vasectomy Reversal

Magnification through the use of an operative microscope is the manner in which VR has traditionally been performed. More recently, da Vinci® robot assistance has been applied

Fig. 19.7 Robotic platform settings including a 4× digital zoom, haptic zoom, a close-up working distance setting, and a three-dimensional viewer mode

to VR. The use of robot assistance for VR was first applied to ex vivo human vas deferens with the findings of an absence of physiological tremor and similar patency rates revealing that the robotic platform is an option as an alternative technology to the operative microscope [54]. Next, RAVV and RAVE were shown to be feasible in the rat model with findings of stability improvement and reduction of extraneous motions during anastomotic suturing [55]. RAVV was then performed in an in vivo rabbit model with a multilayered anastomosis with similar patency rates, further progressing the potential role of the robotic platform use for microsurgery [56]. The first study published in humans who underwent RAVR revealed faster surgical times and early postoperative semen analyses demonstrating higher sperm counts than the cases performed microsurgically for VR [57]. A validating publication on RAVR in men compared to microsurgical VR revealed similar patency rates, surgical times, and sperm concentrations and total motile counts following RAVR. The average anastomosis time in the RAVV group was found to be statistically longer than the microsurgical group in the early robotic cases; this was only a 10 minutes longer average anastomosis time in the RAVR group, with arguable clinical significance [58]. The potential gains in using the operative robot for RAVR include absence of physiologic tremor, a more stable platform, ergonomic advantage for the surgeon resulting in less surgeon fatigue, motion scaling, three-dimensional high-definition real-time image, the surgeon being able to control the camera and three surgical instruments concomitantly, eliminating the need for a specialized assistant skilled in microsurgery, and the possibility of decreasing surgical times [58]. Although early studies show promise, large-scale prospective, randomized controlled trials are needed to validate the broader adoption of robot assistance for VR.

Advantages are gained for more challenging scenarios by use of the robotic platform. One of these scenarios in particular is use for intra-abdominal VR for men who have obstruction of the vas deferens secondary to a previous inguinal hernia repair or men who had a laparoscopic vasectomy performed simultaneously with another procedure [47, 48].

19.15 Robot-Assisted Microsurgical Vasovasostomy

RAVR mandates the same level of meticulous tissue handling principles utilized during microsurgical VR. The instruments used in both the left and right robotic arms are the black diamond microsurgical robotic forceps. A zero-degree camera is selected with 4× setting. A ratio of 3:1 is chosen for scalability of motion. The anastomosis for RAVV may be performed by two-layered or the author's preference of a modified one-layer anastomosis, for which four to eight sutures of interrupted 9-0 nylons are placed through the vasal lumens with full-thickness bites of each end of the vas deferens (Fig. 19.8) (Video 19.1). Microsurgical suture and needle handling techniques utilized with microsurgical instruments are applied in a similar fashion while using the robotic black diamond forceps to prevent bending needles or breaking sutures. After the transluminal sutures are placed, the muscular layer of the adventitia is approximated with interrupted 9-0 nylon sutures between the already placed full-thickness luminal sutures to decrease tension on the anastomotic sutures (Fig. 19.9) [59]. Once completed, the anastomosis should be watertight with luminal mucosal approximation and the vasal adventitia

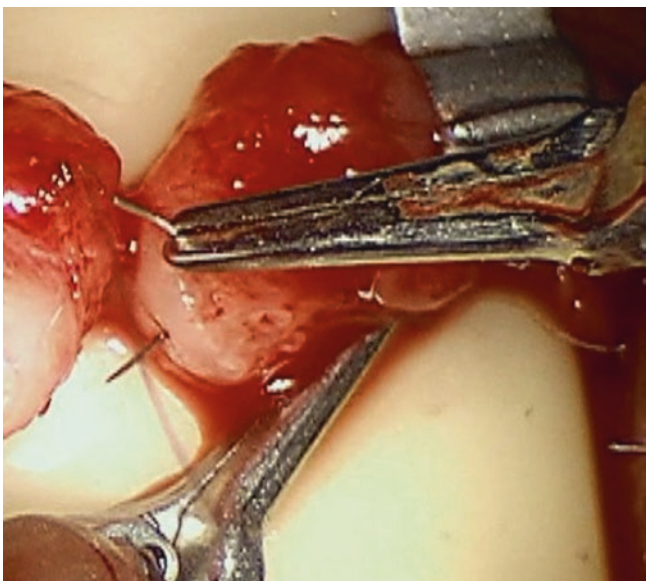

Fig. 19.8 Placement of a transluminal anastomotic suture with robot assistance

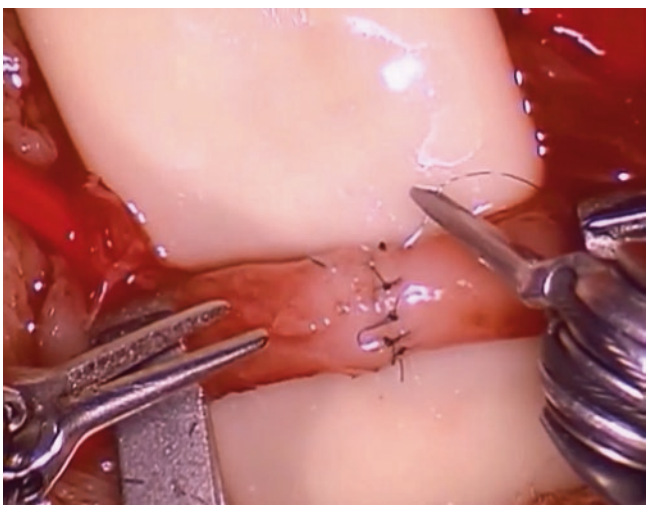

Fig. 19.9 Placement of interrupted suture in the seromuscular layer of the vas deferens between the transluminal anastomotic sutures with robot assistance

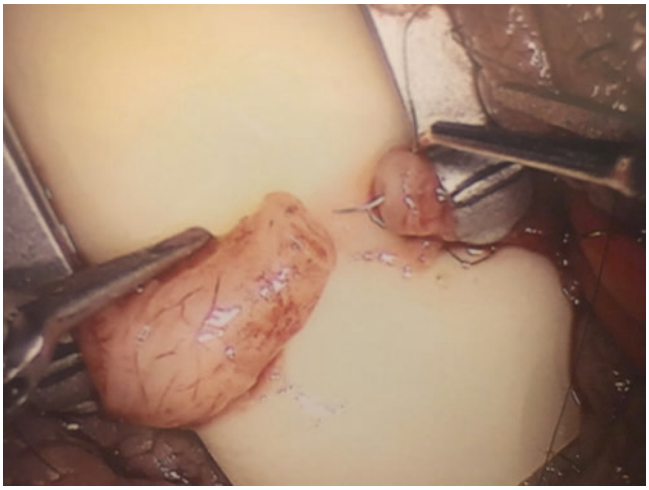

Fig. 19.10 Microscopically visible microvasculature in the adventitia of the vas deferens as a transluminal suture is being placed with robot assistance

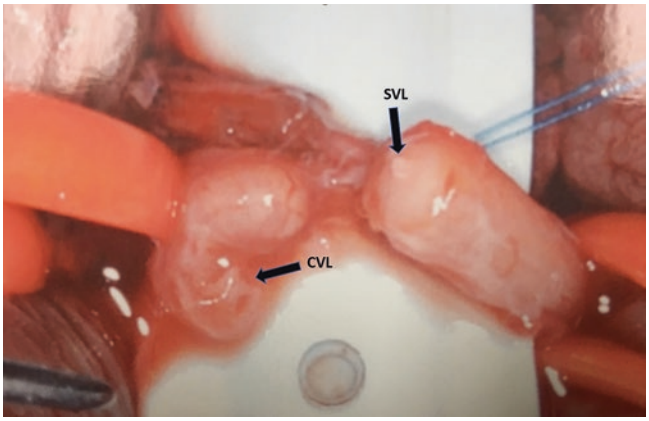

Fig. 19.11 Preparation for the anastomosis between the convoluted vas deferens and straight vas deferens lumens. The convoluted vas deferens lumen (CVL) is not concentric and is found at the end of the tortuous convoluted vas deferens. The straight vas deferens lumen (SVL) is demonstrated

should have been maintained to decrease the risk of stricture from micro devascularization (Fig. 19.10). Some surgeons have a preference for a complete two-layer anastomosis, which requires placement of five to eight interrupted 10-0 nylon sutures for approximation of the inner mucosal edges of the lumens of the vas deferens. This is followed by placement of seven to ten interrupted 9-0 nylon sutures in the muscular layer for tension-free reinforcement [52]. Robotic microsurgeons experienced in RAVV make up for the discrepancy between the diameters of the approximating lumens of the abdominal and testicular ends of the vas deferens visually while performing the anastomosis. Otherwise, placement of microdots with a marking pen with a microtip helps for planning the placement of sutures before the anastomosis is performed [60].

A successful anastomosis in the convoluted vas deferens during VV depends on extremely precise and meticulous techniques. When expertise and microsurgical principles are applied by skilled microsurgeons, patency rates are similar to those of anastomoses in the straight portion of the vas deferens, although the anastomosis in the convoluted vas deferens is technically more challenging (Fig. 19.11) [61, 62]. Most RAVVs may be performed through a single small incision, usually smaller than 1 cm longitudinally which improves the ease of recovery and is a cosmetically appealing incision with dissolvable sutures in the skin (Fig. 19.12). In difficult scenarios, a useful maneuver is the crossed trans-scrotal VV. This is used when an anastomosis of one testicular end of the vas deferens is made to the contralateral abdominal end of the vas deferens. This is useful in situations with a unilateral inguinal vas deferens obstruction associated with an atrophic testis on the contralateral side or obstruction of an inguinal vas deferens and epididymal obstruction on the contralateral side [2, 52, 63, 64]. Repeating a VR is a reasonable choice for men

Fig. 19.12 Demonstration of a single, less than 1 cm incision after closure following bilateral robot-assisted vasovasostomies

who underwent an unsuccessful initial VR. Repeating a VR should include consideration of the time interval since vasectomy, the initial VR, and the skill and experience of the surgeon performing the redo VR [65, 66].

Postoperative patency is demonstrated by the presence of sperm in the ejaculate in up to 99.5% of men when VVs are performed after sperm is identified in the vasal fluid of at least one side [60]. Comparable patency rates have been demonstrated when comparing outcomes of one-layer VV and two-layer VV [67, 68]. Within 2 years of VR, pregnancy

rates of 52% have been reported and pregnancy rates up to 63% have been reported when excluding female factor and when based on female partner age and the time since vasectomy [22, 69–73]. Rates of spontaneous pregnancy in couples following VR are dictated by postoperative semen parameters and female factors and age of the female partner [67, 74].

19.16 Robot-Assisted Microsurgical Vasoepididymostomy

RAVE is a highly technically challenging surgery which should only be performed by skilled robotic microsurgeons with high levels of training and experience in this procedure who perform it commonly. In scenarios that require a VE, anastomoses are more likely to succeed and less technically challenging when they can be performed in the more distal tubules of the epididymis, as the wall of the epididymis progressively thickens more distally with more smooth muscle cells. Beyond the caput, the epididymis becomes a single microscopic tubule forming the corpus and cauda; therefore, blockage at any site will result in complete obstruction preventing sperm from reaching the vas deferens. Optical magnification is crucial to improve VE patency rates [75, 76].

VE has been performed in multiple manners. End-to-end and end-to side anastomoses have been used to perform VE [32, 33]. Anastomoses performed end-to-end have predominantly fallen out of favor. To perform an end-to-side VE, significantly dilated epididymal tubules are identified under magnification, and the muscularis and adventitia of the vas deferens are approximated to a specific opening in the epididymal tunica. This should be performed through a meticulous, atraumatic technique and should be relatively bloodless [33, 76–80]. A scrotal incision is made through which the testis is delivered. A vessel loop is used to isolate the vas deferens at the junction of the convoluted and straight vas deferens. The vas deferens is sharply divided at a 90-degree angle and preparation of the vas deferens is done as previously described above. The epididymis is inspected under magnification after incising the tunica vaginalis. The planned epididymal anastomotic site is identified proximal to the suspected site of obstruction, where dilated epididymal tubules are visualized. A tunical incision overlying the dilated tubules of approximately 3–4 mm is made using the tip of the robotic micro-Potts scissors. Exposure and gentle dissection of the epididymal tubules is performed. The selected dilated epididymal tubule is punctured with the sharp tip of a 10-0 nylon needle, and microscopic examination of the epididymal fluid is done to identify sperm. The vas deferens is anchored to the tunica of the epididymis with three to four 6-0 polypropylene interrupted sutures allowing for approximation of the vasal lumen to the opening of the tunica of the epididymis in a tension-free manner. With high magnification, 10-0 double-armed nylon monofilament sutures with tapered fishhook needles are utilized for approximation of the posterior mucosal edge of the epididymal tubule the posterior vasal mucosa. An additional two to four 10-0 nylon sutures are placed for the anterior mucosal anastomosis. An additional six to ten interrupted 9-0 nylon sutures approximate the outer muscularis and adventitia of the vas deferens to the incised edge of the epididymal tunica. Following completion of the anastomosis, the robotic system is undocked and the scrotal content is gently replaced into the tunica vaginalis followed by a multilayered closure of the scrotum.

The preferred technique for performing RAVE of the author is the two suture intussusceptions technique. Two needles of double-armed 10-0 nylon sutures are placed in parallel in the selected dilated tubule of the epididymis longitudinally, leaving them in place rather than pulling them through to prevent leaking of tubular fluid resulting in collapse of the epididymal tubule of interest. The sharp tip of a 10-0 nylon needle or the robotic microsurgical Potts scissor tips is used to create a longitudinal opening in the tubule between the previously placed and parallel placed needles. The epididymal fluid is examined under the visualization of an inverted light microscope for sperm. The needles of the preplaced 10-nylons are then passed inside out the vas deferens mucosa to perform the intussuscepted anastomosis (Fig. 19.13) [76, 80–82]. The muscularis and adventitia are anchored to the epididymal tunica as described above (Fig. 19.14).

Acceptable VE patency rates should be in the range 50% and 85% in the hands of experienced skilled microsurgeons [81, 83]. With techniques such as the classic end-to-side or older less frequently performed end-to-end anastomosis, respective patency and pregnancy rates of approximately 70% and 43% have been reported [75, 84].

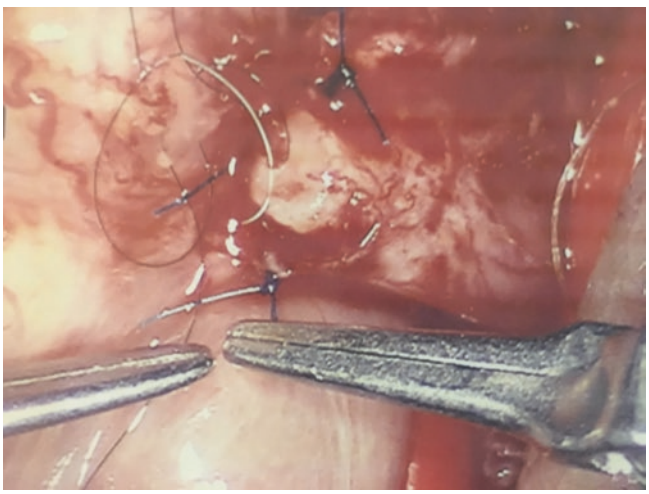

Fig. 19.13 Performing the anastomosis of a robot-assisted vasoepididymostomy with a two-suture intussuscepted technique

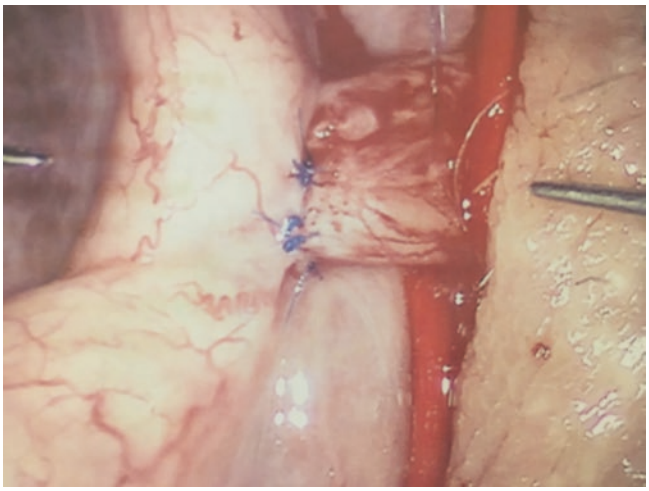

Fig. 19.14 Completed vasoepididymostomy anastomosis

The intussuscepted techniques offer high patency rates ranging between 70% and 90% [76, 80, 85].

19.17 Robot-Assisted Microsurgical Vasectomy Reversal Learning Curve

Once a new technology has been applied to a surgical procedure, and the safety and efficacy have been demonstrated, the learning curve should be assessed. A study evaluated the learning curve for a purely microsurgically fellowship-trained reproductive urologist with minimal robotic console training transitioning to RAVV for his first 100 cases of RAVV excluding RAVEs and redo operations from previous failures from other surgeons performing vasectomy reversal for uniformity. Endpoints were assessed at 25 chronologic case intervals and each group of 25 cases had similar variable obstructive intervals from very short to very long intervals since vasectomy. Patency rates were equivalent at 92% for the first three 25 case groups, and patency rates increased from 92% to 96% for the last 25 cases. Although this was not statistically significant, it may be argued whether it is clinically significant [86]. The same surgeon's anastomosis and operative times with pure microsurgical VRs were published in a previous study [45]. In comparison to the same surgeon's progression with RAVV, the operative times were faster than microsurgical operative times, even in the first 25 RAVV cases. The data revealed that excellent patency rates are feasible very early in the transition from pure microsurgical VV to RAVV across wide intervals of time since vasectomy and mean sperm concentrations in the initial semen analyses after RAVV are similar over time with more case volume. It was found that 75 RAVVs were necessary to reach optimal anastomosis times and operative times for pure microsurgeon without formal training in robot-assisted microsurgery [73].

19.18 Future of Evolution of Robot-Assisted Microsurgical Vasectomy Reversal

Future technology should include improvement of optics and instrumentation. Although the black diamond forceps which are currently the standardly used instruments for RAVR are adequate to perform microsurgery, they do not mimic the traditional microsurgical handheld instruments. Robotic instruments which replicate handheld microsurgical instruments would be optimal for advancement of robot-assisted microsurgery. The other major component would be improving magnification and decreasing pixilation at high magnification with the robotic visualization system.

19.19 Postoperative Care

Postoperatively following RAVR, the patient should be placed in a tight fitting scrotal supporter with fluff gauze. Antibiotics are not indicated postoperatively. Analgesics are offered. The majority of men are back to work 3 days following RAVR when their work is not physically strenuous. Restrictions include abstinence from sexual activity including ejaculation, avoiding strenuous activity and refraining from exercise for 3 weeks postoperatively. Semen analysis is performed at 6 weeks, 3 months, and 6 months following RAVR and then is repeated at 6-month intervals thereafter until the couple is successful conceiving or if assistance is needed to assist with conception. Failure of RAVR is clear if 6 months after RAVR the semen analysis continues to reveal azoospermia.

19.20 Complications

Rare complications of RAVR include hematoma and infection. A progressive decrease in sperm motility followed by diminishing sperm counts and ultimately azoospermia indicates a delayed stricture resulting in obstruction. After VR, delayed obstruction has been reported in 5% to 12% at 18 months postoperatively [85, 87]. As a safety backup, all men are recommended to cryopreserve sperm following RAVVR once motile spermatozoa are visualized in the semen as a precaution.

19.21 Conclusions

RAVR is a viable and effective option for patients interested in VR with potential advantages for the operating surgeon. Although there is a learning curve for operative time and anastomosis time to match those of pure microsurgical VR which is ultimately faster robotically, patency rates are similar very early in the series for microsurgeons trained in VR.

19.22 Review Criteria

An extensive search of studies on vasectomy reversal, vasovasostomy, vasoepididymostomy, and robot-assisted vasectomy reversal was performed using search engines including PubMed and Google Scholar. The start and end dates for these searches were 1938–2018, respectively.

Robot-Assisted Vasectomy Reversal (Vasovasostomy)

20

George A. de Boccard

Key Points

- The outcome of vasectomy reversal dramatically improved with the use of an operation microscope.
- The precision of movements is increased with robotic assistance during microsurgery.
- The results of robot-assisted microsurgical vasectomy reversal are at least as good as with conventional microsurgery.
- New platforms dedicated to microsurgery with new concepts and new tools are being developed and will definitely make the difference.

20.1 Introduction

At the very end of the nineteenth and the early days of the twentieth century, vasectomy was used for eugenic and therapeutic purposes, but soon after World War I, it was adopted by liberal people, mainly workers and anarchists, seeking for sexual freedom, in Austria, Germany, France, and Spain [1]. Nowadays, this procedure is widely used as a contraceptive tool, and it is estimated that about 50 million men have relied on vasectomy for family planning. In Europe there is a great variation among countries, in the United States; vasectomy is used as contraceptive method by nearly 11% of married couples [2]. A minor indication for vasectomy is to prevent urogenital infections after prostatitis or prostatic surgery.

In the early years of the past century, Dr. Edward Martin, surgeon at the University of Pennsylvania, was the first to perform vasoepididymostomy in men who had obstruction secondary to epididymitis, but not vasectomy [3].

The number of vasectomy reversals is rising because of the rising popularity of vasectomy combined with the continuing upward trend of divorce and remarriage, especially in industrialized countries. The younger the vasectomy is performed, the higher the percentage of reversal [4]. The first described postvasectomy reversal was performed as soon as in 1938 [5]. Most of the demand is related with the desire of a child in common in a newly formed couple, and in order to plan the more appropriate intervention to reach pregnancy, the chances of success in terms of patency of vas and pregnancy should be considered based on the experience of the surgeon combined with the access to an assisted procreation center and the experience of the team, patient's health history, age, results of physical examination, and reproductive capacity of his partner. A potential alternative is TESE or MESA for ICSI. Some men simply wish to restore a normal physical situation without any specific desire of pregnancy. In most men, vasectomy reversal is technically feasible, but success rates depend on a variety of factors determined by both male and female fertility factors [6].

Vasectomy reversal outcome has dramatically changed with the use of the operating microscope with optical magnification in 1971 by Earl Owen who performed the first microscopic vasectomy reversals. A number of procedures were then developed using various microsurgical techniques [7–9]. This chapter reviews the application of robot-assisted microsurgery for vasectomy reversal.

20.2 Robot-Assisted Vasectomy Reversal

Robotic assistance provides a number of benefits for the microsurgeon: elimination of tremor, scaling of motion, and stereoscopic magnification. The stable robotic platform with four arms eliminates the need for a microsurgical assistant. These are the main advantages for this technically challenging procedure.

Almost all centers performing vasectomy reversals are already equipped with a da Vinci robotic platform; therefore

S. J. Parekattil et al. (eds.), *Male Infertility*, https://doi.org/10.1007/978-3-030-32300-4_20

additional cost for a vasectomy reversal is only a few hundred dollars. Many studies have reported the results of robot-assisted vasectomy reversal in animal models and in humans: Fleming [10], Kuang et al. [11, 12], Schiff et al. [13], De Boccard [14], Parekattil et al. [15, 16], and Kavoussi [17].

20.3 Surgical Technique

The surgical technique has been previously described in detail [18]. The preparation of the vas deferens for robotic vasectomy reversal is identical to the one used for classical microsurgical technique. A scrotal median incision is made (about 3 cm in length). The previous vasectomy sites are identified, and the proximal and distal ends of the vas deferens are mobilized and exposed. The testicular side of the vas is transected, and the fluid pouring out from this end is evaluated on a slide under 200× microscope magnification for the presence of sperm cells. The inguinal vas end is flushed with saline to assess for patency. Both vasa are tested at first, and then the two ends of the right vas are marked with a long 4-0 suture and left inside the scrotum. The two ends of the left vas are now placed on the microspike approximator. A white multitubular drain is tailored and placed as a background for a better visualization of the sutures and a permanent drainage of fluids from the operating field (Fig. 20.1).

Once the vas ends have been safely installed, the arms of the robot (da Vinci Xi system, Intuitive Surgical, Sunnyvale, CA) are brought into the field. The robotic system is placed on the left side of the patient as in a robot-assisted left kidney surgery and the corresponding program is selected. The laser guidance is activated using the surgeon's thumb of the open hand as the target to position the optic trocar (0° Optic is placed in arm 2) on an imaginary line that mimics an abdominal wall approximately 20 cm over the actual operating field. Then the other instruments are placed on a row: Black Diamond microforceps in arms 1 and 3 placed with a 45° angle with the optic and Potts scissors in arm 4. A special

Fig. 20.1 Placing of the stiches with precision

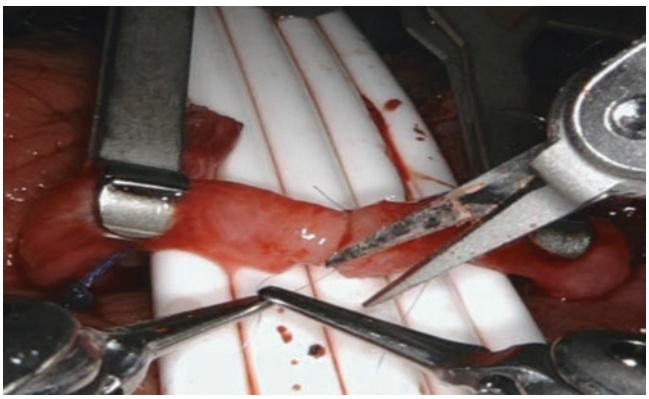

Fig. 20.2 Cutting of the threads without losing focus

attention is needed for the Potts scissors placement in order to avoid a conflict between arms 3 and 4. The scissors must appear in the field opposite of the camera. The surgeon goes then to the console. The anastomosis is now performed using polyglycolic acid (or Nylon^{R}) sutures. Two interrupted 9-0 sutures are placed posteriorly on the muscularis. Then the mucosa is sutured by six to eight 9-0 or 10-0 interrupted sutures. Finally the muscularis is secured by a corresponding number of 9-0 sutures. The use of the fourth arm with the Potts scissors improves the speed and efficiency of the procedure by maintaining a permanent focus during changing of tools (Fig. 20.2). During the anastomosis nothing should interfere with the movements, only flushing with saline in order to keep a clear view on the lumen is tolerated. After completion of the first anastomosis, the four arms are moved a few centimeter to the right of the patient, if necessary, manually by the nurse. The nurse then pulls on the 4-0 sutures marking the right vas and places its dissected end on the approximator with the white multitubular drain in the background again, and the anastomosis is performed the same way as described for the left side. At the end of the second side, the robot is pulled back. Undocking is not necessary since the trocars are not placed in the abdominal wall. The surgeon scrubs again, goes back to the field, and closes the scrotal incision with a 4-0 absorbable running suture in two layers.

Our first experiences in robot-assisted microsurgical vasectomy reversal started in 2003. Our cases between 2006 and 2009 were published previously, all 14 cases being patent after 6 months. Further publications by Parekattil et al. [16] and Kavoussi [17] demonstrated that the results of robot-assisted vasectomy reversal were at least equivalent to purely microscopic procedures.

The first advantage of the da Vinci system is its stability while placing sutures with the possibility to interrupt a movement and restart it at the very point it was left. The visibility is excellent with a stereoscopic view. The movement and zoom functions of the camera are easy without the need to

leave the tools as it is the case with many operative conventional microscopes. The movements of the arms are tridimensional allowing suturing in otherwise difficult angles with the feeling of having two right hands. The changing of tools, e.g., forceps to scissors, is done without losing focus. The forceps can keep on holding the needle while cutting the thread with the scissors. And last but not least, the surgeon sits comfortably, resting on his arms, thus avoiding many back and neck pain at the end of the day. The haptic feedback is not a concern, and it has been demonstrated that the feeling of the tension of the suture and the quality of the tissue is obtained visually and even literally felt in the hands after mastering the technique. In fact this already happens with conventional microsurgery when using smaller than 9-0 sutures.

The da Vinci surgical robotic system is already applied in almost all fields of surgery: it started with cardiac surgeons, was developed by urologists, and was soon adopted by gynecologists and general surgeon and now by plastic surgeons, ENT, and orthopedists [19]. The robot allows surgeons to significantly simplify the more complex reconstructive steps of laparoscopic and many open procedures. Almost all urological procedures are using da Vinci assistance, and we must admit that robotic technology is now the gold standard of minimally invasive surgery. And new applications for the robot are published every day as more centers report their results.

The precision of suture placement is enhanced with the elimination of the physiological tremor together with the magnification of the robotic camera (10×) even though it is not as high as that of the operating microscope. Enhanced control with motion reduction compensates for this difference. Data coming from the literature show that the precision of suture placement resulted in a more rapid and watertight anastomosis. Moreover, the robotic technology gives the surgeon an ambidextrous capacity allowing placing sutures without difference with the right or the left hand. Clinical confirmation is found in the percentage of patent anastomosis.

There is still a need for a specific microsurgical training in order to learn the techniques of suturing and the tissue response, but afterward the training curve specific to microsurgical procedure like vasectomy reversal is probably shorter than traditional microscopic techniques and benefits achieved with the surgical robot are acquired with a short learning curve. Experienced microsurgeons who already master robot-assisted surgery have an even shorter learning curve if any. A surgeon without expertise in microsurgical technique should participate in a rat microsurgery course and should have extensive lab animal microsurgery [20]. Vice versa, experienced microsurgeons need to learn to use the robot at first in a dry lab practicing suturing on different models ranging from the Konnyaku noodle [21] to the chicken thigh vessels.

The current disadvantages in using a robot for vasectomy reversal are the suboptimal instrumentation available, not originally designed for microsurgery, and the low magnification of the optic, but not the lack of haptic feedback. Those problems are about to be solved with the introduction of new robotic platforms especially designed for microsurgery like the Dutch Microsure™ system using a conventional microscope and classical microsurgical tools adapted to the robotic arms placed on a circle [22] or the Italian MMI system with its independent arms holding the finest robotic tools, driven by joysticks without a console [23]. Other systems are on their ways, dedicated to microsurgery and aiming to lower the costs of the procedure.

20.4 Outcome

With the first robot-assisted vasectomy reversal cases, we had the immediate feeling that the outcome would be at least as good if not better than with conventional microsurgery. This was soon demonstrated by animal studies [13], than by Parekattil et al. [16] and Kavousi [17] with two studies which allowed to achieve a 96% patency rate; however pregnancy rate differed only slightly with 65% in the robotic group against 55% in the manual group. Such results can be achieved manually only by longtime trained surgeons (Goldstein [24]). Contrary to some affirmations, the lack of haptic feedback doesn't lead to a less delicate handling of the tissue. The stability of the tools avoids useless manipulation, better placement, and thus more watertight anastomosis.

20.5 Costs

It has been shown by McCullough and Lipschultz [24] that costs can be hardly estimated since institutions as well as individual surgeons charge very different fees. The real cost of the robotic tools for a vasectomy reversal is approximately 450 USD since a single tool can be reused up to 10×.

The time in the operating room is the same or even less, and in an institution with a high number of robotic procedures, the cost of the robot itself for a vasectomy reversal becomes marginal.

20.6 Conclusion

Robot-assisted vasectomy reversal has become an attractive alternative to the microsurgical reversal vasectomy procedures. During the past years, this technique has reached maturity. Many publications can be found worldwide using as search terms vasovasostomy, vasectomy reversal, and robot on PubMed. This proves that this procedure has

become a standard associated with the wide diffusion in the United States and Europe of the da Vinci robots. New microsurgical platforms will improve the accessibility of the technique together with the results and probably diminish the costs, and in the coming years, the number of centers using this technology will certainly increase.

20.7 Review Criteria

An extensive search of studies on the origins of vasectomy and vasectomy reversal was performed using already published textbooks and search engines as PubMed and Google book. The start and end dates for searches on vasectomy were from 1890 through today, for vasectomy reversal from 1920 through today, and for robot-assisted vasectomy reversal from 2004 until today.

The research was based on the following keywords: vasectomy, vasectomies, male sterilization, male contraception, vasectomy reversal, vasovasostomy, vasovasostomies, microsurgery, microchirurgie, robot, robotics, robotique, and da Vinci. Research was made both in English and in French. Results in other languages (Spanish, German) were also considered. Book chapter citations and unpublished data like conferences or web videos were also considered and are included.

Robotic-Assisted Varicocelectomy

21

Tung Shu and Run Wang

Key Points

- A varicocele is currently the most common surgically correctable finding identified in men being evaluated for infertility.
- Of several surgical approaches available for the treatment of varicocele, including the retroperitoneal approach (high ligation via open, laparoscopic, retroperitoneoscopic, single-incision laparoscopic, or robotic-assisted), the inguinal approach (open), and the subinguinal approach (open microscopic), the subinguinal microscopic approach offers the best outcomes, including shorter hospital stays, preservation of the testicular arteries and lymphatics, least number of postoperative complications, recurrence, and a higher number of pregnancies.
- Microscopic assisted varicocelectomy, however, takes longer time to perform because surgeons are unaccustomed to use micro-instruments and two-dimensional vision and are unable to see their own hands.
- By using indocyanine green with the SPY Elite fluorescence imaging system, the testicular artery can readily be identified in an efficient way with minimal learning curve required.
- With miniaturized wristed instruments, 3-D camera, and computer technologies, the da Vinci® Surgical System filters and translates surgeon's hand movements seamlessly into precise micromovements of the da Vinci instruments; dramatic improvements in tissue handling, time, and skill can be achieved.

21.1 Introduction

A varicocele is defined as a meshwork of distended blood vessels in the scrotum. It is usually left-sided resulting from the dilatation of the spermatic veins or pampiniform plexus. It is currently the most common surgically correctable finding identified in men being evaluated for infertility and is observed in 8–16.2% of the normal male population and in 21–39% of infertile men [1, 2].

Several theories have been proposed to explain the observed pathophysiology of varicoceles. Semen quality uniformly declines in animals with induced varicoceles, even when there is only a left varicocele. The reduction in scrotal temperature after varicocele ligation supports a causative role of increased temperature on the infertility produced by varicocele. It has been hypothesized that varicoceles cause hypoxia, which might play a role in altering spermatogenesis in the varicocele patients [3]. A higher frequency of sperm cells with fragmented DNA has been reported in the ejaculate of subjects with varicocele, in comparison with fertile donors, a phenomenon that might be correlated with an increase in reactive oxygen species [4].

Numerous studies have reported the significant benefits on semen parameters with surgical treatment of varicocele. [4–8] Currently, there are several surgical approaches available for the treatment of varicocele [9–12], including the retroperitoneal approach (high ligation via open, laparoscopic, retroperitoneoscopic, single-incision laparoscopic, or robotic-assisted), the inguinal approach (open), and the subinguinal approach (open microscopic). Of these approaches, the subinguinal microscopic approach offers the best outcomes, including shorter hospital stays, preservation of the testicular arteries and lymphatics, least number of postoperative complications, recurrence, and a higher number of pregnancies [2, 12]. The microscopic assistance, however, takes longer time to perform because surgeons are unaccustomed to use micro-instruments and two-dimensional vision and are unable to see their own hands.

The da Vinci® Surgical System has helped surgeons overcome the limitations for both traditional open and conventional

S. J. Parekattil et al. (eds.), *Male Infertility*, https://doi.org/10.1007/978-3-030-32300-4_21

minimally invasive surgeries. With miniaturized wristed instruments, 3-D camera, and computer technologies, the da Vinci® Surgical System filters and translates surgeon's hand movements seamlessly into precise micro-movements of the da Vinci instruments. With added experience from using the da Vinci® Surgical System, dramatic improvements in tissue handling, time, and skill can be achieved [13, 14]. With preliminary experience, we have used the da Vinci® Surgical System to perform robotic-assisted subinguinal varicocelectomy in comparison with the standard microscopic approach for the treatment of varicocele [15].

21.2 Materials and Methods

Eight patients aged 29.1 ± 12.5 years underwent microscopic subinguinal varicocelectomies: seven patients with left-sided repair and one patient with bilateral repair. Eight patients aged 22.0 ± 8.0 years underwent robot-assisted varicocelectomies: seven patients with left-sided repair and one patient with bilateral repair.

All varicocelectomies were performed through inguinal incisions (Fig. 21.1a). The spermatic cord was exposed and delivered out of the wound with a Penrose drain placed underneath the cord structures (Fig. 21.1b). At this time, the da Vinci® Surgical System or operating microscope was brought in and placed above the surgical field (Fig. 21.1c). The testicular artery and vas deferens with vassal artery and small vassal veins were identified and isolated (Fig. 21.1d). Other veins within the cord were isolated (Fig. 21.1e) and ligated with 5-0 Vicryl sutures and divided (Fig. 21.1f). At the completion of the varicocelectomy, only the testicular artery, lymphatics, and vas deferens with its vessels remained.

In our later group of patients, in order to identify the testicular arteries in an accurate and efficient way, we adapted the usage of indocyanine green (ICG) intraoperatively with SPY Elite fluorescence imaging system, NOVADAQ®, Stryker Corporation. We were the first to incorporate the technology for varicocelectomy. Indocyanine green was injected intravenously. By using the SPY Elite fluorescence imaging system, a low-level light source excites ICG, and fluorescence is captured in real-time and displayed on the monitor (Fig. 21.1g). After varix ligation, ICG was used again to make sure all veins were ligated with no injury to the testicular arteries (Fig. 21.1h).

21.3 Results

The average operative time for the microscopic subinguinal varicocelectomy was 73.9 ± 12.2 minutes, whereas the robotic-assisted approach took 71.1 ± 21.1 minutes. Average follow-up time for the patients in the microscopic group was 34.3 ± 6.4 months, whereas it was 10.9 ± 7.1 months in the robotic-assisted group (Table 21.1).

In our experience, there was no difficulty in identifying and isolating vessels and the vas deferens with the robotic-assisted approach. With the aid of indocyanine green, time to identify the testicular artery was not decreased due to additional setup for the SPY Elite fluorescence imaging system. However, the accuracy of identifying testicular artery was beneficial. A short learning curve for tying with 5-0 sutures was required because of the lack of tactile sensation when using the da Vinci® Surgical System. Patients in both groups were able to resume daily activities on the day of surgery and full activities within 2 weeks. There was no intraoperative or postoperative complication. No recurrence of varicocele was observed in either group of patients.

21.4 Discussion

In 2006, we performed the first robotic-assisted subinguinal varicocelectomy using the da Vinci® Surgical System [15]. From our continuing experience, we believe that the robotic-assisted varicocelectomy can be safely and effectively performed when compared to traditional microscopic approach. There was not a significant difference with regard to operative time; however, with increased experience with the da Vinci® Surgical System, the time should decrease. When compared to the microscopic approach, the tremor is completely eliminated with the robot. More importantly, the advantage of decreased intraoperative and postoperative complications experienced with microsurgical approach is maintained with the robotic approach.

Our goal, ultimately, is to have all urologists feel comfortable to perform a microscopic varicocelectomy especially in hospitals where a robotic system is available but not a surgical microscope. The biggest challenge for a novel urologist performing a varicocelectomy is to confidently identify the testicular artery. By using indocyanine green SPY Elite fluorescence imaging system, we were the first to incorporate the technology for varicocelectomy, the testicular artery can be readily identified in an efficient way with minimal learning curve required. Of note, we advocate using indocyanine green for either robotic-assisted or microscopic-assisted subinguinal varicocelectomy.

We are currently studying the cost-effectiveness and efficacy with regard to the improvement of semen quality and pregnancy for patients with infertility with our described robotic-assisted subinguinal varicocelectomy.

(**f**) Spermatic vein ligated and divided. (**g**) By using indocyanine green, the testicular artery can readily be identified. (**h**) Post-varicocele ligation, using indocyanine green

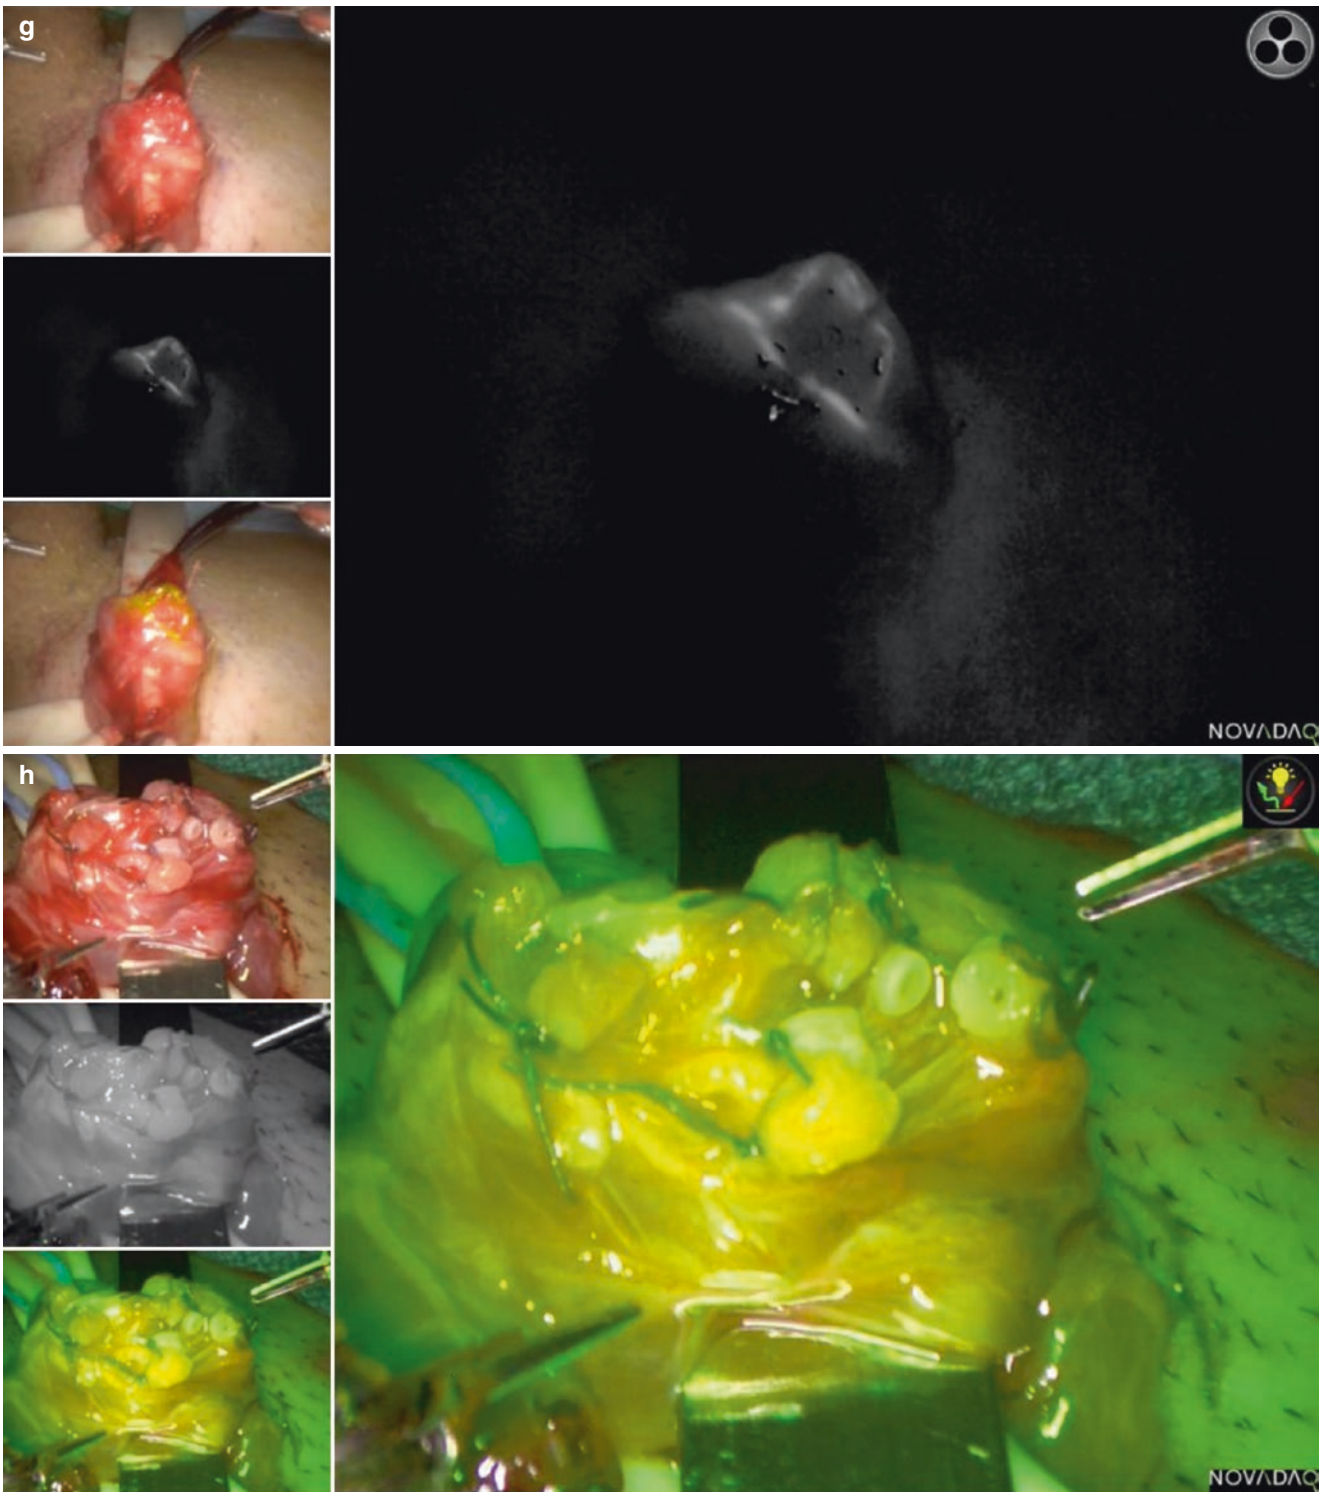

Fig. 21.1 (continued)

Table 21.1 Data of microscopic- and robot-assisted varicocelectomies

	Age (years)	Average operative time (min)	Follow-up time (months)
Microscopic technique 8 patients, 9 varicocelectomies	29.1 ± 12.5	73.9 ± 12.2	34.3 ± 6.4
Robot-assisted technique 8 patients, 9 varicocelectomies	22.0 ± 8.0	71.1 ± 21.1	10.9 ± 7.1

21.5 Conclusion

With the popularity and versatility of the da Vinci® Surgical System, hospitals throughout the world have purchased at least one system if not more for multispecialty usage. With da Vinci® Surgical System, urologist will not have to undergo a microscopic training course or a fellowship in order to perform any microscopic surgery. In the case of varicocelectomy, robotic assistance would allow any urologist to take care of a common urologic condition efficiently and effectively. By adding indocyanine green intraoperatively with SPY Elite fluorescence imaging system, the testicular artery can be readily identified in an efficient way with minimal learning curve required.

21.6 Review Criteria

An extensive search of studies examining robotic-assisted varicocelectomy was performed using search engines such as ScienceDirect, OVID, Google Scholar, PubMed, and MEDLINE. The start and end dates for these searches were Jan 2000 and Jan 2019, respectively. The overall strategy for study identification and data extraction was based on the following keywords: "varicocele," "robotic-assisted microsurgery," "varicocelectomy," and "male infertility." Articles published in languages other than English were also considered. Data that were solely published in conference or meeting proceedings or websites were not included. Websites and book-chapter citations provide conceptual content only.

Management of Fertility Preservation in Male Cancer Patients

22

Rakesh Sharma, Marlon P. Martinez, and Ashok Agarwal

Key Points

- Improvement in cancer treatment has men living beyond their reproductive years.
- All cancer therapies are potential threat to a man's reproducible potential.
- It is not possible to predict whether a man will recover spermatogenesis after cancer treatment.
- Sperm cryopreservation is the best cost-effective means if preserving man's fertility.
- With availability of ART procedure such as ICSI, it makes sperm freezing a very viable option in cancer patients.
- Barriers to sperm banking still exist, but these can be overcome by patient and provider education.

22.1 Introduction

Cancer is a common disease process that can significantly challenge individuals of all ages [1]. Of those patients who are diagnosed with cancer, 9% of them are younger than 45 years old, while 1% are younger than 20 years of age [2]. In the past 20 years, advancement in cancer therapies has significantly improved survival outcomes for young children and older adults. However, these improvements are not demonstrated in the reproductive aged population of adolescent and young adult [3].

Chemotherapy, radiation, and surgery are the primary treatment modalities for cancer. However, the potential toxicities have detrimental effects on a number of biological processes. One of the major drawbacks of cancer treatment is infertility [4, 5]. The cause of infertility may be secondary to the underlying malignancy or cancer treatment itself. Cancer affects male infertility through various mechanisms. Men are known to be at high risk of gonadal dysfunctions after cancer treatment due to the direct effect of treatment on the testes where the germ cells, Sertoli cells, and Leydig cells are present [6]. These cells are responsible for spermatogenesis and testosterone production. Any insult to these cells will lead to hypogonadism, altered semen parameters, and subsequent infertility [6].

These patients should be counseled and managed by a multidisciplinary team of healthcare specialists such as medical oncologists, urologists, reproductive biologists, and psychologists who are familiar with the cancer treatment and its complications, particularly infertility in the patients of reproductive age group. Fertility preservation must be recommended before the initiation of cancer treatment especially to those patients whose fertility is likely to be compromised [7]. The aim of this chapter is to discuss the impact of cancer on male fertility and available options for fertility preservation.

22.2 Incidence of Cancer

Adolescents and young adults are defined as men from 15 to 39 years at the time of detection of cancer diagnosis. In the United States, around 700,000 of these patients are diagnosed with malignancy each year [5]. Data from the US National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) database report that male adolescents, 15–19 years old, have had an annual increase of 0.67% in the incidence of cancer for all sites during the period of 1975–2012 [8]. This included a remarkable increase in thyroid cancer

(1.59%), testicular cancer (1.55%), and non-Hodgkin's lymphoma (1.38%). These findings imply an overall increase of cancer incidence by more than 25%. During 2008–2012, the incidence of cancer among this male age group for all sites was 22.9 per 100,000. From birth to age 19, an estimated 15,780 new cases of malignancy were detected in 2014 in the United Sates, reflecting an annual incidence of 186.6 per one million [9]. Likewise, 1 in 285 children will be diagnosed with malignant disease before they reach age 20. However, roughly 1 in 530 young adults (20–39 years) will become a childhood cancer survivor [9].

Overall, the estimated new cases of cancer in 2018 were 1.73 million in the United States (SEER), and the estimated number of deaths is 609,640 from all cancer types. Based on 2011–2015 cases, the number of new cases of cancer of any site was 439.2 per 100,000 men. During a man's lifetime, approximately 38.4% of them will be diagnosed with malignancy of any site. In New Zealand, 1541 new primary cancers were detected in men 25–29 years old between the period of 2000 and 2009 [10]. Men in this age group have twice the risk of developing cancer compared to men of 15–24 years old.

22.3 Quality of Life Concerns and Reproductive Aspirations in Men with Cancer

All men of reproductive age should be provided with adequate details about the impact of cancer therapies including their effect on future fertility. Green et al. [11] determined the effect of treatment of childhood cancer on their reproductive potential through questionnaires. 941 out of 6224 men (15–44 years) expressed their desire to father a child 5 years after being diagnosed with cancer. Radiation therapy greater than 7.5 Gy to the gonadal organs caused a decrease in initiating a pregnancy (hazard ratio = 0.12). Similar results were reported in higher cumulative alkylating agent dose score or treatment with cyclophosphamide (hazard ratio = 0.48) or procarbazine (hazard ratio = 0.48). Likewise, Armaund et al. [12] mailed postal questionnaires to 484 cancer survivors to address their concerns after cancer treatment. Men who had not initiated a pregnancy at diagnosis and were young expressed a desire to father a biological child 3–7 years after cancer diagnosis. On the other hand, 17% who did have a desire for children prior to cancer treatment changed their decisions about their wish of children posttreatment.

An online focus group discussion with childhood survivors was conducted by Nilsson et al. in Sweden [13]. A total of 134 participants including 66 males who were diagnosed with cancer before the age of 18 years and at least 5 years after the diagnosis were included in this program. Patients were concerned about the negative impact of risk of cancer treatment on infertility, their well-being, and intimate relationship with their partner. In addition, they also raised their concerns on their reluctance of being a parent due to the known consequences of having a malignant disease. In another study, 15 participants finished a 2-month web-based program focused on sexual problems and fertility distress 1–5 years after the diagnosis of cancer [14]. Although a small number of participants were included in the program, all subjects expressed their disturbed sexual functions and concerns regarding infertility.

In an exploratory qualitative study by Flink et al. [15] including 27 individuals with newly diagnosed cancers, "concern for future fertility" was the top reason for fertility preservation, while "parenthood" was the top priority [15]. Although financial constraints may hinder the utilization of fertility preservation, 50% still pursued it despite this barrier [15].

In a cross-sectional survey done on individuals at least 18 years old who banked sperm or testicular tissue before the start of cancer treatment [16], among the respondents that included 131 males, almost two-thirds who completed the questionnaires expressed desire to have a child at the present and in the future. Ninety percent of men who attempted to conceive had a child since completing cancer therapy. At the time of completion of the survey, 27% of men used their cryopreserved sperm. Although evidence is limited on the reproductive experiences of these patients, this may help those patients contemplating fertility preservation. These findings can be used to counsel male cancer patients with high risk of infertility before the initiation of cancer treatment.

22.4 Cancer in Children and Adolescents

In the United States, 18 in 100,000 children and adolescents are detected with malignancy each year [8]. It is well-recognized that young individuals diagnosed with malignancy must be provided biological, psychological, and reproductive health information [17]. Treatment of cancer in childhood and adolescence usually results in a good outcome with a 5-year survival rate for all malignancies of 80% [18]. Despite this effective treatment in this age group, modern cancer therapies may affect their reproductive ability and reduce fertility potential.

In a population-based matched cohort study in Sweden by Armuand et al. [19], male adolescent cancer survivors' ability to have a child measured had lower hazard ratio than childhood cancer survivors (0.56 vs. 0.70). The authors concluded that cancer survivors during childhood or adolescence had a lower chance of having a first live birth. In another study comprising 43 patients diagnosed with cancer between ages 14 and 18 years old who underwent cancer treatment

for at least 6 months, 3 major concerns were raised by these patients [20]. These include infertility issues, emotions when discussing infertility, and treatment options to address infertility. Fifty percent of males expressed their uncertainty about their possibility to father a child. Five males decided to cryopreserve their sperm before the anticancer therapies. It is important to recognize these treatment-associated reproductive risks in order to advise male childhood cancer survivors to improve their fertility and quality of life in the future.

22.5 Impact of Cancer Therapies on Male Fertility Potential

The main treatment options for malignancy are chemotherapy, radiotherapy, and surgery. Complete understanding of these therapeutic modalities is valuable in order to choose the most effective treatment with least deleterious sequelae [21].

22.5.1 Radiation Therapy

Radiotherapy is used as a treatment option for men diagnosed with cancer. However, radiation therapy can result in gonadotoxic effects leading to transitory or permanent detrimental effect on male reproductive potential. A dose as low as 0.1 Gy radiation can affect the rapidly dividing spermatocytes because these cells are most sensitive to radiation effects. Severe oligozoospermia and azoospermia may be observed at doses up to 0.65 Gy. Permanent sterilization can be observed at doses higher than 1.2 Gy [22].

Although considered to be the most resistant cells to radiation effect, Leydig or interstitial cells are vulnerable to damage from radiation compared to its effect from chemotherapy. Higher doses of radiation can lead to Leydig cell failure which can substantially compromise the spermatogenesis. Radiation dose less than 20 Gy can cause Leydig cell dysfunction leading to elevated luteinizing hormone (LH) levels [23]. However, radiation doses of 20–30 Gy can lead to primary hypogonadism requiring testosterone supplementation [24]. Normal testosterone production can still be seen in most men who underwent <20 Gy fractionated radiation treatment to their testis. On the other hand, young men with testicular relapse of acute lymphoblastic leukemia who received >24 Gy fractionated radiation had high risk of Leydig cell dysfunction [25].

22.5.2 Chemotherapy

Cytotoxic chemotherapeutic drugs can actively target the rapidly dividing cells. This will affect both malignant and normal cells [26]. Spermatocytes are rapidly dividing cells during spermatogenesis that are at the highest risk for the cytotoxic effects of drugs within the germinal epithelium [27]. Due to lack of cell division, more mature spermatids are less sensitive to chemotherapy. Likewise, Leydig cells are more resistant to cytotoxic drugs but when exposed to higher doses can lead to elevation of gonadotropin levels.

In an earlier study examining the use of PEB (cisplatin 20 mg/m^2, etoposide 100 mg/m^2, and bleomycin 15 mg/m^2) for the treatment of testicular cancer, conventional dose showed statistically higher sperm density compared to high-dose PEB (median 5.83 million/ml vs. 0.0005 million/ml, $p = 0.008$). In addition, a lower number of patients who had azoospermia were also reported (19% vs. 47%) [28].

Van Beek et al. [29] evaluated long-term gonadal sequelae in 56 males with childhood Hodgkin's lymphoma after the combination treatment with ABVD or EBVD (adriamycin/epirubicin, bleomycin, vinblastine, dacarbazine) with or without MOPP (mechlorethamine, vincristine, prednisone, procarbazine). Sperm concentration was significantly reduced in men who received MOPP compared to men who were treated without MOPP (1.05 million/ml vs. 49.5 million/ml, $p < 0.05$). In this treatment group, both median gonadotropin levels were significantly elevated ($p < 0.001$). In another study comprising 49 men with Hodgkin's disease treated with chemotherapy, azoospermia was observed in 42 men, while sperm concentrations below 1 million/ml were documented in 7 men [30]. Although decreased sexual drive and activity was reported in a majority of patients during treatment, it returned to normal after completion of chemotherapy. Green et al. [31] performed semen analysis on 214 adult male survivors of childhood cancers who were given alkylating agents for their chemotherapy. Azoospermia and oligospermia were observed in 25% and 28% of patients, respectively. Normal spermatogenesis was demonstrated in 89% of patients when cyclophosphamide equivalent dose less than 4000 mg/m^2 was used [31]. Nevertheless, the potential of chemotherapy affecting sperm chromatin and aneuploidy cannot be ruled out which is a major concern of embryo development [32, 33].

22.5.3 Surgery

Unilateral radical orchiectomy is considered the gold standard for the treatment of men presenting with testicular mass. This surgical procedure has a negative impact on semen quality in men with testicular cancer. Semen parameters were poorer in men with nonseminomatous testicular cancer compared with seminomatous testicular cancer. In a study by Liguori et al. [34], the median sperm concentrations before and after surgery for men with nonseminomatous testicular cancer (17.9 million/ml and 8.16 million/ml) were lower compared to men with seminomatous testicular cancer

(35.47 million/ml and 23.99 million/ml). In another study, the median sperm concentration decreased from 17 million/ml to 7 million/ml. This occurred in 30 out of 35 men who underwent radical orchiectomy and azoospermia was observed in 9% of patients [35].

Any surgical procedure performed within the pelvic cavity and retroperitoneum can cause parasympathetic nerve damage which is responsible for erection. Injury to the sympathetic nerves of the hypogastric and pelvic plexuses may lead to seminal emission and ejaculation dysfunction. Surgery, particularly retroperitoneal lymph node dissection (RPLND) as a treatment option for testicular cancer, can be a contributing factor for the development of infertility. Retrograde ejaculation is the main andrological complication in this type of surgery. In a study by Matos et al. [36] examining 297 men who underwent non-nerve-sparing RPLND, fertility rate was only 37% compared to 62% who underwent nerve-sparing RPLND. On the other hand, a fertility rate of 77% was demonstrated in men in whom RPLND was not performed. Likewise, lower abdominal surgeries for colorectal, urinary bladder, and prostate gland cancers may also lead to ejaculatory and erectile dysfunction [37]. Radical prostatectomy in particular results in the removal of a portion of the vas deferens and seminal vesicles, both of which are integral for the transport of semen outside the body.

22.5.4 Immunotherapy and Other Modalities

Immunotherapeutic agents can cause negative gonadal impact resulting in infertility. Interferon alpha has not been extensively studied with regard to its effect on male fertility. In a case report of a 38-year-old man with relapsing stage III cutaneous melanoma treated for 5 years with interferon alpha 2a (9 million units 3× a week), semen analysis revealed azoospermia and higher follicle-stimulating hormone (FSH) (14.6 mU/ml) levels. Azoospermia was observed even after 1 year of stopping the immunotherapy [38]. This is believed to be secondary to degeneration of spermatogenic cells and complete atrophy of the seminiferous tubules as demonstrated in an animal study [39]. Further studies are needed in order to conclude the negative effect of interferon alpha on male infertility.

Immunosuppressive agents used for kidney transplantation including sirolimus and everolimus can produce deleterious effects on the testis with resultant impairment of the gonadal functions. These are rapamycin inhibitors that act on the inhibition of a stem cell factor/c-kit-dependent process in immature germ cells such as spermatogonia. Almost all of the studies included in the review of Huyghe et al. [40] showed decreased level of testosterone and increased levels of LH and FSH after immunotherapy. Both transplanted patients and healthcare providers should be aware of the potential detrimental effect of these immunomodulators before commencement of the treatment.

Imatinib, a tyrosine kinase inhibitor, plays a significant role in the regulation of germ cells in the gonadal development. However, this drug can cause adverse effects on testosterone production and spermatogenesis. Shash et al. [41] reported a 36-year-old male diagnosed with chronic myeloid leukemia and treated with imatinib 400 mg/day. Despite the treatment, he fathered 2 children during the 22 months of treatment period. On the other hand, oligospermia was observed when an adolescent received a higher dose of imatinib (800 mg/day) for hypereosinophilic syndrome [42]. Likewise, prolonged administration of imatinib for chronic myeloid leukemia in an 18-year-old male resulted in severe oligozoospermia [43]. These case reports document the potential adverse effect on the derangement of semen parameters in men receiving treatment with tyrosine kinase inhibitors especially when these are given before the complete maturation and development of the gonadal organs and at higher doses.

22.6 Fertility Preservation Counseling for Men, Couples, or Family

There is an increase in cancer survivorship due to the improvement in cancer therapies. Despite of this achievement, infertility is a growing concern among men diagnosed with cancer especially young adults. That is why it is important to understand the value of fertility preservation prior to initiation of cancer treatment [44].

The only established technique for fertility preservation in men is sperm cryopreservation [45]. This is considered as an established method of fertility preservation that should be offered to children or adults of reproductive age before initiation of any cancer treatment [46].

The American Society for Reproductive Medicine (ASRM) [21] and American Society of Clinical Oncology (ASCO) [47] have formal recommendations to patients and healthcare providers regarding the detrimental impact of cancer therapies on reproductive potential and the option for fertility preservation. Sperm cryopreservation should be offered when necessary, although in some areas of this field, controversies still arise. An international recommendation from physicians with expertise in the field of fertility preservation in patients with malignancy was made in 2015 [48]. There were ten recommendations made including the recommendation that physicians discuss, as early as possible, with all patients of reproductive age their risk of infertility from the disease and/or treatment and their interest in having children after cancer, and help with informed fertility preservation decisions. Sperm cryopreservation and embryo/oocyte cryopreservation are standard strategies for fertility

preservations in male and female patients. These recommendations provide data addressing the cancer survivors' concerns about their fertility, although there are issues that still remain controversial.

Fertility preservation is not a well-documented option of concern for male cancer patients who undergo treatment. Of the 231 records comprising 4 cancer centers, only 26% documented infertility risk discussion, 24% documented fertility preservation option discussion, and 13% documented referral to fertility specialist [49]. Likewise, records were less likely to document infertility risk discussion, fertility preservation option discussion, and fertility specialist referral for patients aged 40 years old ($P < 0.001$, <0.001, and 0.002, respectively) and those who already had children (all $p < 0.001$) [49]. In another study, only 29% ($n = 201$) of male with cancers were counseled regarding their fertility risks after chemotherapy, while 11% attempted sperm cryopreservation. Of these 11%, 87% successfully banked their sperm [50].

A prospective, single-group observational study by Klosky et al. [51] on 146 adolescent males demonstrated 53.4% attempted to collect a semen sample (collection attempt) and 43.8% had successful sperm banking. Likelihood of collection attempt increased following consultation with fertility specialist ($p = 0.007$), Tanner stage >3 ($p = 0.003$), and recommendation of parent to bank ($p = 0.007$). On the other hand, history of masturbation ($p = 0.025$), banking self-efficacy ($p = 0.012$), parent ($p = 0.010$), and medical team ($p = 0.008$) recommendation to bank were associated with increased likelihood of completion of sperm banking [51].

Even though the healthcare providers are aware of the adverse effects of anticancer treatment on reproduction, men are less informed about their option of sperm banking particularly in the developing countries where banking options are limited. It is the role of the healthcare provider to educate and address the fertility concerns and options available for sperm banking to the family of the patient. In a study of oncologists' compliance with guidelines on cancer treatment-related infertility, 83% of patients were informed about this concern [52]. However, compared to women, men are less informed regarding the awareness of fertility-related concerns (OR, 3.57; 95% CI, 1.33–9.60; $p = 0.012$).

Although some of the studies show less awareness of fertility preservation, others are practicing it as part of the treatment options in cancer therapies. There is an increase from 1.73 to 5.57 per 100,000 persons per year in the overall incidence of sperm cryopreservation according to a French sperm banks between 1990 and 2013 [53]. In 2020, the projected incidence will increase to 6 per 100,000.

It is well documented that both type of malignancy and associated treatment may negatively affect male infertility. Although fertility preservation in young patients diagnosed with cancer has raised controversial concerns ethically and legally, sperm cryopreservation is still the management strategy for men before the initiation of anticancer treatment. Referral for fertility counseling and sperm banking can address fertility preservation in men diagnosed with cancer at the time of initial treatment. Members surrounding the patient play an important role in their treatment. In a systematic review by Taylor et al. [54] on the perspective, experiences, and preferences of adolescents, parents, and providers regarding fertility preservation, all these individuals were considered as key stakeholders in a shared decision-making process in every step of the treatment of the cancer patient.

22.7 Sperm Parameters and Semen Quality in Men with Cancer

Cancer and its treatment modalities can negatively affect sperm production and gamete quality. Pretreatment semen parameters in men with malignancy were extensively studied by Williams et al. [55]. During a 5-year period from the cryopreservation laboratory, 409 men with a total of 717 semen samples showed a normal range for semen volume (mean = 2.8 ml), sperm density (mean = 47.4 million/ml), and sperm motility (mean = 50%). However, testicular cancer patients had statistically reduced semen quality compared to men with other causes of malignancies. The authors recommended pretreatment cryopreservation for this set of patients before the initiation of gonadotoxic therapies. In a retrospective study ranging over a 15-year period in Korea, 66 cases of male cancer patients (age range = 19–58 years) evaluated the semen parameters prior to chemotherapy [56]. Testicular cancers accounted for 47% of cases. Among the different types of malignancy, sperm concentration (42.3 ± 48.6 million/ml, $p = 0.033$) and viability (52.4 ± 15.5%, $p = 0.012$) showed significant difference. On the other hand, semen volume (2.0 ± 1.3 ml, $p = 0.127$), motility (30.2 ± 19.1%, $p = 0.075$), and morphology (14.1 ± 10.2%, $p = 0.549$) demonstrated no significant difference. In another study, Negoro et al. [57] reviewed the records of 257 men (germ cell tumors = 113; hematological disorders = 111) with cancers who underwent cryopreservation. Of these, 25 men had successful reproductive outcomes. Men with germ cell tumors have significantly lower average sperm concentrations compared to men with hematological disorders (32.6 vs. 46.1 million/ml, $p < 0.05$). Other semen parameters showed nonsignificant results [57].

Paoli et al. [58] conducted a longitudinal study examining the sperm quality of 519 men [adolescent (13–17 years) = 50; adults (18–51 years) = 454] to determine if Hodgkin's lymphoma itself or its various treatment modalities caused impairment of sperm production impairment. Sperm concentration was normal in 75% of patients. Males (13–17 years old) had significantly lower sperm concentra-

tion (63.7 + 69.9 million/ml) and volume (1.8 + 1.3 ml) compared to other age groups, although mean semen parameters were still considered as normal. A significant decrease in sperm concentration and total number of sperm were noted after 6 ($P < 0.001$) and 12 months ($p < 0.01$) of treatment with ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine). Likewise, a significant reduction was also reported in progressive motility ($p < 0.001$) after 6 months of treatment [32].

Hotaling et al. [59] documented the raw and test-thaw semen parameters in 1010 samples from men with newly diagnosed cancer after cryopreservation. Men with prostate cancers showed best mean total motile count of raw (155.1 million) and post-thaw (53.2 million) semen quality. On the other hand, men with lymphoid leukemia showed worst raw total motile count (26.8 million), while men with myeloid leukemia had the worst post-thaw total motile count (6.9 million). Men with testicular cancer ($p = 0.0314$) and lymphoid leukemia ($p = 0.0291$) demonstrated statistically significant decreased proportion of semen samples with total motile count more than 5 million.

Although testicular cancer represents only 1% of all newly diagnosed male malignancies, it is still the most frequent cancer in adolescents and young adults in developed countries. A systematic review by Djaladat et al. [60] showed an association between testicular cancer and abnormal semen parameters even outside the treatment effects of orchiectomy, chemotherapy, and radiation.

22.8 Semen Collection for Male Cancer Patients

Patients must be encouraged to initiate and complete sperm cryopreservation before starting any cancer therapy that affects the reproductive system. Semen for sperm cryopreservation is generally obtained by masturbation. For many men, this may be an embarrassing or uncomfortable process due to cultural or religious limitations. Men may collect a semen sample at home or another location than the clinic, provided that they keep the specimen at body temperature and return it to the lab within approximately 45–60 minutes after collection. Lubricants should be avoided as they can contaminate the specimens. The entire specimen should be collected, in a widemouthed specimen container to avoid any spill out. The adolescent male population is one in which extremely careful counseling and tactful, age-appropriate instructions are necessary, as these patients are at risk for emotional distress from this process. Parents should be included in discussions, although separate sessions with the adolescent are useful. Unfortunately, no guidelines exist for the best approach to semen cryopreservation in the adolescent male, but individual institutional strategies are available [61].

At the time of diagnosis, many cancer patients are admitted in hospital as indoor patients, and this may be the appropriate time that they are offered sperm cryopreservation option. Some men are quite ill and debilitated by their cancer and are unable to produce a sample. In these cases, surgical/electroejaculatory sperm retrieval can be offered. A semen analysis is performed on all samples prior to cryopreservation. Semen parameters should be documented, and multiple collections are recommended depending on the concentration and number of motile sperm seen in the ejaculate.

22.9 Techniques for Sperm Cryopreservation

There are many steps in the process of successful preservation and storage of sperm for future use. Technical oversight in any step can adversely affect the final reproductive potential of the patient's sample.

22.9.1 Sperm Preparation Prior to Cryopreservation

Semen samples of men diagnosed with malignancy are of poor quality. Sperm washing allows the separation of the sperm and seminal plasma before cryopreservation. Sperm preparation by density gradient concentration method is another way to perform sperm washing protocol [62]. In this method, two different layers of density gradients are layered in a test tube. The high density gradient (lower phase) is layered at the bottom and the lower density (upper phase) is layered on top. The semen sample is carefully layered on the top. After centrifugation for 20 minutes, followed by resuspending the pellet, a highly motile sperm fraction is obtained that is cryopreserved.

22.9.2 Slow Freezing

Manual slow freezing usually takes to 2–4 hours to complete. Cleveland Clinic's method of controlled, slow freezing involves the complete liquefaction of the semen sample by placing the specimen in an incubator at 37 °C (Fig. 22.1) [63]. Cryovials are labeled and color coded. Freezing medium equal to 25% of the original specimen volume is gradually added to the centrifuge tube with a sterile pipette, and the specimen with the freezing medium is gently rocked for 5 minutes on a test tube rocker (Fig. 22.2). This is repeated until the added freezing medium equals that of the original

Fig. 22.1 Incubator set at 37 °C and depiction of sample undergoing liquefaction. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2014–2019. All Rights Reserved)

Fig. 22.2 Sample placed on a test tube rocker for 5 minutes after the addition of Test-yolk buffer. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2014–2019. All Rights Reserved)

specimen volume (Fig. 22.3). The cryodiluted patient sample is added to pre-labeled cryovials using sterile serological pipettes (Fig. 22.4). The labeled vials are placed in a labeled cryocane and covered with a cryosleeve (Fig. 22.5). The cryocane with 2 cryovials is placed upright in a freezer at −20 °C for 8 minutes (Fig. 22.6). Following this, the canes are removed from the -20 °C freezer and placed upright in LN_2 vapor tank (–80 °C) for a minimum of 2 hours (Figs. 22.7 and 22.8). The vials are exposed to LN_2 vapors only. The canes are flipped after 24 hours and plunged in LN_2 (–196 °C) and placed in long-term storage until ready for use (Fig. 22.9).

After 24 hours, the test vial is removed; the cap is loosened and placed in the incubator at 37 °C. The sample is mixed and analyzed using the computer-assisted semen analyzer for count, motility, curvilinear velocity, linearity, and amplitude of lateral head movement. Sperm cryosurvival is calculated by examining the percentage motility of post-thaw specimen to that of the pre-freeze specimen. The number of inseminations possible from the frozen specimen is calculated based on the fact that 15–20 million are required for one insemination [64].

The major drawback with this technique is that ice crystals can form within cells if the cooling rate is too fast. Additionally, slow cooling can shrink the cells due to water osmosis and cooling rate [65]. Slow, staged freezing using automated, computerized methods limits cryodamage of low-quality sperm [66]. However, automated freezers are time-consuming and expensive, requiring up to five times more liquid nitrogen [67].

Slow freezing technique, as proposed by Behrman and Sawada, [68] is widely applied for sperm cryopreservation. This technique progressively cools the sperm over a period of 2–4 hours. Using a programmable freezer, this can be done either manual or automatic. Slow freezing is based on dehydration which happens during cooling process. Ice masses containing crystalline water are created. Compared to rapid freezing, this technique allows the sperm to slowly adjust to lower temperature. As a result, it causes less osmotic strain on the cellular membrane of the sperm [69].

Using the manual technique, this is simultaneously performed by lowering the semen temperature while putting cryoprotectant in a stepwise manner [70]. The optimal initial cooling rate of the semen sample from room temperature to 5 °C is 0.5–1 °C/min. Before the sample is plunged into liquid nitrogen at –196 °C, the sample is frozen from 5 °C to –80 °C at a rate of 1–10 °C/min. Although slow freezing is a commonly used method for sperm cryopreservation, another technique such as vitrification is a faster, easier, less toxic, and less expensive method [71].

22.10 Rapid Freezing

Rapid freezing protocols are commonly used for sperm cryopreservation and provide better post-thaw motility and cryosurvival than slow freezing protocols in non-oncologic controls [72]. The Irvine Scientific method is a fast and convenient cryopreservation method that can be used to rapidly freeze and store sperm for a longer term. With this method, the entire volume of freezing medium is added at one time, and the specimens are immediately immersed in liquid nitrogen [64].

This rapid freezing technique requires direct contact between the straws and nitrogen vapors for 8–10 minutes before plunging into liquid nitrogen at –196 °C. Due to the formation of extracellular ice crystals, it lessens the cryoprotectant toxicity and osmotic damage as well [69]. The semen sample is first mixed with equal volume of cryoprotectant. It is placed in a vial or straw and then in nitrogen vapor at −96 °C for 2 hours. Finally, it will be immersed in liquid nitrogen at −196 °C. Compared to slow freezing method, rapid freezing showed superior motility and survival outcomes after thawing [64].

22.11 Sperm Vitrification

Recently, sperm vitrification has been advocated as an alternative to slow freezing method. Vitrification, an ultrarapid freezing method, may offer improved results compared to rapid freezing protocols [73–76]. The vitrification technique is advantageous in that it requires no equipment and is straightforward, quick, and inexpensive. It is more commonly used to freeze oocytes and embryos. Spermatozoa are osmotically fragile, and the use of high concentrations of permeable cryoprotectants is cytotoxic, drastically reduces spermatozoal motility, and compromises sperm DNA quality. Cooling can be achieved using either liquid nitrogen or liquid nitrogen vapor phase. Vitrification—either with no cryoprotectant or very low levels of cryoprotectant—has been reported [77, 78]. In normospermic samples, no significant difference was reported in the sperm recovery rate and motility rate between spermatozoa cryopreserved without any cryoprotective agent and those preserved with sucrose [78]. Furthermore, the authors reported a higher viability and lower DNA damage than those cryopreserved with sucrose using a cryotop carrier. Lack of cryoprotectant is compensated by the use of high cooling rates achieved by directly plunging samples into liquid nitrogen [~720,000 K/min]), and the use of an extremely small sample volume increases the surface area for exchange of heat [79].

This technique rapidly cools the semen sample at a rate of more than 1000 °C/min without the risk of ice formation [69]. A comparative experimental study was done by Riva et al. between slow freezing and ultrarapid freezing method [80]. They showed that slow freezing had lower progressive motility and higher nonprogressive and immotile sperm count compared to ultrarapid freezing. In addition, the former had significantly higher sperm DNA fragmentation (47.3 ± 13.4% vs. 14.6 ± 4.6%, $p < 0.05$).

In another study, vitrification was not superior to rapid freezing in men with normozoospermic sample. In 30 normal ejaculate samples, Agha-Rahimi et al. demonstrated no significant difference in sperm DNA fragmentation between the two techniques (15.7 ± 4.4% vs. 16.6 ± 5.6%, $p > 0.05$) [81]. Progressive motility and viability showed nonsignificant relations as well. According to the latest meta-analysis

comparing vitrified and conventional cryopreserved samples [82], post-thawed sperm following vitrification demonstrated significantly higher total motility (weighted mean difference (WMD) 6.98; 95% CI, 2.94–11.02; $p < 0.0001$) and progressive motility (WMD 4.59; 95% CI, 0.78–8.39; $p = 0.02$). Sperm DNA fragmentation did not show any significance between the groups being compared. However, due to the small number of studies available, the authors suggested a large well-conducted study in order to validate these findings accurately.

22.12 Options for Home Banking: An Innovation-Based Approach

An attractive alternative option for patients who are unable to travel or for those who find providing a semen sample at a sperm bank emotionally challenging is the introduction of a home sperm banking kit called NextGen. With this kit, patients can collect a semen sample in the privacy and comfort of their home and ship it overnight to a sperm banking facility. Cryosurvival rates were examined in sperm collections from patients with and without cancer—both on-site and off-site—using remote collections with the NextGen kit [83]. Pre-freeze and post-thaw sperm motility, total motile sperm, and percent cryosurvival rates were compared. Cryosurvival rates were similar between the NextGen and on-site collection samples in both infertile men (53.14 ± 28.9% vs. 61.90 6 ± 20.46%; $p = 0.51$), respectively, and men with cancer (52.71 ± 20.37% vs. 58.90 ± 22.68%; $p = 0.46$). Cancer patients can bank sperm effectively using the NextGen kit.

22.13 Cryopreservation of Epididymal or Testicular Tissue: Indications and Techniques

The advancement and development of assisted reproductive technology (ART) particularly intracytoplasmic sperm injection (ICSI) using the surgically retrieved testicular and epididymal sperm have dramatically altered the reproductive potential of men with obstructive azoospermia (OA) and nonobstructive azoospermia (NOA) [84]. In intrauterine insemination (IUI) and in vitro fertilization (IVF), use of ejaculated sperm is standard practice due to availability of enough large number of live and motile sperm even after thawing. In addition, less contamination with blood cells and cellular debris can be observed in ejaculated sperm sample. However, some conditions and scenarios will dictate the use of cryopreserved testicular and epididymal sperm in the management of male infertility.

With the current advancement in the field of cancer treatment, the overall outcome of a patient with malignant disease has improved significantly. In male children and adolescents diagnosed with cancer, in whom spermatogenesis has not yet been initiated, cryopreservation of testicular tissue before the start of cancer treatment like chemotherapy and radiation will offer reproductive potential in the future [85]. In prepubertal boys, cryopreservation of the testicular tissue is the only way of preserving the future fertility [86]. Keros et al. cryopreserved testicular tissues from five prepubertal boys before the initiation of gonadotoxic treatment [87]. There were no clear structural changes observed in the fresh and cryopreserved testicular tissue samples. For young boys whose sperm production is not yet evident, cryopreservation of immature testicular tissue is an option [88].

Azoospermia is the main reason for attempting sperm retrieval from the testis or epididymis. In men with NOA, a wide list of possible etiologies and severity of the underlying conditions can be faced by the specialist. This may prove a challenge in obtaining enough sperm sample for cryopreservation. History of chemotherapy or radiation exposure can contribute to NOA [84]. The gold standard of sperm retrieval for men with NOA is microdissection testicular sperm extraction (microTESE) [89, 90]. In a recent meta-analysis of the comparison of different sperm retrieval techniques, microdissection TESE had a 1.5 times more probability of sperm retrieval rate (SRR) compared to conventional TESE [91]. On the other hand, SRR was twice more likely with conventional TESE compared to testicular sperm aspiration (TESA).

Sperm can be surgically retrieved from the testis or epididymis in patients with OA [92]. Contrary to men with NOA, retrieval is restricted to the testis. Testicular sperm retrieval can be performed by an open testicular biopsy or testicular sperm aspiration (TESA). The conventional method of testicular extraction provides the best chance of acquiring large number of tissues. However, Schlegel revolutionized this technique into microTESE removing significantly less testicular tissue (9.4 mg vs. 720 mg) with superior SRR compared to conventional technique [90]. Multiple testicular sperm extractions can cause irreversible damage and to some extent can lead to testicular atrophy [90]. On the other hand, testicular sperm aspiration is a relatively fast and easier method of testicular sperm retrieval [85]; however, SRR is lower compared to open testicular biopsy especially in men with NOA [93]. Retrieval of epididymal sperm can be done by percutaneous epididymal sperm aspiration (PESA) or by microsurgical epididymal sperm aspiration or by fine needle aspiration (FNA). These procedures are good options for men with obstructions at the level of the vas deferens or epididymis and offer good SRR [84].

22.14 Fertility Preservation in Prepubertal Boys: Experimental Techniques with IRB Guidelines

Although ICSI using frozen sperm has revolutionized infertility treatment, it is not applicable in prepubertal boys since spermatogenesis has not begun. In such cases preserving spermatogonial stem cells (SSCs) can be recommended to prepubertal patients diagnosed with cancer and who are at a risk of losing their SSCs or are at a risk of developmental genetic disorders [94]. Testicular tissue with spermatogonial stem cells may be used in the future for fertility preservation in men and boys prior to treatment, as these cells are capable of self-renewal, proliferation, and repopulation of the seminiferous tubules [95]. Although germ cell transplantation has become an important research tool in rodents and other animal models [96–102], the clinical application in humans remains experimental. The technique of autotransplantation of SSCs in testicular tissue has shown promising results in animals and nonhuman primates. However, cryopreserving the testicular tissue containing SSCs is the first step in translating SSC-based cell therapy into clinical practice, and it is important to evaluate their quantity and functionality as a translational therapy.

Regarding testicular grafting as another exciting strategy for fertility preservation in males prior to gonadotoxic therapy, both autologous and xenologous transfer of immature tissue revealed a high regenerative potential of immature testicular tissue and generation of sperm in rodents and primates [97]. Like germ cell transplantation, however, further research is needed before an application in humans can be considered safe and efficient. Despite current limitations with regard to generation of sperm from cryopreserved male germ line cells and tissues, and since future improvements of germ cell transplantation and grafting approaches are likely, retrieval and cryopreservation of testicular tissue prior to therapy should be offered to young men with cancer who are at high risk of fertility loss, as this could be their only option to maintain their fertility potential after treatment [103, 104]. Additionally, prepubertal testicular tissue from boys facing gonadotoxic treatment may be cryopreserved under special conditions. Doing so may offer fertility preservation for young patients in the future [87].

A potential concern about using spermatogonial stem cells and testicular grafts is the theoretical risk of restoring cancer cells back into the recipient. This effect has been demonstrated in leukemic rat models [104]. But efforts have been made to reduce this risk using telomerase in culture [105]. The use of embryonic stem cell technology to treat infertile men is also under investigation; however, significantly more translational research is needed, before these technologies are applied to the treatment of human male infertility [106].

Experimental protocols for cryopreservation of human testicular tissues from boys recently diagnosed with cancer have been developed [107, 108]. Another protocol has been introduced [108] for testicular tissue banking by collecting biopsies from both testis of prepubertal boys diagnosed with cancer and undescended testicles. While experimental testicular tissue banking is an option for future fertility applications in humans, the in vitro germ cell differentiation using cryopreserved testicular tissue has been demonstrated [109, 110].

22.15 Sperm Quality After Cryopreservation

Sperm quality in cancer patients (before freezing and after thawing) is generally worse than those of healthy donors [59]. Prostate cancer patients show the best pre-freeze total motile count (TMC) (155.1×10^6), whereas lymphoid leukemia the worst (26.8×10^6). Of all the semen parameters, compared with the controls, motility was most affected in cancer patients ($<5 \times 10^6$ TMC). Sperm quality also depends on the abstinence time between semen collections. When the cancer treatment is urgent, the normal abstinence time can be reduced from 2 to 5 days to more frequent collection schedule, sometimes multiple ejaculations within a day or two [111].

In a recent report, men with testicular germ cell tumor (TGCT) had a sperm survival rate of only 44.8% and had the lowest odds of a post-thaw total motile cell (TMC) above 5 million compared with controls and men with other types of cancers; they also had the lowest odds of successful intrauterine insemination (IUI) [59]. Men with seminoma demonstrated higher sperm concentration, TMC, and percentage motility than those with nonseminomatous germ cell tumor (NSGCT) [112, 113]. On the other hand, NSGCT histology was associated with a higher post-thaw TMC (OR: 4.3) than seminoma. The association between TGCT histology and cryosurvival is not clear and may be related to testicular development, Sertoli cell function, or gene and protein expression [114, 115]. Semen quality is comparable in repeated ejaculates from cancer patients [116]. However, conflicting results have been reported between cancer stage and semen parameters [59, 117, 118].

22.16 Procedure for Post-thaw Sperm Preparation

When semen is cryopreserved, a small aliquot of the sample is frozen separately, thawed, and reanalyzed after the initial freeze. This “test thaw” allows the post-thaw survival to be determined as it can vary among individuals and even among different ejaculates from the same person [61]. Post-thaw

sperm motility is a good representation of the entire ejaculate and gives a reliable estimate of the total motile sperm count for that sample in the future [119].

22.17 Number of Ejaculates Stored Prior to Use of Cryopreserved Sperm

The number of vials cryopreserved is determined by the quality of sperm, health of the individual, the type of cancer, time to start cancer therapy, and the type of ART procedure that will be required to achieve a pregnancy [120]. Therefore, optimizing the post-thaw TMC and cryosurvival is important [121]. While sperm quality is poor in cancer patients and may not be optimal for IUI, sperm of poor quality can be used for intracytoplasmic sperm injection (ICSI).

Cancer patients have worse parameters compared to controls, so this must be taken into consideration for the post-thaw total motile count for IUI [59]. As a rule of thumb, given a 50% cryosurvival from conventional cryopreservation, many laboratories would consider a pre-thaw motile sperm count of 10 million necessary to obtain approximately 5 million sperm after thawing, and this number is adequate for IUI [122–124]. This would be the ideal number of sperm frozen per vial so that each vial could be used with each subsequent IUI. Sperm concentration of >5–10 × 10^6 sperm is predictive of successful IUI [122, 125]. It is recommended that patients with TGCT freeze a minimum of 15 vials (about 1 million/vial) before oncological treatment, thereby providing adequate sperm for two IUI attempts. A similar number (>5×10^6 TMC) is needed to freeze for conventional IVF. If the sperm count or other parameters are lower than this, the samples can be aliquoted into a number of vials to be used for intracytoplasmic sperm injection [59].

22.18 ART Outcomes in Cryopreserved Sperm

Success rates of IVF and ICSI treatment using cryopreserved sperm are almost as high as fresh semen [126–128]. In cancer patients, using cryothawed sperm, the pregnancy rate per cycle and per couple in the IUI group was 11% and 32%, while it was 37% and 68% in the ICSI group. ICSI has been suggested as the preferred method of treatment for achieving pregnancies using cryopreserved sperm in cancer patients [129–134].

Naysmith et al. assessed the effect of cancer treatments on the natural and assisted reproductive potentials of men. Semen samples were analyzed before and after cancer therapy. Twenty-seven percent of the men had abnormal semen parameters before treatment, whereas 68% of the samples were abnormal after cancer treatment. Twenty-three percent of men developed azoospermia after treatment. Sperm cryopreservation prior to treatment improved the fertility potential of 55% of the patients. The authors commented that improving awareness and education of patients and providers on the impact of cancer and cancer treatments on fertility is essential. They also stressed that with the advent of ICSI, all men with cancer should be offered pretreatment sperm cryopreservation, as even in men with very low sperm concentrations, the chances of conception are very reasonable [135].

Schmidt et al. [136] reported their experience with couples referred for ART because of male factor infertility due to cancer and cancer treatment. Most of their patients had testicular cancer and lymphomas. Ninety percent of the men had adjuvant treatment with chemo- and/or radiation therapy. Perhaps, most impressively, semen was cryopreserved in 82% of the men prior to treatment. Following cancer therapy, 43% of the men had motile spermatozoa in the ejaculate, while 57% were azoospermic. Both fresh and cryopreserved sperm were used, and the clinical pregnancy rates per cycle were 14.8% after IUI, 38.6% after ICSI, and 25% after ICSI-frozen embryo transfer, with corresponding delivery rates of 11.1, 30.5, and 21%. Cryopreserved semen was used in 58% of the pregnancies. Of note, the delivery rate per cycle was similar after use of fresh or cryopreserved sperm. The authors concluded that male cancer survivors have a good chance of fathering a child by using either fresh ejaculated sperm or cryopreserved sperm and that ICSI be used as a first choice, given the better success rates with ICSI as well as the need for overall higher total motile sperm counts for IUI which are not always available post-thaw [129]. These reports of successful pregnancies with cryopreserved sperm in male cancer survivors are supported by numerous other studies [133, 137–143].

Van Casteren et al. reported their experience with ART using cryopreserved semen of cancer patients [130]. Five hundred and fifty-seven male cancer patients banked 749 semen samples. Out of the total group of 557 men who cryopreserved semen, 218 (39%) returned for semen analysis after cancer treatment. Motile sperm were found in 155 (71.1%) of these 218 men. Twenty of these 218 men reported a natural pregnancy. While only 42 of the cancer survivors (9.6%) ultimately requested the use of their banked semen, half of these men were successful in having live births using IVF/ICSI [130] indicating the importance of sperm cryopreservation before cancer therapy.

22.19 Utilization of Cryopreserved Samples

A few studies have looked at the utilization of cryopreserved sperm by male cancer survivors. In one study of 258 men, only 18 returned for treatment [144]. Ginsburg et al. found

that at their fertility center, 19 male cancer survivors underwent a total of 35 IVF cycles, and 11 of these cycles used cryopreserved semen [142]. In two studies, Magelssen et al. and Edge et al. looked at posttreatment paternity in 1388 testicular cancer survivors. Four hundred and twenty-two of these men had cryopreserved semen after orchiectomy. Overall, only 29 men (7%) used their cryopreserved semen for ART, while 67 men (17%) fathered at least one child with fresh semen [145, 146]. Lastly, according to a study by Saito et al., if male cancer survivors resume spermatogenesis following treatment, none would choose to use their cryopreserved sperm. Even if the cryopreserved sperm was not used, as in most cases, a positive psychological effect of having banked sperm was achieved [147]. The utilization of frozen samples remains low [148]. It is difficult to know the fertility status of the patients who do not come forward for follow-up testing, those conceiving naturally, those with no intention of conceiving, and those who may have psychological reasons for not participating. Because utilization of banked specimens is low, sperm banks should be carefully managed to ensure that resources are targeted to the patients in most need.

22.20 Challenges, Barriers, and Safety Issues of Sperm Cryopreservation

When cryopreserved samples leak in liquid nitrogen, there is a potential for cross-contamination to occur [149]. Regulatory bodies have issued current good tissue practice (CGTP) guidelines to prevent any adverse events resulting from these risks. All facilities offering sperm banking are regulated by the FDA and American Association of Tissue Banks (AATB) guidelines and are required to be registered with these bodies. The FDA has issued guidelines for businesses that provide human cells, tissues, and cellular- and tissue-based products; these establishments must follow the requirements in the CGTP regulations.

Crawshaw et al. [150] reported five main challenges of sperm banking in young cancer patients: attributes of professionals, skills of professionals, consent issues, issues relating to the effects of the process on the young men, and follow-up services. This study outlined the difficulties in building and maintaining an adequate knowledge and skills base in this field and lack of appropriate training [151]. Challenges also arise about what is to be done with stored materials in the event of the patient's death.

There are a number of barriers that can prevent patients from receiving fertility preservation counseling: lack of time during a patient visit, anxiety at the time of diagnosis, conflicting cultural or religious views, loss to follow-up during referral to a specialist, an inadequately communicated sense of seriousness regarding fertility loss, and a physician who is poorly informed about fertility preservation options [152].

Naturally, discussing potential fertility loss can cause patients to become very anxious—58% of patients felt that their levels of anxiety had affected their ability to think about fertility. It may be beneficial instead for physicians to discuss fertility preservation options initially at the time of diagnosis and again perhaps a week later but still before the start of treatment. Cultural or religious views that oppose masturbation or artificial insemination, for example, may also prevent fertility discussions from occurring productively [153].

Physicians who do not work in reproductive medicine may have a suboptimal knowledge of the effects of cancer and associated treatment on fertility, and this may be the limiting reason why many patients do not receive fertility counseling [107, 154]. The American Society of Clinical Oncology (ASCO) in their 2006 guidelines recommended sperm banking as a standard part of care, but it is still not implemented as often as it should be. Educating both physicians and other healthcare providers to integrate sperm banking awareness among the difficult discussions with their patients is vital [155].

Counseling adolescent patients poses an additional challenge to healthcare providers [154]. Doctors must work to alleviate patient anxiety by considering biological issues and acknowledging the psychological needs and individual situation when counseling young cancer patients [156]. Uncertainty on how to navigate the legal and ethical issues may discourage them from appropriately counseling these patients.

Many patients and their families make use of open and spontaneous discussion about fertility [154]. Such discussions can encourage patients to look to the future and reassure them that the aim of cancer therapy is cure. Sperm banking options must be on a case-by-case basis, especially in instances where a patient may be too sick with a very poor prognosis to produce a semen sample—in this case, sperm cryobanking may not be worth the effort.

Future infertility is not a problem of an individual, but of the couple, and a product of a family. As a result, decisions regarding fertility preservation can impact others besides the patient. This is true in case of minors, where these patients have little autonomy to decide sperm banking without their parents' approval [107]. In other instances, some families may not be comfortable discussing masturbation, sexuality, or reproduction issues with their son. The boys themselves may feel particularly uncomfortable talking openly about these issues or providing a sample via masturbation, or they may not fully understand the future implications of a more immediate loss of fertility if they are too young to be thinking about having children. Asking them to produce a sample when accompanied by a parent may unduly embarrass them.

Another serious ethical issue is the postmortem period in cases where the patient did not use his semen sample. Who does the sample belong to? Each clinical circumstance is unique, and each individual patient's diagnosis, prognosis, current desires and future hopes, relationship status, and (specifically in adolescents) maturity level must be taken into account when discussing fertility preservation options.

22.21 Factors Preventing Individuals from Banking

While options for fertility preservation or sperm banking are available, and more patients continue to be referred by their oncologists to discuss their fertility options, knowledge regarding the medical application of fertility preservation is still lacking particularly in the developing countries and in remote areas of developed countries. Even when patients were properly informed regarding infertility risk and cryopreservation, 42–54% did not use sperm banking [157]. Despite the well-established link between antineoplastic therapy and infertility, only 18–24% of young men with cancer were reported to have banked their semen prior to treatment [158]. Studies have shown that only 5–10% of patients who bank their semen prior to treatment return for IVF treatment using their cryopreserved specimens [137].

The psychological consequences of banking/not banking among patients in need of fertility preservation, particularly in the context of oncofertility, have been reviewed recently [159]. In another report, a significant variability was reported in the practice of fertility preservation for patients with cancer [160]. In that study, a 36-item survey was sent to board-certified reproductive endocrinologists. The results showed that 83% of the participants reported counseling men with sperm banking with 22% recommending against sperm banking for men previously exposed to chemotherapy. Overall, 79% of the respondents reported knowledge of the American Society of Clinical Oncology fertility preservation guidelines—knowledge that was associated with providers offering gonadal tissue cryopreservation in both men and women diagnosed with cancer, suggesting variability in how reproductive endocrinologists manage fertility preservation in cancer patients.

Effective promotion of sperm banking involves adequate communication regarding the severity and personal risk for infertility, assessment of the importance of having children, emphasis on the benefits of banking, and addressing possible obstacles such as cost, misperceptions, or cultural and other factors [161].

There are various factors for underutilization of sperm banking among young men. Some of the common factors cited were:

(i) Priority

Sperm banking is not usually a priority for patients who have already completed their family and for those that do not want to have children or for patients who are too young to understand the impact [161].

(ii) Cost

Presumed high cost by healthcare professionals is a major factor in sperm banking for patients [162]. In most instances, banking is not covered or is partially covered by insurance agencies. As cancer, itself, may already have a profound financial impact, many patients have concerns regarding the cost of sperm banking and continued long-term storage of specimens [161]. A survey of patients revealed that financial constraints were a major obstacle for 7% of cancer survivors who chose not to bank sperm [158]. Cost may play an even larger role in younger patients with limited or no income [161].

(iii) Time interval

The urgency to start therapy as soon as possible is also a major factor that prevents young patients from sperm banking [163]. Patients with leukemia have a relatively short time interval between initial diagnosis and the initiation of gonadotoxic therapy [164].

(iv) Lack of information

Very few men diagnosed with cancer bank their specimens, and the most common reasons in one study were lack of information or the attitude of the oncologist and practices regarding banking of sperm before cancer treatment [165]. There is a lack of education/counseling services by healthcare professionals [166] and limited use of cryopreservation by urologists and gynecologists in most fertility programs due to a lack of information regarding the effectiveness of gamete cryopreservation and a lack of agreement on the best universal method.

(v) Psychosocial issues with sperm banking—anxiety and emotional stress

A diagnosis of cancer at any stage of life (young or old) can provoke a life-altering crisis. The diagnosis itself and the threat of infertility both can cause a tremendous stress on these individuals [158, 165, 167]. Schover et al. [158, 165] noted some interesting psychological aspects in cancer survivors: (1) they may experience a higher level of infertility distress than healthy controls with (2) adolescents being more distressed than adults, (3) women are more often distressed than men, (4) those with inheritable cancers are more frequently distressed than those with noninheritable cancers, (5) a lower quality of life might be associated with less concern with regard to infertility, (6) cancer survivors might view their relationship with children more positively and (7) be more likely to prefer adoption or third-party donation, and (8) overall, they may lack accurate risk knowledge [167, 168]. These factors need to be acknowledged by healthcare professionals and utilized in proper care and treatment of these patients.

Surveys show that failure of physicians to provide patients with sufficient information in a timely manner is one of the

main reasons patients fail to utilize cryopreservation [169]. This could include situations in which the option was not presented entirely [158], the actual risk of infertility was downplayed by the physician [161], or patients who expressed interest failed to receive counseling and referral to a sperm bank [158]. These investigators reported that although more than 90% of oncologists felt that male patients at risk for infertility should be offered sperm banking [158], only 52% discussed the option with their patients [169]. Providing the patient with accurate information may help restore the patient's perception of the benefits of sperm banking. Rates of cryopreservation might be further improved by presenting sperm banking as a standard practice to patients and their families.

22.22 Counseling and Ethical Considerations

Counseling patients on fertility preservation, especially at the time of an initial oncologic diagnosis, can be challenging. The counseling should be offered by the oncologist or the physician who is delivering the diagnosis [130]. The important task of the oncologist is to clearly explain, in a compassionate manner, the disease, possible lines of therapy and probable implications of the disease, and its effects on male infertility. It is important to highlight the role healthcare practitioners play in patient decision-making with regard to fertility preservation [153]. Early and open communication with patients and implementation of a multidisciplinary oncofertility team are vital.

Because cancer and cancer treatment both adversely affect spermatogenesis, the onus is on the oncologist to discuss the effects on fertility and fertility preservation options and stress the importance of cryopreservation. It is the responsibility of the reproductive medicine specialist to ensure that other physicians are aware of the relatively good pregnancy outcomes that can be achieved with cryopreserved semen [130]. Educating physicians outside reproductive medicine as to when to refer a patient to a fertility specialist and discuss sperm banking and subsequent future fertility options is vital [130]. Oncologists should also be aware of contemporary ART treatment options available such as ICSI that require single healthy sperm for fertilization.

One organization, SaveMyFertility.org, is dedicated to increasing awareness of fertility preservation options among both providers and patients by providing informative materials that facilitate and stimulate discussions on the importance of sperm cryobanking (save my fertility.org). It is recommended that physicians initiate and guide sessions on fertility preservation with their patients. An informed nurse and other healthcare provider staff, however, may be helpful in providing continuing support throughout oncologic treatment [155].

22.23 Cost-Effectiveness of Fertility Preservation in the ART Era

Presumed high cost by healthcare professionals is a major factor in sperm banking for patients [162]. A survey of patients revealed that financial constraints were a major obstacle for 7% of cancer survivors who chose not to bank sperm [165]. Cost may play an even larger role in younger patients with limited or no income [161]. A recent study by Gilbert et al. [114] reported the cost-effectiveness of pretreatment fertility preservation vs. posttreatment fertility management in patients with testicular cancer. Sperm cryopreservation before chemotherapy or radiation therapy remains the most cost-effective strategy for fertility preservation across a range of possible costs associated with surgical sperm retrieval and ART.

22.24 Future Research Strategies

Sperm cryopreservation prior to undergoing chemotherapy or radiotherapy remains the most cost-effective strategy for fertility preservation, across a range of possible costs associated with surgical sperm retrieval and in vitro fertilization/intracytoplasmic sperm injection [114]. As part of education and informed consent before cancer therapy, healthcare providers (including medical oncologists, radiation oncologists, gynecologic oncologists, urologists, hematologists, pediatric oncologists, and surgeons) should address the possibility of infertility with patients treated during their reproductive years (or with parents or guardians of children) and be prepared to discuss fertility preservation options and/or to refer all potential patients to appropriate reproductive specialists. Sperm cryopreservation is considered a standard practice [170]. Other fertility preservation methods should be considered investigational and should be performed by providers with the necessary expertise. According to the latest ESHRE-ASRM Expert Update on fertility preservation [45], semen cryopreservation is the only established method of fertility preservation in men diagnosed with cancer at this stage.

Testicular tissue cryopreservation can be offered under IRB guidelines as an experimental procedure in prepubertal boys, because fertility restoration strategies by autotransplantation of cryopreserved testicular tissue have not been tested for safe clinical use for humans. Genetic stability of long-term culture of human SSCs from two cancer patients has been reported [171]. Fertility restoration strategies using autotransplantation of cryopreserved testicular tissue have not been tested for safe clinical use in humans [172]. Using proteomic platform to understand the underlying alterations in major reproductive pathways affecting the fertilizing

potential in cancer patients cryobanking their specimens before cancer treatment can shed further light on future management strategies in these men [173].

22.25 Conclusion

Improvements in cancer treatments have resulted in more men living into their reproductive years, and fertility is an important measure of quality of life in this patient population. However, all cancer therapies—chemotherapy, radiation, and surgery—are potential threats to male reproductive potential. The type of treatment(s) and individual susceptibilities to the deleterious effects of these treatments make it next to impossible to predict whether or not a man will recover spermatogenesis after therapy and what will be the status of fertility potential in these individuals. Stem cell transplantation technologies may hold promise in the future but are unavailable for use in humans at this time.

Many men in various stages of life could benefit from utilizing sperm cryopreservation. This makes sperm freezing a very viable option for cancer patients. Fertility preservation options should be discussed at an early stage during treatment planning for cancer. Efforts continue to optimize sperm freezing methods including recent research efforts in providing cryoprotectant-free sperm vitrification and refining the cooling and warming protocols to obtain optimal outcomes with vitrification. Assisted reproductive techniques such as ICSI offer a promising solution to enhance the rate of successful fertilization and subsequent pregnancy.

Barriers to sperm banking still exist, but the sensitive nature of this option can be overcome by patient and provider education, as well as deliberate, coordinated strategies at comprehensive cancer care centers to make fertility preservation for male cancer patients a priority during pretreatment planning. By all indications, the role for fertility preservation is only likely to increase over the next several decades. Providing fertility preservation options to these survivors is therefore imperative. It is important to offer the patient the option of fertility preservation rather than precluding his chance of fathering a biological child.

22.26 Review Criteria

An extensive search of studies examining the relationship between cancer and fertility preservation was performed using search engines such as Google Scholar and PubMed. The start and end dates for these searches were September 1985 and December 2018, respectively. The overall strategy for study identification and data extraction was based on the following keywords: “male infertility,” “cancer,” “chemotherapy,” “gonadotoxicity,” “sperm retrieval,” “sperm banking,” “semen parameter,” “fertility preservation,” “freezing techniques,” and “challenges in sperm cryopreservation.” Articles published in languages other than English were excluded. Data published in conference or meeting proceedings, websites, or books was also excluded.

Clinical Management of Men with Nonobstructive Azoospermia due to Spermatogenic Failure

23

Arnold P. P. Achermann and Sandro C. Esteves

Key Points

- Azoospermia denotes the lack of any sperm after examination of centrifuged semen specimens.
- Medical history, physical examination, and endocrine profile (FSH and total testosterone serum levels) are helpful to establish the type of azoospermia (obstructive vs. nonobstructive). Together, these factors provide a > 90% diagnostic accuracy.
- Clinical parameters and hormone testing results are unreliable markers for determining the chances of sperm acquisition in men with nonobstructive azoospermia due to spermatogenic failure (NOA-SF).
- NOA-SF men desiring fertility should be screened for Y chromosome microdeletions. Retrieval attempts should not be offered to men with AZFa and/or AZFb microdeletions. AZFc microdeletions will be invariably transmitted from father to son by ICSI.
- Hormonal therapy and microsurgical varicocele repair might increase sperm retrieval success in selected patients with NOA-SF.
- Micro-TESE is the technique of choice for SR in NOA-SF. The method increases the chance of retrieving testicular sperm for ICSI and minimizes testicular damage.
- Sperm fertilizing potential is lower in NOA-SF men than other male infertility categories. Compliance with state-of-the-art laboratory techniques and quality control is essential when handling testicular tissue taken from NOA-SF men.
- Men with NOA-SF have a reduced chance of achieving a live birth by ICSI compared to men with other infertility categories. The short-term profile of resulting offspring by testicular sperm ICSI does not seem to be adversely impacted by the spermatogenic failure.

23.1 Introduction

Azoospermia affects approximately 1% of all men and 10–15% of infertile males. Its definition relies primarily on the examination of the centrifuged pellet confirming a complete absence of spermatozoa in the ejaculate [1, 2]. Spermatogenic failure (also termed nonobstructive azoospermia [NOA] or secretory azoospermia) is a severe form of male infertility [3]. However, the testes of men with NOA might contain areas exhibiting full spermatogenic activity. In such cases, sperm production is minimal precluding sperm to appear in ejaculates. Among men desiring fertility, sperm retrieval (SR) remains the only viable option as treatment to restore spermatogenesis is not effective. The goal of SR is to harvest viable testicular sperm for intracytoplasmic sperm injection (ICSI) [4–6]. Testicular sperm taken from men with NOA are capable of fertilizing the oocyte and induce normal embryo development, thus allowing such men to achieve biological parenthood [7–9].

In this chapter, we discuss the clinical management of men with NOA due to SF according to the algorithm used in our center. Figure 23.1 depicts a brief overview of the consecutive steps, which will be detailed further.

23.2 Step 1: Confirm the Diagnosis of NOA due to Spermatogenic Failure

23.2.1 Semen Analysis

The diagnosis of azoospermia primary relies on the results of semen analysis. Thus, a rigorous method should be applied to reduce analytical error and enhance precision [2, 10]. The semen of men with NOA due to SF has normal volume (>1.5 ml; 95% confidence interval 1.4–1.7) and pH (~7.2), therefore confirming that the seminal vesicles are functional and that the ejaculatory ducts are patent [11].

The azoospermic semen on an initial examination should undergo centrifugation as a few spermatozoa might be present in the pellet [2]. An earlier study conducted in the 1990s showed that about 23% of men with azoospermia had spermatozoa in the pellet [12]. Centrifugation forces of >1000 *g* for a minimum of 10–15 minutes are needed to pellet the cells [13]. The examination of multiple semen specimens rather than a single specimen is vital for establishing the diagnosis of azoospermia. The reason relates to the reports of transient azoospermia secondary to toxic, environmental, infectious, or iatrogenic conditions [14, 15]. Examination of multiple semen analyses is also critical given the sizeable biological variability observed in semen specimens from the same individuals [10, 14, 15]. Finding viable sperm in the pellet could allow sperm injections to be performed without the need of SR. However, a 2015 small cohort study involving 57 patients with transient azoospermia showed that fertilization rates and embryo development were decreased when only immotile sperm were found in the ejaculate and used for ICSI. Nevertheless, pregnancy outcomes were not affected [16]. At our andrology laboratory, the azoospermic semen is centrifuged at 3000 *g* for 15 minutes, followed by a careful examination of the resulting pellet (Table 23.1).

23.2.2 Medical History

Nonobstructive azoospermia (NOA) relates to genetic and congenital abnormalities, postinfectious exposure to gonadotoxins, medications, varicocele, trauma, endocrine disorders, and idiopathic diseases. Thus, a detailed medical history should be carried out to underlie these conditions. Information should be obtained concerning: (a) diseases during childhood and puberty (e.g., viral orchitis, cryptorchidism); (b) previous surgeries, in particular, those involving pelvic/inguinal regions and genitalia; (c) history of genital trauma; (d) history of infections (e.g., orchiepididymitis and urethritis); (e) physical and sexual development; and (f) exposure to gonadotoxic agents (e.g., radiotherapy, chemotherapy, and steroid abuse) [1, 9].

23.2.3 Physical Examination

The affected patients have normal epididymides and palpable vasa deferentia, but the testes are often small (<15 ml in volume) and soft. However, men with NOA associated with spermatogenic maturation arrest (MA) have well-developed and normal-volume testes [17, 18].

23.2.4 Endocrine Profile

The pulsatile secretion of pituitary gonadotropins controls spermatogenesis. Follicle-stimulating hormone (FSH) and luteinizing hormone (LH) stimulate the Sertoli cells and Leydig, respectively, promoting differentiation of immature germ cells to mature spermatozoa within the seminiferous tubules and androgen production. FSH levels higher than twice the normal upper limit is a reliable indicator of spermatogenic failure [19]. Indeed, FSH levels are often high in

Table 23.1 Interventions and recommended actions in the clinical management of azoospermic men with nonobstructive azoospermia seeking fertility

Clinical management step	Intervention	Action	Interpretation
Differential diagnosis	Medical history, physical examination, endocrine profile (FSH and testosterone levels at a minimum; LH, prolactin, thyroid hormones, and estradiol are added as needed), and examination of pelleted semen in multiple occasions Testicular biopsy could be considered in selected cases in which the differential diagnosis could not be determined	Confirm that azoospermia is due to spermatogenic failure, and identify men with severely impaired spermatogenesis with presence of few sperm in the ejaculate	A differential diagnosis between obstructive azoospermia, hypogonadotropic hypogonadism, and spermatogenic failure should be established as management varies according to type of azoospermia
Determination of proper candidates for sperm retrieval	Y chromosome microdeletion screening using multiplex (PCR) blood test The basic set of PCR primers recommended by the EAA/EMQN for the diagnosis of Yq microdeletion includes: sY14 (SRY), ZFX/ZFY, sY84 and sY86 (AZFa), sY127 and sY134 (AZFb), sY254 and sY255 (AZFc)	Deselect men with microdeletions involving subregions AZFa, AZFb, and AZFb+c	Approximately 10% of men with NOA-SF harbor microdeletions within the AZF region SR success in men with YCMD involving the subregions AZFa, AZFb, and AZFb+c are virtually nil and such patients should be counseled accordingly SR success in men with AZFc deletions range from 50% to 70% Genetic counseling should be offered to men with AZFc deletions because testicular spermatozoa used for ICSI will invariably transmit the deletion from father to son
Identification of patients who could benefit from medical therapy or varicocele repair before sperm retrieval	Serum levels of total testosterone and estradiol	Medical treatment with gonadotropins, aromatase inhibitors, or clomiphene citrate should be considered for the patients with hypogonadism (TT < 300 ng/dL) or T/E ratio < 10	Patients should be counseled that the evidence of a positive effect of medical treatment remains equivocal
	Physical examination to identify the presence of clinical varicocele and analysis of testicular biopsy results (if available)	Microsurgical repair of clinical varicocele	Microsurgical varicocele repair might increase SR success Patients with testicular histopathology indicating Sertoli-cell-only are unlikely to benefit from varicocele repair Evidence of a positive effect of varicocele repair is limited, and patients should be counseled accordingly
Selection of the most effective surgical method for testicular sperm acquisition	Analyses of testicular biopsy results (if available) and of whether sperm have been obtained in previous treatment and by which method	Microdissection testicular sperm extraction is the SR method of choice Conventional testicular sperm extraction may be considered in cases of previous success with TESE, particularly when testicular histopathology indicates hypospermatogenesis	Micro-TESE in NOA-SF is associated with higher SR success (42.9–63%) than conventional TESE (16.7–45%) The lower tissue removal facilitates sperm processing and lessens testicular damage
State-of-the-art laboratory techniques to handle surgically extracted testicular spermatozoa	Extraction of a minimum volume of tissue by micro-TESE facilitates tissue processing and search for sperm Testicular tissue preparation techniques include mechanical and enzymatic mincing and erythrocyte lysis	Sterile techniques, stable pH and temperature, and high laboratory air quality conditions useful to optimize micromanipulation efficiency and safety Excess sperm not used for ICSI should be cryopreserved for future attempts	Spermatozoa collected from NOA-SF men are often compromised in quality and are more fragile than ejaculated counterparts The reproductive potential of such gametes used for ICSI is differentially affected by NOA-SF

EAA European Association of Andrology, *EMQN* European Molecular Genetics Quality Network, *ICSI* intracytoplasmic sperm injection, *micro-TESE* microdissection testicular sperm extraction, *NOA-SF* nonobstructive azoospermia due to spermatogenic failure, *PCR* polymerase chain reaction, *SR* sperm retrieval, *T/E* testosterone to estradiol ratio, *TESE* testicular sperm extraction, *TT* total testosterone

men with NOA due to SF. By contrast, total testosterone levels are either low (<300 ng/dl) or around the lower limit [1, 20] in about 45% of the affected patients [21, 22]. A decrease in testosterone levels is likely indicative of Leydig cell deficiency, which may be associated with high luteinizing hormone (LH) levels [22, 23].

In most cases, however, LH levels will be within normal limits. Testosterone secretion follows a circadian cycle with an early morning peak between 8 and 10 am; it is, therefore, essential to instruct our patients to collect blood specimens accordingly. Bioavailable testosterone (free or unbound testosterone) levels may vary depending on sex hormone-binding globulin (SHBG) and albumin concentrations.

Notably, low testosterone levels could result from obesity, metabolic dysfunction, or thyroid dysfunction [24, 25]. Obesity can increase peripheral serum levels of estradiol and estrone due to increased peripheral aromatization of testosterone and androstenedione under the influence of aromatase [26]. High estradiol levels have a direct inhibitory effect on testosterone biosynthesis and might reduce the pulse amplitude of cyclical pituitary LH and FSH secretion [24, 27]. Furthermore, obese men have excessive circulating leptin that exerts an effect on steroidogenesis mediated by its adverse action on specific Leydig cell receptors, thus reducing the serum levels of androgens further [28].

Men with NOA-SF can also have a normal endocrine profile. The control of FSH and LH secretions relies on the quantities of spermatogonia and Leydig cells, respectively, which are well-preserved in men with maturation arrest. Indeed, patients with diffuse spermatogenic maturation arrest and 10% of those diagnosed with the Sertoli-cell-only syndrome (SCOS) present with non-elevated endogenous gonadotropins [17, 18]. Nevertheless, the combination of a testis long axis < 4.6 cm and FSH levels >7.6 IU/l was shown to predict NOA in 89% of men [29].

23.2.5 Hypogonadotropic Hypogonadism

Despite being rare, hypogonadotropic hypogonadism (HH) falls in the category of nonobstructive azoospermia (NOA). HH is characterized by failure of spermatogenesis due to lack of appropriate stimulation by gonadotropins. By contrast, spermatogenic failure relates to an intrinsic testicular impairment [30]. Unlike SF, men with NOA due to HH have remarkably low levels of pituitary gonadotropins (FSH and LH < 1.2 mUI/ml) and androgens (TT < 300 ng/dl), usually associated with signs of absent or poor virilization. NOA due to HH includes both patients with congenital forms of HH and those whose sperm production is suppressed by excess exogenous androgen (e.g., anabolic steroid abuse). The patients with HH benefit from specific hormonal therapy. These patients usually show remarkable recovery of spermatogenic function with exogenously administered gonadotropins or gonadotropin-releasing hormone [30].

23.2.6 Testis Biopsy

Testis biopsy is the "gold standard" test for confirmation of azoospermia due to SF. The common histopathology phenotypes include hypospermatogenesis, germ cell maturation arrest, germ cell aplasia (Sertoli-cell-only syndrome), tubular sclerosis, or a combination of those. The specimens are placed in fixative solutions such as Bouin's, Zenker's, or glutaraldehyde. Importantly, formalin should not be used as it may disrupt the tissue architecture. We only perform testicular biopsies when we could not establish the differential diagnosis between obstructive azoospermia and NOA. In these cases, we use either a percutaneous or an open "window" technique without testis delivery [1, 31]. When we find mature sperm on a wet examination, we routinely offer the patient sperm cryopreservation [31, 32].

Histopathology results have also been used to predict the chances of finding testicular sperm on retrievals. Patients with SCO have lower SR rates (19.5%) than those with MA (40.3%, $p = 0.007$), and these rates in both categories are lower than that of hypospermatogenesis (100.0%, $p < 0.001$) [33]. However, performing a testicular biopsy in men with NOA for diagnostic purposes remains controversial. Firstly, due to testicular heterogeneity, none of the histopathology phenotypes can predict with certainty who may or may not have sperm retrieved [33, 34]. Secondly, extraction of testicular parenchyma might inflict additional harm as men with NOA usually have small testes and abnormal androgen production. Lastly, biopsied specimens might contain mature spermatozoa that would be wasted after fixation and staining. Thus, despite the clinical utility of histopathology data for counseling, caution should be applied to recommend it for men with NOA routinely. If one opts to do so, it is advisable to also perform a wet examination of the extracted specimen and freezing the testicular parenchyma in case sperm is identified.

23.3 Step 2: Define Who Are Possible Candidates for Sperm Retrieval

The uncertainty of sperm acquisition in men with NOA due to SF makes prognostic factors desirable (Table 23.1). In a study involving 60 men with SF, we found that infertility etiology, testicular volume, serum levels of pituitary gonadotropins, and testicular histopathology results have low accuracy overall to predict who will have a successful SR [35]. In this study, the areas under the ROC curve for FSH, testosterone,

and testicular volume as regards a successful SR were 0.53, 0.59, and 0.52, respectively. Others have shown that a combination of testicular volume, FSH levels, and histopathology results yielded a diagnostic accuracy of 74% [36]. Sperm retrieval success varies from 25% to 70% in cryptorchidism, post-orchitis, Klinefelter syndrome, radio-/chemotherapy, and idiopathic infertility [37–41].

By contrast, genetic screening of the long arm of the Y chromosome has proved to be of value not only to identify those patients in whom Yq microdeletions is the cause of NOA but also to predict the chances of retrieving sperm [4, 42–49]. The region Yq11 at the long arm of the Y chromosome, known as "azoospermia factor" (AZF), clusters 26 genes involved in spermatogenesis regulation [46, 49–51] (Fig. 23.2). About 10% of men with azoospermia due to spermatogenic failure harbor microdeletions within the AZF region that might explain their condition [46, 51]. In practical terms, finding a microdeletion within the AZFa or AZFb region means that the odds of harvesting sperm from the seminiferous tubules are virtually nil, irrespective of the method used for sperm acquisition [52]. By contrast, patients with isolated AZFc microdeletions often harbor residual spermatogenesis, with SR success ranging from 50% to 70%.

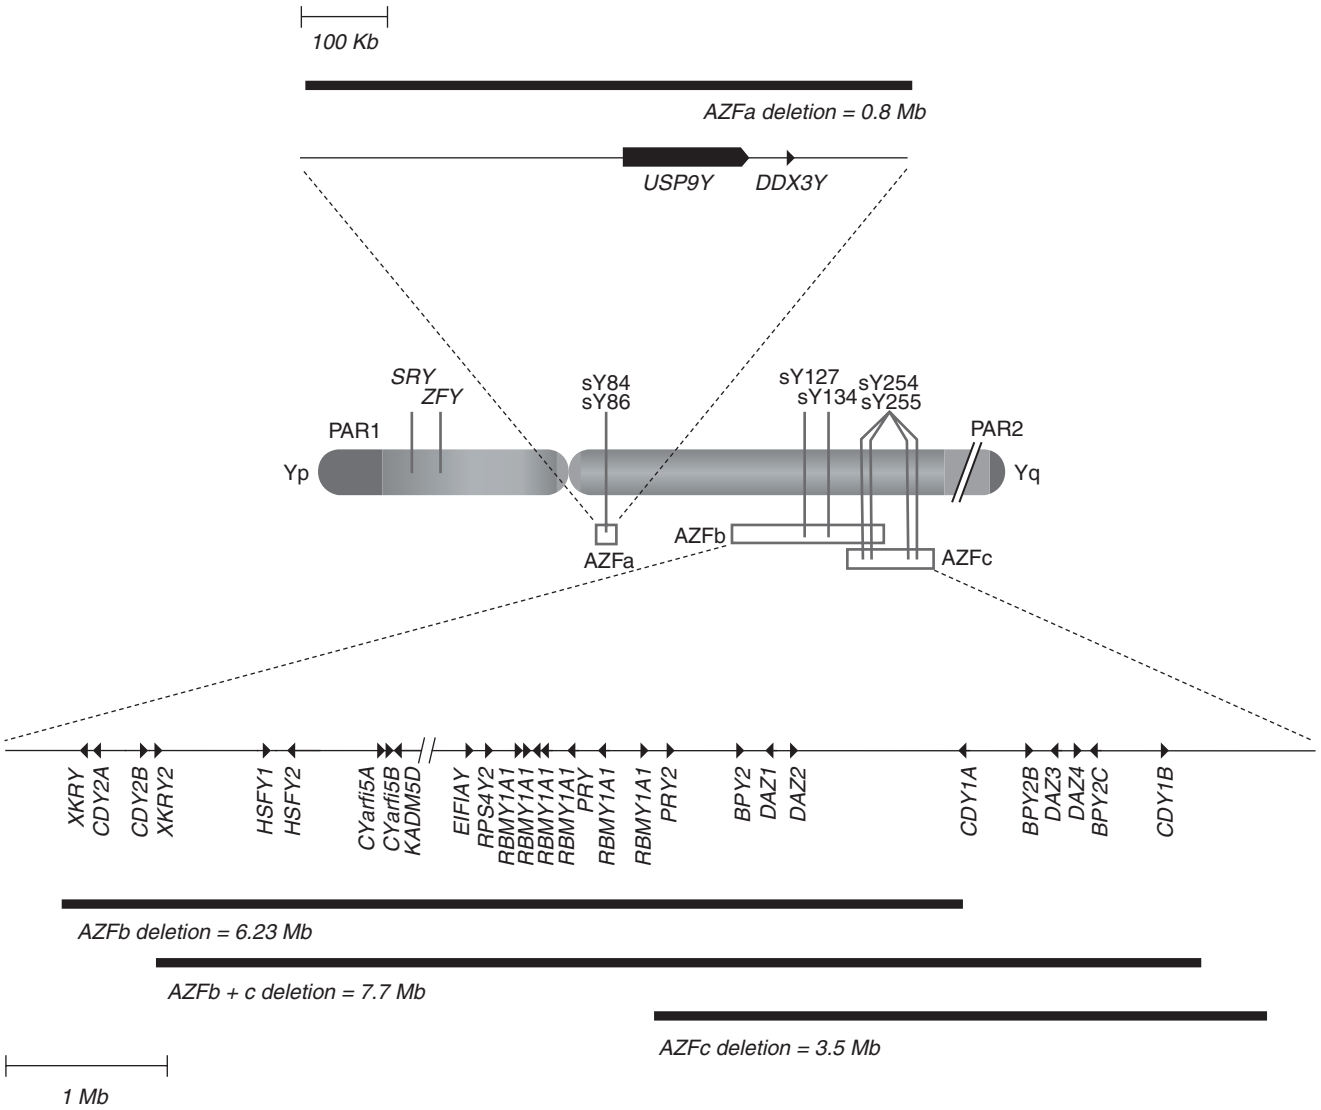

Fig. 23.2 Human Y chromosome map depicting the AZF subregions and gene content. The AZFa region maps from approximately 12.9–13.7 Mb of the chromosome and contains two single copy genes, USP9Y and DDX3Y. AZFb spans from approximately 18–24.7 Mb of the chromosome and AZFc from approximately 23–26.7 Mb. Both regions contain multiple genes as depicted in the bottom of the figure. The location of the basic set of sequence-tagged sites primers to be investigated in azoospermic men with spermatogenic failure, according to the European Association of Andrology and the European Molecular Genetics Quality Network 2013 guidelines, are identified by solid vertical lines. 23.4 Step 3: Define Who Can Benefit from Interventions Before Sperm Retrieval

23.4.1 Medical Therapy

Some studies have examined the effect of therapies to boost testosterone production in men with NOA-SF and hypogonadism. Testosterone is essential for spermatogenesis [53, 54], and its levels are over 100-fold higher in the testes than in the serum [55]. Thus, boosting testosterone production could restore intratesticular androgenic bioactivity that is essential to sustain spermatogenesis when combined with adequate Sertoli cell stimulation with FSH [56]. Clomiphene citrate, gonadotropins (human chorionic gonadotropin and FSH), and aromatase inhibitors [22, 24, 38, 57–61] are among the tested medical interventions. Table 23.2 [22, 58, 59, 61–65] summarizes the existing studies and their main outcomes. Although an overall beneficial effect has been observed, the evidence is currently limited and based mostly on case series. Hence, a firm conclusion on the role of medical and surgical intervention therapy in men with spermatogenic failure and azoospermia cannot be drawn yet. Randomized controlled trials are needed to precisely assess the impact of such interventions on sperm production and sperm retrieval outcomes.

Table 23.2 Summary of studies concerning medical therapy in NOA-SF

Study	Design	Study group	Control group	Medication	Main findings
Pavlovich et al. (2001) [58]	Case series	43 men with T/E ratio < 10	N/A	Testolactone, 50–100 mg twice daily for a mean of 5 months	None of the 12 men who completed 3 months of treatment had sperm in ejaculate; T/E ratios were restored to normal range (>10) in all treated men
Hussein et al. (2005) [63]	Prospective cohort	42 men with favorable histology (hypospermatogenesis or maturation arrest)	N/A	CC, 50 mg every other day for men for 5 months; dose titrated by 25-mg increments until target T levels between 600 and 800 ng dl^{-1} were achieved	64.3% of the men had sperm in posttreatment semen analysis (mean density of 3.8 million ml^{-1} and motility of 20.8%). All of the men ($n = 15$) who remained azoospermic had success at SR
Selman et al. (2006) [64]	Prospective cohort	49 men with normal endocrine and genetic profile in whom diagnostic testis biopsy showed maturation arrest and no sperm on wet examination	N/A	rec-hFSH, 75 IU SC on alternate days for 2 months and then dose increased to 150 IU and hCG (2000 IU SC twice weekly) added for another 4 months	None of the patients had return of sperm in ejaculate; posttreatment SRR were 21.4%
Ramasamy et al. (2009) [59]	Case series	56 men with nonmosaic Klinefelter syndrome and T levels lower than 300 ng dl^{-1}	N/A	Testolactone (50–100 mg) or anastrozole (1 mg) were used orally, alone, or combined with subcutaneous (SC) hCG (up to 2500 IU 3× week) for at least 3 months	SRR were increased by 1.4-fold (77% vs. 55%; $p = 0.03$) in men who had an elevation of 150 ng dl^{-1} T levels from baseline after medical therapy compared to ones who did not
Reifsnyder et al. (2012) [22]	Retrospective cohort	307 men with T levels lower than 300 ng dl^{-1}	41 men with T levels lower than 300 ng dl^{-1}	AI (50 to 100 mg testolactone orally twice daily or 1 mg anastrozole daily), hCG (at a dose of 1500 to 2000 IU SC 2-3× a week SC), or CC were used, alone or combined, for at least 2 to 3 months before surgery	None of the patients had return of sperm in ejaculate; SRR were not different in treated (51%) and untreated (61%) men; SRR were not different between treated males with T levels lower than 300 ng dl^{-1} (51%; $n = 307$) and untreated ones with T levels greater than 300 ng dl^{-1} (51%; $n = 388$)

Table 23.2 (continued)

Study	Design	Study group	Control group	Medication	Main findings
Shiraishi et al. (2012) [65]	Prospective cohort	28 men with idiopathic[a] NOA who had negative SR	20 men with idiopathic[a] NOA who had negative SR	At least 6 months after the first SR attempt, patients received treatment with hCG (5000 IU SC 3× weekly) for 3 months. If FSH levels decreased after hCG (<3 mIU ml^{-1}), recombinant FSH (rec-hFSH, 150 IU SC 3× weekly) was added for 2 months	Sperm was obtained at the second SR attempt in 6 (21%) of the 28 treated men ($p < 0.05$), but in none of the untreated men
Hussein et al. (2013) [61]	Prospective cohort	612 unselected men	116 unselected men	CC (50 mg every other day) alone or combined with hCG (5000 IU SC twice a week) and hMG (75 IU SC once weekly) were administered for an average of 5.4 months	Sperm were found in ejaculates of 10.9% of the treated males; in patients who remained azoospermic, SRR were higher in those who received medical therapy compared with controls (57.0 vs. 33.6%, $p < 0.001$)
Hu et al. (2018) [62]	Prospective cohort	25 NOA men with failed SR by TESE and hypospermatogenesis on testis histology (treatment group)	10 NOA men with failed SR by TESE and hypospermatogenesis on testis histology (no treatment; control group)	Goserelin (3.6 mg 1× every 4 weeks for 24 weeks). hCG (2000 IU IM 1×/week started 4 weeks after G and was given for a total of 20 weeks). hMG (150 IU IM 2×/week) was started 4 weeks after hCG and was given for a total of 16 weeks	6 months after treatment, SR was repeated, and sperm were acquired in 2 of 25 treated patients. Both of them received medical therapy, and sperm was found in the ejaculate in one of them Increase in inhibin B levels was found in 25% of treated group

AI aromatase inhibitor, *CC* clomiphene citrate, *FSH* follicle-stimulating hormone, *G* Goserelin, *hCG* human chorionic gonadotropin, *hMG* human menopausal gonadotropin, *IM* intramuscular, *IU* international units, *NOA* nonobstructive azoospermia, *rec-hFSH* recombinant human FSH, *SC* subcutaneous, *SR* sperm retrieval, *SRR* sperm retrieval rates, *T* total testosterone, *T/E* testosterone to estradiol ratio, *TESE* testicular sperm extraction, *N/A* not applicable

[a]Exclusion criteria were men with Klinefelter syndrome, testis volume less than 4 ml, T levels less than 200 ng dl^{-1}, varicocele and cryptorchidism

23.4.2 Varicocele Repair

Varicocele is found in 4–13% of men with NOA-SF [66, 67]. The surgical repair of clinical varicoceles, mainly using microsurgical techniques, has been carried out in an attempt to improve sperm production in such men [66–68]. The goals are to increase the chances of finding sperm in the semen or retrieving sperm from the testis.

A 2016 review systematically evaluated the role of varicocele repair in men with NOA [69]. Sixteen studies accounting for a total of 344 men reported data related to sperm return to the ejaculate post repair of clinical varicoceles. The age and follow-up duration of the treated population were 32.5 years (± 2.3) and 12.4 months (± 5.5), respectively. The proportion of patients with postoperative return of sperm to the ejaculate was 44% (range 20.8%–55.0%). Postoperatively, the mean sperm count and motility were 1.8 million/mL (SD 1.6, 95% CI 0.9–2.7) and 23% (SD 15%, 95% CI 12%–33%), respectively, and the interval between varicocele repair and appearance of sperm in postoperative ejaculate varied from 4.5 to 11 months. Three studies provided surgical sperm retrieval (SR) data between treated and untreated men with varicocele and NOA and therefore were meta-analyzed [69]. The observed pooled effect size involving 400 patients indicated that SR success was significantly higher in the treated varicocele group than in the untreated one (OR 2.6, 95% CI 1.7–4.1, $I^2 = 0\%$, $P < 0.0001$). The time interval between varicocele repair and SR was 10.8 months (SD 11.1, range 3–23.6 months). Two studies involving 140 couples in total reported data on pregnancy by ICSI using testicular sperm harvested from the seminiferous tubules [70, 71]. These studies included a control group of men with NOA and untreated varicocele for comparison. The estimated pooled increase in the odds of achieving a clinical pregnancy and a

live birth by ICSI using testicular sperm from treated men were 2.2 (95% CI OR 0.99–4.83, $P = 0.05$, I^2 0%) and 2.1 (95% CI OR 0.92–4.65, $P = 0.08$, $I^2 = 0\%$), respectively [69]. The results discussed above were corroborated by Kirby et al.'s meta-analysis, which showed that SR rates (OR = 2.5) and pregnancy rates (OR = 2.3) were significantly higher in persistently azoospermic men after varicocele repair [72].

23.5 Step 4: Use the Optimal Method for Harvesting Testicular Sperm

The primary goal of sperm retrieval in NOA-SF are to obtain the optimal quantity of good quality sperm, which can be used for ICSI promptly or cryopreserved for future ICSI attempts (Table 23.1). Retrieval methods should also minimize testicular damage thus preserving androgen activity and the chance of repeated retrieval attempts.

Both microdissection testicular sperm extraction (micro-TESE) and conventional TESE have been used to retrieve sperm from NOA-SF men. Conventional TESE involves open single or multiple testicular biopsies taken at random, which are processed and examined for the presence of sperm [5, 9, 36, 73]. Since the prediction of both the existence and the geographic location of the islets of normal spermatogenesis is not possible before SR, more than one specimen is usually required to find sperm. TESE with multiple biopsies results in higher SRR than fine-needle aspiration (TEFNA), a variation of testicular sperm aspiration (TESA), particularly in cases involving SCO and maturation arrest [74]. A disadvantage of TESE is that removal of large fragments of testicular tissue might affect the already compromised androgen production, transiently or permanently [75]. Added to this, laboratory processing of such large quantities of testicular tissue taken by TESE is time-consuming and labor-intensive [31, 32, 76].

Microdissection testicular sperm extraction (micro-TESE) is a microsurgical method of sperm retrieval [76]. Micro-TESE is preferred over TESE due to the higher SR rates and lower surgical complications such as hematoma formation, fibrosis, and testicular atrophy. Also, the lower tissue removal facilitates sperm processing and lessens testicular damage [5, 32, 41, 57, 73, 76–80]. Micro-TESE aims at identifying focal areas of sperm production within the testes, based on the size and appearance of the seminiferous tubules, with the aid of the operating microscope (Fig. 23.3). Such areas are selectively extracted thus allowing minimal tissue removal, which has been shown to be 50- to 70-fold less when compared with conventional TESE [5, 73, 76]. The use of optical magnification also reduces the chances of vascular injury by proper identification of testicular blood supply, thus reducing the chances of hematoma formation and testicular devascularization [41]. Although a decrease in

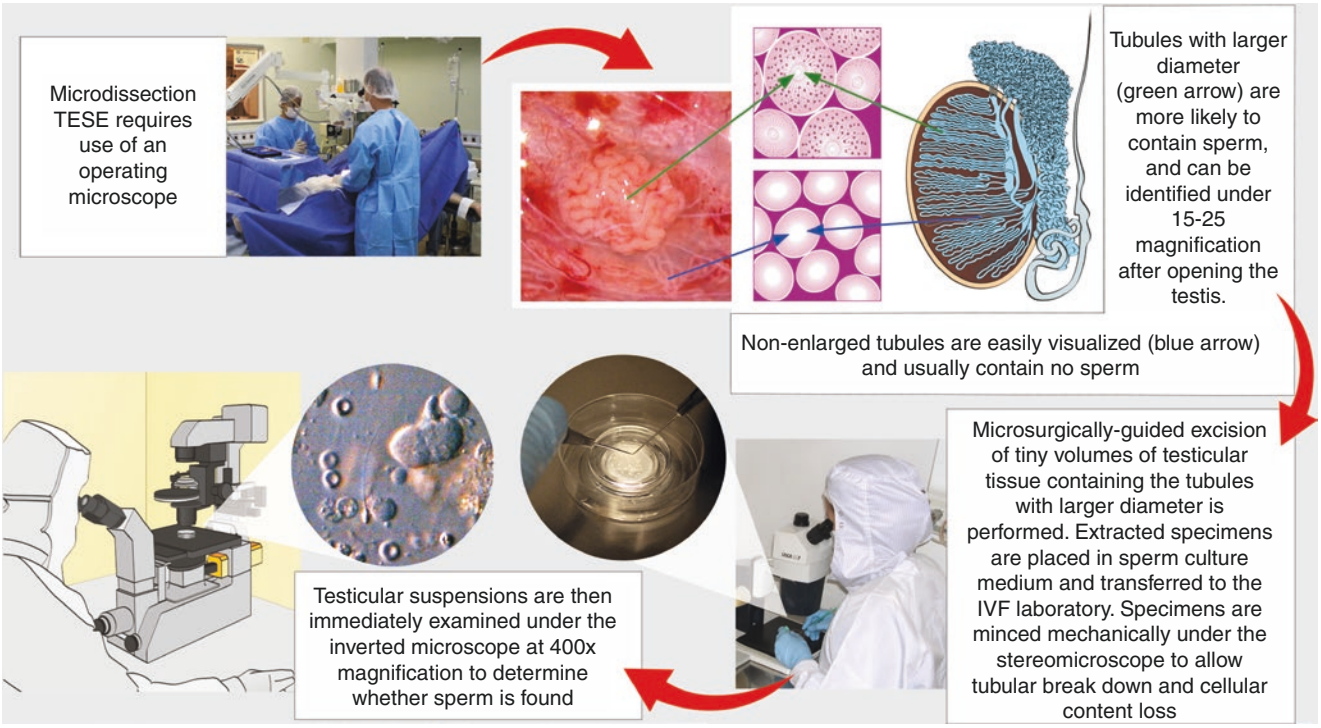

Fig. 23.3 Microdissection testicular sperm extraction. Flowchart illustrates the consecutive steps from the microsurgical procedure to the laboratory processing of testicular specimens. (Reprinted with permission, ANDROFERT© 2018. All rights reserved)

serum testosterone has been documented after removing testicular parenchyma by micro-TESE, especially in men with severely compromised androgen activity such as those with Klinefelter syndrome [38], testosterone levels return to pre-surgical values in 95% of the subjects within 18 months following surgery [81].

In a controlled study involving sixty men with SF, we compared SR rates between micro-TESE and conventional single-biopsy TESE [35]. The SRR was significantly higher with micro-TESE (45 vs. 25%; $p = 0.005$) both overall and after stratifying the patients by testicular histopathology phenotype (hypospermatogenesis 93 vs. 64%; maturation arrest 64 vs. 9%; Sertoli-cell-only syndrome 20 vs. 6%; $p < 0.001$). Controlled studies have corroborated our results by showing that micro-TESE has higher sperm recovery and lower complication rates (below 5%) than conventional TESE [77–80]. We have recently reported our updated experience involving 356 patients with SF who have undergone micro-TESE. SRR was 41.4% overall [7] and 100.0, 40.3, and 19.5% according to the histopathology phenotypes of hypospermatogenesis, maturation arrest, and SCO, respectively [33]. Micro-TESE might rescue approximately one-third of the cases that failed in previous retrieval attempts with conventional TESE or TESA and is particularly useful for men with spermatogenic failure presenting the worst-case scenarios [57, 76]. Lastly, a recent systematic review involving seven comparative studies and 1062 patients confirmed that micro-TESE in SF was associated with a more favorable sperm retrieval rate ranging from 42.9% to 63% compared with 16.7–45% in conventional TESE [82].

23.6 Step 5: Laboratory Handling of Testicular Sperm

The laboratory handling of surgically retrieved gametes requires special attention because spermatozoa collected from NOA-SF men are often of reduced quality and more fragile than ejaculated counterparts [83]. Both sperm DNA fragmentation and aneuploidy rates are higher in testicular sperm obtained from men with spermatogenic failure compared with ejaculated sperm obtained from infertile men with various etiology categories [84, 85]. Consequently, lower fertilization, embryo development, and pregnancy rates have been achieved when ICSI is carried out with gametes retrieved from men with SF [7, 83].

From the surgeon's perspective, attention should be taken to deliver the best-quality extracted sample as possible for the laboratory personnel, with minimal or no contaminants such as red blood cells and harmful microorganisms. Micro-TESE allows extraction of a minimum volume of tissue, which is advantageous. The searching process in lower-volume testicular tissue increases laboratory efficiency and minimizes missing spermatozoa in the sea of cells and noncellular elements [32]. Testicular tissue preparation techniques have been developed to increase sperm retrieval rates that have been used to handle these specimens, including mechanical and enzymatic mincing. These techniques promote tubular wall breakdown and cellular content loss [32, 86, 87].

The laboratory team must master the processing techniques to minimize iatrogenic cellular damage during sperm preparation (Table 23.1). State-of-the-art laboratory practice standards, including sterile techniques and laboratory air quality conditions, are of utmost importance to optimize micromanipulation efficiency and safety assurance [32, 88]. Critical aspects to be controlled include (i) centrifugation force and duration; (ii) exposure to ultraviolet light and temperature variation; (iii) laboratory air quality conditions; (iv) dilution and washing steps; and (iv) quality of reagents, culture media, and disposable materials. At our center, we perform sperm retrieval and all related laboratory steps involved in the handling of testicular specimens in controlled environments. The latter includes tissue processing, microinjection of surgically extracted sperm, the culture of embryos generated from such procedures, and cryopreservation. At Androfert Center, the IVF and andrology laboratories, the operating theater in which oocyte and microsurgical sperm harvestings are carried out, and embryo transfer rooms were constructed according to cleanroom standards for air particles and volatile organic compounds [89].

Lastly, whenever possible, techniques to improve sperm fertilizing potential should be applied, including the use of chemical stimulants and methods to select viable sperm for ICSI. The latter is particularly important when only immotile spermatozoa are available as their vitality may be reduced. After a successful SR in NOA-SF, cryopreservation of surplus testicular sperm is highly recommended because such patients often require more than one ICSI treatment to establish pregnancy, but repeated retrieval attempts are not always possible. Cryopreservation of testicular sperm from NOA-SF men can be done with either conventional straws and liquid nitrogen (LN) vapor techniques or low-volume straws and ultrafast LN freezing [90–92]. In a meta-analysis of 11 studies and 574 ICSI cycles, there was no statistical difference between fresh versus frozen-thawed testicular sperm with regards to fertilization rates (RR 0.97, 95% CI 0.92–1.02) and CPRs (RR1.00, 95% CI 0.75–1.33) [93].

23.7 Outcomes of ICSI

The clinical outcomes of ICSI using surgically extracted testicular sperm from NOA-SF men are lower than ejaculated and obstructive azoospermia counterparts [7, 83, 94–96]. Apparently, such sperm have a higher tendency to carry deficiencies in centrioles and genetic material, which might affect

their potential to activate the oocyte and to trigger the formation and development of a normal zygote and a viable embryo [84, 85].

In an early series involving 330 patients with different infertility conditions including 53 azoospermic men with SF, we examined ICSI outcomes according to the source of spermatozoa and the type of azoospermia. We found that 2PN fertilization rates were significantly lower with testicular sperm from NOA-SF men than from those with ejaculated and testicular/epididymal sperm of men with obstructive azoospermia (52.2, 71.1, and 73.6% in SF, ejaculated sperm, and OA, respectively; $p < 0.05$). Embryo development and pregnancy rates are also negatively affected by SF [35]. In two series involving a larger cohort of NOA-SF men, we compared ICSI outcomes and analyzed the health of offspring according to the source of sperm and the type of azoospermia. In one study, 182 women underwent ICSI using sperm from partners with NOA-SF, and the outcomes were compared with a group of 182 and 465 women whose partners had OA or where non-azoospermic. Live birth rates after ICSI were lower in the SF group (21.4%) compared with the OA (37.5%) and non-azoospermic sperm (32.3%) groups ($p = 0.003$). In this report, 326 live births resulted in 427 babies born. Despite a tendency towards poorer neonatal outcomes in the azoospermia categories, differences in gestational age, preterm birth, birth weight, and low birth weight were not noted [96]. In another series, we compared 365 azoospermic men with SF who underwent micro-TESE with 40 men with SF who used donor sperm for sperm injections due to failed retrieval and 146 men with OA who underwent percutaneous sperm retrieval. The SR rate in SF was 41.4%, and the results were lower than the OA group (100%, adjusted odds ratio 0.033, 95% CI 0.007–0.164, $p < 0.001$). Live birth rates were lower among couples whose male partners with SF had their own sperm used for ICSI (19.9%) than those who used donor sperm (37.5%, adjusted odds ratio 0.377 [95% CI 0.233–0.609, $p < 0.001$]) and obstructive azoospermia (34.2%, adjusted OR 0.403 [95% CI 0.241–0.676, $p = 0.001$]). Neither the miscarriage nor the newborn parameters (gestational age, birth weight, malformation rate, perinatal mortality) of infants conceived were significantly different among the groups [7]. Although the data on the health of resulting offspring after ICSI using the sperm of men with azoospermia due to SF is reassuring, only five studies have compared to date the neonatal profile of such babies [7, 8, 96–98]. The limited population analyzed calls for continuous monitoring, and studies on the physical, neurological, and developmental outcomes of children conceived are limited [99].

23.8 Complete Aspermatogenesis

Aspermatogenesis relates to either a complete lack of germ cells or its presence as immature forms only. The condition affects 25–45% of NOA-SF men [100]. Spermatids are the earliest male germ cells with a haploid set of chromosomes. The use of spermatids for ICSI has been attempted when mature sperm are not available, but more than two decades since its introduction, the clinical efficacy of spermatid injection in humans has been merely anecdotal [101, 102]. Besides, ethical and safety concerns related to potential transmission of genomic imprinted disorders have driven the ban of spermatid injection in the United Kingdom. In the USA, spermatid injection is considered as an experimental procedure [103]. In 2015, Japanese scientists reported the birth of 14 babies after refinement of spermatid injection by activation with electric current [104]. The resulting offspring were found to have no notable physical, mental, or epigenetic problems. However, the number of children born to date is too small and the follow-up period too short to consider this approach a safe option.

Current efforts focus on the differentiation of preexisting immature germ cells or the production/derivation of sperm from somatic cells [105]. In humans, generation of human haploid-like cells from pluripotent stem cells of somatic origin has been achieved using in vitro sperm derivation. Despite promising, these methodologies are experimental, and the in vitro production of gametes is a highly complex process which has not been translated to humans yet [100].

23.9 Conclusions

The clinical management of infertile men with azoospermia starts with a proper diagnostic workup that allows the differentiation between NOA-SF and other types of azoospermia. Patients with NOA-SF should be screened for Y chromosome microdeletions. Currently, sperm retrieval (SR) should be offered only to men with no Yq microdeletions or microdeletions involving the AZFc region solely. Nevertheless, genetic counseling should be given to NOA-SF patients with AZF Yq microdeletions as the use of their testicular sperm for ICSI will inevitably transmit the deletion from father to son. Before sperm retrieval, medical therapy to boost endogenous testosterone production and microsurgical repair of clinical varicoceles can be offered to selected men. These interventions could increase the sperm retrieval likelihood of success or eventually allow the finding of a few sperm in the ejaculate, which might be used for ICSI. Micro-TESE is the SR technique of choice for NOA-SF men. The method not only increases the chance of retrieving testicular sperm for ICSI but also minimizes testicular damage. Compliance with state-of-the-art laboratory techniques is essential to both avoid jeopardizing the sperm fertilizing potential and improve ICSI outcomes when handling testicular specimens extracted from NOA-SF men. The likelihood of harvesting sperm for ICSI is reduced in men with NOA-SF compared to those with obstructive azoospermia. These patients are also at a reproductive disadvantage concerning ICSI outcomes when compared to other

male infertility categories. However, the short-term profile of infants conceived after sperm injection does not seem to be negatively affected by NOA-SF. Current research efforts on biotechnology techniques aiming at producing artificial gametes could rescue fertility in men whose germ cells are entirely lacking or present only in immature forms.

23.10 Review Criteria

An extensive search of studies examining the relationship between nonobstructive azoospermia and infertility, with a focus on spermatogenic failure, was performed using search engines such as ScienceDirect and PubMed. The end date for these searches was September 2018. The overall strategy for study identification and data extraction was based on the following keywords: "non-obstructive azoospermia," "spermatogenic failure," "azoospermia," "sperm retrieval," "infertility, male," "assisted reproductive technology," "intracytoplasmic sperm injection," "semen parameters," "reproductive outcomes," and "pregnancy rate." We have not included articles published in languages other than English. Data that were published in a conference or meeting proceedings, websites, or books were used to provide conceptual content only.

Conflict of Interest The authors have nothing to disclose.

Novel Approaches in the Management of Klinefelter Syndrome

24

Muhammad Asharib Arshad, Mohamed Mostafa Arafa Omar Yamani, Haitham Tharwat Elbardisi, and Ahmad Majzoub

Key Points

- Klinefelter syndrome is the most common sex chromosomal anomaly in men that occurs mostly due to meiotic nondisjunction, but most of the cases remain undiagnosed.
- The diverse phenotypic expression in its presentation requires a great deal of conjecture from the clinician caring for such patients.
- Early diagnosis and treatment of boys with KS should be emphasized as it can have beneficial effects on their physical, social, and academic development.
- Cryopreservation of sperm is offered to the adolescent KS patients who are able to provide a semen sample.
- Pharmacological therapy with aromatase inhibitors prior to micro-TESE has the highest sperm retrieval rates in azoospermic men.

24.1 Introduction

Klinefelter syndrome (KS) was initially described in a report published by Klinefelter et al. in 1942 on nine men, who had sparse facial and body hair, enlarged breasts, and small testes [1]. The genetic basis of KS was discovered in 1959 when an extra X chromosome was found in the genetic profile of those patients [2]. The occurrence of KS ranges from 85 to 223 per 100,000 live-born males. Hence, it is the most frequent sex chromosomal anomaly [3]. It is encountered in approximately 3–4% of infertile males and the occurrence rises to 10–12% in patients with azoospermia [2]. It is estimated that only 25–40% of the subset of patients with KS are ever diagnosed and only around 10% of these patients are identified during their childhood and adolescent years [4]. The reason behind the underdiagnosis of KS can be explained by the wide variability in its presentation requiring a great deal of conjecture from the clinician caring for such patients.

The management of patients with KS is still provided by endocrinologists who may not particularly focus on the reproductive aspects of this disease. That being said, KS patients can have a good chance of fathering their biologic children provided that proper fertility-preserving treatment is offered to them. While a subset of KS patients can still produce sperm, testicular sperm can be retrieved from azoospermic KS patients and used in assisted reproductive procedures. The latter finding has triggered the interest of reproductive specialists to explore methods that could increase the reproductive outcome of such patients.

24.2 Genetic Background

Initial research on the genetic profile of patients with KS showed that they typically carry a 47XXY karyotype [2]. Further studies have shown that this karyotype is held by 85–90% of males with KS, while in the remaining patients, a mosaic karyotype (46,XY/47,XXY), a supernumerary chromosome (47,XXY/48,XXXY, 48,XXYY, 48,XXXY, 49,XXXXY), or structurally abnormal sex chromosome can be present [5, 6]. A national survey done in Denmark on 4477 patients with KS and a cohort study done in the UK showed that the karyotype 47XXY was present in 86.3% of

patients, while the frequencies of the remaining karyotypes are listed in Table 24.1 [4, 5].

Meiotic nondisjunction is the basic genetic defect in patients with KS. The improper separation of the sister chromatids during the process of cell division results in the abnormal number of chromosomes in daughter cells that is called aneuploidy. It is generally accepted that most trisomies in autosomal chromosomes occur due to nondisjunction in the maternal meiotic division, whereas the paternal errors occur in less than 10% of the patients [7]. It has been suggested that the paternal origin of a chromosomal aneuploidy having an extra Y chromosome should impart an effect on the phenotype of KS patients having this chromosomal anomaly. However, most of the studies could not find any association, whereas only a few were able to find some effect on phenotypic traits due to the parental errors including particularly an effect on the time of onset of puberty [8] and the waist and height ratio to the arm span [9]. Differences in the communication skills and motor function were also found [10] as well as correlations with some psychiatric morbidities such as schizotypal and autistic traits [11].

Table 24.1 Karyotype distribution among 4477 Klinefelter syndrome patients

47XXY	3863 (86.3%)
46XY/47 XXY	383 (8.5%)
48 XXXY	157 (3.5%)
49 XXXXY	66 (1.5%)
48,XXY + trisomy of chromosome 18	5 (0.1%)
47,XXY/48,XXXY	2 (<0.01%)
Undetermined	1 (0 < 0.01%)

Based on data from Ref. [4 and 5]

When the sex chromosomal aneuploidy is due to maternal origin, it can occur due to nondisjunction of the homologous chromosomes in the first or second meiotic division, whereas in a sex chromosomal aneuploidy with an extra X chromosome due to paternal error, the meiotic nondisjunction must occur in the first meiotic division as if it occurs in the second stage of meiosis, then it will result in only two possibilities that are either XX or YY gametes (Figs. 24.1 and 24.2). On the contrary, the mosaic forms of KS are either a result of the loss of an additional X chromosome in a 47XXY genotype or due the nondisjunction of the homologous chromosomes in mitotic division at early stages of cell division in a normal 46XY zygote; this process is named as trisomy rescue.

Bojesen et al. proved that maternal age was an important risk factor for KS. The authors found that there was a fourfold rise in the occurrence of KS cases if the age of the mother was more than 40 years [5]. However, paternal age has not been considered highly influential on the prevalence of KS [12]. Recent work by Fonseka et al. confirmed that paternal age has a little effect on sex chromosomal trisomies and an even lower effect on autosomal aneuploidy [13]. However, some studies depicted that paternal age was influential on fathers who had an offspring with paternally inherited chromosomal aneuploidy [14].

Patients with KS exhibit a broad variety in the phenotype that vary from being normal or almost normal to having developmental issues at an early age and fertility problems. It is not known why patients with KS present on either end of the phenotypic spectrum. This variation in the phenotype can

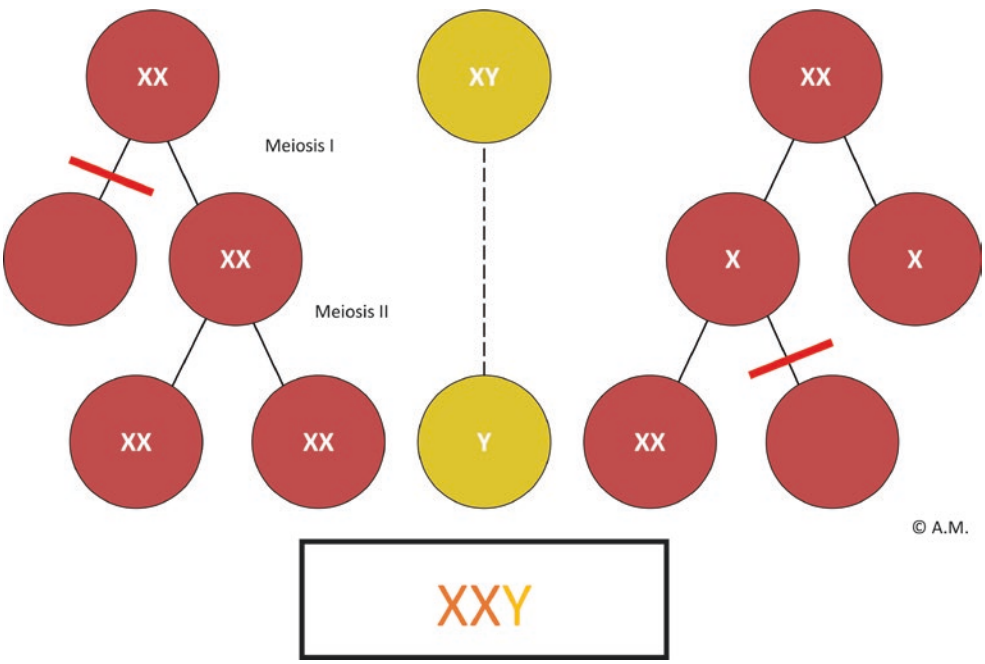

Fig. 24.1 47XXY of maternal origin

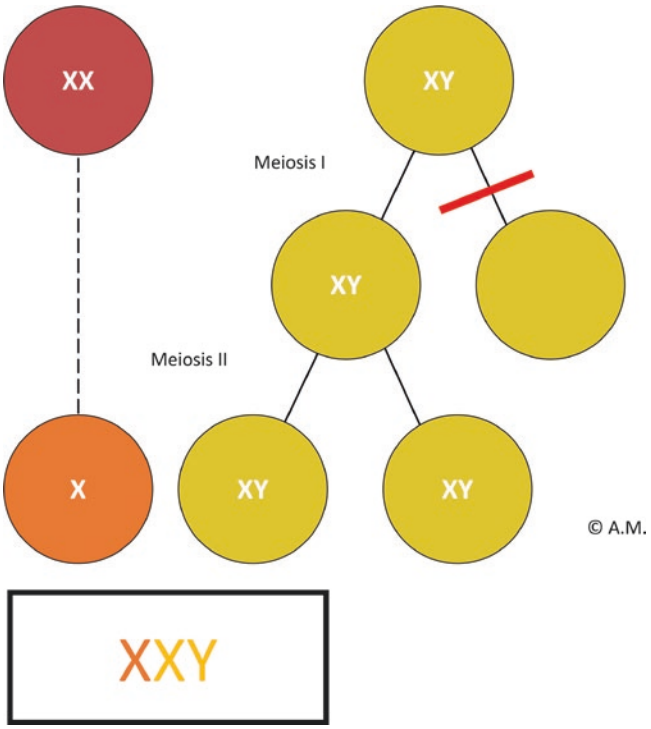

Fig. 24.2 47XXY of paternal origin

be described by a phenomenon called genomic imprinting, in which certain genes are expressed in the phenotype, while others are silenced depending on their parent of origin [10]. Gene polymorphisms occurring after the inactivation of the X chromosome provide more explanation. Gene polymorphisms in the form of CAG repeat sequence encode the androgen receptor (AR) which is located on the X chromosome. The relationship between the functional response of the AR and CAG repeat sequence has an inverse relation. To further clarify, the longer the AR CAG repeat sequence, the less marked is the androgen effect. Nonrandom or skewed inactivation of the X chromosome is seen in patients with KS in which the shortest AR CAG repeat sequence is inactivated [15]. Studies have shown that there is a negative correlation between the length of the CAG repeat sequence and penile length [16], higher education and strong relationships [15]. KS patients with shorter CAG repeat sequence respond better to androgen therapy. On the other hand, longer length of the CAG repeat sequence is related to enlarged breasts, deranged anthropometric measures such as body height and arm span, and poor bone density and testicular volume [15]. The variety in the phenotype of KS patients might be clarified by the concept of nonrandom inactivation of the X chromosome. Recent studies have shown that DNA methylation profile in patients with KS is related to the changes in the brain and blood tissue. It might be possible that the mechanism of DNA methylation plays a role behind the broad phenotypic spectrum in KS patients [17, 18].

24.3 Endocrine Function and Spermatogenesis in KS

Recent studies show that the initial embryonal development of the testicles is similar in infants having KS and infants with normal 46XY karyotype. Germ cells originate from the yolk sac and then migrate to the urogenital ridge [19]. The secretory function of the Leydig and Sertoli cells that originate from the mesenchyme is initiated after this migration of germ cells [19]. Work done by Hunt et al. showed that the mitotic proliferation of the germ cells that undergo migration to the urogenital ridge is reduced as the testicular development progresses [20]. This was further confirmed by Mikamo et al. who demonstrated that during the first year of an infant's life, the number of spermatogonia gradually declines from 24% to 0.1% compared to the control value [21]. Studies performed on boys with KS during their prepubertal age have demonstrated that a number of spermatogonia are markedly decreased. They also found evidence of arrest in maturation at the spermatogonium and the early primary spermatocyte stage [22]. Furthermore, the ability of the immature Sertoli cells to transform into the mature Sertoli cells is also reduced [23].

This creates a conflict on how spermatogenesis occurs in KS patients. To clear this conflict, two hypotheses have been given. The first hypothesis suggests that the spermatogonia of the 47XXY patients are able to complete the process of meiosis that clarifies the increased rates of aneuploidy in the sex chromosomes [22, 24]. The second hypothesis states that the compromised testicular environment in KS patients results in errors in the meiotic cell division that results in a higher rate of aneuploid sperm, while some traces of the normal 46 XY spermatogonial stem cells may still exist [25]. The histopathologic examination of the testicular tissue of adult patients with KS has shown patches of hyalinization of the seminiferous tubules and areas showing extensive fibrosis [26] intermixed in larger areas containing more matured cellular structure [27]. However, as the majority of patients with KS are non-mosaic, this fact can reject the second hypothesis.

Unlike spermatogenesis, the endocrine function appears to be normal in patients with KS until the age of puberty. Previous studies have shown evidence that KS patients in their prepubertal age have normal serum levels of luteinizing hormone (LH), follicular-stimulating hormone (FSH), testosterone, and inhibin B before the beginning of puberty [28–30]. The level of serum testosterone rises initially, then the level plateaus, and afterward it remains at the lower limit of the normal range constantly during the entire puberty [29, 30]. However, this level of serum testosterone is adequate for boys having KS to develop during puberty and attain adequate secondary sexual characteristics [28, 31].

Boys with KS in the prepubertal and pubertal age mostly have high levels of estradiol, despite the presence or absence of gynecomastia, with a predisposition to have a higher ratio of estradiol/testosterone ratio during puberty [28, 32]. The levels of inhibin B in KS patients show an early rise before the beginning of puberty just like normal boys, but due to the rise in levels of serum testosterone, they drop rapidly [23, 29]. A gradual increase is seen in the serum levels of FSH and LH in patients with KS as they progress from the midpuberty onward. The rise in FSH levels appears early and is more marked than LH levels [28, 29, 32].

24.4 Clinical Manifestations

The clinical presentation of KS patients varies according to the age of the patient and his phenotypic expression. It is difficult to recognize KS male patients before the onset of puberty because of the endocrine reasons discussed in the previous section. Physical anomalies that are present in KS patients including increased length of the lower limbs and mild decrease in the testicular volume often go unnoticed. After the onset of puberty, a variety of symptoms of deficiency of androgens characterize the syndrome. These symptoms in KS patients can be classified into the following:

Consequences of Hypogonadism A recent study determined a link between the levels of testosterone in the prenatal period and the adult phenotypic features in normal men showing that the levels of testosterone in the umbilical cord were associated with more masculine features. They also showed that the levels of testosterone in the adult period did not seem to affect such features [33]. This might be the case in patients with KS, but still no study has been conducted to prove this association. Most of the patients are able to attain a normal penile size, but about 70% of patients have complaints of decreased libido and potency as they approach the age of 25 years [34].

Gynecomastia In the first description of KS by Klinefelter et al., all the patients had gynecomastia, and it was considered to be a characteristic trait [1]. However, later studies showed that it was present in about one-third of the patients [35]. Gynecomastia was due to the deficiency of testosterone or the decreased ratio of testosterone to estradiol [36].

Anthropometry and Body Composition An increase in the anthropometric measures such as hip, waist circumference, body weight, total and abdominal fat, and total fat percentage was found in a cohort study done on 73 males when they were compared to age-matched controls [9]. The height of patients with KS is higher when compared to normal men with a mean of 5–7 cm. However, this increased height is attributed to the relative hypogonadism in KS patients during puberty that causes delayed epiphyseal closing resulting in longer leg length [9]. A recent study conducted on adult KS males in Korea found that 57% of them were having normal BMI [37]. The increase in BMI is most likely due to a trend of general increase in BMI in the general population. BMI as an indicator of fat mass of the body should be interpreted cautiously in patients with KS, as they have an increased height and lower lean body mass. However, KS males have an increased truncal fat percentage, evaluated by dual-energy X-ray absorptiometry, for any given BMI [9, 38].

Bone Mineralization Patients with KS have altered bone mineralization secondary to the degree of hypogonadism they most likely have, placing them at higher risk for bone fracture and osteoporosis [4, 39, 40]. Bone mineral density (BMD) has been found to be decreased in KS patients in many clinical studies but without any clear correlation with the levels of serum testosterone [41, 42]. Furthermore, some clinical studies detected the presence of decreased levels of 25-hydroxyvitamin D and decreased muscle strength in KS patients [41, 43]. Lower levels of insulin-like growth factor 3 (INSL3) have been detected in KS patients. While this hormone is known to correlate with osteocalcin, a marker of bone formation, no clear relationship was found between the levels of BMD and INSL3 [44].

Diabetes and Metabolic Syndrome A threefold rise in the occurrence of diabetes in KS patients has been found in epidemiological studies of both mortality and morbidity [38, 40]. A study conducted on 39 male patients with KS found that the average age at diagnosis of diabetes mellitus was 27.1 years, with a prevalence of 12.5% [45]. The prevalence of diabetes was higher in the KS patients when compared to the control group that comprised of men with idiopathic hypogonadotropic hypogonadism. The authors proposed that the deficiency of testosterone alone cannot clarify the increased prevalence of diabetes in KS patients. The extra X chromosome might play a role in the development of diabetes as the prevalence of diabetes is higher in patients with more than normal X chromosomes [45]. The prevalence of type 1 diabetes is also higher in KS patients as the levels of autoimmune antibodies directed against diabetes-specific autoantigens in patients with KS were 8.2% compared to less than 1% in controls [46]. The incidence of metabolic syndrome in KS seems relatively higher when compared to other populations of men with hypogonadism. This suggests that metabolic syndrome is related to a more specific genetic background [47]. A recent study conducted in Germany including 132 patients with KS reported higher level of triglycerides and lower levels of HDL compared with controls [48].

The risk of diabetes and metabolic syndrome significantly rises with hypogonadism. However, this relationship seems to be related more to the adiposity rather than the deficiency of testosterone because insulin sensitivity improved in obese patients only and did not improve the sensitivity of insulin in lean patients [49].

Cardiovascular Disease Mitral valve prolapse and impairment of the diastolic function of the ventricles and the chronotropic function of the heart are more common among KS patients [50–53]. Clotting defects are also seen in KS patients that can lead to thromboembolic events. The high BMI and low levels of testosterone levels that are characteristically seen in KS patients are related to elevated levels of plasminogen activator inhibitor-1 (PAI-1) which can have detrimental effects on fibrinolysis [54, 55]. Di Minno et al. documented an increase in the activity of platelets among KS patients [56]. Increased levels of C-reactive protein, LDL cholesterol, and triglycerides combined with low levels of HDL cholesterol are thought to be factors that can aggravate the risk of getting IHD in KS patients. Adiponectin is a secretory protein that is specific for adipocytes and is protective against hypertension, and diabetes [57] is negatively correlated with the levels of testosterone in the body [58]. Interestingly, a study conducted by Swerdlow et al. found a slightly decreased mortality rate in KS patients (standardized mortality rate (SMR) (95% CI); 0.7 (0.5–0.9)) [4], whereas another study conducted by Bojesen et al. noticed an increased incidence of IHD in KS (hazard ratio (HR) (95 % CI); 1.71 (1.28–2.29)) [40].

Cancer The risk of malignancies in KS patients is almost similar to that of the normal population [40, 59]; however, certain malignancies such as breast cancer, mediastinal tumors, and hematological disorders are more likely to occur in KS patients, while KS has a protective effect against prostate cancer. The risk of breast cancer in patients with KS increases to 50-fold [60]. Most of the mediastinal germ cell tumors arise before 30 years of age and have been seen in more than 40 patients [61]. Non-Hodgkin lymphoma and leukemia are the hematological malignancies mostly related to KS [62]. Significantly decreased risk of prostate cancer is attributed to the decreased levels of testosterone [59]. A study done in the UK in 2017 showed that diabetes and increased body fat have a protective effect on prostate cancer, so they could be the reasons behind the decreased risk of prostate cancer in KS patients [63].

Cognitive Disturbances KS patients commonly exhibit verbal deficits, detected in approximately 70–80% of patients [64]. KS patients were compared to dyslexic children in intellectual activities planning, concept formation, problem-solving, and switching tasks [65].

Table 24.2 Frequencies of psychiatric illnesses in Klinefelter syndrome patients

Learning Disorders	65%
Attention deficit hyperactivity disorder	63%
Depressive disorders	24%
Psychotic disorder	8%
Schizophrenia	2%

Based on data from Ref. [69]

Psychiatric Disturbances Epidemiological studies have shown that people with chromosomal aneuploidy having an extra X chromosome as in KS have a higher incidence of psychiatric illnesses when compared to cytogenetically normal population [66]. Children of school age with KS exhibit low self-confidence, apprehension, temperament disorders and problems of socialization [67]. Work done by Ross et al. demonstrated that the presence of problems in early life with poor socialization often resulted in psychiatric disorders [68]. A study conducted on 51 KS boys based on the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR; APA, 2000) revealed the presence of psychiatric disorders in them [69]. The frequencies are shown in Table 24.2.

24.5 Diagnosis

KS diagnosis requires clinical suspicion and a high level of awareness about its clinical presentation such as sexual dysfunction, delayed puberty, low levels of testosterone, and infertility. The condition should be investigated when signs and symptoms of hypogonadism are seen during the initial evaluation of male fertility. Clinical findings such as decreased facial and body hair with enlarged breasts are usually evident. Genital examination reveals small testes with a firm consistency. In a study conducted in Japan, atrophy of prostate is seen in 30% of the cases on digital rectal examination [70].

The testes of KS patients undergo slow degeneration during childhood, which progresses during puberty resulting in fibrosis and hyalinization of the seminiferous tubules, which is a characteristic feature of KS [71]. This evidence of degeneration of testicular tissue in early life was supported by Wikstrom et al. who observed that only 50% of KS males in their peripubertal age had germ cells in their testes [23]. In another study, the same authors observed that the germ cells are arrested at the early stages of cell division [72]. As a result, during ejaculation, only 8.3% of KS males are able to produce sperm [73]. Endocrine evaluation of adult KS patients exhibits lower levels of serum testosterone in about 80% of patients, secondary to impairment of Leydig cells during puberty [36]. The serum concentrations of sex-hormone-binding globulin (SHBG) are high in KS patients,

which further aggravates the reduction of free testosterone. On the contrary, the testosterone/estradiol ratio is disrupted due to the higher levels of estradiol in KS patients compared to normal men. The concentrations of LH and FSH are raised emphasizing a hypergonadotropic hypogonadism picture. The levels of FSH are consistent demonstrating the coherent damage of seminiferous tubules [74], which is secondary to decreased levels of inhibin B [29].

Early diagnosis and treatment of boys with KS should have beneficial effects on their physical, social, and academic development [75]. Unluckily, only 10% of men having KS are identified at a young age, the time during which treatment may be most beneficial. To screen KS patients, children with learning difficulties or those having developmental problems should be the target population so that timely detection and prompt treatment can be done [75].

Testing for Barr bodies by taking sample from the buccal mucosa, which corresponds to the inactive supernumerary X chromosome, is an obsolete method [76]. Currently, the diagnosis is confirmed through cytogenetics by the chromosomal analysis of lymphocytes [76]. Skin fibroblasts or testicular biopsy samples might be required if a normal karyotype is reported to confirm chromosome mosaicism. Microdeletion analysis of the Y chromosome is also indicated in patients having KS, as some reports have suggested that KS patients are at an increased risk for such deletions [77].

KS patients are at an increased risk of osteoporosis and osteopenia due to androgen deficiency so DEXA scan should be regularly done to check bone density. If the presence of osteopenia or osteoporosis is confirmed, then further laboratory tests should be done that include serum calcium, serum phosphorus, parathyroid hormone (PTH), and vitamin D3.

KS patients should be informed that they are at an increased risk of breast cancer, and they should be educated on performing self-breast examinations regularly. They should also be encouraged to seek medical advice when they feel a change in the consistency of breast tissue or if they notice any discharge from the nipples.

24.6 Management

A multidisciplinary approach toward the management of KS patients is essential to encounter the multiple features of the disease. However, attaining fertility is the fundamental goal while treating KS patients, the clinician should not undermine other consequences of the disease that can have an impact on the quality of life and health of the patient. Some factors must be taken into account while managing a patient with KS that include the presenting complaint of the patient, the age at which the diagnosis was made, and the status of the fertility of the patient.

24.6.1 Managing Hypogonadism

24.6.1.1 In Adolescents and Adults

The hypogonadism in KS patients needs to be treated by testosterone replacement (TRT) at some point during the course of the therapy. The impact of TRT on fertility in men with KS is still not known in studies done till date. In a study conducted by Schiff et al. [78], TRT was given to five patients for a time span ranging from 2 to 14 years, but sperm retrieval was successful in only one patient through testicular sperm extraction (TESE). Another study conducted by Ramasamy et al. observed a worse sperm retrieval rate (SRR) in patients who had received TRT [79]. Recent treatment practice statements recommend to initiate TRT in KS patients in the age of early-to-midpuberty, or at the time of commencement of hypogonadism [80, 81, 2], to ascertain the completion of puberty and to minimize the long-term undesired effects of androgen deficiency. Some physicians choose to initiate TRT therapy even at an earlier age trying to correct the relatively decreased penile length in KS boys [82]. There are no established protocols for TRT therapy in KS patients. Clinical Practice Guidelines for treatment of hypogonadal men can be used to determine dosage according to age [83].

Some reports have emphasized that hormone replacement therapies can enhance sperm production and can decrease the harmful effects of exogenous testosterone. In study of 10 patients who were administered topical testosterone for a period of 1–5 years with an aromatase inhibitor in combination before doing micro-TESE, sperm retrieval rate (SRR) was 70% [84]. In another study on relatively larger sample size of 21 non-mosaic KS patients, the sperm retrieval rate (SRR) was 57%, which was comparatively less [85]. Aksglaede et al. investigated 22 studies in which the overall sperm retrieval rate was 50% [71]. The levels of testosterone need to be monitored after TESE, as it takes more than 12 months for the testosterone levels to return to its normal level [86]. The combination of intramuscular injections of human chorionic gonadotropin or clomiphene citrate are other available options that can be used. These regimens are not specifically used in patients with KS; however, some evidence can be deduced from their use in men with androgen deficiency. A retrospective study conducted on 26 men documented no differences in the semen parameters of the patients after 1 year of treatment with human chorionic gonadotropin (HCG) in combination with TRT; surprisingly 35% of the couples became pregnant spontaneously [87]. In another study, the lower doses of HCG were used and they were successful in sustaining adequate intratesticular levels of testosterone [88]. A disadvantage that is encountered after the continuous use of HCG is that FSH replacement therapy should also be started after some time so that the process of spermatogenesis is maintained. In hypogonadal men, clomiphene citrate has been acknowledged as an equitable

alternative to exogenous testosterone. In spite of having a lower efficacy than testosterone in its injectable form, clomiphene citrate is efficient to achieve comparable symptom relief [89]. A new estrogen receptor modulator—enclomiphene citrate—was successful in normalizing the endogenous production of testosterone and restoring the sperm counts by restoring the functioning of the hypothalamic-pituitary-testicular axis [90]. Concerns about the safety regarding the use of clomiphene and its derivatives for a longer period of time arose. Moskovic et al. worked on this issue by doing a follow-up of 46 patients being treated with clomiphene citrate for more than 12 months. He was unable to find any adverse effects in that group of patients, so making it clear that it can be used in appropriate patients for longer-term therapy [91]. Still more studies are required to ensure the safety of patients on a larger population for a longer period of time.

24.6.2 Fertility Management

24.6.2.1 Peripubertal KS Boys

Based on prior knowledge, there is a progressive decline in the testicular function that begins at puberty. Some researchers suggest to seek fertility preservation at an early age even before staring TRT. In a study conducted on adolescents aged 12–20 years, Mehta et al. were able to confirm the presence of sperm in the ejaculates of 70% of the patients [92]. Research on testicular tissue samples in this age group are justifiably scarce. In a case report by Damani et al., successful sperm retrieval was done on a boy aged 15 years [93]. Work done by Aksglaede et al. [71] confirmed that the loss of germ cells in the testicular tissue occurs after the age of 10 years. Wikstrom et al. [23] examined testicular tissue samples in 14 boys with KS aged 10–14 years and found germ cells in only half of the patients, proposing that testicular dysfunction is present in the peripubertal period in KS patients. Furthermore, all the samples that contained germ cells were from boys aged less than 12 years with normal testicular volume according to their age and normal serum FSH and serum inhibin B concentrations. Researchers have predictive markers that would allow sperm retrieval to be done at the most accurate time to ensure its success. As the levels of serum inhibin B levels are in the normal range during the prepubertal and early pubertal periods [29], it makes it an optimal marker to exhibit the number and integrity of Sertoli cells. Unfortunately, this notion was not supported as the levels of inhibin B even within the normal range did not correlate with the presence of spermatogonia [22]. The levels of anti-Mullerian hormone also did not correlate with spermatogenic activity even though its levels rise during prepuberty and early puberty in KS boys and decrease subsequently [94]. Insulin-like factor 3 (INSL3), a marker of Leydig cell function, also did not correlate with spermatogenic activity as it is within normal levels before the onset of puberty in KS patients and decreases subsequently [72]. In a study conducted on both children and adults, Rohayem et al. determined that if the levels of testosterone are above 7.5 nmol/l and the levels of LH are below 17.5 U/l the sperm retrieval rates by mTESE are higher [95]. This concept was supported by another study conducted generally on men with azoospermia; low levels FSH and LH combined with higher levels of serum testosterone were acknowledged as positive predictive markers. However, in KS patients, the predictive value of serum testosterone still remains unsettled [96].

24.6.2.2 Cryopreservation in Adolescents

Moral concerns arise when attaining sperm from patients in the adolescent age via masturbation. Practices such as idiosyncratic masturbation or anejaculation that are frequent in this age group would further exacerbate the challenge. The clinician should be capable to handle this sensitive issue by actively involving parents and dealing with the patients according to their respective ages. Cryopreservation of sperm is offered to the adolescent KS patients after their detailed counselling with their parents. Current guidelines support sperm banking for all males who are at or above Tanner stage III, particularly if progressive motile sperm are found on semen analysis [97].

Stimulatory techniques can be used if masturbation cannot be executed. Penile vibratory stimulation or electroejaculation can be attempted under anesthesia. Surgical Sperm Retrieval techniques can also be used of which the most commonly used are percutaneous epididymal sperm aspiration (PESA) or testicular sperm aspiration (TESA). Schlegel et al. conducted a study to compare the SRR in patients undergoing standard TESE and micro-TESE. He determined a statistically significant difference in the SRR that was 45% in standard TESE as compared to 63% in micro-TESE, and he also found a difference in the spermatozoa yield that was 160,000 in micro-TESE as compared to 64,000 in standard TESE [98].

Furthermore, micro-TESE has decreased the damage to the blood supply of the testicles and decreased the amount of testicular tissue needed. Most of the research related to the use of these procedures in adolescents is done on cancer patients for fertility preservation. In a study conducted on the attitudes of patients and their parents on sperm banking of boys who are undergoing chemotherapy for cancer treatment, Van den Berg H et al. noticed that 70% of them were in the favor of using electrostimulation or masturbation to obtain sperm for sperm banking [99]. Invasive procedures for sperm retrieval in adolescent age are not advocated as the sperm retrieval rates are higher in adulthood, and sperm retrieval can have a negative impact on the endocrine system.

A new modality for the preservation of fertility has been proposed in which the spermatogonial stem cells (SSCs) are preserved from testicular tissue cryopreservation. These cells can be used later for the restoration of spermatogenesis or for in vitro maturation into a viable sperm [74]. Since the procedure is still experimental requiring surgery on minors, its utility is still not justified. Further studies should be done on this procedure to ensure its practicality as well as factors that can recognize potential patients for whom this procedure can be beneficial.

24.6.2.3 Adult KS Men

During the past two decades, treatment of infertility associated with KS has undergone considerable advancements making it feasible for KS patients to father their biologic children. Spontaneous pregnancy is a rare outcome in KS patients, so to achieve pregnancy, intracytoplasmic sperm injection (ICSI) is considered to be a more realistic approach. Few case reports have reported successful pregnancies in KS patients after ICSI was performed on ejaculate sperm [100]. In spite of that, most patients present with azoospermia and would require sperm extraction procedure before doing ICSI. Sperm retrieval procedures have been used in KS with nonobstructive azoospermia over the past two decades with SRR ranging from 30% to 70% [84, 101]. Microsurgical TESE has higher success rate as shown in the recent reviews [102]. In almost 50% of all the published cases of patients with KS in which TESE was utilized for sperm retrieval and ICSI, pregnancy and live birth were attained [102].

Hormonal therapy is advocated in KS patients prior to their scheduled sperm retrieval procedure. We have previously determined that the results of SRR in patients with prior hormonal stimulation were better compared to patients without prior hormonal stimulation [101]. Pharmacological treatment modalities such as the use of HCG, clomiphene citrate, and aromatase inhibitors have been tried in patients with KS [78]. Some studies have proposed the notion that aromatase inhibitors should be preferred based on the characteristic features of the disease, specifically the disturbed testosterone/estradiol ratio and increased truncal fat mass [101]. In controlled studies, these medications have been found to improve semen parameters such as sperm concentration and semen motility and also increase the testosterone-to-estradiol ratio [103]. However, aromatase inhibitors should not be used for more than 2 months prior to surgery as they can result in tachyphylaxis.

Several reports have tried to consider the prognostic factors for successful TESE. The baseline levels of testosterone and response to medical treatment are usually beneficial, although this concept is not supported by some studies. The levels of FSH and inhibin B have been thought of as prognostic factors for adequate spermatogenesis in normal men with no chromosomal abnormality [104]; however, this concept is not of much importance in KS patients. In reality, patients with inhibin B levels even below the detectable limit have undergone TESE successfully [105]. As testicular function deteriorates with age, the age of the KS patients undergoing TESE is of significant importance to the outcome [106]. One study determined a cut-off age of 32 years to be a well-established predictive parameter of successful sperm retrieval in KS patients [79, 107]. Nevertheless, the age factor has not been persistent among studies [71, 101].

24.7 Genetics Risks to Offspring

The advancements allowing us to overcome the infertility issues of KS patients have raised concerns regarding passing genetic anomalies to the offspring. In a survey conducted on KS patients, most of them expressed a desire to father children [108]; however, 70% of them acknowledged to have concerns about the safety of transmitting chromosomal anomalies to their offspring [108]. Semen analysis of the ejaculates of KS patients have revealed a high percentage of sperm with abnormal morphology [109]. Consequently, due to high percentage of abnormal sperm, it has been proposed that patients with KS have significantly greater ratio of chromosomal aneuploidy when compared to normal males [75]. On the contrary, most of the offspring biologically fathered by KS men have been healthy and normal with no chromosomal abnormalities [110], proposing that only the normal haploid sperm may be capable of fertilizing an ovum and results in a pregnancy. In a cohort study of 42 men, Schiff J et al. noticed that the incidence of phenotypic or chromosomal anomalies did not rise in the boys fathered by KS patients [78]. Nevertheless, the conception of offspring with an extra chromosome with the karyotype 47,XXY has been reported [111].

In order to protect the offspring of KS men from chromosomal abnormalities, it is recommended to have preimplantation genetic diagnosis (PGD) of embryos. Staessen et al. [112] have proposed a notion that PGD should be compulsory; the morphology of the embryo sometimes does not exclude any underlying genetic anomaly. In their study, they assured that frequency of normal embryos was 54% in KS patients, which was lower than the normal controls who had a frequency of 77.2%. They also determined that the anomalies can occur on both autosomes and sex chromosomes. PGD is not commonly available due to its expense and requirement of skilled workforce for its operation. Not to mention that PGD may be unacceptable in certain religious groups. In conclusion, KS couples undertaking ICSI should get PGD done unless there is an objection about its use.

24.8 Conclusion

KS is the most common sex chromosomal abnormality that has a significant impact on the patients' health and fertility. It is characterized by testicular failure and hypergonadotropic hypogonadism, which worsens as the age progresses. Early diagnosis can prevent the negative impact of the androgen deficiency on KS patients. Adolescents concerned about fertility should be asked to provide a semen sample if possible and should be offered sperm cryopreservation. Invasive procedures for sperm retrieval in adolescent age are not advocated as the sperm retrieval rates are higher in adulthood and sperm retrieval can have a negative impact on the endocrine system. Hormonal therapy is advocated in KS patients prior to their scheduled sperm retrieval procedure as it can produce superior results. KS couples undertaking ICSI should get PGD done unless there is an objection about its use.

24.9 Review Criteria

An extensive research exploring Klinefelter syndrome was performed using search engines such as ScienceDirect, OVID, Google Scholar, PubMed, and MEDLINE. The start and end dates for these searches were December 2000 and December 2018, respectively. The overall strategy for study identification and data extraction was based on the following keywords: "Klinefelter syndrome," "male infertility," "treatment," "testosterone," "genetics," "semen parameters," and "assisted reproduction." Articles published in languages other than English were also considered. Data that were solely published in conference or meeting proceedings, websites, or books were not included.

Assisted Reproductive Technology and Its Impact on Male Infertility Management

25

Alice Rhoton-Vlasak, Joseph M. Kramer, and Elizabeth Plasencia

Key Points

- In vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI) have become the standard of care for severe male factor infertility.
- Semen analysis is the standard by which each male patient is initially assessed in order to categorize his level of contribution to the couple's sub- or infertile condition.
- There are a variety of methodologies for selection and processing of sperm, some of which may be better suited for particular cases based on concentration, motility, and morphology.
- Insurance coverage for IVF and fertility preservation services remain limited in the United States.
- In cases of severe male factor infertility, a genetic, hormonal, and urological workup should be completed.

25.1 Introduction

Approximately 12–15% of sexually active couples are infertile. The etiology of infertility is likely multifactorial. Previous work has estimated that 50% of infertility is attributed to the female, 30% to the male, and 20% to both the male and female. Male factors are partially or completely responsible for infertility in up to 50% of cases. Recent advances, mainly in the assisted reproductive technologies (ART), have allowed some couples with severe male factor infertility to establish a pregnancy. The most significant advance is in vitro fertilization (IVF) with intracytoplasmic sperm injection (ICSI) [1, 2]. ICSI was introduced in the early 1990s as one of the most dramatic technological breakthroughs in assisted reproductive technology. After its introduction, the technique was rapidly incorporated into the routine clinical practice of fertility centers throughout the world [3].

Previously, these couples had at best only a remote chance of establishing a pregnancy due to severely reduced sperm concentration, compromised sperm function, or uncorrectable obstruction. Donor sperm or adoption may have been the only option for family building. As a result of the high success of IVF/ICSI, and as a by-product of the fact that fertility visits are often initiated by the female partner, the practice of modern ART can oftentimes proceed without a complete evaluation of the male partner. Instead, almost any couple, even those with a severe male factor, after being evaluated by only a reproductive endocrinologist, can theoretically become pregnant using IVF/ICSI [4]. Male evaluation is critical, as male factor infertility has been shown to independently affect reproductive outcomes, including the setting of assisted reproductive medicine [5].

There has also been increasing attention placed on male factor infertility as it relates to patient health. Currently, there are still many barriers to care, including geographic, financial, socioeconomic, political, and awareness. This chapter outlines updates and future advances in male infertility care, beyond the use of standard IVF with ICSI. Potential additions to culture media, sperm treatments, and new sperm selection techniques will be discussed.

25.2 Male Infertility Workup and the Role of Urologists

Despite the trend toward unilateral care of the female partner in the reproductive health community, it is important to consider the couple as a whole unit. According to the National Survey of Family Growth (NSFG), as many as 27% of males do not complete an evaluation among couples seeking infertility care [6]. Lack of male investigation or limited urologic services can lead to potentially reversible, life-threatening, and/or genetic conditions being missed. Management of men with obstructive or nonobstructive etiologies that request or require sperm retrieval techniques also needs to be coordinated [7]. A study by Kolettis and Sabanegh evaluated potential factors that could be missed by bypassing a urological evaluation in infertile male patients. The study took place at two academic infertility practices. This study showed that significant medical pathology was discovered in 33/536 (6%) of patients. A total of 27 patients had genetic abnormalities, including cystic fibrosis mutations in 24 and karyotypic abnormalities in 3. Of the remaining six patients, one had testicular cancer, one had prostate cancer, three were found to have diabetes mellitus, and one had hypothyroidism [8]. Any couple proceeding directly to ART without even a basic urologic evaluation may not have their underlying medical pathology detected or discussed with them. Semen quality has also been recognized as a possible marker of male health [9].

Despite growing literature as above, there remains some debate about the importance of a urological evaluation. At first glance, this does not seem a problematic notion at all. If infertile couples can be afforded the opportunity to have a child in a time-efficient, cost-efficient, and safe manner, it can be concluded that this event represents an ideal outcome. However, when determining whether the male patient even needs to be evaluated given the availability of IVF/ICSI, several simple, conceptual problems do present themselves. Indeed, a large volume of data exists that argues that failure to evaluate the male is less safe for male patients, their partners, and their offspring and can be less cost-efficient. There is existing medical evidence in support of the idea that an evaluation of the male partner is mandated by both patient safety and cost-effectiveness [4]. According to the American Society for Reproductive Medicine (ASRM) committee opinion, when screening shows abnormal male reproductive history or abnormal semen analysis, a specialist in male reproductive health should be involved [10]. Review of this information will highlight the importance of infertility and ART centers having male infertility specialists in their practice area to optimize male factor patients' workup and treatment. The ideal infertility practice would involve a multidisciplinary clinic with both reproductive endocrinology and infertility (REI) and urology specialists. Other important clinical infertility team members would include embryologists, psychologists, and nurse specialists.

A multidisciplinary approach to male infertility patients including a urologist results in safer outcomes for couples. ART safety is a topic that has been extensively studied since the initial use of IVF in 1978 [11]. Safety issues that must be detected by a male infertility evaluation include detection of endocrine, genetic, or malignancies underlying an infertility diagnosis [8]. A thorough male infertility evaluation may also uncover genetic abnormalities, which could have implications for the health of future offspring. The identification of genetic conditions, such as Klinefelter's syndrome, microdeletions of the Y chromosome, and cystic fibrosis/congenital absence of the vas deferens, in patients with male infertility had profound implications for the offspring as well [12–14]. A complete workup of a man with obstructive azoospermia could lead to the finding of his being a carrier of a mutation for the cystic fibrosis membrane regulator (CFTR) gene. This has important implications for testing his partner to see whether she is a carrier or not. Obviously, if both were carriers of the cystic fibrosis gene, there is a higher chance they could have an offspring with this condition. Therefore, especially in the case of cystic fibrosis, it is imperative that the partner of an affected patient be screened to adequately counsel the couple on the risks of potentially passing this condition on to their anticipated offspring.

In much the same way, the identification of any genetic condition through a routine evaluation of male infertility is doubly important for the reason that couples can be counseled regarding the passage of these conditions to their offspring. Male offspring of patients with Azoospermia factor (AZF) region Y chromosome microdeletions can be expected to have the same deletion and are, therefore, likely to be subfertile or infertile themselves [4]. A review of these causes of male factor infertility highlights the importance of the complete urologic evaluation of the male partner to result in a safer outcome for the male patient, his partner, and their potential offspring.

There is a growing body of literature that has shown an association of male infertility and long-term health consequences, including risk for malignancy [15]. The rates of testicular and high-grade prostate cancer seem to be at least double the risk of the general population. There is also an association between infertile men and cancer risk in first- and second-degree relatives. Testicular cancer risk has been shown to be 52% higher in first-degree relatives of infertile men, and there is a two- to threefold increase in childhood cancer among siblings of infertile men.

Another reason for emphasizing the importance of a urologic evaluation in male infertility is that there is proven cost efficiency of evaluating and treating underlying male infertility, especially in cases where an anatomic or hormonal abnormality is found and correctible, thereby even allowing attempts at natural conception [4]. Medical or surgical treatment can potentially eliminate the need for ART or decrease the level of assistance needed. In the case of male varicocele, surgical correction can result in improvement in semen parameters, which improved the chances of conception naturally, with IUI or with assisted reproduction [16]. A cost analysis of effectiveness by Garceau considered four studies where IUI and IVF/ICSI were compared; a significant improvement in cost efficiency was observed in the IUI cohort across all studies, even when comparable populations were considered. The only exceptions to this conclusion were cases of severe male factor infertility or tubal obstruction. Certainly, in cases with treatable causes of male infertility and no single female factor that precludes IUI, it would seem reasonable to offer treatment to the male partner [17].

Fertility preservation is another service that is crucial to male well-being and emotional health. Every year in the United States, 9,000 males between 15 and 35 years of age are diagnosed with cancer. Male children less than 15 years old represent another 4,000 cancer victims annually. Cure rates are only increasing, given new research and innovative technology, increasing the number of males who will need sperm preservation therapy or ART later in life. It is currently recommended that all patients who are about to undergo treatment for cancer be counseled by a fertility specialist. There are multiple organizations, such as LIVESTRONG, the Alliance for Fertility Preservation, RESOLVE, the Oncofertility Consortium, and ASRM, which are currently attempting to make fertility preservation the standard of care for these patients [18].

It is clear that it is cost-effective to support treatment of reversible causes of male infertility and that safety is improved where there is a male urologic evaluation. There is also an increasing demand for oncofertility counseling and therapy. The existing evidence supports the rigorous evaluation of the male partner. Both the ASRM and the American College of Obstetricians and Gynecologists (ACOG) guidelines for best practice on infertility are in agreement on this point [19, 20]. Despite the significant advances in ART, there remains a very important role of the urologist in the evaluation of male infertility in order to maximize the safety for both the male and female partners and their offspring. Furthermore, it is cost-effective, especially in the setting of the identification of a treatable or reversible cause of male infertility.

25.3 Multidisciplinary Clinical Care

A multidisciplinary clinic system with reproductive endocrinologists and urologists working side by side is the optimal way to offer the highest level of reproductive care to infertile couples. A multidisciplinary clinic such as this has been highly effective and well received by patients. A study by Nangia [7] assessed the spatial distribution of ART centers and male infertility specialists by location, driving distance from ART centers, and potential male population in need of these resources. It was a cross-sectional study which found that a disparity of urology male infertility specialists exists in the United States, with large areas of the country being underserved and the overserved based on the location of the ART centers. The study identified 197 male infertility specialists and 390 ART centers (Figs. 25.1 and 25.2). On a state level, the highest male population in the reproductive years was seen in California, Texas, and Florida. The highest male populations per male specialists were found in Oregon, Tennessee, and Oklahoma. The Northeast region had the highest number of male specialists within ART service areas. The distribution of male population per male specialist was independent of a state's mandated insurance status for ART services. This study highlights the importance of proximity of male specialists to ART centers for the overall care of the couple with male factor infertility. This is related to the common understanding and interaction between urology and ART specialists regarding joint management or procedures for the couple. Lack of this joint care can potentially lead to significant biases, incomplete evaluation, and poorly informed discussion about treatment choices [21].

Offering the highest level of male infertility care could involve use of an interdisciplinary clinic with a urologist and reproductive endocrinologist. Decision trees could be used to enhance interdisciplinary teamwork within the reproductive medicine clinic. A common scenario would involve an infertility patient coming to clinic with her partner with known male factor infertility. If a reproductive endocrinologist and urologist hold clinic on the same day, the female history, exam, and testing could be discussed and performed while also allowing the couple to see the urologist to begin a focused male infertility evaluation. A collaborative interaction between these two specialists could allow coordination of any genetic or hormonal testing. Ultimately, collaboration between these two specialists could lead to a decision regarding whether or not the best treatment involves management of an underlying medical condition causing male infertility, a correctible underlying cause, which could be treated with medications or surgery allowing attempts at pregnancy with IUI, or whether ART and ICSI are needed. At our institution, we had such an interdisciplinary clinic, which allowed the

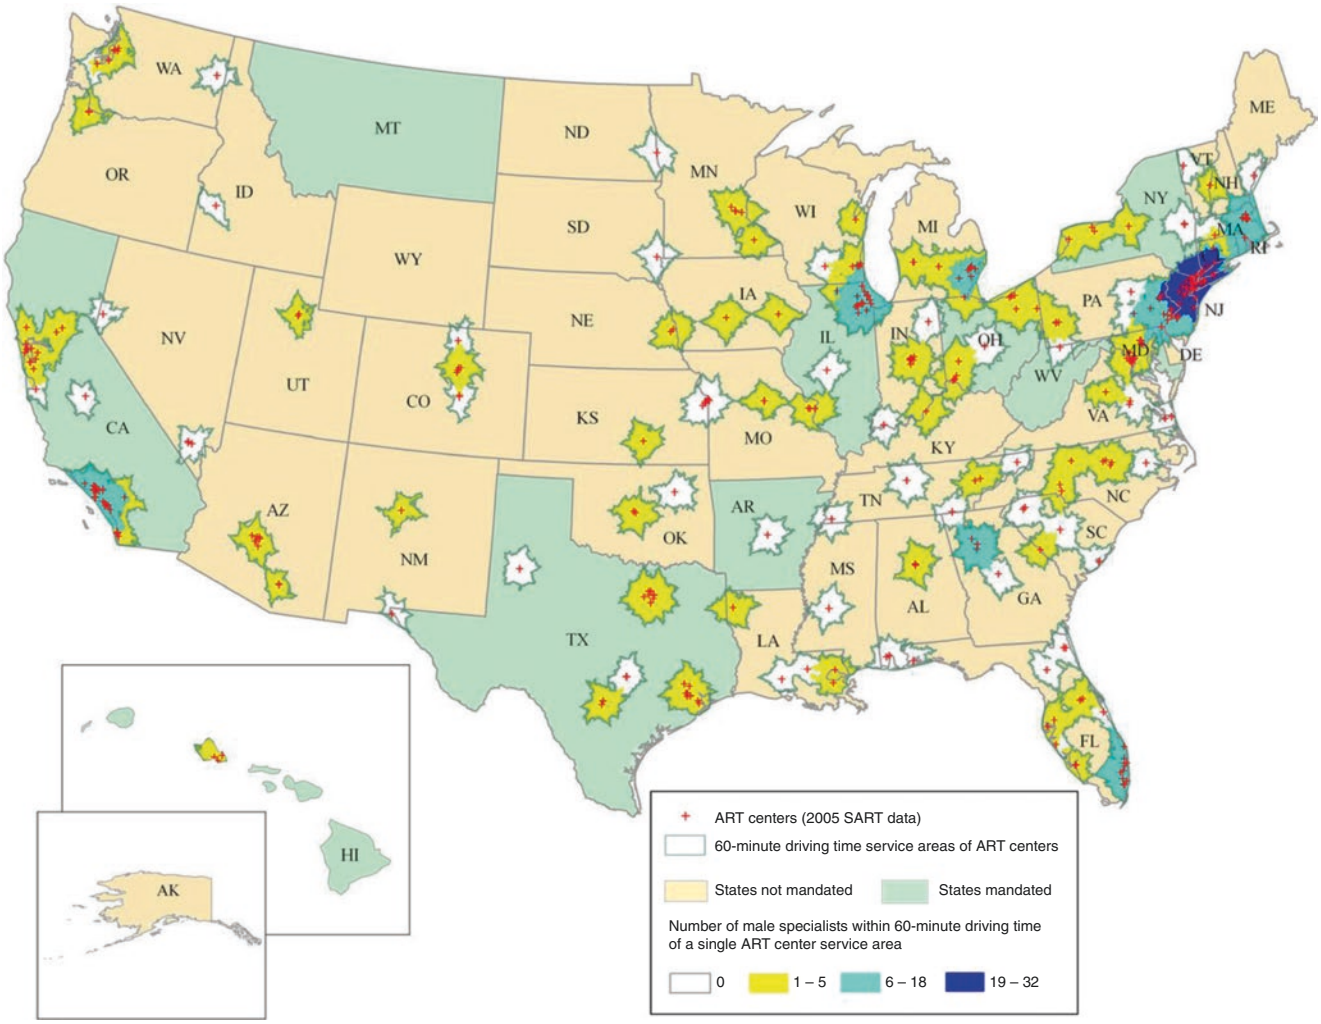

Fig. 25.1 Number of male specialists within 60-min driving distance of a single ART center. (Reprinted from Nangia et al. [7]. With permission from Elsevier)

coordination of many complicated male infertility cases, even in terms of scheduling fresh sperm aspiration procedures on the same day of oocyte retrievals and ICSI. On the other hand, having the immediate availability of a urologist in our clinic allowed patients referred for severe oligospermia to be evaluated and then treated for underlying hormonal conditions with resolution of their poor sperm counts, therefore, allowing them the chance at a natural conception and bypassing the use of ART. Options regarding surgery such as varicocelectomy can also be discussed at this time, and potential differences in cost depending on treatment strategy can be discussed.

A large barrier to care currently is the insurance coverage for male and female infertility. Infertility was recognized as a disease by the ASRM in 2008; however, access to infertility treatments continues to be viewed as an elective option and not a basic right in the United States [18]. Currently, infertility coverage is up to the discretion of the state. Dupree et al. [22] determined which states required insurance coverage for infertility. There were 15 states that mandate insurance coverage for infertility. Of these, only six states (California, Connecticut, Massachusetts, New York, New Jersey, and Ohio) included male infertility evaluation or treatment. Certain male treatments such as cryopreservation or vasectomy reversal are specifically excluded in some of these states (Fig. 25.3). While mandated health insurance coverage was associated with increased use of ART, according to a study by Griffin and Panak, no evidence of overutilization of ART by patients with low chance of reproductive success was found [23].

25.4 The Techniques and Impact of the ART Laboratory on Male Infertility

The treatment of the male, within the context of a couple, may not always allow for the months of treatment necessary for long-term hormonal interventions or, for that matter, vas reversals following years of sterility. These situations are best assessed by the urologist in collaboration with the treating infertility specialist. The array of available treatment options is also a matter of the overall abilities of the ART laboratory and its ability to bring to bear the necessary technology appropriate for the specific patient treatment requirements.

With the availability of various ART/ICSI procedures now used in clinical settings, the treatment of combined male and female infertility issues, or just those associated with the male partner only, becomes a choice of expediency. The primary road to expediency is of course due to the age of the female.

From the viewpoint of what technologies are now available for the treatment of the male's contribution to the couples' infertility issues, we should look closely at the ability to firstly assess the conditions that directly impact the patient's sperm fertilizing potential and secondly the steps required to overcome this disability.

The semen analysis procedure is the standard by which each male patient is initially assessed in order to categorize his level of contribution to the couple's sub- or infertile condition [24]. Aspermia, azoospermia, and/or severe asthenospermia all place this patient in line for some type of assisted

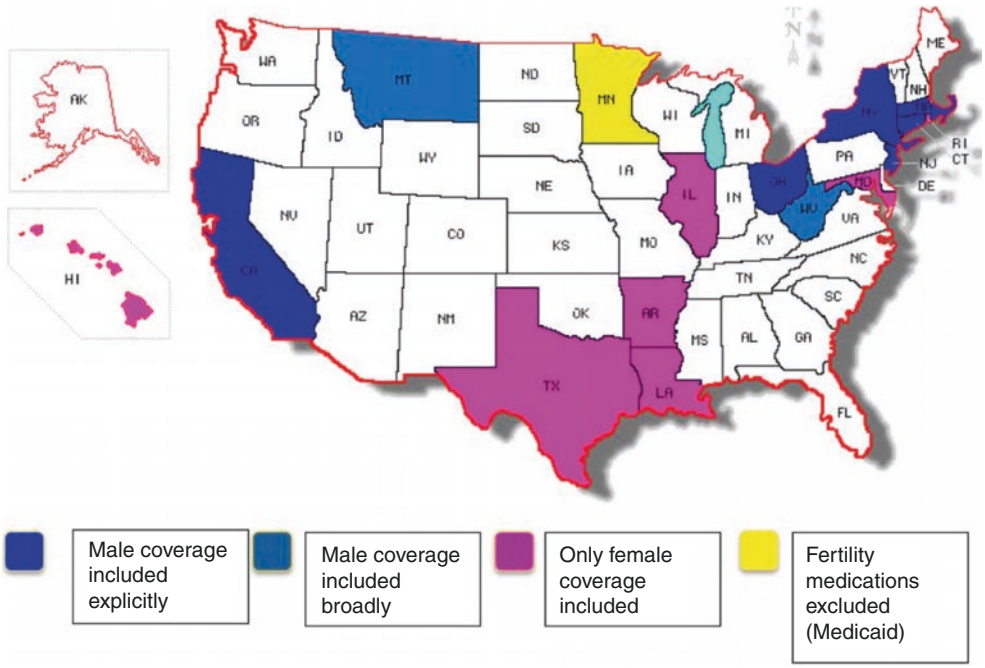

Fig. 25.3 Mandated health insurance coverage spectrum for male factor infertility. (Reprinted from Mehta et al. [18]. With permission from Elsevier)

reproductive treatment or intervention. It may also be useful to address the use of donor sperm under these circumstances as well. However, all of the abovementioned conditions are potentially treatable. In addition to these most serious conditions, semen volume, coloration, viscosity, and pH are often included in an initial assessment of a semen sample [25]. Further assessment of various vital sperm characteristics is also essential; these will include sperm concentration, sperm motility, sperm morphology, antisperm antibodies, and in the case of severe asthenozoospermia, vital staining tests [26]. The question, however, is: do these assessments in aggregate, or any one of them individually, actually allow the physician to determine whether or not these sperm can carry out normal fertilization?

There is also controversy as to the meaningfulness and significance of attached cutoff values. The WHO laboratory manual for the examination and processing of human semen, fifth edition, published by the World Health Organization in 2010, generated debate even before publication [27–31]. However, there exists a very predictive diagnostic test that the couple could undergo in order to answer this question, and that is in vitro fertilization. Since this diagnostic test would be considered far too expensive and invasive, it tends not to be used for that purpose, although IVF procedures sometimes turn out to answer that question. Because of the potential outcome called "failed fertilization," many ART programs prefer to utilize ICSI micromanipulation as their first-round defense to treat male infertility.

If there was a validated, reasonably priced sperm diagnostic test able to determine the fertilization capacity of the male patient's sperm sample, how might it change the clinical decision-making and the use of invasive ART practices like ICSI? One might also ask "what are present-day ICSI usage criteria?". One very broad axiom in use today is "once ICSI always ICSI," and this covers almost any treatment proposal if a program always starts a protocol using ICSI. What then are the prospects of being able to determine the ability of sperm function in order to avoid the use of micromanipulation or prepare for its expedient use if the procedure is necessary? Following a decision to employ micromanipulation, is it also necessary to choose a particular sperm within the available sample which will ensure proper embryonic development?

The following procedures or tests are offered in order to assist in the diagnosis and treatment planning of the male infertility patient. These tests may be available through collaboration with reproductive endocrinologists, urologists, and in vitro laboratory embryologists.

25.5 Oxidative Burden and the Use of Antioxidants

Since sperm function relies heavily on sperm membrane integrity and intramembrane lipid fluidity, the potential oxidative impact of oxygen radicals and peroxides, generated within the reproductive tract, can irreversibly damage the sperm's ability to undergo membrane alterations and respond to ionic signaling required during spermatogenesis [32–34], the process of membrane fusion at the time of fertilization. It is possible to measure antioxidant levels and capacity of seminal fluid in order to determine whether sperm is adequately protected during the collection process [33, 35–37].

There have also been studies reporting favorable outcomes using oral antioxidants as enhancers of sperm function [38–40]. Low levels of vitamin C are associated with an increase in oxidatively modified DNA base, 8-hydroxydeoxyguanosine in sperm DNA [41]. However, the type and mix of antioxidants used in this prophylactic manner have not been adequately resolved [33, 42].

25.6 Use of Antioxidant Additives During Fertilization and Embryo Culture

As well as employing antioxidants during sperm production and processing, selected compounds have also been utilized to enhance culture conditions during fertilization and embryonic culture [43, 44]. In vitro culture systems lack many of the protective elements found in follicular fluids and the fallopian tube environment. The higher levels of oxygen generally found within in vitro culture systems is of concern due to its ability to overwhelm what little antioxidative capacity resides in commercial media with unlimited sources of deleterious oxygen radicals. Therefore, the first strategy that should be put into place to reduce these reactive elements is to lower the oxygen content within culture incubators to levels thought to be present in the female reproductive tract (5–7%).

The application of various compounds that may be able to destroy or convert dangerous levels of reactive radical species when added to culture systems have been explored [45]. To date, none seem to be convincingly more efficient or useful than added taurines and cysteines. Vitamins such as vitamin C and vitamin E have been used as culture antioxidants in a number of human and animal systems [43]. However, these additives have not shown consistent beneficial results in order to warrant their inclusion. Because current culture systems are static in nature, it may be that a cascade of oxidative reducing elements (vit E®, lipoic acid®, vit C) may be required within a dynamic culture environment such as those proposed using microfluidics where oxidized compounds can then be removed [46].

25.7 Selection of Sperm

Among the fundamental procedures within the ART laboratory is the attempt to replace the natural selective processes occurring within the female reproductive tract in which semen is reduced to a population of viable motile sperm capable of fertilizing an egg. Integral to this process is the removal of seminal plasma to allow for capacitation of sperm. Over the past few decades, numerous techniques have been described for selecting sperm cells for use in ART, each of which has advantages and disadvantages.

25.7.1 Centrifugation

Density gradient centrifugation (DGC) is the primary processing step to separate seminal plasma containing nonmotile cells from motile sperm. After liquefaction, the semen sample is typically laid on top of a discontinuous gradient composed of silica particles within a conical tube and centrifuged at maximum of 300 × *g* for 20 min. During the centrifugation process, motile sperm are aided by gravitational force and move toward the end of the tube, forming a soft pellet. Nonmotile sperm cells, leukocytes, and seminal fluids are mostly trapped within the upper columns of the gradient. Following DGC, the sperm pellet is typically resuspended in a fresh wash medium and either subjected to an additional round of centrifugation (wash step) or utilized in a swim-up procedure. As a whole, DGC centrifugation is highly effective with normozoospermic samples but less useful for cases where sperm counts are below normal ranges.

Simple sperm wash alone is the preferred method for oligozoospermic samples. Semen is gently mixed with wash medium and centrifuged for 5 min to separate sperm cells from seminal plasma. Unlike DGC, the resulting sperm pellet will contain a greater concentration of nonmotile cells, including leukocytes. Motile sperm can easily be further selected during ICSI.

The major concern with sperm centrifugation is the potential damage to sperm cell function. Aside from physical damage, the removal of antioxidant-rich seminal plasma during centrifugation combined with potential concentration of ROS producing immature germ cells and peroxidase-positive leukocytes may negatively affect mitochondrial membrane potential and DNA integrity [47–49]. For DGC, a trade-off between total sperm recovery and functionality of sperm recovered is proportional to the g-force and duration of centrifugation. In terms of oxidative stress, DGC, when carefully monitored for g-force and duration, has been shown to be effective in reducing oxidative stress in processed sperm [50, 51].

25.7.2 Swim-Up

The swim-up procedure selects motile sperm by allowing those with good mobility to naturally migrate into a layered column of medium over a period of 1–2 h. The concentration of sperm aspirated from the upper layer of medium is generally too little from raw semen to be useful for IUI or conventional IVF. However, when swim-up is utilized following a first round of DGC, the recovery rates with normozoospermic samples are sufficient for most ART procedures. In addition, the combination of DGC and swim-up yields higher motility and lower DNA fragmentation than either processing method alone [52].

25.7.3 Electrophoresis

Electrophoresis, a traditional molecular laboratory technology to separate macromolecules based on size and charge, can be utilized to separate sperm [53]. During sperm maturation, sperm naturally develop a negative net charge. When placed into an electrophoresis instrument, sperm with negatively charged membranes will migrate toward the anode. Several studies have shown that when compared to positively charged sperm, a sperm with negatively charged membranes is more likely to be morphologically normal and have lower levels of DNA damage [54–56]. Furthermore, there is some evidence to suggest negatively charged sperm are associated with higher embryo development and higher pregnancy rates [56]. While these studies are promising, the technology may be limited for use with microelectrophoresis chambers designed for use during ICSI.

25.7.4 Magnetic-Activated Cell Sorting

Magnetic-activated cell sorting (MACS) is a sperm preparation method that isolates immunologically labeled sperm using a high-gradient magnetic field. This technology has been used for the selection of acrosome-reacted sperm [57], removal of leukocytes within semen [58, 59], and separation of apoptotic sperm [60]. Non-apoptotic sperm sorted by MACS based on the expression of phosphatidylserine are also associated with decreased DNA fragmentation [61–63] and improved motility, morphology, and viability [63–65]. In addition, there is data to suggest the use of MACS and ICSI improves embryo quality in select couples [66]. More studies are warranted, however, to define which populations would benefit from MACS technology.

25.7.5 Microfluidics

Newer approaches with microfluidic devices are showing promising results in the selection of sperm in a clinical setting [67]. Unlike traditional microfluidic devices that used complex pump systems or gravitational flow to sort motile and morphologically normal sperm [68], these newer chemical- and flow-free chips use small volumes and microchannels to constrain the migration of slow and nonmotile cells. Initial studies have shown these devices to select sperm with good motility and reduced levels of DNA fragmentation [67], although the concentration is lower compared to traditional DGC. Future studies will need to evaluate whether the quantity of highly motile sperm recovered can be suitable for procedures other than ICSI.

25.8 Further Selection for ICSI

25.8.1 Sperm-Hyaluronic Acid Binding

During conventional insemination, sperm must pass through a hyaluronic acid (HA)-rich extracellular matrix of cumulus cells in order to access the egg. Healthy normal sperm contain the enzyme hyaluronidase, which aids in breaking down the extracellular matrix. This principal interaction between sperm and HA has led to the development of Physiological ICSI (PICSI), a commercially available sperm-HA binding assay that can be used to further select healthy sperm to use for ICSI. Several studies suggest the utilization of PICSI increases characteristics such as minimal DNA fragmentation, normal shape, low frequency of chromosomal aneuploidies, as well as high DNA chain integrity [69, 70]. There is also some evidence that using PICSI may increase the pregnancy rate and reduce the miscarriage rate when the overall level of HA binding is low in a sperm sample.

25.8.2 High-Magnification Sperm Selection ICSI

Intracytoplasmic morphologically selected sperm injection (IMSI) is the combination of motile sperm organelle morphology examination (MSOME) and ICSI. The typical inverted microscope used for ICSI has a total magnification of 200–400×, which is not sufficient for an embryologist to select sperm based on strict morphological examination during injection. In contrast, with IMSI utilizing a 100× oil objective and 1.5× optical enhancer, the digital magnification enhancement can produce a high-resolution (6,000–10,000×) real-time imaging of sperm in an ICSI dish. Utilizing this enhanced visualization of sperm morphology, especially taking into account head vacuolization and midpiece abnormalities, has led to successful outcomes for severe male factor patients [71–73]. Additionally, live birth success has been correlated to types and grades of sperm abnormalities viewed under high magnification [74]. Unfortunately, this procedure tends to be time-consuming and technically challenging.

25.9 Additional Sperm Processing

25.9.1 Culture and Supplementation

Temperature and duration of incubation of sperm after processing until insemination can impact the quality of sperm and potential success of ART. While short-term incubation of sperm at 37 °C is suggested to improve sperm capacitation

[75], longer periods (>2 h) of storage at room temperature or body temperature (37 °C) have been shown to reduce motility and viability [76–78]. Processed samples stored for >2 h. are also associated with reduced IUI success [79, 80]. Additional causes for concern are studies that show prolonged incubation of processed sperm at 37 °C is correlated with increased DNA fragmentation [78, 81]. In many ART clinical programs, timing is usually at the convenience of the patient and physician, and the duration from semen collection, processing, and utilization may often be 4 h or more. To lessen the risk of declining sperm function, busy ART laboratories should consider lower temperatures throughout processing until time of use.

As in the case of treating a patient with supplements of vitamins and other antioxidants in order to reduce the effects of oxidative stress on systems responsible for sperm production and processing, the use of vitamins, metal chelators, Glycerophospholipid (GPL) micelles, proteins, and disulfide compounds in the medium used to process sperm samples for assisted reproductive treatments has shown to be useful for sperm viability and function [82, 83]. Sperm membrane stability is preserved by reducing or eliminating peroxidation, and nuclear DNA is protected from damage by highly reactive radical species [44]. These protective compounds will help to enhance in vitro embryo development.

25.9.2 Cryopreservation

Semen and sperm cryopreservation has a long history in both human and domestic animal reproduction [84], and for the most part, glycerol has been used as the primary ingredient responsible for retention of viability post-thaw. Additional components have since been added to enhance viability and thawed motility through incorporation of processed egg yolk in an attempt to stabilize membranes through a low-cost source of phospho- and glycolipids, such as phosphatidylcholine (PtdCho), phosphatidylethanolamine (PtdEtn), phosphatidylinositol (PtdIns), and phosphatidylserine (PtdSer) [85]. Since typical semen specimens tend to comprise many millions of sperm, a return rate of 50% of the initial live sperm content is considered very acceptable to most users.

On the other hand, if the sperm sample has been obtained through invasive urological procedures and is to be used in expensive assisted reproductive treatments, then each sperm takes on a significant value to both the patient and the laboratory staff. Cryopreservation under these conditions requires a system that not only maintains high levels of viability but also allows for the efficient retrieval of the few thawed sperm that may have been obtained [86].

A number of semi- and/or micro-sperm freezing systems have been proposed ranging from the use of harvested empty zonae [87] or cryo-devices [88] for the storage of one or two sperm to a Cell Sleeper unit [89] housed in a standard cryovial, allowing storage of anywhere from a few to a few hundred collected sperm. The use of these sperm cryo-storage systems can improve the use of limited number of sperm available for couples with severe male factor infertility.

25.10 Use of Testicular Sperm

Extraction of testicular sperm for treatment of azoospermia is routine for modern ART laboratories. These expensive urological procedures are usually performed in outpatient surgical centers or occasionally within the clinical office. Extracted testicular tissue and fluid are then transported to the ART laboratory for further processing. Methods, such as microdissection with fine needles or mincing with homogenizing pestles, can be used to tease sperm from extracted portions of seminiferous tubules [90, 91]. Recovered sperm can then be used for ICSI or cryopreserved for future use.

Aside from treatment for azoospermia, testicular sperm extraction is a controversial option for couples struggling with infertility in which the male partner has a high level of sperm DNA fragmentation. While initial efforts to decrease DNA fragmentation should focus on lifestyle modifications and antioxidant treatment [92], there is evidence to suggest testicular sperm extraction can be used to select healthy sperm with nuclear DNA integrity [93].

25.11 Stem Cells

For young men affected with testicular failure arising from malignant and nonmalignant conditions, there is growing optimism for restoration of fertility with use of spermatogonial stem cells (SSCs). Isolation of human SSCs was demonstrated over a decade ago [94], and the transplantation of SSCs has been shown to be successful in mice [95] and nonhuman primates [96]. Cryopreservation technologies currently available in the ART laboratory can easily be adopted for preservation of testicular tissue that could be used for isolation of SSCs for transplantation or possibly used for in vitro gametogenesis.

In vitro gametogenesis is attractive, in particular for survivors of malignant disease that may be at increased risks for reintroducing potentially malignant cells during SSC transfer. Differentiation of SSCs into sperm has been demonstrated with animal models using organ culture systems, embryonic stem cells (ESC), induced pluripotent stem cells (iPSC), and germline stem cells (GSC) [97]. While it is only a matter of time before this technology proves successful in humans, studies are needed to verify paternal-specific patterns of epigenetic imprinting in in vitro produced sperm that could have short- and long-term concerns for children derived with this technology.

25.12 Conclusions

Over the past 40 years, the development and integration of ART has transformed the practice of reproductive medicine. While many of the advances have improved overall IVF success, there is no debate that the single greatest tool for treating male infertility was the introduction of ICSI. With that said, the success of IVF and ICSI is in part limited by the quality and health of the sperm. As discussed in this introductory chapter, well-established methods and recent technological advances will be focal areas of improvement as we look to extend the clinical reach of the infertility specialist and urologist.

With this acknowledgment of the key role played by the advancing technologies derived from research and delivered in the ART clinical laboratory, the initial patient assessment and diagnosis of both the male and female must still set the stage for treatment workup and outline the long-term algorithmic pathway. There is perhaps more appreciation today that there is an impact of general chronic poor nutrition on reproductive health, and attendant conditions that release systemic inflammatory by-products can often take their toll on reproductive function. High technology is not required to address these problems in initial phases of treatment. Even if a standard semen analysis cannot guarantee assessment of the total fertilizing capacity of the male's semen, if performed correctly, it is able to highlight various obvious physiological problems which need to be addressed.

25.13 Review Criteria

Search of studies examining the relationship between male factor infertility, availability of urologist, and laboratory methods for selecting and examining sperm was performed using search engines such as ScienceDirect, Ovid, PubMed, and MedLine. The start and end dates for these searches were January 2000 through October 2018, respectively. The overall strategy for study identification and data extraction was based on the following keywords: "male infertility," "sperm selection," "oxidative stress and sperm," "male urology services," "state infertility mandates," and "sperm selection for ICSI." Articles published in languages other than English were not considered. The previous book chapter and citations remained, where appropriate, based on the current chapter updates.

Acknowledgments We would like to acknowledge Bernie Amaro for his excellent editorial services.

Sperm Physiology and Metabolism

Fuel/Energy Sources of Spermatozoa

26

Pallav Sengupta, Damayanthi Durairajanayagam, and Ashok Agarwal

Key Points

- Both the oxidative phosphorylation and glycolysis pathways generate energy in spermatozoa, of which oxidative phosphorylation is a more efficient pathway for ATP production compared to glycolysis.
- Mitochondrial oxidative phosphorylation is the primary energy source for sperm motility, while glycolysis in the sperm head and tail is the main source of ATP along the flagellum.
- Sperm energy metabolism is supported by the unique anatomical and physiological characteristics of spermatozoa, as well as coordination between Sertoli cells and spermatogonial cells during energy production.
- Clear understanding of sperm energetics will help improve the medium for longer in vitro storage of spermatozoa while maintaining sperm function in robust conditions.
- Deeper knowledge on sperm energy metabolism would be useful in developing non-hormonal contraceptives based on reduction or cessation of sperm energy generation.

26.1 Introduction

Spermatozoa are haploid cells that are highly specialized. The cellular processes of the spermatozoa, such as motility, hyperactivation, capacitation, and acrosome reaction, are necessary for fertilization to be successful. The energy required for sperm to carry out these functions is provided by a small, water-soluble molecule called adenosine triphosphate (ATP) [1]. Removal of a phosphate group (hydrolysis) from the ATP molecule forms adenosine diphosphate (ADP) in a reversible reaction. The interconversion of ATP and ADP (phosphorylation) provides energy for the cell, and as such, ATP acts as the "energy currency" of the cell [2].

The production of ATP typically occurs via two metabolic pathways: oxidative phosphorylation and glycolysis. Between the two, ATP synthesis happens 15 times more efficiently via oxidative phosphorylation than it does via glycolysis [3, 4]. Oxidative phosphorylation involves the respiratory chain and ATP synthase found at the inner mitochondrial membrane [5]. For every molecule of oxidized glucose, 30 molecules of ATP are generated via the process of oxidative phosphorylation. The availability of ADP is the primary rate-determining factor for oxidative phosphorylation and therefore the generation of ATP [3, 4]. Glycolysis involves the breakdown of six carbon monosaccharides via a sequence of enzyme-catalyzed reactions that yield two to three molecules of pyruvates. For every molecule of glucose oxidized, there is a net yield of two molecules of ATP generated via glycolysis. Subsequently, pyruvate is further oxidized whereby CO_2 and an acetyl group (of acetyl-coenzyme A) is formed, which is then oxidized completely to CO_2 via the citric acid cycle [3, 6].

Metabolic processes such as glycolysis and the citric acid cycle yield electron donors, namely the reduced form of nicotinamide adenine dinucleotide (NADH) and flavin adenine dinucleotide ($FADH_2$). Besides glycolysis, NADH and $FADH_2$ are also formed by the citric acid cycle and fatty acid oxidation. Each of these energy-rich molecules contains two electrons with a high transfer potential, i.e., an electron-motive force [2]. Reduction of molecular oxygen to water by these electrons releases plenty of free energy, which can be utilized

to produce ATP. Conversion of the electron-motive force into the proton-motive force is facilitated by electron-driven proton pumps, which are transmembrane complexes with multiple oxidation-reduction centers. The proton-motive force is subsequently converted into the phosphoryl transfer potential [2].

The process of oxidative phosphorylation yields ATP due to the transfer of electrons from NADH or $FADH_2$ to molecular oxygen (O_2) via a sequence of electron carriers, i.e., the electron transport chain. Electron flow from the NADH or $FADH_2$ to O_2 through the protein complexes within the inner mitochondrial membrane causes protons to be pumped out of the mitochondrial matrix, which leads to an uneven distribution of protons. The resulting transmembrane electrical potential and pH gradient generate a proton-motive force. As the protons flow back to the mitochondrial matrix through the ATP synthase enzyme complex, ATP is synthesized [2].

However, it is still debatable as to which of these metabolic pathways has the most crucial role to energy production in the spermatozoa. Mammalian spermatozoa require energy for its motility, which is generated by the beating of the lengthy flagellum that makes up more than 90% of the total length of the spermatozoa [7]. Thus, all mammalian sperm are faced with a similar challenge in that the energy (intracellular ATP) generated must be transferred along the whole length of the flagellum to ensure efficient movement [8]. Loss of forward progressive motility due to depletion of energy sources/disorder in motion characteristics or both could greatly impede sperm function and very likely jeopardize fertilization. Therefore, spermatozoa must implement various metabolic strategies to ensure sufficient energy is supplied from its fuel machineries to support its high motility requirement [1].

The chapter will review the unique functional ultrastructure of sperm that support its fuel machineries, sperm energy metabolism and pathways involved, potential mechanisms by which spermatozoa obtain the energy to fuel its motility, hyperactivation, capacitation, and acrosome reaction necessary to achieve successful fertilization as well as the impact of fuel depletion on sperm function. This chapter also highlights how understanding the concepts of energy metabolism in spermatozoa could improve in vitro sperm storage and contribute toward the development of energetics-based, nonhormonal contraceptives.

26.2 Functional Ultrastructure of Sperm: Fuel Machineries

26.2.1 Flagellar Ultrastructure

The flagellum of the mammalian sperm has three distinctive regions, namely the midpiece, the principal piece, and the terminal endpiece (reviewed in Ref. [9]). The axoneme extends centrally throughout the flagellar length. The surrounding outer dense fibers also extend at different lengths down the flagellum. The mitochondria are organized in a helix surrounding the outer dense fibers and axoneme in the midpiece. The midpiece serves as the energy powerhouse of the sperm where mitochondria are exclusively localized (reviewed in Ref. [10]). About 72–80 mitochondria are localized within a mature spermatozoon, and they comprise about 15–22% of the total cellular volume [11]. These mitochondria play a role in the acrosome reaction and oocyte penetration [12].

The mitochondria can be divided into four distinct subcompartments, namely, the (i) outer mitochondrial membrane, (ii) inter-membrane space, (iii) inner mitochondrial membrane, and (iv) matrix. However, the mitochondrion of the sperm differs morphologically and functionally from that of its somatic counterparts [13, 14]. This could be due to the tight wrapping of the mitochondria around the axoneme of the spermatozoon, which results in a mitochondrial capsule. This capsule is made up of selenoprotein and disulfide bridges [15], which provide stability to the mitochondrial sheath [16, 17].

The principal piece makes up most of the length of the spermatozoa and is a region devoid of mitochondria [4]. Within the principal piece lies a unique cytoskeletal structure known as the fibrous sheath, which is specific to the mammalian sperm [18]. The fibrous sheath is located just beneath the plasma membrane as two vertical columns attached by lateral ribs. Not only does the fibrous sheath have a structural function, but it also plays an important role in sperm motility. The short endpiece begins where the fibrous sheath terminates (reviewed in Ref. [10]).

26.2.2 Spermatozoa ATPases

Ion-exchanging ATPases have a crucial role in sperm motility, hyperactivation, chemotaxis, and acrosome reaction. These necessary functional modifications of the spermatozoa leading to fertilization appear to be regulated by the different ATPases. Moreover, the location of the ATPase within the cell seems to reflect its function [19].

Na^+/K^+-ATPase is a transmembrane protein involved in the active exchange of three intracellular sodium ions for two extracellular potassium ions across the plasma membrane. In mammals, four α (catalytic subunit of the enzyme) and three β (enzyme localization and maturation) subunits have been identified as isoforms of Na^+/K^+-ATPase [20]. The α4 along with α1 isoforms are expressed in the midpiece of the sperm flagellum [21]. Selective inhibition of the Na^+/K^+-ATPase α4 isoform by ouabain resulted in decreased sperm motility [21, 22]. Activity of the Na^+/K^+-ATPase α4 isoform contributes indirectly to the maintenance of intracellular calcium levels and sperm pH [22].

Calcium is a key cellular second messenger essential for sperm motility and other sperm functions. Plasma membrane Ca^{2+}-ATPase (PMCA) pumps out calcium ions against the transmembrane electrochemical gradient to maintain low intracellular calcium ion concentrations. In the sperm, calcium ion homeostasis is controlled by PMCA located at the head and principal piece of flagellum [23]. The importance of PMCA function in calcium homeostasis for sperm motility has been shown by several studies. Deficiency of PMCA isoform 4 located in the sperm tail led to impaired sperm motility and hyperactivity [24]. The antioxidant quercetin caused inhibition of PMCA activity leading to dose-dependent decreases in sperm motility [25]. Sperm incubated with cadmium displayed lowered sperm motility due to inhibition of PMCA and axonemal dynein-ATPase activity [23].

Dyneins are specific ATPases of the sperm flagellum that provide energy for the sliding movement between the microtubule doublets. Besides their vital role in the whipping movement of the flagellum, dyneins also contribute to transport along the sperm axoneme within the flagellum [26].

In summary, activities of the Na^+/K^+-ATPase and Ca^{2+}-ATPase enzymes in human spermatozoa contribute to the maintenance of the membrane gradient required for sperm motility (reviewed in Ref. [27]). The dynein ATPases that are associated with the axoneme serve as the main consumers of ATP in spermatozoa [28, 29]. Therefore, energy must be transferred from the mitochondria at the midpiece down the length of the flagellum.

26.2.3 Unique Properties of Sperm Glycolytic Enzymes

Glycolysis in mammals supplies, albeit less efficiently, a high-throughput local production of ATP along the length of the principal piece. Once the substrates for glycolysis penetrate the plasma membrane of the flagellum, they are acted upon by the highly abundant glycolytic enzymes, which are firmly bound to the fibrous sheath cytoskeleton [30].

The fibrous sheath of the principal piece acts as a scaffold onto which multiple glycolytic enzymes anchor along the length of the flagellum [30]. Tethering of the glycolytic enzymes could potentially hinder protein function in several ways, including by interfering with a necessary conformational change or obstructing the binding site of a substrate. To prevent these unwanted events, mammalian sperm-specific variants of several enzymes in the glycolytic pathway have domains that distinguish them from their somatic cell isoforms [10].

Three such sperm-specific isozymes are the glyceraldehyde 3-phosphate dehydrogenase-S (GAPDS), phosphoglycerate kinase-2 (PGK2), and lactate dehydrogenase-C4 (LDH-C4). These isozymes are encoded by genes which are expressed exclusively during spermatogenesis [31–33]. In mammalian sperm, the GAPDS isozyme has a novel N-terminal proline-rich domain that binds it tightly to the fibrous sheath cytoskeleton [34]. Compared to its somatic isoenzyme, the sperm-specific GAPDS is far more stable and does not perform non-glycolytic functions [35].

Other sperm cell glycolytic enzymes also have its distinctive functional or structural properties [36–38]. The unique characteristics of these sperm glycolytic enzymes may play a vital role in ensuring an adequate localized supply of ATP down the length of the flagellum, which is essential for sperm motility [39].

26.2.4 Seminal Plasma Components

Following ejaculation, mammalian sperm gain energy from the nutrients available in the seminal fluid and female reproductive tract. With the testis being an exception, the other tissues of the male reproductive tract are able to produce fructose and sorbitol [40]. Secretions of the seminal vesicles, a major accessory reproductive gland in humans, contain a high amount of fructose. However, seminal plasma fructose concentrations vary in different species. While a high amount of fructose was detected in the bull and ram, almost none was present in the dog and stallion [41].

Fructose undergoes glycolysis to form pyruvate. Sorbitol can be reversibly converted to fructose via the NAD-sorbitol dehydrogenase enzyme and to glucose via the NADPH-aldose reductase enzyme [7]. The presence of the enzymes required for the production of both sorbitol and fructose in human spermatozoa has been verified using Western Blot analysis [42]. Between the two substrates, fructose is the principal reducing sugar and therefore the main fuel source for spermatozoa in human seminal plasma [43]. Therefore while still in the seminal fluid, human spermatozoa utilize fructose as an energy supply to meet its metabolic needs. Within the female reproductive tract, human spermatozoa switch to using glucose as its energy source [44].

26.3 Energy Production in Spermatozoa

A spermatozoon is made up of two distinctive regions: the head and the flagellum. The sperm head comprises the acrosome, equatorial segment, and post-acrosomal region. Also present within the sperm head is the nucleus containing the compacted paternal genome. As discussed in Sect. 26.2.1, the sperm flagellum can be distinctively divided into the midpiece, the principal piece, and the terminal endpiece (reviewed in Ref. [9]).

As is the case with all eukaryotic cells, the generation of energy in the spermatozoa is also compartmentalized [45]. In the spermatozoa, the generation of ATP via oxidative phosphorylation takes place in the mitochondria of the midpiece, while glycolysis occurs in the head and fibrous sheath within the principal piece of the flagellum.

26.3.1 ATP Production via Oxidative Phosphorylation

The process of oxidative phosphorylation occurs in the mitochondria, which is available within the mitochondrial sheath in the midpiece of the mammalian sperm [13]. The midpiece is the only region of the spermatozoa that contain mitochondria, which are the most efficient producers of cellular energy in the form of ATP. The inner mitochondrial membrane folds to form structures known as cristae, which are the principal sites for oxidative phosphorylation and ATP generation.

Sperm mitochondria contain specific isoforms of proteins and isozymes such as cytochrome C [46, 47], hexokinase subunit VIb of the cytochrome C oxidase [48], and lactate dehydrogenase (LDH) [49]. All of these isozymes are however absent in somatic cell mitochondria [50].

26.3.2 ATP Production via Glycolysis

The process of glycolysis contributes greatly toward the production of ATP in the mammalian sperm. The head and principal piece of the spermatozoa contain glycolytic enzymes but lack the necessary respiratory enzymes for oxidative generation of ATP. Therefore, ATP production in these areas can only take place glycolytically [7].

The fibrous sheath in the principal piece of the sperm flagellum contains several glycolytic enzymes that are sperm-specific, namely, glyceraldehyde-3-phosphate dehydrogenase (GAPD), phosphoglucokinase isomerase, phosphofructokinase, hexokinase, and LDH isozyme [4, 38, 45, 51].

The localization of a unique ADP/ATP carrier protein termed sperm flagellar energy carrier (SFEC) along with the glycolytic enzymes on the fibrous sheath of human spermatozoa appears to play a vital role in sperm motility [4].

26.3.3 Metabolic Coordination of Sertoli Cells and Germ Cells in Spermatogenesis

The intricate process of spermatogenesis relies heavily on the firm metabolic cooperation between the developing germ cells and the Sertoli cells. Besides providing physical support to the developing germ cells, Sertoli cells are also involved in the maintenance of an appropriate metabolic [52] and ionic [53, 54] milieu necessary for sperm differentiation and functional maturation.

Germ cells rely strongly on lactate for its development and survival [55]. In addition to its role as an energy source, lactate also confers an anti-apoptotic effect on the germ cells [56]. Sertoli cells preferentially metabolize glucose, which is converted from pyruvate into lactate during glycolysis. Lactate production by the Sertoli cells commences with the uptake of glucose, either actively by sodium-dependent glucose transporters or passively by glucose transporters [57]. Thereby, the transport of glucose through the plasma membrane plays a role in the regulation of lactate secretion by Sertoli cells.

Glucose metabolism in Sertoli cells is subject to intricate control by several hormones, including insulin, 5α-dihydrotestosterone (DHT), follicle-stimulating hormone (FSH), 17-estradiol (E2), and thyroid hormones [58–60]. Tight hormonal control of these metabolic processes involves a variety of complex signaling cascades that are yet to be fully elucidated [61]. Moreover, the precise molecular mechanisms coordinated by the respective hormone during Sertoli cell glucose uptake and metabolism are not fully known [62], although studies have begun to shed some light on the matter.

FSH and insulin stimulate lactate production [63] by regulating the activity of enzymes involved in either carbohydrate metabolism and/or glucose transport regulation [64]. Since FSH induces androgen receptor expression, it may also regulate the sensitivity of Sertoli cells toward androgens [65, 66]. Insulin stimulates various Sertoli cell functions including lactate production, uptake of free nucleosides, synthesis of DNA and protein, transferrin secretion, and glycide metabolism [59, 67–69].

Not only do the sex steroid hormones DHT and E2 modulate glucose utilization and lactate production in human Sertoli cells [70], but they also regulate the apoptotic signaling of Sertoli cells [71]. With thyroid hormone receptors being present in Sertoli cells [72], it is probable that the thyroid hormones have a regulatory role in Sertoli cell proliferation and lactate production.

Locally produced factors such as transforming growth factor alpha, tumor necrosis factor alpha, interleukin 1 alpha, basic fibroblast growth factor, and epidermal growth factor [73–75] have been proposed to increase lactate production by enhancing glucose uptake along with total LDH activity [55]. Endocrine disruptors are also reported to modulate glucose metabolism in Sertoli cells [76].

Glucose metabolism in Sertoli cells is a well-controlled process essential for normal spermatogenesis. As such, any compromise in the Sertoli cells' ability to metabolize glucose could jeopardize the energy supply to the germ cells, which would then disrupt spermatogenesis and subsequently impact male fertility [62].

26.4 Energy Utilization by Spermatozoa

Biological energy fuels all the physiological functions of spermatozoa from the time of deposition in the female reproductive tract till achievement of successful fertilization. Mammalian fertilization involves multiple courses of processing mainly due to the semen deposition site being distant from the fertilization site in the female genital tract [77, 78]. It requires synchronized spermatozoa functions including robust sperm motility, capacitation, hyperactivation, and finally acrosome reaction [79]. These vital spermatozoa actions are all energy driven, which explains the prime importance of biological energy in male gamete functions. In the subsequent section, energy utilization for sperm functional processes is discussed.

26.4.1 Sperm Motility and Flagellar Movements

Sperm flagellum contains the apparatus for motility that aids the forward propelling action of a spermatozoon until it penetrates an oocyte [80]. The movements of the microtubules, especially the dynein "arms" present in the eukaryotic flagellum, enable the flagellum to bend to bring about "flagellar movements" [81]. The regulation of these flagellar movements is quite complex, and several research studies have attempted to put forth the mechanisms involved [82].

The rhythmic flagellar beating is powered by the axonemal protein, dynein [83]. As dynein ATPases get activated, the externally placed axonemal doublet microtubules slide which cause bending of the flagellum [7]. Thus, dynein generates the required force for flagellar movements by converting the chemical energy obtained via ATP hydrolysis into the desired mechanical energy [84].

As mitochondria are heavy organelle, they are located in the midpiece of the sperm cell and not in the flagellum to prevent mechanical restrictions in flagellar movements [85]. Mitochondrial electron transport chain (ETC) mediates efficient ATP production, but it is not yet clear whether the mitochondrial ATP are the ones that sufficiently diffuse along the full length of spermatozoa flagellum to fulfill the energy requirement of flagellar beating.

Researchers, especially the biophysicists [86], have calculated the ATP diffusion rate from the midpiece to the flagellum in mammals like bulls and sea urchins. They suggested that the rate of ATP diffusion into the flagellum is sufficient to support its required beating pace. This explains the hypothesis that sperm motility is gauged by mitochondrial membrane potential, reduction of which leads to decreased sperm motility and fertilization ability [87]. This had also been demonstrated by Paoli et al. [79] who found that nonlinear sperm motility positively correlates with mitochondrial membrane potential in asthenozoospermic patients.

Modulations in the activities of the mitochondrial respiratory chain enzymes have also been reported to affect sperm motility [88]. The mitochondrial ETC has two mobile electron carriers (cytochrome C and coenzyme Q) and four complexes (I, II, III, and IV). Each of this essential machinery of mitochondria finds importance in electron transport and activation of ATP synthase to generate ATPs. As such, alterations of these components are suggested to be the basis of idiopathic asthenozoospermia [88].

This hypothesis of mitochondrial ATP generation and sufficient diffusion to the flagellum for its robust beating is contradicted by the views of Tombes and Shapiro [89]. Their observations suggest that ATP in spermatozoa is produced by the mitochondria or cell body that is located far from the sperm flagellum through glycolysis or oxidative phosphorylation. But this generated ATP does not suffice the energy requirement for proper flagellar movements owing to the poor ATP diffusion capacity to the area of high energy demand. However, this hypothesis is still not confirmed in human spermatozoa [11]. Moreover, as the flagellar movements are ATP driven, it is needed to prevent accumulation of the products of its hydrolysis such as ADP, inorganic phosphate (Pi) and hydrogen ions that may impose kinetic and thermodynamic stress to the spermatozoa [90].

These contradictory hypotheses have led to several other studies that have suggested an alternative pathway of sperm energy generation. The hypothesis proposes the presence of an ATP source in proximity to the site of ATP utilization for flagellar movements. This may be achieved through the glycolytic pathway by the glycolytic enzymes present in the fibrous sperm flagellar sheath [45]. In addition, mammalian spermatozoa have several options of carbohydrate to use as a substrate for production of ATP [42, 91]. This explains the views that the flagellum may generate its own ATP required for its movement independent of mitochondrial activity [45].

Glucose is the most important substrate for ATP generation and reportedly induces increased flagellar beating frequency. Mukai and Okuno, in their study, used a glucose analogue (2-deoxyglucose—DOG), to hinder spermatozoa glycolysis. It was observed that DOG inhibited pyruvate and lactate activities but did not affect mitochondrial respiration (confirmed by a fluorescent probe) [92], while the study outcome indeed led to a reduction in ATP content and low sperm motility [92]. This study provides the evidence that glycolysis is a key energy contributor for sperm motility, which, if suppressed, results in reduced sperm motility even though the mitochondrial substrates are unaffected.

The fact that DOG did not disrupt ATP synthesis in the mitochondria can be explained by the unaltered ATP concentration in the presence or absence of carbohydrate metabolism

along with DOG. This may indicate that ATP production by normal mitochondrial respiration is not adequate to meet the energy demand required for sperm flagellar motility. These facts firmly support glycolysis as the preferred energy source, particularly for sperm motility.

Spermatogenic-specific enzyme isoforms required for glycolysis are present along the fibrous sheath of the sperm flagellum, among which a key enzyme is the GAPD enzyme. Mouse spermatogenic cells contain the GAPD-S [39], while the human has its ortholog as GAPD-2. The GAPD is the first catalytically active enzyme evident to be present as attached to the fibrous sheath of the flagellum of spermatozoa [45]. Being a key glycolytic regulatory enzyme, it aids spermatogenesis and is vulnerable to the adverse effects of environmental factors that may affect male fertility [33]. According to a study, GAPD-deficient mice displayed lower sperm motility compared to the control group with working GAPD-S genes [39]. There have been similar observations with GAPD-2 genes in humans [33].

Another evidence to suggest that mitochondrial respiration does not bear a role in sperm motility is put forth by the study that used carbonyl cyanide m-chlorophenylhydrazine (CCCP), an uncoupler inhibiting mitochondrial ATP synthesis [92]. Moreover, lactate dehydrogenase-C (LDH-C), a glycolytic enzyme that is used to catalyze pyruvate to lactate conversions [50], is essential for sperm motility in anaerobic respiration. LDH-C gene disruption in mice displayed neither tyrosine phosphorylation nor hyperactive motility that is required for capacitation [93]. It has also been proposed that oxidative phosphorylation is not needed for increasing sperm motility in hyperactivation [94]. By exogenous supplementation of glucose and pyruvate, it was seen that the glycolytic pathway is the predominant source of ATP for sperm motility and capacitation [95].

26.4.2 Sperm Capacitation, Hyperactivation, and Acrosome Reaction

Fertilization is a multistep process that occurs in a synchronized manner [96]. Sperm are deposited in the female reproductive tract at the time of copulation, and this is followed by a sequence of events, which is collectively called capacitation. It occurs before successful fertilization is possible [12]. Capacitation refers to modifications in cellular and biochemical processes of sperm in response to specific stimuli necessary for acrosome reaction to take place [12]. Incubation of sperm in the capacitation medium showed that 10–20% of the sperm had adopted motility patterns that resembled the state of hyperactivation [97]. These important events of spermatozoa activation require an efficient and adequate supply of ATP [98]. Spermatozoa capacitation leads to modifications at the sperm head surface and also along the length of the flagella [99]. Energy-aided activation of spermatozoa results in a successful acrosome reaction, thereby releasing hydrolytic enzymes from the acrosome vesicles, followed by sperm binding and successful penetration of the oocyte.

The molecular events involved in acrosome reaction begin with signals from the oocyte, which activate G-proteins present in the sperm. This leads to a rise in intracellular Ca^{2+} levels activating specific kinases and phosphorylation of several other proteins. Intracellular rise in Ca^{2+} level can be achieved by the influx of Ca^{2+} either through the cell membrane protein channels (proteins of CatSper family) or release of Ca^{2+} from the endoplasmic reticulum and other organelles [100]. The redundant nuclear envelope (clustered membrane vesicles) [101] is also a vital Ca^{2+} ion store located at the base of the mitochondrial sheath in sperm midpiece. Increase in Ca^{2+} levels in spermatozoa in response to acrosome reaction stimuli enhances the sperm flagellar beating intensity resulting in increased hyperactivation [102].

Therefore, adenosine triphosphate is a critical player in the maintenance of acrosome integrity and induction of acrosome reaction because it is needed for ATPase activity, the formation of cyclic adenosine monophosphate, and phosphorylation.

Mitochondria are essential to mediate tyrosine phosphorylation in capacitated mammalian spermatozoa [103]. The Ca^{2+}-ATPase-aided secretory pathway in the spermatozoa midpiece may mediate the clearance of excess intracellular Ca^{2+} released from the redundant nuclear envelope [104]. Moreover, spermatids express an abundant level of selenium-dependent phospholipid hydroperoxide glutathione peroxidase whose activities greatly increase in the post-pubertal testis [105]. Mature spermatozoa express this only at the midpiece region [15], which embeds the mitochondrial helix and contributes in mitochondrial function and sperm maturation [106]. Tyrosine phosphorylation in human sperm capacitation still warrants detailed research.

As previously discussed, mammalian spermatozoa depend on the availability of glucose, pyruvate, and lactate for its fuel [107], and these are all present in the oviductal fluid [108]. In pigs and sheep, the oviductal fluid seems to contain lactate, which acts as a prime substrate for ATP production that aids in spermatozoa activity. In mice, glucose and pyruvate have been observed to bring about and sustain vigorous sperm motility [109]. Thus, metabolic substrates used for ATP generation are species specific, which consequently determines the preferential metabolic pathway for production of ATP in spermatozoa to obtain flagellar movements and adequate capacitation [17].

As a back-up arrangement of sperm fuel, if there is the unavailability of such glycolysis substrates, metabolism of respiratory substrates is triggered in spermatozoa [92]. These respiratory substrates undergo gluconeogenesis in the sperm midpiece producing glucose as the main end product. Now glucose may diffuse from the midpiece to the regions of fla-

gellum which can again utilize glucose to produce ATP for its movements. Bull spermatozoa rely upon oxidative phosphorylation to generate energy for capacitation, while human spermatozoa appear to depend on glucose-mediated ATP [110]. Despite glucose-derived ATP acting as an immediate source of energy for sperm capacitation, mitochondrial function was also found to heighten during this time [111].

Mitochondrial functionality of spermatozoa during capacitation had been assessed in sperm samples, pre- and post-swim-up treatment, with different times of incubation. Mitochondrial respiratory activity was significantly higher in the spermatozoa incubated under capacitating states than those in spermatozoa before swim-up treatment. This observation suggests that sufficient ATP has been generated through oxidative phosphorylation during capacitation [112].

26.5 Consequences of Fuel Depletion in Sperm Functions

It is well known that human or animal spermatozoa require biological energy for their normal physiological functions. It has been shown in fish spermatozoa that a substantial reduction in ATP leads to decrease in flagellar beat frequency from almost 60–20 Hz within just 20 sec [113].

The ionic composition of the sperm dilution medium is also a determining factor in such experiments. This has been evident from observations that motility was initiated in trout spermatozoa without adding any external calcium, and flagellar movements stopped abruptly in spite of the presence of adequate ATP to sustain sperm motility. Whereas when sperm medium contained calcium ion of about 10 mM, flagellar movements did not abruptly cease. Instead, both movements and the ATP concentration gradually decreased as all the ATP became depleted. This suggests that the axonemal machinery (and/or the dynein-ATPase) activation is associated with calcium ion-dependent cAMP regulation. The fact that ATP content in sperm does not get totally depleted and their ATPase activities are lower in the recovery phase as compared to their motility phase supports this interpretation. Moreover, sperm with recovered ATP at levels close to that in quiescent sperm are unable to swim or hydrolyze ATP to gain energy unless there is again an external supply of sufficient Ca^{2+} [113].

It has been put forth that progressive depletion of ATP in fish spermatozoa, owing to its consumption by movements of sperm axoneme, may modify the shape of the flagellum, for example, by stiffening of the flagellar distal part [114]. This flagellar stiffening may be the result of a deficiency of local ATP in the distal part of it which is quite distant from the mitochondrial ATP generation site [115]. This may lead to blockade of the dyneins to render it in a state of rigor, perhaps by making the distal portion of the sperm axoneme to become very rigid. This action in combination with alterations in intracellular ionic concentration directly affects dynein activity [116]. The local axoneme regulators also contribute to this rigidity, such as the hydin, and the acentral pair protein of cilia and flagella [117].

26.6 Knowing the Energy Sources of Spermatozoa Contributes Toward Improving:

26.6.1 Handling of Gametes In Vitro: Cryopreservation

Spermatozoa storage should assure that the functionality of the sperm is retained along with its longevity. As is the case with horse sperm storage, it is preferred to be stored before the artificial insemination stage to ensure greater longevity as the nature of ovulation in mares is asynchronous [118]. If artificial insemination is needed within 12 h of semen collection, the sperm can be kept at room temperature. However, if sperm longevity is needed, they are either chilled (up to 72 h) or cryopreserved (for an indefinite time) in order to cease sperm metabolism. This helps to reduce ROS production as well as decrease acidification of the storage medium by accumulated metabolic products, such as carbon dioxide and lactic acid from oxidative phosphorylation and glycolysis. Since it becomes arduous for the sperm to tolerate the stress of chilling or cryopreservation, improved storage medium needs to be developed to extend sperm longevity [119].

Cryopreservation is currently the lone viable in vitro sperm storage method, used for more than 72 h of preservation. The process of cryopreservation and repeated thawing of the spermatozoa, mainly via osmotic stress, decreases their acrosomal integrity, sperm viability, motility [120, 121], and even formation of DNA lesions on vital genes that mediate fertilization and embryonic development [122]. Moreover, the cryoprotectants render the cryodiluent to be hyperosmotic, which can dehydrate the spermatozoa via exosmosis [123]. This dehydration is required to retain sperm viability after thawing. However, extreme hyperosmolarity leads to stress due to the loss of excess fluids from spermatozoa via membrane water channels to balance the osmolarity [124]. These result in sperm membrane damage [125], DNA disintegration [126], and excess ROS generation causing alterations mimicking those during capacitation [127].

26.6.2 Handling of Gametes In Vitro: Ambient Temperature Storage

Sperm storage in ambient temperature will help to prevent the stress that the sperm needs to combat owing to chilling or cryopreservation. Development of an advanced sperm stor-

age medium is required, preferably one that renders sperm storage temperature to be ambient where they can be stored for at least a week. This would allow export of the stored sperm to other geographical locations that would transmit new genetics into isolated areas, without any loss of fertility that is caused by chilling and cryopreservation methods. For ambient temperature storage, additions of animal-derived products are not required and thus sperm can easily be transported without biosecurity risks.

The implications associated with using higher temperatures for in vitro sperm storage should be considered. Among these, the first complication is the bacterial growth in the storage medium, which is a nutrient-rich semen extender. While collecting semen from a horse, it is inevitable that the bacteria contaminating the penis will also contaminate the ejaculate [128]. These bacterial strains, or at least some of them, can potentially affect sperm vitality and motility. Besides it obviously happening in ambient temperature, this can occur even during storage at 4 °C [129] and in cryopreservation [130].

To mitigate the adverse effects of these bacteria in the sperm storage medium, development of various antibiotic formulations is under research [130]. It has been put forth that sperm storage medium containing 50 μg/mL streptomycin, 0.25 mg/mL gentamicin and 50 IU/mL penicillin is able to inhibit bacterial growth for up to one week at ambient room temperature [131]. Apart from this, the second concern is that if metabolism in stored sperm is not ceased by chilling or cryopreservation, the continued oxidative phosphorylation will lead to excessive ROS generation [132]. These will eventually disrupt sperm functions [133, 134].

The protective measure that has been attempted to nullify the effects of ROS on sperm is by antioxidant supplementation in the storage medium, but it did not show the anticipated results in horse semen [135], and even in some occasions, had adversely affected sperm function [136]. However, in human spermatozoa, antioxidant supplementation showed positive results [137], which may be attributed to their alternative ATP production mode.

Of late, carnitine has been gaining popularity for its antioxidant properties [138], with L-carnitine being able to significantly reduce mitochondrial ROS production and oxidative damage in horse spermatozoa during in vitro storage [138, 139]. However, L-carnitine supplementation alone may not be able to prevent ROS-mediated cell damage in totality, and thus there is a need for combination treatment to completely scavenge ROS [138]. Further investigations are needed to come up with appropriate antioxidant supplementations for a sperm storage medium in ambient temperature.

Since mitochondrial metabolism serves as the prime ROS generating source, in order to minimize oxidative damage to sperm while in a storage medium, it may be beneficial to utilize mitochondrial antioxidant to regulate sperm mitochondrial bioenergetics. L-carnitine meets this requirement but as discussed before, the overall protection can be achieved through the combination of L-carnitine with additional antioxidants. Such additional antioxidants could possibly be the coenzyme Q_{10} (a vital integral component of the ETC), an antioxidant that strongly combats ROS-induced lipid peroxidation [140], and melatonin, a pineal hormone which acts as a free radical scavenger, decreases nitric oxide production in mitochondria, and mediates bioenergetic functions via regulation of respiratory complex and influx of calcium ions as well as by increasing mitochondrial permeability [141].

Yet another implication of storing spermatozoa in ambient temperature is ATP depletion through continued metabolism, thus gradually reducing sperm motility [142] and ultimately triggering sperm cell death [143]. If ambient temperatures are to be used for sperm storage, it is essential to support mitochondrial energy generation to avoid ATP depletion. There is also a need to prevent the increased pressure on ATP-dependent pathways vital for cell functions, such as the regulation of ionic influx or efflux [144]. If sodium chloride in the storage medium is replaced by non-ionic, organic osmolytes such as carbohydrates, amino acids, and betaines, the pressure on the Na^+/K^+-ATPase pump can be reduced which in turn will decrease ATP utilization in the medium [144].

Research has shown that a combination of pyruvate (the prime energy source for oxidative phosphorylation), L-carnitine [145], and an organic, non-ionic osmolyte [146] could maintain sperm motility and viability at ambient temperature for up to 72 h [138]. In the case of horse spermatozoa, it consists of a number of proteins of beta-oxidation whose inhibition can reduce sperm motility [147]. L-carnitine, being vital for beta-oxidation and also acting as an osmolyte and an antioxidant, induces mitochondrial ATP generation by transporting acetyl groups of pyruvate to the mitochondrial matrix and buffering the free CoA. Thus, the importance of L-carnitine for maintenance of sperm quality in vivo is well recognized [148].

Moreover, in the body, spermatozoa contain the highest intracellular L-carnitine concentrations as androgen stimulates the epithelial cells to produce and secrete L-carnitine in high concentrations into the epididymal lumen [149]. This accounts for an L-carnitine concentration of up to 2000-fold higher than that of blood [150]. Hence, L-carnitine is definitely a molecule of high importance in male fertility. Oral L-carnitine supplementation showed higher pyruvate uptake by spermatozoa [151], which suggests that L-carnitine is associated with overall sperm metabolism.

26.6.3 Non-hormonal Male Contraception

Due to the uncertainty and higher failure rates of physical contraception and disadvantages of hormonal contraception, non-hormonal contraception affecting sperm functions

are becoming a priority in current contraception research. Chemicals and drugs affecting sperm motility have been used as useful tools for non-hormonal male contraception. For instance, EPP055 is an agent that is found to have anti-sperm motility functions and has been used in different animal species as non-hormonal contraception. EPP055 affects a sperm surface protein, EPPIN, to cause loss of forward and progressive motility. EPPIN binds to SEMG1 on the sperm surface and leads to a substantial decrease in intracellular pH, which in turn reduces internal calcium levels [152–154].

Therefore, the normal physiological cascades for fertilization mediated by increased internal pH to activate CatSper calcium channel gets disrupted. This leads to reduced calcium influx, which then inhibits cAMP production to mediate pathways for ATP production. This, in turn, prevents normal sperm capacitation and hyperactivation. Sperm motility remains low at least 78 h after infusion but it fully recovers by the 18th day after the treatment is ceased, which indicates its potential efficacy as a non-hormonal contraceptive agent [154].

Soluble adenylate cyclase (sAC) is also an interesting target to inhibit sperm activities. sAC is required to produce cAMP in the sperm cytoplasm to aid capacitation and hyperactivation [155]. sAC inhibitors thus potentially inhibit cAMP production and thereby down-regulate energy generation to bring about sperm motility. The sodium-hydrogen exchanger that is needed for sAC expression is found in sperm and thus is also a target for non-hormonal contraception [156].

Sperm motility is maintained via proper regulation of sperm volume and concentration of potassium chloride. In this regard, the co-transporters and ion-specific channels are crucial entities which can be targeted for contraception [157]. The SFEC is also a potential contraception target as it mediates the transportation of ATP into the principal piece of sperm for energy generation and utilization to activate flagellar movements for capacitation [4].

26.7 Conclusion

Energy generation and utilization in spermatozoa, though an integral part of sperm functionality, still remains partly ambiguous. This may be due to the unique anatomical and physiological characteristics of spermatozoa. This chapter thus discussed the unique functional ultrastructure of sperm that supports its energetics. It puts forth the preferred metabolic pathways in spermatozoa, both glycolytic as well as mitochondrial oxidative phosphorylation, to generate energy as per utilization. The coordination of Sertoli cells and spermatogonial cells in terms of energy metabolism is described for a clear understanding of energy sources for spermatogenesis. The chapter also vividly presents the possible mechanisms by which spermatozoa fuel their own hyperactivation, capacitation and acrosome reactions until fertilization is obtained. The proper concepts of energy metabolism help in improving the in vitro storage medium for spermatozoa as well as in evaluating the efficacy of non-hormonal contraceptions, based on cessation or reduction of sperm energy generation. Further interventions are encouraged for precise understanding of sperm energetics as that will help in designing a better medium for longer storage of spermatozoa while keeping their functionalities in robust conditions.

26.8 Review Criteria

An extensive search of studies examining the source, production and utilization of energy by spermatozoa was performed using search engines such as PubMed, MEDLINE, OVID, Science Direct, and Google Scholar. The start and end dates for these searches were July 2018 and December 2018, respectively. The overall strategy for study identification and data extraction was based on the following keywords: “sperm energy metabolism,” “sperm energetics,” “sperm fuel,” “sperm fuel machinery,” “sperm energy utilization,” “oxidative phosphorylation,” “glycolysis,” “ATP,” “sperm ATPases,” “sperm glycolytic enzymes,” “spermatogenesis,” “sperm function,” “hyperactivation,” “capacitation,” “acrosome reaction,” “sperm motility,” “sperm storage,” “cryopreservation,” “male contraception,” and “non-hormonal male contraception.” Articles published in languages other than English were also considered, provided that the abstract was in English. Data that were solely published in conference or meeting proceedings, websites, or books were not included.

Physiological Role of ROS in Sperm Function

27

Sulagna Dutta, Ralf Henkel, Pallav Sengupta, and Ashok Agarwal

Key Points

- ROS generation is a universal property of spermatozoa of all mammalian species.
- ROS can be endogenously generated or induced by exogenous sources.
- ROS mediate some essential intracellular signaling cascades needed for normal sperm functions.
- ROS pay essential role in sperm production, maturation, capacitation, and acrosome reactions.
- Excess ROS production leads to redox imbalance and OS inducing oxidative damage to the sperm.

27.1 Introduction

Male reproductive functions present a complex physiological mechanism, which are still far from complete understanding. Among the multivariate factors playing roles in mediating reproductive functions in men, reactive oxygen species (ROS) find immense importance in recent interventions from both physiological and pathological aspects [1]. The reports on the decline in semen quality over the last few decades have added to the necessity of a better understanding of sperm functions [2–5]. It is evident that most of the disruptors of sperm functions, be it endogenous, environmental, or lifestyle mediated, may operate via unregulated ROS. This leads to a condition of oxidative stress (OS) [6, 7] with generation of reactive species (oxidants) superseding total antioxidant capacity (reductants) in the seminal plasma.

ROS are, as oxygen metabolism by-products, highly reactive oxygen derivatives that are obviously toxic beyond physiological levels [8–10]. However, at normal physiological concentrations, they mediate not only essential bodily functions but also male reproductive functions [11]. ROS facilitate vital intracellular signaling cascades for appropriate sperm functions such as maturation, hyperactivation, and capacitation as well as acrosome reaction (AR) [11, 12]. In addition, they play a crucial role in the fertilization process.

This chapter provides distinct concepts on the vital contribution of ROS in normal sperm physiology by mainly elucidating (a) the endogenous and exogenous sources of ROS in male reproductive tract and (b) the physiological role of ROS in different phases of spermatozoa production, maturation, and attainment of maturity, until fusion with the female oocyte and fertilization.

27.2 Reactive Oxygen Species

An atom is in its ground state when its outermost shell has two complementary paired electrons with opposite spin directions. In such condition, the atom is stable and inert enough not to react with its surroundings. If atoms or molecules miss one electron, i.e., have only one free electron in the outer orbit, they are called radicals. Atmospheric oxygen does not occur in atomic form, but in molecular form as diatomic oxygen (O_2), and as per its electronic conditions, oxygen is a diradical with two free unpaired electrons in the outer orbit. This electronic condition causes the chemical reactivity of oxygen.

Oxygen is required for cellular respiration and for sustenance of survival. If oxygen is reduced, it leads to the generation of an extremely reactive oxygen metabolite, the superoxide anion ($•O^{2-}$), which is also a radical. This metabolite may interfere with various cellular functions. If this reduced metabolite further gains an electron, it is converted to peroxide (O_2^{2-}) which is not a free radical [13]. $•O^{2-}$ dismutation produces hydrogen peroxide (H_2O_2), another endogenous electronically not charged oxidant. It is found in abundance and, due to the fact that it is not a radical, relatively less reactive. However, due to its uncharged character, H_2O_2 can penetrate plasma membrane just like water.

A number of metabolic reactions in the human body produce H_2O_2 that includes, but not limits to, the peroxisomal pathway by monoamine oxidases and β-glycolate [14]. Both $•O^{2-}$ and H_2O_2 are susceptible to chains of transformations by Fenton and Haber-Weiss reaction to form the highly reactive hydroxyl radical (OH•). The Haber-Weiss reaction consists of an $•O^{2-}$-mediated reduction of ferric (Fe^{3+}) to ferrous ion (Fe^{2+}) and O_2, followed by the Fenton reaction, in which Fe^{2+} catalyzes the conversion of H_2O_2 to OH• and OH^- [15]. The superoxide anion may also react with nitric oxide (NO) forming peroxynitrite ($ONOO^-$). NO generation is aided by the enzyme nitric oxide synthase (NOS). NO is a reactive radical consisting of odd electron number [16]. Other ROS species, such as organic peroxyl and alkoxy radicals and ozone, may also be present but do not bear much biological significance [17]. ROS include all free radicals with an oxygen atom, and many people include hydrogen peroxide, which is not a radical, but a reactive oxygen derivative. As oxidants, these molecules capture electrons from adjacent cellular structures to reach ground state and in the process render the donator molecules (reductants) as free radicals. These chains of reactions continue to amplify the level of disruption in the neighboring cellular components [18].

27.3 Origins of ROS in Male Reproductive Tissues

ROS generation is a universal property of all cells including spermatozoa of all mammalian species. There are two proposed mechanisms of ROS production by spermatozoa: (a) via the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase system in the sperm membrane and/or (b) via the nicotinamide adenine dinucleotide-dependent redox reaction in the sperm. Spermatozoa are mitochondria-rich cells owing to their constant requirement of energy for their motility [19]. ROS are mostly contributed by electron leakage from mitochondria, induced by various factors that disrupt the electron transport chain. Elevated numbers of dysfunctional spermatozoa in seminal fluid are a strong inducer of ROS generation. The prime ROS produced in human spermatozoa is $•O_2^-$ that via dismutation produces H_2O_2. In presence of transition metals, iron and copper, H_2O_2 and $•O_2^-$ undergo the Haber-Weiss reaction to yield the most reactive and toxic metabolite, $•OH^-$. This may initiate lipid peroxidation in sperm membranes followed by the chain of reactions impairing sperm functions [20, 21].

27.4 Endogenous Sources of ROS in Seminal Plasma

27.4.1 Leukocytes

Peroxidase-positive leukocytes, such as the polymorphonuclear leukocytes (50% ~ 60%) and macrophages (20% ~ 30%), originate from the seminal vesicles and the prostate gland. During urogenital infections or inflammations, these cells may generate even 100 times more ROS higher than in normal conditions as part of the immune response. In turn, the production of NADPH via the hexose-monophosphate shunt also increases [1]. An inflammation-induced rise in pro-inflammatory mediators and decreased antioxidant capacity may trigger respiratory burst leading to OS [22]. Leukocytospermia refers to a condition in which semen contains greater than one million peroxidase-positive leukocytes per milliliter of semen and is associated with high degree of impairments to sperm functions [23].

27.4.2 Immature Spermatozoa

Normal physiological events in sperm maturation include extrusion of excess cytoplasm. However, when spermiogenesis is disrupted, spermatozoa retain excess cytoplasm around the midpiece, thus impeding its functions (excess residual cytoplasm, ERC).

Immature spermatozoa with distorted head morphology and cytoplasmic retention are thus a major source of seminal ROS [24]. The retention of the excess cytoplasm in immature sperm is the cause of surplus of metabolic enzymes, such as the glucose-6-phosphate dehydrogenase (G6PD) and NADPH oxidase, and NADPH oxidase as enzymes intimately involved in free radical production via the intermediate NADPH formation [25]. G6PD is a key enzyme to catalyze the hexose-monophosphate shunt, mediating the reaction with $NADP^+$ and glucose-6-phosphate to form reduced NADPH. Thus, ERC may activate the NADPH system via the hexose-monophosphate shunt, paving the way for ROS production and OS [26].

Normal spermatozoa are able to generate ROS by means of two different sources: NADPH oxidase in their plasma membrane and NADH-dependent oxidoreductase (diaphorase) of their mitochondria [27, 28]. NADH diaphorase is a

major participant of the high ATP-generating Krebs cycle. This biochemical pathway is common to almost every aerobic organism that yields high energy, and one of the functions of this cycle is acetate oxidation. The Krebs cycle yields three NADH molecules from NAD^+. NADH transports electrons to be utilized for generation of via mitochondrial electron transport chain and, in the process, leads to generation of some ROS as well. However, ROS generation mediated by sperm mitochondrial has been reported to be considerably low [28].

27.4.3 Sertoli Cells

Sertoli cells have also been documented to be able to generate ROS [29–31]. Studies have shown that addition of so-called scavestrogens (synthetic steroidal estrogens with potent antioxidant properties [32]) inhibits the production of reactive oxygen species from Sertoli cells [31]. Scavestrogens potentially scavenge free radical scavengers and can restrict iron-induced cell damage in vitro [31]. Thus, it may be suggested that Sertoli cells, in normal in vivo conditions, aid spermatogenesis mediated by ROS production. Further investigations are required to clarify the role of Sertoli cells in ROS production.

27.4.4 Varicocele

Varicocele, an abnormal venous dilation in the pampiniform plexus around the spermatic cord, affects about 40% of male partners among overall infertile couples and is one of the leading causes of male subfertility and infertility [33]. There are several mechanisms explaining the pathophysiology of varicocele-induced alterations in sperm functions. However, it has been put forth that the most common mechanism includes varicocele-mediated testicular hyperthermia and hypoxia in causing OS-induced sperm dysfunctions [33, 34]. A meta-analysis has confirmed a higher incidence of oxidative stress parameters such as ROS and lipid peroxidation in semen samples from varicocele-affected infertile patients as compared with healthy fertile donors [33, 35]. The levels of seminal ROS levels have suggested to have direct correlation with the grade of varicocele [36].

27.5 Exogenous Sources of ROS in Seminal Plasma

27.5.1 Radiation

Mobile phone radiation greatly induces ROS generation in seminal plasma and leads to deleterious effects on semen quality. It triggers sperm DNA damage and epigenetic modifications disrupting sperm motility, count, and vitality [37, 38]. Electromagnetic waves, via the cytosolic charged molecules, lead to alterations in the process of intracellular electron transfer along sperm membranes and thereby impair sperm functions [39]. Radio frequency waves influence male fertility via thermal as well as nonthermal mechanisms. Testes are susceptible to disruptions by electromagnetic energy as testicular temperature regulation depends mostly upon surface conduction unlike other organs that mainly depend on blood flow for temperature regulations. Radiation may lead to raised scrotal temperature and affect spermatogenesis, which is sensitive to even a 1 °C increase in its temperature. The nonthermal effects of radiation are mediated through oxidative stress or changes in cell membrane potential affecting spermatogenesis and inducing spermatozoa apoptosis. Chronic exposure to radiation also brings about degeneration of Leydig cells [40].

27.5.2 Lifestyle Factors

Smoking is a modifiable lifestyle factor that severely disrupts the balance of ROS production and antioxidant defense. Smoking may lead to an increase in seminal leukocyte concentrations by 48% that accounts for the increase in seminal ROS by 107%. The seminal antioxidant capacity gets diminished accompanied by an increase in 8-OHdG concentrations (a potent oxidative damage biomarker) [41, 42]. Furthermore, smoking elevates lead and cadmium concentrations in semen and blood. In turn, this increases ROS production affecting sperm functions [39]. Germ cell apoptosis and DNA damage are generally common in smokers [43]. Alcoholism is another crucial factor that paves the way to excess seminal ROS generation and reduction in antioxidant capacity. Acetaldehyde, produced as a by-product through ethanol metabolism, yields ROS reacting with sperm cellular components. This significantly reduces the percentage of functional spermatozoa [9].

27.5.3 Toxins

Industrialization and domestic sophistications are responsible for increasing environmental toxins and endocrine disruptors in an individual's immediate environment. These intrude the body and may potentially induce excessive testicular ROS generation and OS, which in turn impairs morphology and functions of sperms. Exposure to environmental toxins leads to ROS-induced germ cell apoptosis [44]. For example, increased use of plastics has led to rise in exposure to phthalates which in addition to toxic metals such as lead, manganese, cadmium, chromium, and mercury afflict sperm quality, count, and spermatogenesis [5, 45].

27.6 Physiological Role of ROS on Different Sperm Functions

As discussed earlier, ROS can be detrimental to sperm functions when their seminal levels exceed physiological limits. Nonetheless, at regulated levels, ROS mediate some essential sperm functions including sperm maturation, capacitation, hyperactivation, acrosome reaction, and sperm-oocyte fusion [11, 28, 46–50].

27.6.1 Sperm Transformational Stages

The spermatozoon nucleus comprises of a haploid paternal genome so that it complements the female haploid genome present in the oocyte. Fertilization involves nuclear fusion of male and female gametes resulting in the formation of a diploid organism [28].

Formation of mature, normal spermatozoa from developing spermatids is the primary criterion toward successful fertilization. After production of immature germ cell in the seminiferous tubules of the testis, the cells migrate to the epididymis where they are stored and mature under the influence of the adjacent epithelial cells. This maturation phase in the epididymis transforms nonmotile spermatozoa into motile germ cells able to fertilize an oocyte. Spermatogenesis further comprises of nucleus condensation, a process which is finalized by the oxidation of protamine sulfhydryl groups to disulfide bridges, which further stabilize the sperm nucleus. During ejaculation, secretions of different accessory glands are mixed with the spermatozoa to form semen [28].

Semenogelin, a secretion from the seminal vesicles, is the most abundant seminal protein which aids semen coagulation upon ejaculation [51]. Prostate-derived prostate-specific antigen (PSA) later degrades the semen coagulum. ROS may also play a vital role here in the process of seminal coagulation and liquefaction by mediating redox reactions. Hamada et al. had shown that higher ROS levels in patients accounted for increased semenogelin levels in their semen [52]. On contrary, Chatterjee et al. [53] had also reported that $\bullet O^{2-}$ amplifies the process of semen liquefaction. The discrepancies in scientific reports of the role of ROS may be due to the multifarious actions of ROS at the same time. Alternatively, it may owe to the use of a higher concentration of $\bullet O^{2-}$ in vitro in the study by Chatterjee et al. as compared to its in vivo levels [28].

Mature spermatozoa are highly polarized and compartmentalized, comprising of a head with very little cytoplasm and condensed chromatin in nucleus and a flagellum (tail) separated in midpiece, principal piece, and end piece. The acrosome is part of the anterior sperm head, taking up an area between 50% and 70%. It is an inactive, enzyme-filled structure, which derives from the Golgi apparatus and is enclosed by its membrane. The midpiece of the spermatozoon is referred to as its "powerhouse" owing to the presence of a profuse number of mitochondria that generate energy for flagellar movements [54]. The flagellum contains the axoneme as motility-generating structure and the outer dense fibers (ODF), which contribute to the stability, rigidness, and efficient energy conversion of the flagellum [55–57]. In addition, the ODF are responsible for the typical "whiplike" flagellar motion of mammalian spermatozoa [58, 59].

Following ejaculation, mature spermatozoa may enter the female reproductive tract. This event marks the onset of several physiological changes in spermatozoa that render them potent for recognition and binding to zona pellucida of the oocyte. This reversible, preparatory process, which takes a few hours to complete, is termed capacitation. The cellular alterations taking place during this phase attribute to increased sperm plasma membrane fluidity, efflux of cholesterol, activation of adenylyl cyclase and increased intracellular cyclic AMP (cAMP) and calcium levels, membrane hyperpolarization, increased intracellular pH, tyrosine (Tyr) phosphorylation of proteins, and hyperactivation of the spermatozoon [60, 61].

On completion of the capacitation process, spermatozoa approach the oocyte and acrosome reaction (AR) can be initiated [28]. This process involves membrane hybrid vesicle formation between the sperm plasma membrane and out acrosomal membrane resulting in exocytosis of the acrosomal enzymes following the sperm penetration of the zona pellucida [62]. In contrast to capacitation, acrosome reaction is an irreversible process that not only goes along with morphological but also physiological changes of spermatozoa. Physiological triggers of acrosome reaction are the zona pellucida glycoprotein 3 (ZP3) or progesterone [63].

From the production of spermatozoa in the testes, until their fusion with oocyte, spermatozoa pass through different specialized maturational steps to attain their functional competence to successfully fertilize oocytes. The morphological integrity of the matured spermatozoon and their physiological functions are facilitated by extracellular cues from their immediate environment, in which ROS play a vital role as stimulatory factors that are required by the male germ cells to attain their complete functional competence [64].

27.6.2 Maturation

The epididymis is the site of spermatozoal maturation. The maturation steps include sperm membrane alterations,

membrane protein rearrangement, enzymatic modulations, and nuclear remodeling [11]. These steps are mediated via appropriate cell signaling pathways modulated by levels of seminal ROS [28, 49]. Since smaller-sized protamines replace the histones as nuclear proteins in mammalian spermatozoa, it is possible to highly condense the DNA in an array-type structure instead of supercoiled solenoids [65]. The cysteine residues of the protamines have inter- and intramolecular disulfide bonds between them to impart chromatin stability [66]. This formation of disulfide bond is aided by ROS to ensure chromatin stability and prevent damage to the chromosomal DNA. ROS, especially peroxides, also play a role in the mitochondrial capsule formation, which is formed by network of proteins with several disulfide bonds preventing proteolytic degradation of mitochondria [11, 67].

27.6.3 ROS as Signal Transducers

ROS are well-suited as intracellular signaling molecules for their tiny size, ubiquitous nature, and short half-life. They mediate all vital physiological functions of sperm such as maturation, motility, activation, capacitation, and acrosome reactions [28]. ROS actions are mainly carried out through the regulations of the redox status of cysteine residues. The redox status of thiol groups determines enzymatic activity, which acts via activation of adenylate cyclase (AC) by increasing the intracellular cyclic AMP (cAMP) concentration. cAMP in turn activates protein kinase A (PKA), thereby triggering various downstream cell signaling pathways specific to different phases of spermatozoa maturation [11].

27.6.4 Motility and Hyperactivation

Hyperactivation refers to a state of exaggerated nonlinear motility in sperm with relatively high-amplitude asymmetric, whiplash-like, flagellar movement, and increased sidewise displacements of sperm head [68]. It is suggested to be a part of the capacitation process and is essential for successful attainment of sperm oocyte fusion and fertilization. ROS mediate upregulation of sperm hyperactivation processes [49]. The underlying mechanism includes initiation of capacitation and hyperactivation by induction of Ca^{2+} and HCO_3^- influx possibly through inactivation of plasma membrane Ca^{2+}-ATPase (PMCA) and cytosol alkalization. Calcium ions and ROS, specifically $\bullet O_2^-$, mediate AC activation and increased production of cAMP which activates PKA. This process triggers NADPH oxidase and thereby further upregulates ROS generation. Moreover, PKA leads to phosphorylation of serine (Ser) and Tyr residues, thereby activating protein tyrosine kinase (PTK). PTK phosphorylates the subsequent tyrosine residues in the axoneme fibrous sheath and the sperm flagellum cytoskeleton. ROS, especially H_2O_2, trigger phosphorylation of tyrosine by activating PTK and inhibiting phosphotyrosine phosphatase (PTPase) from dephosphorylating the Tyr residues. These ROS, especially superoxide, inducing phosphorylation of tyrosine residues are suggested to be the final step in sperm hyperactivation [11, 39].

27.6.5 Capacitation

Capacitation is the final functional processing of spermatozoa maturation, which potentiates them and renders them competent for fertilizing an ovum. Extensive research has suggested essential functions of ROS at physiological levels in facilitating capacitation. There is supportive evidence that ROS are vital for the amplification in phosphorylated tyrosine residues (P-Tyr) of proteins (molecular weight ~100 kDa) [69]. ROS possibly potentiates this process by mediating cell signaling pathways, which involve an increase in intracellular cAMP levels followed by activation of PKA and phosphorylation of mitogen-activated *protein* kinase (MEK) and the downstream regulatory proteins. The overall impact of ROS-mediated activation of fibrous sheath proteins orchestrates the physiological process of sperm capacitation and the male germ cells acquiring the required potency to execute acrosome reaction [39, 70].

Ca^{2+} and HCO^{3-} influx via the inactivation of an ATP-dependent Ca^{2+} regulatory channel (PMCA) and cytosol alkalization may initiate the possible biochemical pathway in regulation of sperm capacitation and hyperactivation. ROS, especially $\bullet O^{2-}$, along with Ca^{2+} activate AC, followed by production of cAMP, which phosphorylates PKA. PKA in turn induces ROS generation by activating membrane-bound NADPH oxidase. PKA also phosphorylates serine (Ser) and tyrosine (Tyr) residues that participate in protein tyrosine kinase (PTK) activation and subsequent phosphorylation and activation of threonine-glutamate-tyrosine residues of fibrous sheath proteins surrounding the axoneme [70, 71], which is the flagellar cytoskeletal component. ROS, especially H_2O_2, highly induces Tyr phosphorylation by triggering PTK activity and via inhibition of phosphotyrosine phosphatase (PTPase) activity that acts to dephosphorylate Tyr residues [11, 28] (Fig. 27.1).

27.6.6 Acrosome Reaction

The primary criterion for successful fertilization is sperm-oocyte fusion followed by penetration of sperm head through the zona pellucida. To accomplish the same, hyperactivated spermatozoa need to cross the layer of cumulus cells to reach the zona pellucida of oocyte. The completion of acrosome reaction (AR) refers the end in maturational stages of the spermatozoon as at this point it acquires the ultimate fertilizing ability. ROS facilitate the acrosome reaction possibly by induction of phosphorylation of specific plasma membrane proteins [11, 28]. The anterior part of the sperm head gets modified to release the acrosomal enzymes as the sperm comes in contact with the zona pellucida. Acrosin, a trypsin-like serine proteinase, is an essential enzyme for acrosome reaction and sperm-zona penetration as it facilitates dissolving the zona pellucida, thereby creating a pore for the sperm to penetrate [67].

Induction of the AR can take place via both physiological and nonphysiological stimulators, including ROS, the zona pellucida itself, or progesterone [72]. It is initiated by Ca^{2+} influx and Ca^{2+} release from the acrosomal calcium store as occurred during capacitation. This leads to production of diacylglycerol (DAG) and inositol triphosphate (IP3) from phosphatidylinositol-4,5-bisphosphate (PIP2). This is followed by activation of actin-severing proteins, triggering acrosomal fusion with plasma membranes, and subsequent exocytosis of acrosomal contents. DAG eventually phosphorylates protein kinase C (PKC), leading to yet more Ca^{2+} influx that activates phospholipase A2 (PLA2) (Fig. 27.2). The huge quantity of membrane fatty acids release during AR elevates sperm plasma membrane fluidity required for its fusion with oocyte [28, 39].

27.6.7 Sperm-Oocyte Fusion

ROS essentially participate in increasing the plasma membrane fluidity during sperm-oocyte fusion by mediating the activation of biochemical cascades for capacitation followed by successful acrosome reaction. Along the entire duration of spermatozoa capacitation, ROS impede the deactivation of PLA2 via inhibition of protein tyrosine phosphatase activity. Thus, the activated PLA2 potentially cleaves the secondary fatty acid from the membrane phospholipid triglycerols and enhances the plasma membrane fluidity [73].

27.7 Conclusion

ROS are essential for sperm functions at all levels of sperm production, storage, and fertilization when their concentrations are within physiological limits. As discussed, both endogenous and exogenous sources of ROS contribute to the levels of ROS in seminal fluid. ROS ensure the morphological modulation of spermatozoa by being mediators of key intracellular signaling pathways that aid sperm chromatin condensation, motility, chemotaxis, capacitation, hyperactivation, and acrosome reaction to attain successful fertilization. On the other hand, excess ROS generation is resulting in deleterious effects on the male reproductive system by induction of OS. Therefore, it may be suggested that complete sperm functionality with utmost fertilization capacity is attained by a well-balanced processes of generation and scavenging of ROS.

Further research is needed to unveil the proteins that are expressed and phosphorylated in spermatozoa in response to oxidative stress and how ROS mediate specific intracellular signaling pathways. Proper concepts regarding the intricate oxidative balance playing essential physiological roles in sperm functions find immense importance in the diagnosis, prevention, and treatment of male subfertility and/or infertility.

27.8 Review Criteria

An extensive literature search has been performed to find the relationship between oxidative stress and male infertility using search engines such as Science Direct, OVID, Google Scholar, PubMed, and MEDLINE. The overall strategy for study identification and data extraction was based on the following keywords: “oxidative stress,” “reactive oxygen species,” “infertile men,” “infertility,” “semen parameters,” and “assisted reproduction” and the names of related oxidative stress markers and specific ROS assessment methods. Articles published in languages other than English were also considered. Data that were solely published in conference or meeting proceedings, websites, or books were not included. Websites and book chapter citations provide conceptual content only.

Sperm Physiology and Assessment of Spermatogenesis Kinetics In Vivo

28

Matheus Roque, Giuliano Bedoschi, and Sandro C. Esteves

Key Points

- Adult men produce millions of spermatozoa daily, dependent on adequate testicular environment and hormonal control. Proper functioning of the hypothalamic-pituitary-gonadal axis, which is regulated via the release of gonadotropin-releasing hormone (GnRH) is essential to sustain both spermatogenesis and steroidogenesis.
- FSH and LH action in germinal cell development is affected by androgen and FSH receptors on Leydig and Sertoli cells, respectively. While FSH acts directly on the germinative epithelium, LH stimulates secretion of testosterone by the Leydig cells.
- Spermatogenesis is a complex process that leads to the transformation of primordial germ cells into mature spermatozoa, starting with diploid cells and completing with highly specialized haploid cells, and this process is estimated to take 64 days.
- In vivo, ejaculated sperm are unable to fertilize until they have undergone capacitation, which allows the acrosome reaction to take place when spermatozoa approach or contact the oocyte.

28.1 Introduction

Spermatogenesis and steroidogenesis depend on the proper functioning of the hypothalamic-pituitary-gonadal axis, which is regulated via the release of gonadotropin-releasing hormone (GnRH). Hypothalamic neurons secrete GnRH in a pulsatile form; the latter is then transported to the anterior compartment of the pituitary gland where it binds to specific receptors located in the gonadotropic cells to modulate the synthesis and secretion of pituitary gonadotropins, the follicle-stimulating hormone (FSH), and luteinizing gonadotropins (LH). These hormones are secreted into the systemic circulation and act on the testes. FSH acts via receptors located in the Sertoli cells, whereas LH stimulates Leydig cells to produce testosterone, an essential prerequisite for male fertility and maintenance of spermatogenesis [22, 50, 108]. Steroids and gonadal peptides are subsequently secreted into the systemic circulation to modulate the hypothalamic and pituitary hormone secretion [64, 118].

Spermatogenesis is a complex process that leads to the transformation of primordial germ cells into mature spermatozoa, starting with diploid cells and completing with highly specialized haploid cells [57]. This is a continuous process throughout the reproductive life that is controlled by paracrine, autocrine, endocrine, genetic, and epigenetic regulators, occurring within the seminiferous tubules [82]. The complete process comprises (i) the proliferation of spermatogonia, (ii) the differentiation of spermatogonia into spermatocytes, (iii) production of spermatids through the meiotic division of spermatocytes, (iv) maturation of round spermatids, and lastly, (v) release of mature spermatozoa into the lumen of the seminiferous tubules [104].

Although the resulting spermatozoon acquires its final shape and size in the testis, it only achieves full potential for natural fertilization after passage through the epididymis, in a process known as epididymal maturation and capacity building. Finally, sperm capacitation takes place after contact with the female reproductive tract [40, 64, 118].

In this chapter, we will present and discuss the critical features of sperm physiology, spermatogenesis, and steroidogenesis.

28.2 The Testis: Structure and Function

The primary functions of the testis are the synthesis of steroid hormones (steroidogenesis) and the production of mature sperm (spermatogenesis). The testis performs its functions through the coordination and interrelation between its various cell types, such as Sertoli cells, Leydig cells, peritubular myoid cells, and germ cells [7].

The testicles are outside the abdominal cavity and lie within the scrotum. Thermoregulatory mechanisms maintain the testicular temperature at approximately 2–3 °C lower than the body temperature. Since male germ cells are thermosensitive, this location is critical to maintaining adequate spermatogenesis. Changes in the mechanism of temperature control can lead to infertility, as it occurs in cases of varicocele and cryptorchidism. The testicular parenchyma is covered by a capsule of connective tissue (the tunica albuginea), and externally to the albuginea, there is the vaginal tunic [110]. The testicular and epididymal blood supply originates from three main arterial branches, namely, the internal spermatic testicular artery, deferential artery, and external or cremasteric spermatic artery. The spermatic artery is a branch of the abdominal aorta, originating distally from the renal artery. It is associated with a network of veins that anastomose and form the pampiniform plexus. The vascular arrangement of this plexus facilitates the exchange of heat and small molecules between arteries and veins. In healthy men, the heat exchange that occurs in the spermatic cord causes the intratesticular temperature to be lower than the corporal temperature. Inside the testicular capsule, the testis is divided into about 200–300 lobules by septations arising from the tunica albuginea [82]. In each lobe, there are seminiferous tubule loops, each loop ending in the rete testis network. This network is connected with the efferent ducts, thus allowing sperm to reach the head of the epididymis. Within each lobe, the testis is divided into two compartments, that is, (i) intratubular compartment, which is composed of the seminiferous epithelium and contains two cell types, the sperm cells at different stages of differentiation and the Sertoli cells, and (ii) peritubular or interstitial compartment, which is composed of Leydig cells, connective tissue cells, mast cells, macrophages, nerves, blood vessels, and lymphatics; in human testicles, the interstitial tissue represents 20–30% of the testicular volume [94].

28.2.1 Seminiferous Tubules

The seminiferous tubules are long, enveloped structures that arise and terminate in the rete testis network, an anastomotic network of tubules that drains into the efferent ducts. The total length of the existing 600–1200 tubules in the human testicle is approximately 250 meters. The rete testis network coalesces to form 5–10 efferent ducts, which will carry the testicular fluid and spermatozoa to the region of the head of the epididymis. The seminiferous tubules provide a unique environment for the production of germ cells through their germinative elements (sperm cells at various stages of development) and the "supporting cells," which harbor and provide a physiological basis for male germ cells differentiation. "Supporting cells" include Sertoli cells and basement membrane cells, both remaining in intimate contact with the sperm cells. The germinative elements comprise a population of epithelial cells, including the primordial germ cells, spermatogonia, spermatocytes, and spermatids [94]. Each seminiferous tubule consists of a basement membrane covered by Sertoli cells interspersed with germ cells at various stages of maturation. The germ cell maturation, better known as the spermiogenesis process, occurs in a centripetal way, with the most immature cells present in the periphery and migrating toward the lumen as they progress through the sequential stages of maturation [5] (Fig. 28.1). In the pre-pubertal phase, the seminiferous tubules are called seminiferous cords, being constituted only by Sertoli cells and spermatogonia. As the testosterone production by Leydig cells increases after puberty, the remaining germline cells appear [14].

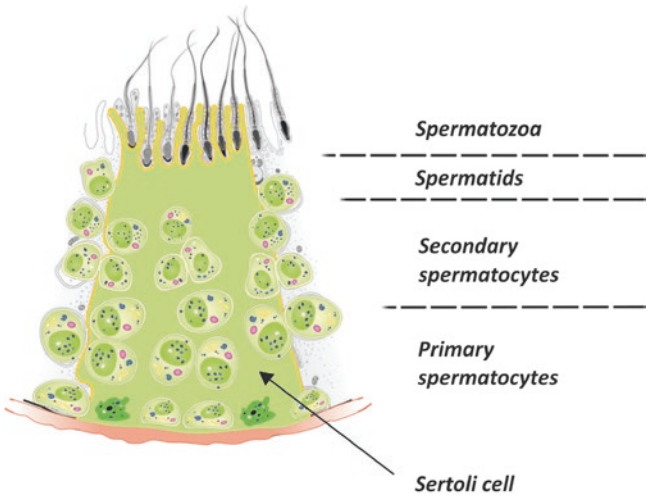

Fig. 28.1 Schematic representation of a histologic cross-section of a single seminiferous tubule depicting its cell components. (Reprinted from Ref. [119] with permission from Elsevier)

28.2.2 Sertoli Cells

Sertoli cells—the true epithelial cells of the seminiferous epithelium—are pyramidal cells that rest on the basal membrane of the seminiferous tubules with their filamentous ramifications extending toward the lumen of the tubules. They provide a structural support to the seminiferous epithelium and

surround the sperm cells, being responsible for both maintenance of the hematopoietic barrier and development of the germ cells. The Sertoli cells also have functional properties related to the secretion of hormones (anti-Müllerian hormone and inhibin) and phagocytosis. The Sertoli cells produce a large amount of fluid that provides not only a suitable environment for the spermatozoa but also helps to move the immotile sperm from the seminiferous tubule to the epididymis [110].

The Sertoli cell population is established early in postnatal development and is the main determinant of both sperm production and release during adulthood. At puberty, the Sertoli cells go through a period of proliferation, in which FSH acts as an important regulator [14]. Tight-junctions are found between adjacent Sertoli cells, which make the physical basis for the hematopoietic barrier. The Sertoli cells support the development of germ cells by creating a suitable microenvironment in the adluminal compartment of the seminiferous epithelium; they also facilitate the migration of the differentiating germ cells to the tubular lumen [28, 110].

The Sertoli cell cytoskeleton consists of actin filaments, intermediate filaments, and microtubules. Actin filaments are composed of actin monomers and, through their binding to myosin, allow motions between the cells. The actin filaments are found predominantly as components of tubulobulbar complexes and ectoplasmic specializations. The tubulobulbar complexes are attached to the spermatids, on the apical surface of the germinal epithelium, and also between the Sertoli cells along the basolateral membrane. It is speculated that these complexes have a role in shaping the spermatid head. The ectoplasmic specializations are located in the apical region of the germinal epithelium in association with the spermatids, but are also found in the basolateral membrane between Sertoli cells and the basement membrane. They are responsible for the adhesion between Sertoli cells and between maturing spermatocytes and spermatids [69, 81]. Microtubules are tubular polymers composed of α and β tubulin, involved in the assembly and release of elongated spermatids. Their polarity allows the movement of spermatids and other substances toward the apical membrane [6].

Sertoli cells express androgenic and FSH receptors, allowing spermatogenesis to be sustained indirectly by functional stimulation [95]. They also express aromatase (CYP19), which converts testosterone derived from Leydig cells into 17-β-estradiol. Sertoli cells produce androgen-binding protein (ABP), which acts as the intracellular carrier of androgens, thus helping to maintain high androgen levels both in the adluminal compartment as well as in the lumen of seminiferous tubules. Furthermore, the Sertoli cells play an essential phagocytic role, eliminating residual bodies, which correspond to sperm cytoplasmic excess eliminated during spermiogenesis.

Inhibin B is a glycoprotein secreted by Sertoli cells. The secretion of inhibin B is controlled by gonadotropins, Sertoli cells, Leydig cells, and germ cells. Before puberty, Sertoli cells are the predominant cell type in the seminiferous tubules, whereas in the adult testis germ cells prevail. This pattern may be necessary for the maintenance of inhibin B secretion and consequent inhibition of FSH before the onset of puberty. Inhibin acts by negatively regulating the synthesis and release of FSH by the anterior pituitary. The expression and secretion of inhibin B correlate with Sertoli cell activity, sperm number, and spermatogenesis pattern and is inversely related to FSH levels [21, 71].

28.2.3 Hemato-testicular Barrier

The hemato-testicular barrier divides the seminiferous epithelium into basal and apical (adluminal) compartments. Spermiogenesis and spermiation occur in the apical compartment, while the spermatogonia renewal and the early stages of spermatogenesis (up to the prelopten stage of the spermatocyte) occur in the basal compartment [28]. The blood-testicular barrier has the function of blocking the passage of substances from the blood to male germ cells. It allows Sertoli cells to control the supply of nutrients to germ cells and to create an immunologically safe environment for spermatogenesis, thus avoiding an autoimmune reaction by defense cells against germline cells. The blood-testis barrier, owing to its continuous characteristics, facilitates the dynamic interaction between germ cells and Sertoli cells, as well as the migration of germ cells to the adluminal surface [110].

Sertoli cells adhere to germ cells to form a highly specialized epithelium, in which the various junctions (tight junctions and adherens junctions) between adjacent Sertoli cells allow creation of an immunological barrier within the seminiferous tubules. The immunological barrier seems to have three different levels, the first being formed by tight junctions between Sertoli cells. The other two levels are located in capillary epithelial cells and peritubular myocyte cells. The blood-testicular barrier is the only human immunological barrier in which tight junctions and adherens junctions are located contiguously and working together. The proper functioning of this barrier is crucial for the maintenance of male fertility [6].

28.2.4 Peritubular Microenvironment

Several layers of peritubular tissue and a complex capillary network provide adequate nutrition for the seminiferous tubules. Separating the interstitial tissue from the tubule, there is a first adventitious layer comprised of fibrocytes. The next layer consists of myoid cells intercalated by connective tissue, whereas the third layer is composed of a large amount of collagen adjacent to the basement membrane underlying

the seminiferous epithelium. Peritubular myoid cells have a contractile function and secrete various substances such as fibronectin and collagen type 1. The peritubular compartment also contains Leydig cells, which are steroidogenic stromal cells [94]. The peritubular cells are distributed concentrically in layers around the seminiferous tubules, separated by collagen fibers. These cells produce extracellular matrix, connective tissue proteins (collagen, laminin, vimentin, fibronectin), and proteins related to cellular contractility such as smooth muscle myosin and actin. The peritubular cells also synthetize adhesion molecules, such as nerve growth factor (NGF) and monocyte chemoattractant protein 1 (MCP-1) [93]. Secretion of the above-mentioned factors is regulated by tubular necrosis factor-α (TNF-α), which in turn is produced by mast cells; therefore, an interaction between peritubular and mast cells is suggested. It has also been shown that the number of mast cells increases in the testis in certain infertility cases [11]. Peritubular cells have contractility properties that aid in the transport of sperm through the seminiferous tubules. Peritubular contractility is regulated by oxytocin, prostaglandins, androgens, and endothelin [90, 107, 115]. Endothelin is, in turn, modulated by the relaxant peptide adrenomedullin produced by Sertoli cells [90]. Peritubular cells also secrete insulin-like growth factor-1 (IGF-1) and cytokines that modulate Sertoli cell function [107]. Due to the complex interactions between peritubular cells and other cellular elements, it has been suggested that these cells have a role in fertility. In fact, loss of contractility markers, tubular fibrosis and sclerosis, and an increased number of mast cells are seen in conditions involving derangements of spermatogenesis leading to subfertility [11, 52, 88]. Peritubular and interstitial fibrosis, in association with spermatogenic damage, have also been demonstrated in the testis of vasectomized men [87].

28.2.5 Steroidogenesis

Leydig cells are located in the interstitial space of the testis and are responsible for testosterone production, which is essential for proper spermatogenesis. The differentiation of Leydig cells is determined, at least in part, by peritubular and Sertoli cells, which secrete leukemia inhibitory factor (LIF), platelet-derived growth factor-α (PDGF-α), and other factors that trigger Leydig stem cells to proliferate and migrate into the interstitial compartment of the testis, where they differentiate into the so-called progenitor Leydig cells. Subsequently, growth factors and hormones (LH, IGF-1, PDGF-α, among others) transform the Leydig stem cells into immature Leydig cells and, finally, into adult Leydig cells, which is primarily responsible for the production and secretion of testosterone [100].

In adults, binding of LH to its receptors on Leydig cells activates cyclic AMP and a cascade of intracellular events, including increased gene transcription and steroidogenic enzymatic activity, which culminates with production of testosterone. LH binding to high-affinity receptors on the plasma membrane of Leydig cells results in hydrolysis of cholesterol esters, increased expression of steroidoenic genes, and expression of LDL and HDL receptors. LH also has a long-term trophic effect, which promotes the growth and proliferation of Leydig cells. The lack of stimulation by LH, in turn, results in a decrease in steroidogenic enzymatic activity and, as a consequence, cellular atrophy [39].

Testosterone is the main product secreted by the testis, with a daily production rate of 5–7 mg. It is estimated that the intratesticular content of testosterone is 100 times greater than that in the peripheral circulation. Reduced testosterone levels might result in low spermatogenic activity, leading to oligozoospermia or even azoospermia. Testosterone is transported into the bloodstream linked to albumin or sex hormone-binding globulin (SHBG). Only about 2% of total testosterone circulates freely in the bloodstream. Plasma testosterone levels are closely correlated with LH levels [91, 116].

The major substrate for androgen synthesis is cholesterol. The limiting point of the steroidogenesis rate is the transfer of cholesterol from external mitochondrial membrane to internal mitochondrial membrane, where bioconversion to pregnenolone by the cytochrome P450SCC (side-chain cleavage) enzyme occurs. This transfer depends on the synthesis of steroidogenesis regulatory protein (StAR) and mitochondrial translocator protein, synthesized after the binding of LH to its receptors on Leydig cell surface. Mitochondrial enzymes cytochrome P450SCC or CYP11A1 (cytochrome P450, family 11, subfamily A, polypeptide 1) transforms cholesterol into pregnenolone, a process limited by the availability of cholesterol substrate. In the so-called delta-4 pathway, pregnenolone is converted to progesterone by 3β-hydroxysteroid dehydrogenase, which in turn is converted to 17α-hydroxyprogesterone and androstenedione by 17α-hydroxylase or CYP17A; androstenedione is finally converted to testosterone by cytochrome P450c17 (Δ4 pathway: pregnenolone → progesterone → 17α-hydroxyprogesterone → androstenedione). In the delta-5 pathway, pregnenolone is hydroxylated to 17α-hydroxypregnenolone and dehydroepiandrosterone by 17α-hydroxylase or CYP17A, which in turn are converted to androstenediol by cytochrome P450c17; finally, androstenediol is transformed into testosterone by 3β-hydroxysteroid dehydrogenase (Δ5 pathway: pregnenolone → 17α-pregnenolone → dehydroepiandrosterone → 5-androstenediol). Testosterone can be converted to estradiol by aromatase or to dihydrotestosterone by 5α-reductase. LH stimulates the transcription of genes that encode the enzymes involved in the steroidogenic pathways to testosterone [22].

28.2.6 Spermatogenesis

Spermatogenesis is a highly efficient and coordinated process that results in the production of mature spermatozoa. The entire spermatogenic process is thought to require approximately 74 days, but recent studies suggest that the duration in normal men might vary between 42 and 76 days, taking approximately 64 days in humans. Every 16 days, a new group of spermatogonia enters the process of spermatogenesis [42, 77, 94].

Spermatogenesis is classically divided into three phases: (1) a proliferative or mitotic phase, in which the primitive germ cells/spermatogonia pass through a series of mitotic divisions, forming new stem cells or forming cells that will originate the spermatocytes; (2) meiotic phase, in which spermatocytes pass through two consecutive divisions to produe spermatids (haploid cells); and (3) spermiogenesis, in which spermatids differentiate into spermatozoa [5, 97].

Spermatogonia are specialized diploid cells located in the basal membrane of the seminiferous tubules. They are the precursors of all other types of germ cells and are present in the testicles throughout the lifespan. To maintain the supply of mature sperm, spermatogonia must perform three functions: (1) differentiation, (2) self-renewal, and (3) control [27]. From the least to the most differentiated, spermatogonia can be divided into (based on their heterochromatin contents) dark type A (Ad, dark) and pale type A (pallid) spermatogonia.

Ad-type spermatogonia have the ability to perform mitotic divisions, generating new Ad cells, which are considered reserve spermatogonia. Spermatogonia type Ap is located in the basal compartment of the seminiferous tubules and are the precursors of type B spermatogonia: the latter can differentiate into spermatocytes. During spermatogenesis, meiosis occurs sequentially and without interruption. The spermatogonia type B passes through the process of mitosis originating the primary spermatocyte (diploid cell), which is the most abundant cell of the spermatogenic lineage and that will undergo meiosis. This cell spends most of the time in prophase I, which is the first stage of meiosis I and where gene recombination occurs. At the end of meiosis I, the two daughter cells are called secondary spermatocytes, containing a haploid number of chromosomes with each chromosome containing two chromatids. A second division begins (meiosis II) and gives rise to four spermatids, with a haploid number of chromosomes with a single chromatid in each. The spermatids, still rounded, undergo a process of transformation and remodeling, known as spermiogenesis and spermiation, which result in the formation of spermatozoa, a tiny elongated cell in which it is possible to distinguish three regions: head, middle part, and tail [5, 14, 94] (Fig. 28.2).

Androgens play a crucial role in the initiation and maintenance of spermatogenesis [67, 92]. Through their binding to androgen receptors (ARs), they regulate the end of meiosis and the transition from spermatocytes to round spermatids

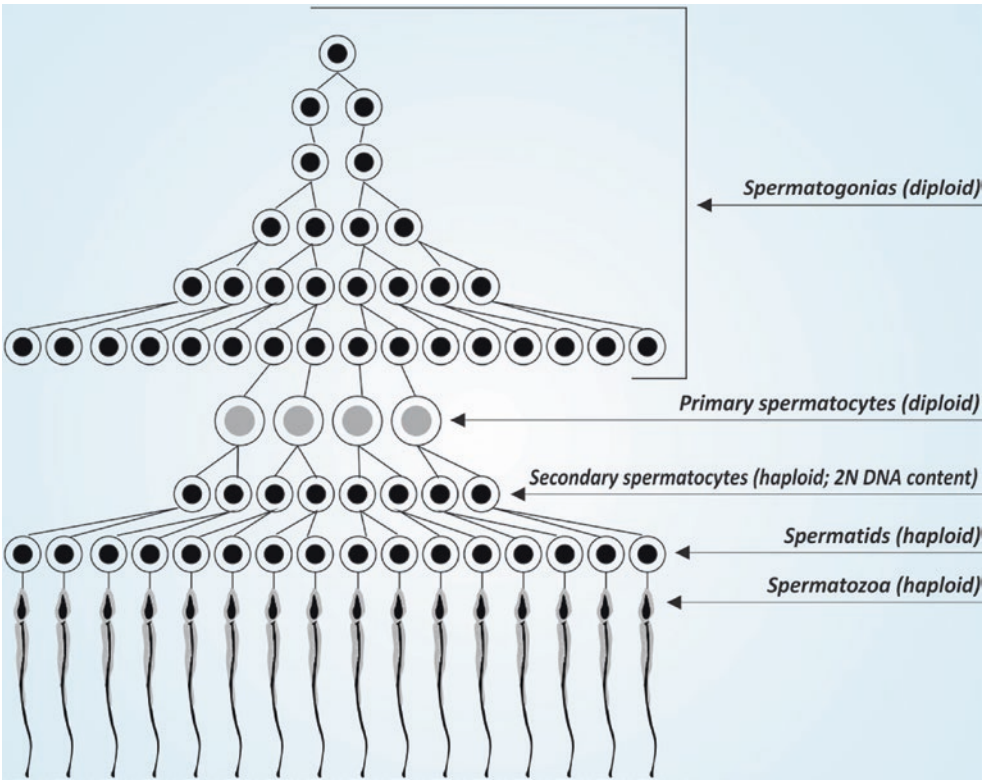

Fig. 28.2 Schematic representation of cell division stages during spermatogenesis. (Reprinted from Ref. [119] with permission from Elsevier)

[36]. The location of ARs in the epididymal tissue is of vital importance for the production of a physiological environment that allows sperm maturation. The androgenic action is mediated by aromatase, an enzyme that catalyzes the conversion of androgens to estrogens. Several growth factors and cytokines are also involved in this complex process of spermatogenesis [13, 23, 117].

28.2.7 Spermiogenesis and Spermiation

Spermiogenesis refers to the period in which the germ cell undergoes a process of metamorphosis acquiring various organelles and accessory structures, such as the acrosome and the flagellum. During this period, extensive changes occur in the cytoplasm and nucleus of spermatids [94]. The acrosome originates from the Golgi complex and consists mainly of hydrolytic enzymes, including proteases, hydroglycolases, and esterases, such as hyaluronidase, cathepsins, and acrosin [1]. These enzymes will be subsequently secreted to aid the passage of sperm through the barriers that protect the oocyte, thus aiding in fertilization. During spermiogenesis, cell volume decreases at the expense of cytoplasmic volume reduction due to the elimination of residual bodies containing Golgi complex remnants, ribosomes, mitochondria, and lipid droplets. Part of the residual bodies are phagocytosed by the Sertoli cells, and part is released into the lumen of the seminiferous tubule. The residual body should not be confused with the "cytoplasmic droplet," which consists of the excess of cytoplasm present in the mature spermatozoa and that will be released only in the lumen of the epididymis, thus maximizing sperm motility. The mitochondria migrate to the base of the future sperm mid-piece along with the microtubules derived from the centrioles, to constitute the mitochondrial sheath. The microtubules form the structure of the flagellum, which is critical for sperm motility. The accumulation of mitochondria is crucial for the energy supply necessary for flagellar movement [5, 14]. Early spermatids contain two centrioles arranged at right angles. The distal centriole that is oriented parallel to the long axis of the sperm cell originates the axial filament of the flagellum, denominated axoneme. The axoneme consists of microtubules organized in the classic 2 + 9 formations (2 central microtubules surrounded by a circular array of 9 microtubule pairs). The axoneme is formed early during spermiogenesis and can already be seen as a protrusion from the elongated spermatid [5]. The spermiation process refers to the release of germ cells into the lumen of seminiferous tubules as mature spermatozoa and removal of the last traces of cytoplasm (particles/cytoplasmic excess) [5, 14].

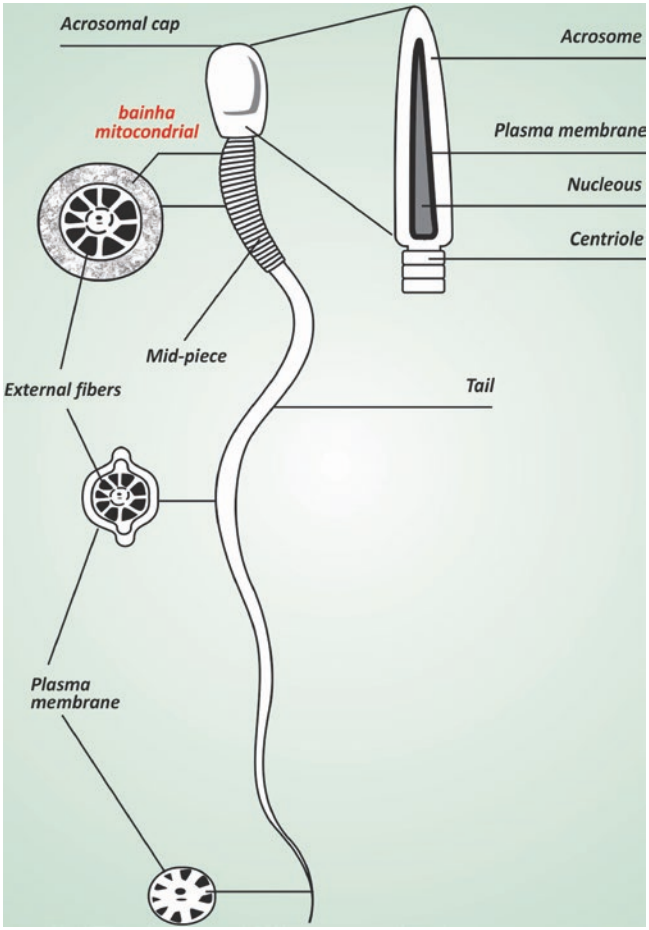

Fig. 28.3 Schematic representation of a mature human spermatozoon showing its components, the head, midpiece, and tail. (Reprinted from Ref. [119] with permission from Elsevier)

Spermatozoa are the end product of spermatogenesis. Each spermatozoon has a length of approximately 60 μm. The final structure of the spermatozoon includes three regions: head, mid-piece, and tail (flagellum). The oval head, approximately 4.5 μm long and 3 μm wide, is subdivided into an acrosome and post-acrosome region. Most of sperm head volume is occupied by the ovoid nucleus containing the highly compact chromatin. The acrosome results from the fusion of Golgi complex vesicles and contains hydrolytic enzymes necessary for sperm penetration through the outermost layers of the oocyte during the fertilization process. The mid-piece is a highly organized segment consisting of helically distributed mitochondria surrounded by dense fibers, being responsible for the supply of ATP for flagellar movement. The tail (flagellum) consists of a central axoneme, composed of microtubules surrounded by dense fibers that extend from the head to near the end region of the flagellum. The axoneme consists of 2 central microtubules surrounded by nine microtubule pairs, with the typical 9 + 2 configurations [5] (Fig. 28.3).

28.3 The Epididymis: Structure and Function

The epididymis is vital for sperm function, with the following roles, namely, maturation, transport, concentration, and storage [94]. Sperm that emerges from the testis are functionally immature. Maturation occurs during transit through the epididymis and female reproductive tract [40]. After release in the lumen of seminiferous tubules, spermatozoa, immersed in testicular fluid, migrate through the network of efferent ducts and reach the epididymis, a tubular organ composed of the head, body and tail regions [106]. The head of epididymis consists of 10–15 efferent ducts and the proximal segment of the epididymal duct. The lumen of the efferent ducts is broader and more irregular near the testis, becoming narrower and oval near the junction with the epididymal duct. The diameter increases as it advances through the other epididymal regions. Externally to the basal lamina of the efferent and epididymal ducts, there are contractile cells, which decrease in number and are replaced by smooth muscle cells in the tail of the epididymis. There are regional differences in epididymal portions concerning anatomy, innervation, vascularization of the tubules, and histology, suggesting that the epididymis is a succession of different tissues [94].

28.3.1 Sperm Maturation

As they progress through the various epididymal regions, spermatozoa undergo biochemical and molecular changes. Motility and fertilizing potential are obtained during this process, both of which increase considerably from the head to tail of the epididymis. Testicular spermatozoa are unable to fertilize the oocyte unless injected directly into its cytoplasm by intracytoplasmic sperm injection (ICSI) [106]. Sperm maturation depends on the secretory capacity of epithelial cells, which creates a unique microenvironment that induces biochemical changes in both sperm cytoplasm and membrane. These modifications enhance sperm motility, stabilize the chromatin, and allows acquisition of binding and fusion sites with the zona pellucida.

28.3.2 Sperm Transport

The transit of the spermatozoon through the epididymis takes 2–6 days. Therefore, the maturation process occurs rapidly compared to other species. Sperm transport through the epididymis relies on the hydrostatic pressure of testicular fluid and the rhythmic and spontaneous contractions of the contractile tissue surrounding the ducts [105]. After transiting through the head and body of the epididymis, the spermatozoa are stored in the tail. In humans, approximately 55–65% of epididymal sperm are found in the tail region [106]. During ejaculation, millions of sperm are expelled from the epididymis. The epididymal fluid containing sperm mix with secretions from the seminal vesicle and prostate, thus making the semen. Seminal fluid provides an adequate environment for short-term sperm survival after ejaculation [14].

28.4 Sperm Function

28.4.1 Hyperactivation

Hyperactivated spermatozoa exhibit an extremely vigorous but nonprogressive motility pattern, as a result of Ca^{2+} influx, which promotes increased flagellar curvature [70] and vigorous lateral movement of the sperm head [80]. Proteasome participates in activating calcium channels that also leads to increased membrane fluidity and permeability [58, 75, 78, 114]. These events are followed by or occur simultaneously with (i) a decrease in net surface charge, (ii) devoided area of intramembrane protein and sterols, and (iii) increased concentrations of anionic phospholipids [73, 114]. Hyperactivated motility is essential for sperm penetration into the intact oocyte-cumulus complexes both in vitro and in vivo [61, 112].

28.4.2 Capacitation

In vivo, ejaculated sperm are unable to fertilize until they undergo capacitation, which allows the acrosome reaction to take place when spermatozoa approach or contact the oocyte [46, 55, 61, 103, 111]. Capacitation is a time-dependent phenomenon, with the absolute time course being species-specific [79]. It prepares the sperm to undergo the acrosome reaction with the accompanying release of lytic enzymes and exposure of membrane receptors, which are required for sperm penetration through the zona pellucida and fusion with the oolema [79]. Sperm transport through the female genital tract can occur quite rapidly (times as short as 15–30 min have been reported in humans), whereas capacitation may take from 3 h to 24 h [79]. It is speculated; therefore, that capacitation is not completed until after the spermatozoa have entered the cumulus oophorus. This delay is physiologically beneficial because spermatozoa do not respond to acrosome reaction-inducing signals until they approach the zona pellucida, preventing premature acrosome reactions that lead ultimately to the sperm inability to penetrate the egg vestments [48, 79]. Sperm capacitation is a

post-ejaculatory modification of the sperm plasma membrane, which involves mobilization and/or removal of surface components, such as glycoproteins, decapacitation factor, acrosome-stabilizing factor, and acrosin inhibitor. Sperm capacitation involves major biochemical and biophysical changes in the membrane complex and energy metabolism. The presence of high concentrations of cholesterol in the seminal plasma, which maintains a high cholesterol concentration in sperm membranes, seems to be the most important factor for inhibiting capacitation [33]. Capacitation is associated with increased membrane fluidity caused by the removal of cholesterol from sperm plasma membrane via sterol acceptors present in the female tract secretions [66, 80].

28.4.3 Acrosome Reaction

The acrosome reaction is a stimulus-secretion coupled exocytotic event in which the acrosome fuses with the overlying plasma membrane [19, 113]. The multiple fusions between the outer acrosomal membrane and the plasma membrane result in the release of hydrolytic enzymes (mostly acrosin) and exposure of new membrane domains, both of which are essential for fertilization. The hydrolytic enzymes released from the acrosome digest the zona pellucida, allowing the spermatozoa to penetrate the oocyte [18]. The acrosome reaction (AR) seems to be physiologically induced by natural stimulants such as the follicular fluid (FF), progestin, progesterone, and hydroxyprogesterone [73]. Follicular fluid and cumulus cells have protein-bound progesterone that has been identified as one of the most important acrosome reaction-inducing agents [19, 102]. Follicular fluid stimulates the acrosome reaction in a dose-dependent manner [20, 102]. A link between locally produced estradiol by ejaculated spermatozoa, acrosome reaction and sperm capacitation has been described [12]. Moreover, evidence indicates that environmental estrogens can significantly stimulate mammalian sperm capacitation and acrosome reaction [2].

The acrosome reaction is probably initiated when ligands produced by the oocyte bind to the receptors on the spermatozoa. This signal is transduced intracellularly via second messengers, ultimately leading to exocytosis [15]. A number of second messenger pathways have been identified in human spermatozoa, including those that result in the activation of cyclic adenosine monophosphate (cAMP), cyclic guanosine monophosphate (cGMP), and phospholipid dependent protein kinases [16, 37, 38, 114]. These kinases are called, respectively, protein kinase A, protein kinase G, and protein kinase C. It is possible that these pathways interact to assure an optimal response at the correct place and time during the fertilization process. Although the concentration of cGMP in ejaculated human semen is almost seven times lower than cAMP, it is speculated that both nucleotides have a similar role in the AR since their dependent protein kinases are closely related proteins [17, 51, 89]. The AR can also be induced by artificial stimulants that cause an increase in sperm intracellular calcium [43, 114].

28.4.4 Sperm-Zona Pellucida Binding and Penetration

The spermatozoon binds to the zona pellucida (ZP) with its intact plasma membrane after penetrating into the cumulus oophorus. Sperm binding occurs via specific receptors to ZP glycoproteins located over the anterior sperm head [18]. Glycosylation of ZP glycoproteins is important in sperm–ZP interaction. It is believed that human ZP glycoprotein-3 (ZP3) has a central role in initiating the acrosome reaction [63]; however, it has been recently demonstrated that human ZP1 and ZP4 are also implicated in the process [30, 49].

Acrosome integrity is crucial for normal fertilization. A high proportion of sperm with intact acrosomes is seen in ejaculates of normal men. In such individuals, ~5–20% sperm cells may exhibit spontaneous acrosome reactions that are of no clinical significance [43]. Conversely, several abnormal conditions affecting the sperm acrosome might lead to decreased fertilization ability. Acrosomeless round-headed spermatozoa (globozoospermic spermatozoa) are unable to fertilize the oocytes, and increased percentages of morphologically abnormal acrosomes were related to fertilization failure in assisted reproductive technology (ART) using conventional in vitro fertilization (IVF) [62].

The AR is a time-dependent phenomenon that cannot take place prematurely or too late [34]. Premature acrosome reaction and the inability of the spermatozoa to release the acrosomal contents in response to proper stimuli (acrosome reaction insufficiency) have been associated with idiopathic male infertility [101]. Although the cause of premature acrosome reaction is unknown, the premature (stimulus-independent) initiation of acrosomal exocytosis seems to be related to a perturbation of the plasma membrane stability. In this situation, the acrosome reaction might not involve a premature activation of the receptor-mediated process, but rather reflect an inherent fragility of the sperm membrane, leading to a receptor-independent acrosomal loss [44]. Antisperm antibodies (ASA) can adversely affect the ability of sperm to undergo capacitation and acrosome reaction [31]. Chang et al. [26] reported reduction in fertilization rate either by IgG directly bound to sperm or IgM present in female serum. The combination of IgG and IgA may have a synergistic negative effect on fertilization [35, 60, 74, 76].

Toxic substances to sperm can also impact the AR. High concentrations of dietary phytochemicals, such as genistein,

isoflavone, and β-lapachone, were shown to suppress the AR in a dose- and time-dependent manner in the rat model [33]. Inhibition of AR by genistein seems to involve the protein kinase C pathway, while β-lapachone has a direct cytotoxic effect on sperm cell membrane. It is suggested that genistein and β-lapachone may impact male fertility via AR suppression in high doses and AR induction in low doses [65]. Calcium channel blockers may also interfere with the AR exocytotic event. Sperm incubation with different blockers, such as trifluoperazine (calmodulin inhibitor), verapamil (Ca^{2+} channel inhibitor), and nifedipine (voltage-dependent Ca^{2+} channel inhibitor), significantly reduced the ability of hamster sperm to undergo the acrosome reaction [45].

Recent publications on acrosome reaction focused on the biochemical and functional aspects of sperm-oocyte fusion. It has been demonstrated that in humans, ZP1 in addition to ZP3 and ZP4 binds to capacitated spermatozoa and induces acrosomal exocytosis [30, 49, 53, 54]. The ZP3-induced acrosome reaction involves the activation of T-type voltage-operated calcium channels (VOCCs), whereas ZP1- and ZP4-induced ARs involve both T- and L-type VOCCs. Chiu et al. reported that glycodelin-A, a glycoprotein present in the female reproductive tract sensitizes spermatozoa to the zona pellucida-induced acrosome reaction in a glycosylation-specific mechanism involving the activation of the adenylyl cyclase/PKA pathway, suppression of extracellular signal-regulated kinase activation and up-regulation of zona pellucida-induced calcium influx. It is therefore suggested that glycodelin-A might be important in vivo to ensure full responsiveness of human spermatozoa to the zona pellucida [29].

28.4.5 Chromatin Condensation/ Decondensation and DNA Integrity

During spermatogenesis, significant morphological and functional changes occur in the nucleus of germ cells. In round spermatids, the nucleus is found in a central position, but as the spermatid lengthens, it moves to a more eccentric position and undergoes a significant condensation, reaching 10% of its initial size, thus favoring sperm hydrodynamics. The sperm chromatin is a highly organized and compact structure, consisting of DNA and heterogeneous nucleoproteins [3]. At this point, the chromatin is insoluble and condensed, which is essential to protect genetic integrity during transport of the paternal genome through the male and female reproductive tracts [41]. The compact sperm chromatin also ensures that the paternal DNA is delivered into the oocyte, enabling the fusion of two genomes and development of a genetically normal embryo [96, 109].

In round spermatids, the nuclear DNA is arranged around nucleosomes composed of histones as in other somatic cells. However, in mature spermatozoa, histones are replaced by protamines, which are small proteins rich in arginine. Protamination is responsible for both condensation of the sperm DNA and resistance to denaturation [5]. The role of protamines relates to condensation of spermatic nucleus transforming it into a more compact and hydrodynamic form, protection of the genetic code, maintenance and repair of sperm DNA integrity, and genetic imprinting [85].

The human sperm nucleus contains two types of protamine, namely, protamine 1 (P1) and protamine 2 (P2), expressed in a ratio of 1:1. It has been shown that changes in expression of P1 and P2 are associated with male infertility [10, 24], and that altered levels of protamine relates to an increased susceptibility to sperm DNA damage [25]. For a spermatozoon to be fertile, it must be capable of undergoing decondensation at an appropriate time during the fertilization process [9]. Thus, in sperm with normal chromatin structure, condensation and decondensation processes are essential for sperm fertilizing ability [41].

Protamination of sperm DNA is critical as it allows a compacted paternal genome to be transported through the female genital tract. Furthermore, DNA integrity is essential for the accurate transmission of paternal genetic information. A number of in vivo and in vitro studies supports the importance of DNA integrity in fertilization, early embryo development, implantation, and pregnancy outcomes [4, 98, 99]. Abnormal spermatogenesis, varicocele, inflammatory processes, and other conditions associated with excessive oxidative stress might cause sperm DNA integrity defects, leading to functional modifications that might impact reproductive outcomes negatively, both in a natural conception or even assisted conception [86].

28.5 Assessment of Spermatogenesis Kinetics In Vivo

28.5.1 The Past

The identification of the seminiferous epithelial cycle in mammals was among the most important discoveries in the field of spermatogenesis in the past century [32, 68]. The experimental approach used animals to determine the duration of the germinative cycle. It consisted in analysing the rate of disappearance of germ cells from the seminiferous tubules after testis irradiation. When administered in proper doses, X-rays destroy a large percentage of spermatogonia, which results in a progressive loss of spermatocytes and spermatids in the seminiferous tubules. Naturally, this method could not be applied to humans.

With the advent of radioactive tracers and the development of radioautography, it became possible to perform quantitative analyses of the tubular cross-sections containing

labeled cells. The method involved radiographic analysis of sequential biopsies after the testes have been injected with tracers. Tritiated thymidine, which is selectively incorporated into the nuclei of cells preparing for mitosis or meiosis, became the label of choice and was extensively used to time the cycle.

In 1963, a human study conducted by Heller and Clemont evaluated seven vasectomy candidates who received injections of tritiated thymidine, followed by serial testicular biopsies [56]. Based on this study, it was estimated at 16 days the transition from spermatogonia to spermatocytes. The total duration of the three phases of spermatogenesis combined, namely, (1) proliferation of spermatogonia to produce diploid spermatocytes; (2) meiotic division, which originates spermatids; and (3) cytological transformation, which leads to mature spermatozoa, was estimated at 64 days. The transit time through the epididymis was estimated at 5.5 days, and this estimation derived from previous animal studies with pigs [47]. The common knowledge that spermatogenesis would take approximately 3 months to complete comes from these data, which have been used for the past five decades to guide treatment of male infertility [47].

The aforementioned studies could never be repeated in humans, due to its toxicity and invasiveness. Nevertheless, their findings have helped investigators to understand different cellular events that occur during spermatogenesis. For instance, although a clear-cut cycle of the seminiferous epithelium was difficult to describe in humans due to an apparent mixing of germ cells, the analysis of serial sections in well-fixed biopsies revealed typical cell associations into six stages. A mixing of germ cells at the interface of adjacent cell associations was present, including a frequent absence of one or more germ cell generations. Of note, the number of germ cells at the same developmental stage was relatively small and occupied restricted tubular areas [32].

28.5.2 The Present

In 2006, Misell and colleagues described a nontoxic and noninvasive method for measuring spermatogenesis in vivo. The overall mean time to detection of labeled sperm in the ejaculate was 64 ± 8 days [77]. They performed the study using a stable isotope labeled with 70% enriched heavy water (^2H_2O) and analysed DNA isotopic enrichment in ejaculated sperm by gas chromatography/mass spectrometry (GC/MS). The authors characterized the kinetics of human spermatogenesis in vivo in a group of healthy men with normal sperm production [77]. The volunteers had a daily intake of ^2H_2O for 3 weeks in order to achieve and maintain a body water enrichment of approximately 1.5%. This level of body water enrichment has been previously shown to allow adequate label incorporation for subsequent analysis of DNA synthesis [72, 83, 84]. In their experiment, a total of 11 healthy men with normal sperm concentrations ingested deuterated (heavy) water (^2H_2O) and semen samples were collected every 2 weeks for up to 90 days. Label incorporation into sperm DNA was quantified by gas chromatography/mass spectrometry, allowing the calculation of the percentage of new cells in ejaculates.

The aforementioned study was the first noninvasive direct kinematic measurement of human spermatogenesis in vivo. In contrast to the study of Heller and Clermont, in which spermatogenesis was estimated to take 64 days excluding epididymal transit time, Misell and colleagues showed that spermatogenesis duration was shorter. The authors showed that the appearance of new sperm in ejaculates of normal men occurred at a mean of 64 days, but this value included epididymal transit time.

The time to new sperm in the ejaculates varied from 42 to 76 days, as observed by Misell and colleagues, which denotes a significant interindividual variation, thus contradicting the current belief that spermatogenesis duration is fixed among individuals. While in one subject the time lag to detect greater than 33% of new sperm was 42 days, in all others it took at least 60 days. All subjects achieved greater than 70% new sperm in the ejaculate by day 90, but plateau labeling was not attained in most men, thus suggesting rapid washout of old sperm in the epididymal reservoir. Although these findings can be related to a variation in spermatogenesis per se, it could also be possible that epididymal transit time influenced the results, since a separate analysis of spermatogenesis and epididymal transit duration was not possible using their methods. Indeed, it has been speculated that epididymal transit time varies due to the rate of passage through the epididymis cauda, which is, in turn, influenced by ejaculatory frequency [8]. Furthermore, it has been suggested that men with high testicular sperm production have shorter epididymal transit time than men with lower testicular sperm output [59]. This difference might be explained by a direct association between the production of sperm and fluid, since testes that produce more sperm also produce more fluid, so the movement of spermatozoa along the epididymal duct could be more rapid.

Misell and colleagues data also suggest that in normal men sperm released from the seminiferous epithelium enter the epididymis in a coordinated manner with little mixing of old and new sperm before subsequent ejaculation. It is a novel concept since it had been suggested that because of mixing, in any segment of the epididymal duct, the population of sperm would be heterogeneous in age and biological status. Their kinetic data showed a sharp increase and a subsequent steep decrease in sperm enrichment in men with complete labeling curves, thus indicating that the sperm age is not heterogeneous. If significant mixing of young and old sperm had occurred, the slope of the labeling curve would

have been far more gradual. These kinetic data suggest that the epididymal reservoir is purged of old sperm fairly rapidly and completely in normal men.

28.6 Conclusions

Spermatogenesis is a highly organized and complex sequence of differentiation events that generates genetically distinct male gametes for fertilization. Sperm production is a continuous process, initiated at puberty and continuing throughout life, which occurs in the seminiferous tubules within an immune privileged site. Spermatozoa released from the seminiferous tubules into the epididymis undergo post-testicular maturation. Before fertilization can occur, spermatozoa must undergo further biochemical changes via capacitation and acrosome reaction, both of which occur after ejaculation. Recent knowledge that originated from a novel direct measurement of human spermatogenesis kinetics in vivo indicates that the entire sperm production process is shorter than previously believed. Moreover, there is large individual biological variability concerning the duration of spermatogenesis. Both spermatogenesis and steroidogenesis depend on the proper functioning of the hypothalamic-pituitary-gonadal axis which is regulated through the release of GnRH. Any event that affect spermatogenesis and steroidogenesis might impact sperm quantity and/or quality, with a potential adverse effect on fertility.

28.7 Review Criteria

A thorough search of medical literature was conducted with the MEDLINE, EMBASE, Science Direct, and Scielo databases until January 2019. We used relevant terms, related to "sperm physiology," "spermatogenesis," "steroidogenesis," and "sperm kinetics."

Origins of Sperm DNA Damage

29

Ralf Henkel and Kristian Leisegang

Key Points

- Male inf ertility is a major issue of concern as it affects more people during their lifetime as a common disease, diabetes mellitus.
- Among these infertile men, the prevalence of sperm DNA damage is up to 80%.
- DNA damage modifications include (i) the chemical change of bases as 8-oxo-2′-doxyguanosine (8-OHdG), (ii) a single-strand break, (iii) double-strand break, (iv) a base missing from the DNA backbone, (v) modifications in purine, pyrimidine, and deoxyribose, (vi) introduction of abasic sites, and (vii) DNA cross-linking.
- Causes of sperm DNA damage are chromatin remodeling, oxidative stress, varicocele, scrotal hyperthermia, or poor lifestyle habits.
- Medication and aging also contribute to sperm DNA damage.

29.1 Introduction

Globally, an estimate of 7% of the males at reproductive age are infertile [1], amounting to an overall contribution of about 50% of all cases of couple infertility [2]. Clinical studies show that oxidative stress is the cause of the male infertility in about 40% of unselected cases and in up to 96% in patients with spinal cord injuries [3–5]. Oxidative stress, in turn, has been widely accepted as a major cause of male infertility and sperm DNA damage [6].

Although standard semen analysis comprising of the analysis of sperm concentration, motility, viability, and normal sperm morphology is still the cornerstone of andrological diagnostics, it has been proven to be very limited in its clinical value [7, 8], as it does not detect the male germ cells' functional capabilities. Consequently, in about 20% of infertile men, abnormalities in standard sperm parameters are not detected [9] and resulting in high numbers of idiopathic infertile men [10]. Therefore, it is crucial to identify and validate reliable, evidence-based new male fertility markers with high predictive value in order to improve andrological diagnosis [11]. One of these promising tests is sperm DNA fragmentation/damage, which is, despite some debate and negative results [12–15], currently advocated as it is a more stable parameter with lower biological variability compared to sperm count or motility [16]. It appears that concise and strict guidelines are necessary in order to establish sperm DNA fragmentation/damage as a robust clinical test [17].

29.2 What Is Deoxyribonucleic Acid Damage?

While a mutation is a change in the sequence of standard base pairs, DNA damage is defined as the occurrence of an abnormal chemical structure of the DNA and causes structural changes in the DNA that prevents replication mechanisms from functioning and performing properly [18]. Sperm DNA damage is the consequence of modifications of the molecular structure of the DNA [19]. These modifications include (i) the chemical change of bases as 8-oxo-2′-doxyguanosine (8-OHdG), (ii) a single-strand break, (iii) double-strand break, (iv) a base missing from the DNA backbone, (v) modifications in purine, pyrimidine, and deoxyribose, (vi) introduction of abasic sites, and (vii) DNA

cross-linking [20, 21]. As a consequence, gene transcription can be either blocked or induced, final transduction pathways can be induced, errors in DNA replication can occur, attrition of telomeric DNA can increase, and the genome can become unstable [22–24].

There are two main types of DNA damage, namely, endogenous DNA damage caused by assaults of reactive oxygen species (ROS) and exogenous damage caused by radiation, thermal disruption, certain toxins, or mutagenic substances. These can be further classified into subgroups according to the nature of the endogenous cellular processes involved and according to the type of exogenous agent (UVA light, UVB light, ionizing radiation, etc.). The extent of natural and environmentally caused DNA damage occurring per day has been reported between 10,000 and 1,000,000 lesions per cell on a daily basis [25]. Although in spermatozoa repair mechanisms for DNA damage are highly effective, these are only functional during mitosis and meiosis before the last 3 weeks of spermatogenesis. Since the male germ cell has no repair mechanisms from this point in time, sperm are highly susceptible to DNA damage during spermiogenesis, the process in which haploid round spermatids differentiate and morphologically transform into elongated, highly polarized spermatozoa. During this process, the whole chromatin is remodeled from a voluminous toroid structure with histones as nuclear proteins to an extremely condensed and compacted chromatin organization where the negative charges of the DNA are neutralized by basic protamines to allow fitting the entire genome into the small space of about 5 × 2.5 μm of a human sperm head. Sperm with defective DNA can therefore fertilize oocytes [26, 27] and the repair of the sperm DNA damage would then be left to the ability of the oocyte to repair at least some of these damages [28]. If repair is not possible, this can lead to pregnancy failure, malformations, or early childhood cancer [29].

29.3 Spermatogenesis and Chromatin Packaging

Spermatogenesis is the process in which male germ cells are produced in the testes. This process can be divided into three steps, the proliferative, maturation, and differentiation. The latter step is also called spermiogenesis, which, in turn, is divided into four phases, Golgi phase, Cap phase, acrosome phase, and maturation phase. Spermiogenesis is a highly complex process, during which sperm DNA is undergoing major multistep changes including an exchange of histones as nuclear proteins by so-called transition proteins and finally by protamines resulting in a dramatic compaction of the male genetic material. This process is also characterized by a transform of the male germ cells from round cells into elongated ciliated spermatozoa [30].

29.4 Mechanisms of DNA Damage

There are three main theories explaining the origins of sperm DNA damage, namely, (i) reactive oxygen species (ROS) causing oxidative stress, (ii) sperm chromatin packaging, and (iii) apoptosis.

29.4.1 Reactive Oxygen Species

Reactive oxygen species (ROS) are highly reactive oxygen derivatives with half-life times in the nano- to milli-second range causing oxidative stress. Oxidative stress can be caused by endogenous and exogenous factors such as smoking, alcohol abuse, radiation, or environmental toxicants. As most important endogenous factors, male genital tract infection/inflammations, obesity, and diabetes mellitus are to be mentioned. Like any other somatic cell, spermatozoa also produce their own ROS as a result of electron leakage from the mitochondrial electron transfer chain. In cases where leakage exceeds the normal physiological levels, elevated levels of superoxide are produced which are dismutated into hydrogen peroxide leading to membrane damage through lipid peroxidation which triggers even more damage to mitochondrial membrane causing even more ROS leakage. Eventually, this will be resulting in a vicious cycle [31] with the sperm cell entering the intrinsic apoptotic pathway with externalization of phosphatidylserine as another early marker of apoptosis and eventually sperm nuclear DNA damage as a late sign of apoptosis [32].

ROS from any source, intrinsic from the sperm cells themselves or from leukocytes, initiate lipid peroxidation (LPO) of membrane lipids, not only in mitochondrial membranes but also in all other cell membranes. LPO is characterized as a radical chain reaction by which polyunsaturated fatty acids present in the membranes will be oxidized and a variety of lipid metabolites including lipid peroxyl radicals, alkoxyl radicals, malondialdehyde, 4-hydroxynonenal (4HNE), and acrolein are produced [33, 34]. 4HNE can bind to mitochondrial proteins and trigger the generation of ROS, thereby forcing the sperm cell to enter the vicious cycle of mitochondrial membrane damage and apoptosis. This process is eventually leading to oxidative DNA adduct formation, DNA strand breakage, and cell death [35]. These aldehydes are also powerful oxidants themselves that can exacerbate mitochondrial electron leakage with more production of ROS and can thereby not only cause damage to the sperm DNA but also to other sperm functions.

29.4.2 Sperm Chromatin Packaging

This transformation of the sperm nucleus with the packaging of the chromatin is a critical process to reduce the size of the nucleus from the normal somatic size to a small size of the spermatozoon. During this process, about 90–95% of the histones are eventually replaced by protamines [36]. In order to replace histones by protamines, the DNA nicks are created to provide relief of torsional stress, thereby facilitating histone disassembly and aiding chromatin rearrangements [37]. These nicks disappear completely at the time when chromatin packaging is completed [37–40]. McPherson and Longo [37] hypothesized that chromatin packaging required an endogenous nuclease, topoisomerase II, to create and ligate nicks in order to facilitate protamination [41]. In accordance with this hypothesis, it has recently been shown that topoisomerase II plays a major role in linking DNA replication to chromosome condensation and that it interplays with a large protein complex, i.e., condensation, which has key functions in mitotic chromosome assembly and organization [42, 43]. In addition, it has also been shown that topoisomerase II is present in the human seminiferous tubules [44] which are the location of spermiogenesis. This enzyme is also mainly involved in the DNA repair of elongating spermatids [45]. Furthermore, poly(ADP-ribose) polymerase inhibits topoisomerase II. This polymerase is activated as a result of DNA strand breakages [46].

The DNA remodeling that occurs during spermatogenesis is unique in that it produces a cell type in which the nucleus is transcriptionally inactive and a large part of the cell is stripped off. It is therefore not surprising that the human ejaculate normally contains a heterogenous population of spermatozoa that possess a variety of abnormalities at the nuclear, cytoskeletal, and organelle levels. In the human, it is well known that the chromatin of the mature sperm nucleus can be abnormally packaged [47]; furthermore, there is a strong relation between abnormal chromatin packaging and sperm nuclear DNA damage [48–51], and there is a strong association between the presence of nuclear DNA damage in the mature spermatozoa of men and poor semen parameters [38, 52]. This process of histone replacement is facilitated by hyper-acylation of histone tails loosens the chromatin structure causing DNA strand breaks and making the DNA more susceptible to damage [53, 54]. In turn, once this process is finished and stabilizing intra- and inter-molecular disulfide bridges in the protamine molecules are formed during the epididymal passage [55, 56], this high rate of cross-linking affords sperm DNA with a high amount of protection against assaults and compensates for missing DNA repair mechanisms in sperm [57]. Changes in the DNA repair mechanisms can have serious consequences for the genomic integrity of the male germ cells.

29.4.3 Apoptosis

The process of apoptosis is also known as programed cell death. In vertebrates, two apoptotic pathways have been proposed, namely, an intrinsic, mitochondrial pathway and an extrinsic, death receptor-mediated pathway [58, 59], triggered by Fas and other members of the TNF family activating the initiator caspase-8 to trigger executing caspase-3. In the intrinsic pathway, mitochondria are playing a major role with many stimuli involved integrating the death signals via members of the BCL-2 family and caspase activation with subsequent release of cytochrome c [60]. In mammalian sperm, however, phosphatidylinositol 3-kinase (PI3K) normally prevents the cell from entering this pathway, and sperm can only initiate the intrinsic pathway, if PI3K is inhibited. Initiation of this pathway will eventually lead to elevated mitochondrial ROS production, the cell undergoing apoptotic changes, and oxidative DNA damage [61].

Aitken and coworkers [21] pointed out that in contrast to somatic cells, spermatozoa are highly compartmentalized by their structural differentiation into head, midpiece, and tail. In addition, sperm have only one enzyme, 8-oxoguanine DNA glycosylase, for the base excision (BER) pathway available located in nucleus and mitochondria, hence shortening this pathway as compared to somatic cells. Since downstream factors such as apurinic endonuclease-1 are missing, abasic sites at the DNA that have already been affected by 8-hydroxy-2′-deoxyguanosine are formed, this is resulting in DNA strand breaks. Such DNA base changes are mutagenic and cause DNA damage [62].

29.5 Etiological Factors of DNA Damage

Apart from exogenous factors such as radiation, environmental toxins such as pesticides or other chemical exposure, there are numerous endogenous factors that can cause sperm DNA damage (Fig. 29.1). Among them are heat exposure, genital tract infections/inflammations, poor nutrition, obesity, and diabetes mellitus the most common factors.

29.5.1 Varicocele and Increased Testicular Heat

Varicocele is an abnormal tortuous enlargement of the pampiniform venous plexus in the scrotum. These veins drain blood from the testes back into the body. Considering that, together with the testicular, deferential, and cremasteric arteries, the pampiniform venous plexus forms a countercurrent mechanism that cools down the blood coming from the

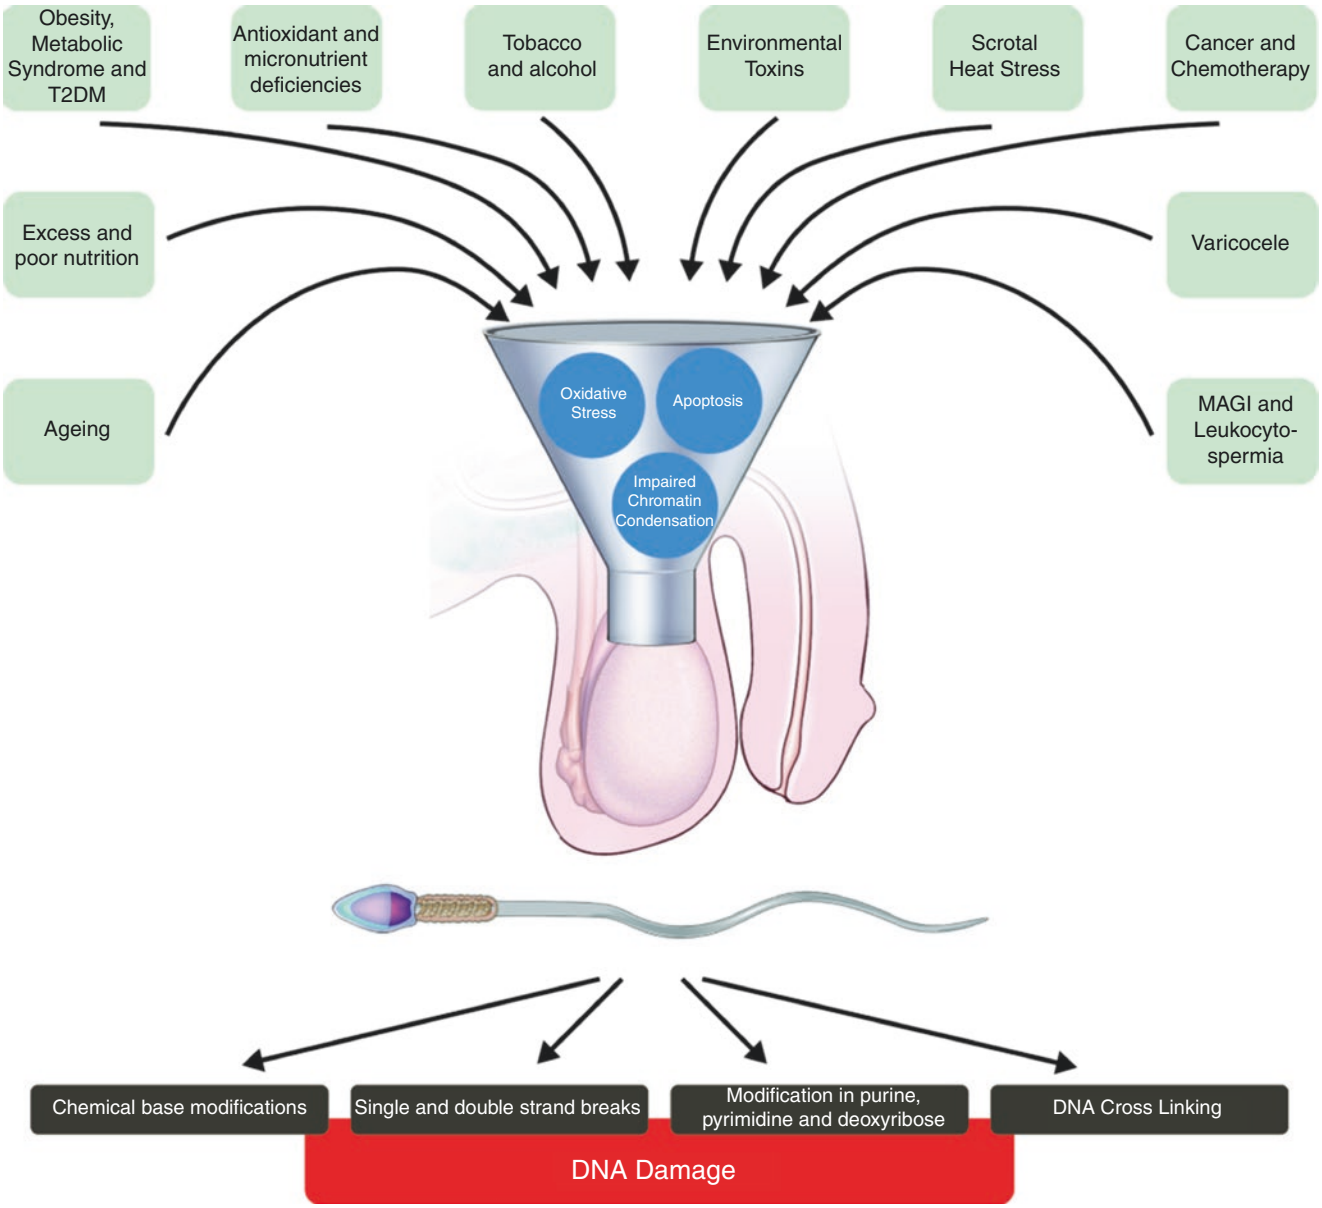

Fig. 29.1 Etiological factors of sperm DNA damage: Sperm DNA damage can be caused by numerous endogenous and exogenous factors such as aging, poor lifestyle, environmental toxins, infections, or some medical treatments. As a direct result, testicular and/or seminal oxidative stress is induced which will lead to apoptosis and impaired chromatin condensations. Apart from induction of lipid peroxidation and direct damages to proteins, oxidative stress also initiates various forms of DNA damage including base modifications, DNA strand breaks, modifications in purine and pyrimidine, as well as DNA cross-linking. aorta from body core temperature of 37 °C to about 35 °C. Globally, varicocele represents the most common cause of primary and secondary male infertility with an estimated 35–40% and up to 80%, respectively [63, 64]. Varicocele affects male fertility via several pathophysiological mechanisms as it can impair spermatogenesis significantly by elevating scrotal temperature, causing hormonal disturbances, testicular hypoperfusion, hypoxia, a reflux of toxic metabolites, or an accumulation of cadmium [65]. Heat stress causes significant increases in mitochondrial, cytoplasmic, and plasma membrane ROS production [66, 67].

The most often discussed pathophysiological mechanisms of varicocele are oxidative stress and testicular heat stress, and oxidative stress seems to be associated with all mentioned pathophysiological mechanisms [65, 68]. Although the presence of elevated seminal ROS levels is quite common with a reported prevalence between 25% and 40% in unselected cases of male infertility [3, 4] and up to 96% in patients with

spinal cord injuries [5], varicocele exacerbates high ROS levels and oxidative stress [69]. The latter association is closely related to the size of the varicocele with higher levels of oxidative stress in patients with larger varicocele and is evident not only by increased levels of ROS but also by increased levels of markers of sperm DNA damage [70–72].

Scrotal hyperthermia, caused by either varicocele or other sources of heat stress, such as hot bathes, welding, sedentary positions, or tight underwear, is negatively affecting Leydig cell and Sertoli cell function with significantly lower intratesticular testosterone concentrations and lower androgen-binding protein activity, respectively, in animals with varicocele and therefore higher testicular temperature [73, 74]. In contrast to Leydig and Sertoli cells and spermatogonia A, spermatogonia B, pachytene spermatocytes, and early spermatids are considered even more thermosensitive as these cells have not been exposed to higher temperatures in the uterus [75, 76]. Thus, scrotal heat stress is affecting the whole process of spermatogenesis leading eventually to high levels of sperm DNA damage [77]. Scrotal cooling as a therapeutic option has been shown to improve sperm motility and morphology [78].

29.5.2 Genital Tract Infection and Inflammation

According to Nieschlag [79], male genital tract infections and inflammations are the third single most common cause of male infertility, following idiopathic male infertility and varicocele. Other authors indicate a prevalence ranging from 6% to 15% in andrological outpatient clinics [80] or even up to 30.1% [81]. Considering that infections are mostly caused by bacteria, the infection itself is potentially treatable with antibiotics and the inflammation with anti-inflammatories to relieve obstruction of the excurrent genital ducts as a consequence of the infection [82]. A problem with which clinicians are confronted is that male genital tract infections are often asymptomatic [83, 84]. In addition, men do not readily consult a doctor. Hence, the diagnosis and treatment are often coming late.

Urogenital infections trigger leukocyte infiltration of the infected organ with a subsequent release of high amounts of ROS and pro-inflammatory cytokines such as IL-6, IL-8, or tumor necrosis factor alpha [85, 86]. In turn, these cytokines directly and indirectly exert their detrimental effects on sperm functions and sperm DNA integrity through oxidative stress and lipid peroxidation [87–89].

29.5.3 Poor Nutritional Intake

Poor nutritional intake affects the quality of semen through spermatogenesis [90–92]. Food beneficial for male fertility includes increased antioxidant fruits and vegetables, seafood (especially omega 3 polyunsaturated fatty acids), whole grains, nuts, seeds, vegetable oils, and micronutrients (e.g., β-carotenes, folate, vitamin C, vitamin E, selenium, and zinc) [91, 92]. This can be achieved through adherence to the Mediterranean or similar "prudent" diets, which improve fertility parameters in men across a BMI range [93–95]. Modern Western obesogenic diets have been correlated with poor semen quality and reproductive outcomes in males. This is represented by high-energy and nutrient-poor food and drinks, including increased refined sugars, trans-fatty acids, red meat, processed foods, soy and alcohol, and reduced fiber, fruits, vegetables, polyunsaturated fatty acids, micronutrients, and antioxidants [90]. These nutritional exposures lead to OS and increased spermatozoa DNA fragmentation index compared to males with favorable diets. Epigenetic modification is further demonstrated in spermatozoa and transferred to the offspring, although causality is not demonstrated [96–98] increasing transgenerational disease risk, including metabolic disorders and cancer [98]. Animal models demonstrate that high-fat diets, low-protein diets, reduced folate, and exposure to pesticides and herbicides cause DNA damage, are mutagenic, and modulate DNA methylation, chromatin remodeling and small coding RNA functions [97].

Excess macronutrient intake, including fats, carbohydrates, and proteins, contribute to systemic ROS. Increased energy consumption increases OS further through increased NADPH oxidase activation and reduced endogenous antioxidant defenses [99, 100]. This results in inefficient germ cell metabolism and impaired spermatogenesis with impaired mitochondrial function and DNA integrity [101, 102].

Westernized overnutrition of energy dense foods conversely lead to micronutrient deficiencies that increase reproductive tract OS and have a detrimental effect on sperm, including DNA fragmentation [103]. Many important nutrients for spermatogenesis and genomic stability include carotenoids, vitamin C, folate, vitamin E, zinc, selenium, copper, glutathione, α-lipoic acid, N-acetylcysteine, and coenzyme Q10 [104]. These can be acquired through adequate nutritional sources or over-the-counter supplements, which are associated with improved semen quality [96]. Particularly, vitamins A, C, and E have been found to improve DNA stability in spermatozoa [105, 106]. Conversely, over-supplementation with carotenoids and ascorbic acid can result in DNA damage and DNA adduct formation [107]. Uncontrolled over-supplementation with antioxidants may result in reductive stress which is regarded as dangerous as oxidative stress [108]. Furthermore, excessive antioxidants may result in the antioxidant paradox, inhibiting redox-regulated functions such as chromatin condensation, acrosome reaction, capacitation, and oocyte binding [109].

Macronutrient undernutrition also remains a significant public health concern, and underweight males are associated

with subfertility and poor semen parameters [110]. Chronic undernutrition and protein energy malnutrition (PEM) cause increased OS in the reproductive tract [111] and also negatively affect embryonic development causing poor testicular structure and infertility as an adult [112]. Within this context, appropriate caloric restriction that does not result in micronutrient deficiency (MND) reduces systemic OS and chronic disease risk and increases the life span [113]. This is in part mediated by increasing DNA repair mechanisms reducing inflammation and OS markers. This has a positive effect on DNA integrity, reducing cellular apoptosis [113]. However, the impact on male reproduction of appropriate dietary restriction (DR) is not yet elicited [114, 115].

29.5.4 Obesity and Metabolic Syndrome

Obesity is described as an excess accumulation of visceral adiposity, and clinically defined by a body mass index (BMI) > 30 [116]. Increasing BMI is associated with increased morbidity and mortality through numerous metabolic, endocrine, and immune mechanisms [116]. Metabolic syndrome (MetS) further describes a clustering of five obesity phenotypic comorbidities: increased waist circumference, hypertension, increased triglycerides and glucose, and/or reduced HDL-cholesterol. Any three of these five parameters diagnostically define MetS [117]. Both obesity and Mets have significantly increased in recent decades, alongside an increasing obesogenic environment and concurrent decline in semen parameters [116, 118]. Well-described complications of obesity and MetS include cardiovascular disease (CVD), type 2 diabetes mellitus (T2DM), neurodegeneration, malignancies (including colorectal and prostate), nonalcoholic fatty liver disease, and obstructive sleep apnea [116, 117]. Furthermore, in males, hypogonadism, erectile dysfunction, and poor semen quality have been reported [119].

The pathophysiology and comorbidities are due to underlying mechanisms including chronic systemic inflammation, OS, hyperinsulinemia, adipose tissue dysfunction and altered adipokine secretion, and hyperestrogenemia and hypogonadotropic hypogonadism. Testicular inflammation and ROS have been demonstrated to impair testicular spermatogenesis and steroidogenesis and epididymal sperm maturation and cause DNA fragmentation. This is further transmitted to the offspring through epigenetic modification, although this is variable [118, 120]. Furthermore, impaired fertility in males has emerged as a predictor of metabolic comorbidities commonly mediated by OS, inflammation, and hypogonadism [121].

Obesity is correlated with sperm parameter defects, including damaged DNA in spermatozoa [120]. Within this context, animal and human studies directly associate increased adiposity with reproductive tract OS and resulting alterations in sperm DNA. Altered OS genes in testicular tissues include antioxidant defenses such as superoxide dismutase (SOD), glutathione peroxidase (GPx), catalase, and Nrf2 [122–124]. Increased paternal adiposity therefore has negative impact on DNA integrity alongside epigenetic modulation [116]. Studies consistently report an association with excess adiposity and DNA damage in numerous tissues, including hypothalamus, skeletal muscle, liver, pancreas, prostate, and testes [116, 125]. Adiposity-induced sperm DNA damage and epigenetic modification increase risk for reduced live birth rates and ART success, recurrent pregnancy loss, impairments in embryo development, and health effects on the offspring [116]. Obesity alters the environment for spermatogenesis, resulting in poor sperm quality, altered membrane lipids, and DNA fragmentation mediated particularly through OS and inflammation [120]. Similarly, MetS patients have increased DNA fragmentation in sperm, demonstrated in animal and human studies [119, 126–129]. However, the overall understanding of the impact and mechanism of obesity on DNA damage remains relatively poor.

Epigenetic programming resets methylation marks in DNA, regulating monoallelic gene expressions and establishing paternal-specific methylation in normal development. Sperm DNA methylation and noncoding RNA modification are proposed to transfer metabolic and health derangements to the fetus and offspring through paternal obesity, which is emerging as a further public health concern [120, 130, 131]. Sperm genes that have been identified to undergo inappropriate differentially methylated regions in paternal obesity include MEG3, NDN, SNRPN, and SGCE/PEG10. These are involved in embryonic and fetal development and tumor growth [130]. Current evidence further suggests that weight loss prior to fertilization may prevent some of the negative effects of obesity and MetS on the offspring [116]. However, the quality of human studies is generally low, with numerous confounding factors relevant to environment, nutrition, and lifestyle that require further investigation [132].

29.5.5 Diabetes Mellitus

Diabetes mellitus (DM) describes chronic hyperglycemia due to insulin dysregulation, resulting in impaired carbohydrate, protein, and fat metabolism among numerous other dysfunctions [133]. Type 1 (T1DM) is characterized by hypoinsulinemia due to a chronic autoimmune response in β-cells of the pancreas [134]. Type 2 (T2DM) is characterized by chronic hyperinsulinemia due to unfavorable lifestyle factors and environmental exposures related to obesity and metabolic syndrome [117].

There is a significant increase in DM in recent years, particularly T2DM, including younger men of reproductive age

and an alarming increase in adolescents and even children [135]. As glucose and insulin are important in spermatogenesis and steroidogenesis, DM negatively affects reproductive and sexual functions and is an established cause of reduced semen parameters (particularly sperm concentration, motility, normal morphology), DNA fragmentation, acrosome reaction, and increased apoptosis in humans and animals [136]. DM causes a negative alteration in spermatogenesis and testicular tissue structure on histology, particularly in the epididymis [137, 138]. T1DM more specifically reduced ejaculate volume due to epididymal voiding and reduced motility due to mitochondrial damage. T2DM is associated with inflammation and ROS generation, negatively affecting motility and DNA fragmentation [137]. Mechanisms of DM-induced testicular dysfunction include endocrinopathy, inflammation, glycation, neuropathy, and OS [138].

Evidence strongly demonstrates significant DNA damage in DM, including genomic and mitochondrial DNA, mediated by increased OS [136–140]. Importantly, DM also results in epigenetic modification during spermatogenesis, and these are inherited by the offspring [136]. T2DM has been more strongly associated with OS-induced sperm DNA damage, complicated by metabolic comorbidities. This increases testicular ROS generation and reduces endogenous and exogenous antioxidants, alongside increased enzymatic glycation end products, sperm lipid peroxidation, mitochondrial dysfunction, and DNA fragmentation [137]. In T2DM, OS has been suggested to impair male fertility, targeted potentially at the epididymis, resulting in greater percentage of spermatozoa with impaired MMP, DNA fragmentation, and in late apoptosis [137]. Epigenetic modification through impaired DNA methylation and histone modifications has also been demonstrated with significant impact on embryo development and offspring health [136]. Importantly, significant investigation into the mechanisms and potential novel therapeutic targets are required in clinical and preclinical studies.

29.5.6 Alcohol and Tobacco

Tobacco continues to be socially acceptable, affecting up to 30% of males globally [141]. Although the negative effects of these practices are well defined, the negative impact on reproduction is generally underappreciated [142]. It is difficult to do experimental studies in humans due to ethical considerations, and therefore this evidence relies on observation data, retrospective data, and preclinical studies [142]. Exposure to numerous chemicals through tobacco consumption clearly reduces male fertility parameters from available literature [143–146], up to 22% decline in standard semen parameters compared to nonsmokers [141]. These mechanisms are unclear and involve ROS, mitochondrial, and chromatin damage, inhibition of acrosome reaction and capacitation, spermatozoa morphological alterations, and smoking-induced hypoxia [142, 147, 148]. Tobacco is established to cause DNA damage in numerous tissues, including spermatozoa DNA and chromatin condensation alongside aberrant DNA methylation [148–153]. This appears to be strongly mediated through increased ROS and reduced endogenous antioxidants [148].

Chronic and heavy alcohol consumption is known to impair spermatogenesis, negatively affect semen parameters and reduce testosterone synthesis through reduction in testicular size and Leydig cell numbers [154–157]. As with tobacco smoking, heavy alcohol use also appears to increase seminal leukocyte concentration, potentially mediating poor fertility [158]. However, the effect of moderate alcohol consumption on male reproduction appears minimal, with only ejaculate volume seemingly affected, and acute alcohol intake appears to have minimal impact compared to chronic consumption [156, 159, 160]. In fact, some studies suggest an improvement in reproductive parameters and even ART outcomes with moderate consumption [160]. Semen parameters appear to be negatively affected above 20 or 25 units per week [161–163]. Several studies have indicated that the alcohol may induce spermatozoa DNA damage and apoptosis indices associated apoptosis in spermatozoa and Leydig cells [148, 163–166]. This is mediated through increased ROS and reduced endogenous antioxidant mechanisms [148]. However, these findings have not been consistent [167, 168]. Ethanol-induced DNA damage appears to upregulate Fas system, alongside increased p53 and caspase activation, cytochrome c translocation, and apoptosis in germ cells [164, 169]. Furthermore, ethanol exposure induces epigenetic changes that are transferred to the next generation, including inheritance of alcohol-related pathology [170]. The role of paternal alcohol exposure is emerging as an important factor in the risk and development of alcohol-related growth defects in the fetus, mediated through alterations in sperm DNA methylation profile [171].

29.5.7 Cancer and Chemotherapy

Incidence of testicular cancers are increasing in young men, necessitating chemotherapy and radiotherapy [172]. Chemotherapy treatment has been well established in germ cell testicular carcinoma and lymphoma, where chemotherapy (e.g., coadministration of bleomycin, etoposide, and *cis*-platinum) significantly improves 5-year survival rates above 90% [173, 174]. Patients with testicular cancer and lymphoma, prior to onset of chemotherapy, have been shown to have reduced sperm DNA integrity and compaction, even in the setting of and normospermic standard semen analysis [172, 175–177]. Interestingly, male infertility is a risk factor

for cancer, particularly testicular germ cell cancer, prostate cancer, lymphoma, and melanoma. Although poorly understood, it is hypothesized that common mediators include testicular dysgenesis syndrome, chromosomal abnormalities (including Y chromosome abnormalities), and reduced DNA integrity through damaged DNA repair mechanisms [178].

The current chemotherapy treatment further negatively affects testicular function, reduces spermatogenesis, and damages spermatozoa chromatin integrity [173, 174, 177, 179]. This is influenced by dose and type of chemotherapy [180]. Furthermore, damage to DNA integrity and compaction following chemotherapy in cancer survivors persists for up to 24 months in patient survivors, with additional damage to seminal parameters during and post-treatment [174, 179]. Importantly, adolescent chemotherapy has been suggested to permanently reprogram the spermatogenic stem cell epigenome, with the potential to transfer this epigenetic inheritance to the offspring [181].

Alongside chemotherapy, radiation treatment in cancer causes DNA damage in spermatozoa, for 2 years following treatment. Combination treatment is more genotoxic than either alone [182]. This necessitates the need for appropriate reproductive and fertility counseling on the effects of cancer and chemotherapy, including cryopreservation advice based on DNA integrity assessments in cancer patients undergoing chemotherapy [175, 177, 179].

29.5.8 Pollution and Environmental Toxins

Air pollution has significantly increased in recent decades, particularly in urban and industrialized regions, increasing disease risks. Although associated with poor semen quality, any association with male reproductive system and infertility remains relatively unclear [183, 184]. Current evidence demonstrates a negative effect of air pollution exposure on sperm morphology defects, with less evidence relevant to sperm concentration, motility, and DNA fragmentation [184]. The latter has been demonstrated in only a handful of studies where air pollution was associated as a significant cause of spermatozoa DNA fragmentation [185–187], with other studies showing no association [188–190]. Polycyclic aromatic hydrocarbons (PAH) particularly, through air or nutritional sources, are increasingly known to damage DNA through the production of PAH-DNA adducts [191]. This includes chronic exposure to environmental air pollutants particle matter (nitrates, sulfates, ammonium, carbon metals, and organic material suspended as liquid drops in the air), nitric oxide (NO), carbon monoxide (CO), carbon dioxide (CO_2), and ozone (O_3) alongside increased blood, urine, and seminal plasma markers for exposure including polycyclic aromatic hydrocarbons (PAH), nitrogen dioxide (NO_2), lead (Pd), and cadmium (Cd) [183]. Pollution exposure is also reported to induce polymorphisms in spermatozoa DNA, including XRCC1, which further mediates adverse effects on PAH-DNA adducts [192]. However, the evidence remains weak in this regard and any potential mechanisms and causal relationships are poorly investigated [183].

29.5.9 Medications and Recreational Drugs

Numerous medications are associated with a negative impact on the male reproductive system. Drugs that have a good body of evidence for male infertility include testosterone, antiandrogenic drugs, sulfasalazine, anabolic steroids, cyproterone acetate, opioids, tramadol, GhRH analogues, and sartan. Drugs with known negative impact on DNA integrity include sulfasalazine azathioprine, mycophenolate mofetil, and methotrexate [193]. Antidepressant medication negatively affects sperm parameters, including sperm concentration, motility, and morphology [194, 195]. Selective serotonin reuptake inhibitors (SSRI) medication may have negative effects on DNA integrity mediated through OS [196–198]. Methylenedioxymethamphetamine (MDMA), ecstasy, and opioid use are associated with increased OS in the ejaculate and sperm DNA damage [197, 199]. However, the evidence is very weak currently for most medications and DNA integrity.

29.5.10 Aging

Aging is associated with a gradual decline in various biological tissue structure and function alongside a declining quality of life [200]. Importantly, aging is an independent risk factor for obesity, CVD, T2DM, neurodegeneration, and common malignancies (including breast, colon, and prostate carcinoma) [200]. This is strongly mediated by a gradual age-related shift toward OS, particularly through declining endogenous antioxidants [201]. In fact, OS remains a leading theory in the mechanism of aging and age-related pathophysiology [128, 202]. Male reproductive function gradually declines with age. This includes hypogonadism, erectile dysfunction, and testicular dysfunction, alongside increased risk for chronic prostatitis, benign prostatic hyperplasia, and prostate cancer [203].

There is a decline in quantity and quality of sperm produced in aging men, although generally men continue to produce spermatozoa throughout their life span [204]. Elderly men have reduced germ cell quality and quantity than younger men [205]. Aging increases DNA damage through OS in germ cells [205]. Again, young men typically have improved percentage of sperm with intact DNA and chromatin quality compared to older men [206]. An increase in abnormal gametes with DNA damage is apparent, particularly due to reduced ability to repair DNA damage, further generating ROS. This accelerates apoptosis rates through

OS-induced caspase activation and germ cell apoptosis alongside declining spermatogenesis and sperm DNA integrity [207, 208]. Increased paternal age has demonstrated increased DNA fragmentation and single-gene mutations in sperm [209]. This is mediated through variations in single nucleotides that arise from DNA replication errors through ROS. Additional risks include environmental toxin exposure, endocrine, and immune changes, aging, and genetic abnormalities in germ cell lines [210].

In addition to increased risk of pregnancy complications, evidence demonstrates increased disease susceptibility in the offspring of aging males [211–213]. Increased paternal age has been associated with epigenetic transfer to the offspring, increasing risk of congenital defects, cancers (e.g., lymphoma, prostate), and neuropsychiatric disorders including autism, bipolar disorder, and schizophrenia [209]. This is transferred through accumulation of increased rates of DNA mutations through spermatogenesis [209, 212, 214]. Age-related DNA methylation of spermatozoa is apparent in more than 100 genes currently, including genes associated with risk for neuropsychiatric disorders [212, 215]. In fact, DNA methylation describes clear patterns in the sperm epigenome that can be used as a reliable predictive marker of the paternal age of the donor [211]. However, causal relationships have not been found. With increased life expectancy and many couples opting for parenting at older ages, the impact and mechanisms of aging on male reproduction and infertility require further attention and clinical consideration in management of older males wanting to conceive [211, 216].

29.6 Conclusion

Sperm DNA damage has been recognized as a major molecular reason for male infertility and has also been identified as a more stable and therefore more reliable diagnostic parameter than standard semen analysis. In recent years, it became evident that, apart from genital tract infections and inflammations, certain poor lifestyle behaviors and aging lead to an excessive production of reactive oxygen species and thereby oxidative stress. Due to the high reactive potential of the oxidants driving these processes, the sperm nuclear material can be significantly damaged which can not only lead to fertilization or pregnancy failure but also to more serious problems for the offspring as early childhood cancer was reported as a result of sperm DNA damage. These issues do not only include the direct or indirect damage to the DNA through oxidative assaults but also epigenetic changes which in turn can contribute to and exacerbate the problem. Although recent reports brought more light into the etiology of sperm DNA damage and its molecular mechanisms, more work has to be done to fully understand its implications and more importantly the pathophysiology in order to develop rational treatment option for these patients.

29.7 Review Criteria

An extensive search of studies examining the impact of infections on male fertility was performed using search engines such as Google Scholar and PubMed. The searches were not limited for time. Yet, the most recent records were preferred. The overall strategy for study identification and data extraction was based on the following keywords: “sperm DNA damage,” “oxidative stress,” “varicocele,” “male infertility,” “obesity,” “environmental factors,” “lifestyle,” and “sperm DNA fragmentation.” Articles published in languages other than English were not considered. While books were included in the search, data that were solely published in conference or meeting proceedings or websites were not included. Websites and book chapter citations provide conceptual content only.

Seminal Oxidation-Reduction Potential

30

Mohit Rana and Ashok Agarwal

Key Points

- Oxidative stress (OS) has extensive implication on male infertility due to its ability to induce lipid peroxidation of the spermatozoa's membrane.
- Previous methodologies have been developed to assess how reactive oxygen species affect sperm directly or indirectly by decreasing total antioxidant capacity (TAC). However, these methods are time-consuming and technically demanding and require expensive instruments. Nitroblue tetrazolium (NBT) was an assay to avoid these pitfalls, but the uncertainty of what causes it to indicate OS calls into question its diagnostic accuracy.
- The MiOXSYS system was developed to allow an easy determination of oxidation-reduction potential without requiring an expensive instrument and laborious methodologies.
- Preliminary tests validated the MiOXSYS system's sensitivity to OS, its reliability, and reproducibility.
- The most accurate way to determine an oxidation-reduction potential cutoff is to assess semen with abnormality versus semen without abnormality. Several investigations have led to the refinement of the current cutoff of 1.34 mV/10^6 sperm/mL.
- Global studies on this cutoff value show a deviation cutoff ORP, suggests further investigations into how ORP and OS changes reflect ethnic-specific pathology.

30.1 Introduction

Currently, male infertility is assessed globally by performing a routine semen analysis, which is the cornerstone of andrology. However, it has received criticism in its ability to assess male infertility [1]. The controversies surrounding basic semen analysis stem from three discrepancies. The first is the failure of the World Health Organization (WHO) fifth edition semen analysis results to predict male fertility [2–5]. The second is the lack of inclusion of Middle East, Latin American, Asian, and African countries in the formation of the WHO fifth edition guidelines [6]. The exclusion of Northern and sub-Saharan African countries is particularly negligent as these countries have the highest global prevalence of infertility [7]. The third is the failure to assess the functional health of the sperm as semen analysis does not necessarily reflect the sperm's ability to fertilize the oocyte [5, 8].

Male fertility functional tests can provide a variety of information regarding the health of the sperm. Acrosome reaction testing can indicate if spermatozoa are able to undergo the necessary acrosome reaction to fertilize the oocyte [9]. Once sperm have prematurely undergone acrosome reaction, they cannot fertilize the oocyte, which indicates a pathological process in the semen [10–12]. Zona sperm penetration assay assesses if spermatozoa are capable of penetrating the zona pellucida membrane of the oocyte [13]. Inability of the spermatozoa to penetrate the zona pellucida indicates a pathological process either in capacitation, acrosome reaction, or zona pellucida binding/penetration [13, 14]. As reactive oxygen species (ROS) initiates acrosome reaction and facilitates zone pellucida penetration, an overproduction of ROS could cause premature initiation of either process and facilitate infertility, and subsequent functional tests could determine the etiology of infertility [9, 15, 16]. However, with the advent of intracellular sperm injection (ICSI), both functional tests provide little clinically useful information as ICSI is the resolution to both aforementioned pathologies [8]. Since ICSI bypasses

all biological barriers preventing sperm, an emphasis has been placed on sperm DNA fragmentation (SDF) as one of the last sperm factors that can influence fertilization success. One pathology which directly increases SDF is oxidative stress (OS).

30.2 Oxidative Stress

OS is the condition when ROS overwhelms spermatic antioxidants [17–20]. Sperm production of ROS was first investigated in 1943 when sperm incubated in high oxygen concentrations had improved motility with the addition of catalase [21]. While elevated ROS production decreases sperm viability, a small amount of ROS is needed to induce physiological processes of capacitation and acrosome reaction [22–24]. Therefore, ROS have both a beneficial and detrimental role in sperm function (Fig. 30.1).

Reactive oxygen species traditionally are free radical oxygen molecules with an unpaired electron but can also act as powerful oxidizers [25]. Hydrogen peroxide is an example of a powerful oxidizer and is significant in male infertility as it is more stable than other forms of ROS [26]. Free radical ROS are subdivided into categories based on the oxygen functional group that contains the radical [22, 23]. More clinically relevant subtypes of free radicals with regard to male infertility are peroxyl (ROO^-), hydroxyl (OH), and superoxide ($\cdot O_2^-$) [27, 28]. While ROS technically only have oxygen as the reactive atom, it has become an umbrella term to include other nonoxygen-based radicals too. Reactive nitrogen species (RNS) are involved in OS [29]. RNS subdivided into groups based on the functional nitrogen group

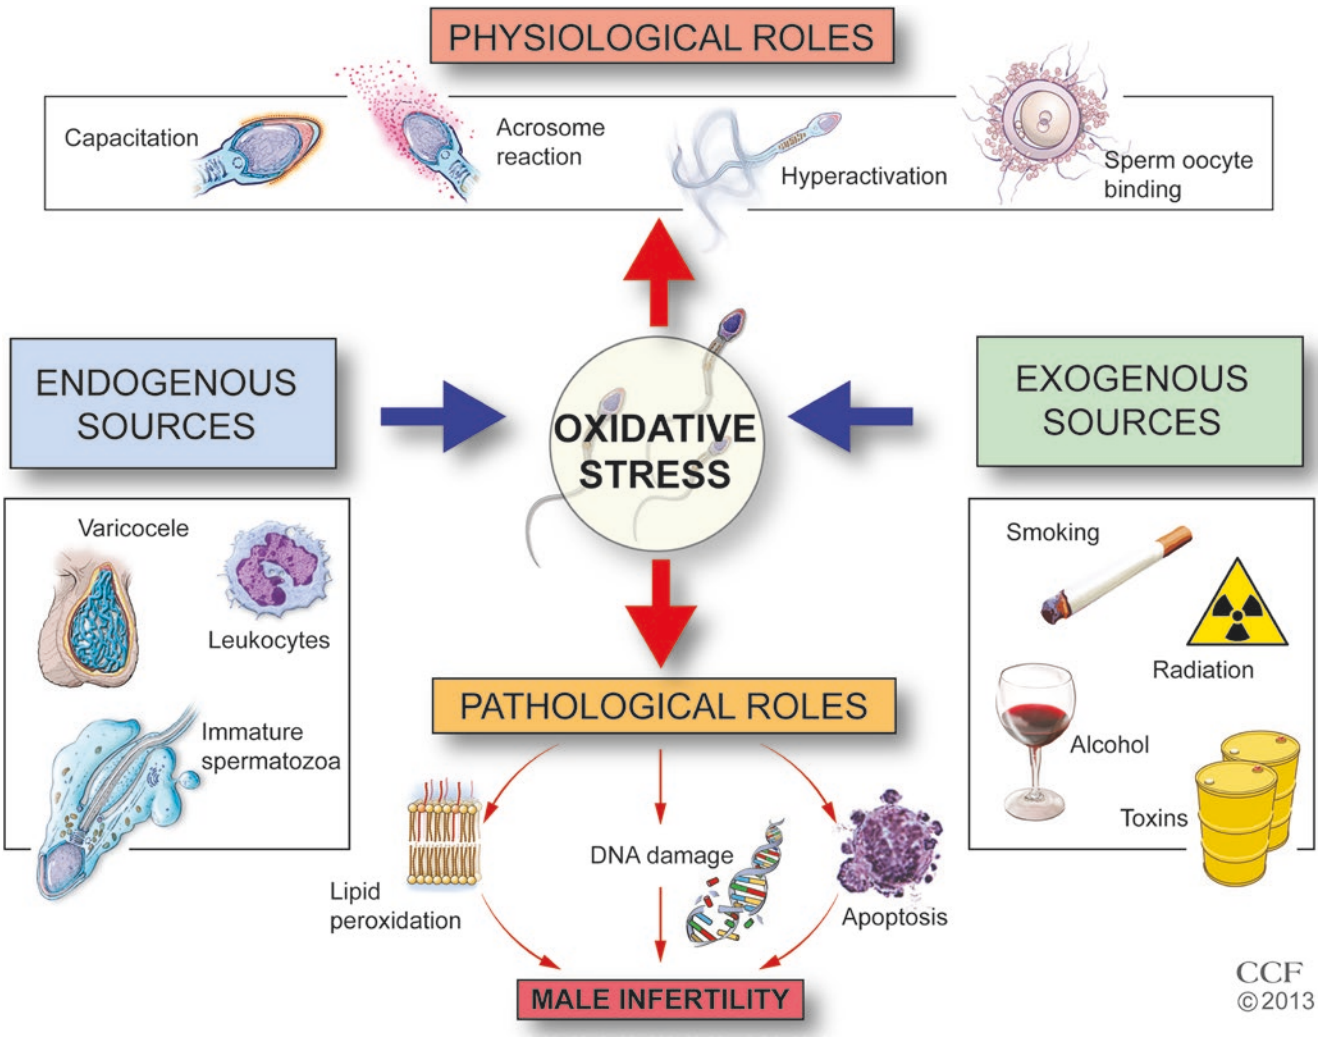

Fig. 30.1 An overview of how reactive oxygen species are involved in physiological processes, such as capacitation and acrosome reaction. When ROS, from either endogenous or exogenous etiologies, are overabundant, pathological processes develop, thus leading to male infertility. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2013–2018. All Rights Reserved)

attached to the radical, too [22]. Clinically relevant RNS are nitric oxide (NO) which, in reaction to superoxide, produces peroxynitrite ($ONOO^-$) [28, 29, 30].

Elevated reactive oxygen species are present in 20–80% of all male infertility patients [31], and antioxidant concentrations are depleted compared to fertile men [17, 18]. Sources of ROS can be either exogenous or endogenous to the spermatozoa. Endogenous sources of ROS are varicocele, diabetes mellitus type 2, metabolic syndrome, infection, immature spermatozoa, and elevated body temperature [26, 32–35]. Exogenous sources of ROS are alcohol abuse, drug abuse, mobile phone use, radiation, heavy metal exposure, prolonged exposure to high temperatures, and semen processing [36–40].

Spermatozoa can metabolically form superoxide, hydroxyl, and nitric oxide radicals [41]. In fertile men, metabolic ROS production is sequestered by enzymatic and low molecular antioxidants [42]. However, in idiopathic infertility, OS causes depletion of antioxidants and allows propagation of ROS-mediated damage [43, 44]. As spermiogenesis removes excess cytoplasm, deregulation of this process produces immature spermatozoa which retain an abundance of cytoplasm [17, 45]. The cytoplasm contains NADPH oxidase which continually produces ROS [46]. Leukocytospermia is a condition where leukocytes, particularly granulocytes, are excessively present ($>1 \times 10^6$/mL) in semen, which results in significant increase in ROS production [47, 48]. Leukocytes are particularly destructive as they produce up to 100 times the ROS compared to that of immature spermatozoa [49]. Sperm are susceptible to ROS-mediated damage by a variety of pathways. The first is the composition of the sperm plasma membrane primarily being comprised of polyunsaturated fatty acids which undergo electrophilic reactions with ROS, thus resulting in lipid peroxidation [18, 50–52]. Reactive oxygen species can destabilize the mitochondrial membrane potential which results in increased ROS production and depletion of adenosine triphosphate [53–56]. The most significant effect of ROS-mediated infertility is the increase in sperm DNA damage. In the presence of ROS, spermatic DNA forms base adducts which results in single-strand DNA breaks as spermatozoa lack the enzymes to repair a basic site (Fig. 30.2 [57–59]). High levels of SDF results in the failure of sperm to fertilize the oocyte in natural conception and assisted reproductive techniques [60–63]. Therefore, assays to determine ROS levels and their effects on antioxidant concentrations have been developed to understand and diagnose ROS-mediated infertility.

Assays to determine ROS in infertile men are evaluated by chemiluminescence, total antioxidant capacity (TAC), and, more recently, nitroblue tetrazolium (NBT) [31, 64–69]. Each methodology showed different pathologies with male infertility and presented with their own advantages and disadvantages (reviewed in Table 30.1). Chemiluminescence utilizes luminol as an ROS probe to determine concentrations of ROS either intracellular or extracellular to spermatozoa [70]. Elevated ROS results in lipid peroxidation of the sperm membrane, acrosome-reacted sperm, axoneme damage, and DNA damage [18, 50, 57, 71, 72]. TAC assays determine how well a semen sample can suppress the effects of ROS. Assays for the measurement of TAC utilize a source of ROS propagation and a probe which is sensitive to ROS-induced photon emission. The probe utilized can be either chemiluminescent, such

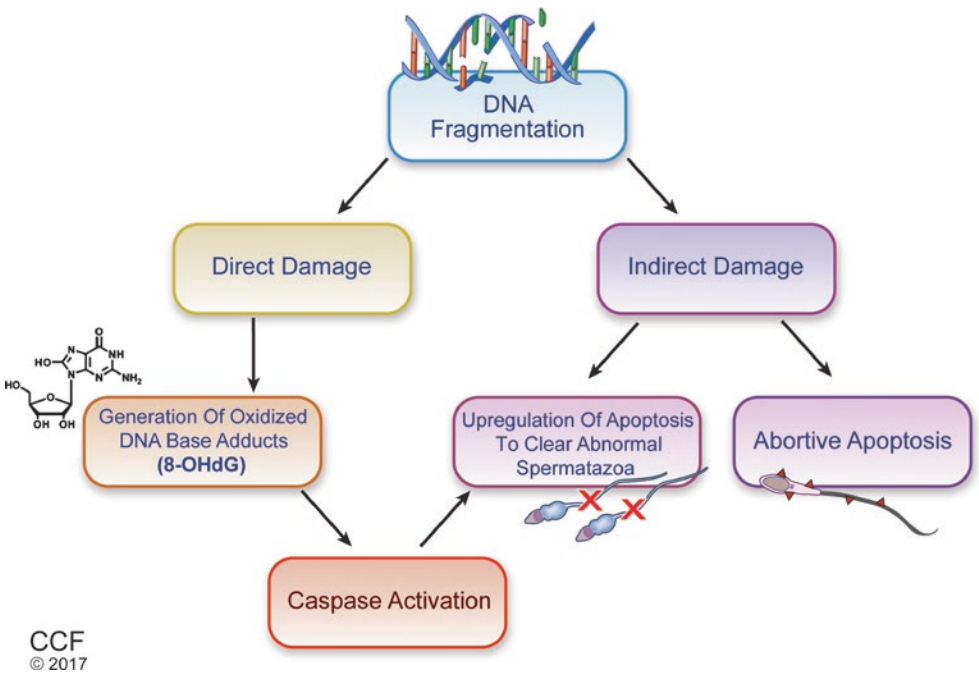

Fig. 30.2 OS can directly lead to formation of 8-OHdG base adducts. As spermatozoa are unable to repair these adducts, spermatozoa shall enter apoptosis when fragmentation is elevated. Table 30.1 Current assays used to determine OS in semen

Assay	Description of finding	Advantages	Disadvantages	References
Chemiluminescence (ROS)	Commonly utilizes lucigen or luminol probes which react with ROS and emit a photon	The assay directly measures both intracellular and extracellular concentrations of ROS	Time-consuming, equipment is expensive, semen age affects the results, must be conducted in the dark to avoid interference with external light sources	[31, 64, 70]
Total antioxidant capacity (TAC)	The semen's ability to suppress chemiluminescence or colorimetric expression when exposed to a source of ROS determines the relative amount of antioxidant in the sample	Measures antioxidant concentration in semen Colorimetric method allows for a quick result	Requires expensive equipment; the length of the assay can change the results obtained	[66, 67, 121, 122]
ROS-TAC score	A statistical model used to determine semen quality and ability to compensate for OS	ROS-TAC scores are easy to comprehend, wholesome indicators of OS in semen	Time-consuming, requires calibration for the center's demographics prior to diagnostic capability, requires both a plate reader and a spectrophotometer	[19, 43, 123]
Nitroblue tetrazolium (NBT)	NBT is a clear, yellowish probe which turns indigo when exposed to ROS	Requires a fluorescent microscope, significantly reduces testing costs	NBT has questionable specificity for only ROS to cause the color changes	[69, 76, 124]
Thiobarbituric acid reactive substances (TBARS)	Able to detect lipid peroxidation by detecting MDA adduct formation	MDA formation is stable and is additive over time, showing OS damage over time Flow cytometer allows determination of 5000 sperm over the 200 from microscope evaluations	Requires a flow cytometer and strict quality control to produce reliable results	[125, 126]
Oxidation-reduction potential (ORP)	Provides a measurement of redox balance or ORP through an electrochemical measurement of all known and unknown oxidants and antioxidants	The only assay that measures redox balance exclusively. System procedure requires very little technician involvement and is easy to standardize	Affected by high levels of semen viscosity. Cannot be tested in stored samples containing sperm preparation media, buffer, or cryoprotectants	[77, 83, 112]

as luminol, or colorimetric, such as 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) [66, 73]. The antioxidants in a semen sample will prevent either a photon emission or a color shift and, thus, produce the TAC. Low TAC values indicate a decrease in antioxidants present within the semen and subsequent pathological processes.

While chemiluminescence and TAC methodologies have advanced the pathological understanding of OS, they have poor diagnostic characteristics. Both methodologies are time-consuming, laborious, and require skilled personnel and expensive instruments [74, 75]. To circumvent these limitations, NBT was explored as an alternative to chemiluminescent techniques. To assess OS with NBT, a bright field microscope is required and visual acuity to determine sperm that have minimum color from those with dark-blue staining [68, 69]. While NBT has questionable specificity for oxidation strictly by ROS, the low cost of the assay allows NBT to be economical for developing nations, thus allowing OS to be standardized across the globe [46, 76]. Given the clinical significance of OS in male infertility evaluation, there is a need for a simple, cost-effective, and robust methodology.

30.3 The MiOXSYS System

The MiOXSYS system (Fig. 30.3) is an innovative system for diagnosing OS-induced infertility. The principle is to determine oxidation-reduction potential (E^{ORP}) of the Nernst equation (Eq. 30.1) [43, 43, 44]. The MiOXSYS system measures E^{ORP} utilizing a galvanostatic measurement of a working solution [74, 77]. Galvanostatic measurements are not innovative in their own right, as they were originally described in 1941 [78]. The original use of these systems was to measure potential changes in electrolytic processes. The most widespread application of electrolytic chemistry was in municipal water supply chlorination [79–81]. Biological application of oxidation-reduction potential was observed in donor-acquired organs for transplantation, as ORP can be used to monitor ischemia-induced organ injury [82]. However, there was a limited use for ORP in biological samples due to the large volume of specimen required, the large size of the analyzers, and the impracticality of handling multiple samples in a timely manner [74, 80]. The MiOXSYS System enables the scope of ORP to be applied to semen and other biological samples:

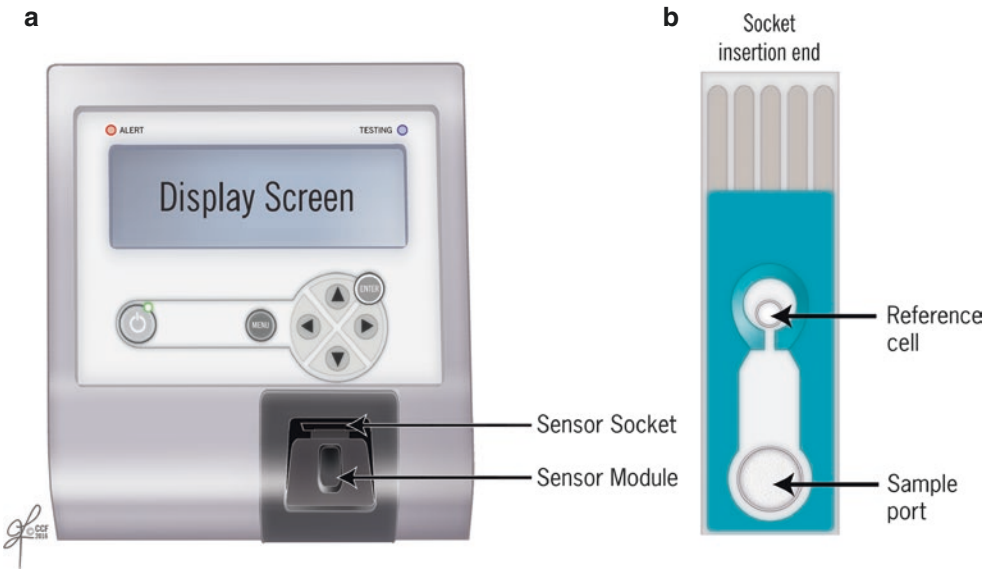

Fig. 30.3 (**a**) The MiOXSYS instrument is a compact and simple instrument. (**b**) Due to the use of disposable sensors, semen samples can be applied to the sample port and through capillary action connect the reference cell to a working circuit. Once these circuits are connected, the instrument assesses the resistance of the sample and generates an ORP value. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2013–2018. All Rights Reserved)

$$E(\mathrm{ORP}) = \frac{E^0 - \mathrm{R}\cdot\mathrm{T}}{n\cdot\mathrm{F}\cdot\ln\dfrac{[\mathrm{Ox}]}{[\mathrm{Red}]}} \qquad (30.1)$$

E (ORP) is the oxidation-reduction potential of the sample (in mV), E^0 is the standard reduction potential of hydrogen, n is the number of electrons exchanged (in moles), T is the absolute temperature (in degrees kelvin), F is Faraday's constant, R is the universal gas constant, [Ox] is the concentration of oxidations in the sample (in moles), and [Red] is the concentration of reductants in the sample (in moles).

The MiOXSYS System utilizes two primary components: a disposable single use platinum based sensor and a small galvanostat analyzer. The test sensors allow 30 μL of sample which is applied to the sensor port and connects the working circuit to the reference circuit [83]. The MiOXSYS analyzer is compact and requires very little laboratory bench space. The MiOXSYS system procedure takes approximately 5 minutes and requires very limited hands on time. The MiOXSYS System applies a low voltage current to the sample and the electron activity is measured in millivolts (mV). Results from the MiOXSYS system require the ORP to be normalized by the concentration [77].

30.4 Oxidation-Reduction Potential and Male Infertility

While other methods determine OS either by measuring ROS, TAC, or both, ORP is an independent measure of OS. Oxidation-reduction potential cutoff values were validated as a clinical marker of OS in infertile males (reviewed in Table 30.2). The first study was to establish if ORP can determine semen quality according to the WHO fifth edition guidelines.

30.4.1 Semen Quality and Oxidation-Reduction Potential

Prior to the diagnostic validation of the MiOXSYS system, a series of analytical studies were undertaken to determine the reliability and repeatability in a clinical laboratory setting. Agarwal et al. [77] established the ORP does not significantly vary between the time of collection and 120 min after liquefaction, validating ORP is stable in semen up to 2 h. In addition to the stability of time and ORP, the difference in ORP between semen and seminal plasma was determined. Agarwal et al. [43] validated that both semen and seminal plasma were time-independent and had ORP values correlating with each other.

Additional investigations examining the influence of oxidants on biological semen samples being analyzed by the MiOXSYS System were performed. Agarwal et al. studied the effects of cumene hydroperoxide in fresh and frozen semen samples. The study also investigated whether freezing of semen samples induced exogenous OS, which increased ORP [87]. Both motility and viability decreased significantly in a dose-dependent manner when exposed to cumene hydroperoxide. The ORP readings increased significantly in a dose-dependent manner, as well, but failed to show a significant correlation with the decrease in motility and viability [87]. In addition, it was validated that an increase in ORP is indicative of OS.

Table 30.2 Determining a cutoff value for ORP to diagnosis male infertility

ORP cutoff ($mV/10^6$ sperm/mL)	Pathologic indication	Sensitivity	Specificity	PPV	References
1.635	> 4 abnormalities on semen analysis				[91]
3.29	Abnormal morphology of < 4%		89.1	85.7	[92]
1.57	Able to detect at least one abnormality on semen analysis				[109]
1.42	one abnormality on semen analysis across nine different centers	97.1	43.7	94.2	[116]
1.48	Abnormality on semen samples from a neat semen sample	60	75		[77]
2.09	Abnormality on semen analysis with seminal plasma	46.7	81.8		[77]
1.57	Detect one abnormality and able to determine oligozoospermic with greatest accuracy among patients	70.4	88.1	95.5	[105]
1.38	One abnormality on semen analysis with a better odds ratio than 1.41	63.3	87.8	97.6	[89]

ORP oxidation-reduction potential, *PPV* positive predictive value

Initial clinical validation of ORP was performed using semen samples from fertile donors and infertile patients. Cutoff value of 1.36 $mV/10^6$ sperm/ml was established with a sensitivity 69.6%, specificity 83.1%, positive predictive value 85.3% and negative predictive value 65.9% using MiOXSYS analyzer [106]. ORP levels were lower in fertile controls (1.03 $mV/10^6$ sperm/mL) compared with infertile patients (5.49 $mV/10^6$ sperm/mL) [89]. In fertile donors, ORP values were negatively correlated with sperm concentration [77]. Whereas, in infertile patients, ORP values were negatively correlated with both concentration ($r = -0.883$) and total motility ($r = -0.369$) [43]. Arafa et al. also reported a negative correlation between the ORP levels and semen parameters such as sperm concentration, total sperm count, total motility, progressive motility, and normal sperm morphology [89, 90]. Poor semen parameters with increased ORP indicates a state of OS.

Elbardisi et al. [91] divided patients into those who had an abnormality in at least one semen parameter ($n = 364$) and those with no abnormalities on semen analysis ($n = 64$) according to WHO fifth edition guidelines. ORP readings from the seminal plasma between abnormal and normal semen parameters revealed ORP did not correlate with motility but did so with progressive motility and morphology [91–94]. Seminal plasma ORP was most effective at differentiating patients with >4 abnormalities and was not effective in patients with a single abnormality on semen analysis [91]. Majzoub et al. [93] determined ORP values between infertile patients who had a significant correlation between abnormal morphology, particularly sperm head defects ($r = 0.34$), and SDF (measured by sperm chromatin dispersion assay; $r = 0.73$). Arafa et al. [95] assessed ORP's ability to correlate semen parameters and SDF. SDF was evaluated by Halosperm and significantly correlated with ORP ($r = 0.351$). Interestingly, patients with lower ORP values had higher total motility [95]. Subsequently, ORP correlated significantly with SDF values, it serves as a surrogate marker for centers without the capabilities to determine SDF [96].

While ORP comparisons between fertile and infertile patients assess how semen quality varies between patients of all etiologies to fertile controls, other studies determined if the MiOXSYS system can differentiate ORP values from patients with known OS-induced pathologies. Semen cryopreservation diminishes post-thaw sperm survival due to cryo-injury which is partially caused by OS induced by the increased metabolism during the thawing process [97]. The post-thawed semen samples produced higher ORP values which negatively correlated with post-thaw total motility, total semen counts, and cryo-survival [98]. Roychoudhury et al. [99] determined that grade 3 varicocele had significantly higher ORP levels compared to other varicocele grades in idiopathic infertile patients and fertile controls. Saleh and Agarwal [100] confirmed this difference between varicocele and idiopathic infertility. In addition, patients with varicocele had ORP levels which correlated with total motility, total motile count, progressive motility, abnormal morphology, and leukocyte concentration [100]. Varicocelectomy improves OS markers in male infertility patients [101–103], and, as expected, ORP reflects this in post-surgery patients [104]. Patients who had undergone varicocelectomy had significantly reduced ORP three months post-operation [104]. For patients with leukocytospermia, empiric doxycycline treatment reduced ORP by 56% after completion of the treatment [105]. With ORP reflecting poor semen quality, investigations were pursued on establishing various cutoff values to diagnose different aspects of male infertility.

30.4.2 Determining a Cutoff to Diagnose Infertile Men

In determining a cutoff value for the MiOXSYS system, a fundamental question prior to establishing a value is how many readings are required to produce a reliable result. To produce a reliable result, the MiOXSYS system requires a single reading. ORP values determined in duplicates change insignificantly by 0.1 $mV/10^6$ sperm/mL, indicating one reading is accurate [89]. Assaying how the observer can induce a change in the reading is an important aspect of any clinical test as readings can vary between a single

observer (intraobserver) and multiple observers (interobserver). Readings between a single observer and multiple observers vary by 3.61% by 8.39%, respectively, validating that the MiOXSYS system produces a reproducible and reliable diagnostic marker [106, 107]. Clinicians are reported with only a single ORP reading.

A cutoff ORP value for men with infertility versus fertile controls can be determined in a multitude of ways (reviewed in Table 30.2). One method to determine an ORP cutoff is to compare its values from fertile men and infertile men and establish a cutoff which distinguishes with the greatest accuracy between those two populations. Agarwal et al. [77] determined such a cutoff by evaluating both semen samples and seminal plasma from fertile and infertile men. The cutoff value for semen is 1.48 mV/10^6 sperm/mL with an accuracy of 78.9%. However, there is a difference between semen and seminal plasma cutoffs as seminal plasma cutoff is 2.09 mV/10^6 sperm/mL with an accuracy of 72.9%.

Reports have examined a second method to determine an ORP cutoff which can distinguish between semen without an abnormality and those with an abnormality according to WHO fifth edition guidelines [108]. When comparing men with completely normal semen parameters to men with at least one abnormality on semen analysis, an initial cutoff of >1.57 mV/10^6 sperm/mL indicates a patient has one abnormality on semen analysis and has OS [105, 109]. The cutoff values have a sensitivity of 70.4%, specificity of 88.1%, and a positive predictive value (PPV) of 95.5% to distinguish between semen with no abnormality and semen with at least one abnormality. Further refinement by Arafa et al. [110] determined a cutoff of 1.42 mV/10^6 sperm/mL that distinguishes infertile men with at least one abnormality with a specificity of 78% and PPV of 95.7%. A cutoff of 1.64 mV/10^6 sperm/mL differentiates 96% of infertility patients with greater than four abnormalities on semen analysis [91].

For a more specific cutoff value, ORP values which can distinguish abnormal morphology were further investigated as morphology has the highest predictive power to differentiate between infertile and fertile men [108]. A cutoff of 3.29 mV/10^6 sperm/mL distinguishes semen with high abnormal morphology [92]. When the sample size was increased from 400 infertile men to 1168, the cutoff was refined to 1.73 mV/10^6 sperm/mL with a sensitivity of 76%, specificity of 72%, and PPV of 69.2% [111].

To determine which method to utilize for a definitive cutoff value, Arafa et al. [89] compared fertile and infertile men. A cutoff of 1.36 mV/10^6 sperm/mL was determined with ORP from men with one abnormality on semen analysis. A second cutoff was determined by comparing infertile versus fertile ORP values regardless of semen analysis results which produced a cutoff of 1.41 mV/10^6 sperm/mL. By comparing which cutoff had a better odds ratio in distinguishing fertile from infertile men, the more accurate cutoff was determined as the ORP with an abnormality on semen analysis [89]. An ORP based on a semen abnormality by semen analysis can differentiate between normozoospermic and oligozoospermic men but cannot differentiate with asthenozoospermic men [108]. The cutoff of 1.36 mV/10^6 sperm/mL was further evaluated and has a sensitivity of 69.6%, specificity of 83.1%, and PPV of 85.3% [106]. Men with ORP values greater than 1.36 mV/10^6 sperm/mL had negatively correlated concentration ($r = -0.823$), total count ($r = -0.728$), motility ($r = -0.485$), and normal morphology ($r = -0.238$). While the cutoff value was determined, validation with more than one individual infertility center is required to validate the utility on a global scale.

30.4.3 Global Validation

The first multi-center was completed by a center in the USA and in Qatar. The main objective was to determine the ORP values in infertile men and fertile donors at both the centers and to establish a cutoff value. Both populations had a significant difference between fertile controls and infertile patients in concentration, motility, progressive motility, and normal morphology [112, 113]. To determine a cutoff, patients and controls were divided with the presence of one abnormality on semen analysis. Interestingly, the study found a difference between normal morphology and motility between infertile patients, validating the criticism of subjectivity in semen analysis [114, 115]. The cutoff was 2.26 mV/10^6 sperm/mL for the United States and 1.42 mV/10^6 sperm/mL for Qatar. When the two populations were combined, the cutoff was determined to be 1.42 mV/10^6 sperm/mL [112]. Infertility centers from the United States, Qatar, Japan, the United Kingdom, Turkey, Egypt, and India (nine in total) determined a cutoff of 1.34 mV/10^6 sperm/mL [112]. The data from the centers revealed ORP has the highest predictive value to differentiate fertile from infertile men, compared to traditional semen analysis [116].

30.4.4 Oxidation-Reduction Potential and In Vitro Fertilization

Continuing this trend, two studies evaluated whether ORP can determine the effect of various culture media on sperm. To determine if culture medium responses to OS are distinguishable by ORP, Panner Selvam et al. added varying concentrations of ascorbic acid and cumene hydroperoxide to culture media [117]. The effect on media shows ascorbic acid reduced ORP and cumene hydroperoxide increased

ORP. When comparing baseline ORP values of various media, a trend emerged; ART media had lower ORP values than sperm wash media and cryopreservation media had ORP values in between [117]. The findings suggest the antioxidant capacity of ART media is higher than that of cryopreservation and sperm wash media. Comparing the effect of ART media versus a neat semen sample after 1 h revealed polyvinylpyrrolidone (PVP) had a lower ORP than either hyaluronic acid or neat semen [118]. The results show PVP allows for better antioxidant capacity over a prolonged time compared to neat semen.

30.5 Five-Year Outlook

While the MiOXSYS system provides a novel method to determine OS, the system requires further validation within the IVF setting prior to universal acceptance.

Subsequently, the effect of ART media and semen is interesting; however, determining the physiological ORP of sperm will allow a more comprehensive understanding of how changes in ORP affect sperm. Understanding how media causes semen to deviate from physiological ORP allows the development of media which maintain semen quality longer. Subsequently, media refinement would minimize the effect of OS on successful fertilization after cryopreservation and assisted reproductive technique.

Oxidation-reduction potential correlates with SDF determined using Halosperm assay. As different methods to evaluate DNA fragmentation assess different aspects of SDF, investigating if ORP correlates with TUNEL and/or SCSA is required [119, 120]. This will better reassure the robustness of ORP as a surrogate marker for SDF.

30.6 Conclusion

OS and idiopathic male infertility has been well documented in the literature. Evaluating redox balance in a patient's semen has been explored previously, but the techniques are labor intensive, time-consuming, and unable to be standardized in routine clinical practice. The MiOXSYS System provides a rapid and accurate measure of redox balance in a simple and standardizable method. The MiOXSYS system cutoff based upon semen analysis abnormality produces the highest predictive power to distinguish between fertile and infertile men.

30.7 Review Criteria

An extensive review of the literature regarding OS, male infertility, and oxidation-reduction potential was performed using PubMed, Google Scholar, and Medline databases. Articles were initially assessed for the following keywords: "oxidation-reduction potential," "MiOXSYS," "male infertility," "semen analysis," "sperm functionality," and "oxidative stress." Only articles published in English were reviewed.

Part III

Common Conditions and Factors Affecting Male Reproductive Health

Varicocele

31

Daniel Suslik Zylbersztejn and Sandro C. Esteves

Key Points

- Approximately 8% of men in reproductive age seek for medical assistance for fertility-related problems. Of these, 1–10% carries conditions that compromise the reproductive potential, and varicocele accounts for 35% of these cases.
- Epidemiology data show that approximately 35% of men with primary and 80% of men with secondary infertility have varicocele. The higher frequency of varicoceles in both the elderly and in men with secondary infertility suggests that it is a progressive disease. Bilateral varicoceles are more common than previously reported.
- Impaired drainage or pooling of blood around the testicles leading to increased scrotal temperature, hypoxia, increased testicular pressure, reflux of renal and adrenal metabolites, excessive oxidative stress (OS), and decreased pH in the spermatozoa cytosol and seminal plasma are the leading theories to explain the detrimental effects of varicocele on spermatogenesis.
- The concept that varicocele causes infertility relies on three main aspects: (i) the increased incidence of this condition among infertile men, (ii) the association of varicocele with reduced semen parameters and testicular size, and (iii) the improvement of semen parameters and pregnancy rates after surgical repair of clinical varicoceles.
- Varicoceles diagnosed by physical examination, which is the preferred diagnostic method, are termed "clinical." Clinical varicoceles are graded according to the size. When a varicocele is not palpable, but other diagnostic methods detect a retrograde blood flow, the varicocele is termed subclinical. The significance of a positive test result using adjuvant diagnostic techniques in infertile men remains uncertain.
- Varicocele treatment is indicated for men with clinically palpable varicocele and abnormal semen parameters. Open microsurgical inguinal or subinguinal techniques are considered the best treatment modalities because they result in higher natural pregnancy rates and fewer recurrences and postoperative complications than laparoscopic, radiologic embolization and macroscopic inguinal or retroperitoneal varicocelectomy techniques. There are no absolute predictive factors for successful varicocele repair, and existing evidence does not support the recommendation for treating infertile men with subclinical varicocele (SCV).
- Recovery of spermatogenesis can be achieved after repair of clinical varicocele in infertile men with nonobstructive azoospermia (NOA). Testicular histopathology is predictive of success, and men with maturation arrest (MA) and hypospermatogenesis (HS) are more likely to ejaculate motile spermatozoa after surgery.
- Functional markers for oxidative stress and DNA integrity are impaired in infertile men with clinical varicocele but may be significantly improved after varicocele repair.
- Surgical repair of varicocele increases the chance for either natural or assisted conception in infertile couples whose male partner has a clinical varicocele. Also, the chance of retrieving testicular sperm

for ICSI is optimized in nonobstructive azoospermic men with treated clinical varicocele.
- Lifestyle modifications may benefit reproductive health. When considering therapeutic measures to treat varicocele-associated infertility, counseling toward lifestyle modifications should be strongly encouraged.
- Varicocelectomy treatment can be offered to men with clinical varicocele and hypogonadism as a means to improve androgen production and potentially avoid testosterone replacement therapy.
- Soon, proteomics and genomic studies might help identify the ideal candidates for varicocele treatment. Such studies might also be able to identify those individuals who need early interventions to avoid deterioration of testicular function.

31.1 Introduction

Approximately 50 million couples suffer from infertility worldwide and the percent of infertility that is attributable to men ranges from 20% to 70% [1]. Varicocele is a common finding mong men with infertility complaint. In a group of 2875 infertile couples attending our tertiary center for male reproduction, we found the presence of varicocele in 21.9% of the male partners.

The first reports concerning the existence of varicose veins surrounding the testes date back to the first century AC [2]; however, the association between varicocele and infertility was only suspected at the end of the nineteenth century when surgical occlusion of dilated veins was shown to improve semen quality [3]. Later, in 1952, Tulloch was the first to report that bilateral varicocele repair in a male with azoospermia resulted in an increase in sperm concentration that resulted in a natural pregnancy [4]. In 1965, MacLeod first reported that most semen specimens obtained from infertile men with varicocele had decreased sperm count, decreased motility, and increased abnormal forms [5].

The term "varicocele" derives from Latin *varix* (a dilated vein) and Greek *kele* (tumor). It comprises the dilation of the veins of the pampiniform plexus that drain the blood from the testicles. Typically, small one-way valves prevent the backward blood flow. Valve abnormalities or vein compression by adjacent structures can cause vein dilation.

The pathophysiology of varicocele and its impact on the male reproductive potential have been debated for the past 50 years. Varicocele is still one of the most controversial issues in the field of male infertility, especially regarding why, when, and to whom treatment should be applied. Varicocele repair is considered the treatment of choice for varicocele-associated infertility, but its effectiveness still elicits heated debate. Although the ultimate endpoint for the treatment of male factor infertility is a live birth, efforts to maximize the couple's fertility potential by improving testicular function should not be overlooked. This chapter discusses the current concepts and controversies regarding the epidemiology, pathophysiology, diagnosis, treatment, and significance of clinical and subclinical varicoceles (SCV) in male infertility. It also reviews the management of varicoceles in azoospermic patients and the indications of varicocelectomy in the era of assisted reproductive technology (ART).

31.2 Epidemiology

Approximately 7% and 10–25% of prepuberal and postpubertal males have a varicocele, respectively [6, 7]. Varicoceles are found in up to 43% of adult males [8]. The prevalence of varicocele increases over time, and it is estimated that a 10% rise in incidence occurs for each decade of life. Approximately 35% of men with primary and 80% of men with secondary infertility have varicose veins [1, 9]. The higher frequency of varicoceles in both the elderly and in men with secondary infertility suggests that the condition is progressive. Although the frequency of unilateral left-sided varicocele has historically been reported to be approximately 85–90%, recent data indicate that bilateral palpable varicoceles are found in more than 50% of the affected subjects [6].

Whether or not a varicocele might be inherited remains equivocal. Some authors have described an increased prevalence of varicocele in men whose first-degree relatives also have varicose veins [10–12]. Others, however, studying adolescents, could not find a direct association in first-degree relatives, although it has been acknowledged that young men with high-grade varicocele might have a hereditary predisposition [13]. Further studies are needed to establish the relationship between varicocele and genetic inheritance conclusively.

31.3 Pathophysiology

The etiology of varicocele formation is likely to be multifactorial. The right internal spermatic vein inserts directly into the inferior vena cava at an acute angle, while the left one inserts into the left renal vein at a right angle. It is also suggested that a partial obstruction of the left spermatic vein due to the compression of the left renal vein between the aorta and the upper mesenteric artery might be the causative factor in some cases (the "nutcracker" phenomenon). An increase in the hydrostatic pressure of the left spermatic vein may be transferred to the venous plexus of the spermatic cord causing its dilation [14]. Moreover, primary insufficiency of the

internal spermatic and subsequent malfunction of the external spermatic and cremasteric vein valves may lead to regression of blood [15, 16]. Also, there seems to be an inverse relationship between the occurrence of varicocele and body mass index [17]. Moreover, intense physical activity (2–4 h daily, 4–5 times per week) over several years appears to worsen the semen quality of men with varicoceles and abnormal semen parameters [18].

A fivefold increase in the hydrostatic pressure of the spermatic veins has been observed in men with varicocele compared to controls [19]. Microscopic evaluation of the spermatic vein fragments reveals alterations in the longitudinal muscle layers and a decrease in the number of nerve elements in the vessel wall [20]. These findings suggest a defective contractile mechanism of blood transport through the pampiniform plexus that may lead to a reversal of the pressure gradient and cause a hypoxic status.

Several theories aim to explain the impact of varicoceles on testicular function, but none of them can fully elucidate the variable effect of varicocele on human spermatogenesis and male fertility [14]. Proposed mechanisms include hypoxia and stasis, testicular venous hypertension, elevated testicular temperature, increase in spermatic vein catecholamine leading to testicular underperfusion, and increased oxidative stress (OS) [21]. It is believed that reflux of warm blood from the abdominal cavity to the varicose veins increases the scrotum temperature, but the mechanism by which temperature influences spermatogenesis is not clearly understood.

Germ cell apoptosis and subsequent oligozoospermia, a common phenomenon in men with varicocele, can be attributed to increased scrotal temperature, increased intratesticular cadmium concentration, and reduced levels of androgens [22, 23]. An increased concentration of toxic metabolites inside the testicles (e.g., catecholamines from the kidney and adrenal glands) can cause chronic vasoconstriction of the intratesticular arterioles, contributing, along with impaired venous return caused by valve insufficiency, to persistent testicular underperfusion and subsequent dysfunction of the spermatic epithelium [24]. Biopsies of varicocele-affected testicles showed a decrease in E-cadherin and alpha-catenin in the Sertoli–Sertoli junction and subsequent disruption of the blood–testis barrier that can contribute to the pathology and impairment in sperm production [25]. However, histopathologic findings typical of varicocele have not been observed [26].

Excessive oxidative stress (OS) is often seen in infertile men with varicocele. High production of reactive oxygen species (ROS) in the reproductive tract impairs both the fluidity of the sperm plasma membrane and the integrity of deoxyribonucleic acid (DNA) in the sperm nucleus. Abnormal high levels of sperm DNA damage are associated with a decrease in several fertility markers including fertilization rate, embryo cleavage rate, implantation rate, pregnancy rate, and live birth rate [27]. Fertility impairment in men with varicocele might result from decreased pH in the spermatozoa cytosol and seminal plasma [28]. According to this hypothesis, testicular underperfusion diminishes cell oxygen and glucose supply to the metabolically active tissues. Under conditions of low glucose supply, the flux through the pentose phosphate pathway is markedly decreased, as well as the provision of reductants to the antioxidant system. Indeed, the drastic fall in the reduced nicotinamide adenine dinucleotide phosphate/oxidized nicotinamide adenine dinucleotide phosphate (NADPH/NADP+) ratio leads to an impairment in the tissue antioxidant capacity because glutathione regeneration is retarded. Under such pathologic circumstances, ROS production surpasses the antioxidant capacity and causes increased oxidative stress [24]. Spermatozoa are susceptible to damage by oxidative stress through ROS, especially lipid peroxidation [27], owing to the low amount of cytoplasm and abundance of polyunsaturated fatty acids in the sperm plasma membrane. Lipid peroxidation damages the membrane function in sperm head and midpiece, thus not only decreasing sperm motility but also intracellular pH, partly because of malondialdehyde-mediated reactions.

Malondialdehyde, produced by the peroxidation of polyunsaturated fatty acids, reacts with spermine, a polyamine essential for sperm activity, forming Schiff bases. It results in a further decrease of pH as well as in a direct impairment of spermine-dependent cellular functions. The optimum pH for ROS scavenging by the enzymatic antioxidant systems ranges from neutral to slightly alkaline, but their activity is markedly depressed in low pH. It has been observed that antioxidant enzyme activity is significantly impaired in infertile men with varicocele, and it may further diminish sperm motility [27].

The hypothesis mentioned above is novel and adds to other proposed mechanisms for defective sperm function in men with varicocele, such as the peroxidation of the unsaturated fatty acids in the sperm plasma membrane and the impaired acrosome reaction and DNA integrity induced by ROS [24]. However, it has also been speculated that individual differences may exist; therefore, the mechanism described above may not be deterministic. If, for example, the glucose supply is less restricted or the accessory glands are particularly efficient, the accumulation of ROS and acidification of the seminal plasma could be minimized. These observations might help us understand the variable effect of varicocele on male fertility.

31.4 Infertility

The concept that varicocele causes infertility relies on three main aspects: (i) the increased incidence of this condition among infertile men, (ii) the association of varicocele with

reduced semen parameters and testicular size, and (iii) the improvement of semen parameters and pregnancy rates after surgical repair of clinical varicoceles.

In a large observational study involving 9034 men, it was observed that 25.6% of men with abnormal semen analysis had varicocele. It was also noted that total sperm count and testosterone levels were lower in men with varicoceles than those without varicoceles. Also, the testicular size was significantly reduced at the varicocele side as compared to the contralateral one in the cases of unilateral varicoceles [29]. Surgical repair of varicocele was shown to restore testicular temperature in both animals and humans [24].

The hypothesis that varicocele can cause testicular damage was further confirmed on pubertal boys in which the reduction in the size of the ipsilateral testis was restored by surgical repair of varicocele [30]. Despite the proven association between varicocele and infertility, it is still unclear the reasons why about two-thirds of men with varicocele retain their fertility [3, 31] and why fertility potential is not always improved after surgical varicocele repair [32, 33].

31.5 Diagnosis

Currently, physical examination with the patient standing in a warm room is the preferred diagnostic method (Fig. 31.1). Varicoceles diagnosed by this method are termed "clinical" and graded according to the size. It is essential to ask the patient to perform a Valsalva maneuver during the examination. Large varicoceles (grade III) are varicose veins seen through the scrotal skin (Fig. 31.2). Moderate (grade II) and small-sized varicoceles (grade I) are dilated veins palpable without and with the aid of the Valsalva maneuver, respectively [34].

Physical examination is limited by a sensibility and specificity of about 70% compared to other diagnostic modalities [35, 36]. Interobserver and intraobserver variabilities have been observed among practitioners. Indeed, the physical examination can be inconclusive or equivocal in cases of low-grade varicocele and in men with a history of previous scrotal surgery, concomitant hydroceles, or obesity. Imaging studies may be recommended when the physical examination is inconclusive. When a varicocele is not palpable but retrograde blood flow is detected by other diagnostic methods such as venography, Doppler examination, ultrasonography, scintigraphy, and thermography, the varicocele is termed subclinical [35, 37].

The gold standard method to diagnose blood reflux into the veins of the pampiniform plexus is the percutaneous venography of the spermatic veins; however, it is not routinely used because of its invasiveness [35, 37]. Among the noninvasive diagnostic modalities, color Doppler ultrasound (CDU) is the best diagnostic tool. The commonly accepted CDU criterion for varicocele (maximum vein

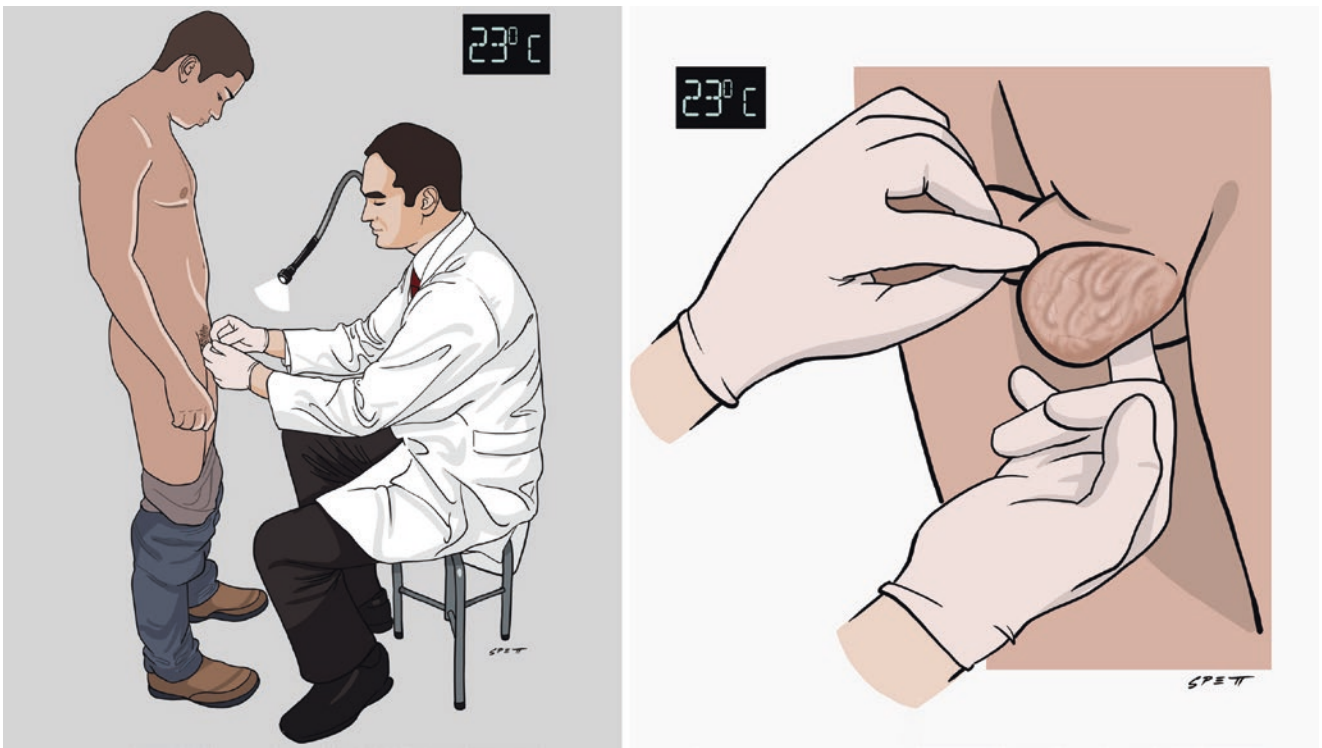

Fig. 31.1 Illustration depicting the scrotal examination of a young male with a varicocele. Adequate illumination and room temperature are essential to allow proper assessment of clinical varicoceles (Reprinted with permission from ANDROFERT. All Rights Reserved)

Fig. 31.2 Photograph of a large left varicocele (grade III) seen through the scrotal skin (left). The illustration depicts varicose veins on the left spermatic cord and normal-sized veins on the right side (right) (Reprinted with permission from ANDROFERT. All Rights Reserved)

diameter of 3 mm or greater) has a sensitivity of about 50% and specificity of 90% compared to physical examination [38].

Notably, a scoring system, incorporating the venous diameter, the presence of a venous plexus, and the change of flow on Valsalva maneuver, yields sensitivity and specificity greater than 85% when compared to physical examination [38] or venography [36]. Besides, a pencil-probe Doppler (9 MHz) stethoscope is an inexpensive tool that may aid in the diagnosis of the varicocele. The patient is examined in the upright position, and a venous "rush" representing blood reflux is heard with or without the Valsalva maneuver. Although simple and easily performed in the office, Hirsh et al. demonstrated that more than 50% of men without clinical varicoceles exhibited Valsalva-maneuver Doppler-positive reflux [39]. Despite that, Doppler examination has been advocated as a useful tool to examine the contralateral spermatic cord to determine if a subclinical varicocele exists when a clinical varicocele is found on the other side [40]. Unfortunately, none of these adjunctive diagnostic methods can differentiate between clinical and subclinical varicoceles. The significance of a positive test result using any of these adjuvant techniques in infertile men remains uncertain.

31.6 Treatment

The varicocele treatment in infertile men should aim to achieve the most significant improvement concerning the fertility status, with lower rates of complications such as recurrence or persistence, hydrocele formation, and testicular atrophy. Current recommendations suggest that treatment should be offered for couples with documented infertility whose male partner has a clinically palpable varicocele and abnormal semen analysis. Additionally, an adult male presenting with palpable varicocele and abnormal semen analyses who is not currently attempting to achieve conception but has a desire for future fertility is also a candidate for varicocele repair [41]. The ideal treatment must combine low complication rates with the highest seminal improvement to either increase the chances of natural conception or to optimize assisted conception outcomes. Along these lines, the ideal surgical technique should aim for ligation of all internal and external spermatic and cremasteric veins, with preservation of spermatic arteries and lymphatics. Only the inguinal or subinguinal microsurgical approaches allow the ligation of both the internal and external spermatic veins (Table 31.1).

An increase in natural pregnancy rates after the treatment of varicocele is difficult to ascertain due to a variety of factors

Table 31.1 Treatment results of varicocele repair in infertile men. Vein ligation sites, postoperative recurrence, hydrocele formation, and natural pregnancy rates among different techniques[a]

Technique	Internal spermatic vein ligation	External spermatic vein ligation	Recurrence rate	Hydrocele formation rate	Natural pregnancy rate
Retroperitoneal high ligation	Yes	No	7–35%	6–10%	25–55%
Laparoscopic	Yes	No	2–7%	0–9%	14–42%
Embolization	Yes	No	2–24%	NR	20–40%
Macroscopic inguinal	Yes	Yes	0–37%	7%	34–39%
Microscopic inguinal or subinguinal	Yes	Yes	0–0.3%	0–1.6%	33–56%

[a]Vein ligation sites, postoperative recurrence, hydrocele formation, and natural pregnancy rates among different techniques (values are expressed as range)

that includes the lack of a uniform posttreatment follow-up interval and, in particular, female factor confounders. Moreover, varicocele repair in men with inadequate lifestyle only solves part of the problem. Lifestyle modifications are likely beneficial in the context of fertility restoration in men with varicocele [42–44]. As such, when therapeutic measures to treat varicocele-associated infertility are considered, counseling toward lifestyle modifications should be strongly encouraged. This strategy, along with the cause-specific treatment, is more likely to lead to a marked improvement in the male reproductive health as compared to varicocele repair alone.

The role of medical therapy in varicocele-related infertility is poorly understood, and well-designed studies are rare. In one study, the use of L-carnitine in combination with the nonsteroidal anti-inflammatory agent cinnoxicam did not affect semen parameters of infertile men with clinical varicoceles [45]. Likewise, the use of clomiphene citrate in men with subclinical varicoceles showed no benefit [46]. By contrast, kallikrein therapy for three months (600 units orally per day) improved sperm motility and morphology in a small group of infertile men with left-sided varicocele and asthenozoospermia [47]. The use of menotropin in association with varicocelectomy yielded better improvement in sperm parameters than varicocelectomy alone [48]. Daily oral administration of pentoxifylline, zinc, and folic acid for three months was shown to improve sperm morphology in men with varicocele-associated infertility [49]. Also, a combination of vitamins and minerals was shown to significantly improve sperm count in men with persistent oligozoospermia after varicocele embolization, although natural conception rates were not increased in a one-year follow-up period [50].

Currently, varicoceles are treated either by surgery (open with or without magnification and laparoscopy) or percutaneous embolization of the internal spermatic vein. Although techniques vary, the central concept is the occlusion of the dilated veins of the pampiniform plexus. The high retroperitoneal (Palomo), radiologic, and laparoscopic approaches are performed for internal spermatic vein ligation, while the inguinal (Ivanissevich) and subinguinal approaches also allow the ligation of the external spermatic and cremasteric veins that may contribute to the varicocele (Table 31.1).

Percutaneous embolization is accomplished in approximately 90% of the attempts. It is associated with faster recovery and minimal pain as compared to the standard surgical approaches, but with higher recurrence rates (Table 31.1). Embolization requires interventional radiologic expertise and has potentially serious complications such as vascular perforation, coil migration, and thrombosis of pampiniform plexus [51–54]. Nonetheless, percutaneous embolization may have a role in the treatment of persistent or recurrent varicoceles previously treated by surgery [55].

Laparoscopic varicocelectomy provides higher magnification with a low incidence of hydrocele formation. However, external spermatic veins, the second most frequent cause of varicocele recurrence, are not ligated, leading to a recurrence rate of approximately 5% [52]. The laparoscopic approach requires extensive training, and the cost of instrumentation is high. It might be argued that it is more invasive than an open microsurgical approach, requiring general anesthesia and placement of a urethral catheter [56, 57]. Complications include intestinal and vascular injuries that occur in approximately 8% of the cases [52]. In a recent meta-analysis, microsurgery was compared to laparoscopy; the authors concluded that microsurgery resulted in a more considerable increase in sperm concentration and a significant decrease in hospital stay, complication, and recurrence rate [58].

Open surgical varicocele repair is often performed using a retroperitoneal, inguinal, or subinguinal approach (Fig. 31.3). High ligation of the internal spermatic vein can be easily performed via the retroperitoneal approach, but it is associated with high recurrence and hydrocele formation rates (Table 31.1). Inguinal and subinguinal approaches are advantageous as they allow the ligation of external spermatic veins. Internal and external spermatic veins can be identified via inguinal/subinguinal approaches macroscopically, but the use of magnification facilitates identification and preservation of internal spermatic artery and lymphatics, which may prevent testicular atrophy and hydrocele formation, respectively [59] (Fig. 31.4).

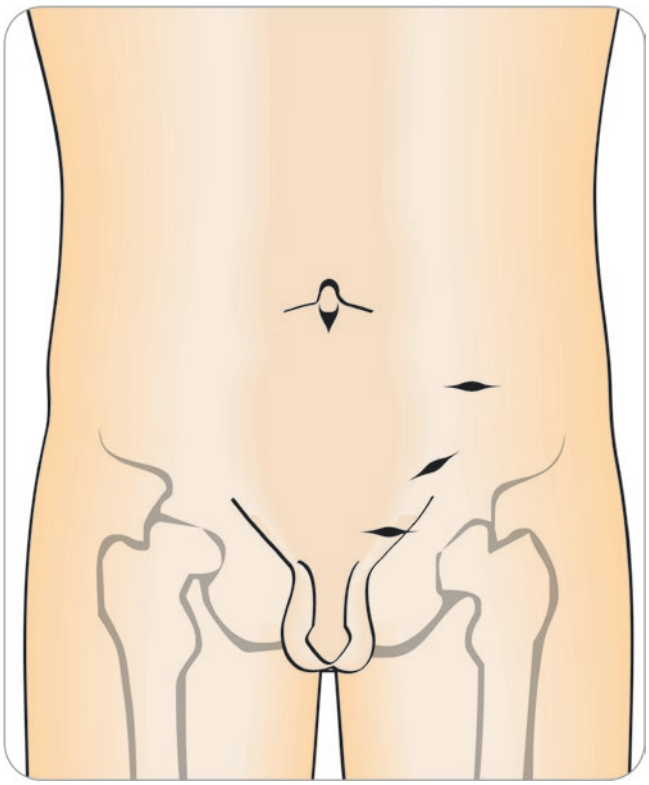

Fig. 31.3 Incision sites used for subinguinal, inguinal, and retroperitoneal open surgical varicocele repair. In the subinguinal approach, a transverse incision is made just below the level of the external inguinal ring. An oblique incision is made along the axis between the anterior superior iliac spine and the pubic tubercle for the inguinal approach. In the retroperitoneal approach, a transverse incision is made medial to the anterior superior iliac spine (Reprinted with permission from ANDROFERT. All Rights Reserved)

Microsurgical varicocelectomy can be performed via an inguinal or subinguinal approach with similar results; the reported recurrence and hydrocele formation with these approaches are below 2% (Table 31.1). The main advantage of the subinguinal over the inguinal approach is that the former obviates the need to open the aponeurosis of the external oblique, which usually results in more postoperative pain and a longer time before the patient can return to work (Figs. 31.3 and 31.4).

The urologist who opts to treat varicocele using microsurgery should obtain appropriate training. It is also essential to have adequate microsurgical instruments and a binocular operating microscope with foot-control zoom magnification. Microsurgical varicocelectomy, either using inguinal or subinguinal approaches, requires more skill as compared to other surgical modalities because a higher number of internal spermatic vein channels and smaller-diameter arteries are seen at the level of the inguinal canal. It is believed that subinguinal microsurgical varicocelectomy requires more microsurgery skills because it is associated with higher number of arteries and internal spermatic veins with a smaller diameter as compared to the inguinal approach [52]. However, histomorphological studies were unable to find differences in number and wall thickness of spermatic cord veins and arteries between the subinguinal and inguinal levels [60].

A systematic review including 4473 individuals was performed to define the best treatment modality of palpable varicocele in infertile men [52]. The authors concluded that open microsurgical inguinal or subinguinal varicocelectomy techniques resulted in higher natural pregnancy rates and fewer recurrences and postoperative complications than laparoscopic, radiologic embolization and macroscopic inguinal or retroperitoneal varicocelectomy techniques in infertile men.

Overall, varicocelectomy studies report significant improvements in one or more semen parameters in approximately 65% of men [61]. The mean time for semen improvement and natural pregnancy after surgery is approximately five and seven months, respectively [62]. However, it is still unknown why fertility potential is not always improved after varicocelectomy. Studies evaluating predictors for successful varicocele repair would aid in the identification of the best candidates for treatment, but to date, few reports exist, and results are conflicting [52, 61, 63–68]. From the existing data, it seems that infertile men either with higher preoperative semen parameters or undergoing varicocele repair for large varicoceles are more likely to show postoperative semen parameter improvement [61, 67].

Men who achieve a postoperative total motile sperm count greater than 20 million seem to be more likely to initiate a pregnancy either naturally or via intrauterine insemination [65]. On the other hand, reduced preoperative testicular volume, elevated serum FSH levels, diminished testosterone concentrations, and subclinical varicocele, as well as the presence of Y chromosome microdeletions, seem to be negative predictors for fertility improvement after surgery [21, 63, 64, 66, 68–70]. Notably, paternal age does not seem to have significant influence on the reproductive outcomes of men with varicocele-associated infertility [71]. In the presence of bilateral palpable varicocele, it is recommended to perform surgery on both sides at the same operative time [72].

In our practice, when a clinically palpable varicocele is identified in one side, the contralateral cord is examined using a pencil-probe Doppler (9 MHz) stethoscope to determine if a subclinical varicocele exists. If so, it is treated at the same time as the coexistent clinical varicocele. This strategy relies on the observation that altered blood flow after varicocelectomy may unmask an underlying venous anomaly and result in clinical varicocele formation [40, 73]. In the early years, we used loupe magnification to facilitate the ligation of the dilated varicose veins. However, this method is not good enough for identification of both testicular arteries and lymphatics. With loupes, we found that instillation of papaverine

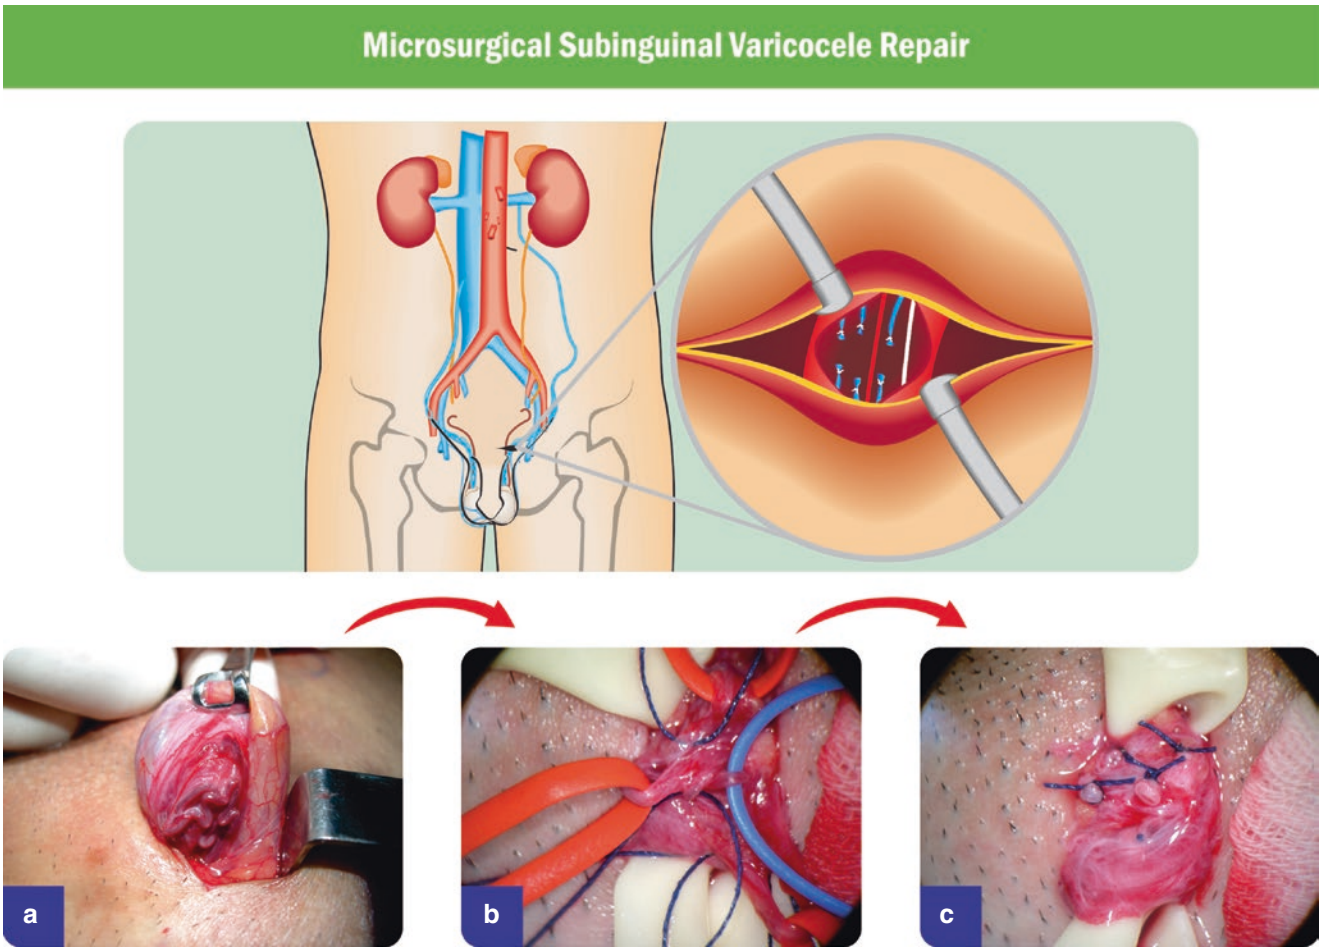

Fig. 31.4 Subinguinal microsurgical varicocele repair. A 2-cm transversal skin incision is made immediately below the external inguinal ring (upper). The muscle layers and the inguinal canal are not violated. The lower panels show intraoperative photographs of the spermatic cord structures. The spermatic cord is exteriorized and the cremasteric veins are identified and ligated (**a**). In panel (**b**), the spermatic cord is dissected to allowing the identification of testicular artery (blue vessel loop), dilated varicose veins (red vessel loops), and lymphatics (blue cotton sutures). The testicular artery and lymphatic channels are preserved, whereas the dilated veins are ligated with nonabsorbable sutures and then transected (**c**) (Reprinted with permission from ANDROFERT. All Rights Reserved)

was needed in most cases to aid in the identification of arterial pulsations, thus increasing the operative time. Also, recurrence seems to be higher when loupe magnification is used in association with the inguinal or subinguinal approach to repair varicoceles (Table 31.2). Our current surgical method is the subinguinal microsurgical varicocele repair with the use of an intraoperative pencil Doppler (9 MHz) to aid in the identification of the artery pulsations.

An earlier 2011 meta-analysis found that microsurgical techniques are associated with higher natural pregnancy rates (mean, 44.7%; range, 33.8%–51.5%) and reduced rates of hydrocele formation [74]. More recently, in 2017, these results were corroborated by Yuan et al. [75].

In later years, varicocele has also been treated using robotic surgery. In addition to the ergonomic benefits, the primary advantage of robotic surgery is tremor elimination which is typical for inexperienced surgeons performing microsurgical varicocele repair. However, the total cost of robotic treatment is still very high when compared to microsurgery, thus limiting its general clinical utility [76–79].

31.7 Subclinical Varicocele

Subclinical varicocele (SCV) refers to the presence of retrograde blood flow that cannot be detected by physical examination of the spermatic cord during Valsalva maneuver and requires adjunctive tests for diagnosis, such as Doppler examination, color Doppler ultrasound (CDUS), scrotal thermography, isotope imaging, or venography [35–39].

The role of subclinical varicocele as a cause of male infertility remains debatable. Currently, the evidence does not support the recommendation for treating infertile men with subclinical varicocele [32, 46, 69, 80]. The optimal

management of infertile men with a unilateral clinical varicocele and a subclinical one at the contralateral side remains to be elucidated. Zheng et al. compared the efficacy of bilateral and left unilateral varicocelectomy in a group of 104 infertile men with left clinical and right subclinical varicoceles, and found that bilateral varicocelectomy had no benefit over the left clinical varicocelectomy [81]. In their study, however, a retroperitoneal approach was used for vein ligation, which was shown to be associated with a high recurrence rate [52]. Elbendary et al., in a prospective trial, studied a group of 145 infertile men with clinical left and subclinical right varicoceles [82]. Patients were randomized to undergo either unilateral inguinal repair of clinical varicocele or bilateral repair of both clinical and subclinical ones. Although a significant improvement in sperm parameters was observed in both groups, the magnitude of change in sperm count and motility and the natural pregnancy rates were significantly higher in the group of men who had bilateral varicocele repair. Their findings are in agreement with earlier studies suggesting that bilateral varicocelectomy is more effective than unilateral for such patients [73, 83]. It is also postulated that altered blood flow after unilateral clinical varicocelectomy may unmask an underlying contralateral venous anomaly that may result in a clinically manifested varicocele [40, 73].

As far as the subclinical varicocele is concerned, a 2018 meta-analysis showed that repairing SCV does not improve pregnancy outcomes, albeit it is associated with a slight increase in total motile sperm count [84]. Since most of the existing studies are retrospective, heterogeneous, and low powered, further research is needed to elucidate whether or not repairing SCV might add any benefit concerning fertility.

As already said, the subinguinal microsurgical varicocelectomy using the operating microscope is the method of choice to treat varicocele-associated infertility at our institution (Table 31.2 and Fig. 31.4). The subinguinal approach provides excellent results, and the surgical intervention can be performed on an outpatient basis using intravenous anesthesia in association with spermatic cord blockade with lidocaine [85].

31.8 Azoospermia

Nonobstructive azoospermia (NOA) comprises a spectrum of testicular histopathology resulting from various causes that include environmental toxins, medications, genetic and congenital abnormalities, trauma, endocrinologic disorders, and idiopathic disorders. Men with NOA have historically been the infertile men most difficult to treat, but since the advent of in vitro fertilization/intracytoplasmic sperm injection (IVF/ICSI) and surgical methods for testicular sperm extraction (TESE), many pregnancies have been achieved with the use of testicular sperm. However, only about 50% of men will have sperm present at the time of TESE [86].

Varicoceles are found in approximately 5% of men with azoospermia, but it is still debatable whether varicoceles can cause or contribute to azoospermia [85]. There has been a renewed interest in varicocele repair in azoospermic men resulting from the introduction of ICSI. Success rates vary, and no predictors of success have been definitively identified because of the small numbers in the case series [85, 87–93].

The first meta-analysis, published in 2010, examined the impact of varicocele repair to recover spermatogenesis in NOA men [94]. A total of 233 infertile men with clinical varicocele and NOA were analyzed in a mean postoperative follow-up of 13 months. Motile sperm was found on postoperative ejaculate in 39% of men. Pregnancies were achieved in approximately 26% of men with sperm in the ejaculate, 60% unassisted and 40% with the assistance of IVF. Postoperative mean sperm density and motility were 1.6 million and 20%, respectively. Levels of serum follicle-stimulating hormone (FSH) and testosterone, testis size, patient age, varicocele grade, and surgical technique did not appear to affect outcomes, but the limited number of patients precluded conclusions. Histopathology was the only predictor of success. Postoperative appearance of sperm in the ejaculate was significantly higher in patients with biopsy-proven hypospermatogenesis (HS) or maturation arrest (MA) than Sertoli cell only (odds ratio 9.4; 95% confidence interval [CI] 3.2–27.3). Combined success was 48% with HS or MA compared to 11% with SCO (Table 31.3). Unfortunately, randomized control trials are lacking, and studies included in the meta-analysis of Weedin et al. were case series without a control group that did not undergo varicocele repair. Although an argument can be made that a control group would remain azoospermic, it is not rare to observe that NOA men occasionally ejaculate small quantities of motile sperm despite any intervention. Therefore, one cannot exclude that the appearance of a minimal number of motile sperm in the ejaculates after varicocele repair may be merely coincidental.

Moreover, reports including men with germinal cell aplasia who ejaculated motile sperm after varicocele repair are intriguing [91]. It is unlikely that men lacking any sperm precursor within the testicle may benefit from treatment, but the only way to investigate this relationship is to repeat the testicular biopsy after the surgical repair of varicocele. In one series [85], patients with SCO were re-biopsied six months after varicocele repair, and testicular histopathology results remained unchanged. The persistence of SCO after surgery denotes that varicocele coexisted with primary testicular failure, which of course was not affected by the surgery. However, testicular biopsy has many limitations and may not reflect the most advanced site of spermatogenesis due to the heterogeneity of sperm production within the testicle; therefore, it is still possible to retrieve sperm from men whose testicles exhibit SCO [95].

Even with the improvement in spermatogenesis in up to half of the NOA patients with favorable testicular histopathology after varicocele repair, intracytoplasmic sperm injection (ICSI) will be necessary for most couples to initiate a pregnancy [85, 94]. However, the use of motile ejaculated sperm is preferred for ICSI, since their fertilizing ability is higher than that of sperm retrieved from the testis [96], except when the proportion of ejaculated sperm exhibiting DNA fragmentation is elevated [97].

Nonetheless, continuing azoospermia after varicocele repair is still a potential problem, and sperm extraction before ICSI will be inevitable for many individuals. Results of testicular sperm extraction (TESE) for men who remain azoospermic after varicocelectomy are scarce and conflicting [98, 99]. Schlegel et al. reported sperm retrieval (SR) rates of 60% per attempt using testicular microdissection (micro-TESE) in men with NOA and varicocele, regardless of whether the previous varicocelectomy had been done [99]. It is questionable, however, if the inclusion of patients with subclinical varicocele biased their results since the benefit of treating subclinical varicocele is debatable [69, 80]. On the other hand, Inci et al., also using micro-TESE, reported a 2.6-fold increase in the chances of retrieving testicular sperm for ICSI after repair of clinical varicoceles [98]. Unfortunately, testicular histopathology results were not available in their study. Therefore, it cannot be excluded that higher retrieval rates were obtained after varicocelectomy because of patients with favorable histopathology patterns for successful sperm retrievals, such as the ones exhibiting hypospermatogenesis or maturation arrest, which biased this group [100, 101].

In the past years, additional studies have been added to the literature. Zampieri et al. evaluated the effect of varicocelectomy in two different groups of patients. In one group (19 patients), the patients were subjected to TESE three months after the varicocele repair, whereas in the other group (16 patients), varicocele repair was carried out during microsurgical TESE. The sperm retrieval success rate was significantly higher in group 1 (57.8%) than in group 2 (25%, $p < 0.05$), thus suggesting that varicocelectomy might

[a]Not all studies reported data

enhance the chances of retrieving sperm in selected men with NOA [102].

In a 2016 systematic review comprising 18 studies, we summarized the scientific knowledge regarding the effect of varicocelectomy in men with NOA (Table 31.3). The pooled estimates indicated a 2.6-fold increase in the sperm retrieval rate among treated patients compared to untreated patients. Moreover, a total of 44% of men subjected to varicocelectomy had sperm return to the ejaculate, thus potentially allowing ICSI to be performed without the need for testicular biopsy [103]. In the study mentioned above, there was a trend toward higher pregnancy rates and live birth rates by treating a varicocele before sperm retrieval in men with NOA. Our results have been corroborated by a concurrent meta-analysis [104]. Notwithstanding the above findings, further well-designed studies are needed to understand the real benefit of varicocelectomy in azoospermic patients better.

31.9 Hypogonadism

Since varicocele can negatively impact the testicular function, research has been conducted to investigate the role of varicocele repair on androgen production. Indeed, varicocele is associated with hypoxia on the Leydig cells and, consequently, reduction in testosterone production [105–107]. In a 1984 study, varicocele induced testicular hyperthermia and inhibited 17-alpha-hydroxyprogesterone aldolase, an enzyme involved in the conversion of 17-hydroxyprogesterone to testosterone [108]. In another study, it was shown that in the presence of varicocele, free radicals exerted deleterious effects on Leydig cell mitochondria, inhibiting the expression and function of the steroidogenic acute regulatory (StAR) protein, thus contributing to a reduction in testosterone [109].

In recent years, this matter has gained renewed interest as it has been suggested that testosterone levels are linked to the overall health condition, risk of diseases, and life expectancy. In a 2011 case–control study, Tanrikut et al. showed that men with clinical varicocele have significantly lower testosterone levels than those without varicocele. Moreover, the authors showed that testosterone levels increased after microsurgical varicocelectomy regardless of the age of the patient, varicocele grade, and laterality. The authors concluded that varicocele was an independent factor of androgen deficiency and its repair might provide beneficial effects concerning testosterone production [110].

Along the same lines, a 2018 review concluded that varicocelectomy is a real option to improve androgen levels in older hypogonadal males, in particular when one does not desire continuous testosterone therapy and continuous laboratory monitoring [111].

31.10 Oxidative Stress Markers

Infertile men with clinical varicocele have significantly lower sperm production and quality than normal controls and fertile men with varicocele [112]. Such differences are observed not only in the conventional sperm parameters, such as sperm count, motility, and morphology, but also in the novel functional markers for oxidative stress and DNA integrity.

Seminal plasma total antioxidant capacity (TAC) and sperm mitochondrial activity are decreased [27, 113, 114], while the frequency of sperm exhibiting abnormal DNA integrity and chromatin immaturity is increased [113, 115] in ejaculates of infertile men with varicocele. Although elevation of scrotal temperature is seen in both fertile and infertile men with varicocele, an increase of oxidative stress (OS) is only observed in the latter, thus indicating that a disturbance of the OS scavenging system is likely to play a significant role in the pathophysiology of varicocele-associated infertility [27, 116].

Novel noninvasive contrast imaging has shown that intratesticular microcirculation perfusion, which is altered in men with clinical varicocele, affects spermatogenesis [117]. Molecular biology studies show that high cadmium content and hypoxic conditions induce overexpression of metallothionein, a metal-binding protein that protects against cell apoptosis, in internal spermatic veins of infertile men with clinical varicocele [118]. Ichioka et al. determined the distribution of antioxidant enzyme gene genotypes in infertile men with varicocele. Their preliminary data suggest that genetic polymorphisms in the glutathione S-transferase T1 gene may affect individual response to varicocelectomy [119].

When clinically palpable varicocele coexists with impaired semen quality, surgical repair is the best treatment option. Varicocele repair can improve spermatogenesis and fertility, and it offers better cost-effectiveness as compared to ART [120]. Several meta-analyses demonstrated a beneficial effect of varicocelectomy on the fertility status of infertile men with clinical varicocele [112, 120–122]. Agarwal et al. examined the effect of varicocelectomy on semen parameters and demonstrated that sperm concentration increased by 9.7 million/mL (95% CI 7.34–12.08, $p < 0.001$), sperm motility increased by 9.9% (95% CI 4.90–14.95, $p < 0.001$), and WHO sperm morphology increased by 3.1% (95% CI 0.72–5.60, $p = 0.01$) after varicocelectomy [112]. Ficarra et al. reviewed randomized clinical trials for varicocele repair and found a significant increase in the pregnancy rates for patients who underwent varicocele treatment (36.4%) compared to ones having no treatment (20%) [121].

Similarly, Marmar et al. reported a significantly higher pregnancy rate (33%) after varicocelectomy compared to the group of patients having no surgery (15.5%) [122]. In their

study, the chances of obtaining a natural conception were 2.8 times higher in the varicocelectomy group as compared to the group of patients who received either no treatment or medication. Additional studies demonstrated that markers of sperm function were also significantly improved after varicocele repair [123–128]. It has been reported that seminal oxidative stress may be attenuated by varicocelectomy in infertile men with varicocele, but this beneficial effect is not always associated with an improvement in the conventional sperm parameters [124–126]. Sperm DNA integrity is also increased six months after repair in infertile men with clinically palpable varicocele [126, 128]. Smit et al. reported a decrease in sperm DNA fragmentation (SDF) after varicocelectomy and an association between DNA fragmentation index and the ability to conceive either naturally or via assisted reproduction [127].

In the last ten years, many studies investigated the role of varicocele repair to improve sperm chromatin integrity. A 2012 meta-analysis concluded that varicocelectomy alleviates sperm DNA fragmentation [129]. In a recent prospective controlled study, Aahathal et al. recruited 29 infertile men with abnormal seminal parameters, high DNA fragmentation index, and clinical varicocele. All of them underwent microsurgical varicocelectomy. The control group comprised of six normozoospermic healthy fertile men. The authors found that the surgical repair was associated with a significant decrease in sperm DNA fragmentation index, supporting the hypothesis that varicocelectomy improves spermatogenesis and reduces oxidative stress [130].

Recently, in 2018, we performed a recent systematic review to summarize the existing evidence concerning the role of varicocelectomy on sperm DNA fragmentation (SDF) [131]. We concluded that repair of clinical varicoceles was unequivocally associated with reduction of SDF. Among the studies evaluating pregnancy rates, partners of couples achieving pregnancy had lower SDF than counterparts who remained childless.

31.11 Varicocelectomy, ICSI, or Both?

Even though natural pregnancy remains the litmus test for evaluating varicocele treatment success, many patients with varicocele-related infertility will require ART due to the severity of sperm abnormalities and/or the presence of a significant problem affecting the female partner. The indication of varicocele repair before IVF/ICSI is still unusual, but increasing evidence indicates that varicocele repair before ART might be beneficial in selected case scenarios.

Varicocele repair in men with non-obstructive azoospermia with favorable testicular histopathology might help to increase the likelihood of finding sperm in ejaculates [94]. Although small sperm numbers are usually seen after varicocele repair in this case scenario, presence of sperm in the ejaculate allows the possibility of IVF/ICSI without the need for surgical sperm retrieval (SR). Moreover, SR success in patients who remain azoospermic after varicocelectomy increases, and as a result, the couple's chance of having a baby increases as well [98].

Varicocelectomy also has the potential to obviate the need for ART or to downstage the level of ART needed to bypass male factor infertility [123]. Esteves et al. showed that surgical treatment of clinical varicoceles might also improve the outcomes of assisted reproduction in couples with varicocele-related infertility [131]. The authors enrolled 242 infertile men with treated and untreated clinical varicoceles who underwent intracytoplasmic sperm injection (ICSI) and found significantly higher live birth rates after ICSI in the group of men who underwent microsurgical varicocele repair before ART (46.2%) as compared to the ones undergoing ICSI in the presence of a clinical varicocele (31.4%). In this study, the chances of achieving a live birth (odds ratio = 1.87; 95% CI 1.08–3.25; $p = 0.03$) by ICSI were increased, while the chance of miscarriage occurrence after obtaining a pregnancy by ICSI was reduced (odds ratio = 0.433; 95% CI 0.22–0.84; $p = 0.01$) if the varicocele had been treated before assisted conception.

A 2017 recent review clarified the role of varicocelectomy before ART. The authors concluded that varicocele repair could improve spermatogenesis and, therefore, decrease the complexity of the method of assisted conception needed to achieve a pregnancy [132].

31.12 Future Diagnostic Approach

Although the varicocele onset begins at puberty, the disease is rarely diagnosed at this stage. The reasons stem for the lack of awareness and the uncommon visit of the adolescent to the urological office.

Notwithstanding, varicocele is a time-progressive disease; thus, the sooner the diagnosis, the better the outcome concerning treatment to restore fertility and androgen production.

As far as the adolescent varicocele population is concerned, it is well known that just a small part of these individuals will show deterioration of their fertility potential in adulthood. Thus, it would be ideal to identify which adolescents benefitted from early surgical treatment. In this population, a semen analysis is not a reliable test for the evaluation of the varicocele detrimental effect because the hypothalamic-pituitary-testicular axis is still immature. Moreover, the current clinical criteria for recommending surgery based on testicular growth retardation are suboptimal, since these findings relate to an already inflicted testicular damage [133–135].

Since 2010, researchers have been focused on studying the seminal proteomic approach of adolescents and adults with varicocele. Indeed, both sperm and seminal plasma are rich in proteins [136, 137].

Proteomics is a new field of study that aims to analyze globally the set of proteins expressed in a cell or tissue, i.e., the proteome. Protein expression is dynamic and can vary according to the conditions that the environment imposes at a given moment. Therefore, the study of proteins can generate critical information, including the understanding of which proteins are expressed, their levels of expression, when they are produced, and the responses expressed by the cells in different situations or treatments. The study of the proteome represents a way to evaluate protein functions and to investigate metabolic processes to better understand the functioning of a cell or tissue at the molecular level [138–140].

The search for a protein marker in the seminal plasma, an early indicator of impairment to spermatogenesis, could make possible to recommend varicocele repair before it inflicts damage to testicular function as a whole and spermatogenesis in particular. The discovery of specific biological protein marker might be used as a routine during the workup of adolescents and adults with varicocele to understand better who are at higher risk of infertility, thus allowing better clinical management [141, 142].

31.13 Conclusions

Varicocele is a common disease affecting males with fertility issues. The central pathophysiology mechanism of varicocele-related infertility involves excessive oxidative stress, which impairs sperm quality and quantity through a variety of nonexclusive mechanisms. The diagnosis of varicocele mainly relies on the physical examination since improvements in fertility endpoints after varicocele treatment are typically seen only among men with clinically palpable varicoceles. Among treatment modalities, microsurgical varicocele repair is the method of choice due to the achievement of better sperm quantity/quality with fewer complications. Varicocele repair has been recommended to selected men with non-azoospermia and before assisted reproductive technology (ART) to increase success rates of sperm retrieval and ART outcomes, respectively. Notwithstanding, it is still unknown why many men remain fertile despite a varicocele and why improvement after varicocele repair is not universal. Given the complex nature of varicocele-related infertility, counseling toward lifestyle modifications should be strongly encouraged in addition to varicocele treatment.

Besides fertility, varicocele repair can be offered to men with clinical varicocele and hypogonadism as a means to improve androgen production and potentially avoid testosterone replacement therapy. Emerging tools, including proteomics studies, might help identify the ideal candidates for varicocele treatment.

31.14 Review Criteria

A systematic search using PubMed/Medline, Scielo, EMBASE, and Google Scholar was performed to identify eligible studies. The following terms and descriptors were used: "varicocele," "microsurgery," "oxidative stress," "sperm DNA fragmentation," "adolescents," "testosterone," "proteomics," "infertility," "azoospermia," "subclinical varicocele," "varicocele repair," and "varicocele treatment." We also carried out a search using the PubMed Search Builder for the following words: "varicocele/surgery," "varicocele/diagnosis," and "varicocele/classification." The newest and more relevant studies were used to update our chapter for the second edition of this textbook.

Acknowledgments The authors are indebted to Mrs. Fabiola Bento for her editorial assistance and text revision.

Infection in Infertility

32

Ralf Henkel

Key Points

- Male infertility is a major issue of concern as it affects more people during their lifetime as a common disease, diabetes mellitus.
- Among these infertile men, the prevalence of male genital tract infection is reportedly between 20% and 40%.
- Many pathogens, including bacteria, protozoa and viruses, are sexually transmitted and require treatment of the couple.
- Among the sexually transmitted bacteria, infections with *C. trachomatis* and mycoplasms are most prevalent, while *E. coli* causes the most prevalent non-sexually transmitted male genital tract infection.
- Among the viral infections, mumps and HIV infections are the most important as mumps can cause permanent infertility due to mumps orchitis and HIV can be carried by spermatozoa from the testis or epididymis.

32.1 Introduction

Globally, due to population growth, the absolute numbers of couples suffering from infertility has increased from about 42 million in 1990 to 48–50 million in 2010 [1], which is an estimated 15% of couples. The male partners are solely responsible for the infertility in 20–30% of the cases with an overall contribution of 50% [2]. Although the percentages of primary and secondary infertility did not change in most parts of the world [1], infertility has to be regarded as a serious global health issue. On the other hand, human fecundity is reportedly declining in both developed and developing countries [3–5]. Reasons for this remarkable decline are manifold and include socio-economic changes [4], changes in lifestyle with higher prevalence of obesity [6, 7] or environmental pollution [8]. In general, data on the prevalence of infertility, i.e. the inability of a sexually active, non-contracepting couple to achieve pregnancy within 1 year's time [9], vary considerably between 3% and 25%, of which 15% seek for medical assistance [10, 11]. Infertility is a couple problem as both male and female partner contribute more or less equally, with prevalence reported for male infertility between 30% and 50% [12]. Approximately 7% of all men are confronted with fertility problems during their reproductive lifetime, thus making male infertility a problem, which has an even higher prevalence than diabetes mellitus with an overall estimate of 2.8% in the year 2000 and 4.4% in 2030, and which is considered a common disease [13, 14].

However, according to Article 16 (1) of the United Nations Universal Declaration of Human Rights, 'Men and women of full age, without any limitation due to race, nationality or religion have the right to marry and found a family' [15] enshrines the human right of healthy reproduction. In turn, this requires clinicians and scientists to find solutions to this increasing problem. Potentially correctable causes of male infertility are genital tract infections [16], which play a major role in male infertility. Infections and inflammations are not only seriously affecting spermatogenesis and sperm transit during ejaculation as can be seen in clinical findings in cases of oligozoospermia, asthenozoospermia or azoospermia [17, 18] but also the cause of dysfunctional male accessory glands [16] and significantly impaired sperm functions [19, 20]. These changes can be triggered in various ways, namely direct action of the pathogens on spermatozoa and sperm functions [21] or indirectly by inducing inflammatory processes in the seminal tract by activating leukocytes [22]. Globally, the prevalence of male genital tract infection-related infertility varies between 10% and 20% in non-selected cases and amounts up to 35% in a large study comprising more than 4000 patients consulting for infertility

Table 32.1 Diagnostic methods of several pathogens. A variety of different diagnostic methods are generally available. However, some of the laboratory methods are challenging and a general lack of standardization can be noticed

Pathogen	Diagnostic methods	References
Chlamydia trachomatis	Clinical presentation of symptoms *C. trachomatis* culture with immune-fluorescent staining of reticulate bodies	
	PCR amplification of bacterial rDNA in semen	[25, 26]
	Nucleic acid hybridization tests	[27]
Mycoplasma hominis	Real-time PCR	[28]
M. genitalium	PCR	[29–32]
Ureaplasma urealyticum	Standard semen culture PCR should be the diagnostic method of choice	[26]
U. parvum	Standard semen culture, PCR	
Neisseria gonorrhoeae	Clinical presentation Gonococcal culture	[33, 34]
	Nucleic acid hybridization tests	[27]
Escherichia coli		
Viruses	Clinical presentation of symptoms	
CMV	PCR	[35]
HSV	PCR	[36]
HIV	PCR	
Protozoa *Trichomonas vaginalis*	PCR	[37]
Treponema pallidum *Trypanosoma brucei* *T. cruzi*	PCR	[38]
Schistosoma spp.	Serological tests	[39]
	PCR	[40]

[23]. It also appears that bacterial infections have a more detrimental effect in fertility-compromised patients than in fertile men [24], indicating that the impact of such bacterial genital tract infections may have to be differentiated.

From a diagnostic point of view, a number of techniques including the microscopic, molecular and serological tests are available. However, these laboratory methods are sometimes challenging and lack standardization (Table 32.1).

32.2 Pathogens Causing Male Genital Tract Infections

Male urogenital tract infections can be classified according to the kind of microorganism causing the infection and the location, namely the testis (orchitis), epididymis (epididymitis), prostate (prostatitis) or urethra (urethritis). These pathogens can be bacteria, viruses, protozoa or even parasites. The most prevalent bacterial pathogens are *Chlamydia trachomatis*, *Ureaplasma urealyticum*, *Neisseria gonorrhoeae*, *Mycoplasma hominis*, *Mycoplasma genitalium* or *Escherichia coli* [41]. While the former bacterial pathogens are sexually transmitted, *E. coli* is regarded as the most common cause of non-sexually transmitted urogenital tract infection, particularly of epididymo-orchitis or prostatitis where it is the cause of 65–80% of the cases [42]. Furthermore, viral infections like mumps virus, human papillomavirus (HPV), herpes simplex virus (HSV) and particularly human immunodeficiency virus (HIV) have also been associated with increased seminal leukocyte concentrations [43]. The latter virus can infect the testes and male sex accessory glands [44]. With the recent outbreak of Zika virus infections in French Polynesia in 2013 and in Brazil in 2015, a new threat for human reproduction has emerged [45].

The pathological mechanisms involved in these infections include not only the attraction of leukocytes but also the release of toxic substances. All of these increase the release of reactive oxygen species (ROS) and thus oxidative stress in the whole body including the male reproductive system. Consequently, spermatogenesis and sperm functions are compromised leading to sub- or infertility (Fig. 32.1).

32.3 *Chlamydia trachomatis*

C. trachomatis is a Gram-negative bacterium that is worldwide one of the most frequently sexually transmitted bacterial pathogens, accounting for an estimated 92 million new urogenital infections per year [47]. This number may be underestimated because of the high asymptomatic nature of the pathogen, with approximately 70–80% of women and up to 50% of men infected being asymptomatic [48]. Yet, in males, this infection can become even more symptomatic than in females [49]. Reportedly, in symptomatic men, the prevalence of infections varies from 4% to 10% [50]. Another report found a prevalence of up to 35.9% in men and 38% in women [51]. Since a high number of chlamydial infections remain undiagnosed, the pathogen can even be transferred to the newborn during delivery accounting for 25–50% of conjunctivitis and 10–20% of pneumonia in newborns, thus posing a health risk on the offspring as well as enormous costs for diagnosis and treatment on countries' health systems. For the United States, these costs estimate to $2.2 million for each 500 cases [48].

In men, *C. trachomatis* has been associated with prostatitis, epididymitis and urethritis. The bacterium has been detected in the testis including Leydig cells [52], the prostate [53] and even epididymis and seminal vesicles [54]. Apart from the lesions triggered by the infection and the implications and acute inflammation can cause in the male genital

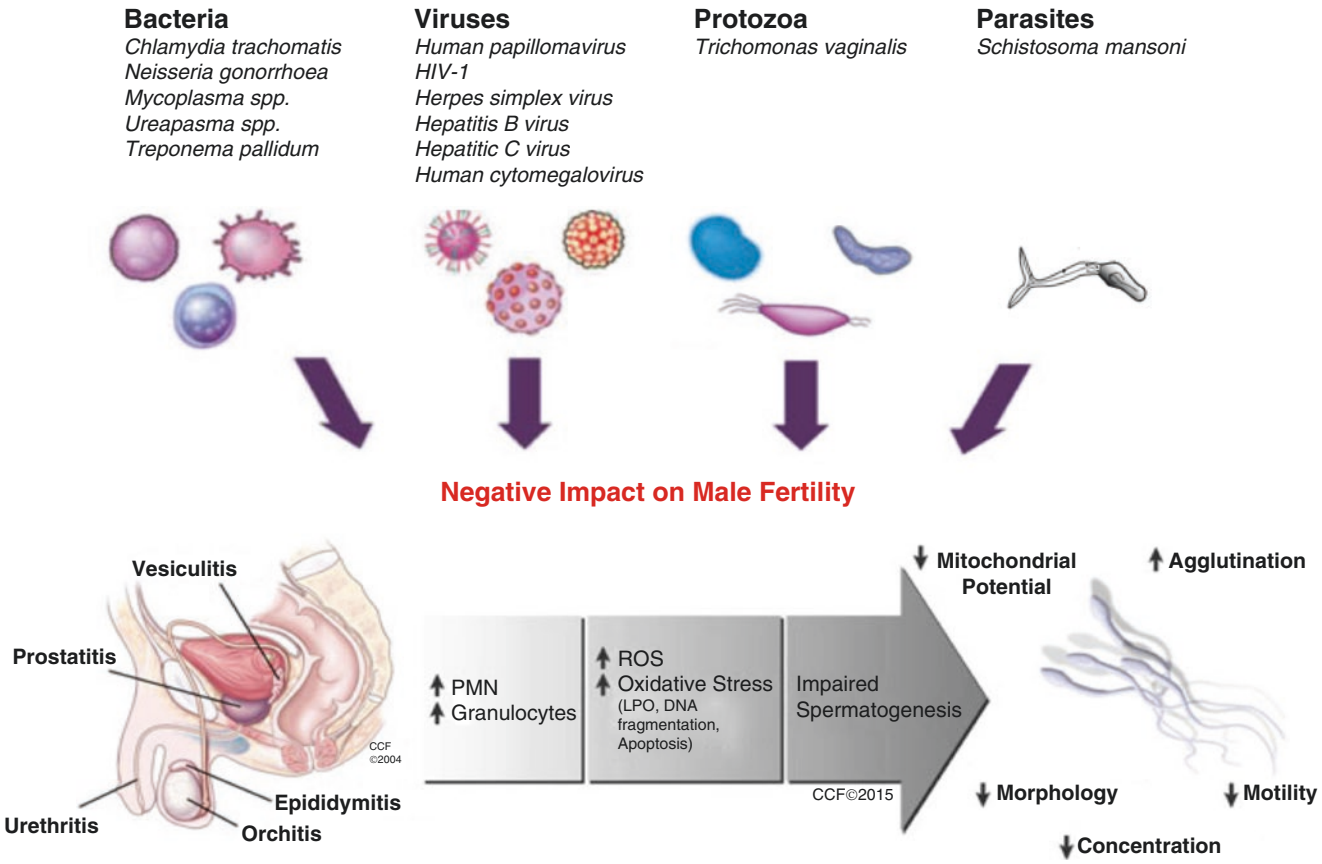

Fig. 32.1 Impact of various pathogens on male reproductive functions leading to low sperm count, motility and compromised sperm functions. (Adapted from Ref. [46] with permission from Springer Nature)

tract, reports on the influence of chlamydial infections on male fertility are inconsistent. While some authors [55, 56] found no significant association, most others have shown a direct negative influence of the chlamydial infection on male fertility [53, 57, 58]. The direct effect on sperm parameters such as sperm concentration, viability, normal sperm morphology and motility is also controversially reported with most studies showing clear negative effects [59–62]. Even acrosome reaction appears to be negatively affected in *Chlamydia*-infected males [63, 64].

In vitro studies by Hosseinzadeh et al. [65–67] even indicate that the pathogen directly causes changes in sperm proteins and premature cell death induced by lipopolysaccharides (LPS) secreted by Chlamydiae. These LPS can bind to the 54 kD CD14 glycolipid-anchored receptor which is implicated in the regulation of T- and B-cell activation and function [68]. LPS are also reported to trigger ROS production, which, in turn, cause a decrease in sperm motility [69].

The discrepancies in findings may be due to the fact that in numerous cases, chlamydial infections are accompanied by other microbial infections making a clear association of infertility with the chlamydial infection difficult [70]. Besides, the duration of the infection can also influence the results of the studies; the method by which the infection is detected might also be important [64] as various detection methods for the pathogen in asymptomatic cases appear challenging, and especially the sensitivity and specificity of serological markers were regarded as problematic [48]. For that reason, recent studies suggest polymerase chain reaction (PCR) amplification of bacterial rDNA in semen as this approach seems to be promising especially to identify asymptomatic patients [25, 71].

32.4 Mycoplasms

Mycoplasms and ureaplasms belong to the family of *Mycoplasmataceae*, which are widely distributed in vertebrate species. They are the smallest bacteria replicating in culture and are lacking a cell wall [72, 73]. Five species colonize the male urogenital tract and may contaminate the semen during ejaculation, namely *Ureaplasma urealyticum*, *U. parvum*, *Mycoplasma hominis*, *M. genitalium* and *M. fermentans*, of which only the first four are pathogenic.

32.5 *Ureaplasma urealyticum, U. parvum*

Both these microorganisms normally colonize the male urethra and contaminate ejaculates during the ejaculation [74]. Although both *U. urealyticum* and *U. parvum* are pathogenic species, it is particularly *U. urealyticum* that is reported to cause non-gonococcal urethritis, pelvic inflammatory disease or infertility [16, 75, 76]. Incidences of infection between the two pathogens vary considerably between 5% and 42% for *U. urealyticum* [77] and 2.9% for *U. parvum* in a Tunisian population [51]. There is no difference in the effect of the infections by either *U. urealyticum* or *U. parvum* on seminal parameters such as volume, pH, sperm concentration or motility [51]. Yet, in preparation for assisted reproduction in the embryology lab care must be taken with the sperm separation since simple washing of sperm does not entirely remove these bacteria from the sperm suspension [78].

In the past, the association between ureaplasma infections and male infertility was discussed controversially [79, 80]. In a recent large study including 346 selected subjects, Wang et al. [81] showed that ureaplasma infections cause higher seminal viscosity, decreased sperm concentrations and lower pH. Although this study could not find any further effect on other sperm parameters, Potts et al. [80] found significantly increased seminal reactive oxygen species (ROS) levels and Reichart et al. [82] higher levels of sperm DNA damage. These discrepancies might be due to the fact that *U. urealyticum* shows a distinct energy metabolism-dependent effect on sperm activity [83]. According to this theory, sperm motility is impaired by the bacterium at low pH since it competes with sperm mitochondrial energy production. On the other hand, at higher pH, sperm motility will even be enhanced as ureaplasma stimulates glycolysis.

The prevalence of male genital ureaplasma infections among infertile men varies considerably from 10% to 40% [84], most probably as a result of different diagnostic methods used in various studies and different population groups examined. Like in patients with chlamydial infections, detection of *U. urealyticum* and mycoplasms is particularly problematic in asymptomatic patients because these patients may shed fewer colony-forming units (CFU; organisms) to be detected in a standard culture assay. Therefore, PCR should be the diagnostic method of choice [26].

32.6 *Mycoplasma hominis, M. genitalium*

Although the direct impact of these two bacteria on male fertility was debated in earlier years, recent reports associate *Mycoplasma hominis* and *M. genitalium* with genitourinary infections and infertility [85, 86]. Nevertheless, it appears that the pathological mechanism is elusive [87]. Reportedly, frequencies of infection are with 10.8% for *M. hominis* and 5% for *M. genitalium*, respectively, lower than for other pathogens [76]. However, for patients presenting with recurrent urethritis, *M. genitalium* seems to be with 19–41% the predominant pathogen [88]. Both species can attach to and penetrate human sperm plasma membrane [89, 90], which might have a significant long-term impact on male fertility on the onset of pregnancy and the health of the offspring. In the case of *M. hominis*, this could be due to dysfunctional spermatozoa [77]. While the first may contribute to the distribution of the bacterium to the female to cause cervicitis and endometritis [91] or an alteration of the plasma membrane affecting acrosome reaction [92], the latter might particularly be caused by the sperm DNA damage triggered by the infection [57].

32.7 *Neisseria gonorrhoeae*

These Gram-negative, immotile cocci grow in pairs (diplococci) and cause one of the most common infectious diseases in men leading to urethritis, prostatitis and epididymitis which in turn may impair male fertility. These bacteria have pili on their surface, which facilitate attachment to other cells [93]. In sperm, an asialoglycoprotein receptor has been identified that recognizes and binds lipopolysaccharides in gonococcal membranes [94]. Since chlamydial lipopolysaccharides can cause death of human sperm by inducing apoptosis [95], it is conceivable that Neisseria lipopolysaccharides might also induce such reactions. Yet, this has not been shown thus far.

Even though its incidence has been declining in Western countries during the past decades, 150–400 new infections per 100,000 are still recorded in Europe per year [93]. Presumably, due to socio-economic and behavioural factors, these numbers are much higher in Third World and developing countries, with highest numbers in Sub-Saharan Africa and South and Southeast Asia [96]. Imudia et al. [97] found a prevalence of 0.4% for *N. gonorrhoeae* infections in women presenting for infertility treatment. Considering that this pathogen is sexually transmitted, one can assume that the prevalence in the male partners would be similar. However, according to a newer study by Abusarah and co-workers [77], the prevalence of *N. gonorrhoeae* infections is about 6.5% in infertile men while no infection was diagnosed.

32.8 *Escherichia coli*

E. coli is a Gram-negative bacterium that belongs to the family of *Enterobacteriaceae* and is responsible for most urogenital tract and male accessory gland infections between 65% and 80% of type I and type II prostatitis [98] with patients presenting with type II prostatitis having signifi-

cantly lower sperm vitality and total and progressively motility, while seminal volume and sperm concentration were not affected [99]. In contrast to other uropathogens like *Enterococcus* or *Staphylococcus saprophyticus*, *E. coli* has significant direct negative effects on sperm motility [100]. An in vitro study by Köhn et al. [92] revealed that this microbe can even negatively affect sperm functions like acrosome reaction. This might be due to morphological alterations, particularly on the acrosome and flagellum, seen after exposure of human sperm to the pathogen [101]. Studies by Fraczek et al. [102, 103] show that in patients with seminal bacterial contamination (*E. coli*, *Bacteroides ureolyticus*), not only the sperm membrane stability may be compromised but also mitochondrial membrane potential and sperm DNA integrity [104]. Since the latter effect is even more pronounced in sperm fractions after density gradient centrifugation, inflammatory mediators might be directly responsible for the damage [103]. Another reason for the impaired fertility may be an epididymal obstruction [105] caused by uropathogenic *E. coli* [106].

Due to the direct interaction of bacterial pili with the sperm plasma membrane [107], *E. coli* is interfering with sperm motility [108]. A study by Schulz and co-workers [109] demonstrated two mechanisms by which *E. coli* affects spermatozoa, the described direct interaction and by action of soluble factors that induce apoptosis and a breakdown in the mitochondrial membrane potential. Potential candidate substances causing these cellular reactions might be α-haemolysin and Shiga-like toxin as these have already been associated with sperm motility loss [110] and apoptosis in Hep-2 cells [111], respectively. In a mouse model, Kaur and Prabha [112] found that sperm-agglutinating *E. coli* rendered infected females infertile.

32.9 Viruses

A number of viruses are also able to infect all parts of the male genital system, namely the testes (e.g. mumps virus, HIV-1), epididymis (e.g. Coxsackie virus), seminal vesicle (e.g. cytomegalovirus [CMV]), prostate (e.g. HPV, HSV, HIV-1) and the semen (e.g. HSV, HPV, HIV) [113]. In a recent study including 241 asymptomatic patients attending an infertility clinic for semen analysis, viral DNA was detected in 45 patients: CMV (8.7%), HPV (4.5%), HHV-6 (3.7%), HSV (3.6%), Epstein–Barr virus (0.4%) and hepatitis B virus (0.0%) [114]. Recently, another viral infection made headlines as it not only replicates and persists in the male reproductive tract but was also detected in semen 6 months after the infection: the Zika virus [115, 116].

While some of the viral infections like HSV or HIV-1 are associated with poor semen and sperm quality [43, 117], this could not be confirmed for CMV and human herpes virus type 6 (HHV6) [114]. Thus, the latter viruses appear not to cause male infertility. However, in patients with viral infections affecting male fertility, leukocytospermia (>1 × 10^6 leukocytes/ml ejaculate) is strongly associated with the infection as well as with elevated levels of inflammatory markers like polymorphonuclear (PMN)-elastase or interleukins [114].

A matter of concern is the high number of globally more than 65 million people infected with HIV, out of which a growing number of HIV-positive people are seeking for assisted reproduction to have children without infecting the partner or the offspring. Since a few years, some IVF centres started treating infected couples and received acceptable pregnancy rates, the worst in couples where both partners were infected [118]. In these patients, not only the risk of vertical transmission from a seropositive mother to her unborn child has to be dealt with but also the fact that semen is a vector of viral propagation and sperm can bind and incorporate the virus via a CD4-independent receptor and/or the HIV co-receptor CCR5 [119, 120]. Despite it being generally accepted that motile sperm are not productively infected by HIV, sperm can carry viral particles deriving from the testis or epididymis [121, 122]. In view of the fact that seminal leukocytes shed different viral strains than those in the blood [123], the question rises whether infected leukocytes and free virions contaminating the semen are of different origin, and an infected testis might represent a special reservoir for the virus as this area is resistant to antiviral drugs due to the blood–testis barrier [122]. Therefore, special care must be taken when separating sperm for assisted reproduction, particularly for intracytoplasmic sperm injection (ICSI).

Studies on Zika infections confirm the risks of replication in the male reproductive system [124]. Most Zika virus patients remain asymptomatic; however, patients can suffer from fever, myalgia, arthralgia and conjunctivitis [125]. Although the disease is benign in most cases, death was reported in chronically sick patients, and its implications should not be underestimated [126]. The virus causes testicular damage, testicular inflammation and epididymitis in a male mouse model [127, 128]. In pregnant women, congenital microcephaly and Guillain–Barre syndrome (GBS) have been reported in the offspring [129, 130].

Transmission of this virus occurs mostly via mosquitoes, especially *Aedes aegypti* and *Aedes albopictus*. However, sexual [131, 132] and perinatal [133] transmissions have also been observed. Recently, Zika virus has been detected in the amniotic fluid and umbilical cord blood after conception by in vitro fertilization [134]. However, additional testing for Zika before assisted reproduction does not exclude the risk of getting infected during pregnancy. One also has to consider that the risk of getting infected is high, but the risk of microcephaly in the offspring would not be higher than the risk of a miscarriage or birth defects due to other pathogens [135].

32.10 Protozoa

The most common non-viral sexually transmitted disease is trichomoniasis. *Trichomonas vaginalis*, a motile flagellated non-invasive parasitic protozoon, infects about 248 million people every year [136]. Despite this high number of new annual infections, trichomoniasis is only poorly studied with respect to its virulence properties, pathogenesis and immunopathogenesis [137]. *T. vaginalis* is regarded as a relatively rare cause of male infertility [138] with cohort-dependent prevalences between 0.009% and 38.8% [139]. In the male, the protozoon inhabits the urethra, epididymis and the prostate and is regarded a major cause of prostatitis with *T. vaginalis* being the cause in 10.5–19% [140, 141]. The pathogen has also been associated with balanoposthitis, epididymo-orchitis and non-gonococcal urethritis [142]. In prostate tissue from patients with benign prostatic hyperplasia, a high detection rate was observed [143]. The interaction of *T. vaginalis* with spermatozoa seems to be direct via adhesion and phagocytosis of sperm [144] as well as via the secretory extracellular polymeric substances from *T. vaginalis*, which significantly decreased motility, viability and functional integrity and thereby decreased fertilization rate in a mouse model [145].

32.11 *Treponema pallidum*

Treponema pallidum is a highly contagious pathogen causing syphilis, and despite relatively cheap antibiotics being available, there is still an excess of 10 million people globally infected with about 30% of the patients developing tertiary syphilis [146]. However, the reasons how the pathogen can evade a patient's immunological response is still not clear [147]. On the one hand, *T. pallidum* has a sufficient amount of lipoproteins to activate macrophages and dendritic cells [148–152]. On the other hand, pathogen-associated molecular patterns are not freely available to Toll-like receptors to activate the host's innate immune system, because these lipoproteins are not readily exposed on the outer surface of the bacterium [147]. The restricted exposure of the pathogen to innate and adaptive immune response is not sufficient to keep the pathogen under control, thus resulting in a substantial number of bacteria evading leukocytotic phagocytosis [147].

Despite *T. pallidum* infecting the male genital system, a direct detrimental effect has not been reported. Nevertheless, numerous complications affecting male fertility are described. Among these, epididymitis, chronic obstructive endarteritis and interstitial inflammation are the most common and can lead to small, fibrotic testicles [153].

32.12 *Trypanosoma spp.*

In this context, two species of trypanosomes are important to mention, *T. brucei*, the pathogen of sleeping sickness, and *T. cruzi*, the pathogen of the Chagas disease, affecting estimates of 70 million and 18 million people, respectively [154, 155].

With respect to male fertility, clinical signs of an infection with *T. brucei* include scrotal dermatitis, orchitis, periorchitis, thrombosis of the pampiniform plexus vessels, degeneration of the seminiferous tubules and testicular degeneration. In addition, studies have shown that trypanosomes can damage the pituitary, thereby affecting the hypothalamus–pituitary–gonadal axis [156] with patients demonstrating pituitary fibrosis being described [157], which, in turn, can lead to significant impairment of spermatogenesis and hypogonadism [155]. Impotence and decreased libido have been reported in 70% and 45.5% of the cases [158].

For *T. cruzi* causing Chagas disease, very little has been published, and it seems that the effects on the male reproductive system are similar to that caused by *T. brucei*. In a study by Lamano Carvalho et al. [159] including 34 patients, 35% presented with oligo- or azoospermia. The same group reported a decrease in Leydig cell numbers [160]. Moreira et al. [161] reported no changes in the LH levels in patients with Chagas disease with testosterone levels being normal in some patients. Yet, individual LH levels in the patient group receiving clomiphene citrate were abnormally scattered suggesting hypothalamic dysfunction similar to that in *T. brucei* infections [162]. More recent reports on *T. cruzi* effects on the reproductive system report rather on female reproduction as the parasite reduces female fertility and induces foetal death in a mouse model [163].

32.13 *Schistosoma spp.*

Another group of parasites that can also cause male infertility is *Schistosoma*, flatworms of the genus of trematodes, which are responsible for schistosomiasis (bilharziasis), a disease, which, following malaria, has devastating socio-economic consequences [164]. Although this disease is affecting globally more than 230 million people [165], not many reports are published on its impact on male fertility. In 1995, a case of a traveller returning from Africa and South America was diagnosed having had a *Schistosoma haematobium* infection in the genital tract with *Schistosoma* ova microscopically demonstrated in the semen [166]. The authors concluded that infertility may develop in cases with Schistosoma infection of the genital organs. Omer [167] reported that 13% of infertile Sudanese men with oligozoo- or azoospermia had a history of schistosomiasis, which is due to testicular infarction with partial or complete occlusion

of the spermatic venous plexus by the parasites' ova and subsequent granuloma formation [168]. Abdel-Naser et al. [169] report another case of azoospermia due to schistosomiasis.

32.14 Male Genital Tract Infections

32.14.1 Orchitis

As per definition by the European Association of Urology, the term *orchitis* describes an inflammatory lesion of the testicle, which is associated with a leukocytic exudate inside and outside the seminiferous tubules, resulting in tubular damage [17]. The condition can be a reason for spermatogenic arrest and testicular atrophy leading to low seminal sperm concentration and poor sperm quality [17, 170]. An acute infectious orchitis is characterized by an abrupt onset of severe pain with visible swelling of the affected testicle as well as of the inguinal lymph nodes and can be accompanied by fever. Further symptoms are similar to those of testicular torsion and can include haematuria and blood in the ejaculate. Subacute and chronic inflammatory conditions, however, often remain asymptomatic [171]. Yet, an orchitis may lead to intratesticular obstruction, which is the case in about 15% of obstructive azoospermia [17].

In contrast, non-infectious inflammations of the testis may occur in patients with testicular seminoma where predominantly CD8-positive T-lymphocytes infiltrate the tumour tissue, and macrophages are found in the fibrovascular septae and at the periphery [18]. Such infiltration of activated T-lymphocytes into testicular tissue is also indicative of a significant disturbance of the local immunoregulation [172]. Thus, due to an impaired blood–testis barrier, these inflammatory cells overcome the testicular immunosuppressive mechanisms and the formation of anti-sperm autoantibodies under such conditions would be conceivable, particularly in cases of prolonged inflammatory processes as in chronic orchitis [173]. On the other hand, except for a few cases with positive titres for autoantibodies in patients with a mumps history, only little evidence is available for this relationship [174, 175].

As reported in a large study, the prevalence of an isolated orchitis is 0.42% among relatively low testicular pathologies [176]. However, due to retrograde ascending infectious lesions, a 'non-specific' orchitis triggered by *Pneumococcus* spp., *Salmonella* spp., *Klebsiella* spp. or *Haemophilus influenza* is in most cases associated with an epididymitis as epididymo-orchitis. The close vicinity of the different compartments as well as the ascending nature of the infections makes a distinction between inflammations, i.e. isolated epididymitis vs. epididymo-orchitis, very difficult in the clinical routine [173].

Sexually transmitted bacteria like *C. trachomatis* and *N. gonorrhoeae* are the cause of the acute infection in men younger than 35 years, while *E. coli* is the predominant trigger in older men [18]. On the other hand, an orchitis can also occur after haematogenous dissemination of pathogens like the Coxsackie B or the mumps virus [17] as a complication of a systemic viral infection. For instance, the mumps virus may affect the testes (mumps orchitis) in 20–30% [177] and lead to infertility in 13% of the cases with unilateral orchitis and in 30–87% of patients with bilateral orchitis [178, 179]. However, clinicians should realize that an epididymo-orchitis can also develop secondary to the mumps infection, even in the absence of a parotitis [180]. While bacterial infections as described above cause a 'non-specific' orchitis, *Mycobacterium tuberculosis*, *M. leprae*, *Treponema pallidum* or *Brucella* spp. may cause a 'specific', predominantly granulomatous orchitis [17].

32.14.2 Epididymitis

Epididymitis, an inflammation of the epididymis, is a painful, feverish, almost unilateral condition with tender swelling of epididymis and scrotum. Based on the duration of the symptoms, epididymitis may be sub-classified as acute, subacute and chronic. In the latter, symptoms are present for more than 6 weeks. In cases of acute infectious epididymitis, an involvement of the testicle due to ascending canalicular bacterial infections can represent a complication which may occur in up to 60% of affected patients as epididymo-orchitis [181]. Although up to 35% of patients consulting for fertility problems present with male genital tract infections [23, 182], data on the prevalence of epididymitis/epididymo-orchitis vary considerably from 0.29% of all consultations [183] to 20% of all urologic admissions in an US Army setup [184].

As for orchitis, *C. trachomatis* and *N. gonorrhoeae* are the most common cause of epididymitis in sexually active men younger than 35 years. In contrast, Gram-negative *Enterobacteriaceae*, of which *E. coli* is the predominant pathogen, are aetiologically responsible for the disease in older men [16, 181], which are also particularly at risk of having urethral strictures, bladder neck obstruction or benign prostate hyperplasia (BPH) resulting in increased voiding pressure to empty the bladder resulting in a reflux of contaminated urine into the excurrent genital ducts and subsequent infection [185].

Potential risk factors for epididymitis include sexual activity, strenuous activities like lifting heavy goods, bicycle and motorbike riding or extended periods of sitting at job or travelling [186]. Even traumatic events such as accidents or scrotal traumas and iatrogenic injury to the epididymis during surgeries can be a cause of epididymitis.

Major problems for male fertility may arise particularly in patients with epididymitis as this disease appears to have a greater influence on semen quality and male fertility than an infection/inflammation of the prostate or seminal vesicle [187]. In addition, in quite a number of patients, the diagnosis of chronic epididymitis is extremely difficult as these patients do not feel discomfort and their health is not compromised [173]. Due to a *silent* nature of the infection/inflammation, epididymitis will only be diagnosed once these patients appear in an andrological clinic consulting for infertility. Eventually, inflammatory lesions of the epididymis can result in dysfunction of the organ and ultimately in obstructive azoospermia, which is the most common cause for this condition [17].

In patients with an acute epididymitis, a semen analysis is not recommended [17]. In cases of chronic epididymitis, semen parameters may be dramatically affected with lower sperm count, motility and seminal α-glucosidase. In contrary, many patients can present with leukocytospermia, i.e. leukocyte count of more than 1×10^6/ml [188], elevated seminal levels of polymorphonuclear granulocyte elastase and atypically stained sperm flagella [173].

32.14.3 Prostatitis

Despite the numbers of urological consultations for prostatitis outnumbered those for benign prostate hyperplasia or prostate cancer [189], prostatitis has been called 'the third most important disease of the prostate gland' [190]. Epidemiological studies revealed an estimated prevalence of 4–11% for prostatitis, which then represents the most common urological diagnosis in men younger than 50 years [191]. A large study with more than 600 men included suggests that only about 5–10% of these cases are of bacterial origin [192]. Yet, more recently, Bjerklund Johansen et al. [193] and Nickel et al. [194] showed that only about 50% of all patients with chronic prostatitis (bacterial and abacterial) respond positively to antibiotic treatment.

According to the classification system suggested by Drach et al. [195], prostatitis was divided into four clinical syndromes, namely, acute, chronic bacterial and chronic abacterial prostatitis and prostatodynia. Considering that this system was never validated and left clinicians confused about diagnostic and therapeutic strategies, particularly since many cases without infection have pathogenic processes outside the prostate, the National Institutes of Health (NIH) introduced a new system classifying prostatitis [196, 197] (Table 32.2). Even though many clinicians diagnose 'prostatitis', it rather represents diverse clinical symptoms ranging from acute bacterial infection to chronic pelvic pain and should actually be referred to as 'prostatitis syndrome' as patients present with a variety of urogenital, perineal and perianal complaints [190, 198].

Table 32.2 NIH classification and definition of the categories of prostatitis

NIH classification		Definition
Category I	Acute bacterial prostatitis	Acute infection of the prostate gland
Category II	Chronic bacterial prostatitis	Recurrent infection of the prostate
Category III	Chronic abacterial prostatitis/CPPS	No demonstrable infection
Category IIIA	Inflammatory CPPS	White blood cells in semen/EPS/voided bladder urine-3 (VB-3 or postprostatic massage)
Category IIIB	Non-inflammatory CPPS	No white blood cells in semen/EPS/VB-3
Category IV	Asymptomatic inflammatory prostatitis	No subjective symptoms detected either by prostate biopsy or the presence of white blood cells in EPS/semen during evaluation for other disorders

Considering the various problems around understanding prostatitis and its diagnosis [199], particularly chronic bacterial prostatitis, it is obvious that the diagnosis of an acute infection does not pose a problem for urologists. The symptoms for the acute bacterial prostatitis are quite clear; the patients are presenting with an urosepsis, fever, obstructive voiding symptoms and local pelvic pain [200]. In about 80% of acute bacterial prostatitis, *E. coli* can be identified as pathogen, while *Pseudomonas aeruginosa*, *Klebsiella* or Enterococci are the cause in the remaining patients [201]. In cases of chronic prostatitis, *C. trachomatis* (19.3%), *T. vaginalis* (10.2%), *E. coli* (8.1%) and Enterococcus (6.1%) were the cause of the disease in the majority of the cases where bacterial contamination could be detected. Other pathogens were *U. urealyticum, Proteus mirabilis, Streptococcus agalactiae, Klebsiella pneumonia* and *Pseudomonas aruginosa*, while in 42.3% of the case no pathogen was detected [202].

Nevertheless, there are major concerns differentiating the category II from category III prostatitis. Many of these patients have a history of recurrent urinary tract infections and are asymptomatic in non-infectious intervals. If the bacterial culture is positive for an established uropathogen like *E. coli* or *Klebsiella* spp., the diagnosis is unproblematic [196] (Table 32.3). However, the classic classification scheme might fail in cases where enterococci or anaerobes are identified in prostate specimens. Even more so in patients who had initially positive cultures but are negative at the time of recurrent symptoms. Apparently, in these cases, the detection is false negative because the bacterial colonization of the prostate can be veiled as bacteria can form microcolonies or aggregates, which are surrounded by a thick protective layer [196, 202].

Table 32.3 Uropathogens causing chronic prostatitis

Established pathogens	Potential pathogens
Escherichia coli	*Staphylococcus saprophyticus*
Klebsiella pneumonia	*Staphylococcus aureus*
Proteus mirabilis	*Staphylococcus epidermidis*
Pseudomonas aeruginosa	*Mycoplasma genitalium*
Enterococcus faecalis	*Ureaplasma urealyticum*
Chlamydia trachomatis	
Trichomonas vaginalis	

Based on data from Ref. [203]

32.14.4 Urethritis

Urethritis is the infectious or non-infectious inflammation of the urethra. While non-infectious causes include injuries through traumas, masturbation, manipulation by the patient or medical treatments, acute infectious urethritis may be caused by known sexually transmitted uropathogens like *C. trachomatis*, *Mycoplasms* or *N. gonorrhoeae* with incidences of 15–26%, 10–21% and 0.4–18%, respectively. In addition, among the not sexually transmitted pathogens, *Enterobacteriaceae* and staphylococci are causing the disease with frequencies between 20% and 31% [204]. Chronic urethritis is a rare condition, which is why the prevalence is not known [205].

The clinical symptoms of an acute urethritis vary considerably. While some patients present with distinct urethral discharge and dysuria, others are symptom-free or only show some pus prior to the first voiding of urine in the morning, which may be occur in 5–10% of the patients. As can be seen for the symptoms, clinical findings also vary from inflammatory stickiness, redness and swelling at the glans penis or the urethral orifice to the absence of any clinical sign. Normally, the infection remains localized to the urethra. However, ascension of gonococci may occur in about 1% of the infected patients causing epididymitis [204].

The impact of urethritis on male fertility is debatable, particularly since the inflammatory discharge present in the anterior urethra makes an ejaculate analysis impossible as the pus contaminates the ejaculate [206] and both direct effect of bacteria [20, 67, 109, 207] and leukocytes [69, 208] demonstrated detrimental effects on sperm functions. On the other hand, obstruction due to urethral stricture or as a result of lesions in the area of the seminal colliculus may result in ejaculatory disturbances [17].

32.15 Male Accessory Gland Infection

According to definition, the male accessory glands comprise the prostate, seminal vesicles and the Cowper's glands (bulbourethral glands). However, in many publications, the term *male accessory gland infection* (MAGI) describes the clinical symptoms of the inflammation as a result of canalicularily ascending infections of the male accessory glands including the deferent duct and the epididymis via the urethra as 'prostate-seminal vesiculitis', 'epididymo-prostato-vesiculitis' or 'male adnexitis' as long as urethritis or a urinary tract infection has been excluded [209]. Considering that in MAGI these organs are commonly inflamed, clear distinctions between prostatitis, epididymitis and glandulitis vesiculitis cannot be made [93]. General symptoms of MAGI are leukocytospermia (more than 10^6 peroxidase-positive leukocytes/ml), elevated seminal levels of polymorphonuclear granulocyte elastase (≥230 ng/ml), C3c complement (≥0.01 mg/ml), ROS and cytokines [210–212].

As a result of the leukocyte infiltration due to the infection as well as the elevated concentrations of pro-inflammatory cytokines like interleukin-6 (IL-6), IL-8 or tumour necrosis factor-α (TNF-α) into the genital system, sperm functions may be compromised by directly affecting sperm function and intensifying the level of oxidative stress, respectively [208, 213, 214]. As a result of the inflammatory processes in the male accessory glands, their secretory function may be impaired, consequently resulting in decreased seminal concentrations of citric acid, fructose, α-glucosidase, phosphatase and zinc [93, 215, 216].

In addition, there are concerns that patients presenting with MAGI are at a higher risk of developing sperm autoantibodies due to the inflammatory processes compromising the immune barrier [217, 218]. Furthermore, like in orchitis or epididymitis, stenosis or obstruction of the excurrent ducts may occur.

32.16 Consequences of Infections on Sperm Fertilizing Capacity

Apart from the specific effects on male fertility described above, male genital tract infections and inflammations cause general reactions that also negatively affect sperm fertilizing capacity by compromising specific sperm functions. In the light of spermatozoa being the most polarized cells in the body, the male germ cell has to maintain its extreme polarization, for which one of the most important prerequisites is a highly fluid plasma membrane. Therefore, sperm cells contain an extraordinary high amount of polyunsaturated fatty acids (PUFA), particularly docosahexaenoic acid, which has six double bonds in its molecule [219]. Since most sperm functions are dependent on membrane functionality, this high content of PUFA is also essential for normal sperm function and respective disturbances result in a loss of sperm function.

As a result of a urogenital tract infection, activated leukocytes infiltrate the infected organs releasing high amounts of ROS and cytokines such as IL-6, IL-8 or TNF-α as inflammatory mediators [220, 221]. Both ROS and cytokines have been shown to be associated not only with the impairment of sperm functions like motility but also to DNA damage and infertility by induction and stimulation of membrane lipid peroxidation through oxidative stress [212, 222–225]. Through this mechanism, male genital tract infections/inflammations do not only damage sperm DNA and reduce sperm count and seminal volume but also impair sperm functions like motility, acrosome reaction or acrosin activity [92, 208, 226–230].

32.17 Treatment of Infections

Generally, the first choice of treatment of male genital tract infections has to be antibiotic in order to eradicate pathogenic microorganisms, normalize inflammatory parameters, prevent transmission to the female partner and decrease the risk of potential complications. Considering that many urogenital tract infections are sexually transmitted, however, simultaneous treatment of the partner has to be considered, particularly in *C. trachomatis* infections. While standardized recommendations only exist for the treatment of acute bacterial epididymitis, epididymo-orchitis and specific granulomatous orchitis [17, 231], guidelines for the treatment of chronic infections and inflammations of the male genital tract have not been drawn up yet and are rather empirical and only few uncontrolled studies are available [17, 181]. For mumps orchitis, the systemic treatment with α-2β-interferon may be considered to prevent testicular atrophy and azoospermia [232].

The very same is true for acute bacterial and chronic bacterial prostatitis. While an antibiotic treatment for these conditions is mandatory, the benefit for patients with inflammatory chronic pelvic pain syndrome is questionable [193]. Still, treatment of the prostatitis syndrome with antibiotics poses the major problem of the penetrability of the agents into the prostate and its secretions, and only a few modern antibiotics like fluoroquinolones have the chemical properties to enter these compartments well [233, 234]. Yet, depending on the pathogen, an adequate treatment regime should be started soon after proper examination which should also include bacteriological testing of the semen including antibiotic resistance [235].

In order to alleviate the inflammatory lesions, therapy with both corticosteroids and non-steroidal antiphlogistic substances has shown considerable positive effects on semen quality in terms of sperm and leukocyte count and sperm motility [236–238]. Furthermore, antioxidative therapies with vitamins and/or antioxidant supplementations to reduce the oxidative stress caused by leukocytes and defective spermatozoa are currently highly debated [239, 240]. Although several studies with various antioxidants alone or in combination have shown a significant reduction in seminal ROS levels [241–243] and improvement in sperm count and motility [244–246], other studies found the opposite [247, 248]. Therefore, notwithstanding the indubitable positive effects of an antioxidative supplementation for general health purposes, no definite recommendation can be made at this point in time with regard to the treatment of male genital tract infections. Most probably, it is not only the administration of singular antioxidative substances that causes the beneficial effects but the combination of different antioxidants at very specific concentrations.

32.18 Conclusion

The purpose of this chapter was to discuss the contribution of male genital tract infections/inflammations to male infertility. Considering that many of these male genital tract infections are sexually transmitted, the knowledge of its impact on the female partner as well as treatment of the couple is mandatory. Moreover, as there is still a lack of knowledge about the impact of such infections on sperm functions, this chapter is dealing with impaired sperm functions as a result of the infection/inflammation. Since many patients suffer from asymptomatic, the so-called 'silent' infections, it is essential for the clinician to identify these conditions and also to urge the patients to continue with the treatment long enough. Appropriate treatment is particularly a problem in prostatitis as only few drugs penetrate the prostate and its secretions sufficiently. Therefore, this chapter is also to give an up-to-date overview on the impact of different male genital tract infections/inflammations on sperm functions and various treatment options.

32.19 Review Criteria

An extensive search of studies examining the impact of infections on male fertility was performed using search engines such as Google Scholar and PubMed. The searches were not limited for time. Yet, the most recent records were preferred. The overall strategy for study identification and data extraction was based on the following keywords: 'infection', 'oxidative stress', '*Schistosoma*', 'male infertility', 'HIV', '*Chlamydia*', '*E. coli*', '*Treponema*', '*Trypanosoma*', '*Neisseria*', '*Mycoplasma*', 'Zika' and '*Ureaplasma*' as well as the names of most common male genital tract infections. Articles published in languages other than English were also

considered. Data that were solely published in conference or meeting proceedings, websites or books were not included. Websites and book-chapter citations provide conceptual content only.

Ejaculatory Dysfunction and Vasodynamics

33

Paul J. Turek

Key Points

- A thorough medical and sexual history and physical examination are fundamental to defining the various behavioral and physiological bases for human ejaculatory disorders.
- There is a growing trend to develop consensus-based, standardized definitions of ejaculatory disorders that should help to more precisely define these conditions in the future.
- The anatomical and physiological bases for ejaculatory duct obstruction and spinal cord injury are clear, but disorders of ejaculatory latency are currently the subject of intensive research to delineate their fundamental underlying pathophysiology.
- Both partial and complete ejaculatory duct obstructions are absolutely definable based on published vasodynamic criteria. Likewise, ejaculatory duct obstruction is distinguishable from seminal vesicle dysfunction.
- The psychosocial aspects of sexual and ejaculatory dysfunction are integral to human sexual behavior and, as such, will require ongoing consideration if our management of these conditions is to improve in the future.

33.1 Introduction

Ejaculation begins approximately 12 months after the onset of puberty in the male. While its importance to reproductive fitness is clear, current knowledge of the physiology of ejaculation is limited. This chapter will review the events of ejaculation, its anatomic and neuroanatomic underpinnings, the range of ejaculatory disorders, and clinical methods for evaluating and treating ejaculatory disorders. Our current understanding of reproductive tract physiology and function as well as ejaculatory duct obstruction will also be reviewed.

P. J. Turek (✉)

33.2 Physiology of Ejaculation

33.2.1 The Events

Ejaculation is two distinct processes: emission and ejaculation [1]. Although not technically considered a separate event, pre-ejaculation, occurring during foreplay, involves closure of the bladder neck that prevents retrograde ejaculation and contractions of the prostate that lubricate the urethra. Importantly, ejaculation is also distinct from orgasm, which is a purely cerebral cortical event. Most often, these two processes are coincident.

Emission combines the transport of both seminal fluid and sperm through peristalsis from the cauda epididymis, vas deferens, seminal vesicles, and prostate into the prostatic urethra. During seminal emission, the ampullary vasa deferentia contents are transported into the prostatic urethra and mixed with prostatic fluid. The expulsion of seminal vesicle contents into the prostatic urethra completes the emission phase. Subsequently, ejaculation is the forceful expulsion of the seminal mixture from the urethra. The ejaculate is expelled from the urethra in a series of spurts, 0.8 seconds apart, caused by the rhythmic contractions of the ischiocavernosus, bulbospongiosus, and other associated periurethral muscles [2]. The entire process is governed by the autonomic and somatic nervous systems and is considered a spinal reflex.

33.2.2 Neural Control

Control of the ejaculatory reflex is mediated by the sympathetic and somatic nervous systems [3]. Control of emission involves mainly the sympathetic nervous system, while

S. J. Parekattil et al. (eds.), *Male Infertility*, https://doi.org/10.1007/978-3-030-32300-4_33

ejaculation is governed largely by the somatic nervous system. Efferent sympathetic nerves emerge from the thoracolumbar spine at T10–L2 and then merge to form the lumbar sympathetic ganglia that encircle the aorta. These nerves subsequently combine in the midline below the aortic bifurcation to form the superior hypogastric plexus (Fig. 33.1). Ultimately, these adrenergic nerves terminate as postganglionic fibers that innervate the bladder neck, prostate, vasa deferentia, and seminal vesicles [4]. The sympathetic outflow generated by these nerves is responsible for closure of the bladder neck and seminal emission.

The muscular expulsion of the ejaculate is mediated by somatic motor efferent nerves derived from the perineal branch of the pudendal nerve (S2–S4). Additional control is provided by relaxation of the external urethral sphincter and the urogenital diaphragm. Interruption at any point in this reflex arc may result in disordered ejaculation.

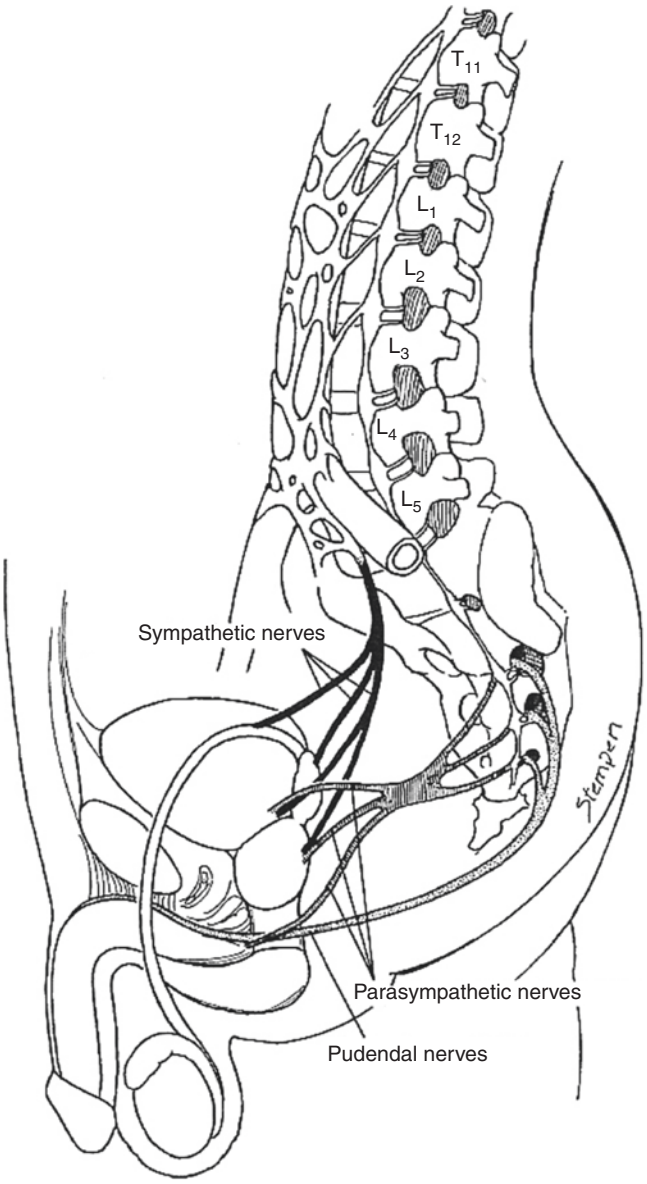

Fig. 33.1 Innervation of the male reproductive tract showing sympathetic and parasympathetic nerves and somatic innervation (Reprinted from Master and Turek [1]. With permission from Elsevier)

33.2.3 Definitions

Aspermia: Disordered ejaculation characterized by an inability to produce semen, despite the occurrence of climax.

Azoospermia: The absence of sperm in the ejaculate.

Anejaculation: The failure of ejaculation, including an absence of seminal emission and ejaculation. Climax is usually absent as well.

Premature ejaculation (*ejaculatio praecox*): Ejaculation that occurs sooner than desired, either before or shortly after penetration, causing distress to either one or both partners.

Delayed ejaculation (anorgasmia): A form of sexual dysfunction characterized by the inability to achieve climax or an extreme delay in achieving climax and ejaculation.

Retrograde ejaculation: Ejaculation of semen in reverse direction into the bladder during climax due to failure of bladder neck closure.

Congenital anorgasmia: Failure of ejaculation as primary, lifelong event.

Ejaculatory anhedonia: Ejaculation associated with a lack of pleasure.

33.3 Evaluation

33.3.1 History

The cornerstone of evaluating ejaculatory dysfunction is a detailed patient history. Critical to obtain from the history is whether or not normal ejaculation was ever present in the past. This differentiates a primary (congenital) or secondary (acquired) cause of sexual dysfunction. In addition, a thorough review of the medical and surgical history can be informative regarding possible neurologic etiologies for disordered ejaculation. Finally, a careful review of current medications such as alpha-blockers or antidepressants can suggest the presence of drug-induced ejaculatory dysfunction [1].

33.3.2 Physical Examination

A complete physical examination should include an assessment of body habitus and secondary sex characteristics, a screening neurological examination, and a thorough genital examination. Testis and epididymis size and consistency,

penile length and morphology, and genital birth defects such as hypospadias, epispadias, or surgical scars suggestive of their correction should be noted. Palpation of scrotum for masses and a check for the presence of the vas deferens should also be performed. A rectal examination noting rectal tone and any masses is also important.

33.3.3 Laboratory Evaluation

An attempt should be made to procure a semen analysis. In cases where no ejaculate is obtained, a post-ejaculate urine sample should be retrieved and assessed for the presence of sperm, suggesting retrograde ejaculation. Blood testosterone, prolactin, and serum luteinizing hormone (LH) levels should also be assessed because low ejaculate volumes may be caused by hypoandrogenism. Further diagnostic evaluation may include imaging with transrectal ultrasonography (TRUS) to define anatomical or structural abnormalities in the prostate, seminal vesicles, or ejaculatory duct complex. If indicated, formal ejaculatory duct chromotubation, seminal vesiculography, and ejaculatory duct manometry can be performed to detect subtle ejaculatory duct abnormalities [5].

33.3.4 Genetic Testing

Patients with disordered ejaculation and a history of infertility or with suspected congenital abnormalities such as congenital absence of the vas deferens or ejaculatory duct obstruction should be counseled on appropriate genetic testing for cystic fibrosis transmembrane regulatory (CFTR) gene mutations [6].

33.4 Management of Ejaculatory Disorders

33.4.1 Anatomic

33.4.1.1 Bladder Neck Incompetence

A patent bladder neck is most commonly the consequence of an incompetent internal urethral (bladder neck) sphincter. The ensuing "dry ejaculate" is due to retrograde ejaculation. It can be caused by α-blocker medication for prostate enlargement or hypertension, diabetic neuropathy, neurologic disorders such as spina bifida or multiple sclerosis, or other congenital anatomic abnormalities. It is also a common postsurgical complication of transurethral prostatectomy (TURP) [7]. Interestingly, from the patient perspective, retrograde ejaculation after TURP is often confused with anorgasmia or erectile dysfunction [8].
