Foreword

The Space Industry as of 2020 continues to be one of the most rapidly growing sectors in the global economy with nearly half a trillion dollars in various activities related to telecommunications, remote sensing and Earth observation, meteorology and climate change monitoring, space navigation, space exploration and experimentation, national defense, as well as a range of brand new space activities. These innovative applications include on-orbit services, RF Geolocation, data analytics, electronic-tracking antenna system in space and on the ground, commercial inter-satellite linkages and data relay, artificial identification systems (AIS), Internet of Things (IoT) services provided by space systems, re-usable launch vehicles, and more. The world of space today has expanded significantly beyond the activities carried out by national and regional space agencies and military and defense-related space agencies. Some market studies have suggested that commercial space activities are now three times larger than governmental and defense-related activities. The so-called "NewSpace" and "Space 2.0" activities have, in large part, been responsible for the rapid growth and expansion of the global space industrial and services activities. Nevertheless, "New Space" systems and small satellite-related industries will be adversely impacted by the Corona-virus along with the rest of the global economy for the next few years.

One of the factors that has driven this new growth is the new small satellite revolution in the space industry. Tens of thousands of small satellites have been proposed to be deployed in constellations – largely in low Earth orbit and largely between 700 km and 1500 km altitudes. These new initiatives to deploy small satellite constellations on a very large scale have, in part, driven new demands for new types of space systems and technology. In particular, it has helped fuel expanded space markets for such new capabilities as highly cost-efficient reusable launch vehicle or highly versatile new phased array antenna systems with electronic-pointing capabilities to support new broadband networking and communications to LEO constellations.

This new *Handbook on Small Satellites* is an important and comprehensive reference source for all aspects of the amazingly fast-growing field of small satellites. It covers everything from the small femtosats (or chipsats) that are below 100 g in mass to picosats (100 g to 1 kg), nanosats (1–10 kg) (which also covers cubesats), microsats (10–100 kg), and even mini-satellites that can be as large as 1000 kg although some limit these to 500 kg or 600 kg of mass. It covers the latest information about chipsats, pocketqubes, and cubesats for experiments and technology demonstrations but also examines the latest innovations related to commercial small satellites for a new range of space applications. In short, it covers every aspect of the small satellite world. Thus there are articles that discuss launch vehicles, facilitators for launch arrangements, and licensing and regulatory issues and concerns, such as end of life de-orbit and orbital debris challenges. It also addresses financing, new applications, and every aspect of small satellite design and technological engineering. The *Handbook of Satellite Applications* that preceded this *Handbook of Small Satellites* provided a broad and useful overview, but this new resource provides within its 82 chapters a wealth of specific information about every aspect of this important new field of space development.

Noted experts around the world from Africa, Asia, Australasia, Europe, North, and South America – over seventy in number – have contributed to this remarkable publication. Many of these contributors have ties to the International Space University and are, or have been, on its faculty or were at one time students of this global university that is devoted to understanding the cosmos as well as every aspect of space applications. I salute this remarkable new reference handbook and especially Dr. Joseph Pelton, who was the first Chairman of the Board and first Dean of the International Space University, plus all of its authors from around the globe.

President, International Space University
Strasbourg, France

Juan de Dalmau

Preface

Why a Handbook on Small Satellites

There are many excellent books and articles now available on all aspects of small satellites. This is a field that has exploded in activity and global interest in the past decade. There are a wide range of individual sources about the technology, others on the applications and services, and yet others about the economics, launch arrangements, policy and regulation, and social and political consequences. Yet there has not previously been a comprehensive and interdisciplinary source of information that collects all of this information together in a holistic way – until now. This *Handbook of Small Satellites* seeks to provide a complete overview of all aspects of the small satellite field.

Thus leading experts from around the world have been recruited to provide in one reference source the latest and state-of-the-art information about small satellites – from the smallest Femtosat to the largest and most sophisticated small satellites that are being deployed in so-called "mega-LEO" satellite constellations. Thus this handbook provides information about the historical development of "smallsats" as well as an explanation of the various types of "smallsats" that are being developed and launched today. It also provides latest information on the space and ground systems technology, the applications and services, and the economic, policy, regulatory, legal, business, and social aspects of this burgeoning field of space activity.

This book seeks to provides information from the perspective of all those interested in space satellites. It thus seeks to provide useful information for the student experimenter and for those undertaking smallsat projects for civilian space agencies and military and defense agencies. It also provides useful information suitable for so-called "NewSpace" business enterprises engaged in small satellite-related businesses as well as the political and legal officials that provide the regulatory oversight for small satellite systems. This includes information about the efficient allocation and oversight of the frequency spectrum needed for these systems to operate effectively.

This *Handbook on Small Satellites* addresses key issues such as orbital space debris, end of life removal of small satellites from orbit, new ways to design and build satellites, frequency spectrum coordination, as well as innovative ways to address the problems of jamming and interference. It even addresses new approaches to the efficient use of space resources and satellites such as placing hosted payloads on larger satellites. It addresses the new opportunities for achieving cost-efficient “space-like” services from high altitude platform systems (HAPS).

It is the hope of all the contributors to this reference work and the scores of participants from around the world that this handbook will be helpful. In particular it is hoped that the many chapters that follow, plus the many references to books and articles found in endnotes, can serve as a useful guide to the design, manufacture, deployment, use, oversight, and business developments needed for the future success of “small satellites” enterprises around the world. The burgeoning number of smallsat systems and launches represent a powerful element in the growth of “NewSpace” or “Space 2.0” ventures. These new space businesses have sprung up around the world. They are now giving new impetus to a rapidly expanding space industry. In time these space enterprises will expand to become a “trillion dollar” industry. These new space industries will help sustain a growing world economy. In short, “smallsats” will touch everyone. They will aid enterprises that range from ecology to banking, from fishing to mining, from airline travel to health care and education.

This is not to say that “smallsats” will replace large satellites. Large and powerful high throughput satellite, for instance, are currently best positioned to provide broadcast television services to small low-cost satellite dishes. Other satellites services, such as for Precise Navigation and Timing (PNT) services and those providing precise radar imaging with active sensing systems, will also require sophisticated satellites with relatively high power levels as well. The technical, operational, and economic reasons for making the “right” decisions on satellite size and architecture will be explained in later parts of this Handbook. Instead of small satellites being a “replacement” to large and powerful satellites, we will see a sort of co-existence of all types of satellites from tiny and small to medium and large-scale. Even so, innovations in one area may very well be shared and transferred. The case of Canada’s new three satellite Radarsat constellation is perhaps an excellent case in point.

Scope and Structure of this Handbook

This *Handbook of Small Satellites* seeks to provide a comprehensive overview of the small satellite field. It thus addresses the history of small satellites and provides insight into the technology and its evolution over time both in terms of the spacecraft, the tracking, telemetry and command aspects of its operation, as well as the corresponding changes to the ground segment for users of this technology that represents a critical part of the evolutionary path of the feasibility and economics of small satellites. Key new features such as hosted payloads, high altitude platform systems, active debris removal, on-orbit servicing, ground systems with electronic tracking capabilities, and more will be addressed as well.

After the technological and operational aspects are presented, the next part will address key aspects of small satellite design, engineering, and manufacture. This will also address business-related concerns such as contracting, resiliency and sparing philosophy, and protection of intellectual property rights.

The next part addresses the great complexity of applications and services and the many different types of small satellites that can be deployed to meet the needs associated with the increasingly diverse range of services as well as the many types of organizations and units that are now pursuing the active deployment and use of small satellites. This even includes the use of small satellites by defense agencies and military ministries.

The final major element of the handbook addresses the economic, legal, and regulatory issues and constraints that are concerned with the increasingly complex field of small satellites.

This is followed by a conclusion part that assesses all of the current trends; major technical, economic, social, and regulatory issues that are pending; and how this relates to the small satellite revolution and Space 2.0 industries. This synoptic final analysis provides a coherent overview of the field of small satellites around the world. It also provides the key trends in the area of small satellites and its ups and downs to broader world goals and objectives such as the United Nations 17 Sustainable Development Goals (see Fig. 1) and the work of the Davos World Economic Forum.

There are also series of "reference articles" in Part 14 that provide information on small satellite projects, companies, and launchers as well as information related to regulatory actions and policies and finally a glossary of terms. In light of the transitory nature of developments in this fast moving field, an effort is made to provide website addresses with current URLs so that the status of projects can be

Fig. 1 New capabilities offered by Smallsats Can Benefit Developing Nations and the UN Sustainable Development Goals. (Graphic Courtesy of the United Nations)

obtained from the official site for small satellite projects. Collectively this handbook should provide comprehensive information about every aspect of the fast moving world of small satellites.

Joseph N. Pelton
Editor

Acknowledgments

This *Handbook on Small Satellites* has taken some time to evolve from concept to reality. Maury Solomon of Springer Nature, with whom I have collaborated for many years on perhaps a dozen books, first proposed the idea of this handbook. I responded that it was too early to do such a large reference book and there was not enough technical content to justify a multi-volume project at the time.

But the growing technological advances, the expanding educational and experimental uses, and the burgeoning commercial use of various types of small satellites all suggested that the rationale for such a book continued to mature. Maury Solomon wisely suggested that this was an area that is growing in scope. She envisioned a handbook that spanned satellite and launcher technology, systems design, expanding applications, experimentation, economics, regulation, markets, and especially commercial innovation. Ms. Solomon presented a strong case that this was a project that called for an interdisciplinary approach.

Over time, the reasons for a handbook on small satellites thus grew. In 2017 my colleague Prof. Scott Madry and I began teaching a course on small satellites at the University of Cape Town. Then, in the following year, I provided editorial oversight in the writing of a new book on small satellites that grew out of the course. In this way, I finally was convinced that such a handbook on small satellites was truly an unmet need.

I thus want to give special credit to Maury Solomon, now retired from Springer Nature, as the first advocate of this project. I also want to warmly thank her successor, Hannah Kaufmann, who has seamlessly and very helpfully supported making this new handbook a reality.

And then there is also the production team at Springer. These professionals have tirelessly toiled for months on end to make this very complex and exhaustive handbook a reality. Saskia Ellis, in particular, has spent many intensive months editing and formatting the scores of articles that kept pouring in from around the world. This included sorting out copyright issues and clarifying ambiguous text. Her help has truly been invaluable. Likewise, Barbara Wolf provided wonderful support when we needed permissions from publishers to use previously published materials. Enormous credit must go to the entire Springer team that has helped every step of the way.

In all, there are over 70 authors from around the world that have provided enormous support to this effort. Their dedication to the growth, development, and success of the many dimensions of the small satellite world is amazing. These authors quickly recognized that this handbook could help contribute to the success of the small satellite phenomena – commercially, experimentally, and educationally. Thus I want to thank all of the contributors who have shared their knowledge and contributed their time and efforts to make this handbook a success. In particular, Dr. Peter Martinez, in his roles in creating the small satellite course at the University of Cape Town and as Director of the Secure World Foundation, provided support and encouragement in a number of ways.

Finally, I wish to thank my close friend and secret weapon in getting this huge handbook to press, Dr. Scott Madry. His efforts in drafting articles, co-authoring articles with me, and helping with editing did yeoman work essential to completing this very comprehensive work. I would also like to thank the sponsors of the handbook, the International Space University and the International Association for the Advancement of Space Safety (IAASS). And in particular, Juan de Dalmau, President of the International Space University (ISU), and Tommaso Sgobba, Executive Director of the International Association for the Advancement of Space Safety (IAASS), for their support.

In all, more than a hundred people helped make this handbook a success and I wish to thank them all for their generous and high-quality work in preparing their various chapters. I wish to express to them all my heart-felt and profound appreciation.

Editor

The Handbook Sponsors

The *Handbook of Small Satellites* was undertaken with the sponsorship of two organizations. Although these two organizations have somewhat different missions, they are both generally dedicated to the study and understanding of outer space and to research and educational programs that contribute to this end. They are both dedicated to the peaceful uses of outer space and a better understanding of the cosmos, in terms of its physics, its commercial potential and applications, and improved safety in space.

The International Space University (ISU) seeks to develop the future leaders of the world space community by providing interdisciplinary educational programs to students and space professionals in an international, intercultural environment. The ISU also serves as a neutral international forum for the exchange of knowledge and ideas on challenging issues related to space and space applications. ISU programs impart critical skills essential to future space initiatives in the public and private sectors while they also promote international understanding and cooperation; foster an interactive global network of students, teachers, and alumni; encourage the innovative development of space for peaceful purposes; and seek to improve life on Earth and advance humanity into space. It offers a Master of Space Studies in its home campus in Strasbourg, France, a Space Studies Program that is hosted at sites around the world, a Southern Hemisphere Space Studies Program, an annual Symposium, books and articles published by its worldwide faculty, and a wide range of other programs.

The International Association for the Advancement of Space Safety (IAASS) was formed with the mission to create an international space safety culture. Its specific goals are: to advance the science and application of space safety; to improve the communication, dissemination of knowledge, and cooperation between interested groups and individuals; to improve understanding and awareness of the space safety discipline; to promote and improve the development of space safety professionals and standards; and to advocate the establishment of safety laws, rules, and self-regulatory bodies at national, international, and industrial level for the civil/commercial use of space. It accomplishes these goals through academic and training programs, the publishing of books, the *Space Safety Magazine* and the *Journal of Space Safety Engineering*, as well as conferences, workshops, and other space safety related programs.

A number of members of these two international institutions supported the research, writing, and production of this handbook.

About the Editors

Dr. Joseph N. Pelton is an award-winning author and editor of some 50 books and over 300 articles in the field of telecommunications and networking, space systems, future technologies, and urban planning. His book *Global Talk* won a Pulitzer Prize nomination and won the Eugene Emme Literature Award of the International Association of Astronautics. In July 2013, he received the British Interplanetary Society International Award known as "The Arthur" in honor of Arthur C. Clarke. Dr. Pelton also received the Arthur C. Clarke Foundation's Lifetime Achievement award in 2001 and the IAASS "da Vinci Award" for lifetime achievement. Most recently he won the Guardian Award of the Lifeboat Foundation, which was previously won by Bill Gates, Elon Musk, and Warren Buffet.

Dr. Pelton is the Founding President of the Society of Satellite Professionals International, the Founder and former Executive Director of the Arthur C. Clarke Foundation, and played a key role in the founding of the International Space University. He announced the formation of the Clarke Foundation at the White House in 1983 while he was acting as the Managing Director of the National Committee for World Communications Year – A US Presidential Appointment. He played a role in the formation of the Arthur C. Clarke Center on the Human Imagination at the University of California-San Diego in 2012 as well as a new STEM education exhibit at the National Electronics Museum that opened in September 2018. He also currently serves as Director of Research for Planetary Defense LLC. His degrees are from the University of Tulsa (B.S.), New York University (M.A.), and Georgetown University (Ph.D.) His most recent books include: *Preparing for the Next Cyber Revolution*, *Space 2.0: Revolutionary Advances* *in the Space Industry*, *The New Gold Rush: The Riches of Space Beckon*, *Smart Cities for Today and Tomorrow*, *Digital Defense*, and *The Farthest Shore: An 21st Century Guide to Space* (*2nd Edition*). He is currently assisting the Hudson Foundation with a re-examination of global space policy. His web page is: www.josephpelton.com. He resides in Arlington, Virginia.

Dr. Scott Madry is a Research Associate Professor of Archaeology at the University of North Carolina at Chapel Hill. He also serves as the President of Informatics International, Inc. Dr. Madry lectures all over the world on the applications of space technology for remote sensing and Earth observation, including its many use for disaster response and recovery and natural and cultural resource management. He is a proponent of open source software and has presented over 150 short courses around the world on the use of free and open source geomatics tools.

Dr. Madry is a well-published author in the field of space applications and geomatics, having published 6 books and over 75 papers and articles. His books include: *Space Systems for Disaster Warning Response and Recovery*; *Global Navigation Satellite Systems and Their Applications*; the *Handbook for Satellite Applications* (*1st and 2nd editions*); *Innovative Design, Manufacturing, and Testing of Small Satellites*; and *Disruptive Space Technologies and Innovations: The Next Chapter*. He has conducted archaeological field research in Burgundy France for over 30 years, has been a three-time Fulbright Scholar, and was twice awarded the President's Volunteer Service Award for his work with the American Red Cross and the URISA GISCorps.

Contributing Authors

Guglielmo S. Aglietti Professor Aglietti is Director of the Space Institute at the University of Auckland in New Zealand where he is also a Professor of Space Engineering. He was previously associated with Surrey Space Technology Ltd and played a key role in the development of small satellite project known as Clean Space that has demonstrated the feasibility of a number of techniques associated with active removal of space debris from Earth's orbit.

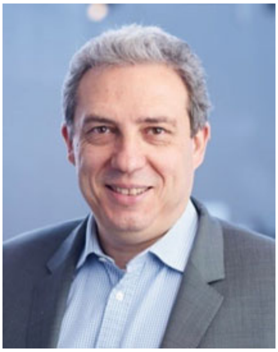
Audrey L. Allison is Vice President of Global Spectrum Management at The Boeing Company in Arlington, Virginia, USA, where she is responsible for radiofrequency spectrum acquisition, compliance, and policy support for Boeing technology, products, services, operations, and customers. Allison is Boeing's lead representative at the International Telecommunication Union (ITU) in Geneva, Switzerland. She is Vice-Chair of the Satellite Industry Association and a Board Member of the United States ITU Association.

Allison also serves as Adjunct Faculty to the International Space University in Strasbourg, France, and Visiting Lecturer to McGill University Institute of Air and Space Law in Montreal. She is the author of The ITU and Managing Satellite Orbital and Spectrum Resources in the 21st Century, Springer, 2014.

Previously, Allison was an Attorney-Advisor to the Satellite Division of the Federal Communications Commission's International Bureau, Counsel in the Office of General Counsel at Iridium LLC, and a Consultant to the

Department of Defense in international spectrum regulatory issues.

Allison earned an M.B.A., *cum laude,* from the International Space University; a Master of International Law from Georgetown University in Washington, DC; a *Juris Doctor* from Catholic University of America's Institute for Communications Law Studies in Washington, DC; and a Bachelor of Arts from the Pennsylvania State University in University Park, Pennsylvania.



Dr. Tony Azzarelli, Eng, M.B.A., M.Sc., CEng, FIET, FRSA, is responsible for several ventures as CEO and Founder of Azzurra Telecom Ltd and Company Director and Co-founder of ACCESS SPACE Alliance Ltd. He is also the CTO at AB5 Consulting and Vice President of Spectrum Licensing Affairs at OneWeb.

Tony has more than 25 years' experience in the telecommunication sector, with senior leadership appointments at Access Space Alliance, Azzurra Telecom, AB5 Consulting, OneWeb, Ofcom UK, Inmarsat, The Boeing Company, the European Space Agency, and ICO Global Communications. He holds a Doctor's degree in Electronics, a Master's degree in Business Administration, and a Postgraduate Certificate from the ISU Summer Session 1993. Tony is a Chartered Engineer, a Fellow of the Institute of Engineering and Technology, and a Fellow of the Royal Society of Arts.

Morgan Bailey is the Head of Communications at Rocket Lab. In this role she leads the company's marketing, communications, community engagement, and government relations strategies across the USA and New Zealand markets. Having worked with Rocket Lab since the unveiling of the Electron orbital launch vehicle program in 2014, Morgan has deep knowledge of the launch industry and the ever-evolving needs of small satellite operators.

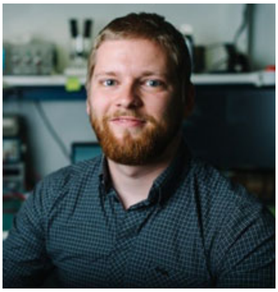
Prior to joining Rocket Lab, Morgan carried out corporate communications work in Australia and New Zealand for Hawaiian Airlines, AIG, Bank of New Zealand, Progressive Enterprises, and more.

Dr. Christoph Beischl holds a Ph.D. in Space Policy and Law from the University of London and is currently a Research Fellow at the London Institute of Space Policy and Law. His main research areas include (i) space policies and regulations in the Asian region, (ii) intergovernmental space cooperation, as well as (iii) political and legal considerations that need to be addressed to ensure the stable use of outer space, for example, concerning the deployment of small satellite mega-constellations, on-orbit servicing, and active debris removal. Christoph graduated with a Magister Artium in Political Science (Major), Law and Modern and Contemporary History (Minors) from the University of Munich focusing, among others, on politics in the East Asian region and political ideology. He is an active member of the Space Generation Advisory Council for many years.

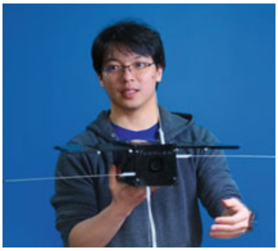
Pierre Bousquet has served as a Senior Expert on Planetology, Exploration and Microgravity in the Scientific project Directorate at CNES in Toulouse, France, since 2017. He is the Project Manager of the French contribution to Bepi Colombo (European mission to Mercury). He is also in charge of several design studies based on small probes for deep space exploration.

Pierre is a Technical Advisor to the French delegation for PB-HME (ESA's Program Board on Human Missions and Exploration). He is a senior member of French Association of Aeronautics and Astronautics (AAAF). Pierre is a corresponding member of the International Academy of Astronautics (IAA). He is also a member of the Space Exploration committee of the International Astronautic Federation (IAF) and member of the UN-mandated "Space Missions Planning Advisory Group" (SMPAG) on the threat represented by near-Earth objects. Pierre has more than 50 publications in international conferences and journals. He has served as an Occasional Lecturer at French engineering schools ISAE, EUROSAE, and EMAC.

Dr. Vitali Braun ESA/ESOC, Space Debris Engineer. Vitali Braun joined ESA's Space Debris Office as an Engineer in 2015. He is supporting operational collision avoidance activities for ESA and third party missions, re-entry predictions, and risk assessments. He is responsible for the maintenance of ESA's Meteoroid and Space Debris Terrestrial Environment Reference (MASTER) model and the Debris Risk Assessment and Mitigation Analysis (DRAMA) tool suite. From 2010 to 2015, he was working as Research Associate at the Technische Universität Braunschweig , performing debris risk analyses, software development, but also supporting university courses on orbital mechanics and supervising students. Since 2016, he holds a Doctor of Engineering (Dr.-Ing.) from the Technische Universität Braunschweig, Germany.



Jeroen Cappaert is the Co-Founder and Chief Technology Officer at Spire. His main mission is to ensure the future technology developments needed to deliver what the businesses require. Jeroen has a background in electronics engineering and aerospace engineering. He carried out his previous work and research, which includes high-enthalpy flow simulation, computational mechanics and fluid dynamics, spacecraft avionics and payload design, and low-thrust astrodynamics, at NASA Ames, the Von Karman Institute for Fluid Dynamics, and the International Space University. Jeroen Cappaert's education includes an M.Sc. in Space Studies from the International Space University, a Master's thesis on Uncertainty quantification for hypersonic flow simulation from Von Karman Institute for Fluid Dynamics, an M.Sc. in Mechanical Engineering (cum Laude), and B.Sc. in Mechanical Engineering (with a minor in Electrical Engineering) from KU Leuven.



Wen Cheng Chong serves as Chief Technology Officer for Kepler Communications. With a knack for tackling complex challenges, Wen has led the team to launch the first Ku-band commercial LEO spacecraft ever, carrying that project from napkin to orbit in 12 months. Wen personally manages all aspects of Kepler's technical undertakings, including its ground systems, user terminals, space operations, and software.

Adriana Elysa Alimandro Corrêa holds a Master in Electronics and Automation Engineering (2013) and a B.S. degree in Physics (2011) from the University of Brasília. She joined the Brazilian Space Agency in 2013. Her past experience includes an aerospace training (2012) at Yuzhnoe State Design Office, Ukraine; a professor (2015–2016) position at the Federal District University Center; and a nanosatellite assembly training at ISRO, India (2019).

Bill Cowley graduated from the University of Adelaide with Science and Engineering degrees. After working for Telstra and the Australian Defence MInistry for several years, he moved to the University of South Australia in 1985 and joined the Institute for Telecommunications Research. He was director of ITR for a 4-year period. In September 2015, Bill retired from his UniSA position of Professor of Communication Signal Processing and is currently an Adjunct Professor at UniSA. He's also an Adjunct Faculty Member of the International Space University. His interests include communications signal processing for RF and optical communications.

Dr. Eric Dahlstrom background is in physics, astronomy, and space engineering. He has worked as a contractor on NASA projects for many years. This has included a significant amount of work on the design of the International Space Station (ISS). For the last 8 years he has been a consultant to support space startup companies in Silicon Valley. For many years he has taught at and been involved with International Space University (ISU) and is currently on its faculty. Over the years he has taught in 10 countries for the International Space University. Further, he has also been strongly involved with the Singularity University, located on the NASA Ames Campus in Mountain View, California. The latest in new space technologies and applications has meant that the barriers to developing new commercial space activities have been lowered. This has allowed for space systems in places like New Zealand. He is currently in New Zealand seeking to develop new space systems and ventures under a Edmund Hillary Grant.

Dr. Kenneth Davidian has worked for the FAA's Office of Commercial Space Transportation (AST) in Washington, DC since 2008 and is currently the AST Director of Research and Program Manager for the FAA Center of Excellence for Commercial Space Transportation. Dr. Davidian serves as a member of the Ohio State University Aerospace Engineering External Advisory Board, Editor-in-Chief of the New Space journal, Chair of the IAF Entrepreneurial & Investment Committee, and Vice Chair of the IAF Space Economy Committee. Dr. Davidian is a corresponding member of the International Academy of Astronautics and an Adviser to the Space Generation Advisory Committee's Commercial Space Project Group. Prior to FAA AST, Dr. Davidian worked for the NASA Lewis Research Center, International Space University, Paragon Space Development Corporation, X PRIZE Foundation, and NASA Headquarters. Dr. Davidian received his B.S. degree in Aeronautical and Astronautical Engineering from the Ohio State University in 1983 and an M.S. degree in Mechanical Engineering from Case Western Reserve University in 1987. He attended the International Space University Summer Session Program in 1989. Dr. Davidian received his Ph.D. in Business Administration from the University of Cape Town, Graduate School of Business, in 2018. His thesis focuses on innovation management and understanding the processes of emerging and evolving markets.

Dr. Kiruthika Devaraj is Director of EE/RF at Planet Labs Inc. where she leads the electrical engineering and RF/communication groups to design and manufacture the avionics, power, and communications systems for Planet's satellites. Planet builds and operates the world's largest constellation of remote sensing satellites to image the Earth on a daily basis and make change visible, accessible, and actionable. A recent notable project includes the architecture and development of Planet's high speed downlink radio and antenna that achieved 1.7 Gbps data throughput from a 3U form-factor CubeSat. Prior to Planet, Kiruthika was a Postdoctoral Research Fellow at the Kavli Institute of Particle Astrophysics and Cosmology (KIPAC) at Stanford University where she built microwave and millimeter-wave instruments to study star formation processes. One of the instruments she built, Argus, a 16-pixel W-band focal plane array, is commissioned at the Green Bank Telescope. She has an M.S. and Ph.D. in Electrical Engineering from the Georgia Institute of Technology. At Georgia Tech, she worked on the NASA mission Juno, building a laboratory analog of Jupiter's atmosphere and studying the microwave properties of gases in the Jovian atmosphere.

David Draper NASA Deputy Chief Scientist Dr. David Draper is an Earth and planetary scientist with 28 years of professional experience in studying the Earth, Moon, planets, and Solar System. These scientific studies explored frontier questions regarding characteristics, processes, and events of and on Earth, the Moon, and Mars. His scientific specialty is in experimental simulations at high temperatures and pressures, using basaltic magmas as probes of the processes occurring within planetary interiors. His prior experience includes leading the Astromaterials Research Office at NASA Johnson Space Center in Houston, Texas, and he has also led teams proposing competed robotic missions of planetary exploration.

Joseph D. Fargnoli is the cofounder of the New York Space Alliance and Managing Director of an associated New York based investing group. He is passionate about working with a range of early stage New Space companies bringing New York's financial, legal, marketing, technical, and manufacturing capacity to help realize the potential in moon shot opportunities.

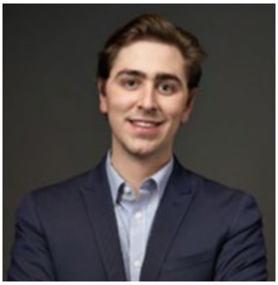
Joseph's areas of technical expertise are in the design and development of telecommunication and remote sensing systems particularly with regards to the exploitation of SAR, hyperspectral and multispectral phenomenology, and in the integration with imagery and other forms of information from multiple modalities and sources. In particular, Joseph has expertise in the development of informatics solutions incorporating remote sensing image science with modern analytic architectures and cloud based IT infrastructure. His career background includes Northrop Grumman Electronic Sensors and Systems group working on Civil and National

Electro-Optical as well as SAR system and Kodak/ITT/Exelis/Harris with focus on National and Commercial systems. He also served as a Technical Fellow within the NRO. After forming the RITRE Corporation, efforts were merged into driving the strategy and business case for the formation of the THIEA Systems Group.

Dr. David Finkleman is Chief Engineer at Sky Sentry LLC. He is also affiliated with the International Standards Organization (ISO). He is a leading authority on civil, commercial, and military space with special expertise in small satellite systems and technology and space traffic management and space situational awareness. He has degrees from Virginia Tech and MIT where he earned Master of Science and his Ph.D. Dr. Finkleman is a retired Colonel from the US Air Force where he served as a member of the Senior Executive Service. He has served as Director of Studies and Analysis and Senior Scientist at North American Aerospace Defense Command and U.S. Space Command, Peterson Air Force Base, Colorado. He also served as Associate Professor of Aeronautics at the U.S. Air Force Academy and was Project Officer for elements of the Airborne Laser Laboratory at Kirtland Air Force Base, NM. Dr. Finkleman also served with the Navy Directed Energy Weapons Program as a civilian. He also played a key role in the creation and initial operation of the Space Data Association. He has numerous publications in the field of space and systems.

Steven Freeland is Professor of International Law at Western Sydney University, Australia, where he teaches both postgraduate and undergraduate students and supervises Ph.D. students in the fields of International Criminal Law, Commercial Aspects of Space Law, Public International Law, and Human Rights Law. He is a Visiting Professor at the University of Vienna; a Permanent Visiting Professor of the iCourts Centre of Excellence for International Courts, Denmark; a Member of Faculty of the London Institute of Space Policy and Law; and was a Marie Curie Fellow in 2013–2014. He has been an Expert Assessor of Research Proposals in Australia, Canada, the Netherlands, South Africa, and Hong Kong and has taught courses at universities in over 20 countries. Among other appointments, he is a Director of the Paris-based International Institute of Space Law and a member of the Space Law Committee of the London-based International Law Association. He sits on the Editorial Board of a number of international journals, including the *Australian International Law Journal*, the Canada-based *Annals of Air and Space Law*, the Germany-based *German Journal of Air and Space Law*, the China-based *Space Law Review*, and the London-based *ROOM Space Journal*. He has authored approximately 300 publications on various aspects of International Law and has presented over 800 commentaries.

Helen Grant recently retired as the Associate Chief Scientist for Programs and Projects in the NASA Office of the Chief Scientist. She has extensive experience as a Project Manager and Systems Engineer for human space flight projects as well as developing systems and technology for scientific research. Before coming to the Office of the Chief Scientist, Ms. Grant managed the NASA organization responsible for performing independent assessments of major NASA programs and projects and improving NASA cost and schedule analysis policy and practice.



Michael Grasso is a leader in the Strategy and Corporate Development team at Blue Origin. Michael supports Blue Origin on corporate strategy, corporate development, sales, and marketing activities. Previously Michael served as an Economic Advisor for Space at the Luxembourg Ministry of the Economy. In this capacity, Michael supported the Luxembourg Government's commercial space strategy and space investment policy. He led the development of the public-private partnership to establish Luxembourg's space focused venture investment fund. Michael also worked at the Avascent Group where he supported commercial and government space clients.

Dr. James L. Green currently serves as Chief Scientist for NASA, an appointment he has held since May 2018. He received his Ph.D. in Space Physics from the University of Iowa in 1979 and has worked at NASA's Marshall Space Flight Center and Goddard Space Flight Center before becoming the Director of the Planetary Science Division at NASA Headquarter in 2006. He has written over 110 scientific articles in refereed journals involving various aspects of the Earth's and Jupiter's magnetospheres and over 50 technical articles on various aspects of data systems and computer networks. In 1988 he received the Arthur S. Flemming award given for outstanding individual performance in the federal government and was awarded Japan's Kotani Prize in 1996 in recognition of his international science data management activities.

Rob Harvey is the Director of Onboard Software at Planet, Inc. He and his team are responsible for developing and maintaining the avionics flight software for over 100 active satellites, including Planet's fleet of Doves, Superdoves and Skysat satellites, as well as developing new systems for future satellite platforms. The flight software team also supports ongoing satellite manufacturing efforts, post-launch satellite commissioning, on-orbit anomaly analysis, as well as ground tooling efforts. Prior to Planet, Robert worked in various embedded software roles in consumer electronics, including building out GPS/GSM telematics products and handheld GPS devices. For many years prior to that, Robert was involved in GPS receiver design, notably being involved in some of the first integrations of GPS into mobile phones for E911 services. Robert has an M.Sc. in Geomatics Engineering from the University of Calgary where he worked on GPS-based precision pointing devices. He has a B.Sc. in Engineering Physics from Queen's University in Kingston, Ontario, Canada.

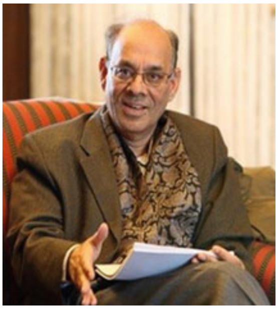
Yvon Henri has over 35 years' experience in the satellite communications field and has worked on space policy and regulatory affairs in both the public and private sectors as well as in intergovernmental organizations at France Telecom (Paris, France), INTELSAT (Washington, DC, USA), and the Radiocommunication

Bureau of the International Telecommunication Union (ITU) in Geneva (Switzerland) where he was Chief of the Space Services Department (SSD) up to June 2017. Throughout his professional career, Mr. Henri has always strived to initiate, develop, and promote policies to enhance the opportunities afforded by the telecommunication/ICT sector, in particular for the global harmonization of space and terrestrial applications, with particular focus on the adaptation of space services to the constantly evolving world.

Mr. Henri has been elected member of the Radio Regulations Board (RRB) at the last ITU Plenipotentiary Conference in Dubai (29 October–16 November 2018)) and is also Chief Regulatory Advisor at OneWeb.

Dr. Henry R. Hertzfeld is the Director of the Space Policy Institute and a Research Professor at the Elliott School of International Affairs, George Washington University. He is also an Adjunct Professor of Law at GW and teaches the Space Law course. He is an expert in the legal, economic, and policy issues of space and advanced technological development. Dr. Hertzfeld has served as a Senior Economist and Policy Analyst at both NASA and the National Science Foundation and is a consultant to both US and international agencies and organizations. He is author of many articles on the legal and economic issues concerning space and technology. Dr. Hertzfeld is a member of the Bar in Pennsylvania and the District of Columbia.

Theresa Hitchens has recently joined *Space Defense* as a Senior Analyst and Lead Reporter. She has spent the past two decades working as a strategic space and defense-related researcher, writer, and opinion-leader on space and cyber security, multilateral governance, NATO, arms control, and international security issues. She is leaving her post as Senior Research Associate at the University of Maryland's Center for International and Security Studies. Before this, she was appointed by the Secretary General of the United Nations to serve in Geneva, Switzerland, as director of the U.N. Institute for Disarmament Research (UNIDIR). She held that post for 6 years. Prior to that she was a reporter on space and defense news for Defense News and the Inside Washington newsletters.



Dr. Ram Jakhu is a faculty member and the former Director of the Institute of Air and Space Law and is on the Faculty of Law, McGill University, in Montreal, Canada. He teaches and conducts research in international space law, law of space applications, law of space commercialization, space security, national regulation of space activities, and public international law. In addition to his extensive academic experience of over 30 years in the field of international and national Space Law and Policy, he has consulted to several private and governmental entities and helped draft national laws and regulations in various countries. Currently, he is the Project Director of an international research project for drafting McGill Manual on International Law Applicable to Military Uses of Outer Space (MILAMOS). He is Managing Editor of the Space Regulations Library Series and Member of the Editorial Boards of the *Annals of Air and Space Law* and the *German Journal of Air and Space Law*.

Prof. Jakhu initiated and managed a comprehensive international and interdisciplinary study related to global space governance, the final report of which has been published as *Global Space Governance: An International Study* (Springer, 2017). He served as Director of the McGill Institute of Air and Space Law; Faculty Member and Director of the Master of Space Studies Program of the International Space University, Strasbourg, France; and Member of the World Economic Forum's Global Agenda Council on Space Security. He has taught Space Law and Policy in several countries. He has made presentations to the United Nations Committee of Peaceful Uses of Outer Space in Vienna and at the United Nations Headquarters in New York.

In 2016, Prof. Jakhu received the "Leonardo da Vinci Life-Long Achievement Award" from the International Association for the Advancement of Space Safety and in 2007 the "Distinguished Service Award" from International Institute of Space Law for significant contribution to the development of space law. He holds Doctor of Civil Law (Dean's Honors List) and Master of Law (LL.M.) degrees from McGill University, Canada, as well as LL.

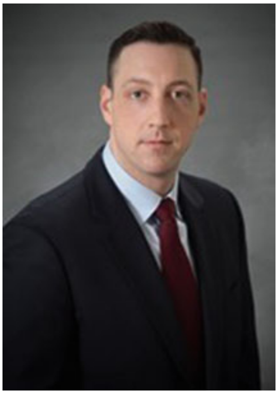
M., LL.B., and B.A. degrees from Panjab University, India.

Martin Jarrold is Vice President International Programme Development, Global VSAT Forum. He has worked for the Global VSAT Forum (GVF) since June 2001. His particular responsibilities include outreach to the member organizations of GVF and the further development of the profile of the association within the satellite communications industry and across the global telecommunications policy and regulatory community. This extends to the development and delivery of programs focused on extending the understanding of, and promoting the use of, satellite-based communications in various key end-user vertical markets.

Mr. Jarrold is a frequent contributor to various telecommunications and other industry publications. In addition, he regularly chairs and contributes to a wide variety of telecommunications conferences, symposia, and workshops around the world, including working with the International Telecommunication Union.

Mr. Jarrold has participated in various European Space Agency programs, leading the GVF contributions to projects on “Two-Way Satellite Communications” and on “Standards Preparation for SOTM Terminals.” A new collaboration with ESA on antenna testing using quadcopter drones is currently underway.

Previously, Mr. Jarrold was Commissioning Editor and Head of Research for *Space Business International* magazine. His earlier career was predominantly in teaching and writing. He holds an honors degree in History and Politics and is based at the headquarters of GVF in London.



Chris Johnson is the Space Law Advisor for Secure World Foundation and has 9 years of professional experience in international space law and policy. He has authored and co-authored publications on international space law, national space legislation, international cooperation in space, human-robotic cooperative space exploration, and on the societal benefits of space technology for Africa.

Prior to joining SWF, Mr. Johnson worked as an attorney in New York City and entered the space field in 2010 as an intern at the United Nations Office for Outer Space Affairs (OOSA) in Vienna, Austria, during the 53rd Committee on the Peaceful Uses of Outer Space. He has also served as an intern in the Office of International and Interagency Relations (OIIR) at NASA Headquarters in Washington, DC and as a legal stagiaire in the International Law and EU Legal Affairs division at the European Space Agency's Legal Department at ESA Headquarters in Paris, France. As a member of the Space Generation Advisory Council (SGAC), Mr. Johnson co-founded the Space Law and Policy Project Group in 2012.

Mr. Johnson serves as a Professor of Law (Adjunct) at the Georgetown University Law Center in Washington, DC, where he co-teaches the spring Space Law Seminar. He is also Adjunct Faculty at the International Space University (ISU) in Strasbourg, France, the Legal Advisor for the Moon Village Association (MVA), and a Core Expert and Rule Drafter in the Manual on International Law Applicable to Military Activities in Outer Space (MILAMOS) project.

Dr. Sanat Kaul serves as the Chairman and Managing Director of Delhi Tourism & Transportation Development Corporation Limited. Dr. Kaul has been the Representative of India on the Council of International Civil Aviation Organization in Montreal, Canada. He has held several important positions throughout his career including Joint Secretary of Ministry of Civil Aviation, Commissioner of Sales Tax Department, Government of NCT of Delhi, and Secretary – Delhi Finance Commission. Dr. Kaul has been an Independent Non-Executive Director of Noida Toll Bridge Company Limited since April 2008. He served as Director of Delhi Tourism

& Transportation Development Corporation Limited. He is now retired from the Indian Administrative Services. Dr. Kaul holds a Ph.D. in Economics from the University of London and a Master's Degree from London School of Economics. He has specialized in Aerospace Law from the Institute of Air & Space Law, McGill University, Montreal, Canada.

Vatsala Khetawat obtained her undergraduate degree (MEng) in aerospace engineering from the University of Sheffield in the United Kingdom. Concurrent to this program, she trained and successfully obtained her European JAA SEP Private Pilot Licence (PPL). After completing her undergraduate studies she participated in a professional development program called the Southern Hemisphere Summer Space Program (SHSSP) of the International Space University in Adelaide, Australia, in 2013, followed by an internship at the Avionics Department at the Indian Space Research Organization (ISRO). She continued her studies at the International Space University to obtain her Master of Science (M.Sc.) in Space Studies. She then worked at NASA Ames Research Center in California for 1 year under and a special ISU Internship program. Most recently she graduated with her Master of Technology Management from UC Santa Barbara in California. In addition to her academic and work experiences, she has also travelled to 29 countries, which gave her the opportunity to experience cultures and understand people's perspective. For the Handbook of Small Satellites she has worked with Professor Pelton to research small satellite constellations.

Christoffel Kotze established a small technology strategic advisory company in 2012 after a successful corporate career spanning two decades. This company specializes in providing assistance to digital transformation projects within organizations, with a special interest in the use of technology resources to support sustainable development. Current research interests include space technology and new approaches to digital transformation and solutions to the "digital divide." His academic background includes a Bachelor of Commerce Honors (Information Systems) – University of Cape Town, Bachelor of Science (Physiology & Microbiology) – University of Pretoria, Diploma in DataMetrics (Computer Science) – University of South Africa, and a number of strategy focused executive management courses at the Graduate School of Business from the University of Cape Town. He hold an M.Phil. (Space Science) degree from the University of Cape Town. He is ISACA Certified in the Governance of Enterprise IT.

Chris Kunstadter is Global Head of Space at AXA XL, a leading provider of space insurance. He is actively involved in all aspects of AXA XL's space activity, including technical, financial, and actuarial analysis, policy construction, claims handling, industry outreach, and business development.

Chris is a recognized leader in global space risk management issues. For over three decades, he has worked closely with satellite operators and manufacturers, launch providers, government agencies, and others to enhance industry understanding of space risk management and responsible space activity.

Chris is a member of the FAA's Commercial Space Transportation Advisory Committee (COMSTAC) and Chair of COMSTAC's Legal and Regulatory Working Group. He serves on the Executive Committee of the International Union of Aerospace Insurers (IUAI) and is a Charter Member of the Consortium for Execution of Rendezvous and Servicing (CONFERS).

Chris joined XL in 2006, after 23 years at USAIG, where he was Executive Vice President in charge of the Aerospace and IT departments.

Chris received a B.A. degree in Literature and an M.S. degree in Engineering from the University of California. He holds a Commercial Pilot license with Instrument and Multi-Engine ratings and is a Certified Flight Instructor. Chris is an avid musician and serves on the boards of several music-oriented not-for-profit organizations.

Shane Laverty is the Technical Writer at Kepler Communications. Shane chiefly supports the management of Kepler's domestic and international regulatory affairs, working to consolidate and communicate its technical endeavors and sharpen its written image.

Dr. Rene Laufer is Associate Research Professor of Space Sciences at Baylor University, Texas, as well as honorary Associate Professor at the University of Cape Town's Space Lab. He co-chairs the International Academy of Astronautics' small satellite committee and is actively involved in several small satellite related conferences and international working groups and co-authored book chapters, journal papers, study reports, and conference contributions in the same field. Dr. Laufer has formerly worked at German Aerospace Center (DLR) and the University of Stuttgart, Germany, in the area of planetary exploration and small satellites and teaches regularly on various space engineering, space exploration, and space science topics in four continents.

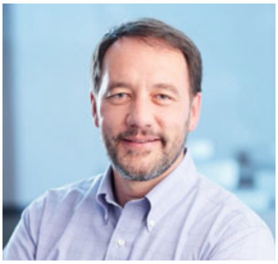
Dr. Rodrigo Leonardi holds a Ph.D. in Astrophysics (2006) from Brazilian Institute for Space Research (INPE) and a B.S. degree (1999) in Mathematics from the University of Brasília. He joined the Brazilian Space Agency in 2017 and nowadays coordinates a portfolio of initiatives to promote space-related science and technology. His past experience includes a Postdoctoral Research Fellow (2007–2009) position at the University of California, a Scientist position at the European Space Agency (2009–2015), and an Advisor position at CGEE, a think tank center for strategic studies, where he conducted prospective studies for the Brazilian space sector. He has coauthored 158 papers in peer-reviewed scientific journals.

Vanessa Lewis is a Communication Systems Modeling Engineer at Kepler Communications. Vanessa models Kepler's satellite network to ensure it complies with regulatory standards, and she assists with spectrum coordination between Kepler and other operators.

Matt Ligon has been involved in the design of space system electronics for the last 12 years. In 2012 he joined Planet Labs (then Cosmogia) as an early stage employee. He has been a key contributor in the development of the Planet Labs satellite systems in the areas of system design and planning, RF hardware design, and antenna design. In 2014, he co-founded Bitbeam to develop radio hardware for the fledgling cubesat industry. Matt returned to Planet in 2015 where he continues to work on radio system development. In 2019, Planet's "SuperDove" 3U satellite system achieved 1.7Gbps downlink throughput, a smallsat record that has yet to be surpassed by a flight proven system. Prior to Planet, Matt worked at Aerojet Rocketdyne developing instrumentation electronics for the J2-X rocket engine. Matt has a B.S. in Electrical Engineering from UCLA and M.S. in Electrical Engineering from USC.

Timothy J. Logue is the Senior Director of Sales and Business Development at Thales Alenia Space, having joined Thales's Washington, DC office in 2009. Mr. Logue has been involved in the satellite and telecom industries for more than 35 years, beginning as a policy analyst with the Communications Satellite Corporation. He has worked for satellite manufacturing companies for the last 13 years after 20 years as a consultant with law firms.

Mr. Logue has also been active in professional organizations, especially the Pacific Telecommunication Council since the 1980s. He attended his first PTC conference in 1981. Most recently he served as Co-chairman and Chairman of the PTC's Advisory Council and then was elected to the Board of Governors in 2013 and again in 2016. He is currently also the Treasurer of The Arthur C. Clarke Foundation, and has held leadership positions with the Space and Satellite Professionals International (formerly the Society of Satellite Professionals International).



Dr. Timothy Maclay is the Director of Mission Systems Engineering for OneWeb. His unit is focused on the network's space system architecture and provides technical and policy support to OneWeb's regulatory activities. Prior to joining OneWeb, Dr. Maclay was the VP of Systems Engineering at Orbcomm, where he spent nearly 20 years in various leadership roles in low-Earth-orbit (LEO) satellite constellation design and operations. He began his career with Kaman Sciences working in the area of space safety research after earning a Ph.D. in Aerospace Engineering Sciences from the University of Colorado in the fields of astrodynamics, debris environment modeling, and hypervelocity impact physics.

Dr. Maclay has served on orbital debris technical committees for the National Research Council, NASA's Engineering Safety Center, the AIAA, and the IAA. He has also served on the board of the Hypervelocity Impact Society. He has chaired a number of conferences and sessions associated with orbital debris and has presented and published extensively on related topics.

Dr. Amit K. Maitra is the U.N. Ambassadors for Refugees-Africa. He is the Founder and Chairman of the Foundation for Emerging Solutions. He has served for many years as a strategist and consultant to NASA, the U.S. Air Force, and the U.S. Department of Defense. He served as an advisor to NASA with regard to international technology transfer arrangements with regard to NASA Space Station Freedom. He has also over the years served as an advisor and consultant to the World Bank, Korean Information Technology, Japanese Aerospace Industry Association, IBM, RCA, and others on infrastructure development projects, including on various satellite communications systems. Dr. Maitra is widely published and has written a number of books on spectrum allocation policies, satellite communications development, the Internet, and information systems.

He has a Ph.D. from the Weatherhead School of Management from the Case Western Reserve University and a M.P.A.-M.A. from the University of Minnesota. He has been a visiting scholar at the Wharton School of Business at the University of Pennyslvania. He received his B.S. in engineering from the University of Calcutta where he graduated Summa cum Laude.

Peter Martinez is the Executive Director of the Secure World Foundation. He has extensive experience in space policy formulation, space regulation, and space diplomacy. He also has extensive experience in capacity building in space science and technology and in workforce development.

Prior to joining the Secure World Foundation, Dr. Martinez held the post of Professor of Space Studies at the University of Cape Town. Before this he acquired 15 years of executive level management experience and associated general management skills gained in the research and development environment of the South African Astronomical Observatory, a National Facility under the South African National Research Foundation, where he served as Acting Director for two extended terms and for shorter periods on numerous other occasions. From 2010 to 2015 he was the Chairman of the South African Council for Space Affairs, the national regulatory authority for space activities in South Africa. From February 2011 to June 2018, he served as the Chairman of the United Nations Committee on the Peaceful Uses of Outer Space (UN COPUOS) Scientific and Technical Subcommittee's Working Group on the Long-Term Sustainability of Outer Space Activities. From 2012 to 2013 he was South Africa's representative on the United Nations Group of Government Experts on transparency and confidence building measures for space activities. He is a member of the International Academy of Astronautics, the International Institute of Space Law, and a Fellow of the Royal Astronomical Society. He has authored or co-authored over 200 publications on topics in astronomy, space research, space law, and space policy.

Attila Matas, satellite Orbit/Spectrum consultant in the field of GSO and non-GSO satellites, is a retired head of the Space Publications and Registration (SPR) Division in the ITU Radiocommunication Bureau – Space Services department. During his 24 years career within the ITU (1993–2017), first as Satellite Engineer responsible for the Space Master International Frequency Register and later as Head of SPR division, he was directly responsible for the processing and publication of GSO and non-GSO space systems and Earth stations, submitted by administrations, for inclusion in the formal coordination procedures or recording in the Space Master International Frequency Register. This involved analysis and processing of applications with respect to the provisions of the Radio Regulations and Rules of Procedure on the use of frequency spectrum related to space services. Mr. Matas represented the ITU at the UN COPUOS meetings. He is an ITU World Radiocommunication Conference (WRC) veteran with participation at all WRC since 1992. On several WRC's he served as a secretary on the agenda items related to frequency allocations and regulation of Radionavigation Satellite and Space Science service or a senior spokesperson on space regulatory matters. He organized the first two ITU-R Small Satellite Symposiums. Mr. Matas holds a degree in radio engineering from the Czech Technical University of Prague, Czech republic.

Dr. Darren Mcknight is currently Technical Director for Centauri (formerly Integrity Applications, Inc. (IAI)) based in Chantilly, Virginia. He leads teams to develop creative solutions across widely disparate domains: global space technology awareness, preventing strategic surprise, modeling infectious disease outbreaks, empirical and analytic assessments of orbital debris, and workforce productivity. Dr. McKnight's latest book, *Make Yourself Indispensable*, leverages his years of serving as productivity catalyst for a variety of government and commercial clients in a wide variety of technical domains. As a member of the International Academy of Astronautics' (IAA) Space Debris Committee, he has been active in position paper development, selection of symposia papers, and execution of the annual International Astronautical Congress. Darren has authored over 100 technical papers and presented them in 18 countries. He has appeared on tens of TV, radio, and newspaper interviews including with Discovery Channel, BBC, CBC, Space News, The Space Show, etc. Dr. McKnight received his B.S. from the United States Air Force Academy, his Master's Degree from the University of New Mexico, and his Doctorate from the University of Colorado.

David Meltzer as the Secretary General of the Global VSAT Forum (GVF). Meltzer has over 25 years of experience in the satellite industry, including serving as a board member for both a regional satellite operator and for a mobile satellite operator. Previously, he served for 16 years in various business and legal roles at Intelsat, culminating in serving as Intelsat's General Counsel and Executive Vice President for Regulatory Affairs. Most recently, Meltzer served as the General Counsel and Chief International Officer of the American Red Cross where he led its legal, international disaster relief, and development activities.

Nishith Mishra is currently engaged by the Center for Research in Air and Space Law, Institute of Air and Space Law (IASL), McGill University, as a Research Assistant and Coordinator and regularly assists the Center with its various projects and academic initiatives. He is a current LL.M. (Thesis) Candidate at the Institute of Air and Space Law, Faculty of Law, McGill University. He joined the Master of Laws (Air and Space Laws) Program of at McGill University in Fall 2018 as a Nicolas M. Matte Fellow and has subsequently been awarded the Graduate Excellence Award in Law (2019) and the Stephen Smith–James McGill Graduate Law Award (2019) for his academic performances.

Prior to joining IASL, he completed his Bachelor of Law B.A. LL.B. (Hons.) Program from National Law University Delhi, New Delhi, India, in 2013 and has worked as a civil and commercial litigator, a private-equity and foreign direct investment transactional lawyer, as well as an associate consultant (Aviation and Space) in New Delhi, India. He wishes to pursue professional and academic engagements in Space Law and Policy matters/initiatives.

Mina Mitry is Co-Founder and Chief Executive Officer of Kepler Communications. Mina combines his aerospace background with an impressive capacity to break down complexity and manage calculated risks. Under his leadership Kepler was named one of the most innovative companies in the world by Fast Company.

Sa'id Mosteshar is Professor of Space Policy and Law, Director of the London Institute of Space Policy and Law (ISPL), and Fellow of the Royal Aeronautical Society (FRAeS). A practicing Barrister and California Attorney, with degrees in physics and econometrics, he advises governments, international agencies, and space corporations on policy and law. Sa'id has served as a member of the UK Space Leadership Council and Adviser to its Delegation to UN COPUOS. He received the 2016 International Institute of Space Law's Distinguished Services Award for "services to the international community and developments in the field of Space Law both as an academic and a practitioner."

Dr. Sreeja Nag is a Senior Research Scientist at BAER Institute, based in NASA Ames Research Center. She is also the Autonomy Ssystems Engineer at Nuro, helping build and validate some of the first self-driving robots on public roads. Her research interests include distributed space systems, space robotics for Earth observation, planning and scheduling of constellations, and space traffic management. Sreeja received her Ph.D. from the Department of Aeronautics and Astronautics at Massachusetts Institute of Technology, Cambridge. As a student, she led the SPHERES Zero Robotics program and has served as an International Fellow at the European Space Agency (ESTEC), NASA's Jet Propulsion Lab, and Goddard Space Flight Center. She has also worked with small satellite startups on systems architecting and constellation design.

Alexandre Najjar is a Consultant at Euroconsult, based in Paris since 2016, and is the Editor-in-Chief of the 5th edition of Euroconsult's Prospects for the Small Satellite Market research report. His expertise focuses on launch vehicle and satellite market studies, the manufacturing industry, access to space, emerging markets, and constellations. He is a regular contributor to Euroconsult's research reports as well as client-specific consulting missions related to launchers and satellites, New Space, and the industrial and economical aspects of the space sector. He has been involved in a wide range of consulting missions covering mega-constellations, spaceports business models, small satellite launch solutions, dedicated launchers, the verticalization of industrial actors, electric propulsion, as well as in-orbit servicing.

Carlos Niederstrasser is a Systems Architect with Northrop Grumman Innovation Systems, working on strategic activities, new business pursuits, and special initiatives. Some of the programs Carlos has supported at NGIS include the Mission Extension Pods, the Antares Accident Investigation Board, and the Dawn interplanetary spacecraft. Carlos is a member of the steering committee for the Khalifa University Space Systems and Technology Program in the UAE. His annual "Small Launch Vehicle Survey" has become the definitive compendium of world-wide small launcher development efforts. Carlos holds degrees from Princeton University and Stanford University.

Jeff Osborne is Co-Founder and VP Business Development at Kepler Communications. His ability to think outside of the box and take risks is a refreshing spin on traditional views of business development. Before starting Kepler, he founded and ran a number of student teams at the University of Toronto developing suborbital rockets and small satellites. Jeff's leadership has allowed Kepler to secure impressive commercial and government contracts whilst still in its early growth stages.

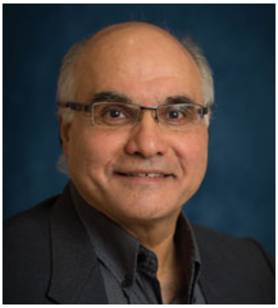
Maxime Puteaux is a Senior Consultant at Euroconsult and has been based in Paris since 2012. He is the Editor-in-Chief of the 22th edition of Euroconsult's *Satellite to be Built and Launched by 2028*. His expertise focuses on launch vehicle and satellite market studies, the manufacturing industry, access to space, as well as emerging markets and constellations. Maxime manages Euroconsult's research reports as well as client-specific consulting missions related to the industrial and economical aspects of the space sector.

Jonathan Rall has a Bachelor of Science degree in Electrical Engineering from Washington University in St. Louis, MO, and a B.S., M.S., and Ph.D. in Physics from American University in Washington, DC. He is currently the Associate Chief Scientist for Programs and Projects within NASA's Office of the Chief Scientist (OCS). Dr. Rall has held a number of positions in NASA including the Planetary Research Director at NASA Headquarters, the Associate Director of the Solar System Exploration Division at NASA's Goddard Space Flight Center, and has spent two decades as an active Research Scientist at NASA developing novel, laser remote sensing techniques for Earth and planetary science applications.

Frank Robert is Associate Vice President of A.T. Kearney and Space Practice Lead for Australia/NZ and a member of the Communications, Media, and Technology practice in Australia. He has contributed to development of space policies and strategies for several decades. He has served on the Australian Space Agency Advisory Group since its formation. He has contributed to several NASA Planetary missions and as well as planning for leading-edge commercial spacecraft. He has competencies in telecommunications, satellite, spectrum, fixed and mobile services, corporate strategy, technology strategy, new products and services, R&D enhancement, and network economics. He is the principal author of an A.T. Kearney White Paper on creating/optimizing economic impact of an Australian Space Agency, Space Policy and Legislative environment. He also led in establishing A.T. Kearney's collaboration with two space law practices. Further he has supported the formulation of strategy for three major multi-spacecraft satellite operators, one involving as Fixed Satellite Services Satellite and two for Mobile Satellite Services.

Mr. Robert received his B.A. from Amherst College in Economics with minors in Geology and Astronomy and his M.B.A. from Cornell University with minors in Radio Astrophysics and Optical Astronomy. He had the great privaledge of working under NASA Grant with Thomas Gold on electrostatic movement of Lunar regolith and under Carl Sagan on Martian suface morphology.

Commodore Mark Roberts is a Faculty Member of the London Institute of Space Policy and Law and Chairman of the Air and Space Power Association. He is the Defence and Security lead for RHEA Group in the UK. Mark is also the project director for the Spaceport 1 Consortium, developing a vertical orbital launch capability in the Outer Hebrides. Previously Mark undertook a variety of lead consultancy roles in the defense, security, energy, education, and transportation sectors and was the Operations Director for the Security Business in a large infrastructure company. Before moving into the commercial world, Mark was in the Royal Air Force, where he was an operational pilot and commanded both 12 Squadron and RAF Lossiemouth. Mark was Director of the Air Staff in MoD (2007–2010), with Space and Cyber Policy in his portfolio, and Head of Capability Deep Target Attack, with responsibility for Combat Air, Complex Weapons, Land Engagement, and elements of the Queen Elizabeth Class Carrier Programme.



Dr. Safieddin (Ali) Safavi-Naeini received his B.Sc. in E.E. from the University of Tehran, Tehran, Iran, in 1974 and both M.Sc. and Ph.D. in E.E. from the University of Illinois (Champaign-Urbana), USA, in 1975 and 1979, respectively. He is a Professor in the Department of Electrical and Computer Engineering at the University of Waterloo and holds the NSERC/C-COM Satellite Systems Industrial Research Chair in Intelligent Radio/Antenna and Novel Electromagnetic Media. He is also the Director of the Center for Intelligent Antenna and Radio System (CIARS) at the University of Waterloo.

His research activities deal with wide range of applications of electromagnetic devices and systems. He has published 200+ journal papers and 400+ conference papers in international conferences. He has led several international collaborative research programs with research institutes in Germany, Finland, Japan, China, Sweden, and USA.

Mike Safyan, Vice President of Launch, Planet. In 2011, Mike Safyan joined the eight-person founding team at Planet (known as "Cosmogia" at the time) where the company was building the first iterations of its Dove cubesat in a Cupertino garage. Since then, Planet has expanded to a global organization leading the NewSpace industry, with the world's largest fleet of Medium-resolution and High-resolution Earth Imaging satellites. Mike is responsible for Planet's Launch strategy and has overseen the launch of over 350 Planet satellites across 22 launch attempts. Mike received his B.S. in Aerospace Engineering from UCLA and an M.Sc. in Space Studies from the International Space University in Strasbourg, France. He started his career working on lunar rover designs for the Barcelona Moon Team competing for the Google Lunar X-Prize and then joined the PhoneSat team at NASA Ames where he worked as a Systems Engineer developing ultra low-cost cubesats utilizing smartphone technologies. In 2018, Mike received the SSPI Promise Award, which recognizes outstanding achievement by satellite industry professionals under the age of 35.

Dr. Mark Skinner joined The Aerospace Corporation in 2017 as a Senior Project Leader for Space Traffic Management in support of the FAA in the development of civil and commercial space traffic management. Prior to joining The Aerospace Corporation, Skinner was with the Boeing Company, heading up the commercial space situational awareness group, conducting research into observational and analysis techniques to advance the state of the art in space surveillance, and developing infrared sensing techniques of resident space objects. Skinner began his career in aerospace in 1991 at Pennsylvania State University as a research faculty member. He also worked on NASA's Chandra great observatory mission. Afterwards, he continued involvement with Chandra, Kepler, and additional civil space new business efforts. He next moved to Ball Aerospace in Boulder, CO, where he served on the NASA Structure and Evolution of the Universe advisory committee. For the last 7 years, he has served as a private sector delegate for the US State Department to the UN COPUOS Expert Group on space debris and space situational awareness. Skinner has published and presented scores of technical papers for various journals and conferences, including the International Astronautical Congress, *Acta Astronomica*, SPIE, *Nuclear Instruments and Methods*, the *Astrophysical Journal*, and the Astronomical Society of the Pacific. Skinner received a Bachelor of Science degree in physics, and a Bachelor of Science in the Humanities and Science from the Massachusetts Institute of Technology. He received a Doctor of Philosophy in experimental astrophysics from the University of Wisconsin-Madison, and a Masters of Business Administration from the International Space University in Strasbourg, France.

Dr. Arunas G. Slekys is the Vice President of Corporate Marketing at Hughes Network Systems, LLC, and the elected Chairman of the Board of the Global VSAT Forum, one of the key organizations promoting the satellite industry. His 40-year career in telecommunications spans technology R&D and business development worldwide. His career began at NASA/Caltech's Jet Propulsion Laboratory and then Bell-Northern Software Research where he played a key role to pioneering 1G/2G/2.5G cellular systems and terminals. He then served as the founding Senior Vice President of R&D for NovAtel Communications, where he co-authored two patents for packet data over cellular. He as served the past 25 years at Hughes Network Systems as Vice President/GM of Wireless, Broadband Satellite Networks and Corporate Marketing.

In 1991, Slekys received the Alberta Centennial Engineering Award for attaining the highest distinction in his profession. He holds a B.Sc. in Electrical Engineering from the University of Toronto, an M.Sc. from the University of Illinois (Urbana-Champaign), and a Ph.D. in Computer/Communications Eengineering from UCLA.

Professor Herman Steyn is head of Satellite Engineering and Control Systems at Stellenbosch University (SU). He holds a Master's Degree in Electrical and Electronic Engineering from SU, a Master's Degree in Satellite Engineering from the University of Surrey in the UK, as well as a Ph..D from SU. Prof. Steyn's space experience started with the development of Africa's first fully indigenous satellite called SUNSAT during the late 1990s. He then had a 4-year stint as Principal Engineer and Team Leader for satellite control systems at Surrey Satellite Technology Limited, where he participated in many European Space Missions, for example, the Rosetta mission to a comet. He returned to South Africa in 2002 as Head of Product Development and Executive Director at SunSpace Information Systems (SA's first satellite engineering company), where he helped to develop, build, and commission earth observation satellites for international customers and SumbandilaSat for the SA government. In 2005 he joined SU full time and established a satellite engineering group in the Electronic Research Laboratory to develop low-cost nanosatellites. He established a spin-off venture from the university with some of his graduate engineers called CubeSpace, supplying ADCS components and systems for CubeSats and other nanosatellites.

Dr. Su-Yin Tan is a Senior Lecturer in the Geomatics Program and Director of the Applied Geomatics Research Laboratory at the University of Waterloo, Canada. She teaches courses on geographic information systems, remote sensing, and spatial data analysis. She is also a Faculty Member and elected member of the Academic Council of the International Space University (ISU), where she regularly serves as a Core Chair and Space Applications Department Chair for the Space Studies Program (SSP) and lectures at the Masters of Space Studies (MSS) program.

Dr. Tan is a distinguished Gates Scholar and received her Ph.D. degree from the University of Cambridge (UK), two Master's degrees from Oxford University (UK) and Boston University (USA), and B.Sc. (Env) from the University of Guelph (Canada). She was previously a Visiting Fellow at the University of

Cambridge; Visiting Researcher at the Environmental Change Institute, University of Oxford (UK); and member of Christ Church College. She received the 2014 Outstanding Performance Award for exceptional contributions to teaching and scholarship at the University of Waterloo.

Dr. Tan has an interdisciplinary background in the environmental sciences and spatial analysis methodologies in a range of application areas, such as climatology, ecosystem modelling, and remote sensing. Originally raised in Papua New Guinea, she has a diverse international background and built a record of teaching and research excellence in North America, Australia, Asia, South America, and Europe. She maintains an interest in issues related to space technologies and environmental applications.

Dr. Morio Toyoshima received a Ph.D. degree from the University of Tokyo, Tokyo, Japan, in 2003 in Electronics Engineering. He joined the National Institute of Information and Communications Technology (NICT) (former CRL, Ministry of Posts and Telecommunications), Japan, in 1994 and soon after was engaged in research for the Engineering Test Satellite VI (ETS-VI) optical communication experiment and later involved in the Ground-to-Orbit Laser-com Demonstration (GOLD) experiment with NASA's Jet Propulsion Laboratory. He joined the Japan Aerospace Exploration Agency (JAXA) (former NASDA) for the development of the Optical Inter-orbit Communications Engineering Test Satellite (OICETS) from 1999 to 2003.

In December 2003, he became a Senior Researcher of the Optical Space Communications Group, NICT. Starting in October 2004, he spent a year as a guest scientist at Vienna University of Technology, Austria, in the field of optical space communications. In 2006 he conducted the ground-to-OICETS laser communication experiments in NICT. He was involved in the development of a Small Optical TrAnsponder (SOTA) for a 50 kg-class micro-satellite and conducted laser communications and basic quantum communications experiments from 2014 to 2016. His research interests are laser beam propagation through atmospheric turbulence, space laser communications, and quantum cryptography. He is now the Director of the Space Communications Laboratory, the Wireless Networks Research Center in NICT, since 2011.

Dr. Richard Welle is a Senior Scientist in The Aerospace Corporation's xLab, where he focuses on the development of new applications for CubeSat-class spacecraft, with a particular emphasis on CubeSat-scale optical communication systems and technologies. Prior to this, Welle was Director of the Microsatellite Systems Department in the Space Materials Laboratory for 10 years, where he was responsible for the Aerospace program developing CubeSats and other kg-class spacecraft, as well as supporting various non-satellite programs and developing new research and technology programs in the field of microsatellites.

Welle joined The Aerospace Corporation in 1986, supporting launch vehicles and satellite systems over a range of disciplines including thermophysics and heat transfer, reacting/radiating flows, multiphase and cryogenic flows, electric propulsion, and mechanical systems. Since 2005 his work has focused on microsatellites and microsatellite systems. Welle earned his bachelor's degree in physics and chemistry from Southwest State University, Marshall, Minnesota, his master's degree in physics from the University of Tennessee Space Institute, and his Ph.D. in aerospace engineering from the University of Southern California. Welle has over 60 technical publications and has been awarded over 25 patents on technologies in the areas of small satellites, microfluidics, identification taggants, solar power, ultrasonics, and optical communications.

Introduction

Introduction to the Small Satellite Revolution and Its Many Implications

Joseph N. Pelton and Scott Madry

Contents

Abstract

This chapter provides a broad introduction to this Handbook on small satellites. It offers information as to why this Handbook was created and its primary uses. It provides guidance as to the structure of the Handbook and its Appendices and a useful information as to how the text of this Handbook and its references can be employed to understand about the history, the technology of small satellites,

J. N. Pelton (ed.), *Handbook of Small Satellites*,
https://doi.org/10.1007/978-3-030-36308-6_1

ground stations and systems for users of these small satellites, the operation of these facilities, launch services, as well as definitions concerning the many different types of these small satellites that exist today. It also provides information, explanations, and definitions about the economic, legal, policy, and regulatory aspects of these systems. It has an entire section devoted to providing information about the many diverse and growing aspects of applications and services that can be used by employing small satellites and how they are uniquely able to provide some of the newer and more entrepreneurial space-based services. There is a chapter that relates the uses of small satellites as a means to achieve the United Nations Sustainable Development Goals (SDGs) for 2030. In short this Handbook seeks to provide a comprehensive set of information about all aspects of smallsats, their uses and applications, the related ground systems, their launch and operation, as well as related economic, legal, policy, business, and financial aspects of these new types of space systems. Finally it seeks to address key issues and challenges for the future that include frequency allocation and management, orbital space debris, space traffic control and management, as well as competitive technological, business, economic, and financial issues. It also notes that the COVID-19 pandemic will have a major impact on the world economy and that this will include a major impact on the small satellite and launch industries. In short there will likely be a number of bankruptcies in this field as a direct or indirect consequence, but these setbacks do not impact the innovative technologies or other information presented in this handbook.

Keywords

Cubesats · Disruptive technologies · Electronic beam-forming ground antennas · Geosynchronous Earth orbit (GEO) · High-throughput satellites (HTS) · Launch vehicles · Low Earth orbit (LEO) · Medium Earth orbit (MEO) · Orbital space debris · “Smallsats” · Satellite constellations · UN Sustainable Development Goals · Global Navigation Satellite Services (GNSS) · Precision Navigation and Timing (PNT)

1 Introduction

There are many excellent books and articles now available on all aspects of small satellites. This is a field that has exploded in activity and global interest in the past decade. There are a wide range of individual sources about the technology, others on the applications and services, and yet others about the economics, launch arrangements, policy and regulation, and social and political consequences. Yet there has not previously been a comprehensive and interdisciplinary source of information that collects all of this information together in a holistic way – until now. This Handbook of small satellites seeks to provide a complete overview of all aspects of the small satellite field.

Thus leading experts from around the world have been recruited to provide in one reference source the latest technical, operational, financial, regulatory, and service information about small satellites on a global basis. This provides information from the smallest femtosat (below 100 g in size) up to the largest and most sophisticated small satellites that range in size up to 500–600 kg in mass. Such "smallsats" are being deployed in so-called mega-LEO satellite constellations that OneWeb, Planet, SpaceX, Telesat, Boeing, LeoSat, Comstellation, and others are deploying or proposing to deploy in the next few years.

The COVID-19 pandemic that occurred in 2020 has caused health and economic consequences of staggering worldwide consequences. This horrific pandemic will impact the small satellite and launch industry in the months ahead. Already LeoSat and OneWeb small satellite constellations have declared bankruptcies, and others will follow. There will be more failures of small satellite constellations, launcher companies, and other associated space services companies. Despite these economic failures, the innovative new small satellite technologies, the new more efficient launch systems, the new ground systems, and the many other innovations discussed in this Handbook remain valid and very useful sources of new enterprise in this field. In the late 1990s, the original small satellite constellations saw major economic collapses. The economic failures constituted by Iridium, Globalstar, ICO, and Orbcomm made a huge impact on satellite development and the ready access to capital financing for some time. Yet recovery was achieved in the years that followed. The same seems likely to occur. Despite these setbacks the information in this Handbook remains useful and quite relevant.

Thus this Handbook provides information about the historical development of "smallsats" as well as an explanation of the various types of "smallsats" that are being developed and launched today. It also provides the latest information about the space and ground system technology and the relevant applications and services, as well as the economic, policy, regulatory, legal, business, and social aspects of this burgeoning field of space activity.

This book seeks to provide information from the perspective of all those interested in space satellites. It thus seeks to provide useful information for the student experimenter and for those undertaking smallsat projects for civilian space agencies and military and defense agencies. It also provides useful information suitable for so-called "NewSpace" business enterprises engaged in small satellite-related businesses as well as the political and legal officials that provide the regulatory oversight for small satellite systems. This includes information about the efficient allocation and oversight of the frequency spectrum needed for these systems to operate effectively.

This Handbook on small satellites addresses key issues such as orbital space debris, end of life removal of small satellites from orbit, new ways to design and build satellites, frequency spectrum coordination, as well as innovative ways to address the problems of jamming and interference. It even addresses new approaches to the efficient use of space resources and satellites such as placing hosted payloads on larger satellites. It addresses the new opportunities for achieving cost-efficient "space-like" services from high-altitude platform systems (HAPS).

It is the hope of all the contributors to this reference work and from the scores of participants from around the world that this Handbook will be found helpful. In particular it is hoped that the many articles that follow, plus the many references to books and articles found in endnotes, can serve as a useful guide to the design, manufacture, deployment, use, oversight, and business developments needed for the future success of "small satellites" enterprises around the world. The burgeoning number of smallsat systems and launches represent a powerful element in the growth of "NewSpace" or "Space 2.0" ventures. These NewSpace businesses have sprung up around the world. They are now giving new impetus to a rapidly expanding space industry. In time these space enterprises will expand to become a "trillion dollar" industry. These NewSpace industries will help sustain a growing world economy. In short, "smallsats" will touch everyone. They will aid enterprises that range from the ecology to banking, from fishing to mining, and from airline travel to health care and education.

This is not to say that "smallsats" will replace large satellites. Large and powerful high-throughput satellites, for instance, are best positioned to provide broadcast television services to small low-cost satellite dishes. Other satellite services, such as Precision Navigation and Timing (PNT) services and those designed to provide military- and defense-related intelligence, will likely continue to require larger space and high-power levels as well. The bottom line is that different services and applications will likely require different types of satellites of varying sizes and power levels.

The technical, operational, and economic reasons for the "right type" of satellite in terms of size, power level, architecture, and mass will be explained in later sections of this chapter. Instead of a "replacement" of large and powerful satellites, we will see a sort of coexistence of all types of satellites from tiny and small to medium and large scale. Nevertheless, small satellites seem likely to provide an ever-expanding range of services in the coming decade.

Even in the area of larger satellite design and deployment, innovations that come from the smallsat field seem likely to have a major impact. Technology from the field of scientific satellites has been traditionally transferred over to the area of application satellites. For instance, the three-axis body-stabilized satellite with enhanced pointing accuracy and enhanced solar power efficiencies that was first developed for planetary research missions was rapidly transferred to the field of application satellites. The same transfer of technological innovation will also be the case with "smallsat" innovations. Miniaturization, enhanced testing, or manufacturing efficiency techniques that come from "smallsat" programs are being and will be shared and transferred to "large satellite" programs. The case of Canada's new three-satellite RADARSAT Constellation is perhaps an excellent case in point.

2 Scope and Structure of This Handbook

This Handbook of small satellites seeks to provide a comprehensive overview of the small satellite field. It thus addresses the history of small satellites and provides insight into the technology and its evolution over time both in terms of the spacecraft, the tracking, telemetry, and command aspects of its operation, and the corresponding changes to the ground segment for users of this technology. Such innovations represent a critical part of the evolutionary path that has furthered and enabled the feasibility and economics of small satellites. Key new features such as improved and accelerated testing processes, the use of hosted payloads, high-altitude platform systems, active debris removal, on-orbit servicing, new ground systems with electronic tracking capabilities, and more will be addressed as well.

After the technological and operational aspects are presented, the next section will address the key aspects of small satellite design, engineering, and manufacture. This will also address business-related concerns such as contracting, resiliency and sparing philosophy, and protection of intellectual property rights.

The next section addresses the great complexity of applications and services and the many different types of small satellites that can be deployed to meet the needs associated with the increasingly diverse range of services as well as the many types of organizations and units that are now pursuing the active deployment and use of small satellites. This even includes the use of small satellites by defense agencies and military ministries. The distribution of smallsat uses for 2018 as developed by Bryce Space and Technology consulting shows the following breakdown. This was 11% for communications, 41% for technology development and verification, 2% for military and intelligence purposes, 37% for remote sensing, 6% for scientific purposes, and 3% for other or unknown uses. But this snapshot of current uses does clearly show current trends. The overwhelming usage that is shown by either national filings or filings with the International Telecommunication Union suggests that communications or networking applications will vault into the number one purpose in the coming years as mega-LEO systems are deployed for this purpose in the future (Bryce Space & Technology 2019).

The final major element of the Handbook addresses the economic, legal, and regulatory issues and constraints that are concerned with the increasingly complex field of small satellites.

This is followed by the conclusion section that assesses all of the current trends, major technical, economic, social, and regulatory issues that are pending, and how this relates to the small satellite revolution and Space 2.0 industries. This synoptic final analysis provides a coherent overview of the field of small satellites around the world. This final analysis relates the key trends in the area of small satellites and its ups and downs to broader world goals and objectives such as the United Nations' 17 Sustainable Development Goals (See Fig. 1) and the work of the Davos World Economic Forum.

There are also a series of appendices that provide information on small satellite projects and activities as well as information related to regulatory actions and policies as well as a glossary of terms. In light of the transitory nature of developments in this fast-moving field, an effort is made to provide website addresses with current URLs so that the current status of projects can be obtained from the official site for small satellite projects. Collectively this Handbook should provide comprehensive information about every aspect of the fast-moving world of small satellites.

Fig. 1 New capabilities offered by smallsats can benefit developing nations and the UN Sustainable Development Goals (Graphic courtesy of the United Nations)

3 Historical Background

Small satellites are not new. The very first satellites that were launched into orbit in the late 1950s and early 1960s such as Sputnik I, Explorer 1, Oscar 1, SCORE, Relay, and Syncom were all "small satellites." At the time, there was of course no thought being given to whether spacecraft were "small," "medium," or "large" in size in those pioneering years. The lift capacity of the launch vehicles in those days, especially those in the USA, could only launch what are now considered small satellites. Thus in the earliest days, the antennas were often simple dipole antennas, and the power was quite limited (see the Oscar 1 satellite shown in Fig. 2).

These very early satellites typically did not exceed the volume of a large beach ball, and their mass was only a few kilograms. This was because these early satellites were largely experimental in nature, limited to launch vehicle capacity, and expectations were accordingly low as to spacecraft size.

These first satellites were thus largely designed to prove that such technology could truly function in outer space. There were limited expectations as to what capacity these spacecraft might make in terms of actually offering commercial services.

Even the first "operational satellites" such as Early Bird (Intelsat 1), Molniya 1, the Initial Defense Satellite Communication System (IDSCS) satellites, and ANIK-1 were relatively modest in their throughput capabilities (i.e., typically less than a few 100 telephone circuits). These early satellites were also quite low in power (i.e., less than 100 watts) and had rudimentary stabilization systems. These earliest satellites accordingly required sophisticated ground stations with huge aperture antennas to receive and transmit signals. They had to be of this size and

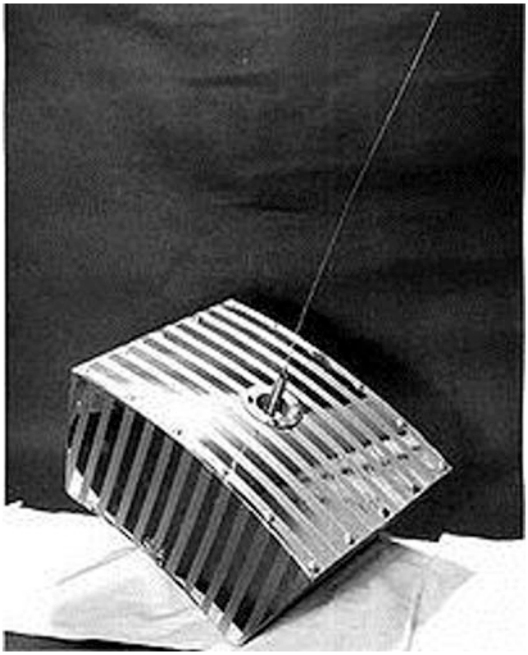

Fig. 2 The Oscar 1 amateur ham radio satellite was an early “smallsat” (Graphic courtesy of the Amateur Satellite Organization (AMSAT))

power to be able to communicate effectively with these early small and low-powered satellites as they circled the Earth.

The first Intelsat Standard A Earth stations that operated in tandem with the first few generations of Intelsat satellites, for instance, were gigantic steerable antenna systems. These gigantic facilities were 30 m (i.e., nearly 100 ft) in diameter and weighed perhaps several tens of tons. These stations were also expensive to operate. These mammoth facilities required staffing on a continuous 24 h a day and on 7 days a week basis with a staff of perhaps 50–60 people. They had cryogenic cooling systems to boost the receiving sensitivity of the antenna’s electronics and massive steering capabilities that were very exact. These huge antenna systems were thus almost like radio telescope systems and cost in the range of $5 million to $10 million dollars apiece. This was at a time when a dollar was valued at three to four times as much as it is today. In the earliest days of satellite communications, the largest investment was thus in the ground stations and not the satellites (Pelton 2003).

But this changed rather quickly in the years and decades to follow.

This major trend in satellite development became known as technology inversion. This phrase referred to the fact that the satellites moved to become more complex and massive. Ground antennas on the other hand became simpler and smaller. Each new generation of the Intelsat satellites, for instance, quickly grew in mass, power, antenna size, and technical sophistication such as adding three-axis stabilization. This allowed precise pointing of the satellite antenna system toward specific locations on Earth as high-gain antennas were added to the satellites.

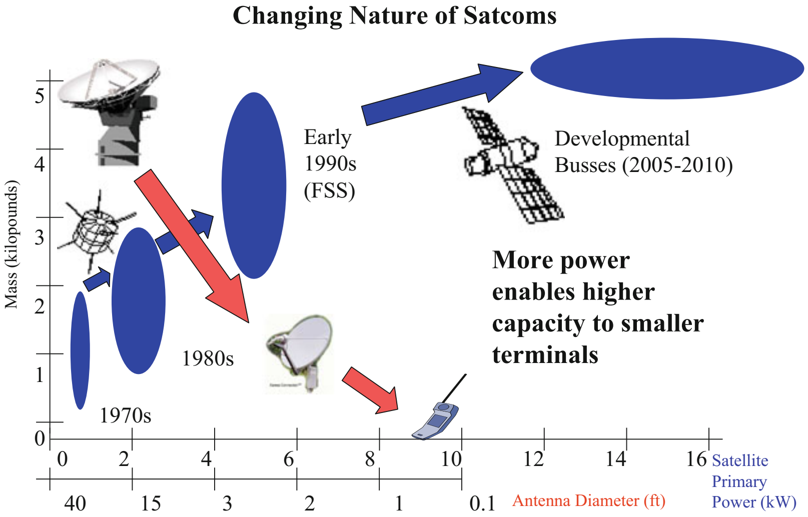

Fig. 3 The technology inversion: satellites grew in size and ground systems shrank (Graphic courtesy of the author)

The objective of this trend was to allow ground antenna systems to be smaller and less costly and to achieve higher throughputs for communications satellites. And communication satellites indeed represented the number one practical application for the satellites that were deployed in the 1960s, 1970s, 1990s, and 2000s.

This 50-year trend from the 1960s to the 2010s is clearly depicted in Fig. 3. The figure below shows this process of technology inversion. During this five-decade-long evolution, the satellites became bigger, higher-powered, and more capable, while the ground stations kept shrinking in cost and size. The current smallsat revolution is serving to reverse some aspects of this longer-term trend.

The primary application for satellites during this time was for satellite communications. And when satellite communications were demonstrated to be possible from geosynchronous orbit (sometimes known as the Clarke Orbit in honor of Arthur C. Clarke who first proposed this type of orbit for global communications in 1945), there was a sudden and indeed voracious demand for bigger and better comsats to fill the demand for international communications, global television broadcasts, and networking associated with international trade, which outstripped the capacities of international coaxial cable networks. The increasing cost efficiency of each new generation of satellites, improved launch vehicle capabilities, improvements in ground antenna systems, the demand for television channels everywhere, and need for long-distance communications around the world led to higher and higher capacity satellites and indeed more different types of satellite networks.

Over a period of some 50 years, the trend in the satellite world was predominately defined by the growth profile shown in Fig. 3. The satellites, especially those for communication services, grew bigger and bigger. The large-scale solar arrays on these increasingly more powerful satellites generated much more power, and there were also larger battery systems to provide backup power during periods of eclipse. The satellites evolved to have three-axis body stabilization that allowed very precise pointing capabilities and also allowed the solar arrays to be constantly oriented to get the greatest amount of exposure to the sun. This, in turn, allowed very large aperture antennas on the satellites to be deployed, so they could be constantly pointed to specific locations on the Earth. This, in turn, enabled increasingly concentrated and tightly spot beams and the ability to reuse spectrum multiple times since the spot beams could be geographically isolated from one another.

These design innovations in the antenna systems to create tightly defined spot beams as they were added to these much larger satellites also saw the addition of polarization isolation in the transmitted beams. These innovations allowed more and more intensive reuse of radio-frequency spectrum. The more powerful and more capable satellites allowed the use of smaller and less expensive ground antenna systems.

The mass, size, and power of satellites thus grew and grew. Although the satellites in the sky were more expensive, the ever-expanding number of user antennas on the ground could be smaller and smaller and much less costly to acquire and eventually automated so that no staff was needed.

The increase in the critical dimensions of the satellites increased their size and power by a factor in the range of 200 times, but the throughput and lifetime performance increased proportionally to a much greater degree. The giant communication satellites of today such as the Intelsat Epic Satellites, the ViaSat-1 and ViaSat-2, and the EchoStar Jupiter satellites have tens of thousands the times of throughput capacity and ten times greater lifetime of the earlier satellites when the field of satellite communications began (see Fig. 4).

There has been a staggering increase in performance that is only paralleled by the increase in the performance of computers over the past 50 years. The increase in cost efficiency and improved performance of communication satellites is staggering when one considers “then” versus “now.” The Intelsat 1, known as Early Bird, launched in 1965, had a capacity of only a few 100 voice circuits compared with the millions of voice circuit or the thousands of television circuit capabilities demonstrated by today’s high-throughput satellites.

In the mid-1980s and 1990s, however, the model of how satellites might evolve for the future began to develop new branches and new schools of thought. CTA and Orbital ATK (now owned by Northrop Grumman) developed a smaller geosynchronous satellite platform with lower power known as the GEOStar-1. This new smaller GEO satellite formed the basis of new satellite communications ventures for developing countries. New platforms of different sizes were developed for different types of users with different levels of service requirements.

Other companies, however, took the idea of smaller commercial satellites in a whole new direction entirely. They began designing constellations of many smaller satellites deployed in low Earth orbit (LEO) for various purposes. These included the Iridium satellite system, the Globalstar satellite system, and the ICO system that were to provide land mobile satellite services to handheld satellite phones. Orbital

Fig. 4 The ViaSat-2 satellite can transmit at a rate of 160 gigabits/s (or the equivalent of 10,000 times the capacity of the Early Bird Satellite of 1965), and its lifetime is 10 times longer (Graphic courtesy of ViaSat)

ATK came up with the idea of even smaller LEO satellites for message relay, and this system was known as Orbcomm. Yet another company that was backed by Craig McCaw and Bill Gates thought it could utilize new frequency spectrum in the millimeter wave spectrum (i.e., the Ka-band) to create a massive so-called “mega-LEO” system. This system was first known as the Calling Satellite System and then renamed Teledesic. This system was to have had 840 satellites plus 80 spares. This system design was to have many innovative features such as the use of phased array antennas on the satellite so as to create the effect of permanently “painted” beams on the ground so that the ground system could be simplified. Thus all of the pointing and switching of beam would be done on the satellite (Teledesic History n.d.). During the 1990s and 2000s, there were many different satellite designs, for many types of satellite services, in different frequency bands, with quite different types of ground systems, and different schemes for their launch into different types of orbits.

What all of these systems had in common was to design, manufacture, and launch a large number of “smaller” satellites into large-scale constellations – mostly in low Earth orbit (LEO). Instead of deploying large and expensive satellites in GEO orbit, there would be a much larger number of smaller satellites launched into LEO orbit much closer to Earth. Some of the orbits proposed were as much as 40 times closer to the Earth surface than the geosynchronous Earth orbit (GEO) satellites. The driving idea was to find more cost-efficient ways to design, manufacture, test, and launch these satellites. They all sought to lower the costs of manufacturing and launch these smaller satellites. They also intended to exploit and leverage the "power advantages" and the much reduced signal delay associated with the lower orbits. The so-called path loss was associated with the weakened signal that had to travel back to Earth from an orbit that was some 35,870 km (22,230 miles) in distance away. Latency was the time lag required for the signal travel to reach the ground from a distance almost a tenth of the way to the Moon.

The signals transmitted from a satellite or sent up to a spacecraft spread out in a circle. This meant that because of the spreading circle, the power loss was a function of the square of the distance traveled. If the satellite was 40 times further away from the Earth, the path loss was not 40 times less, but actually 1600 less (or 40^2). This power advantage inherent in low-orbiting satellites could serve to make the user terminals much smaller and less expensive. The plan, in the case of the land mobile satellite systems, was to create satellite handheld phones that could "talk" to these lower Earth orbit (LEO) satellite constellations. The problem with the design of the small satellites for constellations that would completely cover the Earth was that of solid geography. The closer the satellites were to Earth, the more satellites had to be launched to get global coverage. The closer the satellites were to the ground, the lesser the amount of the coverage. This was somewhat the reverse of issue of a radio or television antenna on the ground. The taller a TV or radio antenna extends, the more coverage it has. The Iridium system with one of the lowest planned orbits came up with a design thus ended up with a constellation that required 66 satellites plus at least 8 spares (Iridium Satellite Constellation n.d.).

This shift in design concept to create low Earth orbit constellations of small satellites versus the deployment of just three bigger and higher capacity satellites in GEO orbit in order to create total Earth coverage was a major change in satellite architecture. The earlier model had been to manufacture, meticulously test, and qualify a small number of large, complex, and expensive highly unique satellites that were then launched into GEO orbit. This new model was envisioned to be quite different. James Stuart, the designer of the Teledesic satellite, stated clearly his vision to me as we worked on the Teledesic system design together at the University of Colorado in the late 1980s. "We are going to design and build these satellites like TV sets or Video Cassette Recorders (VCRs). And through large scale production and automated manufacturing of components and maybe even robotic integration we can achieve large economies of scope and scale" (Conversation with James Stuart at the University of Colorado in the late 1980s n.d.).

But despite the optimism that accompanied all of these small satellite constellations, a rather devastating crush of bankruptcies were to follow. Starting in August 1999, Iridium, Globalstar, ICO Ltd., Teledesic, and Orbcomm all declared bankruptcies.

The reasons for these bankruptcies actually differed. In some cases it related to creating totally new markets for new services. In other cases it related to the long time it took to design, manufacture, and deploy a very large network of small satellites and ground control systems plus marketing and selling handsets or small ground antennas before any revenues could be realized. In some cases it related to the performance of the handsets. In other cases it was because the estimated cost of building the satellites was greatly off. The initial estimated cost of deploying the

Teledesic satellite system was about $4 billion. When the Teledesic system actually went into bankruptcy, the estimated costs had topped $9 billion. The bottom line is that small satellite constellations as a business venture that financial investment banks and investors were willing to back became extremely anemic. Some of those that bought up the shares of systems such as Iridium actually tried, unsuccessfully so, to sue the backers of those systems for fraud. None of the factors are helpful to the deployment of commercial small satellite constellations.

In fact, some technical and financial experts are suggesting that a number of satellite ventures, including the SpaceX Starlink venture with the most small satellites in their constellation proposals of anyone, might be at risk, due to both underfunding and technical and operational constraints. Satellite analyst Tim Farrar has said: "There are several multi-billion dollar NewSpace satellite projects that could suffer the same fate (i.e. the bankruptcy of Iridium). . ... What will that meand for investor perceptions? Will non-NewSpace incumbents benefit? And more fundamentally, is the NewSpace bubble about to burst?" (Farrar 2018).

The failure of one small satellite constellation will not alter the dynamic course and success of "NewSpace" ventures. Space 2.0 is really not about how many small satellites are built but a new way of thinking about space and the creation of new business models. It involves marshalling technological innovation, especially in the areas of IT, digital equipment, and artificial intelligence, to create new more cost-efficient space systems that can open entirely new markets. Yet at the same time, a large number of bankruptcies of "NewSpace" ventures and failure of small satellite constellations will undoubtedly have a negative effect on the space industry around the world. It is as simple as "Success breeds success, and failure brings other failure."

4 The Beginnings of Small Satellite Innovation

But there were other key factors to consider on the small satellite frontiers. Technical experts worked with amateur radio operators to design and build at low cost small satellites for global radio connectivity. These satellites known as Oscar 1, Oscar 2, etc. proved that low-cost satellites were possible to design and build and that simpler methods and materials could produce viable spacecraft at lower cost (AMSAT Live Oscar Satellite Status Page n.d.). NASA and other space agencies created the concept of the cubesat that was 10 cm × 10 cm × 10 cm in size.

The initial programs encouraged university students and researchers to design and build their own space experiments. Over the past three decades, the cubesat experimental design process created a widespread interest in space experimentation. This process has now grown and grown. Over time more and more university students, and then even high school and secondary school students, were offered the chance to design and build their own space experiments. This "cubesat" process has now led to thousands of cubesats to be launched into orbit. Today there are a number of companies with websites online where students and interested individuals from around the world can order a standardized cubesat frame and other key components that can be easily fit into one's cubesat project.

Beginning in 2009, Bob Twiggs, a faculty member at Morehead State University, formally proposed a "PocketQube satellite" that was one-eighth the size of a cubesat. This "picosat" configuration that was 5 cm × 5 cm × 5 cm in size was first flown in November 2013 with four PocketQube satellites packaged together with the Unisat-4 launch. The new Vector R launch vehicle is now expected to offer regular PocketQubeSat launches. The popularity of "PocketQubeSats" is expected to grow as buses, kits, and components are now available online, and this lower-cost alternative to cubesats becomes better known (Pocketqube Satellites n.d.). More information about this new type of "picosat" is provided in the chapter about the "femtosats" and "picosats" that follow.

The miniaturization associated with cubesat projects thus gave rise to a whole new mentality about what is a "satellite" and what can be accomplished by achieving miniaturization of key components in a satellite, the fabrication of quite small spacecraft. The idea was not only to use quite small digital processors, miniaturized sensors, and other very small components but also to be less reliant on extensive, time-consuming, and expensive components. If one of these quite small and much less expensive satellites were to fail, then the idea was to build and launch another one.

What is amazing to some is that all of the critical elements of a satellite can be crammed into the confines of a 10 cm × 10 cm × 10 cm cube. As shown in Fig. 5, these elements include power supply, antennas, sensors, or instruments that are the

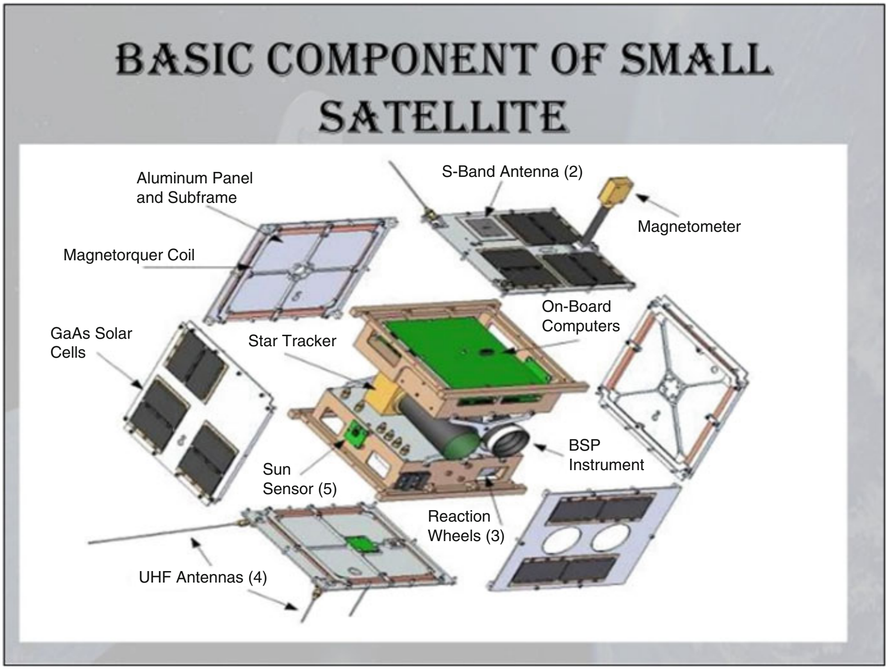

Fig. 5 Exploded view of components of a "cubesat"

“payload,” star trackers or sun sensor, onboard computer and digital memory systems, reaction wheels, and thermal control systems. Some even have a fully functional three-axis stabilization thruster system.

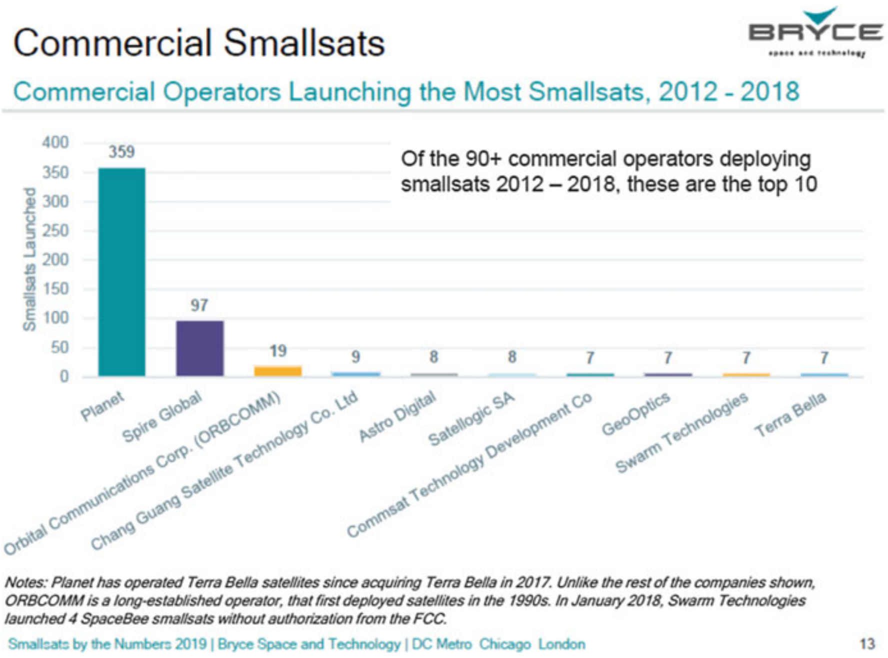
Some have said that this new small satellite approach to space systems was the start of something quite new for the overall industry. Observers look back and say that the “smallsat revolution” was one of the key stimulating factors that have led to what is now called “Space 2.0” or “NewSpace.” This new “Silicon Valley”-type thought process was based on a flurry of questions like “what if we did things differently?” There were questions such as the following: How can we reinvent the space industry to make it better, more agile, and entrepreneurial in style? How can we improve on the R&D processes of the past 30 or 40 years that were largely based on the military-industrial processes and how civilian space agencies have been doing business? How can we do things thinking more like “Silicon Valley” industrial innovators and entrepreneurial business people? How can we create new more agile industrial modes of innovation? How can we do things more quickly with more rapid prototyping? How can we create, build, and test new types of satellites at significantly lower costs, more rapidly, and with less mass? How might we innovate by using the miniaturization of components and “digital processors and sensors” such as those involved with designing digital computers and new electronic and IT industrial products?

If one looks at the launch history of small satellites during the period 2012 through 2018, it can be seen that the predominant source of these new smallsat deployments has been from start-ups who have embraced entirely new models of how to design, test, launch, and operate smallsat system. Planet and Spire Global, two smallsat start-ups, have been responsible for about 40% of the over 1000 smallsats launched, while the much longer established Orbcomm network deployed less than 2% (see Fig. 6 that features a graph showing the top 10 commercial launchers of smallsats out of over 90 commercial operators. In addition over 200 nonprofits launched smallsats as well) (Bryce Space and Technology 2019).

Quite parallel to the new way of thinking about the design and manufacture of small satellites came the new way of thinking about creating more efficient launch vehicles, reusable rocket systems, and space planes that are safe enough to carry people on suborbital flights or even into orbit. Suddenly everyone involved in “NewSpace” or what some call “Space 2.0” began to question the way things had been done in the past and began seeking new ways forward (Pelton 2019).

The new commercial mentality has increased launch options and reduced the cost of launch operations. The number of smallsat launches from 2012 to 2018 is over 1300, but over 700 were launched in 2017–2018, and if filings are an indication, that number will continue to increase. Some 104 cubesat systems (most of these being 3-unit systems) were launched on a single Indian polar satellite launch vehicle in February 2017 (PSLV-C37 Successfully Launches 104 Satellites in a Single Flight n.d.).

During the period 2012–2016, 68 smallsats were lost due to launch failure, but only one of these came in the 2017–2018 period which showed many more launches and much fewer launch failures (Op cit, Bryce space and technology) (Fig. 7).



Commercial Smallsats

Commercial Operators Launching the Most Smallsats, 2012 - 2018

Of the 90+ commercial operators deploying smallsats 2012 – 2018, these are the top 10

Notes: Planet has operated Terra Bella satellites since acquiring Terra Bella in 2017. Unlike the rest of the companies shown, ORBCOMM is a long-established operator, that first deployed satellites in the 1990s. In January 2018, Swarm Technologies launched 4 SpaceBee smallsats without authorization from the FCC.

5 New Ways of Thinking About How to Design, Manufacture, and Launch Satellites

The way this new way of thinking about satellites in terms of the design, manufacture, and testing actually did not start in Silicon Valley at all. One of the places this new way of thinking started was at the University of Surrey just outside of London. Some very smart engineering faculty such as Professors Barry Evans and Martin Sweeting started to work in small satellite technologies with engineering students at the university in 1981 and was formally incorporated in 1985 as Surrey Satellite Technology, Ltd. This is also now known as the Surrey Space Center and headed by Sir Martin Sweeting. This company has been acquired by Airbus, but it is still a separate company within this very large aerospace company. This company, in 1985, designed and built the University of Surrey-1 (UOS-1) satellite that demonstrated that a small satellite could be designed and built with miniaturized components and high-performance digital processors to accomplish a number of sophisticated functions in orbit within a small and relatively inexpensive satellite. The rest is history.

Today the Surrey Space Center can claim a number of distinctions within the "small satellite world" that includes (i) building and arranging for the launch of 2–4 small satellites per year since its first small satellite projects; (ii) arranging for

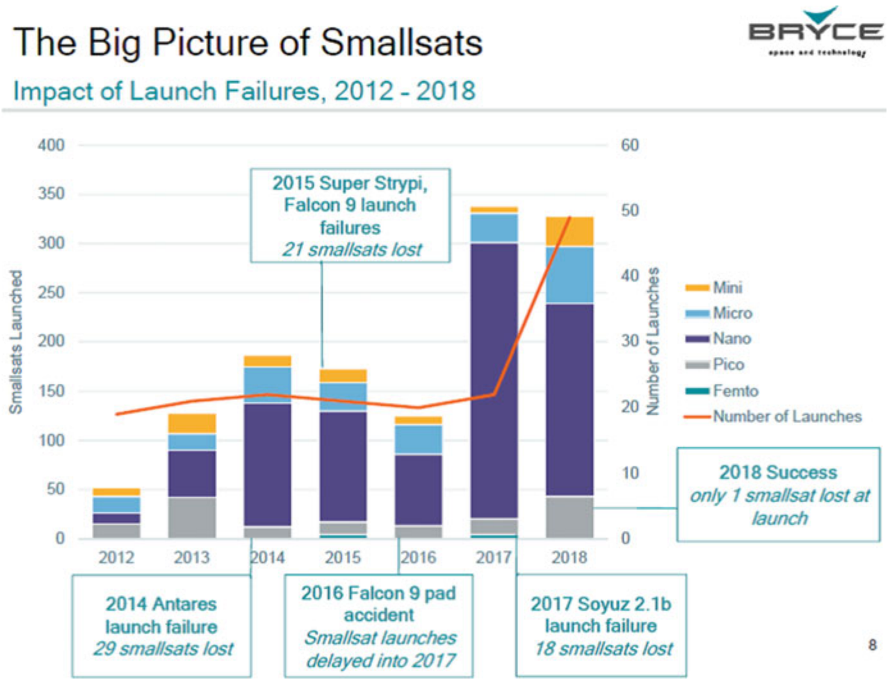

Fig. 7 The Changing profile of small satellite launches (Graphic courtesy of Bryce Space and Technology)

35 launches from 8 different launch sites around the world and manufacturing a total of 60 satellites that have now been launched; (iii) at the current time having 10 satellites and 12 payloads in production; and (iv) conducting 18 satellite training programs for various programs and countries around the world to spread the knowledge about how to design and build small satellites (Surrey Satellite Technology Limited n.d.)

There is also a small satellite research and manufacturing center in the USA. This is known as the Space Dynamics Laboratory (SDL) that is a part of the Utah State University Foundation and is located in Logan, Utah. SDL combines the talents of local aerospace companies with researchers, faculty, and engineering students at Utah State University. SDL has been in existence since 1959 at the very start of the Space Age and has designed and built many small satellites over the years. Utah State University and SDL, together with a wide range of sponsors, and especially the American Institute of Aeronautics and Astronautics, host an annual small satellite conference in August in Logan, Utah (Small Satellite Conference n.d.).

This conference has been running since 1987 when the first conference was held. A complete listing of papers presented at this conferences ever since its founding is available in a special digital library that has been created to preserve the thousands of papers that have been presented at the conference for over three decades. These papers can be accessed via this website: https://digitalcommons.usu.edu/smallsat/. This extensive collection of articles can be accessed under such headings as missions, subsystems, structures and materials, signal processing, applications, and more (Digital Library of Papers Presented at the Small Satellite Conference Since 1987, Digital Commons Library, Utah State University, Logan, Utah n.d.).

6 The Many Different Types of Small Satellites

As the history of "smallsats" has evolved since the 1980s, it has evolved in many different directions.

First: There have been those that have pursued student-based satellite experiments such as the cubesat program to design very small and low-cost systems. Some of these have been as small as 01–09 g femtosatellites or picosatellites (i.e., 10–100 g) but are most typically cubesats that might have a mass of about 3–5 kg in most of these student exercises. Today most student experimental cubesats might be released from the Japanese module on the International Space Station that was built for such smallsat deployments.

Second: Others have developed more sophisticated smallsats for highly sophisticated scientific experiments that are for space agencies or military- or defense-related agencies. Some of these are in the 1–6-unit cube satellite range, while others are quite a bit larger and in some cases are designed as constellations such as the European Space Agency's three-satellite "Swarm" constellation or NASA's MMS four-satellite constellation. These satellites are currently measuring the Earth's magnetosphere and seeking to detect how magnetic North and magnetic South poles are shifting. Defense agencies are also beginning to build or contract for small satellite constellations for various activities related to their missions.

Third: Groups such as SSTL in Surrey, England, and the Utah State University have assisted countries or organizations that wish to create small satellites for specific applications as they first enter the field of space services. In this case they provide assistance and training for these entities or national space initiatives to create their first satellites for such purposes as data relay, remote sensing, or emergency services.

Fourth: There are a growing number of commercial organizations that are designing larger-scale small satellite constellations for remote sensing (i.e., Planet), position location (i.e., Spire), or communications or data networking (i.e., O3b and SpaceX). These satellites can range from 3-unit cubesats such as the "Doves" of the Planet system for remote sensing up to 500 km communications satellite in large-scale LEO constellations, such as those planned by Space X, Boeing, Telesat, and others.

Fifth: There are those that have decided to place "hosted payload" packages on larger satellites such as the Aireon System that is flying on the Iridium NEXT system. The US Federal Aviation Administration's Office of Space Transportation, known as FAA-AST, has created its own satellite classification system as shown in Table 1. (The classification system as provided in Table 1 for femtosats to nanosats is almost universally agreed. The definitions for microsats, minisats, and above, however, do vary.)

Table 1 Definition of types of “smallsats” based on mass

Mass classification system for “smallsats” in kgs (kg)
Femto 0.01–0.099 Kg (10–99 g)
Pico 0.1–1 (100 g to 1 kg)
Nano 1.1–10 (generally akin to cubesats)
Micro 10.1–200 Kgs
Mini 201–600 Kgs
Small 601–1200 Kgs
Medium 1201–2500 Kgs
Intermediate 2501–4200 Kgs
Large 4201–5400 Kgs
Heavy 5401–7000 Kgs
Extra heavy >7001 Kgs

Source: FAA AST, The Annual Compendium of Commercial Space Transportation 2018

Table 2 seeks to sort out the great diversity of “smallsats” that now exists. This diversity in size, mass, orbit, power, application, lifetime, functionality, and ability to maneuver and deorbit is confusing (see Table 2).

What is not obvious in the chart is that small satellites are more adept at providing some services than others. It is possible to shrink some key components of a satellite such as digital processors and sensors, but there are limitations with regard to other components. Satellite antennas and their “gain” (or transmission efficiency) are related to their aperture size which correlates to the square of their radii and the inverse square of their radio frequencies. There are limits on power due to the size of solar cell arrays. The area of the photovoltaic exposed to the sun is directly correlated to the power they can generate. The bottom line is that in the case of telecommunication services that depend on power and antenna aperture size, there are constraints on how much can be done with small satellites for communication services.

As noted earlier, there is advantage for small satellites when they are deployed in much lower orbits. A lower altitude orbit does allow the advantage of reduced path loss and reduced transmit beam spreading. But satellites can only sustain a LEO orbit if they are above about 160 km. In fact they actually need to be higher for two reasons. They need to be higher to achieve broader coverage without unacceptably high levels of switching between beams and from satellite to satellite. As one orbit satellites at lower and lower altitudes, the number of satellites needed for global services goes up exponentially and thus the need for switching frequency that affects reliability and continuous sustainability of service. Also satellites deployed in constellations need to be higher in orbit to stay in orbit for many years. Otherwise gravity and atmospheric drag on the satellites would make them deorbit much more quickly. The International Space Station at an altitude of about 300 km, for instance, has to be quite frequently re-boosted to stay in orbit.

The bottom line is that small satellites are well suited to data relay and optical remote sensing, but the usage of small satellites for broadband services such as for television broadcasting and for active radar imaging is really incredibly difficult to

Table 2 A guide to the many types of small satellites and their uses (This chart needs to be fixed)

The many applications, sizes, and characteristics of so-called smallsats								
Function/size	Telecommunication	Messaging/ data relay	Amateur radio	Remote sensing constellation	Relay to and from ground systems	Meteorological	Scientific experiment	Student experiments
Small mission 100–500 kg	Typical (see, e.g., OneWeb or Telesat constellation)	Typical (see, e.g., Orbcomm)	Not applicable	Typical for some commercial constellations	Typical (see, e.g., Orbcomm)	Typical for LEO and larger	Typical	Rare
Microsat 25–99 kg	Occasional	Typical	Typical	Sometimes	Often	Not applicable	Often	Sometimes
1 U–6 U CubeSat 1–25 kg	Not applicable	Rare	Occasional	Possible, e.g., Planet	Occasional	Not applicable	Sometimes	Typical
Nano-, pico-, or femtosat∗(10 kg–10 g)	Not applicable	Not applicable	Not applicable	Not applicable	Not applicable	Occasional	Not applicable	Typical

[a] Definitions can vary, but a nanosat will typically be in the 1–10 kg range (also this can be a cubesat). A picosat is in the 100 g to 1 kg range and a femtosat is in the 10–100 g range. Smallsats in commercial constellations can often be in the 50–500 kg range, but not always. Planet has 3-unit cubesats that are less massive (All rights reserved by Joseph N. Pelton. Licensed to Springer Press for this book)

provide from LEO satellite constellations using small and lower-power satellite. This is simply a matter of technical design for both the satellite – based on power limitations – and in the case of home-based television reception installed low-cost user ground terminals.

Broadcast satellite systems to the home to low-cost receiving dishes work very well with consumer dishes that are constantly pointed in a fixed direction and do not have to track the satellite. These television broadcast satellite systems that currently provide over 25,000 television channels worldwide also require spacecraft with large aperture antenna dishes and the ability to transmit at very-high-power levels. Low Earth orbit satellites that travel at high speed across the horizon require tracking capability in the ground system (thus adding cost and complexity) and spacecraft with much higher power, large aperture antennas, and suitable spectrum suited to broadband services. Small satellite constellations can support data relay, digital communications for Internet services, and reasonable throughput data links, but direct to the home television remains best suited to GEO satellites and to user ground systems now installed in millions of homes and systems designed to service apartment buildings and condo units. Indeed most of the small satellite constellations that are currently planned for deployment are largely geared to providing new data connectivity to underserved or unserved regions of the world where Internet-based services are quite limited or even nonexistent.

In the case of remote sensing satellites, optical and ultraviolet sensors can be miniaturized with small sensors and passive collection of light and UV signals from the ground. Such systems can operate quite efficiently from low orbit constellations at modest power levels. Indeed such systems as Planet with hundreds of 3-unit cube satellites now operating can collect data and download it quite efficiently on a global basis. Radar systems are another matter. These types of satellite sensing system require high power that must be transmitted down to the ground and then be reflected back up. This does not mean that radar sat operations cannot be accomplished from smaller satellites, but it does mean that power levels constitute a problem and that this represents a challenge for small satellites in the radar sensing area. Canada is currently deploying its new “RADARSAT Constellation” that is quite a bit smaller than its initial first-generation RADARSAT deployed over a decade ago. This new constellation is composed of three satellites in this new network having relatively high power. Even though they are nearly 500 kg per satellite and as can be seen, the satellite has rather substantial solar arrays to support significant levels of operational power. The design of these new satellites has borrowed ideas from the smallsat revolution that allows them to be smaller than the original Canadian RADARSAT enables but still allows for their efficient operation. In short, design improvements and more efficient components can also be transferred to the design and operation of larger satellites to make them more cost-effective and easier to launch (RADARSAT n.d.) (see Fig. 8).

Finally, there are satellite services for Precision Navigation and Timing (PNT). In this case the prime constraint is the very high cost of precise atomic clocks that are deployed on these types of satellites. The network of satellites and the size of the constellation are optimized on the basis of effective global coverage and a

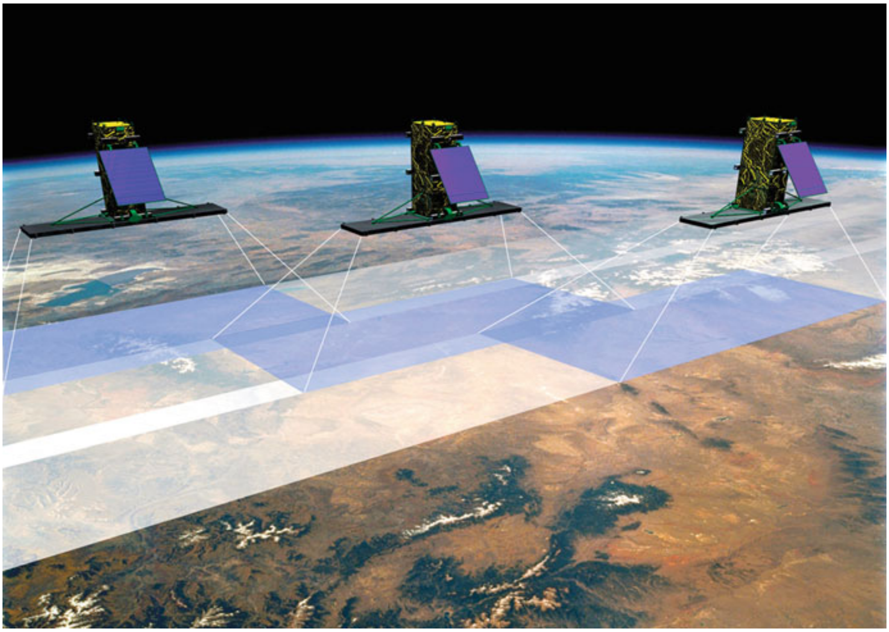

Fig. 8 The new three-satellite Canadian RADARSAT constellation is powerful enough to perform its mission (Graphic courtesy of the Canadian Space Agency)

minimization of the number of clocks that are needed. Deploying of a larger number of smaller satellites in a constellation would drive up costs since it would require the use of more atomic clocks.

The bottom line of this analysis of the relative merits of smallsats, smallsat constellations deployed in LEO orbits, and large and sophisticated satellites generally deployed in GEO orbits is to conclude that there is no single solution that is best. There are different solutions for different applications and services that result in different answers as to the most economic and logical design for satellite services. In some cases small satellite constellations, especially in the case of optical remote sensing, seem to offer a clearly superior answer. Systems, such as the Planet network, seem to provide the most economic and technically sophisticated network design for at least rapid repeat of sensing coverage. Large-scale LEO or MEO networks for digital networking such as represented by O3b, or systems such as those being deployed by Telesat, Boeing, SpaceX, or others, may prove quite cost-effective. The economic feasibility of LEO networks to support corporate enterprise networks for very-high-speed networking using rather large and sophisticated "small satellites" such as that proposed by the LEOSAT system remains to be proven economically. There are questions as to whether LEO smallsat systems designed to provide very high data rate corporate services will be able to provide the needed technical level of standards of service.

7 The Challenges of Design, Manufacture, and Testing of Smallsats

The field of small satellites has led to a host of innovations. This has resulted in a wide range of innovations that has changed a wide range of practices. Many of these innovations have permeated the space industry and affected the practices of space agencies, defense-related space agencies, and traditional aerospace manufacturers. It is interesting to note that some of those planning to fabricate large-scale small satellite constellations include not only SpaceX but also Boeing and AirBus and traditional communications satellite operator Telesat. SES and Intelsat, the two largest traditional satellite operators, have taken more than passing interest. SES has now taken full control and has been expanding the O3b constellation. Intelsat came very close to being directly merged with the OneWeb constellation, and this project was not completed due to Softbank withdrawing its offer of financing.

The change caused by small satellite systems ripples through today's space industry and can now be seen throughout the industry. One of the biggest areas of change relates to design, manufacturing, and testing. The traditional way that application satellites such as for communications or remote sensing were procured was through a set of specifications. These could be via a performance set of specifications that left it to the manufacturer to come up with a design that would meet these performance specs. Commercial operators of satellite systems used this form of procurement because it avoided specification changes and overruns. It capped expenses. This approach could also add incentive fees for meeting schedules and reliable performance. The other approach was to use a design specification that spelled out how the satellite was to be designed and spelled out materials and components to be used and even testing processes. This design specifically more typically came from defense agencies. These types of contracts with design specifications were awarded under a cost plus fee basis and constituted a more expensive form of contracting.

The procurement of satellites was seen as a long, arduous, and demanding process with many steps along the way that were stretched out over many years. There were initial design reviews (IDRs) between the procuring party and manufacturer to start the process. These were followed by other design review and ultimately a final design review, followed by actual manufacture of subsystems with testing undertaken, followed by systems integration and final testing. Some of the largest satellite operators had a team of engineers and scientists at the manufacturers' plant to oversee the manufacturing and test of the satellites. Typical production cycles were 36 months to even 48 months for the most sophisticated large-scale satellite. Production and final testing of large GEO satellites of this type were for a limited number of satellites ranging from perhaps three to six in number. Costs were in the tens of millions to even hundreds of millions of dollars, especially for defense-related satellites that might be especially designed with radiation-hardened components.

When the first commercial small satellite constellations were designed and built for Iridium, Globalstar, and Orbcomm, the whole paradigm as to how one should design, manufacture, and test satellites began to change drastically. One might, for example, use the Iridium system as an example of the change. The procurement was for 100 satellites, not 3 to 6, in number. The concept was to design and build the satellite production line that resembled automated production lines and to use 5 sigma quality and validation standards to produce a satellite of the highest quality so that extensive and expensive testing of each and every satellite was no longer necessary. The idea was to produce satellites not over periods of months and years but in terms of days. When the last of the Iridium satellites were rolling off the production lines at the Motorola plant, they were being produced at the rate of one every 4.5 days.

There were many design innovations that were geared not only to provide new and improved functionality to the satellite but also to aid improved manufacturing and testing reliability. These innovations included the use of phased array antennas that eliminated the need for the precise shaping of transmitting and receiving antennas. Also all of the satellite electronics use solid-state amplifiers rather than radio tubes. Remarkably the accelerated manufacturing and scaled-back testing of each satellite produced a remarkable reliability record. The initial Iridium satellite system that was deployed in 1997 and 1998 is only now being replaced by generation NEXT satellites nearly 20 years later, even though they were originally designed for a 6–7-year lifetime. The Iridium system was also designed with intersatellite links to aid sparing and backup as well as allow the entire global network of 66 satellites plus 8 spares to be controlled by two tracking, command, and control Earth station facilities. All of these innovations have been subsequently included in subsequent small satellite constellations.

This is not to say that Iridium was unique. The engineers, scientists, and production personnel that were involved with the design, manufacturing, and testing of other new small satellite systems such as Globalstar and Orbcomm use many of the same innovations to cut costs, increase production times, limit testing costs, and use solid-state technology. Others provided different innovations. The particular design of the Orbcomm satellites allowed cost reductions related to the ability to launch more satellites more efficiently at the same time, use lower-cost Pegasus launch vehicles, and lower stabilization costs. The common factors that are seen throughout the small satellite industry today are the much more rapid mass manufacturing techniques as well as new and much more efficient approaches to quality and validation testing and verification techniques.

Today the innovation in manufacturing and accelerated testing continue apace. Today there are continuing efforts to use automated manufacture of components in the production of smallsats. This includes the concept of additive manufacturing of components to create consistency of production. The key to reliable 3D printing involves high-quality standards for materials that are used in the printers as well as improved printer designs. It is possible that innovations here can also allow components to weigh less and thus reduce the amount of mass to be launched in large-scale constellations. The other key issue remains the extent to which one can use off-the-shelf components rather than much more expensive space-qualified materials and components.

In some cases inexperienced designers can jump to conclusions about where, when, and how one might use such off-the-shelf materials for wiring, thruster jets, fuels, and digital processors. These might pass tests on the ground but will perform differently in space. This can lead to shorts, fires, or failures in the outer space environment. NASA, ESA, and other space agencies have created test facilities to confirm whether certain materials, wiring, or component elements can be safely utilized in space without overheating, creating a fire, or leading to other hazardous conditions. The key is to recognize that a change in temperature, pressure, or gravity can alter the safety and performance of various materials, wiring, gases, etc. Expert advice needs to be sought when planning to use off-the-shelf materials or non-space-qualified components such as processors, electronic equipment, heat pipes, reaction wheels, fuels and thruster jets, etc.

There are a range of new approaches that are being used with regard to verification and validation testing. One approach that is used with cubesat-type systems such as the "Doves" or 3-unit cubesat remote sensing satellites in the Planet network is to assume that a certain percentage of these satellites will fail but that the constellation has a sufficient population for the network to perform smoothly. Another strategy is to produce enough units at sufficiently low cost to be able to provide sufficient number of spares to replace any satellites that fail. Most small satellite system designers try to do a "type qualification" of their initial satellite under the most stringent conditions. Thus they strive for the highest levels of consistent production so that their first, their tenth, and their hundredth products are produced exactly the same and to the most consistent standards.

There are countervailing influences here. In the case of the Planet production of their smallsat "Doves," there is a team that is consistently seeking to improve their performance. The past generations of satellites, in terms of upgraded performance, were perhaps 4–5 years apart. In the case of Planet, their improved design and upgraded performance may come only months apart. Constant improvements are being sought. The key is to ensure that upgrades in design and performance do not degrade consistency of production, reliability of design, and production quality.

8 Key Challenges for Small Satellite Constellations Related to Regulatory and International Process Issues

Clearly there are a number of advantages that come with the deployment of small satellites that are typically deployed in low Earth orbit. These advantages are (i) reduced transmission path loss due to their deployment in low Earth orbit; (ii) use of lower cost components and more off-the-shelf components that reduce costs; (iii) ability to achieve economies of scope and scale not only in their manufacturing but perhaps especially so with regard to accelerated validation and quality testing; and (iv) also their reduced size and mass and lower orbits making them easier to launch and at a lower cost. For instance, a total of 88 Planet satellites were launched on a single Indian Polar Satellite Launch Vehicle in February 2017. In fact additional 16 cubesats were also launched to set a record of 104 satellites being launched at one time on a single rocket (Foust 2017).

But there are also challenges and difficulties that are also present with the global trend to launch more and more satellites into orbit. There are very real regulatory, spectrum allocation, RF interference, and other constraints that must be addressed.

These difficulties include such problems as (i) orbital debris mitigation and concern about the so-called Kessler syndrome; (ii) radio-frequency coordination and interference avoidance with regard to other LEO satellite constellations and particular concern with regard to interference to satellite in GEO that have protected status; (iii) sufficient RF spectrum and orbital space to accommodate all of the many smallsats now proposed for launch (note: the number of small satellites now proposed for launch exceed 20,000 if they were all placed in orbit); (iv) likely insufficient launch capacity to accommodate the launch of all these systems in a short period of time nor sufficient launch capacity to replenish these satellites when they reach end of life (i.e., 5–7 years); and (v) sufficient ground segment transceivers with tracking capability (i.e., especially electronic tracking capability) to meet the demand for user ground systems.

The detailed market studies that have been carried out concerning these new small satellite consortiums, however, have concluded that only some of these systems will actually be deployed and operated. The Northern Sky Research study has estimated that perhaps only 7000 or so of the minisatellites will be deployed (Northern Sky Research 2018). Further, the Space Works study has concluded that perhaps about 2600 of the nanosat/microsats will finally be deployed in the next 5–8 years (SpaceWorks Announces Release of 2018 Nano/Microsatellite Market Forecast 2018).

These are severe challenges that pose an unprecedented number of problems to be addressed and solved in a short and increasingly urgent period of time for the small satellite industry. Some analysts suggest that many of the proposed systems will not be able to obtain the needed financing to build and launch all of the systems that have been proposed. Thus one of the possible solutions to the various problems noted here might be solved by the simple fact that far fewer of these small satellite constellations will be launched than those that have been proposed. For instance, in the 1980s, the US Federal Communications Commission (FCC) actually approved licenses for 17 new Ka-band satellite systems to be deployed. After the dust had cleared, it turned out that only two of those systems were in fact launched and operationally deployed.

The issues of radio-frequency spectrum and interference represent major issues that are not new. The International Telecommunication Union has sought to find ways to accommodate the growing demand for new application satellite services for many decades. There was an Extraordinary Administrative Radio Conference in 1959 followed by the 1963 Radio Conference that made the first radio-frequency spectrum allocations for NewSpace services. There have been ITU sessions every 4 years since. The latest ITU World Radiocommunication Conference was held in 2019. This represents 15 such ITU World Radiocommunication Conferences since the start of the Space Age. The issues that have been addressed, debated, and sometimes resolved have only increased in scope and intensity of debate. Over the years additional spectrum has been allocated for satellite services. There has been allocation of frequencies in the VHF and UHF bands, largely for mobile, scientific, and military satellite uses. There have been allocations in the C-band, X-band, Ku-band, Ka-band, and most recently the Q/V band for civilian and military uses. As the allocations have moved to higher and higher frequencies, larger bands of spectrum, as large as 2500 MHz frequency bands, have been assigned to satellite use. Smaller bands for meteorological, precision navigation and timing, and remote sensing services have also been allocated (Allison 2014).

Yet, at the same time, there has been additional pressure exerted to convert frequencies, such as those in the S-band and the C-band to broadband mobile services to accommodate the needs for new services such as 5G cellular service.

Other conflicting values have also been exposed, and new regulatory constraints have been imposed at these ITU World Radiocommunication Conferences. This has resulted in assigning “protected status” for GEO satellites vis-a-vis non-geostationary satellites. There has been a division of allocated bands for communications into various specific uses. These have included such specifically defined services as fixed-satellite services (FSS), mobile satellite services (MSS), and broadcasting satellite services (BSS).

Developing countries have felt that the “first come, first served” allotment of frequency use and orbital location registration has worked to their disadvantage. Further countries may agree to global allotments of spectrum for particular uses in their region (i.e., the world of frequency use is divided into three regions, namely, Region 1, Europe and Africa; Region 2, the Americas; and Region 3, Asia and Australasia), but then they add a footnote to say that they take exception for this usage in their own country. Often the world of terrestrial radio usage and the world of satellite communications can come into conflict. The new stratospheric usages associated with UAVs and high-altitude platform systems have complicated spectrum allocation disputes and conflicts even further (Ibid.).

The world of Geo satellites is reasonably straightforward in that there are spacing rules for different types of satellite services. Geo satellite locations are registered in the ITU’s international frequency register after intersystem coordination procedures are conducted. Satellites that drift north or south from the equator more than 7° North or South of the Equator are no longer considered in GEO orbit.

The world of small satellite experimental spacecraft and large satellite constellations in LEO orbits becomes ever more confusing in that more and more constellations are being proposed within increasingly complex and larger orbital configurations. Some of these will have intersatellite links, while others do not. There are currently no precise limits as to how exactly many satellites might be launched within a single constellation of small satellites nor precise standards for station-keeping exactness. When the earliest systems like Iridium, Globalstar, and Orbcomm came online with a maximum size of around 70 satellites (i.e., 66 satellites plus spares), the idea of limits on the number of satellites and their proximity might not have seemed important. But today the largest of the SpaceX constellations now proposed for operation in the Q/V bands would deploy a rather spectacular number of satellites.

9 Regulatory and Technical Innovations to Cope with Orbital Space Debris

The staggering number of small satellites that have now been proposed for launch in the coming years is in excess of 20,000. This has given rise to very serious concerns about orbital space debris. Figure 9 provides a recent inventory of the debris now in Earth orbit and a breakout of where over 6300 tons of debris now orbits the planet.

And these concerns are not only on the part of experts such as those that monitor satellite orbits and debris such as the US Air Force's Joint Space Operations Center (JSpOC) Mission System (JMS). Actually, the companies that are spending billions of dollars to deploy these huge satellite constellations are themselves concerned about their potential risk and possible liabilities (Op cit Northern sky research, small satellite research, 5th Edition).

The problem of the regulatory guidelines about orbital debris removal is obvious to anyone who examines the "math" associated with the current debris removal guidelines that say debris, including defunct satellites, should be removed from orbit within 25 years of the end of life of satellites. This now out-of-date guideline for debris removal was originally based on the time that debris goes through based on two solar max cycles (which occurs over an 11-year period and creates the maximum atmosphere drag on debris). The LEO small satellites have a lifetime of about 5–7 years. Constellations numbered in the thousands will take years to deploy. The replacement cycle will have to take place within 7 years and so on into the future.

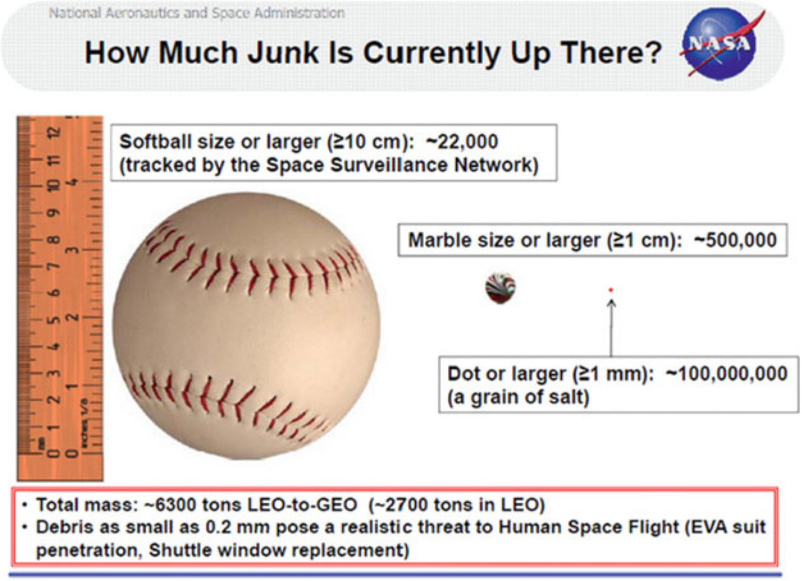

Fig. 9 NASA status of space debris which will only increase as more constellations are deployed (Graphic courtesy of NASA)

The removal of satellites based on a 25-year cycle guideline no longer makes sense. The math simply does not work. Controlled deorbit of satellites at the end of life represents a space safety challenge, and there are serious risk elements to be considered. Operators of these systems are themselves advocating new guidelines that are drastically shorter than the current 25-year guideline.

The current estimates are that there will be a collision in orbit between once in 5 years and once in 10 years, depending on which model (i.e., ESA or NASA) is used. What we do know is that each and every collision contributes to the amount of debris in orbit and especially that in polar orbits and low Earth orbits. Some may believe that since small satellites have smaller cross sections, the chance of a collision is less, but what the small satellites lack in size their sheer volume more than makes up for in terms of on-orbit collision probabilities. The bottom line is that the orbital debris problem and the risk of continuing on-orbit collisions continue to increase in seriousness. This means that active debris mitigation processes are important.

New strategies for coping with orbital debris continue to develop. The abilities for on-orbit servicing and active debris removal or even repurposing of debris in orbit continue to evolve. Currently there are efforts under way to provide new standards and regulatory provisions with regard to rendezvous and proximity operations (RPO). This is an area that needs serious attention as the current debris environment in space continues to worsen (Pelton 2015).

10 Conclusions and Future Directions

This Handbook on space satellites seeks to be as comprehensive and far-reaching as possible. It seeks to cover the technology in terms of the satellites; the ground systems and launchers; the applications, services, and markets; the security concerns; and the regulatory, policy, standards, and economics associated with small satellite systems of all types. It seeks to distinguish the smallest small satellites (i.e., femtosats, picosats, nanosats, and cubesats) from the larger microsats and minisats. Experts from around the globe have been recruited to contribute to this Handbook from the academic world, the regulatory world, and the space industry world. Its objective is to provide useful information about the companies that participate in the small satellite industries, the many small satellite constellations that are now in service or planned, as well as the many companies seeking to provide launch services to support the world of small satellites. In light of the fast-moving nature of the industry and many changes that are occurring almost daily, it is recommended that researchers refer to the URL addresses provided in most instances to determine the latest information. Any omissions or key changes not included in this Handbook are entirely unintentional.

Historical Perspectives on the Evolution of Small Satellites

Scott Madry and Joseph N. Pelton

Contents

Abstract

This chapter reviews the history and the evolutionary development of small satellites and of launch vehicle systems and the evolution of orbital space debris over time. It suggests that the development of space technology, space systems, and rocket launchers has occurred in response to various military, political, economic, scientific, and business mandates. This history that as now cover a period of over a half century has evolved in an almost haphazard fashion, largely

without concern for the space environment in Earth orbit and the need to pay attention to the long-term sustainability of outer space activities. Such concerns for "sustainability" have only come into focus since the 2010s. It also notes that the concept of "smallsats" has continued to evolve and change in many ways over time.

This chapter notes how technical innovation, disruptive technologies, new commercial space opportunities, and entrepreneurial aspirations have all contributed in the past decade to fuel the newest aspects of "New Space" or "Space 2.0" and "smallsat" development. This has created new opportunities to use space systems in new and innovative ways – especially for new entrants and users from developing economies. Yet these new commercial space initiatives and especially new large-scale "smallsat" constellations have also given rise to the problems of excessive amounts of space debris in Earth orbit. There are now particular concerns about the need for space traffic control and management that arise from the fear of runaway proliferation of space debris, known as the Kessler syndrome. This "Kessler syndrome" posits that there could be a real future possibility of a growing avalanche of space debris accruing over time with new major collisions in space happening every 5–10 years. This history seeks to give a comprehensive view of the new opportunities that small satellite systems and new launch systems could bring to global economic growth and new space-based services but also to note negative developments and concerns that need to be addressed to ensure the longer-term sustainability of the space around Earth – especially LEO, MEO, and GEO orbital regions. This history thus seeks to place the development of small satellites into some context that compares their current state of technical and operational evolution in without repeating the historical notes already provided in Chap. ▶ "Introduction to the Small Satellite Revolution and Its Many Implications"

1 Introduction

The history of space and small satellites dates back to the start of the space and even the age of Isaac Newton. When Newton first grasped the concept of gravitational force, he not only understood the gravitational attraction between the Earth and falling objects, but also how artificial satellites could achieve orbit. He was able to calculate what it would take, in terms of accelerative force, to achieve orbital velocity. In his book, *Principia Mathematica*, written in 1685–1686, he produced an illustration showing how a cannon ball fired with sufficient speed would be able to achieve orbit (Writing of Principia Mathematica n.d.) (Fig. 1).

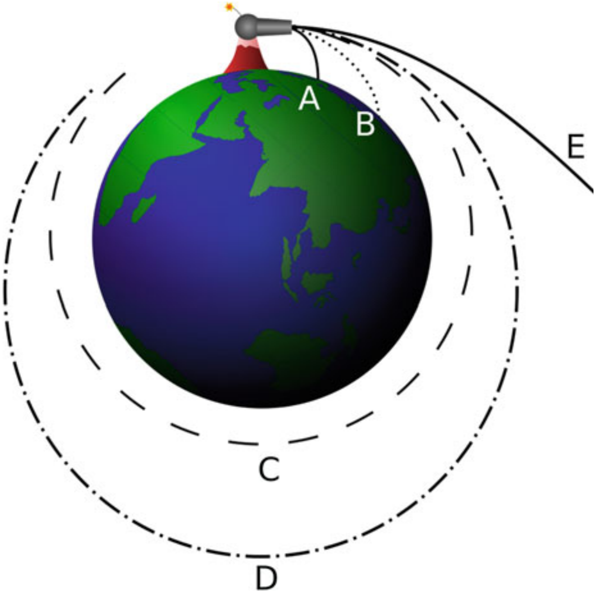

Fig. 1 Isaac Newton's conception of the launch of a satellite from *Principia Mathematica* (1686) (Recreation of Newton's concept of cannon ball launched into Earth orbit). By user: Brian Brondel – Own work, CC BY-SA 3.0. https://commons.wikimedia.org/w/index.php?curid=1657849

Thus, it could be said that the launch of a small satellite was first specifically envisioned, based on a clear conceptual knowledge of the physics involved, at the end of the seventeenth century.

And the very first satellite launches by the USSR with Sputnik 1 and by the USA with Explorer 1 were both small satellite launches. It has been noted by Space Traffic Control advocate Stuart Eves that the very first launch in October of 1957 of Sputnik 1 put not only a small satellite into orbit but the first space debris objects as well. Eves notes that the ejected nose cone, the upper stage of the R-7 rocket stage, and even the Sputnik 1 satellite itself that stopped transmitting after several days of operation all become the first three debris objects in Earth orbit (Eves & Space Traffic Control 2019). Today the many debris objects in Earth orbit, with over 40% of them in low Earth orbit (LEO), have led to rising concern that space debris could eventually deny humans safe access to space.

From the very first days of the space age in the late 1950s and late 1960s, the efforts were to find new ways to make practical use of space systems that extended beyond the earliest use of space as rockets as military instruments to deliver bombs and destruction during times of wars. The creation of civilian space agencies such as NASA thus began to develop satellite applications such as for telecommunications and broadcasting, for remote sensing, Earth observation, meteorology, navigation, precise timing, and so on. In other cases space systems developed for military purposes such as the GPS were adapted to perform a wide range of practical purposes such as aircraft safety, self-driving cars, and mapping. The space agencies and the largest commercial activity, namely, satellite communications, followed a pattern of "bigger and better" spacecraft with more power, wider radio-frequency spectrum allocations; this pattern was shown in Fig. 3.

In the 1970s and 1980s, there were a number of initiatives undertaken first by amateur radio operator technicians and engineers and then by projects initiated by the Surrey Space Centre with regard to non-real-time data relay and machine-to-machine relay and lower-resolution remote sensing activities involving small satellites. These few "off the beaten path" activities were, at the time, not considered "mainline" undertakings. The main space businesses with the large streams of revenues were involved either with major governmental and military projects or commercial satellite activities that were engaged in designing, building, and launching larger and larger satellites.

In the late 1980s and 1990s, however, there began to be a number of new ideas percolating in the industry about what satellites could do in terms of mobile communications satellite services. Most of these new concepts involved the idea of deploying low Earth orbit (LEO) constellations. Most of these new initiatives concentrated on how to deploy lower latency satellite services and using very small handheld user terminals that could provide narrowband data and voice services. There was a lot of thought about how to use more effectively efficient digital compression techniques and application-specific integrated circuits to achieve user transceivers that could be used for personal communications.

2 Evolution of New Small Satellite Systems in Low Earth Orbit for Telecommunications Services

Perhaps the most significant of these new initiatives was the Iridium Satellite network, which was spearheaded by Motorola. The concept that was advanced envisioned a 66 satellite LEO constellation with spares that would utilize phased array antennas on the satellites, inter-satellite links, and new ground antennas that could be made smaller and more efficient using digital processing and application-specific integrated circuit (ASIC) firmware.

This innovative "smallsat" LEO system sought to break the mold of relying on advancement through deploying larger and larger satellites in GEO orbits. This effort to design a system with smaller satellites in low Earth orbit was spearheaded by Motorola and network of partners that Motorola recruited from around the world. Motorola already had a great deal of experience with handheld radio units for cellular radio communications services and high-quality, mass production of consumer products, but a limited amount of satellite experience. It formed a global partnership to design, manufacture, and launch this LEO constellation. Along the way it recruited knowledgeable people from the global Intelsat community and sought a number of commercial participants from the Intelsat network to join in the partnership. It came up with a very innovative design that used 3 phased array antennas to create some 48 reasonably high-powered spot beams. See Fig. 2 (Gupta and Swearingen 2016).

The design was fairly sophisticated for a small satellite and included the ability to create four inter-satellite links to connect to the two satellites to before and after it in the North-South orbit as well as the two satellites to the East and West in the constellation. Despite the sophistication of the design with the phased array antennas and the inter-satellite links, the goal was set to produce these satellites on a rapid production line. And by the end of the production, the Iridium satellites were being produced in a 4.5-day sequence. This was in contrast to the production of large GEO satellites on an 18–24 month or even longer production cycle. Although these satellites were first conceived to have a 7-year lifetime, many of these satellites operated in the range of 15–18 years (see Fig. 2).

The second initiative that followed closely on the heels of Iridium was the Globalstar mobile satellite communications system. In this case the plan was to deploy some 50 small satellites in a LEO constellation covering the Earth between 70° North and 70° South since they saw little market from seals and polar bears. Globalstar also envisioned voice and data satellite communications to handheld units from small satellites in LEO orbit. The INMARSAT network for maritime and aeronautical mobile communications and operated a series of GEO-based satellites also moved to spin off a new venture known as the ICO (or International Circular Orbit). This new venture began to plan and deploy a constellation of 15–18 satellites in MEO orbits. Finally the Orbital Sciences Corporation proposed a constellation of quite small satellites for store and forward data links and machine-to-machine communications (Ibid.).

These various initiatives began to introduce a number of highly innovative technologies. These were, among other aspects, (i) in the design of small satellites and their antenna systems; (ii) in the systems for management and operation of global constellations of satellites in low orbit to avoid collision and to control deorbit activities; (iii) in the design of handheld user units as well as smaller-scale mobile and portable units for military or defense-related use; (iv) in the use of inter-satellite links; and (v) in global billing systems and country access codes that these systems used. The market studies and strategic business plans for these systems were a different matter. In 1998 not long after these systems were

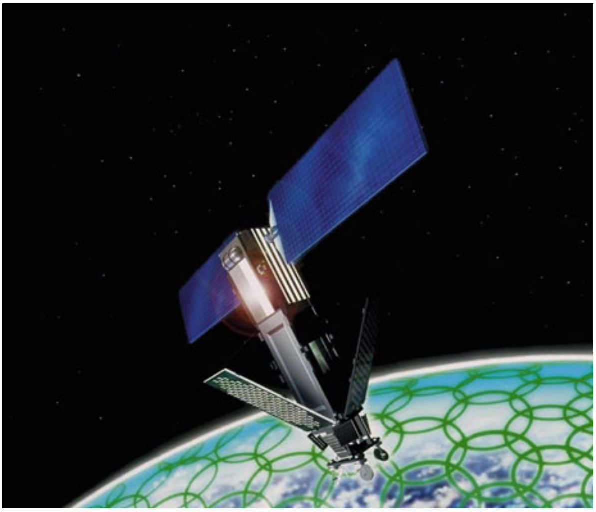

Fig. 2 Iridium satellite in low Earth orbit with spot beam patterns shown below. (Graphics courtesy of Iridium)

deployed Iridium and Globalstar systems declared bankruptcy. The ICO system declared bankruptcy without ever deploying any spacecraft. The Orbcom system which was a much lower-cost system with a smaller capital investment continued to operate longer, but it too was forced to declare bankruptcy as well.

The technologies for these LEO constellations had some issues with link margins especially when handheld units were expected to operate from inside of an automobile or other vehicle. Yet, all three systems (i.e., Iridium, Globalstar, and Orbcom) worked technically despite some initial bugs and improved in the performance over time. Both the small satellite constellations and the ever-improving ground systems and user handsets and user terminals all demonstrated that such systems could provide satellite services directly to end users. Clearly there were problems inside of cities with high rises, in forests, and inside of buildings and cars, but these were problems that second-generation systems with higher power could solve.

The Iridium system provided useful new information about how to operate large-scale constellations and new ways to replace operating spacecraft with technical difficulties with replacement satellites. Iridium engineers developed a clever way to deploy 66 instead of 77 satellites in their constellation by adjusting their orbital elevations and also how to replace efficiently failed satellites with spares on a single launch.

First they raised their orbit slightly to a new deployment altitude of 781 km. At this height they found that they could eliminate 11 satellites from their constellation. The original plan was to have 77 satellites (Note: The atomic number of Iridium is 77) that would be deployed in seven different planes populated by 11 satellites each. With the higher altitude, they were able to go to 6 planes of 11 satellites each and thus reduce the constellation number to 66 satellites (Op cit, Stuart Eves p. 10).

The other lesson learned, in terms of efficient deployment, was to discover a way to populate the Iridium constellation with replacement satellites in two different planes with a single launch which would be carrying multiple satellites. In this particular case, they launched the replacement satellites into an altitude of only 666 km instead of 781 km. They then quickly boosted satellites with onboard thrusters into the correct plane where replacements were needed. They then waited until the remaining satellites meant for replacement of satellites in the adjacent plane to drift into the proper plane position at the lower altitude and they then boosted them up into the proper location 115 km above (Op cit, Stuart Eves p. 10).

The technical problems were challenging. Clearly there were problems of satellite design and performance. And there was an even greater need for improved ground systems design for user transceivers. There were in need of the technology that would come decades later in the form of electronic beam forming and tracking systems that can replace more expensive physical tracking systems that require dishes to physically track satellites as the move across the sky. Technical challenges were addressed and mainly solved over time. It was the market, charging tariffs, and financial failures of all these systems, however, that created the real shock waves, bankruptcies, and crises in financial markets.

And the problems were not limited to mobile satellite services. Further problems for small satellites deployed in constellations came from the Teledesic system proposed around this time. This was the ahead of its time proposal for a so-called MegaLEO system. This proposal advanced the idea of a LEO constellation capable of providing broadband digital services for fixed satellite services via a huge constellation (about a 1000 satellites). The fact that this Teledesic system, backed by billionaires Bill Gates and Craig McCaw, also experienced bankruptcy further discouraged the idea of providing commercial satellite services from small satellite constellations deployed in LEO orbit. As noted in the introductory chapter, this string of bankruptcies took its toll on smallsat constellation concepts. The idea of moving from GEO-based systems to LEO constellations using “smallsats” for communications services was abandoned for years to come.

Although the idea of new entrants providing LEO-based services from “smallsat” in a LEO constellation essentially went on pause, the idea of LEO constellations never went entirely away. Several things served to change the landscape. The Iridium, Globalstar, and Orbcom satellites were bought out of bankruptcy and the reorganized businesses found a way to achieve profitability. Part of this success was based on the low cost of acquiring the satellites from the bankrupt organizations, and part was due to market development. Second-generation satellites for these systems have all now been deployed, and financial viability has been established for all these networks. Ground user systems have greatly improved. Further systems for use on aircraft and marine systems have improved and market demand has increased. Twenty years allows time for many improvements.

Also, most significantly the concept of cubesats was born, and their design, fabrication, and testing for in-flight operation have rippled through universities in the USA and around the world. This development process has found technicians, engineers, and scientists engaged in intensive studies focused on miniaturization of virtually all of the components that were involved in creating and manufacturing truly small operational satellites. This process has led to the development of miniature remote sensing devices. We have seen the creation of exceeding tiny digital processors and digital communications systems. The performance of satellites and especially user terminals has been enabled by all sorts of specialized software, small star and sun sensors, improved and miniaturized stabilization systems, small thrusters, innovative small solar array systems, tiny batteries, small antenna systems, and more. Many of these miniaturized systems were thus invented and successfully deployed for university student experiments, but can today be utilized in commercial systems. New systems such as passive deorbit systems using inflated balloon systems can deploy at end of life to create atmospheric drag. We have seen creative deployable and slide-out body structures and antenna extension systems. These innovative designs have allowed very small cubesats to become highly functional and efficient as antenna and solar arrays deploy and the body structure doubles in space-based configurations.

Many of the experimenters have not only created compact but highly functional new and creative cubesat designs, but they have also found that they could use much lower-cost off-the-shelf components in these satellites. The end result is that an amazing capability could be fitted within these small satellites that were only 10 × 10 × 10 cm in size (or about four in cubes). Even when they have been scaled up to a three-unit cubesat (i.e., 10 × 10 × 30 cm), they are still quite small in mass, and their functionality is increasingly amazing. Of course the savings come not only from having smaller satellites and units that use lower-cost off-the-shelf components. The biggest cost savings is on launch costs. Planet that deployed 88 three-unit cubesats they call "Doves" (i.e., their solar arrays evoke the image of a bird's wings) in a single launch on an Indian PSLV accomplished this entire deployment for a cost less than a third the cost of major communications satellite launch.

Instead of satellites that came from space agency designers, large aerospace companies and military agencies, we saw the emergence of small satellites created with an entirely new mindset. These cubesats created by young innovators and entrepreneurs became the starting point from which to question conventional thought about how big a satellite had to be to accomplish its various missions.

From this starting point, we even saw the invention of ultra-small femtosats, picosats, and nanosats that could accomplish many tasks once thought to require very large satellites that took years to design, manufacture, and test which were ten times, a hundred times, or even larger in size.

This new mindset some have called "Silicon Valley" meets the aerospace industry, or Space 2.0, or just "New Space." Regardless of what one calls this new mindset, it has become the motive power that has given rise to a host of new commercial "smallsat" ventures. This in turn has also helped to fuel a new commercial effort to create new more cost-efficient launch systems as well.

There were engineering students and budding entrepreneurs who jumped at the chance to design and build very small satellites that could engage in commercial remote sensing, data relay, automatic identification services, and even communications services by building and launching constellations of these smallsats.

Undertakings in the "New Space" arena had many sources of inspiration. One such inspiration was the Ansari XPrize. This created the challenge to develop commercially a space plane that could fly with crew of two on a suborbital flight into space and back and then do it again within 8 days. Only if all of these conditions were met would the new space plane developer be entitled to collect a $10 million challenge award. This feat was rather miraculously accomplished in 2004. This remarkable achievement created a huge impetus toward private new space ventures. The key aspect of this challenge was not only that the Burt Rutan and Paul Allen succeeded and actually won the prize in 2004 but that dozens of teams were formed around the world. These various private venture entrepreneurs sought to prove that they could create the new technology to make this happen.

There are now many ventures that have blossomed from efforts to create new and lower-cost launch vehicles, new small satellite ventures for remote sensing, or new ventures for satellite communications and networking services, especially in the underserved areas of the world.

3 The Rebirth of Small Satellites for Telecommunications Services

There is a remarkable man named Greg Wyler who, perhaps more than any other, has given impetus to the current boom in LEO constellations for telecommunications and networking services. He began a quest some two decades ago to provide domestic telecommunications services in Africa. He looked at various models that would deploy fiber-optic cable systems and found that none of these business models would work financially. He finally had his "aha" moment when he looked at the idea of using satellites to cover not just one country, but to create a satellite system that would cover the entire equatorial region of the world as had been first proposed by Brazil in their "string of pearls" satellite along the equator. Wyler decided that as a first step he and his partners would create a medium Earth orbit (MEO) constellation called O3b. This system would be named O3b for the Other Three Billion people in the equatorial region of the world that had limited access to telecommunications, educational services, health care, potable water, and nutrition. He was able to recruit a number of partners such as SES of Luxembourg that operated one of the world's largest GEO networks, Google, Liberty Global (the cable television and Internet service provider that was started by John Malone) HSBC bank, and a number of other backers for this $1.3 billion venture. It began with 4 satellites in its MEO constellation and then grew to 8, 12, and then 16 satellites to provide broadband services with greatly improved latency over GEO satellites. This network was sold to SES that now owns the entire network.

But Greg Wyler had a much more ambitious second act in mind. He left his position at Google and along with Brian Holtz and David Bettinger to start WorldVu in 2014. They created a company with about 30 employees to design and build a large constellation of small satellites that would blanket the world with around 900 satellites to provide low latency broadband services. This number has now been scaled back to about 600 satellites (Henry 2018).

In January 2015 it was renamed OneWeb and key investors started to come into the $3 billion smallsat system. As now planned it is to begin as a 648 network, but plans to expand over time.

There were many innovations here that one can attribute to Weyler and his partners. One of these was that one of the larger investors in the project was AirBus that was selected as the contractor to build this network of 110 kg small satellites. Another large investor was Arianespace which was contracted for the launch of many of the satellites. Thus the companies that provided a significant amount of the financing for this MegaLEO system were also the contractors for building the satellites and launching many of the satellites (https://www.oneweb.world/) (see Fig. 3).

One of the concerns that was discussed with Weyler on the occasion of his being awarded the Arthur C. Clarke Innovator Award was the problem of safe operation of this large network, avoidance of interference with GEO satellites and ground

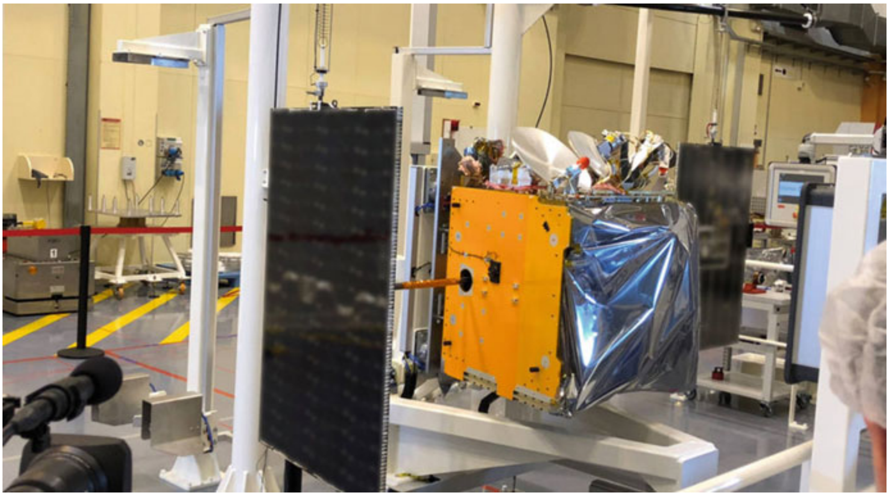

Fig. 3 One of the 110 kg. OneWeb satellites in production in Toulouse, France. (Graphic courtesy of AirBus)

systems, and disposal of the OneWeb satellites at end of life. The altruistic Weyler admitted concerns about avoiding interference and noted that the 25-year period for disposal of satellites at the end of life was inadequate and that this was in 2016 before the spate of additional large-scale systems were proposed for launch (Talk with Greg Wyler in Washington, D.C., n.d.).

OneWeb, however, set off an avalanche of other "smallsat" constellations that were to follow. Some of the constellations, just for telecommunications and networking services, that were to follow are listed below (see Table 1).

4 The Evolution of "Smallsat Ventures" for Remote Sensing, Tracking, and Weather Monitoring

The many new ventures use "smallsats" to provide commercial services in such areas as remote sensing, vehicular and ship tracking, and automatic identification services (AIS) and began to blossom starting around 2010. Many of these started from university-based cubesat.

The Planet Labs Remote Sensing System: This is a story that started quite close to home in that the author of this particular article was teaching at the International Space University (ISU) at its Space Studies Program held at NASA Ames in the Summer of 2009. In partnership with my colleague Dr. Scott Madry, we were co-chairing the Space Applications Department. One of the 20 or so "students" in the department was a very bright and compelling young man named Will Marshall who was also working as an intern at NASA Ames at the time as well as being an ISU participant.

During these NASA Ames sessions, Scott Madry gave a number of enthusiastic talks and demonstrations related to "smallsat" and their utility to a growing list of

Table 1 Some of the "smallsat" constellations for networking (Chart by J. Pelton all rights reserved)

Country	Constellation	Number of sats	Radio-frequency bands
Canada	CANPOL-2	72	LEO and highly elliptical Earth orbit in VHF-, UHF-, X-, and Ka-bands
Canada	Telesat constellation	117 sats plus spares	LEO in Ka-band
Canada	COMSTELLATION	Nearly 800 satellites	LEO in Ka-band
Canada	Kepler	15 to start and 120 in time	LEO in Ku-band
France	Thales Group's MCSat	Between 800 and 4000 in time	LEO, MEO, and highly elliptical Earth orbit in Ku- and Ka-bands
Liechtenstein	3ECOM-1	264	Ku- and Ka-bands
Norway	ASK-1	10	Highly elliptical Earth orbit in X-, Ku-, and Ka-bands
Norway	STEAM	4257	Ku- and Ka-bands
UK	UK / L5 (OneWeb) (Has now declared bankruptcy)	600–750 and increased number in time	Ku- and Ka-bands
USA	Boeing	1396–2956	V-band in 1200 km orbit
USA	SpaceX	Up to 4000	Ku- and Ka-band
USA	SpaceX	7500 plus	V-band
USA	USA/Leosat (Has now declared bankruptcy)	80 to start	Ka-band

remote sensing applications. He stressed how miniaturization and new small-scale components were making very capable new "smallsats" possible for remote sensing activities. Will Marshall took his ISU learning experience to heart. With his clever young colleagues he went on to organize right there in Silicon Valley a new enterprise called Planet Labs. These enterprising entrepreneurs designed three-unit cubesats that they called "Doves." They managed to find backers in the fertile startup soil of Silicon Valley and their new enterprise took root in the skies.

They began deploying and improving with each one of their successive batches better and better "seeing eye" birds. This enterprise continued to grow and prosper until it truly took wing in 2017. They made arrangements to have 88 of their Doves to be launched on an Indian PSLV rocket that placed 2 regular-sized satellites plus a record total of 104 cubesats into low Earth orbit (LEO) as of mid-February 2017 (Indian PSLV Rocket set for Record-Breaking Launch with 104 Satellites, Spaceflight 2017).

The also made an epic arrangement with Google that sold the title of the high-resolution Skybox satellites to Planet Labs in a deal whereby Planet Labs also changed their name to simply "Planet." Part of the sales agreement involved their signing a long-term contract to provide data to Google on a long-term basis (Kaplan 2017).

Amazingly the "Planet" enterprise was started in the garage of the well-known "rainbow mansion" in Silicon Valley, and their Doves are fabricated in what the

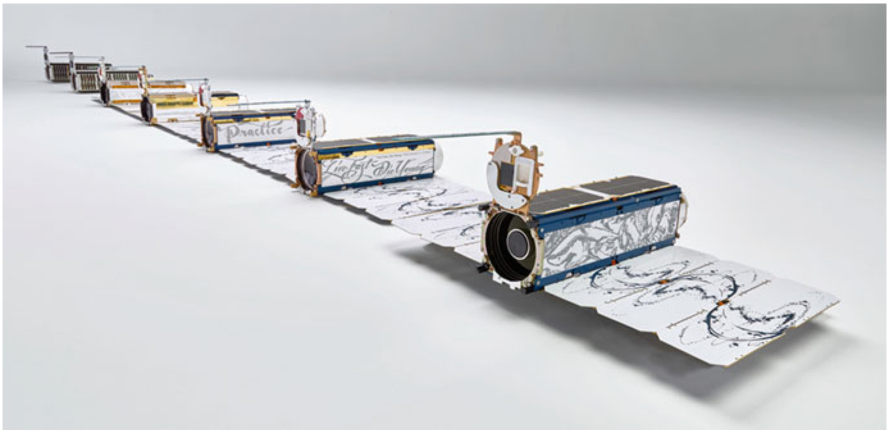

Fig. 4 Several of the Dove cubesat ready for launch (note the individualized art on each satellite). (Graphic courtesy of Planet)

young entrepreneurs call their “Clean Enough Room” in their headquarters, now in San Francisco. This amazing young startup company is now operating in close partnership with one of the world most valuable corporations, Google. It now manages a fleet of hundreds of “Dove” three-unit cubesat plus the entire Skybox/Terra Bella system that Google has sold to Planet as well as several satellites acquired from a German supplier. The part of the story involving remote sensing and “smallsat” startup leading to Skybox and Terra Bella comes next (see Fig. 4).

The Skybox Imaging Company launched in 2011: Another example of rather remarkable startup magic is the case of the four students from Stanford University’s School of Engineering that had the idea that they could design 100 kg small satellites which were only 30 × 30 × 30 cm cubes – about the size of a mini-refrigerator using off-the-shelf components. They submitted the concept for a class project and then decided to make it happen. Their concept was that these “SkySats” could provide high-resolution submeter resolution imaging for the commercial remote sensing market. They managed to convinced several venture capital firms that this was a viable business plan and raised some US$91 million by April 2012 which was sufficient capital to create and start launching this imaging system. The Skybox Imaging startup managed to raise a total of US$91 million of private capital from Khosla Ventures, Bessemer Venture Partners, Canaan Partners, and Norwest Venture Partners to develop and launch the SkySat constellation (SkySat n.d.). Their concept was to not use any expensive “flight-qualified” hardware and instead rely upon commercial electronic and automotive parts, as well as open-source software, including image processing routines developed in the medical industry.

This led to the first launch of SkySat-1 on a Russian Dnepr rocket on Dec. 11, 2013, from Yansy, Russia. This first of the series proved that high-resolution imaging (less than 1 meter) from these “smallsats” was possible and this led to the next launch of a SkySat-2 via a Soyuz 2/Fregat Russian rocket on July 8, 2014. A contract was awarded to SSL to 13 more SkySats according to a refined SkySat-C design. The first four of this series that were built under contract by SSL and then launched on an Indian PSLV (Polar Satellite Launch Vehicle) by the Indian Space Research Organization. The SSL contract covered the building of 13 of the SkySat C design that provides a much higher resolution than the Dove cubesat units. The fully deployed system envisions a network of 25 SkySats to be deployed to create a high-resolution system with frequent global updating capability.

As all of this technical and operational progress was being made, the business and financial arrangements were also rapidly evolving as well. In 2016 the Skybox Imaging Company was sold to Google for a reported price of $500 million. In 2017 Google rebranded the satellite imaging company Terra Bella and then proceeded to sell this system to Planet Labs for a financial arrangement that was indicated to be something like $300 million, but with a long-term service contract to provide imaging data to Google at an advantageous price (Google's Skybox Imaging has new name, business model 2016). This case study underlines the "Silicon Valley" effect that seems to permeate the "New Space" revolution with all of the actors in this case, namely, Planet Labs, Skybox Imaging/Terra Bella, and Google all firmly based in the Stanford, San Jose, Mountain View, and San Francisco area. Today Planet Labs and Terra Bella have morphed together to become just Planet, and they acquire remote sensing of the entire globe every day, including the first video movies from space (see Fig. 5).

The Spire Small Satellite Constellation that started in 2012: The Spire "smallsat" venture is another university-spawned venture. This new system has now deployed several "smallsat" prototypes for a cubesat constellation system that is intended to provide a variety of global tracking, data analytics, and weather monitoring services. It has under contract from the US National Oceanic and Atmospheric Administration (NOAA) launched an experimental smallsat for trial testing of meteorological monitoring and weather tracking services. This startup company has successfully demonstrated a range of new services can be provided by commercial cubesat systems, including automatic identification services, vehicular and ship tracking, data analytics, and even weather tracking. It was founded in 2012 and too started in an unexpected way with its initial capitalization came from a social media campaign (Foust 2016).

Spire was founded initially to develop and launch an experimental cubesat named ArduSat. This company got its money to do this as a crowd-funded project. This first cubesat was named Ardusat and in the rapid construction and launch environment that was typical of many cubesat projects was first launched on August 3, 2013. Thus one of the features that makes this commercial smallsat venture rather unique at the time was that it was made financially possible via a Kickstarter solicitation on the Internet. This initial funding of just over $100,000 led to a round of funding from venture capitalist. This "seed round" had participation by Emerge, Grishin Robotics, Shasta Ventures, Beamonte Investments, and the largest investment coming from Lemnos Labs. In late July 2014, Spire announced an additional $25M "Series A" funding from several venture capital firms that included RRE Ventures, Mitsui & Co., Global Investment, Qihoo 360 Technology, and Moose Capital.

Fig. 5 Planet SkySat 72 cm image of downtown San Francisco, California. (Image courtesy of Planet)

Emerge continued to invest in this second round as well. Spire announced on June 30, 2015, a $40 M traunch in “Series B” capital investments headed by Promus Ventures with participation from Bessemer Venture Partners and Jump Capital and then in November, 2017, yet another round of financing at $70 M through a “Series C” offering, and it also opened a European office in Luxembourg. This lightning fast series of financing sequences and its ability to build its initial series of small cubesats contract for their launch and get them into orbit signified that this was a whole new animal in the aerospace field that did almost everything differently.

The company’s first three ArduSat satellites that were the first test cubesat systems have now been released from the Spire operational satellite constellation in order for it to focus on educational experiments in space for activities that can be carried out for as low as $125 per experiment.

On January 21, 2018, two Lemur-2 CubeSats were launched as part of the payload of a Rocket Lab Electron. These two the experimental prototypes represented the test version of an ultimate small satellite multi-sensor constellation of 125 spacecraft that can perform weather measurements as well as tracking and AIS applications. Spire intends to manufacture and operate this Lemur constellation itself and obtain launch via contract from several suppliers including Arianespace.

The satellites are multi-sensor. Data types such as Automatic Identification System (AIS) service are used for tracking ships, and weather payloads measure temperature, pressure, and precipitation. AIS data is meant for use in illegal fishing, trade monitoring, maritime domain awareness, insurance, asset tracking, search and rescue, and piracy (Spire: Space to Cloud Data & Analytics n.d.).

5 Conclusion

The world of small satellites might seem to many as if this is a totally new phenomenon that has exploded almost overnight. In fact this is a development that started with engineers building the tiny Oscar 1 for amateur radio some 40 years ago. The first low Earth orbit (LEO) satellites for mobile communications and data relay, i.e., Iridium, Globalstar, and Orbcom, were small satellites as well as the Surrey satellites designed and build at what is now Surrey Satellite Technology Ltd. Clearly there has been a lot of innovation and outside the box thinking that has fueled today's small satellite industries and systems as well as all the experimentation and testing of concepts that has come with all of the cubesats and even smaller satellites that are now a part of the so-called “smallsat” world.

Every new idea and development stands on the shoulders of earlier inventors, scholars, philosophers, writers, science fiction visionaries, and free thinkers. The world of smallsat innovation is no different, even though it truly has had a fresh crop of very innovative thinkers that has fueled change in the space industry in the past decade. And the revolutionary thinking has far from run its course. The articles that follow show just how remarkable the innovations now known as “Space 2.0”or “New Space” have been in just the past decade. The ability to do more with less and to find new and innovative ways to launch small satellites into space at even lesser cost is changing the world of space and expanding the range of space ventures in truly remarkable ways.

The Many Types of Small Satellite

Overview of CubeSat Technology

Richard P. Welle

Contents

Abstract

A CubeSat is a small satellite designed to be deployed from a standardized container to facilitate launch as an auxiliary payload. The CubeSat Design Specification places rigid limits on satellite dimensions to enable containerization and places a number of restrictions on the contents and function of the satellite to ensure that it poses no risk to the launch. The resulting ready and inexpensive access to space has fostered a culture of risk and innovation that has led to short development cycles and very rapid advances in the capabilities of CubeSats. From the first launch of six containerized satellites in 2000, the cumulative number launched has doubled about every 2.5 years and passed the 1000 mark in 2018. Initially intended to promote satellite development programs in educational settings, the CubeSat

1 Introduction

In a narrow definition of the term, a CubeSat is a satellite that conforms to one of various CubeSat Design Specification documents describing satellites based on single or multiple units of a 10-cm cube. The original CubeSat Design Specification was developed at California Polytechnic State University in San Luis Obispo (Cal Poly) starting in 1999 and is based on the Poly Picosat Orbital Deployer (P-POD) that was developed at the same time (Puig-Suari et al. 2001). Since then, various derivative CubeSat standards have been developed, each based on an alternative deployer, that are more or less compatible with the Cal Poly standard. What all have in common, though, is that the deployer provides a standard interface with a launch vehicle in the form of a closed container that is designed to carry a secondary payload while ensuring minimal risk to the launch vehicle and primary payload. The P-POD is a simple box with a door and a spring mechanism. Figure 1 shows a photograph of a three-unit (3 U) deployer. The door is opened on command by a signal sent from the launch vehicle, and the spring mechanism pushes the CubeSat(s) out of the box with an ejection speed on the order of 1 m/s. This and other CubeSat

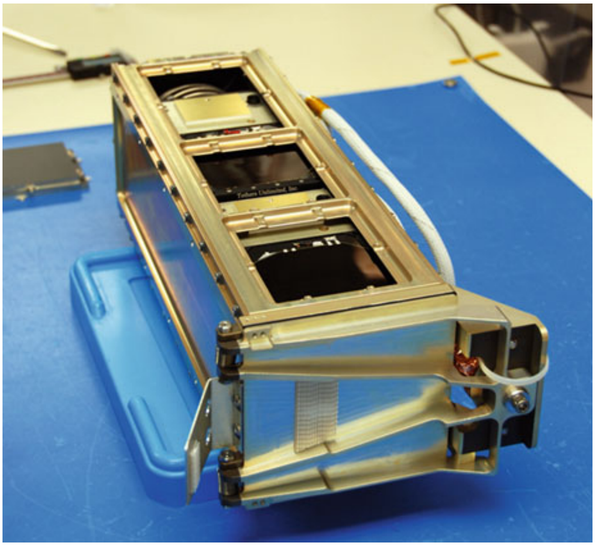

Fig. 1 Photograph of a P-POD CubeSat deployer containing two 1.5 U CubeSats, with access panels removed. (Aerospace Corporation image)

deployers are designed around a standard “unit” volume that is approximately a 10-cm cube. This dimension was selected based on the concept that a volume of 1 liter was a reasonable working volume for an experimental satellite and provides adequate surface area for solar cells on each face (Heidt et al. 2000). While the one-unit (1 U) CubeSat size was prevalent in the first years after the standard was established, many CubeSats today are three units (3 U) or larger. Figure 2 shows a photograph of a 3 U CubeSat with deployed solar panels. The popularity of the 3 U size is a result of that being the size of the most common deployers; the original P-POD was designed to deploy three one-unit (1 U) satellites, with the three satellites configured in a single stack. Although the original intention was to launch three 1 U satellites, a 3 U CubeSat deployer can also carry a single satellite that is 10-cm square and 34-cm-long, two satellites each 17-cm-long (1.5 U), or any combination of satellites that total 34 cm in length.

A somewhat broader definition of the term CubeSat could extend to any small satellite designed to be launched from a closed container. The first satellites fitting this definition were deployed from the Stanford-built Orbiting Picosatellite Automated Launcher (OPAL) in 2000 (Cutler and Hutchins 2000), while the first satellites conforming to the narrower definition of CubeSat were launched in 2003 (Swartwout 2013). While both senses of the term CubeSat refer to standardization of dimensions as well as containerization, the overwhelming majority of containerized satellites launched to date are based on the 10-cm unit cube, and the term CubeSat is most commonly interpreted in this narrower definition. Thus, for the remainder of this chapter, the term CubeSat will be used in the narrower sense, while the broader set of satellites including all those deployed from containers will be referred to as containerized satellites. Although not conforming to the generally accepted scientific usage for scaling prefixes, some additional related terms commonly used in the small-satellite community categorize satellites based on mass rather than physical dimensions and include microsatellite (mass between 10 and 100 kg), nanosatellite (mass between 1 and 10 kg), and picosatellite (mass between 100 and 1000 g). CubeSats can fall into any of these three categories.

Fig. 2 Photograph of a 3 U CubeSat with deployed solar panels. (Aerospace Corporation image)

While the small size typical of CubeSats has supported reduced launch costs, the key innovation of the concept, responsible for both the low cost and ready availability of launch opportunities, is the containerization and associated simplification of the launch interface. The original intent of the CubeSat standard was to provide a simple, reliable, and repeatable interface with a launch vehicle to reduce the effort (and cost) of integrating a secondary payload. The goal was to enable inexpensive flight opportunities that could be used by universities for educational purposes, and the majority of early CubeSats were developed by educational institutions for research or training purposes. Eventually the utility of the CubeSat standard was recognized beyond the university, and the form factor was adopted by government laboratories as well as industry, as a vehicle for technology demonstrations, for science missions, and ultimately in commercial applications.

2 The CubeSat Design Specification

The CubeSat is generally defined in terms of the CubeSat Design Specification (CDS), which defines the interface between the CubeSat and the deployer and sets tight constraints on such factors as dimensions, mass, and potentially hazardous materials. The current version of the CDS is available from www.cubesat.org. The original P-POD CubeSat deployer was designed to satisfy several requirements (Puig-Suari et al. 2001). The three key requirements that supported the rapid growth in CubeSat development were the following: (1) the deployer must protect the launch vehicle and primary payload from any interference from the CubeSats; (2) the deployer must have the ability to interface with a variety of launch vehicles with minimum modifications and with no changes to the CubeSat standard; (3) the resulting CubeSat standard should be easily manufactured without using exotic materials and expensive construction techniques. The first requirement ensured that launch providers and primary payload owners could accept CubeSats on a rideshare basis with minimal risk. The second requirement ensured that launch providers would not have to go through the launch qualification process for the deployer more than once and further ensured that CubeSat builders could start projects without having to identify (and pay for) the launch up front – they could be comfortable knowing that a launch opportunity could be found once the satellite development process was sufficiently advanced to be certain of a launch-readiness date. The third requirement ensured that CubeSats could be built, if desired, at a cost commensurate with typical university budgets.

The CubeSat Design Specification developed for the original P-POD has undergone some evolution as experience was gained with early flights (e.g., removing the prohibition on propulsion and adding limitations on magnetic fields), but the basic requirements outlined in 2001 are still satisfied. The latest version of the CDS is available from www.cubesat.org and should be reviewed thoroughly by anyone planning a CubeSat project. The key requirements of the CDS fall into four broad areas: mechanical, electrical, operational, and do-no-harm requirements.

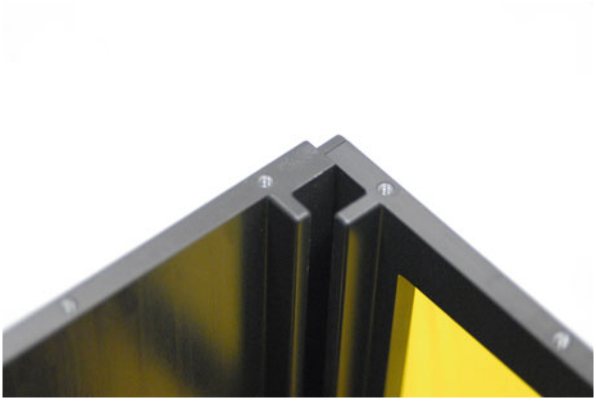

Fig. 3 Close-up photograph of a CubeSat test pod showing the deployer rails on one edge. (Aerospace Corporation image)

Mechanical requirements specify the physical dimensions of the CubeSat (presented in the form of mechanical drawings for each CubeSat size) that allow it to interface properly with the deployer. For most current CubeSat specifications, the mechanical interface is a set of four rails spaced at 10 cm that slide along corresponding rails in the deployer. The four black CubeSat rails are visible on the long edges of the CubeSat in Fig. 2, while the corresponding deployer rails are visible in Fig. 3. The CDS specifies rail dimensions, materials, and surface properties to ensure that the CubeSat will eject from the deployer without binding. The mechanical requirements also set limits on the maximum mass of the CubeSat (on a per unit basis) and limits on the location of the CubeSat center of mass.

Electrical requirements are principally designed to ensure that the CubeSat will remain powered off prior to deployment and include a requirement that there be a deployment switch on the CubeSat that will disconnect all power systems while the CubeSat is in the deployer. Additional inhibits are required to ensure that there will be no inadvertent radio-frequency (RF) transmissions while in the deployer.

Operational requirements include legal requirements (licensing for RF and, if in the United States, licensing for remote sensing), limitations on orbital debris, and start-up restrictions that prohibit actuation of any deployable hardware (such as solar panels) in the first 30 min after ejection of the CubeSat and prohibit any RF transmissions in the first 45 min.

Additional general requirements and testing requirements are designed to ensure that the CubeSat is incapable of doing harm to the launch vehicle and/or primary payload. These requirements include limits on propulsion systems, total stored chemical energy (batteries), materials outgassing, and hazardous materials (including a complete prohibition of pyrotechnics). Testing requirements include random vibration testing, shock testing, and thermal vacuum bakeout (to ensure proper outgassing of components) performed to test levels as specified by the launch provider or P-POD integrator.

Having a standard set of requirements is beneficial to both the launch provider and the CubeSat builder. For the launch provider, the CDS ensures that the CubeSat, as an auxiliary payload, will do no harm. Furthermore, any launch provider can establish the capability to launch CubeSats by qualifying a CubeSat deployer (the P-POD, or its equivalent), without having to delve into the details of each CubeSat that might be launched. For the CubeSat builder, the CDS provides a set of rules that must be met. However, more significant for the CubeSat builder is that the CDS provides for a standard interface that, if met, allows the CubeSat to ride to space on a broad range of launch vehicles with minimal integration effort. This means that a CubeSat complying with the standard will have a selection of ride opportunities at competitive prices and that these ride opportunities will be frequent.

In principle, satellites built to conform with the CDS should be capable of riding on any launch vehicle flying a CubeSat deployer. In practice, launch vehicles come with a variety of launch environments (particularly in the area of vibration loading), and the suitability of a potential ride will depend on whether the CubeSat was built to hold up under the relevant launch environment. While it is possible to build a CubeSat to survive even the most severe vibration environment, for most launch vehicles, such a satellite would be overbuilt. In practice, satellites are often designed for “typical” launch environments rather than extreme environments, possibly leading to rejection of certain launch opportunities that may come with unacceptable environments. Further, some launch providers may occasionally place restrictions on CubeSats beyond the minimum requirements of the CDS. For example, some launch providers may have a complete prohibition on propulsion systems. Other launch opportunities may involve transit through the International Space Station (ISS), in which case the satellites have to be designed and tested to man-rated space systems specifications. Finally, some CubeSat builders find it necessary to build a satellite that does not conform to all aspects of the CDS (e.g., by exceeding the maximum allowable mass or by having a pressure vessel). In this case, the CDS provides a process to request waivers, which are subject to approval by the launch integrator and/or launch provider (and possibly by the owners of other payloads on the launch vehicle).

The CubeSat Design Specification was created with the intention of encouraging flight opportunities for educational purposes. The first CubeSat launch, carrying six university-built CubeSats, took place in 2003. Of the first 100 CubeSats flown (which took until 2012), over 75 were university-built, only three were commercial, and the remainder were built by or for government organizations (NASA and the DoD). However, by 2012, the CubeSat standard began to be recognized by industry as a valuable tool for technology-demonstration flights, and 1 year later, in 2013, the first CubeSat developed for commercial services was flown. The pace of flights of containerized satellites (almost all of them conforming to the CubeSat standard) has continued to accelerate. Since the first flight in 2000, the cumulative number of containerized satellites launched has doubled about every 2.5 years (see Fig. 4). By early 2019, the total number of CubeSats launched had passed the 1000 mark, with just under 300 coming from universities, about 150 from government, and nearly 600 from commercial sources (including over 450 from just two companies, Planet Labs and Spire) (Swartwout 2019).

The CubeSat Design Specification established the defining characteristics of the CubeSat itself: the size, mass, etc., as well as limitations to ensure minimal risk to the

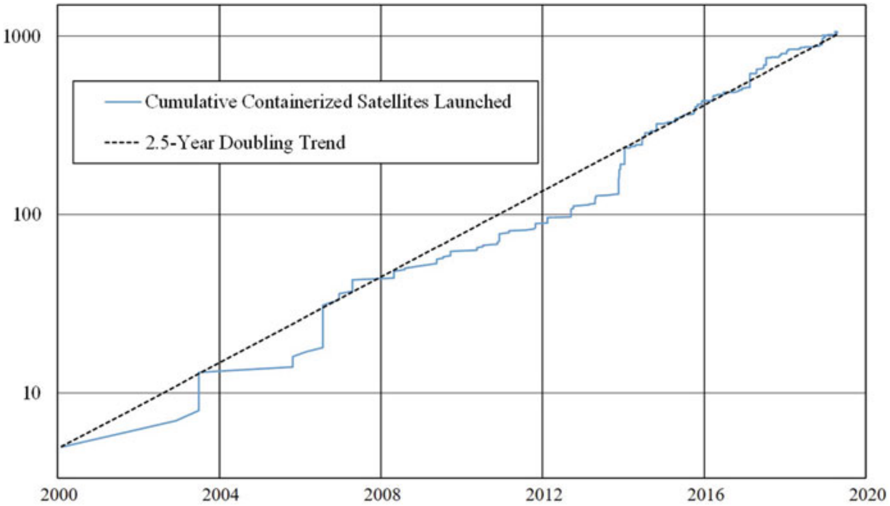

Fig. 4 Cumulative total of all containerized satellites launched as a function of date, compared to a 2.5-year doubling trend. (Aerospace Corporation figure based on data from Swartwout 2019)

host vehicle or primary payload. What was not anticipated was the entirely new approach to space systems enabled by the CDS. A key outcome of the CDS was that the space launch business, at least for kg-class spacecraft, was effectively containerized; the launch provider delivers a box to orbit (the P-POD, or equivalent); and the satellite developer need only design and build a satellite that fits in the box. The CubeSat deployer is analogous to the standardized shipping container that has revolutionize cargo transportation around the world over the past half century by making it possible to pack any cargo into a standardized container and then ship the container to a destination, where the cargo is unpacked. The containers are moved over the road, rail, and ocean transport networks with little regard to their contents, so the transport providers can focus only on efficient transport of the containers without having to develop efficient means of handing all the diverse cargos that might be shipped in the containers. At the same time, cargo owners need only deal with how to pack the cargo into the container, without needing to be concerned about the details of how the container is handled between the point of origin and the destination.

In a similar manner, the CubeSat container provides a standard interface between the launch provider and the satellite. The consequent simplification of the integration process reduces costs for the launch provider and provides a set of standards for the satellite developer which, if satisfied, will allow the CubeSat to ride on any of a number of launch vehicles. Thus, the path to space for a CubeSat is vastly simpler than for traditional satellite programs. It is this ready launch availability, combined with the original goal of the CubeSat as a teaching tool, that leads to a new approach to satellite development. While traditional satellites are built with little tolerance for risk, the low cost of the CubeSat and the availability of high-frequency, low-cost rides to space reduces the cost of a failure and encourages a culture of tolerance to risk, not for the launch vehicle or primary payload but for the CubeSat itself.

3 Risk Tolerance

When the CubeSat was originally conceived as a teaching tool, there was a high value placed on innovation and risk taking. For education purposes, this makes sense; one can learn as much (or more) from a failure as from a success. However, many non-educational programs recognized the potential of the risk-tolerant approach to CubeSats for supporting a program of rapid technology development. For example, technology-demonstration missions can often be flown with a high risk tolerance, particularly when the missions are part of a series of technology-demonstration exercises. Under these circumstances, an anomaly encountered on one flight can serve to inform the design of subsequent flights. Since the development cycle can be very short, a goal of demonstrating a particular technology in space can be applied to a series of flights rather than to a single flight. Under this approach, any single flight can have a high tolerance to risk under the expectation that a series of flights spread over a reasonable time interval will ultimately be able to satisfy all the program objectives.

Similarly, the opportunity to fly a high-risk mission at nominal cost encouraged entrepreneurs to establish programs that required multiple generations of spacecraft designed on a very short cycle, with the understanding that there may be failures on orbit and that any failures would provide lessons leading to improved designs in the next generation of the satellite. In this approach, the success of the program is defined not by the capabilities of the first satellite to fly but by the capabilities of the nth generation of satellite.

This is not to say that all CubeSats can be built using a risk-tolerant approach. For university satellite programs where learning is the primary goal, a risk-tolerant approach is certainly appropriate. For programs focused on technology evolution and/or maturation where the ultimate goal is an operational system or process that may take several years to develop, a risk-tolerant approach will likely be appropriate. However, for programs that are one-off science missions or technology-demonstration missions where the loss of a single satellite will severely impact program success, the tolerance to risk should be much lower, and more traditional approaches to satellite mission assurance must be implemented.

4 Elements of the Risk-Tolerant CubeSat Approach

Many aspects of the risk-tolerant CubeSat approach derive from a goal to keep costs low enough that a satellite failure would not be intolerable. An example of things that CubeSat programs can do to keep costs down is the use of commercial off-the-shelf (COTS) electronics. Traditional satellite programs will use only (or mostly) space-rated (radiation-tolerant) electronics. Typical COTS electronics can tolerate a limited amount of radiation, however, and this limit is rarely reached in low Earth orbit

(LEO) where most CubeSats fly. As such, typical CubeSats will fly exclusively or almost exclusively with COTS electronics. Issues that are encountered due to radiation in one satellite project can be mitigated through elimination of suspect components in subsequent flights, but there is often no systematic effort to evaluate the radiation tolerance of electronic components selected for a flight project.

A corollary to this is that CubeSats are often designed with short lifetimes in mind. For an educational project, the design and build effort provides the majority of the training with an additional gain during initial on-orbit checkout and operations. Beyond that, the marginal value of the satellite for educational purposes is limited. Similarly with technology-demonstration missions, once the technology has been demonstrated (unless on-orbit lifetime is part of the demonstration), there is little marginal value in continuing to operate the satellite. As such, many CubeSats are not designed with lifetimes in excess of 1 year in mind.

Another approach to minimizing costs is to limit the testing regimen throughout the program. In many CubeSat programs, a large portion of the environmental testing can be deferred until completion of the initial satellite build. The overall simplicity of most CubeSats often allows issues encountered late in testing to be corrected quickly because the entire satellite can be dissembled and reassembled in a matter of hours or days. This approach can lead to missed launches if there is insufficient margin built into the schedule to allow correction of issues discovered late in testing. Some CubeSat developers will build an engineering model that is a nominal duplicate of the flight model. Ideally the engineering model will be built before the flight model, with the experience gained through its build and test being available to inform the build and test of the flight model. The engineering model is then available on the ground for testing, software checkout, and anomaly resolution after the flight model is delivered.

Similarly, CubeSat development programs often forgo extensive modeling of spacecraft performance, particularly in the area of mechanical integrity. This can be partially justified in that CubeSats are so small that they become rugged simply by being more compact. Nevertheless, there may still be mechanical issues discovered in testing that could have been caught with careful modeling. However, with CubeSats it may be less expensive simply to expect testing to catch some issues that are then corrected through redesign after testing.

CubeSat developers also often forgo redundancy in the various satellite subsystems; CubeSats typically fly with a much larger compliment of potential single-point failures than traditional satellites. A corollary to this, however, is that the low cost of CubeSats, particularly the marginal cost of building and launching spares, makes it possible to approach redundancy by flying an entire duplicate satellite. Of course, this approach will not mitigate design issues, but it will mitigate workmanship issues, some radiation-induced issues, and operational issues.

An extension of this approach is sequential redundancy where CubeSats are developed as a series. The first of the series is delivered and launched, and the experience gained through the design, build, test, and operations of the first model is then applied to the development of the second unit. Similarly, the design of the third unit is informed by lessons learned with the second unit. In this approach, the success of the program is defined by the success of the first satellite in the series that accomplishes the full mission. Of course, the program goals may evolve as the satellite series progresses, leading to a continuing development effort reaching for ever-advancing goals. The point of the CubeSat Design Specification was to ensure easy access to space at a cost where a satellite failure was not intolerable. The redundant-satellite approach or, even more so, the sequential redundancy approach means that a satellite failure is not necessarily a mission failure.

The sequential redundancy model is used to some extent in all satellite programs involving experienced builders; lessons learned in the build of one satellite are applied to any future satellite where they are useful. However, with traditional satellites the time cycle for this is typically several years long; some complex satellites may be in the development phase for a decade or more and the final design frozen many years before launch. With CubeSats, the development cycle can be measured in months rather than years, so experience builds up rapidly. A related benefit of the CubeSat approach to satellite design is that the fast cycle time typical of such projects means that a team can be kept together through many projects. Thus, a small, dedicated team of engineers can build up the experience of multiple satellite projects, on a timescale short enough that there is not a lot of turnover on the team, and any experience gained by the team is retained.

Although the risk-tolerant approach to CubeSat development can be a valuable tool for advancing the state of the art in CubeSat capability and reliability, it is not applicable in all cases nor, perhaps, even in the majority of cases. The high tolerance to risk is really appropriate in only two circumstances: either a single satellite is being developed in an educational setting where the process of designing and building the satellite has as much or more value than actually flying the satellite or a satellite is being developed as part of a long-term series of satellites where the end goal is a satellite design with capabilities well beyond what can easily be achieved in a single development stage, and the potential for anomalies (or outright failures) in intermediate satellite designs are taken into consideration in the overall plan. The sequential redundancy approach is appropriate if the program goal is either technology maturation for its own sake or the development of a capability that is far beyond the current state of the art and cannot reasonably be achieved in a single design effort.

Although one may be tempted to implement a risk-tolerant approach in the development of a technology-demonstration mission, one must be very careful in this if the technology-demonstration mission is not one of a larger series. Specifically, if a mission has the goal of a flight demonstration of a specific technology and only one flight is planned, then the tolerance for risk is likely to small. The expectations for the mission must be clearly understood, both by the CubeSat developer and by the customer, before assuming that a risk-tolerant CubeSat approach is appropriate.

5 Mission Assurance

The risk tolerance described above is limited in that it applies only to the question of whether the satellite will successfully perform its intended function. The other key aspect of mission assurance is the safety of flight. Safety of flight risks are issues that could potentially harm other mission partners, from the start of launch processing to spacecraft separation on orbit.

Traditional space programs have a low tolerance to risk in either area, so when multiple traditional satellites would ride on a single launch vehicle, they would have had similar approaches to mission assurance. With CubeSats as rideshare, a single launch vehicle may have payloads with widely differing risk tolerances flying together. In response to this, the DoD Space Test Program developed a method for Rideshare Mission Assurance (RMA) that allows multiple satellites with varying risk tolerances to fly on a single launch, while protecting each satellite from risks to on-orbit performance posed by other payloads on the same launch (Read et al. 2019). RMA allows launch partners to accept self-imposed risks to the performance of their own payloads without being exposed to flight safety risks from other payloads.

The objective of the RMA process is to provide mission partners with an assurance that all payloads included on a mission will do no harm to each other or to any operational aspect of the launch. To this end, a set of do-no-harm criteria are defined that parallel similar requirements in the CDS. The principal requirements fall into the categories of launch environments (vibration, acoustic, shock), contamination, debris mitigation, pressure vessels, electromagnetic interference, and electrical inhibits (three inhibits are required to prevent unintentional activation of propulsion systems, any deployable structures, and any transmitters). A more detailed discussion of RMA is provided in (Read et al. 2019) along with a detailed checklist of tests and evaluations needed to ensure compliance with the RMA process.

6 Launch Considerations

Beyond the strict limitation on size and mass, the principal constraint on CubeSat missions is driven by the fact that all CubeSats launched (at least to date) have been as rideshare payloads. Being a rideshare means that the orbital parameters are selected by the primary payload on the launch or, at best, selected by agreement among a number of small payloads. The impact of launching as a rideshare varies depending on the mission. For most educational missions and many tech-demo missions, the orbital parameters are a secondary consideration; particular orbits may be desired, but a range of orbits will still satisfy the mission requirements. In such cases, there are likely sufficient launch opportunities that a ride satisfying the mission requirements will be available within a reasonable wait. In a few cases, a technology-demonstration mission may require a very specific orbit, in which case the wait for launch may be long.

Most operational missions, on the other hand, are likely to have more specific orbital requirements. In this case, the opportunities for rideshare might be insufficient. For missions requiring large numbers of satellites, one option is to design the mission with the intention of building an ad hoc constellation using quasi-random orbits (Gangestad et al. 2015); subsets of the constellation are deployed from multiple launch vehicles going to orbits that are selected based on their relative value to the overall mission of the constellation. An alternative, if the constellation is large enough or has to be distributed over a number of well-specified orbital planes, is to purchase a dedicated launch or launches. While most launch vehicles are designed with payload capacities well beyond anything useful for dedicated CubeSat launches, there are a number of entries in the new generation of small launch vehicles currently under development. Even though most of them will probably never fly, some are likely to make it to market. As of this writing, the Rocket Lab Electron, with a payload capacity in the range of 200 kg (depending on orbit), has already completed ten successful launches.

As the CubeSat industry has matured, the number of launch vehicles capable of carrying CubeSats has grown substantially. In 2018 there were 21 space launches carrying a total of 214 CubeSats, involving 9 different types of launch vehicles. For organizations developing one or a few CubeSats, launch services are typically obtained through a launch broker – organizations that consolidate collections of CubeSats from various developers and act as the interface with the launch provider. Launch brokers work with CubeSat developers to identify launch opportunities and support the launch providers by ensuring that the requirements of the CDS are being met by all the CubeSat developers. One launch option worth noting for US educational and nonprofit organizations is the NASA CubeSat Launch Initiative (CSLI), a program that provides free or reduced-cost access to space for CubeSats from qualifying organizations (CubeSat Launch Initiative). This program has supported the launch of over 80 CubeSats to date.

7 Missions

Although the first launch conforming to the CDS in 2003 included one science mission (Flagg et al. 2004), there was a perception for many years that CubeSats were too small to conduct useful science or other operational missions. In the first decade of CubeSat launches, over 70% were developed either for educational purposes or for technology demonstrations. Over time, however, both science-funding agencies and commercial ventures began to recognize the potential of CubeSats for operational missions. In 2008, the National Science Foundation began supporting CubeSat-based science investigations. In 2013, Planet Labs launched the first of what would become the world’s largest CubeSat constellation with the goal of imaging the entire land mass of the Earth every day. In 2015, the National Academies of Sciences, Engineering, and Medicine undertook a study of the potential utility of CubeSats for science missions (National Academies of Sciences, Engineering, and Medicine 2016) and concluded that “CubeSats have already produced high-value science. CubeSats are useful as instruments of targeted investigations to augment the capabilities of large missions and ground-based facilities, and they enable new kinds of measurements and have the potential to mitigate gaps in measurements where continuity is critical.” As of this writing, over one third of all CubeSats launched to date are part of the Planet Labs imaging constellation, and many other science and commercial satellites have been successfully deployed. Of the 214 CubeSats launched in 2018, less than 40% were categorized as educational or technology-demonstration missions.

The most obvious implication of the CubeSat Design Standard is the constraint on mass, volume, power, etc. that derives from the requirement to launch within a small box. This constraint is well understood and, in most cases, can quickly be used to determine whether a given mission can be accomplished using a CubeSat. In general, many missions will be constrained by simple physics; one cannot squeeze a 1-meter telescope into a CubeSat. But one should be careful in applying the physics constraint to any given mission. For example, it is straightforward to demonstrate that a 3 U CubeSat will not provide ground imaging at 50-cm resolution. So if the mission planner starts by assuming that the goal of the mission is imaging at 50-cm resolution, then a 3 U CubeSat is precluded by definition. But one should ask if the resolution is really the mission. Most often the mission involves determining something about the ground being observed: land use, vegetation, cloud cover, water quality, or another parameter. It is worth asking if the actual mission could be better served by lower-resolution, more frequent observations. The requirements should be about the information to be obtained, not about how it is obtained. Similarly, when designing an imaging system at a larger ground sample distance, say 20 m, it is possible to achieve this in a 3 U CubeSat. However, if the mission requirements call for a field of view that is too large, the optics will no longer fit in a 3 U CubeSat, and a larger satellite will be required. If the requirements specify the data to be obtained rather than the satellite field of view, it is possible to explore the trade between a single larger satellite and some number of CubeSats, each with a smaller field of view but flying in formation to cover the same area.

In general, missions that will remain out of reach for CubeSats are those that require large apertures or high-power instruments or those that require multiple instruments on a single platform. Outside those constraints, CubeSats have the potential to continue to expand their role in the space enterprise. An area where CubeSats may excel is in applications that benefit from distributed sensing, where a swarm or constellation of CubeSats can provide measurements with high temporal and spatial coverage, or in communication applications where, again, high temporal and spatial coverage can benefit the user on the ground. This has been demonstrated by Planet Labs with their use of over 100 CubeSats to provide regular daily imaging of the entire land surface of Earth. Similarly, Spire Global has launched over 100 CubeSats that are used for a number of applications including tracking maritime traffic and aircraft and for weather measurements using GPS radio occultation (Bosch 2019).

Although one tends to think of space missions in terms of services provided or mission data returned to Earth, the role of CubeSats in providing training opportunities should not be discounted. When developed as training missions, the risk tolerance can (and possibly should) be high, which will both enhance the learning opportunity and keep the costs down. The continuing importance of this role is illustrated by launch data indicating that about one in seven of all CubeSats launched in 2018 were developed by educational institutions.

Finally, the technology-demonstration mission continues to be an important role for CubeSats, with over 50 technology-demonstration CubeSats flown in 2018. This category of missions includes pathfinders for components or instruments that may subsequently fly on larger missions or prototype CubeSats that may be the basis for subsequent constellations of CubeSats.

8 Supporting Technologies

Like any satellite program, there is a minimum set of basic satellite bus functions that, depending on the mission, are essential to the success of a CubeSat flight. Functions required for essentially all missions include power, communications, and command and data handling (flight computer). Functions required for a significant fraction of missions include attitude control and navigation. Most CubeSat missions can be completed without propulsion (early versions of the CDS actually prohibited propulsion, a requirement that has now been relaxed), but many more complex missions are being developed that require propulsion for orbit maintenance or orbit changes.

The technologies to support these basic bus functions have been evolving rapidly, and any recitation of the current state of the art would quickly become obsolete. NASA's Small Spacecraft Technology Program (SSTP) compiled a report on the state of the art in 2013 and issued a revised version in 2015. Starting in 2016, the report was moved to an online format and is updated on approximately an annual basis (State of the Art of Small Spacecraft Technology).

Some noteworthy trends have been the rapid advance in communications capability and in the performance of attitude control systems. As of 2012, nearly all CubeSats operated with downlink rates of 9.6 kb/s, and a very few had systems with data rates approaching 1 Mb/s (Mission Design Division Staff Ames Research Center 2014). As of 2019, the peak downlink rate reported from a CubeSat reached 1.6 Gb/s (Devaraj et al. 2019). Similarly, the best pointing precision reported for a CubeSat as of 2012 was about 2 degrees (Mission Design Division Staff Ames Research Center 2014). However, by 2019 integrated attitude control systems for CubeSats were demonstrating pointing precisions two to three orders of magnitude smaller; the ASTERIA mission flown in late 2017 achieved about 2 millidegree body pointing in a 6 U CubeSat and 140 microdegree pointing of an imaging payload using a secondary piezo translation stage to control image placement on a focal-plane array (Pong 2018).

Navigation, at least for satellites in LEO, is easily obtained to a precision of 10 m or less using onboard global navigation space system (GNSS) receivers, including GPS receivers. If precise navigation is not required, then satellite operators can rely on the US space-tracking services (18th Space Control Squadron), which publishes regular updates on the orbital parameters of most satellites at a precision of 1–2 km.

The supporting technology that is perhaps the least mature as of this writing is propulsion. While electronic systems scale well to smaller sizes and are based on rapidly-evolving technologies developed for the consumer electronics industry, propulsion systems typically rely on physical phenomena that do not scale well from large to small and use technologies not often applicable in other industries. As such, the options for CubeSat-scale propulsion are limited but are expanding. The simplest systems use cold gas as a propellant; while these can be relatively easy to integrate and are fairly reliable, they can present a challenge in that they will typically require a waiver of the prohibition on pressure vessels and can provide only a very limited delta-v capability. Chemical propulsion systems present multiple challenges: the chemical reactions and heat transfer do not scale well to small sizes, the high thrust typical of chemical propulsion will produce torques on the spacecraft that may be beyond the capacity of the attitude control system, and the propellants will be restricted by the CDS. Several electric propulsion systems scaled for CubeSat applications are in development, using a wide range of propellants. While these systems may ultimately provide very high delta-v capability, the power limitations on CubeSats will limit the maximum thrust of electric propulsion systems, and any orbit changes will be slow. On the other hand, small electric propulsion systems can provide many years of orbit maintenance.

9 CubeSat Industry

At the start of the CubeSat era, there were few or no commercial vendors capable of providing CubeSat-compatible satellite systems, and essentially all CubeSat programs were “home-grown.” Within a few years, existing and newly formed vendors began offering CubeSat-specific systems including flight computers, power systems, radios, sensors, and complete attitude control packages. Thus, it is possible, for example, for a university program to acquire many or all of the satellite systems through commercial vendors and integrate them in-house to produce a complete satellite. Alternatively, the builder can select which satellite systems will be developed in-house and purchase the rest on the commercial market. A few companies were also formed for the purpose of offering CubeSat development and operation as a service. As such, it is now possible for a customer (e.g., a scientist wanting to fly a small instrument) to contract with a commercial firm to provide a relatively complete satellite service such that the customer need only develop and deliver the payload, which is then integrated, tested, launched, and operated by the commercial vendor.

As with the list of CubeSat technology status, the list of companies providing components and/or services continues to evolve, and any recitation of commercial services would become obsolete in short order. As such, the reader is again referred to NASA’s Small Spacecraft Technology Program (SSTP) report on the state of the art in CubeSat technologies (State of the Art of Small Spacecraft Technology).

10 Conclusion

The creation of the CubeSat standard has led to a very rapid proliferation of satellites in the 1–10-kilogram mass range. Initially these satellites were developed primarily for educational purposes, but their potential value in technology demonstrations and in operational missions did not go unnoticed, and the commercial market for CubeSat systems, CubeSat services, and data produced by dedicated CubeSat constellations has expanded rapidly. The cumulative number of containerized satellites launched has been doubling every 2.5 years since the first launch of six in 2000, and the trend shows no sign of leveling off. The range of missions and the fidelity of data produced by these missions have also continued to grow. The creativity of the

CubeSat community has enabled a number of programs that would have been deemed impossible in kg-class spacecraft 20 years ago.

In general, the approach to mission assurance taken by the CubeSat developer community has been much more relaxed than with traditional satellites. For educational and, to some extent, technology-demonstration projects, this tolerance to risk is appropriate. The potential for high-frequency flight opportunities has led to the concept of serial redundancy in CubeSats. This is the recognition that a high risk tolerance for any given flight is acceptable if the flight is part of a series of flights aimed at incremental technology advances; for any given flight in the series, the risk of failure is offset by the potential gains across the series as a whole. This concept of serial redundancy has led to very rapid advances in the capabilities of space systems but is appropriate only for programs involving multiple flights over an extended time period. However, the lessons learned through sequential redundancy can be, and have been, applied to new missions, yielding highly reliable satellites for a broad range of missions.

Overview of Commercial Small Satellite Systems in the "New Space" Age

Timothy J. Logue and Joseph N. Pelton

Contents

Abstract

"New Space" or "Space 2.0" initiatives are changing the space industry and not in modest or one-dimensional ways. We are today experiencing change in profound ways that permeate the entire space enterprise. Thus smallsats and "New Space-related" changes now impact almost every aspect of the space industry.

These should not be seen as mere disparate or unrelated parts, but as key pieces of a whole revolution in the space industry. There are many changes that are occurring in the world of commercial space, which taken together should be seen as enabling forces. These "parts" are coalescing together to allow significant changes to occur throughout every dimension of the space industry.

In short, all of these various "disruptive" changes are a part of an overall gestalt. It is driven by what might be called a new way of thinking and analysis born of a way of thinking associated with Silicon Valley – namely, an approach that questions old ways of doing things. It asks not how can things be improved but how can new ways of thinking make significant changes that revolutionize how things are done. There is a constant search for major strides that are sweeping – rather than baby steps.

Out of "New Space" thinking has come new technologies, new market entrants, new launcher systems, new ways of financing space ventures, new satellite architectures, efficient new small satellite designs, new types of ground antenna systems with electronic tracking, and market shifts toward networked services. Over-the-Top (OTT) data streaming of entertainment and gaming services and demand for networking access in rural and remote areas of the world are just a few examples. These forces of change and new ways of thinking are converging together to create an integrated nexus of change in the space industry that has produced among other things the great spurt of activity related to commercial small satellite constellations and an effort to bring broadband digital services to the entire world.

Many of the companies in the global aerospace world that have built satellites, launch vehicles, ground antenna systems, provided satellite services, and insured and financed space enterprises for many years have been caught off guard by the swiftness of the change and are now struggling to find their footing in the swirling eddies of transforming markets, spacecraft, ground system, and launcher technologies, and even the regulatory framework that controls these industries.

This chapter explains that this dramatic change in the design, manufacturer, launch operations, architecture of satellite constellations, and business models of those operating small satellite constellations can only be understood in the context of all the forces of change that are coming from perhaps a dozen different basic shifts in the space industry. Those who think one-dimensionally or narrowly about shifts in technology, market forces, capitalization, and global operations will miss the overall scope of this change. This overview of commercial small satellites is actually designed to capture this larger picture. This chapter focuses on what might be called synoptic change in space industry. It is now an industry that is completely beset by new and "disruptive" ways of thinking about every aspect of commercial space industries – the various markets, the changing modes of financing new systems, the diverse technological components of its products and services, and all of the associated regulatory processes.

1 Introduction

There are many commercial technology-based enterprises that started off with just one or two persons tinkering with a new idea in a garage or basement trying to see if they could turn a concept into a meaningful product or service. On the other hand, the earliest satellites launched into orbit may have been small, but they were essentially all governmental projects backed by serious resources and teams of scientists and engineers.

When volunteer scientists and engineers put together the OSCAR 1 amateur radio satellite, launched in 1961, it helped to begin thinking about how to design and build low-cost satellites. This spark eventually spawned a whole school of thought about how to design, build, launch, and operate satellites that percolated through many academic institutions. Many colleges and universities were intrigued by the idea of the cubesat which was a standardized approach to small satellites developed by California Polytechnic State University (Cal Poly) and Stanford University in 1999. For nearly 15 years, the cubesat phenomena remained largely an academic enterprise with the majority of these small satellite projects coming from colleges and universities. The idea was largely to provide an avenue for students to test concepts as to how to design and build satellites more effectively and to carry out in-orbit experiments, when "rides to orbit" could be found, which was not always easy.

But, by 2013 the majority of cubesat launches were, for the first time, commercial or amateur projects that were not just academic undertakings but a serious new type of entrepreneurial space venture. Books written on this sweeping miasma of change have documented how the space business, as driven by small satellites and new types of launcher systems, are transforming the space enterprises in significant ways. Examinations of this dramatic shift, such as *Space 2.0: Revolutionary Advances in the Space Industry* and just published in 2019, seem all but ready for a second edition in 2020 given the rapidity of change in this fast-moving world of innovation and industrial transformation (Pelton 2018).

"New Space" enthusiasts were suddenly converting small satellite projects into real commercial ventures or at least test launches of prototypes for full-fledged commercial smallsat projects (CubeSat).

NASA, ESA, and other space agencies that had started programs to stimulate cubesat student experiments expanded their smallsat programs to spur corporate innovation, spur new small satellite ventures, assist with launches, and initiate their own smallsat experimental projects (NASA Venture Class Procurement Could Nurture Ride 2015).

Today Cal Poly has a structured partnership with 40 other academic institutions to provide the latest version of the cubesat specification (9th version), and there are now specifications for pocketqubes that are one eighth the size of a cubesat and even femtosats that are in the 10–100 g mass range. This supportive environment for the design, building, and launch of small satellites of the cube satellite class or below has grown in the last 25 years, and this trend will likely continue.

Today, according to the UN Office of Outer Space Affairs, some 9,000 satellites have now been launched into Earth orbit and to date less than 10% are associated with commercial satellite constellations. However, based on filings and licensing by national governments, this balance is set to change and change dramatically. Over 20,000 commercial satellites are now proposed to be launched in the next 5 years or so, and most of these are associated with small satellite constellations. The OneWeb and SpaceX Starlink constellations represent the majority of these launches. Amazon has also announced plans to launch its own constellation of thousands of satellites, which it calls Kuiper. This dramatic shift in the number of satellites to be launched and the rise of so-called MegaLEO smallsat constellations gives rise to concern about orbital collisions and even the possibility that deorbiting satellites from large constellations could strike an aircraft or a vulnerable point on the ground. The following

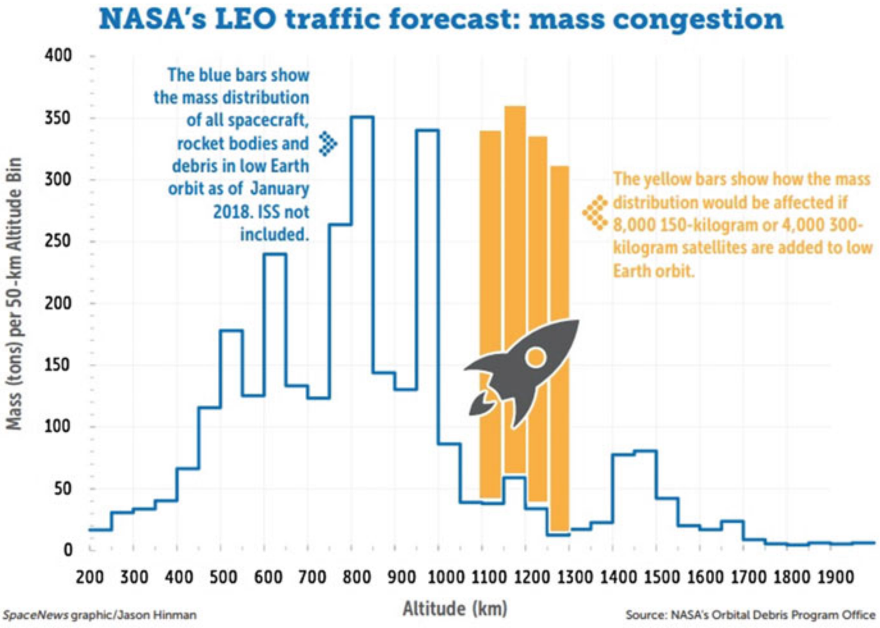

Fig. 1 NASA projected traffic congestion forecast in specific LEO orbit altitudes. (Graphic courtesy of NASA)

graphic shows how deployment of new MegaLEO constellations would create new levels of mass congestion as they are deployed at specific altitudes (see Fig. 1).

The world of small satellite constellations is thus moving rapidly forward. There are new technologies that are enabling constellations to be designed, built, launched, and operated more efficiently. There are new types of digital markets, particularly in the digital streaming and networking services arena, that are quickly developing. There are also new mechanisms to fund these various new ventures and new players in the space application field that are disrupting normal patterns of investment. Finally, there are new concerns with regard to orbital space debris, space situational awareness, space traffic management, and regulatory and liability provisions that all may require change to accommodate this new space environment and almost chaotic pattern of change in the space industry. Each of these new patterns related to commercial small satellite systems will be analyzed in the following pages.

2 Small Satellite Constellations and the New Technologies that Enable These New Systems

The rather steady and deliberate evolution of space technologies and systems and launch operations has been disrupted. It is really not productive to seek to determine which is the “chicken” and which is the “egg” in this rapid period of change. The overall trend is that many innovators in the aerospace industry have embarked on developing new technologies and new modes of operation across all sectors of the aerospace industry (Madry et al. 2018).

Launch Services: The new technology in the launch services industry is blossoming everywhere. There are a number of start-up launch services companies that are seeking to develop launch systems that operate with reusable first stage rocket components such as Blue Origin and SpaceX.

Others such as Virgin Galactic, Sierra Nevada, and now failed Swiss Space Systems have sought to extend the reusability associated with spaceplane development to provide small satellite launch capability.

Vulcan Inc. with its Stratolaunch Systems has sought to eliminate the need for expensive launch sites as well as provide new launch efficiency with regard to large mass air-launched rocket systems that represent an extension of approaches first developed by Orbital Sciences and Burt Rutan.

Yet others such as Vector in the USA, Rocket Lab in New Zealand, and many other start-ups in China, Europe, Israel, etc. have focused on developing highly efficient and quite small launchers for small satellites in particular (see Fig. 2).

India with its Polar Satellite Launch Vehicle (PSLV) and China with its Long March family of launch vehicles have simply focused on creating a conventional launcher that could be manufactured at lower cost and high reliability.

These various and diverse launch service initiatives have fed off of one another. These varied and more efficient launcher systems have served to drive down launch costs significantly in the past 5 years. For many decades launcher systems grew bigger in their capabilities, but the cost per kilogram of mass launched remained

Fig. 2 Efficient Electron launch vehicle offers new options for small satellites. (Graphic courtesy of Rocket Lab)

quite high. Today the cost of launching small satellites either on dedicated small launchers or packaged together on larger rocket systems is rapidly declining.

All of this innovation and these new launch systems that offer lower cost ways to orbit have forced the conventional providers of launch services such as Arianespace, Boeing, Lockheed Martin, United Launch Alliance, and Russian launch manufacturers and services providers to develop new and lower cost launch capabilities to compete with these new providers of launch services. The Ariane 6 vehicle will only have a modest increase in lift capability over the Ariane 5, but its cost per kilogram is expected to be cut in half. The United Launch Alliance's effort to cut costs is focused on the Vulcan launcher. More than a dozen lower-cost launch systems from start-ups in China, Israel, the USA, and Europe are aimed at capturing the small satellite launcher market and to compete with Vector, Rocket Lab, and LauncherOne for this sizable new market.

In several cases the approach to lowering cost is focused on reducing the high cost of operating launch sites. Options such as Stratolaunch and the carrier vehicle for LauncherOne represent one approach. Another concept is to develop simple, truck-mounted launch operations such as that developed for the Vector launcher.

Piggyback launches from larger launch vehicles such as the Polar Satellite Launch Vehicle that launched a record number of 104 cubesats remain extremely cost efficient. The same is true for the dispenser system on the International Space Station that now offers two options for smaller cubesats and more recently for nearly 1-m^2 satellites after the smallsats have been delivered along with other cargo to the station. The various launch options for small satellites continue to grow rapidly. The bottom line is that lower launch costs help to fuel the small satellite revolution in a significant way by lowering the cost to orbit and providing more rapid access to space.

New Ground Systems with Electronic Tracking of Satellites: The next key technology that enables the deployment of small satellite constellations for communications and networking is the new ground systems with electronic tracking capabilities. There is a mad scramble for the manufacturers of user terminals for satellite communications to bring new flat panel antennas with electronic tracking capabilities to market. Flat panel antennas are seen as a needed breakthrough permitting the rapid installation of ground equipment in new or usually restricted places, such as aircraft, smaller ships and yachts, and in rural and remote areas, opening up or expanding markets beyond what can typically be done with traditional parabolic ground terminals especially for MegaLEO constellation services. At the Satellite 2019 Conference and Exposition in Washington, DC, Gilat, SatixFy, Kymeta, Isotropic Systems, ThinKom, Alcan Systems, C-Com, Wafer, EM Solutions, Hughes Network Systems and Phasor were in various ways seeking to respond to this rapidly changing Earth station market in new and innovative ways. The suppliers of these new flat panel antennas include established suppliers, entirely new start-ups, and start-ups with big name backers. Perhaps most notable in this regard is the Kymeta flat panel antennas that feature the use of meta-materials. This innovative product is backed by Microsoft founder Bill Gates, among others (see Fig. 3).

Phasor, the developer of a modular design for antennas that can electronically track LEO satellite signals, is developing a flat antenna that would have increased

Fig. 3 Kymeta flat panel antenna with electronic tracking. (Graphic courtesy of Kymeta)

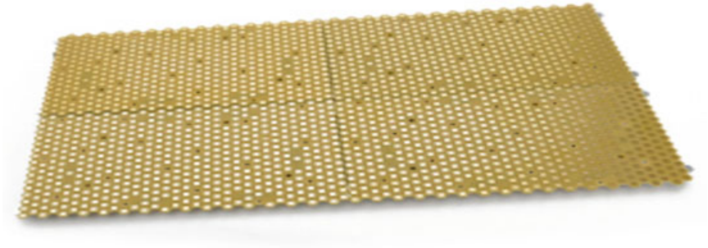

Fig. 4 Phasor modular flat antenna that can be shaped to conform to the sides of aircraft. (Graphic courtesy of Phasor)

sensitivity performance and could be adapted to conform to the side of an aircraft for mobile communications between airplanes and LEO constellations (see Fig. 4).

The principal advantage of GEO orbit satellites in Clarke orbit has always been that user antennas did not need to physically track the satellite's movement across the sky. These satellites seemed to remain fixed in place. LEO satellites, depending on their altitude, typically traverse across the sky in about 5–10 min and thus need ground terminals with rapid tracking capability. If the tracking is done using electronics rather than physical tracking of the satellite's path across the sky, then the Earth station's reliability is increased, and moving parts eliminated entirely. Currently, the cost of these flat panel, or conformal-shaped, antennas for aircraft is relatively expensive compared to classic fixed dishes, but the economies of scale of mass production are bringing these costs down rapidly.

There is clearly trade-offs in technical performance and cost efficiencies involved here. One must consider the relative gain in effective power performance of a LEO satellite which is perhaps 40 times closer to earth than a GEO satellite. This closer altitude provides a significant effective power increase in performance that is some (40 × 40) or 1600 times greater than from a geostationary satellite. Since the signal from a satellite spreads like a widening circle and the area of a circle is calculated as πr^2, the path loss or the effective strength of an electronic signal is represented by the square of the spreading circle.

In addition, there is another key gain in LEO systems. This is in the signal's latency, or path delay, which is 40 times less for a LEO satellite that is 40 times closer to Earth. In a world where digital networking is the prime mode of communications, this suggests that LEO networks, as well as MEO networks, will be better suited for digital networking and streaming services via the Internet. This is especially true for two-way communications links for either data or voice, where delays are most noticeable. The current betting is that these closer-to-Earth satellite constellations will be able to capture a larger market share over GEO satellites over time. A key market driver will thus be how rapidly do flat panel antenna costs come down and how good will their technical performance be at both providing service and avoiding interference to GEO satellites and injecting additional RF interference into adjacent radiofrequency bands used for radio astronomy, GNSS services, etc. The biggest concern of all is over-congestion of LEO orbits that results in collisions and the creation of orbital debris which could create major disruptions for all types of space-based services. This issue will be discussed further in this chapter and elsewhere in this handbook.

3 New Efficiencies in Small Satellite Manufacture

Yet another significant change that has come with the small satellite revolution is new and improved ways of designing, manufacturing, and testing small satellites in large production runs. Early New Space satellite developers used Silicon Valley-like approaches that saw every launch of a handful of satellites as a way to test new technologies and manufacturing techniques. Innovations were rapidly incorporated in the next batch and tested on-orbit like upgrades to software. However, to become commercially viable, these operators and manufacturers needed to shift to a different model that focused on an easily reproducible product designed for manufacturability. In the classic space industry, the production of a handful of GEO satellites in any 1 year by any one manufacturer did not allow for large production run efficiencies and cost-effective means of quality assurance testing. Each satellite was essentially handcrafted and painstakingly tested based on the not unrealistic view that it had to operate for 15 years or more and was largely out of reach after successfully reaching geostationary orbit. Only a few spacecraft, having suffered mishaps in the early stages of their deployments when the space shuttle was still operating, had any chance of being rescued and either sent on their way or brought back to earth for retrofit and relaunch. Today there are strides being made in on-orbit servicing. NASA and DARPA are funding relevant research, and there are some commercial initiatives in this field, but there is still a long way yet to go.

But the production of a large number of satellites with standardized component parts poses a challenge for any manufacturer, whether seasoned or New Space. Supply chains had to be streamlined and prepared for mass production and on-time delivery of parts with high reliability, low cost, and high quality had to be perfected. If the New Space constellation is to be based on "off-the-shelf" components, traditional space equipment suppliers may need to be trained not to go through the painstaking quality checks and testing usually demanded. Alternatively, nontraditional suppliers may have to be briefed on the unique demands of space manufacturing, even if the equipment to be supplied was said to be "off-the-shelf," usually denoting equipment repurposed from established commercial applications on Earth. The development of additive manufacturing added a new potentially cost-saving approach which could reduce costs and manufacturing times. Testing regimes were altered to focus on full testing of the first handful of satellites in a production run using high-quality acceptance standards. Thereafter, only rudimentary testing is to be used for full production runs. Some of these production and testing technique had been developed during the mid-1990s, when the first commercial constellations were developed and launched for Iridium, Globalstar, and Orbcomm, but the lessons learned then, if still remembered, had to be significantly adapted for constellations involving hundreds and thousands of satellites, using the latest production technologies and techniques. Moreover, the commercial success of these constellations maybe based at least partly on the speed and efficiency of production. Whereas it takes only three geostationary satellites to cover most of the earth, for New Space LEO constellations to achieve full market coverage, the satellites must be built quickly and launched in large batches or else operators' revenue will be severely constrained by incomplete coverage. The gap between first launch and full coverage cannot be understated, since many New Space satellites are being designed for relatively short lifetimes on-orbit, often under 6 or 7 years. Thus, while the first satellites launched in a constellation have only limited opportunities to generate revenue, they are already degrading in the harsh space environment. Thus, completion of the constellation quickly becomes critical. This is especially true for smallsat constellations providing telecommunications services, as well as Earth observation systems whose key selling point is rapid revisit of (almost) every point on the Earth.

The incremental costs of satellites on large production runs should decrease significantly. In the case of highly automated production systems, the cost of manufacturing small satellites in thousands of units largely becomes the cost of the materials in the spacecraft. If operators of LEO smallsat constellations can significantly reduce the cost of manufacturing, reduce the cost of quality acceptance and independent verification and validation testing, significantly reduce the cost of launch, and increasingly automate the operation of large constellations, then the total cost of a constellation can be reduced significantly, largely through economies of scale. On the other hand, if the failure rate of such highly automated small satellites continues to be high, such as the 5 small satellites out of the first 60 Starlink satellites launched mid-year 2019, the problem of derelict small satellites remaining in space becomes of prime concern. This issue is discussed further below and elsewhere in this handbook with regard to orbital space debris (O'Callaghan 2019).

It is further anticipated that new flat panel antenna systems with electronic tracking can follow a similar cost reduction curve. SpaceX has filed a petition with the Federal Communications Commission asking for type licensing of a million broadband user terminal transceivers to work with its Starlink satellite constellation. The planned deployment of one million of these future broadband units represents tangible evidence of efforts to achieve major future cost reductions associated with flat panel user antennas (Nyirady 2019).

4 New Markets Such as Over-the-Top Data Streaming Via Commercial Small Satellites

The commercial satellite market is a nearly $300 billion a year enterprise, and the largest sectors are satellite services that represent about $130 billion dollars in annual revenues – followed closely by ground systems sales of about $120 billion. The largest portion of that services market represents subscription sales for direct broadcast satellite services that are now offered as an alternative to cable television subscription services. These industries – both direct broadcast satellite television and subscription television services – are currently experiencing rapid change as many consumers around the world are shifting from watching video via cable TV or DBS subscription to data streaming and viewing videos on laptops or even cell phones, rather than conventional television sets. The advent of 5G cellular service will likely accelerate this trend.

Most analysts foresee the market shifting away from cable TV or DBS subscription-based services delivered from broadcasting satellites or in the case of cable television, fixed service satellites. This shift allows providers such as Amazon Prime, Netflix, Fubo, Hulu, Sling TV, Now TV, Sky Go, and dozens of Internet-based video streaming services to compete with cable TV subscription or direct broadcast satellite TV services. This shift is currently hitting subscription service providers such as HBO, Starz, Cinemax, etc. the hardest. Most of these OTT services offer video programming and broadband access at much lower rates that via cable TV subscription services or the offerings via satellite broadcast networks such as

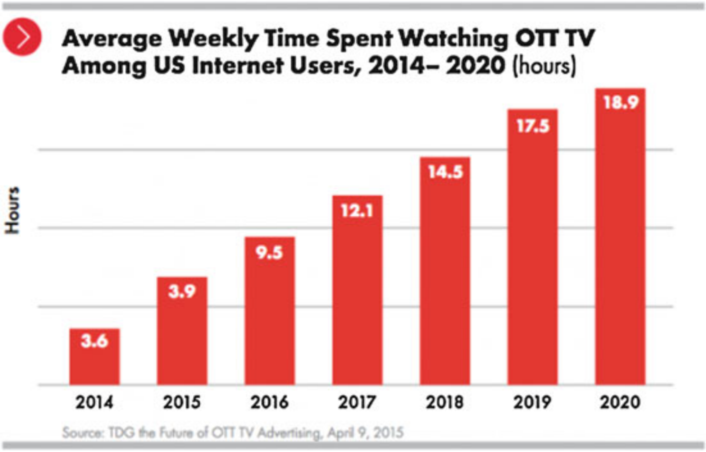

Fig. 5 The rapid rise of OTT television viewing. (Source courtesy for TDG)

DirecTV, Dish, SkyTV, or other DBS providers around the world (The New TV – The State of the New TV Industry).

One of the key questions is how will these video services be paid for in the future. Today video programming is paid for in various ways, often through a combination of subscription fees and paid advertising inserted along with the programming. In the OTT digital streaming model, the subscription fees are less, but advertising with OTT services is now largely absent. However, it is envisioned that ads will become an important part of the future revenue streams (see Fig. 5).

The advantage of GEO-based systems providing direct broadcast television services to fixed dishes is seemingly being lost to data networks that provide services via broadband digital streaming using OTT distribution processes. This is particularly true for users who are opting to have their service provided to smaller computer screens or cell phones rather that television sets. In many cases, such as services offered by Hulu, subscribers are able to control their viewing schedule and see programming when they want rather than when scheduled networking programmers dictate.

Currently direct broadcast satellite service sales, such as for DirecTV, Dish, and SkyTV, are seeing slowing growth rates or even modest declines in the range of 1–2% annually in revenues. This trend is expected to continue. When 5G cellular becomes more widely available and the new small satellite constellations are deployed globally to support 5G services, the revenues within the traditional satellite industry could shift in a way that sees a decline in cable television subscriptions, in subscriptions to direct broadcast satellite services, and in paid entertainment channels subscribed to via either cable or DBS systems.

If small satellite constellations are successfully deployed to provide global broadband Internet access, entertainment distributors, such as Netflix, Hulu, Sling TV, Now TV, Sky Go, and dozens of others now offering streaming entertainment, will be tempted to seek new customers through them. This, in turn, could greatly impact the structure of satellite networks and how these businesses are operated.

Fig. 6 Graphic showing many of the new applications that 5G could provide. (Graphic courtesy of NewTec)

In addition, broadband 5G will be much more than an enabler of more OTT video services. The concept of 5G is that it will open up a host of new applications from driverless cars, to finding a parking place more easily, to improvements in water systems, electrical grids, and more generally grouped under the concept of the Internet-of-Things (see Fig. 6) (What Next for Satellite in a 5G and OTT Era 2018).

The key question is whether 5G and interactive IoT services will be augmented by broadband satellite systems in GEO, MEO, or LEO orbits and whether low latency will be considered essential to many of these applications. Some applications related to IoT monitoring and feedback, such as utility operations, may have a high tolerance for GEO satellite delay and can also be well served by cubesat type LEO systems. But other 5G applications, such as sensors related to driverless cars, may have more exacting limits that require superfast interactive networking and can be only well served by very broadband LEO systems, likely complementing terrestrial wireless systems.

This projected near term future has been described in the following terms by iDirect market analysts. “Today, we are on the verge of seeing what a truly ‘connected world’ looks like. It’s projected that soon there will be 6 billion people, 30 billion devices and 50 billion machines online. That’s essentially everyone and everything connected, across every geography, supporting every application from consumer broadband, mobile gaming and connected cars to global business networks, ships, planes, soldiers, first responders and connected farms” (The 5G Future and the Role of Satellites).

It will be perhaps another decade before it will be sorted out clearly as to which type of satellite service will respond best to which aspect of these burgeoning new data networking markets. These markets may be different for different regions of the world and especially differentiated for applications in developing and highly developed economic markets. What is clear is that there will be an explosive growth in machine-to-machine communications, data networking, and various types of video services in the coming decade. This should sustain growth in terrestrial and satellite service markets and perhaps also engender growth in new areas such as high altitude platform systems. Satellite networks, because of their inherent global accessibility and global coverage, will be part of this mix. Reduced latency of connection as provided by LEO and MEO constellations is expected to drive this satellite growth, while high-throughput satellites in GEO orbit can also fulfill part of this new growth as well.

5 Small Satellites and Their New Backers

The communications satellite industry for five decades or more has been sustained by companies that grew out of the aerospace industries, as well as telecommunications, broadcasting and entertainment companies, or large enterprises associated with the so-called military-industrial complex. These backers and customers relied largely on geostationary satellites to connect far-flung corners of the world and distribute video and later broadband Internet-related services. This support and patronage allowed steady and sustained growth that spread the use of satellite communications across the globe. Satellite services were embraced by most countries of the world, and nearly all joined or used the Intelsat satellite system, which was originally established as an intergovernmental treaty organization until its privatization in 2001. Dedicated national satellite systems or leased capacity on global networks, such as Intelsat, SES, Eutelsat, Telesat, Iridium, Globalstar, Inmarsat, and other systems, extended satellite telecommunications and broadcasting services to virtually every country and territory in the world. Other applications such as remote sensing satellite systems, global navigational satellite services/ precise navigation and timing systems, and meteorological satellite services widened further the extent and impact of global satellite services, though these specialized systems relied even more on the needs of government and government-related customers. While attempts were occasionally made to privatize these services and to attract private capital, especially to remote sensing and meteorological services, commercial markets were for many years too small to support such investments.

Only in the last 10 years have nontraditional financial and business backers expanded into the space sectors. The business world of aerospace and communication has been joined in a dynamic and disruptive way by the world of cyberspace, networking, data streaming, and OTT video services. In short, the world of Silicon Valley, Google, Facebook, and social media has joined the world of commercial satellite services. And as is the custom in this digital world of commerce, these new investors did not look for improvement or change in modest 5% incremental gains. They seek disruptive innovations that change business models and reinvent the way an industry operates in great leaps forward (Madry 2019).

Much of what is described as "New Space" or "Space 2.0" can be traced back to Silicon Valley and entrepreneurial thinking. Skybox and Planet Labs that have reinvented the world of remote sensing came from young people thinking outside the box. They found ways to undertake remote sensing in ways that were ten times less costly than the commercial enterprises highly reliant on government customers that preceded them. The small satellite revolution has now moved to the world of satellites and digital networking (Pelton 2018).

The technology that has led to new ways of designing and building satellites, of designing and manufacturing launch vehicles and ground antennas, and so on has been described earlier in this chapter. But, the driving force behind these various innovations is the entrepreneurial thinkers who envisioned new ways of designing these commercial space industries and seeking new sources of capital investment attuned to disruptive enterprises and new ways of doing business (Madry 2019).

This has not only led to major innovations in how every aspect of how commercial space enterprise is done today but also how such ventures are financed. The new enterprises are today not only being backed by companies like Google, Facebook, Qualcomm, and others from the world of computers and cyberspace but financial institutions that have been investing in these higher growth industries.

And the change in capital formation to support new smallsat initiatives does not end there. Angel investors, investment capital firms, venture capitalists, investment bankers, and others who are pursuing crowd-sourcing opportunities as means to invest in the next big growth industry are finding ways to invest as well. There are now many new start-up commercial satellites systems that have started with such innovative sources of funding. The Spire small satellite system got started with a Kickstarter funding initiative that led to a series of rounds of funding by angel investors.

In the case of Planet Labs and Spire, they have ensured their futures with long-term anchor client contracts to supply data for years to come. In the case of Planet Labs, now just Planet, they are supplying remote sensing data for years to come. In the case of Spire, they have a long-term data supply contract with the European Space Agency worth billions of dollars.

There are other potential investment groups such as sovereign wealth funds, technology investment corporations such as SoftBank of Japan, and other investors that have fueled the rapid growth of many new systems. OneWeb has used an interesting method of including many of its suppliers as investors in the new system. Thus Airbus Defence and Space, which is building the small satellite spacecraft; Virgin Galactic and Arianespace which are providing a significant part of the launch services for the network; Grupo Salinas of Mexico, a major mobile services supplier; and Qualcomm, a major equipment supplier, are all investors in OneWeb. At one point Intelsat and OneWeb were going to merge together with SoftBank financing the transaction costs, although this arrangement was never consummated. Instead, Intelsat remains an investor and close technical advisor and partner.

In OneWeb's latest round of investment, its 7th round, it raised $1.25 billion. These investors included the Japanese conglomerate SoftBank, Mexican conglomerate Grupo Salinas, Qualcomm, and the Rwandan government. There are now some 20 private investors that include aerospace corporations, launcher companies, high-tech computer and Internet companies such as Qualcomm and Google, media companies, as well as large conglomerate investment firms, investment banks, and sovereign funds (Sheetz 2019).

The world of space applications has thus changed dramatically with a new range of investors from the Internet and investment banking world that were not part of this type of business a decade ago. There is clearly a great deal of new technology evolving in the world of small satellites, but much of the change and entrepreneurial spirit that abounds in this field has come from many of the new players who are expecting new (and higher) types of profits from their investments and substantial new benefits from the new technology.

There are some from the financial and space communities who well remember the experience from the first wave of new non-geostationary systems of the 1990s, such as the Iridium, Globalstar, and Orbcomm mobile communications systems, and the broadband Teledesic system. Those ventures ended in bankruptcy, though some have emerged and continue as going businesses. Those with long memories, however, are concerned with the high level of enthusiasm and the massive numbers of filings that now exist in national licensing proceedings and international frequency coordination processes. Currently, there are over 20,000 small satellites proposed for launch in new constellations that suggest the possibility of some significant financial risks with at least some of the new systems. The OneWeb and Starlink systems are just the first of these systems. Additional systems proposed or under construction have yet to find anchor customers for their new systems. The potential for new traffic based on expanded Internet connectivity, 5G broadband cellular systems, Internet-of-Things (IoTs) traffic, automatic identification services, and more is clear, but converting that potential into signed contracts for services represents both a challenge and potential risk.

And, that risk is not just in terms of signed contracts from paying customers, there is also concern about the potential creation of massive amounts of orbital debris. Just managing the traffic in space so that satellites in these large constellations avoid colliding with other objects – possibly defunct spacecraft or rocket launcher stages that remain in orbit – is a major risk and potential long-term barrier to future space infrastructure.

6 Rising Concerns About Orbital Space Debris and New Coping Mechanisms

The people most aware of the space debris problem and concerned about the potential of collision with space debris associated with their new LEO and MEO networks are the very operators of these systems. OneWeb, which is deploying its large-scale network, and SpaceX, which has also now started to deploy an even larger MegaLEO system, have noted their level of concern about this problem and called for responsible operations and effective government regulations, supporting new initiatives began by the US government (Maclay et al. 2019).

They have explained in some detail their own plans to deorbit their own satellites at the end of life of their spacecraft and to bring all of their defunct satellites into a “disposal orbit” that would serve to bring all of these end-of-life satellites back down within 1 year. SpaceX even announced that it would actively deorbit 2 of its first 60 Starlink satellites soon after launch in order to simulate end-of-life disposal. Three other satellites of the first 60, however, failed to activate and were being counted on to deorbit without control and pointing. These early setbacks highlight the potential challenges of deorbiting the hundreds and eventually thousands of additional satellites to be launched by SpaceX, OneWeb, and others (O'Callaghan 2019).

They have also indicated plans to maintain a clear picture of possible conjunctions (collisions) that might occur. The US Air Force, after sometimes equivocal support for providing such warnings, have stepped up their efforts and close cooperation with the private space industry in recent years, especially after an Iridium satellite collided with an old Russian rocket stage in 2009. Long term, the administration of Donald Trump has announced plans and introduced legislation in the US Congress to shift traffic management responsibilities to the US Commerce Department, which already licenses new remote sensing systems. There are detailed plans for carrying out improved space situational awareness that would alert operators of large networks when conjunctions might occur. Thus, those that plan to launch many satellites into low Earth orbit have joined forces with regulatory agencies such as the FCC and the Department of Commerce in the USA to address the need for better space situational awareness, some form of improved space traffic management, and much more strict guidelines for deorbiting of satellites at the end of their life (Brookin 2017).

OneWeb has proposed to launch its satellites into a lower orbit and test them for reliability and functionality before placing them into their operational orbits (Brookin 2017).

Yet, despite all of these efforts and stated goals to manage space debris and prevent satellite collisions that could create thousands of pieces of new debris, the current situation is still considered dangerous. As more satellites are launched, that concern will grow. Efforts by the UN Committee on the Peaceful Uses of Outer Space to develop new guidelines for space debris removal and address the very difficult issue of space traffic management have over the past 5 years made only modest gains.

Currently pending issues with regard to orbital space debris and space situational awareness and space traffic management include the following:

- Concerns about large numbers of deorbiting satellites possibly hitting an aircraft (based on the study by Aerospace Corporation and other analyses).
- Coordination and information sharing between private companies providing space situational awareness data and defence agency operations.
- Improved methods of providing possible conjunction information about potential in-orbit collisions so as not to overload alert systems so that warnings of real possible collisions are taken seriously and evasive actions are taken. These might include improved use of artificial intelligence algorithms to focus on most serious possible collisions.
- Adoption of new "best practices" guidelines to encourage debris removal down from 25 years from end of life to 1 year from end of life.

- National actions to focus on and adopt new regulatory processes related to commercial constellations and debris removal and conjunction avoidance (U.S. Space Policy Directive 3 being one such example) (U.S. Space Policy Directive 3 2018).

7 Conclusions

The development of space applications for many decades followed the trajectory of bigger and better (and more complex) satellites that were more and more cost-effective. These were launched on bigger and better launch vehicles. The small satellite revolution that accompanied the “New Space” revolution has suddenly transformed the paradigm of how to respond to growing demand for digital communications services and the best way to improve satellite applications. This chapter has provided an overview of how new small satellite constellations and the new low latency services that they can provide are a part of the new space industry revolution. The ability to design, build, and test small satellites more cost effectively and launch them at much lower cost into low orbit constellations is changing the entire space industry. It is creating new regulatory issues and concerns but opening doors to innovation and allowing new entrepreneurial ventures to enter these new markets. This chapter has provided an overview of many aspects that will be covered in more detail in later parts of this handbook of small satellites.

The many new commercial satellite constellations that are now being designed and manufactured would not be possible without the new and improved satellite technologies covered in Part 3, the new launcher capabilities described in Part 4, the new approaches to manufacturing discussed in Part 5, the new ground antenna systems discussed in Part 6, and the new uses of small satellites described in Parts 7 and 8. The quite small satellites known as cubesats in some ways pioneered the larger and more sophisticated microsats and minisats that are more typical of very large constellations that are being manufactured and launched today. But the innovations that came with these smallest of the small satellites blazed the trail for the current commercial systems that are staging the next phase of the small satellite revolution.

The Smallest Classes of Small Satellites Including Femtosats, Picosats, Nanosats, and CubeSats

Rene Laufer and Joseph N. Pelton

Contents

Abstract

The term small satellite (or “smallsat”) is almost intentionally vague. In fact, it covers a surprisingly broad range of miniaturized spacecraft – usually defined by its mass. The smallest type of “smallsat” is the tiny “femto satellite” that can have a mass that ranges up to 100 g (or about 3.5 ounces). The next larger class is the “pico satellite.” This type of “smallsat” is defined as ranging from 100 g to 1 kg (or about 2.2 pounds) in mass. A pico satellite is also considered to represent the mass most commonly attributed to a 1-unit CubeSat which has the dimensions

of 10 cm × 10 cm × 10 cm – or a cube that is 2.53 in. on each side. Then there is the so-called nano satellite which ranges from 1 to 10 kg – often a multiunit CubeSat. CubeSats, currently, come in sizes that range from a 1-unit spacecraft up to 6 units, or the equivalent of 6 CubeSats in volume.

What is sometimes overlooked when we talk of "smallsats" are miniaturized experiments which are not independent free flyers. Such systems are considered hosted payloads that can fly on larger spacecraft and derive their power, thermal control, orientation, and commands from the host satellite on which they are mounted in space. These hosted payloads can vary from a few grams to several kilograms, but are typically below 10 kg in mass. Another more recent innovation is the ability to send up experimental packages to the International Space Station (ISS). Companies that facilitate this type of small space experiments include NanoRacks for NASA or Space Applications Services for ESA. These companies manage such facilities on the ISS that are operated by astronauts to carry out experiments that are typically designed by students, academic institutions, or even small companies. This approach is highly cost-efficient especially for student experiments. Future space habitats like the Bigelow Aerospace Genesis habitats and larger facilities like the Chinese Space Station are conceived as test beds for low gravity experiments by governmental, military, corporate, or private experiments. This various types of "hosted" small-scale space missions are designed to be cost-efficient, consolidate launch operations, and also avoid the problem of creating orbital space debris.

But so-called smallsats do not stop with femtosats, picosats, and nanosats. The concept of a small satellite or miniaturized satellite continues to include even larger spacecraft as well. Thus there are "microsatellites" (which are typically defined as ranging from 10 to 100 kg or up to about 220 pounds) and even so-called minisatellites ranging from 100 to 500 kg. Sometimes the range for "minisatellites" is stated as from 100 to 1000 kg, but this is less common.

The spectrum of such small spacecraft sizes thus ranges from about 10 g up to 500 kg in mass. This is a gigantic range that constitutes a ratio of 1 to 50,000 between the tiniest and the biggest of these types of spacecraft. The range is so vast that it essentially makes the term "smallsat" almost meaningless without further information.

In order to make an equivalent analogy, this would be much like saying that a child's toy airplane glider made out of balsa wood and a single-engine private airplane are the same class of aircraft.

In short, one thus needs to know mass, volume, power, stabilization capabilities, operational frequencies, and more to understand what any "smallsat" actually is in fact. This chapter starts the handbook by addressing just the tiniest of "smallsats" and their uses.

It discusses the characteristics and surprisingly wide range of applications of "femto satellites," "pico satellites," "nano satellites," and "CubeSats" that have developed over the past 20-year period. The miniaturization of sensors, digital processors, power supplies, and other components has made these smallest of spacecraft impressively capable.

CubeSat · "Femto satellite," Hosted payload · Microsatellite · Minisatellite · NanoRacks · "Nano Satellite," "NewSpace," Office of Outer Space Affairs · Orbital space debris · "Pico satellite," Registration Convention · Smallsat · Space 2.0 · United Nations Committee on the Peaceful Uses of Outer Space (COPUOS)

1 Introduction

The definition of femtosats, picosats, and nanosats has been provided above. These types of smallsat are typically used to carry out experiments or to test components, but usually not for commercial projects, at least not in units smaller that 3 U CubeSats. The various categories of small satellites and their definitions in terms of mass need not be repeated. It should be noted, however, that the definitions do sometimes vary. A useful discussion of the various types of small satellites and their various uses can be found in the introduction to the recent book on small satellites titled *Innovative Design, Manufacture and Testing of Small Satellites* (Madry et al. 2018).

The following chart, however, seeks to provide some general perspective on what sorts of applications are common using the larger types of "smallsats" versus those that are indeed quite small (see Table 1).

Thus it is possible to divide this discussion between the larger types of "smallsats," i.e., minisatellites, microsatellites, and in some cases 3- to 6-unit CubeSats. This class of larger smallsat is increasingly being used for commercial purposes and most typically being deployed as operational satellite constellations. These commercial smallsats are thus being divided from the truly small satellites discussed in this chapter. These tiniest of space vehicles are the focus of this initial chapter that will be addressing femto satellites, pico satellites, and nano satellites. A CubeSat is usually a nanosat. Multiple unit "CubeSats" nowadays often cross over between the nano- and microsatellite category (NASA).

Table 1 can assist in providing an overview of applications – historically predominately used to undertake experimental tests, to demonstrate the viability of a particular technology, or even just to relay signals from ground-based systems.

2 "Femtosats": Small Satellites of Up to 100 Grams

One might think that a "femto satellite" of only a few grams would be too small to accomplish anything of value. Yet due to miniaturization, it is possible to create an amazing set of capabilities in a very small device. Figure 1 shows such a system that is equipped with an antenna, gyroscope, microcontroller, magnetometer, and solar cells to provide power – all on one electronics board (Space Exploration 2019).

The fingers that hold this extremely small spacecraft (often also called a "chipsat") show its amazingly small scale.

Table 1 The types of small satellites and typical applications

The many applications, sizes, and characteristics of so-called smallsats

Function/ size	**Telecommunication constellation**	**Messaging/ data relay**	**Amateur radio**	**Remote sensing**	**Relay from ground systems**	**Meteorological**	**Scientific experiment**	**Student experiment**
Minisat (100–500 kg)	Typical (see, e.g., OneWeb and Starlink)	Typical (see, e.g., Orbcomm)	–	Typical for some commercial constellations	Typical (see, e.g., Orbcomm)	Typical for LEO and larger	Typical	Rare
Microsat (10–100 kg)	Occasional	Typical	Typical	Occasional	Often	Occasional	Typical	Often
Nanosat (1–10 kg) (multiunit CubeSat)	–	Much more common, i.e., Sky and Space Global	Occasional	Now much more common, i.e., lanet	Occasional	Occasional	Typical	Typical
Pico or femtosat[a] (10 g–1 kg)	–	–	–	–	Occasional	Occasional	Typical	Typical

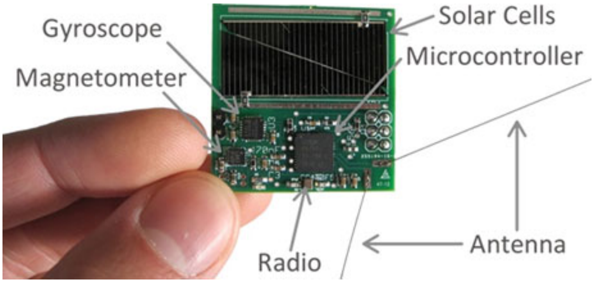

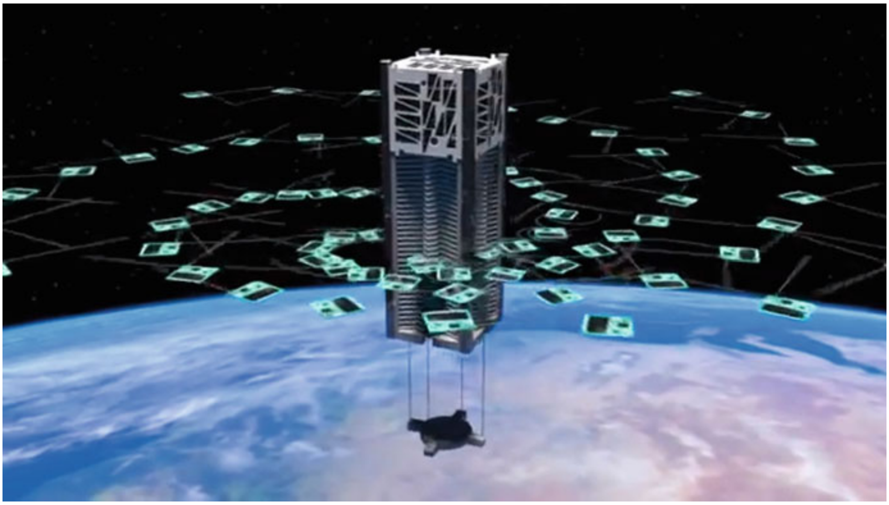

Fig. 2 Kicksat surrounded by a swarm of “femtosats”. (Graphic courtesy of NASA)

Such a tiny spacecraft often does not have the power or capability to communicate directly with Earth or over any greater distance, but a swarm of such miniaturized devices can collect remote sensing or in situ measurement data and then relay it to a close by host satellite. The Kicksat satellite shown with a swarm of “femtosats” or “chipsats” demonstrates how such a configuration would in principle look like in space (NASA 2018) (Fig. 2).

With the Kicksat-2 mission, NASA released 100 chipsats from a 3-unit CubeSat to test the ability of these tiny (3.5 cm^2 or 1.5 in^2) Sprite Chipsats. One objective of this project was to collect data and relay the collected information back to the 3-unit CubeSat host satellite. Such type of data collection method could be used in future, for example, to perform measurements in the proximity of asteroids or other celestial bodies. (Ibid.)

The idea of using “chipsats” in collaboration with one or more larger spacecraft to collect and transmit information is being developed and tested not only by NASA but also by other space agencies and research organizations. One concern that does arise with this type of configuration is that proliferation of orbital space debris. This should be a concern regardless of whether such research missions are in Earth orbit or elsewhere. Solutions that might be found with regard to “femtosats” and “chipsats” might be the possibility of rendezvous and recollecting these elements at the end of such a mission. This or other solutions should also be explored and tested before this type of highly distributed system is utilized extensively.

3 “Picosats”: Small Satellites of 100 Grams to 1 Kilogram Mass

CubeSats with dimensions of 10 cm × 10 cm × 10 cm and a mass of 1 kg for 1 unit (the standard actually allows up to 1.33 kg) are the most common representation of a pico satellite and have pioneered the latest phase of the small satellite revolution. The preponderant number of these projects for the last two decades since the inception of the idea of the CubeSat standard in 1999 has mostly come from academic or research institutions.

There are now literally hundreds of CubeSats that have been launched (mostly now in the multiunit CubeSat nano satellite size). Early examples of CubeSat type projects include (Smallsat Mission Examples and Design Suggestions 2019):

- QuakeSat from Stanford University which was designed to capture extra-long frequency (ELF) precursor signals prior to earthquakes (launched in 2003).
- XI-IV and CUTE-1 from Tokyo University and Tokyo Institute of Technology, respectively. Both achieved several objectives including verification of off-the-shelf components as well as testing transmission and sensing components.
- AAU CubeSat from Aalborg University tasked with testing a camera on a chip system.
- Can-X from the University of Toronto is designed to test the performance of an Atmel ARM microprocessor, gallium arsenide solar cells, CMOS imagers, active magnetic controls for detumbling, and three-axis stabilization.

The earliest CubeSat projects were largely experimental projects developed at universities with little systematic specifications as to power supply, thermal control, antennas, wiring, control units, and stabilization. The only requirement set by funding institutions like NSF and NASA in the USA to universities was the form factor of the CubeSat standard. As the enthusiasm and global interest in CubeSat systems grew, the alternatives available for the provision of CubeSat frames, power, digital controls, antenna systems, motherboards, and other components offered by suppliers have multiplied exponentially. Just some of the many options readily available online include Interorbital (1 kg and 1.33 kg kits), CubeSatShop (kits, buses, and off-the-shelf components), Pumpkin CubeSats (kits, components, and

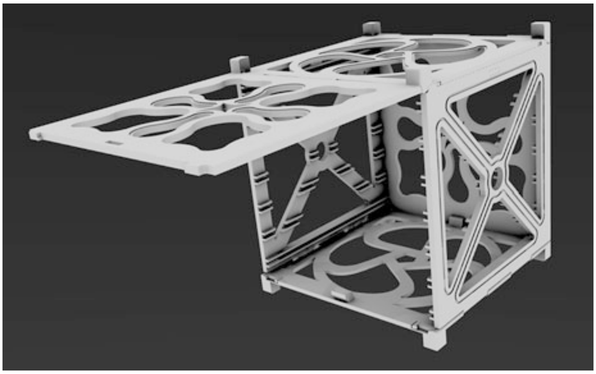

Fig. 3 One of many CubeSat buses that are available for creating a CubeSat today. (Courtesy of Cubesatkit.com)

software), Innovative Solutions in Space (offering CubeSat and PocketQube sat kits and components), GomSpace (supplier for components including electric MEMS propulsion based in Denmark), or Clyde Space (based in Scotland with CubeSat missions commissioned by ESA) (Where to buy CubeSats 2019).

Access to space options now open includes CubeSat missions (and small hosted payload experiments) that can be launched up to the International Space Station to being conducted on-board allowing large cohorts of students to carry out space-based experiments. Tens of thousands more students all over the globe have competed to put together detailed proposals for space experiments to actually fly in space via space agency offered flight opportunities. The cost of arranging for a launch is still sufficiently high that the number of CubeSats actually going into space remains relatively small. The process of designing, making, testing, qualifying for launch, and actually launching is daunting, and the cost is typically over $100,000 or even more depending on the complexity of the payload and the necessary subsystems. Nevertheless the ready availability of kits that can be ordered online all around the world has made this opportunity much more widespread (see "'Picosats': Small Satellites of 100 Grams to 1 Kilogram Mass") (Fig. 3).

A similar approach based on the CubeSat specification leads to a new version within the picosat category known as a PocketQube. In 2009, PocketQubes were developed by CubeSat co-inventor Robert Twiggs at Morehead State University with support from Kentucky Space. The idea was to provide a lower cost option for student experimentation in a standardized way. Pocketqubes are 5 cm × 5 cm × 5 cm in dimension or one-eighth the size of the 10 cm× 10 cm× 10 cm CubeSat (see Fig. 4) (By PocketQubeShop 2019).

Although the majority of PocketQube projects are undertaken as academic programs, there are already at least three start-up companies that assist with components and launch arrangements for the launch of PocketQube satellites, for example, GAUSS Srl, Fossa Systems in Italy and Alba Orbital in the UK. Most of these projects use off-the-shelf components, and a typical PocketQube satellite has a mass of often 200 g and less – especially appealing due to its lower cost not only to

Fig. 4 A pocketqube picosatellite that is one-eighth the size of a CubeSat. (Graphic courtesy open access commons)

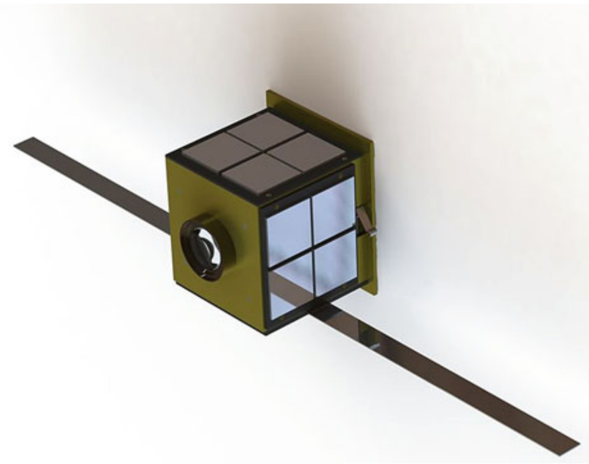

Fig. 5 ESA's Unicorn 2 CubeSat from its Ares development program. (Graphic Courtesy of the European Space Agency)

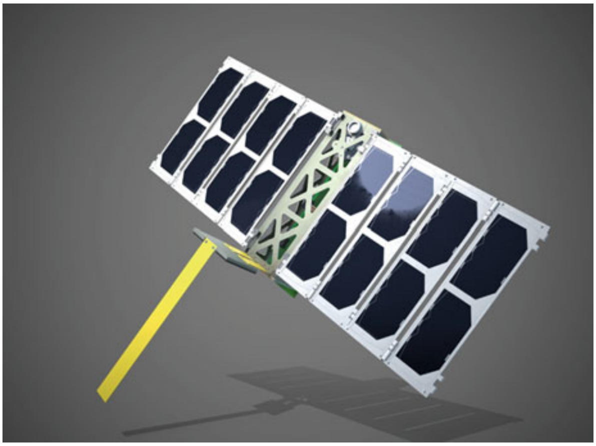

academic experimenters but also to component testers and amateur radio satellite builders (Pocketqube satellite 2019).

What has accompanied the development of PocketQube satellites has been the availability of consolidated launch configurations designed to accommodate these pico satellites. This has, for example, led to the development of the Unicorn missions under funding provided by the European Space Agency's (ESA) Artes program. Within this program 3-PocketQube-unit pico satellites and multi-PocketQube (up to 96) deployers were developed and tested (Pelton 2016), (Alba Orbital Ltd. | ESA's ARTES Programmes 2019) (see Fig. 5).

Pico satellites in the range of up to 1 kg are often limited in what activities that they can carry out in their volume envelope to accommodate certain type of instruments (e.g., optical payloads) or the ability to transmit signals and therefore data over longer distances. Thus they, like femtosats, are most likely to test

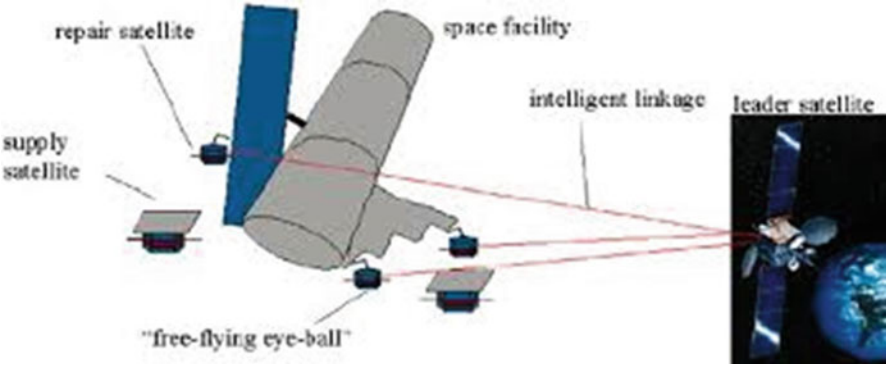

Fig. 6 Pico satellites as "flying eyeballs" in space. (Graphic Courtesy of DARPA)

components or in more and more concepts are to be adjuncts to larger spacecraft – leading into the area of federated and fractionated spacecraft.

One concept that has been examined is that of an inspector or "free flying eyeball" that could be connected to a spacecraft engaged in Rendezvous and Proximity Operations (RPOs) in space (e.g., for in-orbit servicing). Such small pico satellites could provide useful information to docking with a satellite that is being refueled or serviced in space.

In this case there would be a valuable space facility, a supply ship that carries such free flying "eyeballs" or inspector spacecraft that would provide information from various angles to assist with the safe docking and supply operations (see Fig. 6).

Studies done over the last 20 years (e.g., by Drs. Ivan Bekey and Joseph Pelton or at the University of Surrey) examined the possibility of creating large reflectors with a phased array feed system flying in space to create a large number of spot beams (perhaps many thousands in number that would only be a half or perhaps a quarter of a degree in size). Each free flying reflector could be flat since the feed system would use phased array technology to create the large number of beams for a space-based cellular communications system.

The most exotic extension of such a concept for a large-scale space-based communications system would be to create a massive free flying phased array composed of thousands of specifically designed pico satellites. Figure 7 describes such a very large-scale communications satellite virtual antenna system consisting of 100,000 free flying phased array elements with each element having a mass of down to 23 g – therefore in the femtosat range. There would still be a need for a "satellite feed system" flying at the center of the virtual antenna to form the beams within the large distributed array (Iida et al. 2003).

While this example uses femtosats, the first type of distributed phased array network for digital communications will more likely be scaled to something like a hundreds to one thousand elements with a mass of around 500 g in space. These initial entirely theoretical studies acknowledged that there were be many practical problems to be addressed. This included not only how the massive arrays in space would be deployed but, even more importantly, how would this massive "clutter" of

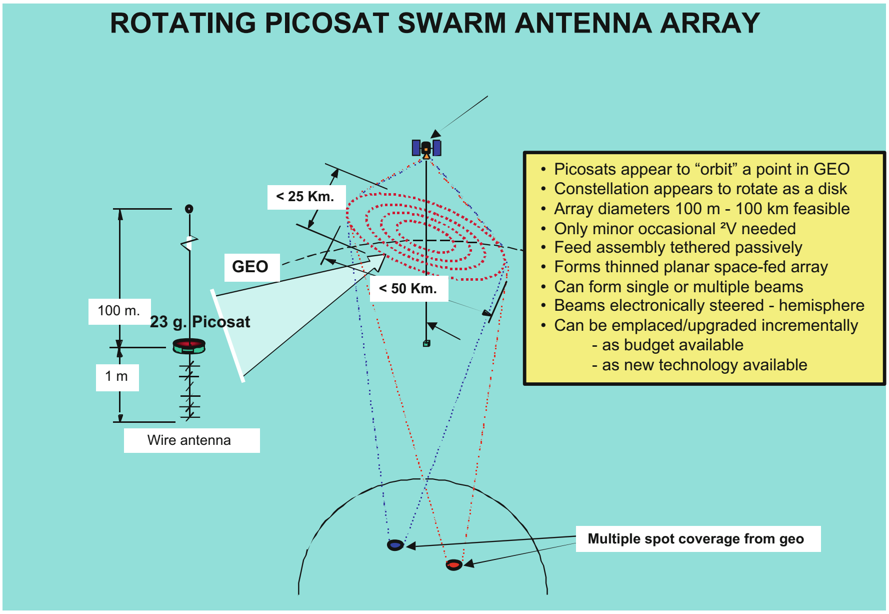

Fig. 7 Creation of a picosat phased array swarm to create super antenna system in space. (Graphics courtesy of Ivan Bekey and Joseph Pelton, All Rights Reserved)

tiny spacecraft elements be collected and deorbited safely at the end of life of this communications swarm, without creating significant orbital space debris posing a threat to other spacecraft. Also there are questions as to whether such an array, when deployed in GEO orbit, would create unacceptable problems and interferences with other satellites operating in the geosynchronous orbit arc (Pelton 2010) (see Fig. 7).

4 Nanosats and Multiunit CubeSats: Small Satellites of Up to 10 Kilogram

While the CubeSat standard grew to become a revolutionary success in the field of small satellites (in particular in the pico satellite category), the constraints of a 1-unit CubeSat became obvious very quickly in terms of the limitations in the extremely small volume and mass for a payload after all necessary satellite subsystems are accommodated. Also institutions like NSF and NASA in the USA or ESA in Europe realized early that the scientific return per cost of a 1-unit CubeSat is quite small in relation to the effort and cost. Based on the CubeSat standard, encouraging the building of multiunit spacecraft, 2-unit (2 U) and especially 3-unit (3 U) nano satellites of around 2.5–4 kg mass became the new common size of CubeSats.

Larger CubeSats (3 U and the more and more common 6 U “six-pack” nano satellites) benefit especially from sizing effects of a similar size/similar mass service segment of the satellite for 2 U, 3 U, or often 6 U spacecraft, therefore increasing the available payload envelope significantly. With such larger payload opportunities especially remote sensing and communication services, payloads became feasible – as shown with Planet's (formerly Planet Labs) "Dove" 3 U Earth observation satellites.

More recently such cost and performance advantages of multiunit CubeSats have attracted research groups and space agencies such as the US Department of Advanced Research Projects (DARPA), NASA, ESA, JAXA, and other scientific research and commercial organizations. There are now more and more missions that are 3-unit spacecraft (30 cm × 10 cm × 10 cm) up to 6-unit spacecraft that have a volume up to 6 liters. These nanosats then typically range from 4 to 10 kg in mass.

This access to complete 3 U or 6 U kits with software and hardware has now made this small satellite technology available not only to professional researchers and university experimenters. There are nonprofit organizations such as the Arthur C. Clarke Institute of Space Education (ACCISE) that recruits student participation in on-orbit experimentation. This international initiative that works closely with the National Center for Earth and Space Sciences Education (NCESSE) focuses on US student participation, but organizations like UNISEC-Global supports small satellite activities all over the world, and UNISEC-Global members already were responsible for several dozens of small satellite missions. As of March 2019, ACCISE and NCESSE had completed some 15 space missions to the International Space Station and carried over 150 student space experiments to the ISS dating back to 2011 (Clarke). UNISEC-Global targets to have 100 countries involved in (small satellite) space missions by 2020 and provide access to space for students in every country on the globe by 2030.

5 The Future of Truly Small-Scale Satellites

Today there are many questions arising about the increasing number of small satellite missions and their future – especially regarding orbital space debris. Those questions are about as to whether there should be new requirements put in place that go beyond the United Nation's voluntary guidelines for orbital debris mitigation by removal from orbit within 25 years after the end of life as adopted in December 2007 (Space Debris Mitigation Guidelines). There are questions as to whether there should be passive systems deployed at end of life for CubeSats and smaller that usually do not have any active means to deorbit. There are, in fact, also a wide range of technical, operational, regulatory, reliability, and frequency interference concerns that small satellite deployments have raised and that the Working Group on the Long Terms Sustainability of Outer Space Activities of the Committee on the Peaceful Uses of Outer Space (COPUOS) has considered in recent years. On one hand there has been an interest in encouraging innovation and creativity and promoting space technology that is of a scale and type that is suitable for use by emerging and developing nations. Yet on the other hand, there are concerns about near Earth orbital space as a limited resource, growing RF interferences, and activities that might work against the long-term sustainability of space.

6 The Technical Issues and Challenges

It is still not clear how much further technical progress can be made to create smaller, smarter, and more capable satellites to provide new types of services or improve and expand existing ones. Constraints that once required satellites to be massive and much larger in volume have been overcome with miniaturization and new electronic beam forming technology that have allowed satellites and ground systems more efficient and low Earth orbit satellites much more viable for many more purposes.

Further improvements have come from increased use of commercially available off-the-shelf components, automation in manufacturing and testing processes, and other entrepreneurial innovations that have allowed simplification of design. Key innovations have also been seen in launch vehicles design. Here innovations have included the use of new materials (e.g., Rocket Lab) and an evolution toward reusable rocket systems (e.g., SpaceX and Blue Origin). We have seen reduced costs and even the elimination of launch facilities by the addition of carrier vehicles that allows high altitude launch from the air (e.g., Virgin Galactic).

The very smallest spacecraft as represented by femtosats and PocketQube satellites have seemingly come up against limits created by the need to communicate with ground-based systems. Communications over longer distance require power and antenna gain to communicate. There are clear limits to broadband communications to and from space-based femtosats, picosats, and even nanosats. For such very small satellites, there are physical limits posed by power levels, antenna gain, and transmission path loss with which to contend. Even so innovations such as federated and fractionated distributed mission concepts might help address some of these technical limitations while also providing opportunities to reduce the cost of access to space for student experimenters as well as commercial entrepreneurs (Joseph 2015).

One example of multipurpose units is the Faraday 1 smallsat platform. This was developed by SSTL and is now provided as a consolidator of smallsat missions by the British company In-Space. In this particular case, In-Space is combining five different experimental missions. In all cases the small-satellite participants wish to provide in-space testing of new technology.

The launch in this case was the Electron rocket from New Zealand. This integrated approach serves to create efficiencies with regard to cost, communications, operations, power, and frequency use. In short there are many benefits from having several different payloads from different customers combined in a single mission – not to mention the added benefit of minimizing orbital debris issues (British In-Space Missions 2019).

Certainly the technical challenges will only continue to increase as the seemingly difficult problems of limits to miniaturization seem to be reached at least in areas like optical payload and communications systems.

7 The Legal and Policy Challenges

As one notable example, the French Government has enacted the French Space Operations Act (FSOA) that will impose a fine for any French spacecraft launched that is not deorbited within 25 years after end of life. This would appear to serve as a model regulation for other nations to follow with regard to putting teeth behind the UN COPUOS voluntary guidelines. The problem is that plans to launch as many as 20,000 and more LEO small satellites into orbit in the next few years with lifetimes of perhaps 5–8 years have now called into question the viability of the 25-year guideline adopted over more than a decade ago. The world of space technology and space innovation is moving quite rapidly, but the world of national and global space policy and regulation is moving quite slowly in comparison. The UN voluntary guidelines actually took some 18 years from start to finish to be adopted. This timetable is not well suited to today's space-related issues.

8 Conclusions

The world of the small satellites and the innovative design techniques and fascinating experimental and even practical uses that are now being used within femtosats, picosats (such as CubeSats or PocketQubes), and nanosats (such as multiunit CubeSats) has created the start of a new era in space systems. Small satellites, including the very smallest of these systems, have shaken the applecart of the entire space enterprise around the world. It has led to a revolution in not only how satellites are conceived, engineered, manufactured, and tested, but it has also stimulated a new view on the design, engineering, and manufacturing of launch vehicles.

Some have said that this revolution has come from the world of computer science intersecting with the world of aerospace. Another way of putting this has been to say: "Silicon Valley has discovered the world of the military-industrial complex and re-invented it." This means that there has not been a single change whereby miniaturization has made satellites smaller. It means that a whole series of mind-sets have been uprooted and many different things have been disrupted and reinvented. The list of these changes is startling to examine (Pelton 2019).

Things that are different in the world of space today due to the "smallsat" revolution includes (but is certainly not limited to) (i) satellites are much smaller due to miniaturization of computers and digital controls and avionics, more use of low Earth orbits, and innovations in the design of antennas having electronically formed beams rather than shaped by antenna dishes both in space and on the ground; (ii) satellites are moving toward mass production and innovations such as the use of additive manufacturing; (iii) design cycles are being rapidly speeding up with perhaps two or more new design cycles every year rather than every 5–7 years; (iv) changes to sparing philosophy and large-scale deployment of small satellites have led to the use of many more available off-the-shelf components and less requirements for expensive space qualified hardware; (v) more reliance for innovation and changes being accomplished by changes to software rather than new black boxes and hardware; and (vi) significant economies being accomplished via lower launch costs. This is certainly not only a matter of smaller and less massive spacecraft and more cost-efficient launchers but also a move to reusable launchers, lower cost launch sites or elimination of traditional launch sites, and more.

The terms Space 2.0 and NewSpace are used for good reason. The world of space as it existed at the start of the space age and as it was defined by governments, space agencies, military organizations, and very large aerospace companies, largely under the control of governments, has changed a very considerable amount since the start of the twenty-first century. Private development like the SpaceShipOne spaceplane to win the Ansari XPrize in 2004 is an example of such a key aspect of that change. The birth of a host of new private space industries such as SpaceX, Blue Origin, Sierra Nevada, Virgin Galactic, Rocket Lab, OneWeb, and many others represents a key indication of a space industry that is more entrepreneurial, more innovative, and more able to respond to disruptive technologies, process, and reinvention of how things get done. If there is one icon that represents that change, it is the “CubeSat” that represents the change within the aerospace world.

Commercial Small Satellites for Business Constellations Including Microsatellites and Minisatellites

Joseph N. Pelton and Rene Laufer

Contents

Abstract

The smaller version of “smallsats” known as “femtosats,” “picosats,” and “nanosats” or “cubesats” was discussed in the preceding chapter. These very small spacecraft, plus small hosted payloads, or tiny space experiments that are carried out in the Nanoracks experimental platform on board the International Space Station provide a gateway into space that can allow students to conduct experiments without huge multimillion dollar investments.

The commercial uses of “smallsats” for 1-unit cubesats and below are extremely rare. Increasingly, there are commercial systems, however, that are using 3U cubesats particularly for automatic identification services (AIS) and for messaging, machine to machine (M2M), and Internet of Things (IoT) connectivity. The other prime commercial applications by 3U and above cubesats are for remote sensing with lower resolution in cases where rapid updates of information and data analytics are the prime purpose of a small satellite constellation.

Thus small space units such as cubesats and even smaller pocketqubes are typically used for student or scientific experiments or used for proof of concept for a much larger follow-on activity. This means that most commercial networks are using the larger class of microsats and minisats for their constellation designs. Thus this chapter is focused on the burgeoning growth of “smallsats” for commercial networks and the “NewSpace” or “Space 2.0” constellations that employ larger spacecraft. These satellites are still far smaller than the typical commercial and space agency research spacecraft that has grown to the size that ranges from 1000 Kg on up many thousands of Kgs.

There is now a huge and rapidly growing new commercial market for what are called “microsats” (e.g., 10–100 kg or 22–220 pounds) and “minisats” (e.g., 100–500 kg or 220–1100 pounds). Others, however, define minisats as being from 100 kg up to 1000 kg (or 220–2200 pounds). These types of “smallsats” unlike those discussed in the preceding chapter are typically being deployed for commercial missions and applications and most often for large constellations to create a global service. Space agencies, military agencies, and established research organizations are finding that these smaller but highly capable satellites can be used for scientific exploration in orbit and in deep space and for proof of concept for larger missions.

These microsatellites and minisats are most often launched in low Earth orbit (LEO) but not exclusively so. GEO-orbiting spacecraft and deep space missions can also use this type of “smallsat” that are performing ever more complex and difficult missions. Even radarsats that require substantial power levels because they require “active sensing” have been deployed as constellations using this type of smallsat such as Canada’s most recent Radarsat Constellation.

This chapter provides the background of the earlier “smallsat” constellations that failed financially, the resurgence in the technologies, financial support, markets for these new “smallsat” systems, and the regulatory and other challenges still to be faced in this highly dynamic market that is still in what might be considered a second shakeout phase of development.

1 Introduction

The demand for “smallsats” is currently projected to increase and rise to a high level as demand for geosynchronous satellites for telecommunications and remote sensing appears to be falling.

The estimates as shown in Fig. 1 indicate that based on historic growth patterns as many as 2600 nanosats and microsats might be launched from the period 2020 through 2024. These estimates as developed by SpaceWorks suggest that the rate of these microsat launches might rise to a high of nearly 700 launches per year by 2022 if current market forecasts for full deployment continue for smallsats in the range of 1–50 kg. (Neiderstrasser 2019).

Yet, as high as these estimates are for microsats, the estimates for minisats (in the range of 50–500 kg) may conceivably be as high at 20,000. Although most estimates discount the full deployment of all licensed microsats and proposed for launch to a much reduced number, even the discounted figures are tremendously high.

The projections by Northern Sky Research in their studies indicate a wide range of possible launches for microsatellite in the range up to 500 kg for large-scale constellations that include networks for OneWeb, LeoSat, Telesat, two systems for SpaceX, Boeing, Comstellation, Theia, and a number of other currently proposed constellations. Even in the case of these constellations, there continue to be filings to add to the size of these networks that are now working their way through licensing processes at the national or international level.

Thus Northern Sky Research has indicated that there is an opportunity of anywhere from 10,000 to 20,000 microsatelllites to be launched over the next 6–7 years. This assessment, however, was made before the Covid-19 corona virus impacted the global economy. In contrast to these historically high number of satellites, there has been a large dip with regard to GEO satellites, especially for telecommunications. In this case there have only been nine large-scale GEO satellites ordered in the past couple of years. Part of this change, of course, is that the new high-throughput satellites are so highly efficient. These huge high-throughput satellites (HTS), at up to 150 gigabits/second, represent the throughput capabilities of 20–30 conventional GEO satellites of the past. Just as there is now a smallsat revolution seemingly underway involving low Earth orbit constellations, there is another revolution underway with regard to the superefficient and very cost-effective high-throughput satellites in GEO (Russell 2018).

There are clearly reasons why the number of possible launches of minisats varies so very widely. If one takes just the case of the SpaceX Starlink systems, one sees that these two currently filed and licensed smallsat systems together would constitute, when fully deployed, some 12,500 new smallsats in low Earth orbit (LEO) – this is far more than all communications satellites currently operating and all comsats ever launched into orbit. This system that would cost over $10 billion if fully deployed involves some 4500 operating in Ku-band and Ka-band frequencies and around 7000 operating in the extremely high-frequency V-band between 40 and 75 GHz.

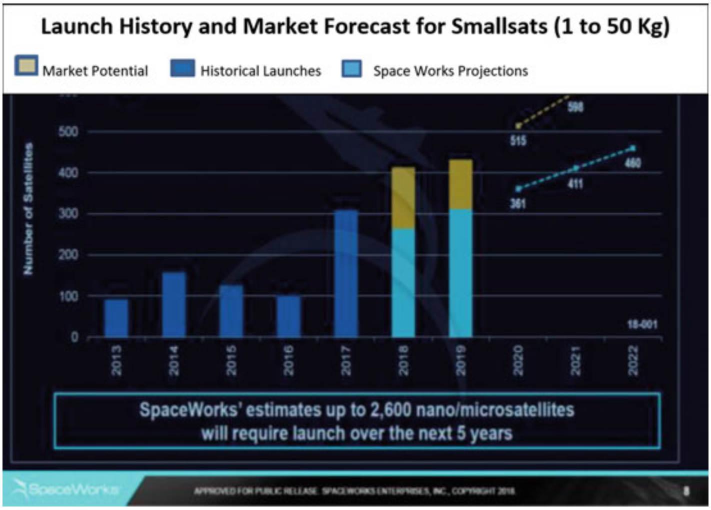

Fig. 1 Projected increases in "smallsat" launches. (Graphic courtesy of SpaceWorks)

And this is not some abstract concept; serious deployment of this network to challenge the OneWeb constellation has now also begun in earnest. Early on May 24, 2019, a reusable Falcon 9 satellite deployed 60 of the Starlink satellites in low Earth orbit in what seems to be the start of deploying a vast array of small satellites into low Earth orbit (LEO). And these satellites are not tiny cubesats but 500 pound (227 kg) spacecraft, many times the size and mass of the Intelsat I (Early Bird) satellite that started the age of global satellite communications in 1965 54 years earlier (Thompson 2019).

The truly vast size of these "megasatellite" systems and the large amount of capital that must be raised to pay for the manufacture and launch of these new systems – some of these constellations containing thousands of satellites – contribute to the uncertainty in the projected number of microsat launches. Thus there is today uncertainty of market forecasts as to the number of smallsats to be manufactured, the number to be launched, and the revenues that will be derived from smallsat constellations designed to provide telecommunications and networking services around the world (Torrieri 2018). There was significant uncertainty in smallsat forecasts even before the Corona virus impacted the global economy. Thus today most projections see a downturn in volume and even more bankruptcies such as has been the case with One Web, Leosat, Vector, Firefly, etc.–with more to follow.

This has set off a large number of "smallsat" launch vehicle development efforts. According to a study conducted by Northrup Grumman in 2018, there are over ten countries seeking to develop new "smallsat" launch capabilities. This is led by some 20 such commercial developments in the United States alone (Op. cit, Carlos Neiderstrasser).

Other developments are widely distributed around the world, i.e., China (six projects), Spain (three projects), the United Kingdom (three projects plus a joint project

with Ukraine), as well as single projects in Argentina, Australia, Australia/Singapore, Brazil, pan-European (ESA), India, and New Zealand (Ibid.) (See Table 1).

The extent to which there are many challenges unknown in the future development, manufacture, launch, and operation of large-scale constellations using smallsats cannot at this stage be overstated.

2 Historical Background

There is not an exact time when the use of commercial smallsats in constellations first came to the fore, but it is convenient to start with the smallsat constellations for land mobile satellite communication which were first planned and launched beginning in the 1990s.

It was in the mid-1990s that the Iridium and Globalstar satellite networks were designed as smallsat constellations bean. These smallsat constellations numbered in the range of 50–70 satellites were in many ways the pioneers. The smaller Orbcomm network was also started in this time frame. Two other proposed networks that were proposed, started, but ended in bankruptcy before launch, namely, ICO and Teledesic, are also part of the early days of the smallsat revolution that began in the 1990s, seemed to pause in the early years of the twenty-first century, and then have come roaring back in the 2010s.

The Iridium and Globalstar smallsat constellations were constituted with the minimum number of spacecraft sufficient to provide continuous coverage for mobile communications services at the LEO selected for these systems. Constellations in LEO-based polar orbits designed to provide Earth observation, meteorological coverage, and remote sensing services had even been deployed with smaller-sized constellations since continuity of service was not required in these cases.

In the late 1980s and early 1990s, the ideas began to percolate. There were various proposals for large-scale constellations with hundreds or even thousands of smaller-scaled satellites deployed in LEO networks. This new type of satellite architecture was premised on a number of innovative ideas.

(i) These ideas included the following rationale with regard to the use of "smallsat" constellations: (i) Smaller satellites in low Earth orbit (LEO) would be able to provide more power with greater efficiency because of lower path loss. The argument was that since they could be up to 40 times closer to the Earth's surface, they would be able to deliver the equivalent of 1600 times greater intensity of power distribution based on "path loss" formulas.
(ii) These satellites would operate with much less transmission delay (or latency) due to being much closer to Earth.
(iii) These new smaller but much more numerous satellites could be mass-produced and be more efficiently tested for performance because of their much larger production runs.
(iv) The design of these "smallsats" might be able to use more off-the-shelf and lower-cost components because of the larger production runs and sparing philosophy that would simply replace any defective satellite with another "smallsat."
(v) Although there were many more satellites to be launched, the launch of low orbiting spacecraft is easier to achieve and easier to operate than spacecraft launch all the way out to geosynchronous orbit – almost a tenth of the way to the Moon.

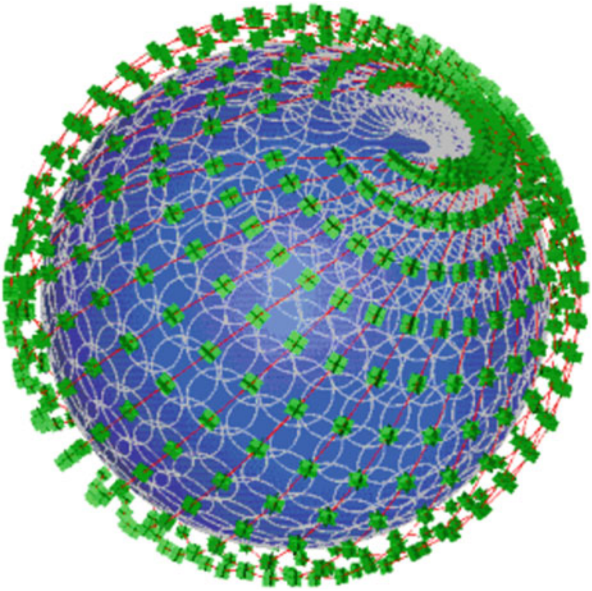
Despite these perceived advantages, there were several significant disadvantages. These were:

(i) The satellites, in low Earth orbit, would have much shorter lifetimes, typically of about 5–8 years, in that their orbit would decay and deorbit over time.
(ii) The GEO-orbiting spacecraft did not require ground stations or user terminals to track them since the GEO sats always appeared to hover over one fixed spot in the sky and thus did not require constant tracking of the satellite as it moved across the sky.
(iii) The signals coming to and being emitted from the satellite would have to be rapidly switched from beam to beam (about once a minute) and from satellite to satellite (about every eight minutes) in the most rudimentary constellations.

This constituted a particular challenge for telecommunications satellites in terms of potentially dropped calls since a typical telephone call lasts over 5 min and this would have required precision switching of beams four or five times for each call. In an environment with millions of calls on line in a global network, this would require an enormous precision of electronic switching accuracy that certainly challenged the state-of-the-art capabilities of the time when these first systems were proposed and the low orbits envisioned for the spacecraft.

For a variety of financial, marketing, operational, and technical problems, the initial systems that deployed LEO satellite constellations, or proposed to do so, all had financial and operational difficulties and ultimately experience bankruptcies. These included the Orbcomm data message relay satellite network, the Iridium, Globalstar, and ICO land mobile communications systems and the Teledesic megaLEO broadband system.

Fig. 2 The 280 small satellite constellations proposed for the Teledesic 2 to have been constructed by the Boeing Corporation. (Graphic courtesy of Global Access Commons)



This last system, backed by Bill Gates and Craig McCaw, was to have been a Ka-band high data rate communications satellite network to support both fixed and mobile communications of all types. This highly innovative satellite systems design that would have deployed a host of new technologies initially envisioned the use of nearly a thousand satellites, including 80 spare satellites.

In the design process, the initial network that would have been built by the Boeing Corporation was reduced to 280 smallsats in low Earth Orbit. This system that would have provided broadband services, rather than thin stream communications for mobile voice communications, was the most ambitious of the earlier "smallsat" constellation. Its bankruptcy, along with Iridium, Globalstar, Orbcomm, ICO, and other proposed LEO constellations, ended the first round of enthusiasms for such types of satellite networks (See Fig. 2).

Today, the early failures and bankruptcies of the early commercial smallsat constellations are considered to be, or at least hoped to be, behind us some 30 years later. There are certainly key advances in communications satellite technology, higher performance switching systems, more experience with high-volume manufacturing, additive and 3D manufacturing and automative testing techniques, improved experience with inter-satellite links, new developments in ground systems that can provide electronic tracking of LEO satellites, and AI-controlled satellite management systems for large-scale constellations. All of these advances have contributed in a renaissance in the what, where, when, and how of LEO satellite constellation design and operation.

New innovations in network control systems artificial intelligence applied to constellations operations to avoid satellite conjunctions and interference to GEO satellites, ground and satellite antenna design, pointing and operation, and efficient manufacturing and testing techniques are all important. All of these advances, plus new and expanded demand for various space-based services, have led to many new proposals for new commercial small satellite constellations to be deployed in the next decade.

The 2020s seem to be the time for deployment of a large number of small satellites. These range in size from 3-unit cubesats (around 5 kgs in mass) such as for the planet remote sensing network (now with over 400 Dovesats in orbit) up to 250–500 kg small satellites to support networks for worldwide networking services such as for Orbcomm, Linksat, the Telesat constellation, and over a dozen other constellations.

3 The Case Study of the OneWeb Smallsat Constellation

One of the reasons that the Teledesic satellite system went into bankruptcy was that the estimated costs for manufacturing of the satellites were underestimated. In the case of the OneWeb Satellite Constellation, the costs of production of the satellites are reportedly significantly underestimated. It seems that the prudent step has recently been taken to reduce the constellation size from around 900 to 600 satellites. This should prove to be a key way to control cost since this will not only reduce the cost of the manufacture and testing of the satellites but will also directly serve to reduce initial launching costs as well. The speculation is that this reduction was driven by the need to raise over a billion dollars in capital that was not readily available (Todd 2018).

If it were not for OneWeb's bankruptcy this system would have been perhaps the first to market, and if possible support from the U.K. government materializes this could still possibly be the case. Greg Wyler, who first conceived to this type of system to serve underserved portions of the world, cleverly tested the idea by organizing the O3b medium Earth orbit (MEO) satellite network. This O3b network, with its name standing for the "Other Three Billion," was designed to provide service to the equatorial regions of the world where some three billion people live with low incomes, inadequate health care and education, poor housing, limited access to potable water and food, and limited access to electricity, lighting, and telecommunications and networking capabilities. This network was started in partnership with the SES satellite network and other partners and is now wholly owned and operated by the SES company, headquartered in Luxembourg, and is one of the world's largest satellite operators.

The experiment with the O3b satellite constellation in MEO orbits led to the much more ambitious further step that has been championed by Wyler. This was a move to provide a network that would allow even smaller ground stations less latency or network delay. This was the OneWeb network that Wyler hoped to deploy in 2021-22 before bankruptcy (Fig. 3).

This network is challenging on many different scales starting with the big three listed below:

1. There is a need to build and quality-test the satellites at sufficiently low cost to be financially viable.

Fig. 3 The highly complex constellation deployment plan for the OneWeb constellation. (Graphic courtesy of OneWeb)

2. There is the challenge of launching the network in an efficient and timely manner so that the very large number of satellites makes it into orbit in sufficient numbers within a narrow time constraint sufficient to provide the global service requirements and not break the budget.
3. There is the difficulty of ongoing viable operations that include avoiding collision of a huge number of satellites; not interfering with other satellites, especially in the GEO arc; and installing a large number of ground systems to interface with users.

With regard to challenge 1, OneWeb has reduced the number of satellites in the original constellation, presumably in part, because of cost overruns in producing the satellites and because of the need for raising more capital.

With regard to challenge 2 of a speedy and massive launch deployment campaign, one can look to the experience of the Iridium Next constellation. Here there was the problem of heavy dependence on a single launcher system. A launch failure when there is only one system does shut down launch operations when the failure analysis occurs. The deployment of the Iridium Next Satellite network was, for instance, seriously delayed by the SpaceX Falcon 9 launch vehicle failure. The following risk assessment was reported in 2016 by TeleAstra concerning the Iridium Next system where only some 70 satellites – not many hundreds – were being deployed. This launch risk assessment was provided in this case several years ago.

“The real issue is that SpaceX has a launch manifest with 26 other launches prior to Iridium NEXT. Once the Falcon 9 launches begin it has taken about one month between launches. This means that the replacement constellation cannot begin to provide new service until early 2018. In the mean time the old satellites are aging, wearing out, or running out of fuel" (TeleAstra assessment of iridium next launch deployment risks. Part 10, 2017 report.). In this case the first-generation satellites continued to operate many years beyond their expected lifetime, and the Iridium Next system is fully deployed, but the point is well taken.

Challenge 3. Even if challenges 1 and 2 can be surmounted, there are still an ongoing series of issues to be addressed. It is an exacting effort to create "fail safe" artificial intelligent control systems that are fully tested to ensure that there are no collisions within the large-scale constellation, that the satellites are pointed away from GEO satellites as they cross the equatorial arc, and that conjunctions with spurious debris are avoided. There are deployment and operational issues of getting thousands, tens of thousands, or perhaps even a million new ground systems installed and operating.

4 The Enormous Challenges of Deploying the SpaceX Starlink System and Achieving Financial Viability

If the OneWeb System faces challenges to be technically, operationally, and financially successful, then the challenges associated with the SpaceX Starlink Systems are much, much greater. This is because the number of satellites, the capital investment, and business model challenges are all much larger.

The challenge of manufacturing, qualifying, and testing of some 12,500 smallsats is an unprecedented set of tasks in the history of commercial satellite undertakings. At $10 billion this would be the most expensive satellite system, and some 7500 satellites would be operating in the V-band spectrum which has never been used operationally for telecommunications and networking services. To some this is a risk comparable to betting on the 3 race exacta at a horse race with long odds on all the horses, but then Elon Musk has already accomplished many long odds challenges with PayPal, Tesla, and SpaceX.

And not all of the risks to the megaLEO satellite network are out in space. In one of the recent actions by SpaceX, it has submitted a petition to the US Federal Communications Commission for a huge investment on the ground as well. In this petition permission is being sought to deploy on the order of one million ground systems to connect to these microsatellites in order to link to users in the underserved locations around the world so that the Starlink satellite network can serve the underserved or unserved populace of the world.

This petition sought approval to receive blanket approval for up to a million Earth stations that would be used by customers of the Starlink satellite for internet networking service. The petition that was filed on behalf of a sister company called SpaceX Services sought that these Earth stations could be considered for "type approval" rather than individual licensing and approval. The design for these Earth stations is now identified as being exclusively based on a flat-panel, phased array system that would be able to transmit and receive signals operating in the Ku-band to

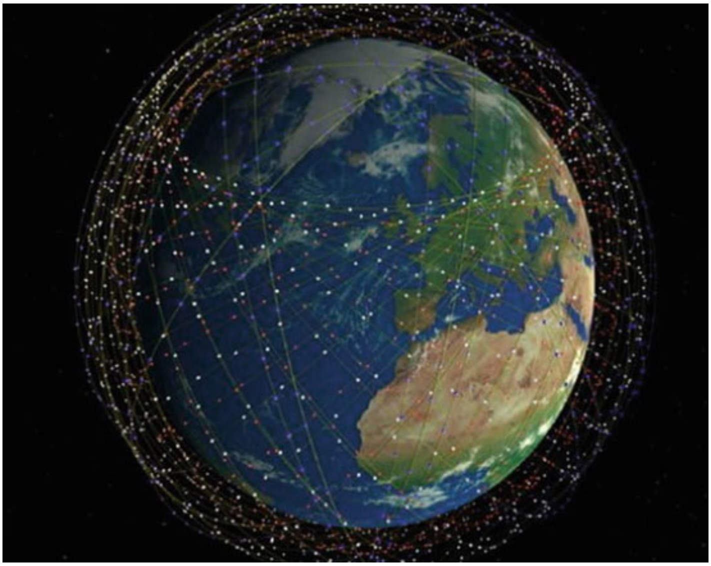


Fig. 4 The megaLEO constellation of smallsats know as the Starlink constellation. (Graphic courtesy of Thales Alenia)

and from the Starlink constellation. Presumably a similar approach will be taken for the V-band system that SpaceX has also proposed (Boyle 2019) (See Fig. 4).

The other aspect of the Starlink constellation is that it is being designed not only to provide access to rural and remote areas of the world that have limited broadband Internet service capabilities, but it is also conceived as a broadband network that would provide very high trunking throughput connections that could compete with fiber-optic networks. Some believe that only if this huge network can serve the developed and the developing world can it achieve sufficient revenues to support the large capital investment that it requires to succeed financially.

In the latest SpaceX filings with the FCC, it is proposed that that the Starlink network would be deployed, at least partially in a much lower orbit than first proposed. This new deployment plan is explained on the basis of seeking to minimize the problems associated with orbital space debris and also with the desire for minimal transmission delay. Low latency, or in effect, very fast end to end connectivity is needed to be competitive with fiber links. In particular the latest proposal from SpaceX is that 1584 of the 4400 plus satellites in the Starlink constellations would be deployed to an altitude of 550 km (342 miles) as opposed to the 1150-km (715-mile) orbit described in SpaceX's initial round of filings with the FCC (Boyle 2018). This filing was made after SpaceX had unexpectedly launched two experimental prototype "TinTinA and TinTInB" satellites into lower orbits than their previous filings had indicated (Grush 2018) (See Fig. 5).

The SpaceX filing has said in support of its lower orbit proposal: "This move will help simplify the spacecraft design and enhance the considerable space safety attributes of SpaceX's constellation by ensuring that any orbital debris will undergo rapid

Fig. 5 The TinTin test satellite for the Starlink constellation by SpaceX Services. (Graphic courtesy of SpaceX)

atmospheric re-entry and demise, even in the unlikely event that a spacecraft fails in orbit." It will also remove a small number of satellites from the constellation design.

The SpaceX filings have indicated that there is also a close focus on the latency issue. It was indicated that the latency experienced with the TinTin experimental satellites is currently 25 ms, but with the network deployed as proposed, it should only experience 15 ms delays. Or as Elon Musk has expressed it, this would support interactive computer game participation. Skeptics thus have indicated that it was latency performance and not concern with regard to orbital debris that has moved the network altitude to a lower level.

The bottom line is that the SpaceX Starlink constellations will face the same types of challenges that OneWeb will face plus a few more. The cost of manufacturing and launching 12,500 satellites and have them operational by 2025 and keeping the costs down to 10 billion dollars is a huge challenge. To this amount must be added the cost of the ground segment that is using the new electronic beam forming technology. Further there can also be issues related to tariffs that might be imposed on ground systems as well as issues within various countries that are not members of the World Trade Organization (WTO) as to local landing rights and other trade or tariffing issues involving local telecommunications and networking companies.

There are also important technical issues involved with the operation of very large and complex megaLEO networks in order to avoid collisions or conjunction with orbital space debris. The ability to provide the high-speed switching from one beam to another at very short intervals and to operate inter-satellite links in very short order that link between multiple satellites to complete a transoceanic link are new challenges to the world of satellite operation. It is remarkable how similar how the technical, operational, financial, and ground system implementation challenges that SpaceX with the world's largest satellite constellation will face in the next five years, that the Teledesic System faced two decades ago. The latest challenge has come from astronomers who are now complaining of visual pollution of the heavens.

5 The Many Other Microsat and Minisat Constellations and the Challenges that They Face

The preceding analysis of the OneWeb and SpaceX Starlink was chosen to be highlighted since these two constellations represent on one hand the first of the megaLEO systems to be deployed and on the other hand the largest system that is planned to be deployed. These two systems are useful case studies for analyses but are still not completely representative of the many smallsat constellations now planned and the wide diversity of services that they might offer in the next few years. The technical, operational, and financial plans for these two systems nevertheless serve to help identify some of the basic issues and challenges that all of these various smallsat constellations will face. There are an ever-growing number of smallsat constellations that are still being envisioned, and the size of these smallsats ranges from the low end of microsats or the high end of nanosats (such as 3-unit cubesats) with a mass of only a few kilogram up to the high end of microsats with a mass up to 500 kg. The diversity is still very great in proposed small satellite constellations. HawkEye 360 only has 3 of 18 smallsats deployed and it is providing new RF Geolocation services. Karousel is to have 12 ellipitical orbit satellites and it is designed for video programming services. At the other extreme is the SpaceX Starlink and V-band networks with a proposed network of over 12,500 smallsats. This exceedingly wide range of planned and proposed networks is shown in Table 2. This diversity is too great to make many generalized statements about smallsat constellations. Thus each proposed commercial smallsat constellation deploying microsat or minisat networks must be considered and assessed on its individual merits (See Table 2).

Various sources of inspiration and backing have led to the proliferation of various new smallsat constellations. In Canada, the Canadian government has backed programs to design and build small satellites. It created a $100 million Innovation Fund for rural communications and small satellites. It also created a streamlined regulatory process to encourage small system. This effort seemed to pay off and to spur innovation in this field (Pugliese 2019).

Indeed at this time there are 13 identified initiatives to create small satellite constellations that represent a total of over 300 new satellites with at least 3 new systems yet to be publicly announced (Boucher 2018) (See Table 3).

There have been additional promotional efforts to encourage smallsat experimentation and new commercial developments. In the United States, there have been numerous conferences, funder conferences, and NewSpace- and incubator-related activities in Silicon Valley, Utah State University, in cooperation with the AIAA, the New York Space Alliance, and more.

In China there has been strong governmental support for new small launcher industries and new small satellite ventures. This has led to a number of new Chinese ventures. These small satellite and launch vehicle startups include the following smallsat constellations Commsat, Hongyan, Lucky Start, and Xinwei. In New Zealand, the government has not only included strong support for the Rocket Lab's small satellite launcher program. New Zealand has now started a global recruitment drive to bring space entrepreneurs to New Zealand as immigrants. All of these efforts are aimed at creating new high-tech jobs and encouraging enterprises to support the

Table 2 Basic information on various planned small satellite constellations

State	Constellation	# of sats	Radio-frequency bands
Canada	CANPOL-2	72	LEO and highly elliptical Earth orbit in VHF-, UHF-, X-, and Ka-bands
Canada	Telesat constellation	117 satellites plus spares	LEO in Ka-band

growth of NewSpace economic enterprises for the twenty-first century. And the examples provided above with regard to the United States, China, and New Zealand are illustrative of efforts elsewhere. The large number of new efforts shown in Appendix C on small satellite constellations and in Appendix D with regard to new launch vehicle industries shows how these new enterprises are spreading worldwide.

What must be considered – amid all this new enthusiasm for space – is the possibility of oversupply of new small spacecraft offering a panoply of new networking bandwidth services, new remote sensing, automatic identification services

(AIS), and other space services around the world. The competition that comes from this disruptive technology and disruptive business models could drive global markets to be priced below incremental costs. In the world of communications and networking satellites, this is not only a matter of new smallsat constellations competing against each other, but there are other dimensions here as well. At the same time there are new high-throughput satellite systems that are disrupting GEO satellite markets. There are also fiber nets connected to 5G systems that are being deployed around the world. Short disruptive technologies in the telecommunications and networking world are transforming global markets and making competition virtually explode in both the developed and developing world.

The listings in Table 2 of new smallsat constellations are not exhaustive, and new systems keep being filed, and even those that are already filed are changing orbits and adding satellites or design features. Today these systems are dominated by US-, Canadian-, and European-based networks, but systems from other parts of the world may still be filed in coming months and years. The appendices found at the end of the handbook are as current as possible, but it is wise to go to indicated websites to get the latest and updated information. The Covid-19 related economic downturn, the rapid rate of technical innovation, and the uncertainty in financial markets and emerging bankruptcies, all suggest turbulent times ahead for new smallsat constellations.

6 The Future

The future of microsats and minisats is currently unclear. Today the world of satellite manufacturing and space launch systems is in a period of transition. The global trend that has existed for nearly 50 years has been toward bigger and more capable satellites with more power and larger aperture antennas for communications and larger remote sensing satellites.

This course has successfully been pursued by such global communications satellite providers such as Intelsat, SES, Telesat, Eurosat, EchoStar, and DirecTV to extend their markets and reduce cost. The same has been true for those providing space-based remote sensing for many decades such as Spot Image, WorldView, GeoEye, Digital Globe, QuickBird, and IKONOS. The world of space-based applications is clearly changing not only for telecommunications but also remote sensing and many new services such as for automatic identification services (AIS) and frequency monitoring. There are many innovations that continue to appear in the world of smallsat constellations. This is very much the case for commercial space services now being offered by 3-unit cubesats, microsats, and minisat constellations.

The graphic in Fig. 6 shows a new landscape in the world of remote sensing that is being driven by start-up constellations using a lot of smallsats, drones, or high-altitude platforms (HAPS), in lieu of a few large-scale satellites. This map of innovators in the remote sensing world shows just how pervasive the changes are becoming as 20 new startups are identified here (Ivanov 2017).

Fig. 6 The exploring number of disruptive new ventures in remote sensing. (Graphic courtesy of AgFunder)

This changing world has yet to come into focus. Some of the new start-up constellations will fail, but others will succeed. In some cases first-generation constellations will fail at first try, but will reinvent themselves with new owners, new management, or creative mergers. The first satellite constellations for mobile services such as Iridium, Globalstar, and Orbcomm went through such transitions to emerge with new strength and improved business plans. The future will remain in a shakedown period through the mid 2020s. The outcomes for the success, failure, or perhaps reinvention of the dozens of smallsat constellations now being launched or proposed will remain unclear until the later part of the 2020.

7 Conclusion

The world of smallsat constellations is clearly swirling with change. There have been major technical changes that have also served to reduce cost. We have seen the miniaturization of various electronic sensing devices, of digital processing and memory systems, and of thrusters, stabilization systems, as well as other components onboard spacecraft. We have also seen the development of ground stations with the ability to electronically form beams to track spacecraft as they move across the horizon. In some instances, these new smallsats can be fabricated using off-the-shelf components. These factors combine to reduce the volume, mass, and cost of satellites to a striking degree. And this is not all. The smaller and lighter smallsats also serve to reduce launch costs – a lot. Further the launch into low Earth orbit with many of the smaller spacecraft being launched at the same time, rather than painstakingly being launched into a precise geosynchronous orbital slot, also serves to reduce cost as well, although this is offset by the fact that many more spacecraft must be launched to create a fully populated global coverage system.

The name of this revolutionary series of changes known as “NewSpace” or “Space 2.0” reveals a lot. The amount of disruption to the various space industries is significant. At the same time newly engineered GEO satellites, called high-throughput satellites, have likewise been disruptive in that these satellites can be ten times more cost-efficient or even more so. This has also served to disrupt markets.

Satellites in low Earth orbit have the power advantages that come from much less path loss or beam spreading that is associated with sending a signal all the way to or from the GEO orbit. Newly deployed commercial satellites in constellations deployed in low Earth with masses that might range from 5 to 500 kg are quite different from their GEO forebears which might have a mass of 5000–8000 kgs. Each one of these smallsat systems may have a different size, shape, configuration, mission, and orbit and a different means of launching. Yet these systems are still recognizable as different from the large spacecraft that have been dominating the commercial satellite industry up until just a few years ago.

There is still not a single rule that applies. Large GEO satellites are still highly cost-effective and still dominant for the most lucrative of all satellite services which is direct broadcast television services that can also provide direct digital services such as software downloads and others to the edge services via DVB-RCS2, DOCSIS, and other such video broadcast standards. The innovations with miniaturization and satellite constellation design are certainly not yet complete. The further development of new interactive ground systems with electronic beam forming and employing meta-materials will be key to reducing costs and these additional innovations.

Perhaps the most interesting part of the unfolding saga with regard to the development of new smallsat constellation of microsats and minisats is not which of the new systems will succeed or fail. The most interesting question is what new applications and services will evolve. Already the new economics and thought process associated with the NewSpace revolution has seen new systems being planned and launched to provide such innovative and unexpected services. We have seen new networks designed to capture the automatic identification service (AIS) signals from ships and other vehicles (i.e., the Spire and HawkEye 360 systems). The HawkEye 360 system is also designed to provide global monitoring of frequency use that might be used to identify sources of frequency interference and assist with law enforcement in such areas as drug smuggling, illegal fishing, or even crimes against humanity.

Abstract

The key and ongoing challenge of small satellites has been to create new systems or capabilities that could accomplish key technical tasks or deliver services with reasonable reliability and proficiency, but within smaller parameters of mass, volume, and, in many cases, cost as well. In other cases there have been focused efforts to find alternative technologies, systems, or components that could approximate the function of larger systems or technologies, but which would allow a significant mass, volume, and/or cost reduction. However, communication, surveillance, and other missions will require relatively large constellations of small satellites, whereas one or a few larger satellites would suffice. Large constellations increase collision risk and are more likely to experience failures even though individual members might be very reliable.

For many years the design of experimental or applications satellites has started with designing a spacecraft with the objective of accomplishing a specific task, mission, or targeted objective. This led to the second step where system design engineers proceeded to design the spacecraft that had the capability in terms of lifetime, reliability, pointing ability, power system, antennas, onboard processing equipment and software, sensors, antennas, or payload equipment to carry out the mission and then arrange for a launch vehicle.

Engineers exercised an abundance of caution with large safety factors and space qualified components with exceptionally high reliability. This led to satellites regularly exceeding design lifetime by factors of two or three. Engineers learned that they need not have been so highly conservative. Missions with durations of only a few years could use off-the-shelf components and less demanding reliability. This experience facilitated smaller satellites.

Developers of small satellites have often approach the design activity as if it were a strategic planning process, taking a specified constraint of mass and volume and seeing how much operational or research capability could be fitted into these limitations and then redesigning the new system to enhance its service or experimental output. This type of thinking has in many ways has helped to create the so-called world of “NewSpace” or “Space 2.0” and being able to do more and more with less and less. This has produced remarkable improvements in productivity and has enhanced technical design.

There are many innovations that now making small satellite industries thrive. These include new manufacturing techniques such as additive manufacturing, new cost-effective launch systems, and new user devices on the ground such as flat panel antennas, whose costs are now reducing. This chapter, however, seeks to provide an overview the new technology and systems associated with the design of small satellites themselves.

This overview chapter thus seeks to give some insight into the progress that is being made into the better design and more effective use of small satellite structures, power systems, antenna, sensors, stabilization, and pointing systems as well as the other key components, systems, and subsystems critical to small

satellites' successful operation. These innovative designs are important to the success of all types of small satellites that range from CubeSats and smaller on one hand plus the microsats and minisats that are key to deployment of the new large-scale commercial constellations. Innovations that apply to one type of small satellite can and often do apply to other types as well.

Finally this section addresses not only technical advances that relate to small satellites as free flyers in space but two other innovations that may become increasingly important in the future. Thus innovations related to hosted payloads that can fly on other satellites – large or small – represent another type of "small satellite." These are also addressed as well as high-altitude platforms (HAPs) that can serve the same function as a small satellite for an island country or in a constellation can provide services akin to that of a satellite.

1 Introduction

The first satellites that were launched from Sputnik 1 to Score to Relay, Telstar, Syncom, and Early Bird were all small satellites. The demand for greater ranges of commercial services and more sophisticated experimental missions quickly changed to size, mass, and volume of satellites and so-called small satellites such as the AMSAT "OSCAR" satellites, designed and built by amateur volunteers, was seen as only a sideline. The primary use of commercial satellites for telecommunication, broadcasting, and networking services that were deployed in Clarke or geosynchronous orbit led to deployment of satellites that were many metric tons in size. This was because the large antenna size and high power systems were needed to compensate for the large "path loss" associated with transmitting signals the nearly 36,000 km between GEO satellites and Earth.

The switch from analog to digital processing based telecommunications satellites was perhaps the first key step in the evolution toward the recognition that small satellites might have a more important in the world of space applications in the future.

The faster and more capable digital processors became, the smaller these units became. Integrated circuits, monolithic devices, and application-specific integrated circuits (ASICs) all became key to the processing of signals for telecommunications, remote sensing, meteorological satellites, and Global Navigation Satellite Systems (GNSS). Also the sensors used for imaging or tracking stars also became digitized as well.

The next large step came when satellite service innovators decided to try developing low Earth orbit (LEO) satellites for mobile communications and also proposed LEO satellites broadband services. Satellite systems such as Iridium, Globalstar, Orbcomm, and Teledesic all proposed to use of the LEO orbit. The objective was to gain the advantage of low-latency transmission and significantly less path loss due to the spreading of the signal that originated at GEO orbit. In the case of mobile satellite service, the satellite would be moving relative to the transceiver on the ground, and so tracking of the satellite would be required in any event. The low Earth orbits, the digital processing of satellite signals, and the ability to use application-specific integrated circuits in the user devices combined to allowed the cost of user devices to be greatly reduced.

The mobile satellite systems (i.e., Iridium, Globalstar, and Orbcomm) proved that this type of technology could work in practice. Further these systems demonstrated that small, compact, and relatively inexpensive transceivers could communicate with LEO satellites that move swiftly overhead and across the horizon as quickly as in 7 min or so. The phased array antenna system that was deployed on the Iridium system also demonstrated that electronically steered signals could work effectively to provide a commercial mobile satellite signal. The second-generation Globalstar mobile satellite system joined in using phased array antennas that used electronic steering of signals rather than relying on dish antennas that required physical tracking via a moving satellite antenna system.

The Teledesic system, which sought to provide truly broadband communications, rather than just voice or data services (as in the case of Iridium and Globalstar) or low rate data (as in the case of Orbcomm), represented the greatest technical challenge. In the case of Teledesic, it set the objective of supporting gigabit/second speeds or video transmission services. Although this multi-billion dollar LEO satellite network was never deployed, it provided a clear theoretical basis for how this type of high-throughput satellite system might operate. In many ways Teledesic provides a firm theoretical basis for the type of new satellite services that current broadband mega-LEO constellations are now in the process of introducing during the 2020s.

In the 1980s and 1990s, the combination of technologies that is now undergirding the current small satellite revolution thus all started coming together. These included (i) constellations of satellites in LEO-based networks; (ii) highly efficient digital communications systems that could use digital encoding and forward error correction that now include Trellis, Turbo, and High Efficiency Video Coding (HEVC) and (H.264) encoding systems (How to configure… 2019); and (iii) phased array antennas and flat panel antennas that can be used as satellite antenna systems and simpler systems for user transceivers on the ground.

In close parallel ground-based cellular networks and Wi-Fi and WiMax wireless networks were expanding to provide broader and broader band services. The third-generation cellular system gave way to the fourth-generation cellular network that are today giving way to the 5th Generation networks that are now operating in the millimeter wave bands. Likewise the latest generation of high-throughput satellites (HTS) were also operating at faster and faster speeds and at higher frequency bands such as the so-called Ka bands (30 GHz and 20 GHz) and now the V bands (48 GHz and 38 GHz). Essentially wireless and satellite networks were both seeking to provide broadband data and video streaming services to consumers at speeds and competitive costs similar to that offered via fiber-optic cable systems. Fiber networks offered blazing speeds and low costs. Yet fifth-generation cellular and high-throughput satellite networks were playing rapid catch-up capabilities to offer mobility as well as broadband and ever lower costs as well.

The final act in this small satellite revolution was the “NewSpace” or “Space 2.0” innovations. Here, suddenly, was a spate of important new innovations. These innovations included (i) lower launch costs via reusable launchers and small launchers built out of new materials; (ii) new methods of efficient manufacturing, including additive manufacturing; (iii) miniaturization of electronic components, sensors, digital processors, and many other elements that can be used in small satellite networks; and (iv) innovative ways to use off-the-shelf components other approaches to developing and testing small satellites to be built and efficiently tested through the processes developed at the Surrey Space Centre, the Surrey Space Technology Ltd., and Utah State University Space Labs.

In the sections that follow, a brief overview discussion is provided first of the technical challenges to be met in terms of viable and safe operation, followed by the need for technical innovations related to performance. Many technical, operational, or systems aspects are concerned with the design and deployment of small satellites that are discussed in the remaining articles found in Part 3 of the Handbook (NASA 2019).

2 Technical Challenges to Be Met by Small Satellite Developers and Operators

There are a number of challenges that are key to successful and safe operation of small satellites. These represent capabilities that are not only key to small satellites but for the long-term sustainability of space and operation of all types of satellites as well. The first in importance is the key technical challenge of safe operation for the entire time of small satellite mission from launch to deorbit (Earle et al. 2019).

2.1 The Challenge of Safe Operation

Safe operation is the paramount requirement. This is achieved most effectively through precise observation, maneuverability, and communication. Each of these objectives can be quite technically challenged. Other aspects of small satellites still have significant knowledge gaps – especially when it comes to safe operation. Many of these safety challenges were codified by young space professionals studying under the auspices of the Space Generation Advisory Council and the International Space University (Esionwu 2014).

There are particular deficiencies in controllable and predictable end of life disposal as well as precise managing exceptionally large constellations of small satellites. Most small satellites reside in low Earth orbits. A number of these rely on atmospheric drag to dissipate orbit energy and thus cause reentry within a few years without any specific provision for deorbit on demand. This will not be sufficient if in the future, there are many thousand small satellites occupying LEO. Elements of each independent mega constellation must be replaced either on schedule or because of unexpected failure. Numerous inoperative satellites present in orbit for many years will represent a growing problem over time. Very small satellites, such as CubeSats and even smaller, often cannot accommodate reliable, on demand, reentry systems (Puig-Suari et al. 2008).

Thus there are proposals to limit small satellites launches that lack the ability to deorbit on demand to quite low orbits such as below 300 km, or to be launched not as free flyers but within a joint platform that has a deorbit capability, or to have passive systems to speed deorbit processes (Pelton 2015).

As constellations of satellites that are much more massive than a few kilograms and deployed in larger numbers, the concern certainly grows. Exquisite collaboration and coordination will be required to accommodate such increased traffic in LEO. Those that are planning to deploy so-called Mega-LEO constellations of small satellites understand the demands of managing thousands of small satellites with compacted coordination. Some proponents of small satellite constellations are considering higher altitudes, and indeed 03b has plans for a significant new mPOWER MEO network.

Some analysts believe this might also have difficulties. Even though fewer satellites are necessary, they must have more electrical energy and power systems and must also have larger antennas, and, in general, be larger. The trade-off between more and smaller satellites against fewer, larger, and longer-lived satellites at higher altitude with a larger cross section that might become a target for collision has not been well addressed.

2.2 Communications and Controllability Challenges

Small satellites must be able at least to downlink data. These communication links enable ranging at least and perhaps angular resolution sufficient for reasonable orbit determination. However, observations of this nature for the smallest of the small satellites are gathered over extremely short arcs and are often conducted with small antennas with poor angular resolution. Gathering and processing sufficient information to determine orbits may require several passes, and there are gaps between observations that are long enough for orbits to change materially due to environmental variability during the intervals when the satellite cannot be observed.

When many small satellites are deployed in succession, it is very difficult to discriminate among them. Some unique electromagnetic emission or reflection is required. If there is full two-way linkage, a satellite can be queried explicitly. Otherwise, observable maneuvers must be commanded, and which satellite executes that maneuver is identified. This is a common occurrence with radio-controlled model aircraft and commercial light aircraft lost over expansive wilderness.

Several small satellites have never been found by any of these schemes, particularly those suffering some debilitation on deployment.

This raises other issues. If the satellite trajectory cannot be controlled or even known very well, then how well can observations of other bodies in space or on the Earth accurately be registered in any reference frame?

2.2.1 Maneuverability

All satellites should be able to maneuver for station-keeping and to diminish the probability of collision. The minisats and microsats that are being deployed in large constellations all have significant maneuverability, but CubeSats and below may not have this capability. If time is not a serious constraint and urgency is not involved in avoiding an orbital conjunction, a few low thrust actions may be adequate. Again with sufficient time warning the command to fire a thruster need not be applied very early. Figure 1 demonstrates this for a past real conjunction with impulsive chemical thrusters.

Maneuver timing is typically not the critical path in collision avoidance. Maneuver planning almost always take much longer. Consequently, observations, orbit update, and communicating commands to a satellite are the critical elements. This is much easier for GEO than for LEO. This favors the French Space Agency (CNES) "middle man" process or the European Space Agency (ESA) ESOC process that both confirm US Joint Space Operation Center (JSPOC) warnings and execute avoidance based on trustworthy, well-understood analysis and data. This is hardly possible for the preponderance of small satellites which do not have the same type of analytical process capability.

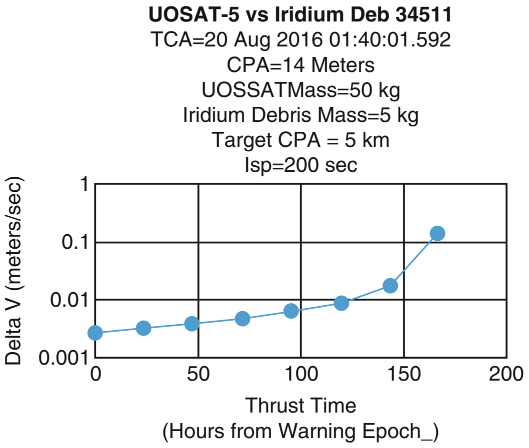

Fig. 1 Thrust levels required depending on advance warning of potential conjunction between smallsat and Delta launch vehicle. (Graphic courtesy of US Air Force)

There are several excellent surveys of small satellite propulsion alternatives. There are chemical, electrochemical, and electric thrusters for small satellites, but few for vehicles as small as CubeSats. Propulsion must not jeopardize large, primary payloads. Both chemical and electric systems add some risk to the launch. Therefore, pressurized cold gas and even water are being considered and indeed have in some cases actually tested. Passive resistance type systems for small satellites to aid deorbit capabilities, such solar sails and aerodynamic devices, have been discussed, but passive systems are not responsive or reliable enough for this type of collision avoidance application.

Avoidance maneuvers cannot be developed more than a few tens of hours in advance because satellite trajectories cannot be estimated with actionable precision more than a few tens of hours in advance, particularly in drag-dominated low Earth orbits.

All of these possibilities are practical for long-term, modest orbit or attitude adjustment, but they seem unsuitable or unreliable for relatively short notice collision avoidance.

Small satellites in conjunction with other small satellites, depending on their size and thruster capability, almost always, have no avoidance alternatives (Tummala and Dutta 2017).

Since desirable missions all favor the same orbit regimes, collisions among small satellites should not be discounted. Conjunction management between small satellites and larger satellites that can maneuver enough to avoid catastrophe becomes the sole responsibility of the larger satellite, which requires more energy to adjust its orbit than the small satellite would.

Having optimized orbit architecture, one must assure that the probability of encountering other satellites during the mission is acceptable. The hypothetical small satellite experiences close approach within 20 km of a Thor Agena D rocket body. The relative geometry between a launcher and a possible small satellite conjunction is very consequential. This is particularly so when the launcher is nearly perpendicular to the satellite's velocity vector. Depending on the duration of the mission, it is important to observe the object closely for most of the mission as well as check regularly for other close approaches. Several satellites approached within 50 km at the time the analysis was conducted.

2.2.2 Observability

If an object in orbit cannot maneuver, knowing where it is becomes critical. The object must be discernible either passively either by its own emissions or reflections of background radiation. Or it might be illuminated actively. The degree to which the object's state of motion can be determined or its future state estimated depends on the distribution of observation opportunities and the density of observations acquired during each observation interval (Finkleman 2013).

Observability should be among principal considerations for the design of a spacecraft of vehicle and also can influence the choice of orbit architecture. As an example, consider a single small satellite for which there are sufficient optical observables. Assume that mission requirements allow any reasonable altitude or inclination. The task is to find an orbit during which there is the greatest cumulative time of observation given a small set of ground-based sensors.

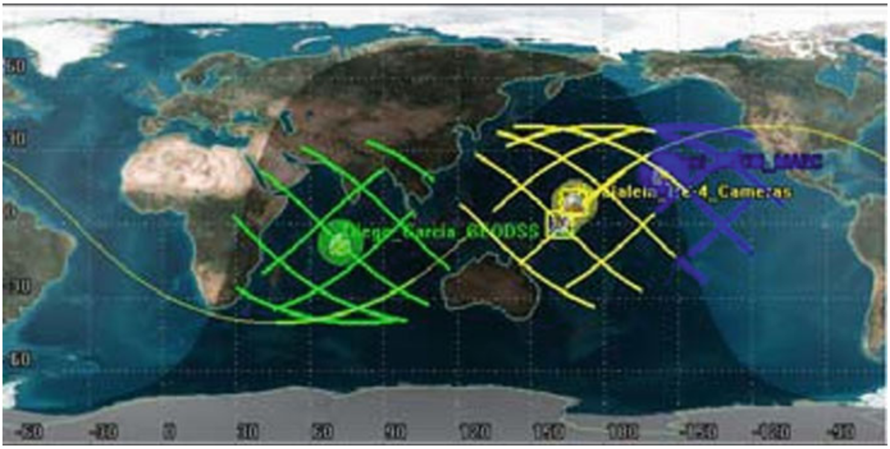

Fig. 2 Small satellite orbit designed for greatest time of observation from designated observation locations. (Courtesy of the US Air Force)

This is shown in Fig. 2 below that depicts a typical situation with tracking instruments around the world that in this case involves tracking facilities in Hawaii (indicated by tracking data in blue), Kwajalein (indicated by tracking data in yellow), and Diego Garcia (indicated by tracking data in green). These three stations are utilized to undertake the assigned tracking.

Safe operation thus often requires some compromise in mission capability. For a single satellite to "see" most of the Earth over time (and thus to be seen), the inclination and apogee should be as high as possible. For example, if one wishes to monitor synoptic energy balance, there would be only rare and brief opportunities for the designated sensors to gather data for orbit estimation. "In this case, the optimal parameters for longest cumulative observation over the course of a day were: inclination 32°, eccentricity 0.1, apogee altitude 8490 km. The observation passes over the course of the day for the satellite chosen for analyses are shown in bold lines in Fig. 2."

> There is also an opportunity to observe small satellites almost ubiquitously with radio telescopes. Almost all satellites have significant radio frequency signatures from instrumentation and internal electronics, not to mention communication devices. Very precise orbit observations are feasible, and the observations can also reveal anomalies in electrical devices onboard. (Finkleman 2016)

3 Small Satellites and Attitude Determination and Control Systems (ADCS)

Constant improvement is being made in the attitude determination and control systems (ADCS) for small satellites. Many of the first of the cube satellites launched well over 20 years ago were fairly crude devices that often were designed by students for short-term experiments and had little or no capabilities for attitude determination and control systems (ADCS). In more recent years, increasingly sophisticated systems and sensors have been developed both to detect the orientation of small satellites and capabilities to maintain stability and even three-axis stabilization. A systematic study of over 350 nanosatellites in the 1–10 kg range in a survey for the period 2003 through 2016 has produced the following findings.

> The ADCS information of 357 nanosatellites were available for statistical analysis. Of the 357 nanosatellites only 5% had no ADCS, 17% used passive magnetic control, 2% used gravity gradient stabilization, 6% used other passive methods of stabilization (e.g., aerodynamic), 2% were spin stabilized, 11% used active magnetic control, 3% were momentum wheel stabilized, and 54% were reaction wheel 3-axis stabilized. (Xia et al. 2017)

It is not clear if this survey can be taken as truly representative of small satellites. But it can be reasonably assumed that significant progress has been made in this area since the earliest days of small sat experimentation. One can thus reasonably assume that at for at least most microsats and minisats that are being launched in today's large constellations a high percentage of these satellites have reaction wheel three-axis stabilized capabilities and also have thruster jets that can allow these larger small satellites to be deorbited from low Earth orbit (LEO) at end of life.

There is still concern for all small satellites not so equipped. There is especial concern for femto-satellites (e.g., chipsats), pico-satellites (e.g., PocketQubes), nanosats (e.g., CubeSats), and even microsats and minisats that are not equipped with attitude determination and control systems (ADCS) nor thruster jets for deorbit capability. Indeed these systems also generally lack passive systems to that can be deployed to assist with deorbit. This suggests that all such truly small satellites without such capabilities should only be launched at lower altitudes, such as 300 km or below, to insure that they will naturally deorbit due to gravitational effects, especially during solar max period when the Earth's atmosphere expands and creates additional drag conditions.

4 Power, Energy Storage, and Power Conditioning Systems for Small Satellites

The power systems for small satellites much like larger satellite depend on a combination of solar arrays that collect energy from the sun and batteries for periods when satellites are obscured from the sun. The further constraint of small satellites is, of course, the limited volume and mass associated with these type spacecraft. Craft as small as picosats (i.e., PocketQubes) still can display solar cells, but in limited number. For CubeSats batteries similar to those used in cellphones, i.e., lithium batteries, can be recharged and support missions that last months and even years (see Fig. 3). Small satellites with short lifetimes might subsist on energy stored in batteries at launch. Solar cells are the only way to replenish energy on orbit.

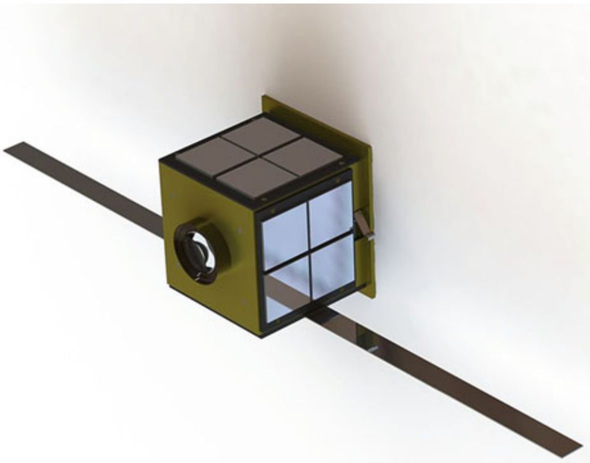

Fig. 3 This PocketQube design only had room for four solar cells since the antenna extension mechanism was deemed more important. (Graphic courtesy open access commons)

Energy often is not extractable with characteristics that onboard electronics require. Relative to large satellites, small satellites lack the design parameter space among orbit, operational access, solar illumination, thermal management, electronics, and other essentials.

The issue of power system design with small satellites often hinges on the cost of the photovoltaic cells that are used. The amorphous silicon PV cells are the lowest in cost. Other more sophisticated cells such as gallium arsenide cells, or violet solar cells with multiple gates, or in future years perhaps quantum dot units can produce more power and can be coated with glass to have longer life. These are trade-off decisions that must be against program cost constraints, desired lifetime, and mass and volume limits. Fortunately small satellite programs can benefit from research that is being undertaken for terrestrial applications or much larger and expensive satellite programs.

5 Small Satellites and Antenna Performance

There is now considerable experience with the Iridium, Iridium Next, and Globalstar OG2 satellites and other smallsat programs that is helpful in the design of high performance phased array antennas. Smallsats, particularly those in the 50–500 kg range are capable of creating a large number of spot beams to achieve a high degree of frequency reuse and to concentrate power quite effectively. The three keys to satellite efficiency and capacity are available spectrum, power concentration, and complexity as achieved through efficient multiplexing, digital encoding, and forward error correction. The latest satellite technology is able to deliver on all three of these dimensions.

Progress in phased array antenna design with electronic beam forming using electrical or optical processing and unique capabilities such as meta-materials or new technology will be key to progress in the small satellite constellations that are now planned for deployment in coming years.

Larger apertures are more effective than smaller ones. Diffraction and the basic laws of physics rule. Small satellites can embody antennas much larger than the satellites themselves. Using shape memory composites, large antennas with complex figures can be rolled and stored in narrow tubes for deployment on orbit. Research organizations have engaged origami artists to develop large objects that can be stored in small spaces.

Phased array antennas are possible for small satellites. However, they suffer sidelobes that monolithic antennas do not experience. They are not as energy efficient, and they are electronically complex. Although the state of the art enables relatively useful small phased arrays, innovative dish antennas can still provide the best technical and cost performance. It is, of course, possible to combine dish reflectors with phased array feed systems. Producing and feeding the electromagnetic energy to be transmitted are also technologically demanding.

Electronically shaped beams and phased array antennas and feed systems have merit when energy must be transmitted or exchanged among many space, airborne, and terrestrial platforms. Higher frequencies experience less diffraction, but they cannot be produced as efficiently as lower frequencies. The highest practical frequencies are optical, light. Optical links between satellites have a long and painful development. Alignment between widely separated, rapidly moving satellites is a challenge. Optical links to the surface of the Earth experience scattering, absorption, and other deleterious phenomena in the atmosphere.

5.1 Small Satellite Radio System Design and Possibility of Optical Links and Processing

The design of radio devices to support various missions related to telecommunications, networking, data relay, tracking, telemetry, command, and other key functions continue to evolve and improve over time. In the earliest days of small sat development, the radio systems were simple and often were operating in the VHF and UHF spectra, but today increasingly sophisticated radio technology is being developed to support broadband throughput needs and radio devices that are operating in the super high frequencies and extremely high frequencies and much more sophisticated and also much higher in cost. There have also been suggestions that optical communications could be used in the case of some small satellite applications such as for intersatellite links. Optical technology such as in the form of optical processing could also be used to replace digital electronic processing as this technology matures.

5.2 Small Satellite Structures

The key to CubeSats is the standardization that allows important components and subsystems to be interoperable and widely available. This standardization of CubeSats into elemental units that can be joined is important. This enables interoperable deployment and launch vehicle fixtures that now range from 1 to 6 units, up to 12 unit, and even up to 27 unit systems (i.e., 30 cm cubes) and also assists with lowering the costs of testing as well as the possibility of accelerating the testing process. This process of standardization of platforms and platform sizes has now even transferred to conventional satellites that are now typically constructed to go on a limited number of platforms. These platforms are often geared to particular sized launch vehicles. There are today suppliers of standardized structures that are not only available online for 1 unit, 2 unit, 3 unit, and 6 unit cube satellites but also are available for PocketQube kits and structures that are exactly one eighth the size of a CubeSat.

This standardization of cost-effective and reliable smallsat structures thus aids at every stage of design, component and subsystem acquisition, construction, testing, and launch service arrangements. The key is not so much in the structures and the materials used in the structures, but the standardization and ease and lower cost of acquisition.

5.3 Deorbit Concepts for Small Satellites

Concerns about the deorbit of small satellites have grown as the number of launches of various sizes of smallsats have risen almost year by year. The prospect for the future of more and more smallsat launches has led to increased concerns about orbital debris and improved ways to remove these satellites at end of life. Along with these concerns has come an increased focus on better space situational awareness, the need for space traffic control, and new ways to address the longer-term sustainability of outer space activities. The 21 new guidelines adopted by the UN General Assembly and the UN Committee on the Peaceful Uses of Outer Space (COPUOS) represent some progress, but there are many other ideas that have been suggested. These ideas include restriction of small satellites without active deorbit capabilities to a particular altitude so that natural deorbit occurs in a reasonably short period of time, consolidation of small satellites into joint missions that would contain an active deorbit capability, requirements for passive systems to aid deorbit, etc. (Guidelines for the Long-Term. . . 2019).

There is quite a bit of technology under development to aid with deorbit of defunct satellites. These developments include lower cost and miniaturized attitude determination and control systems as well as stabilization, pointing, and orientation systems (i.e., devices such as magnetic toque rods and miniature reaction wheels) and low cost and miniaturized thrusters, as well as passive systems to create atmospheric drag. These systems are key to being able to remove small satellites from orbit in a timely way. Yet one of these can cause controlled reentry to a specific location or reveal what might survive reentry. It will take a combination of technology and regulatory reform to address the orbital debris problem effectively.

5.4 Small Satellites and Spectrum Allocations and Registration

There are no allocations of satellite frequencies related to telecommunications, remote sensing, or any other applications that are specifically restricted to small satellite activities. The allocations are based on the application and the three ITU regional districts. There are certainly some applications such as amateur radio frequencies or data relay and messaging where smallsats are used. The issue is the rather that small satellite are sometimes not properly registered with the United Nations or their frequency usage not coordinated through the International Telecommunication Union in the designated way. Efforts are being made to see that these procedures are systematically followed.

The future of commercial space applications seems to be headed toward the deployment of more and more smallsat constellations to provide very large networks in LEO and yet others in MEO. Further these networks appeared poised, based on filings, to move to higher and higher frequencies such as Ka band and V band. It is important that these networks be thoroughly coordinated to avoid interference with protected GEO-based networks as well as to avoid interference with other LEO and MEO systems, high-altitude platform systems, and ground-based systems. As more and more of the networks are deployed, especially those in the so-called Mega-LEO systems with thousands of satellites in these constellations, this challenge appears likely to become more difficult. In this regard new technology to minimize interference and new regulatory processes may both become necessary.

5.5 Small Satellites and Advanced Processing and Networking

There are essentially three ways to make satellite services, particularly telecommunications and networking services, more efficient. These involve more power and more highly focused power into smaller catchment areas, more spectrum, and greater bandwidth, through the use of either higher frequencies or methods to reuse frequencies or more efficient ways to process radio signals with great complexity, improved multiplexing, or encoding to send more bits per Hertz. Small satellites are seeking ways to achieve improved capabilities in all three of these areas. This means use of LEO or MEO constellations so as to concentrate power more efficiency and to avoid the extreme path loss and latency that comes from operating in the GEO orbit. This means finding more ways to reuse spectrum by means of spot beam and thus to allow geographic separation of beams, the use of higher frequencies so as to increase available bandwidth, and use of more efficient phase shift keying and other advanced multiplexing systems coupled with advanced coding and forward error correction.

Digital communications, digital processing, and ever more sophisticated software defined modulation, multiplexing, and processing systems to move satellite communications closer to the absolute efficiencies of the Shannon's Law limits have allowed satellites to gain greater and greater efficiencies. Essentially coder/decoder (Codec) systems in satellites have allowed satellite efficiencies to increase from a level of one bit per Hz to six or even seven bits per Hz simply through advanced software processing of signals. Small satellites, just like large satellites, are digital processors in the sky whose functionality is defined by its software. The key to more efficient small satellites will be through the development of ever better processing systems.

Such enhancements involve both the satellites and terrestrial systems. But terrestrial systems and networks are driven by other established and significant uses. It is unlikely that established terrestrial networks will agree to widespread and expensive changes just to accommodate small satellites. If the small satellites must seek compatibility with existing terrestrial networks, they might no longer be small and inexpensive. These are just some of the dilemmas that small satellite operators will face in years to come.

5.6 Small Satellites and Flight Software, Software-Driven Designs, and Network Control

The future of small satellites is being driven by a significant number of technologies. It is perhaps true that it is new software and artificial intelligence that may end up as one of the very most important drivers of change and innovation. Flight software, network control for satellite constellations, and even use of software to drive the future design of actual satellites are increasingly a part of the mix that is shaping the smallsat revolution. There are at least two key articles in the technology section of the Handbook on Small Satellites that cover the various ways that software and software innovation are shaping the future. These articles discuss the way that small satellites are designed as well as how modest upgrades in performance or reliability are made to small satellite designs as multiple generations of commercial small satellites are created with an ever increasing rapidity that may even come several times within a single year. There is a future for artificial intelligence and software innovation in almost every aspect of the world of small satellites. These can include flight software and network control of a small satellite constellation and in spacecraft design and innovation – from one generation to another in the fast moving spacecraft engineering and performance.

5.7 Optimizing Payloads for Remote Sensing and Monitoring

Most of the articles in Part 3 of the Handbook of Small Satellites address the technical challenges of small satellite and its component elements in terms of design, manufacturing, reliability, cost efficiency, and network operation. There are several articles that address the design and performance of the communications and networking payload and one that addresses the payload characteristics of small satellites for remote sensing. It was the miniaturization of sensors and particularly sensor processing for remote sensing that led the way forward in the small satellite revolution. The first wave was in miniaturized optical sensors. Over time infrared, near-infrared, hyper-spectral sensors, and synthetic aperture radar sensing systems have all been redesigned and shrunk down so as to be used in small satellites that range from 3U CubeSats to minisats. In light of the power requirements associated with radar sensing, that use active rather than passive sensing processes, synthetic aperture radar smallsats are typically larger than

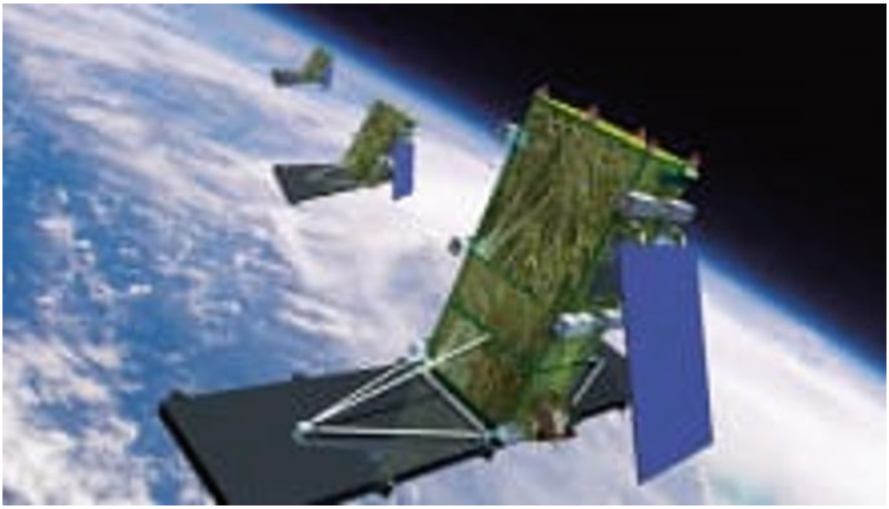

Fig. 4 The new deployed three Canadian RADARSAT constellation that represents the higher end of smallsat design. (Graphic Courtesy of the Canadian Space Agency)

optical remote sensing satellite systems. The Canadian newly launched Canadian RADARSAT Constellation Mission (CRM) deployed in June 12, 2019, represents the largest type of smallsats now used for synthetic aperture radar imaging (Foust 2019) (see Fig. 4).

5.8 Hosted Payloads as a Form of Small Satellite

There are many ideas behind the small satellite revolution. These have included finding ways to use better and more compact designs, creating high efficiency miniaturized components, discovering ways to use off-the-shelf components, developing accelerated and lower cost testing procedures, locating lower cost launch services, as well as developing economies of scale by deploying more small satellites in a constellation. As a part of this process of developing smaller and high efficiency satellites of small scale, it became clear that if one could place a functional payload on a larger satellite where it shared a launch, power, tracking, telemetry and command capabilities, etc. new efficiencies could be gained.

A guest, however, must not inconvenience the host The guest must meet its requirements while joined with the host wherever the host mission requires it to be. These compromises may be possible for some missions, but not for all.

Such a hosted payload might go on a large satellite for the purposes of technology demonstration, but if the host payload were small enough, it might even go on a microsat or a minisat. This, for instance, has been the case with the Aireon ADS-B hosted payload that has been launched onboard of all of the Iridium-NEXT satellites with its 66 satellite constellation (see Fig. 5).

Fig. 5 Aireon hosted payload on Iridium-NEXT satellite. (Graphic courtesy of Iridium)

Thus this handbook has examined this approach to a satellite and provided examples of this approach to small satellite deployment and operation for experiments, technology verification, and even implementation of commercial services.

5.9 High-Altitude Platforms (HAPs) as an Alternative to Small Satellites

Finally the concept of high-altitude platform systems and stratospheric systems is also included in this *Handbook of Small Satellites*. This is because platforms positioned in the stratosphere can be used to create the coverage to provide comprehensive overview or electronic services to an entire island nation or a country with a modest territory. Such high-altitude platforms (HAPs) can provide a range of important governmental services or commercial services. These can, for instance, include high-resolution and hyper-spectral remote sensing, law enforcement, forestry management, agricultural monitoring, fire detection, and particularly communications and broadcasting services (see Fig. 6).

Frequency spectrum has been allocated for UAV- and HAP-type services, and this type of service might be offered by a variety of different technologies that include zeppelins, dirigibles, automated aircraft, and solar-powered platforms. Even the concept of a type of platform that is provided power to operate electric engines and which would be beamed up from the ground have been considered, but not implemented. These transmissions could possibly be microwave, millimeter wave, or even laser-emitted power. Today some companies such as Thales Alenia are offering such systems to deploy high-altitude services by such stratospheric platforms. There have been projects to deploy such systems in countries as large as Japan that would have included the need

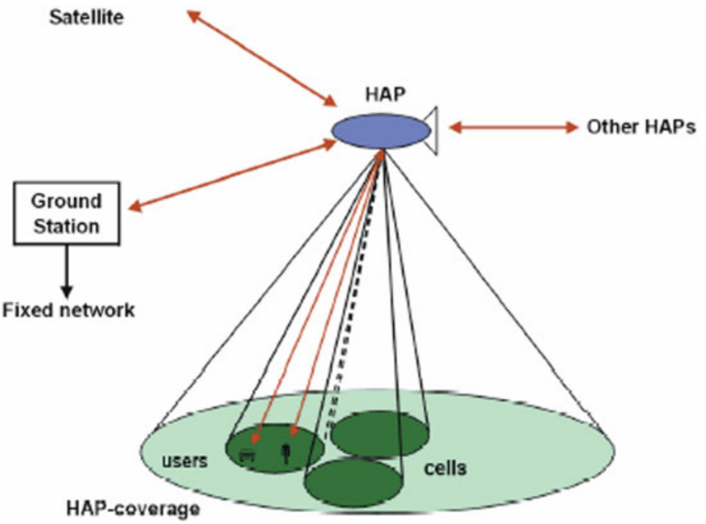

Fig. 6 High-altitude platform (HAP) diagram for telecommunication services. (Graphic from the Global commons)

to deploy as many as 15 such platforms, but his particular program has been discontinued for a number of practical and technical reasons.

6 Conclusion

Small satellites are revolutionary opportunities for organizations and nations. Often the companies building or operating small satellites will have limited financing and other resources. These capabilities should be encouraged and exploited. This article begins with citing the challenges and the risks of unfettered exploitation of this technology. It notes the bounds on the ability of smallsats from minisats and microsats down to nanosats and picosats. It notes the difficulty of small satellites meeting the constraints imposed on larger satellites.

None of these constraints are normative, and very few are broadly legally enforceable. Space mission and commerce stakeholders should consider this small satellite dilemma and arrive at acceptable compromises before compromise ceases to matter if space debris issues mushroom out of control through the lack of regulatory action or at least broad-based agreement on best practices.

Improved technology is essential. The technology that drives innovation in the fields of information, communications, computers, and energy is becoming more powerful each year. The world of small satellites seems to be among the very most dynamic. This is because it is driven by a true sense of innovative thought that is sometimes called “NewSpace” or “Space 2.0.” Many of these innovations grew out of the computer industry and a sense of breakthrough innovation rather than seeking merely a small 5% or 10% gain.

Regardless of the original stimulus, the effort to improve what is possible with small satellites and how they are deployed and used now pervades the industry. Thus there is an effort to increase performance everywhere and in every domain. Thus there is research and innovation related to:

(i) Attitude Determination and Control Systems (ADCS)
(ii) Power systems
(iii) Antenna systems
(iv) Radio and optical communications systems
(v) Use of artificial intelligence and improved software to improve smallsat performance
(vi) Enhancement of their structural design
(vii) Finding better ways to deorbit satellites at end of life
(viii) Improvement of the performance and cost for user terminals on the ground and on the move
(ix) Use of artificial intelligence to design better spacecraft and control constellation networks
(x) Use of advanced processing systems and AI to create better payloads for telecommunications and networking and/or improve sensors for remote sensing
(xi) Creation of even smaller hosted payloads to ride piggyback into space
(xii) Exploration of yet other alternatives to small satellites in the form of high-altitude platforms that can deploy new payloads for communications, broadcasting, law enforcement, agricultural and forestry management, navigation, or other services in perhaps even more cost-effective ways for island countries and other smaller territories

The technology section that follows has sought to be as comprehensive as possible. The articles that follow are filled with innovation and new ideas. It is hoped that this resource will prove useful. Ultimately the goal should not be to make satellites smaller and smaller as an end in itself. The key is to find suitable missions that are suitable for and compatible with small satellite systems and then optimize small satellites that are compatible with those missions. It is accomplishing goals and missions that are the ultimate aim.

Abstract

This chapter gives an overview of the attitude determination and control system (ADCS) of spacecraft, focusing on small satellites. The ADCS is an important subsystem to insure satellite orientation stability and accuracy of pointing various payloads at specific targets. The introductory section will give an overview of the active ADCS feedback loop and lists some requirements and typical control methods utilized. The next section presents some background theory in attitude dynamics, kinematics, and the significant external disturbance torques in low earth orbit (LEO). Then some techniques used for angular rate and attitude determination are presented, followed by the control laws for magnetic detumbling and reaction wheel attitude control. A complete section is dedicated to a practical example of the calculations to determine the pointing accuracy and stability of a high-resolution (Hi-Res) imaging payload on a minisatellite. Finally the chapter concludes with examples and specifications of typical ADCS sensor and actuator hardware that are commercially available.

Keywords

Attitude determination · Attitude control · Passive and active stabilization · Disturbance torques · Coordinate frames · State estimation · Detumbling · Feedback control · Pointing accuracy · Platform stability · Star trackers · Reaction wheels

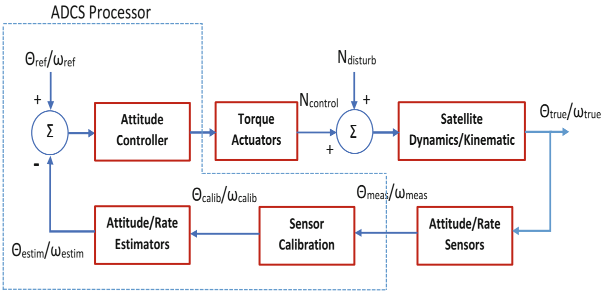
1 Introduction

The use of active attitude control and determination on small satellites is growing, but still less than 60% of all orbiting nanosatellites are 3-axis stabilized. According to an ADCS survey in 2017 by the Chinese Academy of Sciences (Xia et al. 2017) of nanosatellites (mass between 1 and 10 kg), 483 were launched successfully since 2003 until 2016. The ADCS information of 357 nanosatellites were available for statistical analysis. Of the 357 nanosatellites, only 5% had no ADCS, 17% used passive magnetic control, 2% used gravity gradient stabilization, 6% used other passive methods of stabilization (e.g., aerodynamic), 2% were spin stabilized, 11% used active magnetic control, 3% were momentum wheel stabilized, and 54% were reaction wheel 3-axis stabilized. In a 2014 review (Janse van Vuuren 2015) of 42 small satellites (excluding CubeSats) from 6.5 to 94 kg launch mass over the past 25 years, 5% had no control, 19% only passive control, and 76% some form of active control. The list of ADCS sensors was magnetometers (90%), sun sensors (80%), Earth sensors (10%), GPS (33%), rate sensors (40%), and star trackers (35%). The list of ADCS actuators was permanent magnets (20%), magnetic torquers (80%), momentum wheels (8%), reaction wheels (40%), propulsion systems (18%), gravity-gradient booms (15%), and control moment gyros (3%).

2 Attitude Determination and Control Subsystem (ADCS) Overview

The attitude determination and control system (ADCS) detumbles, stabilizes, points, and rotates a satellite into a desired orientation (attitude) despite any external or internal disturbances torques acting on it. A satellite's payload requires a specific pointing direction whether the payload is a camera, a science instrument, or an antenna. Satellites also require a specific orientation for thermal control or power control, i.e., to acquire the sun for their solar panels. The ADCS system uses sensors in order to determine a satellite's attitude or angular rates and actuators to maneuver the vehicle to a required orientation. The ADCS needs to achieve the various mission and payload objectives such as pointing accuracy, stability, rotation rate (slew), and sensing with many physical constraints such as mass, power, volume, computer power/storage, the space environment, robustness/lifetime, and cost. The ADCS is a synthesis of two subsystems the attitude determination system (ADS) and the attitude control system (ACS) which controls the attitude/angular rate of a satellite as depicted below in Fig. 1.

An example of ADCS sensor and actuator hardware for a small 3-axis stabilized satellite is shown in Fig. 2. In this example all the ADCS sensors, actuators, and processors communicate via a distributed dual ADCS CAN (Controller Area



$\Theta_{ref}/\omega_{ref}$: Reference attitude/rate
$\Theta_{true}/\omega_{true}$: True attitude/rate
$\Theta_{meas}/\omega_{meas}$: Measured attitude/rate
$\Theta_{estim}/\omega_{estim}$: Estimated attitude/rate
$N_{control}$: Actuator Torque
$N_{disturb}$: Disturbance Torque

Fig. 1 ADCS block diagram

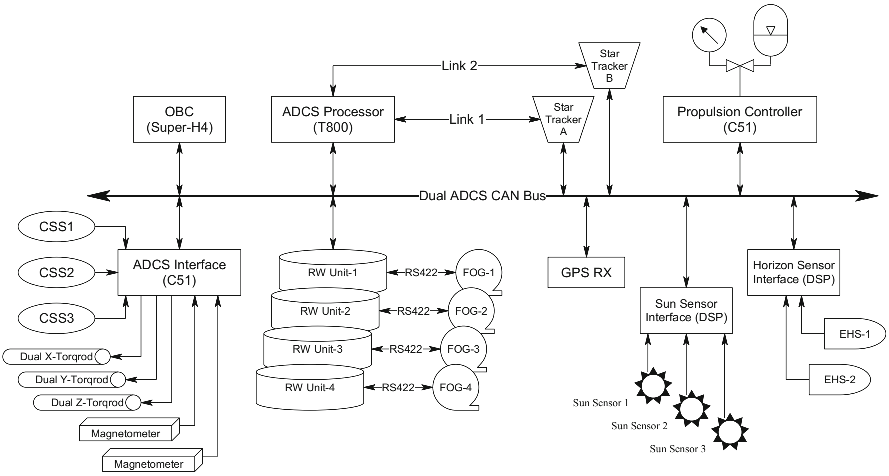


Fig. 2 Example ADCS hardware for a small satellite

Network) bus. The ADCS processor is dedicated to the attitude control system, although the OBC (onboard computer) can serve as a backup ADCS processor. The text in brackets indicates the type of processor used. The ADCS interface samples the coarse sun sensors (CSS1,2,3) and magnetometers and commands the magnetic torquer rods. The reaction wheel units (RW unit-1,2,3,4) are mounted in a tetrahedral configuration for redundancy and interface the fiber-optic gyros (FOG-1,2,3,4) for accurate angular rate measurements. A global position receiver (GPS RX) is used to accurately measure the satellite's orbit position, velocity, and time. A propulsion controller is implemented to control a cold gas propulsion system to do small orbit corrections and maintenance. The accurate absolute attitude sensors are the star trackers (A, B), sun sensors (1,2,3), and earth horizon sensors (EHS-1,2).

3 ADCS Requirements and Control Methods

In this section only active attitude control methods will be considered as most small satellites currently no longer use exclusively passive methods, e.g., permanent magnets to track the local magnetic field direction, gravity gradient torque to align the satellite's long axis with the nadir/zenith direction, and drag-induced aerodynamic torques to align the center-of-pressure (CoP) to center-of-mass (CoM) vector toward the orbit velocity vector. Although these passive methods can damp oscillations of the relevant body axis direction with libration/nutation dampers (typically viscous fluid tubes or rings), the rotations around this stabilized body axis cannot be controlled. For this reason these passive methods will mostly be combined with an active attitude or angular rate controller.

The need for active attitude control is determined by the small satellite mission and its attitude requirements. As mentioned in the introduction, most small satellite missions have specific attitude pointing and stabilization requirements, and thus an ADCS with some capability is needed. Active attitude control also comes in different flavors. Simple tumbling control modes can be implemented with the minimum of hardware and power requirements. Stabilized attitude (roll, pitch, and yaw angles controlled to a constant attitude) can be achieved using a momentum wheel, while full 3-axis control has the ability to perform commanded slew maneuvers which places the most demanding requirements on volume, mass, and power resources. A list of requirements that are usually considered for satellite ADCS are summarized in Table 1 below.

The methods for active attitude stabilization and control are briefly discussed in the following paragraphs:

3.1 Gravity Gradient Assist

It exploits Newton's law of general gravitation and through the use of gravitational forces can always keep a specific spacecraft axis nadir pointing. This is achieved by using a boom extending a small distinct mass (usually a magnetometer in order to minimize magnetic interference) from the spacecraft (which becomes the second distinct mass) by some distance. These two masses which are connected by a thin and light boom can then be used to exploit the difference in gravitational pull on the main satellite platform and on the additional mass (magnetometer) due to the difference in their distance from Earth. This small difference can be sufficient to enable the satellite/additional mass system to be aligned with the radius vector at all times as an orbiting pendulum. The gravity gradient stabilization scheme can be beneficial for coarse pointing (~5 deg) around the nadir axis, while the other two axes still will need

Table 1 General ADCS requirements

Requirement	Definition
Determination/sensing	
Attitude knowledge accuracy	Accuracy of a satellite's orientation estimation with respect to the truth
Attitude range	Range of angular motion over which the accuracy must be met
Control	
Pointing accuracy	Accuracy of a satellite's attitude control with respect to a commanded direction
Pointing range	Range of angular motion over which control performance must be met
Operating conditions	Parts of the orbit where attitude control is needed, such as eclipse/daylight
Stability/jitter	A specified angle bound or angular rate limit on short-term, high-frequency attitude motion
Slew rate/agility	Minimum slew or angular rate required to perform a rapid maneuver
Attitude drift	A limit on slow, low frequency vehicle motion
Settling time	Maximum time allowed to settle at the commanded attitude or angular rate

to be stabilized. The oscillations of the nadir-pointing axis are called librations and can be damped with an active magnetic controller. The rotation around the nadir direction can also be controlled by an active magnetic controller or a moment exchange actuator, e.g., a reaction or momentum wheel for higher accuracy.

3.2 Magnetic

By approximating the Earth's magnetic field in low earth orbit (LEO) as a dipole, it is possible to have a satellite fitted with a magnetometer to measure the Earth's magnetic field vector and use magnetic coils or rods (magnetorquers) to generate torques to control the satellite's attitude and angular rates. Due to a constraint in the direction of these magnetic torques, i.e., they are zero in the direction of the local magnetic field vector, these control torques cannot perfectly compensate for external disturbance torques on the satellite's attitude. This means for accurate attitude pointing the magnetic torques must be combined with passive control torques, e.g., gravity gradient or passively stable aerodynamic torques. The active magnetic torques can also be used to manage the angular momentum buildup on momentum exchange actuators, e.g., to ensure zero bias speeds on reaction wheels or offset reference speeds on momentum wheels.

3.3 Spinners

Spinning a satellite body generates an angular momentum vector which gives inertial stiffness to the satellite's attitude by keeping the spin axis fixed in inertial space. The angular momentum generated provides gyroscopic stiffness to the spinning satellite, making it less prone to external disturbances and more stable for propulsion thruster firings. Spinning the satellite after detumbling into a Y-Thomson attitude (Thomson 1962), where the satellite will align its maximum moment-of-inertia (MoI) axis normal to the orbit plane. This scheme will ensure a low-energy control method using a known spinning attitude with predictable antenna gain for ground communications or solar panel placement for a predictable power input.

3.4 Bias Momentum 3-Axis

For a 3-axis stable attitude, a momentum bias with a single momentum wheel aligned to the pitch axis normal to the orbit plane. Gyroscopic stiffness is used in order to control the vehicle by keeping the momentum wheel spinning at a biased reference speed. Small variations in the wheel speed allow for the control of the pitch axis. Yaw-roll coupling for nadir-pointing applications can be used to control the other two axes. Combined with magnetic controllers, the yaw-roll oscillations (nutations) can effectively be damped and the momentum wheel speed maintained at the biased reference speed. Although the satellite will be 3-axis stable, only the pitch axis can be controlled easily and accurately to a reference attitude. The roll and yaw axes will be controlled to zero angles.

3.5 Zero Momentum 3-Axis

In these systems, reaction wheels are used for each spacecraft axis in order to compensate for external disturbances and to implement various commanded attitude maneuvers. This is the most versatile and accurate attitude control system as pointing and slewing of any satellite axis are possible towards various earth and inertial targets, e.g., ground stations, earth imaging ground targets, sun, moon, stars, etc. A measured or estimated pointing error is used to torque the reaction wheels to ensure angular momentum exchange between the wheel discs and the satellite body to reduce the pointing error to zero. External torque disturbances can lead to wheel angular momentum buildup and eventual saturation. The increase in angular momentum to saturation levels requires a desaturation strategy which is called “momentum dumping” or unloading. This is achieved by using magnetorquers and to a much lesser extend thrusters (typically for larger satellites), thus enabling the wheels to operate around zero speed values. This strategy will also ensure the lowest reaction wheel power consumption as wheel power increase significantly with wheel speed.

3.6 Small Satellite ADCS Accuracies

The typical attitude control accuracies and constraints that can be obtained using the active control methods of the previous sections are summarized in Table 2. The accuracies listed depends also on the satellite’s orbit (external disturbance torques) and satellite size. Smaller satellites are normally less accurate due to a higher sensitivity to external disturbance torques and less accurate attitude and angular rate sensors.

Table 2 ADCS accuracies and constraints

Active control method	Actuators	Accuracy 1-σ	Constraint
Gravity gradient and magnetic, 3-axis stable	Boom and 3-axis magnetorquers	5°	Boom axis toward nadir, free rotation around boom axis (yaw)
Spinners, 2-axis stable	3-axis magnetorquers	10°	Spin axis direction inertially fixed
Bias momentum, 3-axis stable	Momentum wheel and 3-axis magnetorquers	2°	Wheel spin axis direction inertially fixed, free rotation around spin axis
Zero momentum, 3-axis stable	3-axis reaction wheels and 3-axis magnetorquers or thrusters	0.01°	No constraint, accuracy depends on attitude knowledge

4 ADCS Background Theory

4.1 Coordinate Frame Definitions

A satellite's attitude is normally controlled with respect to the orbit referenced coordinates (ORC), where the Z_O axis points toward nadir, the X_O axis points toward the velocity vector for a near circular orbit, and the Y_O axis along the orbit plane anti-normal direction. The aerodynamic $\mathbf{N}_{Aero}$ and gravity gradient $\mathbf{N}_{GG}$ disturbance torque vectors are also conveniently modelled in ORC. The satellite body coordinates (SBC) as defined in the body frame will nominally be aligned with the ORC frame at zero pitch, roll and yaw attitude. See Fig. 3 for a representation of these coordinate frames. Since the sun and satellite orbits are propagated in the J2000 earth-centered inertial coordinate frame (ECI), we require a transformation matrix from ECI to ORC coordinates. This can easily be calculated from the satellite position $\overline{\mathbf{u}}_I$ and velocity $\overline{\mathbf{v}}_I$ unit vectors (obtained using the position and velocity outputs of the satellite orbit propagator):

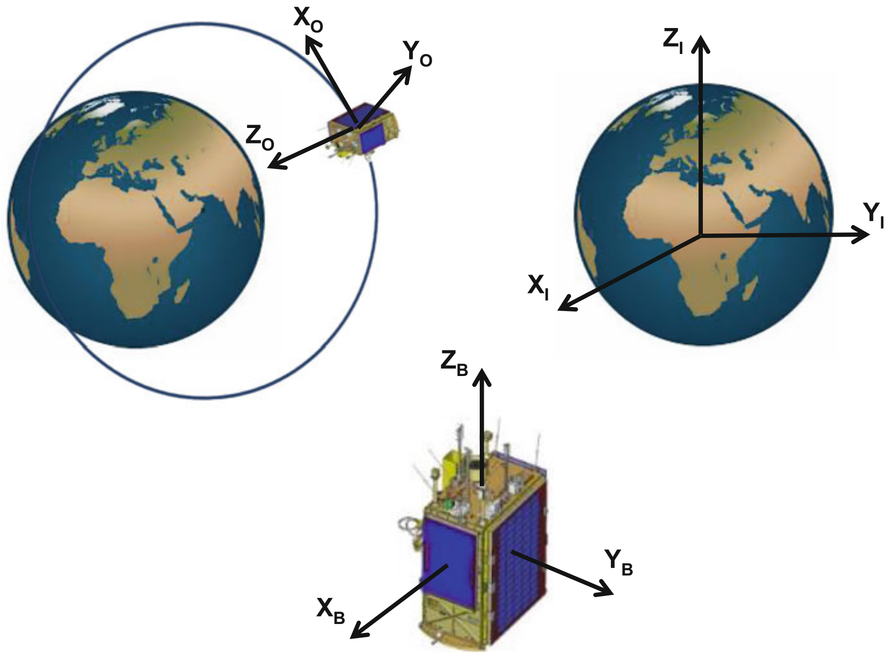

Fig. 3 Orbit (ORC), inertial (ECI), and spacecraft body (SBC) coordinate frames

$$\mathbf{A}_{I/O} = \begin{bmatrix} (\overline{\mathbf{u}}_I \times (\overline{\mathbf{v}}_I \times \overline{\mathbf{u}}_I))^T \\ (\overline{\mathbf{v}}_I \times \overline{\mathbf{u}}_I)^T \\ -\overline{\mathbf{u}}_I^T \end{bmatrix} \tag{1}$$

4.2 Attitude Kinematics

The attitude of an earth orbiting satellite can be expressed as a quaternion vector **q** to avoid any singularities to determine the orientation with respect to the ORC frame. The ORC reference body rates, $\omega_B^O = [\omega_{xo}, \omega_{yo}, \omega_{zo}]^T$, must be used to propagate the quaternion kinematics as:

$$\begin{bmatrix} \dot{q}_1 \\ \dot{q}_2 \\ \dot{q}_3 \\ \dot{q}_4 \end{bmatrix} = 0.5 \begin{bmatrix} 0 & \omega_{zo} & -\omega_{yo} & \omega_{xo} \\ -\omega_{zo} & 0 & \omega_{xo} & \omega_{yo} \\ \omega_{yo} & -\omega_{xo} & 0 & \omega_{zo} \\ -\omega_{xo} & -\omega_{yo} & -\omega_{zo} & 0 \end{bmatrix} \begin{bmatrix} q_1 \\ q_2 \\ q_3 \\ q_4 \end{bmatrix} \tag{2}$$

The attitude matrix to describe the transformation from ORC to SBC can be expressed in terms of quaternions as:

$$\mathbf{A}_{O/B} = \begin{bmatrix} q_1^2 - q_2^2 - q_3^2 + q_4^2 & 2(q_1q_2 + q_3q_4) & 2(q_1q_3 - q_2q_4) \\ 2(q_1q_2 - q_3q_4) & -q_1^2 + q_2^2 - q_3^2 + q_4^2 & 2(q_2q_3 + q_1q_4) \\ 2(q_1q_3 + q_2q_4) & 2(q_2q_3 - q_1q_4) & -q_1^2 - q_2^2 + q_3^2 + q_4^2 \end{bmatrix} \tag{3}$$

Note: In Eqs. (1) and (2), a quaternion definition is used where the first three elements of the quaternion form the vector part and the last element the scalar part of the quaternion. Another definition where the scalar part of the quaternion is in the first element is also commonly used. The former quaternion definition will be used throughout this chapter.

The attitude is normally presented as pitch θ, roll φ, and yaw ψ angles, defined as successive rotations, starting with the first rotation from the ORC axes and ending after the final rotation in the SBC axis. If a Euler 213 sequence (first θ around Y_O, then φ around X, and finally ψ around Z_B) is used, then the attitude matrix and Euler angles can be computed as:

$$\mathbf{A}_{O/B} = \begin{bmatrix} C\psi C\theta + S\psi S\varphi S\theta & S\psi C\varphi & -C\psi S\theta + S\psi S\varphi C\theta \\ -S\psi C\theta + C\psi S\varphi S\theta & C\psi C\varphi & S\psi S\theta + C\psi S\varphi C\theta \\ C\varphi S\theta & -S\varphi & C\varphi C\theta \end{bmatrix} \tag{4}$$

with,

$$\mathrm{C} = \text{cosine function}, \quad \mathrm{S} = \text{sine function}$$

and

$$\begin{aligned} \theta &= \arctan 4\left(A_{31}, A_{33}\right) \\ \varphi &= -\arcsin\left(A_{32}\right) \\ \psi &= \arctan 4\left(A_{12}, A_{22}\right) \end{aligned} \tag{5}$$

This Euler angle representation will allow unlimited rotations in pitch and yaw, but only maximum ±90° rotations in roll.

4.3 Attitude Dynamics

The attitude dynamics of an earth orbiting satellite can be derived using the Euler equation:

$$\mathbf{I}\dot{\boldsymbol{\omega}}_B^I = \mathbf{N}_{GG} + \mathbf{N}_D + \mathbf{N}_W + \mathbf{N}_{MT} - \boldsymbol{\omega}_B^I \times \left(\mathbf{I}\boldsymbol{\omega}_B^I + \mathbf{h}_W\right) \tag{6}$$

with $\boldsymbol{\omega}_B^I = \boldsymbol{\omega}_B^O + \mathbf{A}_{O/B}[0 \; -\omega_o \; 0]^T$ the inertially referenced body rate vector, $\mathbf{N}_{GG} = 3\omega_o^2\left(\mathbf{z}_o^B \times \mathbf{I}\mathbf{z}_o^B\right)$ the gravity gradient disturbance torque vector, with $\mathbf{z}_o^B = \mathbf{A}_{O/B}[0, 0, 1]^T$ the orbit nadir unit vector in body coordinates, $\mathbf{N}_D$ is the external disturbance torques (e.g., from aerodynamic and solar pressure forces), $\mathbf{N}_W = -\dot{\mathbf{h}}_W$ is the reaction or momentum wheel torque vector, with $\mathbf{h}_W$ the wheel angular momentum vector, $\mathbf{N}_{MT}$ is the magnetic control torque, ω_o the orbit angular rate (a constant for a circular orbit and a time variable for an eccentric orbit), and $\mathbf{I}$ is the inertia matrix of the satellite.

4.4 External Disturbance Torques

For satellites in low earth orbit, the typical unmodelled disturbance torques are from aerodynamic and solar pressure forces and from magnetic moments. The unmodelled magnetic moments are mostly caused by poor harness layout where current loops can form when supplying power to the spacecraft subsystems. Another source of magnetic moment disturbances, especially significant on nanosatellites, is from currents flowing in solar panels due to the solar cell connections. The latter has caused many CubeSats to spun up when left uncontrolled for long periods of time, and in some cases, they became unrecoverable when eventually reaching a very high spin rate.

4.4.1 Aerodynamic

The dominant external disturbance torque on a satellite at low altitude, as is the case for many small satellite missions, will be aerodynamic torque disturbances caused by the atmospheric drag pressure force on the external surfaces and deployables of a satellite. These torques can be calculated by using the panel method of partial accommodation theory. The external surface of the satellite is divided into several flat segments and the torque disturbance of each segment calculated and summed for the total disturbance torque (Steyn and Lappas 2011):

$$\begin{aligned}\mathbf{N}_{Aero} = \sum\nolimits_{i=1}^{n} \{\rho\,(\mathbf{u}_I, t)\,\|\mathbf{v}_A^B\|^2 A_i cos(\alpha_i)[\sigma_t(\mathbf{r}_i \times \bar{\mathbf{v}}_A^B) \\ +\{\sigma_n S + (2 - \sigma_n - \sigma_t)\cos(\alpha_i)\}\,(\mathbf{r}_i \times \bar{\mathbf{n}}_i)]\}\end{aligned} \tag{7}$$

$$\mathbf{v}_A^B = \mathbf{A}_{O/B}\mathbf{A}_{I/O}\left[\mathbf{u}_I \times \begin{bmatrix} 0 \\ 0 \\ -\omega_E \end{bmatrix} - \mathbf{v}_I\right] \tag{8}$$

with $\mathbf{v}_A^B$ the atmospheric velocity in SBC and $\rho(\mathbf{u}_I, t)$ the atmospheric density at orbit position and local time, see Fig. 4, $\omega_E =$ earth's rotation rate $= 7.29212 \times 10^{-5}$ rad/s, A_i the surface area of segment i, $\cos(\alpha_i) = \bar{\mathbf{v}}_A^B \bullet \bar{\mathbf{n}}_i$ the cosine of angle between unit atmospheric velocity vector and $\bar{\mathbf{n}}_i$ the normal unit vector of segment i, $\mathbf{r}_i$ the satellite CoM to segment i's CoP vector, $S = v_b/\|\mathbf{v}_A^B\|$ the ratio of molecular exit velocity v_b to atmospheric velocity ≈ 0.05 (for a 700 km altitude), σ_n the normal accommodation coefficient ≈ 0.8 (for a 700 km altitude), and σ_t the tangential accommodation coefficient ≈ 0.8 (for a 700 km altitude).

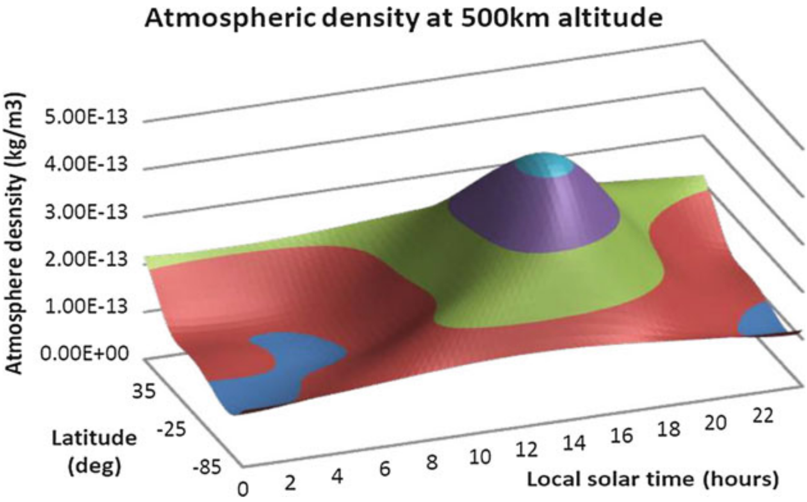

Fig. 4 An example of atmospheric density variation

4.4.2 Solar

The solar radiation pressure force and related torque depend on the absorption, specular and diffuse reflection coefficients of the external satellite surfaces, and deployables. The disturbance torques caused by the solar force are normally about two orders of magnitude less than the aerodynamic disturbances in low earth orbit, and its influence can normally be ignored. Where this force becomes significant is when a large area, highly reflective solar sail is deployed; see (Steyn and Lappas 2011) for a typical solar sail example.

4.4.3 Magnetic Moment

Internal magnetic moments due to currents flowing in an enclosed loop or residual magnetic dipoles from permanent magnets in electric motors, electromagnetic valves, or ferromagnetic material can cause time-varying magnetic moments that are difficult to accurately model or estimate. The sun's rays on solar panel surfaces will also cause magnetic moments normal to the surface and proportional to the sun vector component normal to the surface; the magnetic disturbance torque from a solar panel i can then be calculated as:

$$\mathbf{N}_{M\_SPi} = M_{SPi} H \cos(\alpha_i) \overline{\mathbf{n}}_{SPi} \times \mathbf{B}_B \tag{9}$$

with $\cos(\alpha_i) = \overline{\mathbf{s}}_B \bullet \overline{\mathbf{n}}_{SPi}$ the cosine of angle between the unit sun direction vector $\overline{\mathbf{s}}_B$ in SBC and the $\overline{\mathbf{n}}_{SPi}$the normal unit vector to the solar panel i surface, M_{SPi} the maximum magnetic moment of solar panel i when the sun is normal to the panel, $H = \{0, 1\}$, i.e., 0 when the cosine of angle is negative (sun behind the solar panel) and 1 (sun on solar panel) when positive and $\mathbf{B}_B$ the local B-field vector in SBC.

5 Attitude and Angular Rate Determination

To implement the attitude and angular rate controllers of the next section and to calculate the desired control torques, measurements or estimates of the orbit referenced angular rate vector and attitude quaternion must be known at each sampling instance of the onboard ADCS computer. A quaternion error can be calculated if the reference attitude quaternion and an estimated quaternion representing the current satellite attitude are available. The current satellite quaternion can be determined every sampling period using a TRIAD algorithm (Shuster and Oh 1981) from measured $\overline{\mathbf{v}}_B$ (in SBC) and modelled $\overline{\mathbf{v}}_O$ (in ORC) unit direction vectors from two different attitude sensor types, e.g., magnetometer/sun or sun-earth (nadir) combination of sensors. A more elaborate method QUEST (Shuster and Oh 1981) is optimally combining more than two vector pairs for attitude determination, e.g., from matched star tracker measurements.

As an example, a digital sun sensor can be used to measure the sun direction unit vector $\overline{\mathbf{s}}_B$ in SBC, and an IR earth sensor can measure the nadir unit vector $\overline{\mathbf{n}}_B$ in SBC. If the sun and satellite orbits are modelled, the sun to satellite unit vector in ORC, $\overline{\mathbf{s}}_O$ can also easily be calculated onboard in Eq. (10), and the nadir unit vector in ORC $\overline{\mathbf{n}}_O$ will simply be $[0, 0, 1]^T$, the direction of the ORC Z_O-axis.

The modelled (ORC) sun to satellite unit vector can be calculated from simple analytical sun and satellite (e.g., SGP4) orbit models in ECI coordinates. The ECI referenced unit vector can then be transformed to ORC coordinates using the known current satellite Keplerian angles:

$$\bar{\mathbf{s}}_O = \mathbf{A}_{I/O}\bar{\mathbf{s}}_I \tag{10}$$

with $\bar{\mathbf{s}}_I$ = ECI sun to satellite unit vector from sun and satellite orbit models.

5.1 TRIAD Method for Deterministic Attitude Determination

Two orthonormal triads are formed from the measured (observed) and modelled (referenced) vector pairs as presented above:

$$\begin{aligned} \bar{\mathbf{o}}_1 &= \bar{\mathbf{n}}_B, \quad \bar{\mathbf{o}}_2 = \bar{\mathbf{n}}_B \times \bar{\mathbf{s}}_B, \quad \bar{\mathbf{o}}_3 = \bar{\mathbf{o}}_1 \times \bar{\mathbf{o}}_2 \\ \bar{\mathbf{r}}_1 &= \bar{\mathbf{n}}_O, \quad \bar{\mathbf{r}}_2 = \bar{\mathbf{n}}_O \times \bar{\mathbf{s}}_O, \quad \bar{\mathbf{r}}_3 = \bar{\mathbf{r}}_1 \times \bar{\mathbf{r}}_2 \end{aligned} \tag{11}$$

The estimated ORC to SBC transformation matrix can then be calculated as:

$$\mathbf{A}_{O/B}(\widehat{\mathbf{q}}) = [\bar{\mathbf{o}}_1\ \bar{\mathbf{o}}_2\ \bar{\mathbf{o}}_3][\bar{\mathbf{r}}_1\ \bar{\mathbf{r}}_2\ \bar{\mathbf{r}}_3]^T \tag{12}$$

and

$$\begin{aligned} \widehat{q}_4 &= \sqrt{1 + A_{11} + A_{22} + A_{33}}/2 \\ \widehat{q}_1 &= [A_{23} - A_{32}]/(4\widehat{q}_4) \\ \widehat{q}_2 &= [A_{31} - A_{13}]/(4\widehat{q}_4) \\ \widehat{q}_3 &= [A_{12} - A_{21}]/(4\widehat{q}_4) \end{aligned} \quad \text{or} \quad \begin{aligned} \widehat{q}_1 &= \pm\sqrt{1 + A_{11} - A_{22} - A_{33}}/2 \\ \widehat{q}_2 &= [A_{12} + A_{21}]/(4\widehat{q}_1) \\ \widehat{q}_3 &= [A_{13} + A_{31}]/(4\widehat{q}_1) \\ \widehat{q}_4 &= [A_{23} - A_{32}]/(4\widehat{q}_1) \end{aligned} \tag{13}$$

5.2 Kalman Rate Estimator

To accurately measure low angular rates as experienced during 3-axis stabilization, a high-performance IMU will be required; this will neither fit in a small satellite nor be cost-effective. Low-cost MEMS rate sensors currently are still noisy and also experience high bias drift or temperature sensitivity. A modified implementation of a Kalman rate estimator can be used for the gyroless estimation of the nanosatellite body rates. This estimator was successfully used in many small satellite missions, such as the SNAP-1 nanosatellite mission (Steyn and Hashida 2001). It used magnetic field vector measurements that are continuously available, and the body measured rate of change of the geomagnetic field vector direction can be used as a measurement input for this rate estimator. However, this vector is not inertially fixed as it rotates twice per polar orbit. The estimated inertial referenced body rates will therefore have errors contributed by the magnetic field vector rotation rate. A more accurate estimated rate vector can be determined by measuring the sun vector, which only rotates inertially once per year. As the sun vector measurements are only available during the sunlit part of each orbit, when the sun is within the field of view (FOV) of a sun sensor, the Kalman rate estimator will propagate the angular rates when no measurements are available. A nadir-pointing small satellite is nominally rotating once per orbit within the ORC (around the body -Y_B axis), and full observability, using the sun vector measurement, is typically ensured. The only exception is when the satellite body rate vector is always aligned with the sun vector direction, else the angular rate vector with respect to an almost inertially fixed sun direction can be estimated as $\widehat{\omega}_B^I = [\hat{\omega}_{xi}, \hat{\omega}_{yi}, \hat{\omega}_{zi}]^T$. The expected measurement error will therefore include the sun sensor measurement noise and a negligibly small satellite-to-sun inertial rotation.

5.2.1 System Model

The discrete Kalman filter state vector $\mathbf{x}(k)$ is defined as the inertially referenced body rate vector $\boldsymbol{\omega}_B^I(k)$. From the Euler dynamic model of Eq. (6) without wheel actuators, the continuous time model becomes:

$$\begin{aligned} \dot{\boldsymbol{\omega}}_B^I(t) &= \mathbf{I}^{-1}\left(\mathbf{N}_{MT}(t) + \mathbf{N}_{GG}(t) - \boldsymbol{\omega}_B^I(t) \times \mathbf{I}\boldsymbol{\omega}_B^I(t)\right) \\ \dot{\mathbf{x}}(t) &= \mathbf{F}\,\mathbf{x}(t) + \mathbf{G}\,\mathbf{u}(t) + \mathbf{s}(t) \end{aligned} \tag{14}$$

with

$$\begin{aligned} &\mathbf{F} = [\mathbf{0}], \quad \mathbf{G} = \mathbf{I}^{-1}, \quad \mathbf{u}(t) = \mathbf{N}_{MT}(t) = \ \text{Control input vector} \\ &\mathbf{s}(t) = \mathbf{I}^{-1}\left(\mathbf{N}_{GG}(t) - \boldsymbol{\omega}_B^I(t) \times \mathbf{I}\boldsymbol{\omega}_B^I(t)\right) = \ \text{System noise vector} \end{aligned}$$

The discrete system model will then be

$$\mathbf{x}(k+1) = \boldsymbol{\Phi}\,\mathbf{x}(k) + \Gamma\,\mathbf{u}(k) + \mathbf{s}(k) \tag{15}$$

with

$\boldsymbol{\Phi} = [\mathbf{1}_{3x3}], \quad \Gamma = \mathbf{I}^{-1}T_s$

$T_s =$ Kalman filter sampling period

$\mathbf{s}(k) = N\{\mathbf{0}, \mathbf{Q}(k)\} \ =$ Zero mean system noise vector with covariance matrix $\mathbf{Q}$

5.2.2 Measurement Model

If we assume the satellite-to-sun vector as "inertially fixed" due to the large distance from the earth to sun compared to the earth to satellite and the slow rotation of the earth around the sun, the rate of change of the sun sensor measured unit vector can be used to accurately estimate the inertial referenced body angular rates. The magnetometer unit vector, as an orbit rotating vector, can also be used for continuous measurement updates but with expected rate estimation errors of approximately twice the orbit rate ω_o. For the rest of this discussion and the derivation of the measurement model, we assume the sun vector measurements will be used when they are available to update the Kalman rate estimator. Successive sun vector measurements will result in a small-angle discrete approximation of the vector rotation matrix:

$$\bar{\mathbf{s}}(k) = \Delta\mathbf{A}(k)\,\mathbf{s}(k-1) \tag{16}$$

with

$$\begin{aligned}\Delta\mathbf{A}(k) &\approx \begin{bmatrix} 1 & \omega_{zi}(k)T_s & -\omega_{yi}(k)T_s \\ -\omega_{zi}(k)T_s & 1 & \omega_{xi}(k)T_s \\ \omega_{yi}(k)T_s & -\omega_{xi}(k)T_s & 1 \end{bmatrix} \\ &\approx [\mathbf{1}_{3x3}] + \Lambda\left\{\boldsymbol{\omega}_B^I(k)\right\}\end{aligned} \tag{17}$$

The Kalman filter measurement model then becomes,

$$\begin{aligned}\Delta\mathbf{s}(k) &= \bar{\mathbf{s}}(k) - \bar{\mathbf{s}}(k-1) = \Lambda\left\{\boldsymbol{\omega}_B^I(k)\right\}\bar{\mathbf{s}}(k-1) \\ \mathbf{y}(k) &= \Delta\mathbf{s}(k) = \mathbf{H}(k)\,\mathbf{x}(k) + \mathbf{m}(k)\end{aligned} \tag{18}$$

with

$$\mathbf{H}(k) = \begin{bmatrix} 0 & -s_z(k-1)T_s & s_y(k-1)T_s \\ s_z(k-1)T_s & 0 & -s_x(k-1)T_s \\ -s_y(k-1)T_s & s_x(k-1)T_s & 0 \end{bmatrix} \tag{19}$$

and $\mathbf{m}(k) = N\{\mathbf{0},\ \mathbf{R}(k)\}$ as zero measurement noise, with covariance $\mathbf{R}$.

5.2.3 Kalman Filter Algorithm

Define $\mathbf{P}_k \equiv E\left\{\mathbf{x}_k.\mathbf{x}_k^T\right\}$ as the state covariance matrix, and then the following steps are executed every sampling period T_s, between measurements (at time step k):

1. Numerically integrate the nonlinear dynamic model of Eq. (14):

$$\hat{\mathbf{x}}_{k+1/k} = \hat{\mathbf{x}}_{k/k} + 0.5T_s(3\Delta\mathbf{x}_k - \Delta\mathbf{x}_{k-1})\{\text{Modified Euler Integration}\} \tag{20}$$

with

$$\Delta\mathbf{x}_k = \mathbf{I}^{-1}\left(\mathbf{N}_{MT}(k) - \hat{\boldsymbol{\omega}}_B^I(k) \times \mathbf{I}\hat{\boldsymbol{\omega}}_B^I(k)\right) \tag{21}$$

2. Propagate the state covariance matrix:

$$\mathbf{P}_{k+1/k} = \Phi\,\mathbf{P}_{k/k}\,\Phi^T + \mathbf{Q} = \mathbf{P}_{k/k} + \mathbf{Q} \tag{22}$$

Across measurements (at time step k + 1 and only in sunlit part of orbit):

3. Gain update, compute $\mathbf{H}_{\mathrm{k+1}}$ from Eq. (19) using previous vector measurements $\bar{\mathbf{s}}(k)$:

$$\mathbf{K}_{k+1} = \mathbf{P}_{k+1/k}\mathbf{H}_{k+1}^T\left[\mathbf{H}_{k+1}\mathbf{P}_{k+1/k}\mathbf{H}_{k+1}^T + \mathbf{R}\right]^T \tag{23}$$

4. Update the system state:

$$\widehat{\mathbf{x}}_{k+1/k+1} = \widehat{\mathbf{x}}_{k+1/k} + \mathbf{K}_{k+1}\left(\mathbf{y}_{k+1} - \mathbf{H}_{k+1}\widehat{\mathbf{x}}_{k+1/k}\right) \tag{24}$$

with

$$\mathbf{y}_{k+1} = \bar{\mathbf{s}}(k+1) - \bar{\mathbf{s}}(k)$$

5. Update the state covariance matrix:

$$\mathbf{P}_{k+1/k+1} = \left[\mathbf{1}_{3x3} + \mathbf{K}_{k+1}\mathbf{H}_{k+1}\right]\mathbf{P}_{k+1/k} \tag{25}$$

Finally the estimated ORC angular rate vector can be calculated from the Kalman filtered estimated ECI rate vector, using the TRIAD result of Eq. (12):

$$\widehat{\boldsymbol{\omega}}_B^O(k) = \widehat{\boldsymbol{\omega}}_B^I(k) - \mathbf{A}_{O/B}(\widehat{\mathbf{q}}(k))\,[0\ \ -\omega_o\ 0]^T \tag{26}$$

Figure 5 shows the simulation Kalman rate estimation results of a satellite with a hemispherical FOV digital sun sensor. The satellite is in an approximate 500 km polar orbit with 05h45 LTAN, giving a short eclipse period. The initial ECI referenced body rate vector values are [0.5, 0.0, 1.0] °/s. The estimated rate values track and propagate the true ECI rates accurately. The estimated rates are smooth when they are propagated, e.g., during the eclipse period from approximately 3600 to 4600 seconds. The digital sun sensor has a RMS angular error of 0.1°, and the Kalman rate estimation RMS error is 0.02 °/s.

Figure 6 presents actual Kalman rate estimation results obtained as real-time telemetry data points during the commissioning of a small microsatellite, when using only magnetometer measurements.

5.3 Extended Kalman Filter Estimators

Before any of the wheel control modes can be applied to a satellite, more accurate and continuous angular rate and attitude knowledge will be required. An extended Kalman

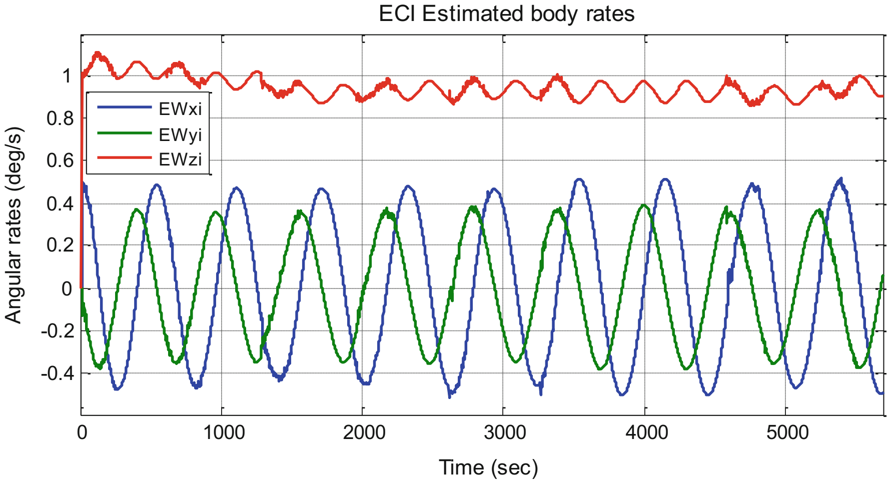

Fig. 5 Simulated sun sensor-based Kalman rate filter results

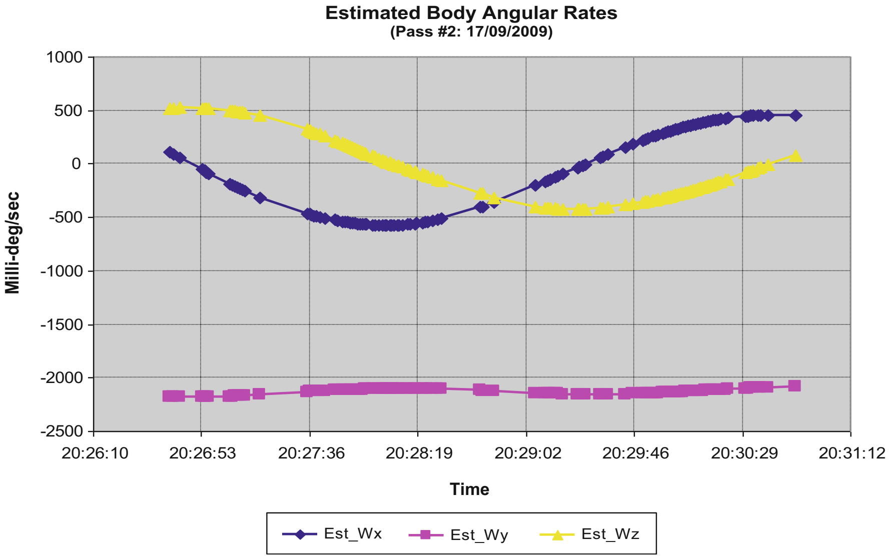

Fig. 6 Onboard magnetometer-based Kalman rate filter telemetry results

filter (EKF) can be used to estimate the full attitude state of the satellite from all attitude sensor SBC measurements (e.g., from magnetometer, sun, nadir, and star sensors) and the corresponding ORC modelled vectors; see (Steyn 1995) for a detailed derivation. The seven-element discrete state vector to be estimated is defined as:

$$\widehat{\mathbf{x}}(k) = \begin{bmatrix} \widehat{\boldsymbol{\omega}}_B^I(k) \\ \widehat{\mathbf{q}}(k) \end{bmatrix} \tag{27}$$

A disadvantage of the full state EKF is that the estimation accuracy will depend not only on the sensor measurement noise but also on the size of the modelling errors in the Euler dynamic model in Eq. (6), i.e., the uncertainty of the spacecraft's moments and products of inertia, the unknown external disturbance torques, and the actual actuator output torques. If the satellite's inertially referenced body rate vector $\boldsymbol{\omega}_B^I(k)$ can be accurately measured with inertial rate sensors (gyroscopes), the EKF does not have to model the spacecraft's uncertain dynamics, and a six-element discrete state vector can be defined as:

$$\widehat{\mathbf{x}}(k) = \begin{bmatrix} \widehat{\mathbf{b}}(k) \\ \widehat{\mathbf{q}}(k) \end{bmatrix} \tag{28}$$

with $\widehat{\mathbf{b}}(k)$ the estimated bias vector of the 3-axis angular rate sensor and inertial rate sensor model:

$$\widehat{\boldsymbol{\omega}}_B^I(k) = \boldsymbol{\omega}_{GYRO}(k) - \mathbf{b}(k) + \mathbf{m}(k)$$

where $\boldsymbol{\omega}_{GYRO}(k)$ is the 3-axis angular rate sensor measurement vector, $\mathbf{b}(k)$ is the rate sensor bias vector, and $\mathbf{m}(k)$ the measurement noise vector. See (Lefferts et al. 1982) for a detailed derivation of the rate sensor-based EKF.

Only extremely expensive and high-performance rate sensors, e.g., fiber-optic and ring-laser gyroscopes, will be able to measure the 3-axis inertially referenced angular rates of satellites with the required accuracy. The angular rate sensor bias can be significant in most sensors, e.g., a MEMS type and when it is required for the attitude to be propagated by integration of the rate sensor measurements, the estimation of the sensor bias becomes mandatory.

The innovation used in the EKF is the vector cross product of a measured body reference unit vector and a modelled orbit reference unit vector, transformed to the body coordinates by the estimated attitude transformation matrix $\mathbf{A}[\widehat{\mathbf{q}}(k)]$:

$$\mathbf{e}(k) = \overline{\mathbf{v}}_B(k) \times \mathbf{A}[\widehat{\mathbf{q}}(k)]\ \overline{\mathbf{v}}_O(k) \tag{29}$$

with $\begin{array}{l} \overline{\mathbf{v}}_B(k) = \mathbf{B}_{magm}(k)/\|\mathbf{B}_{magm}(k)\| \quad \text{or} \quad \mathbf{S}_{sun}(k)/\|\mathbf{S}_{sun}(k)\| \\ \overline{\mathbf{v}}_O(k) = \mathbf{B}_{igrf}(k)/\|\mathbf{B}_{igrf}(k)\| \quad \text{or} \quad \mathbf{S}_{orbit}(k)/\|\mathbf{S}_{orbit}(k)\| \end{array}$, e.g., for magnetic and sun vector pairs

The onboard magnetometer measurements must first be offline calibrated by comparing the measured B-field magnitude to the International Geomagnetic Reference Field (IGRF) model's magnitude. This is can be done by sampling at least a full orbit's raw or pre-launch calibrated magnetometer vector measurements and the corresponding IGRF modelled magnetic vectors. These data samples can then be further ground processed by using an attitude independent 3-axis magnetometer

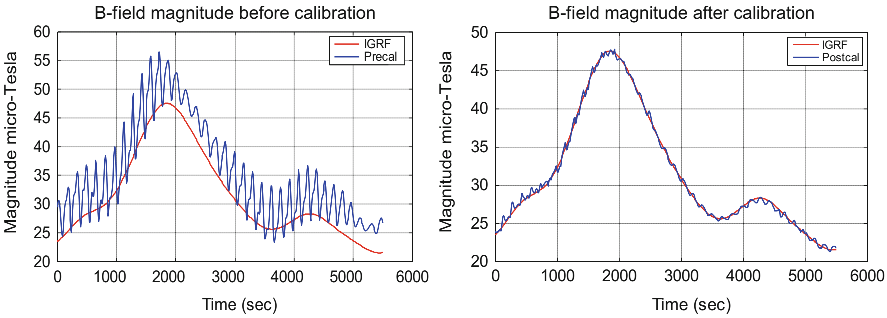

Fig. 7 Magnetometer pre-calibration ($1\sigma = 2.848\ \mu T$) and post-calibration ($1\sigma = 0.365\ \mu T$)

calibration method (Crassidis et al. 2005) to estimate the gain (scaling and orthogonality) matrix $\mathbf{G}_{cal}$ and offset (bias) vector $\mathbf{O}_{cal}$.

Thereafter calibrated magnetometer measurements can be determined for use in the EKF:

$$\mathbf{B}_{magm}(k) = \mathbf{G}_{cal}\mathbf{B}_{raw}(k) - \mathbf{O}_{cal} \tag{30}$$

Figure 7 shows typical pre- and post-calibration comparison results of a magnetometer when the onboard magnetic magnitude is compared to an IGRF model output for a CubeSat in a 400 km International Space Station orbit.

6 Attitude and Angular Rate Controllers

6.1 Detumbling Magnetic Controllers

After release from the launcher stage, the small satellite will first be detumbled using minimum ADCS resources and power, to bring it to a controlled spin rate and/or spinning attitude, typically a Y-Thomson spin (Thomson 1962). A Y-Thomson spin will ensure that the satellite will align its body Y_B axis normal to the orbit plane, i.e., with the satellite rotating within the orbit plane. This not only results in a controlled spin rate but also in a known spin attitude, without the need to estimate onboard the satellite's attitude. The only requirement for a stable Y-Thomson spin will be that the body Y_B axis must have the largest moment of inertia (I_{yy} MOI parameter) and small ($<$ 3% MOI) products of inertia parameters. A simple B-dot (Stickler and Alfriend 1974) magnetic controller will quickly dump any X_B and Z_B axes angular rates and align the Y_B axis to the orbit plane normal vector. Using measurements from a single MEMS rate sensor, the Y_B spin rate can then be magnetically controlled to an inertially referenced spin rate of typically -2 °/s (the reference rate depends on the magnitude of the external disturbance torques and must be high enough to ensure a sufficient gyroscopic stiffness). The magnetic detumbling controllers require only the measured magnetic field vector components (from a 3-axis magnetometer) and the inertially referenced Y_B body rate (from the Kalman rate estimator on Sect. 1.5.2 or a rate sensor measurement) and can be applied continuously. The magnetic-only controllers used during detumbling can be:

$$\begin{array}{llll} M_y = K_d {}^{d\beta}\!/_{dt} & \text{for} & \beta = \arccos\left({}^{B_{my}}\!/_{\|\mathbf{B}_{meas}\|}\right) & \{\text{Bdot controller}\} \\ M_x = K_s\left(\omega_{yi} - \omega_{yref}\right)\,\text{sgn}\left(B_{mz}\right) & \text{for} & \left|B_{mz}\right| > \left|B_{mx}\right| & \{\text{Y spin controller}\} \\ M_z = -K_s\left(\omega_{yi} - \omega_{yref}\right)\,\text{sgn}\left(B_{mx}\right) & \text{for} & \left|B_{mx}\right| > \left|B_{mz}\right| & \{\text{Y spin controller}\} \end{array} \tag{31}$$

with β the angle between the body Y_B axis and the local B-field vector, K_d and K_s are the detumbling and spin controller gains, and ω_{yref} the reference Y_B body spin rate. $M_{x,y,z}$ are the magnetic torquer moments in Am^2 units that can be scaled to pulse width modulated (PWM) outputs $M_{PMW\_x,y,z}$, as most magnetorquers on satellites are current controlled via discrete switching amplifiers. As the magnetorquer magnetic moments can disturb the local magnetic field measurements, we typically limit the magnetorquer on time to 80% of the discrete magnetic controller period T_s to leave a window for undisturbed magnetometer sampling.

The pulse outputs of the magnetorquers are therefore saturated to 80% of the controller period T_s,

$$sat\{M_{PWM\_i}\} = \text{sgn}\left(M_{PWM\_i}\right)\,\min\left\{\left|M_{PWM\_i}\right|, 0.8T_s\right\} \quad \text{for} \quad i = x, y, z \tag{32}$$

The average magnetic moment and torque vector during a controller period can then be calculated as:

$$\mathbf{M}_{avg} = \frac{M_{\max}}{T_s} sat\{\mathbf{M}_{PWM}\} \quad \text{Am}^2 \tag{33}$$

$$\mathbf{N}_{MT} = \mathbf{M}_{avg} \times \mathbf{B}_B \tag{34}$$

with $M_{\max}$ the maximum "on" magnetic moment of the magnetorquer and $\mathbf{B}_B$ the true magnetic field vector SBC.

Figures 8 and 9 show a typical detumbling performance from an initial angular rate of $\omega_B^I(0) = [4, 0, 2]^T$°/sec. During the first 1000 seconds, no control was done, and then the detumbling and Y-spin controller of Eq. (31) were enabled. Within less than an orbit, the satellite was controlled to a − 1°/sec Y-Thomson spin, using only the magnetorquers. The body angular rates were estimated by the Kalman rate filter as presented above utilizing only the raw magnetometer vector measurements.

6.2 Y-Momentum Wheel Controller

From the Y-Thomson body spin of the previous section, a momentum wheel aligned to the Y_B body axis can be used to absorb the Y-body momentum and control the

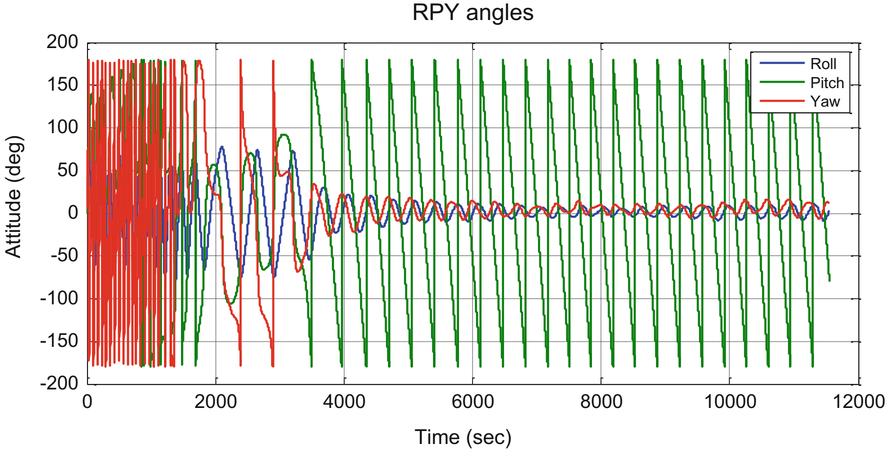

Fig. 8 Attitude angles during magnetic detumbling to a Y-Thomson spin

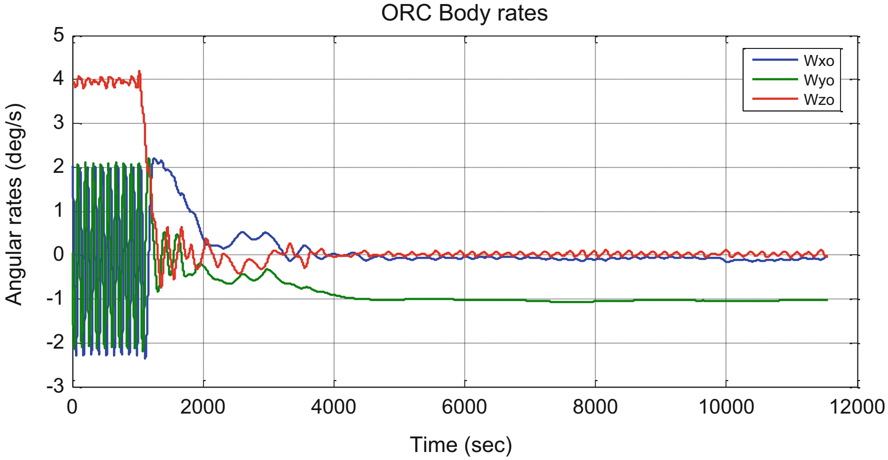

Fig. 9 Angular rates during magnetic detumbling to a Y-Thomson spin

pitch angle with small roll and yaw angles, e.g., to maintain a nadir-pointing attitude for earth imaging payloads and directional antennae for ground station communications. The Y-momentum wheel controller can be implemented with attitude and rate estimations from an EKF, as

$$N_{wy}(k) = K_{py} \arcsin\left(\widehat{q}_2(k)\ \mathrm{sgn}\left(\widehat{q}_4(k)\right)\right) + K_{dy}\widehat{\omega}_{yo}(k) \tag{35}$$

with K_{py} and K_{dy} the proportional and derivative gains.

To maintain the Y-wheel momentum at a certain reference level (corresponding to the initial Y_B body momentum during the Y-spin mode) and to damp anybody nutation rates in the X_B and Z_B axes, a magnetic cross-product control law can be utilized (Steyn and Hashida 2001):

$$\mathbf{M}(k) = \frac{\mathbf{e}(k) \times \mathbf{B}(k)}{\|\mathbf{B}(k)\|} \tag{36}$$

with

$$\mathbf{e}(k) = \begin{bmatrix} K_n \ \widehat{\omega}_{xo}(k) \\ K_h \ \left(h_{wy}(k) - h_{wy-ref}\right) \\ K_n \ \widehat{\omega}_{zo}(k) \end{bmatrix} \tag{37}$$

where K_n is the nutation damping gain, K_h is the Y-wheel momentum control gain, and $h_{wy\,-\,ref}$ is the Y-wheel reference angular momentum.

The cross-product controller of Eq. (36) is applied continuously. During initial commissioning, the Y-momentum control mode can be used to calibrate and determine the alignment of all the accurate attitude sensors, i.e., sun and earth horizon (nadir) sensors and star tracker. After the in-orbit calibration and alignment parameters have been determined, the measurements from these sensors can then be included in an EKF to improve the attitude and rate estimation accuracy. Next, the nanosatellite will be ready for a 3-axis reaction wheel control mode, when required for full 3-axis pointing capability.

Figures 10 and 11 present the detumbling results where an offset Y-wheel speed (momentum) can assist to detumble a satellite into a stable Y-Thomson spin for cases where the Y_B axis MOI is not the largest. The detumbling is done during the first orbit

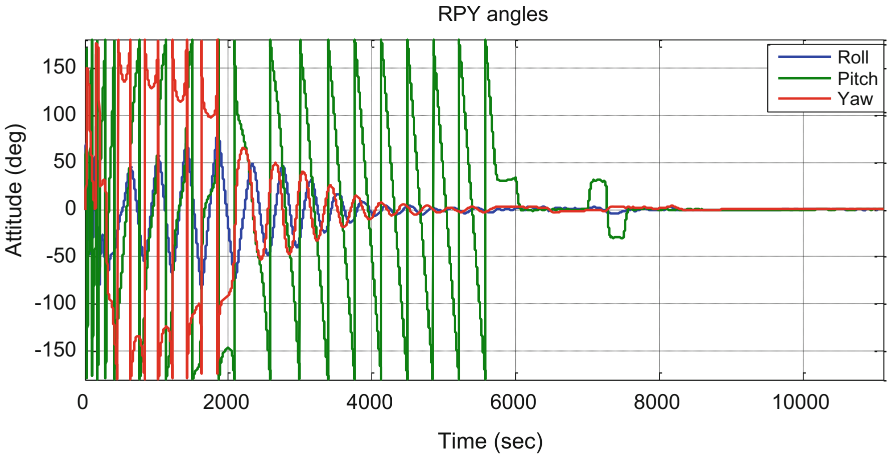

Fig. 10 Attitude angles from Y-Thomson detumbling to Y-Momentum wheel control

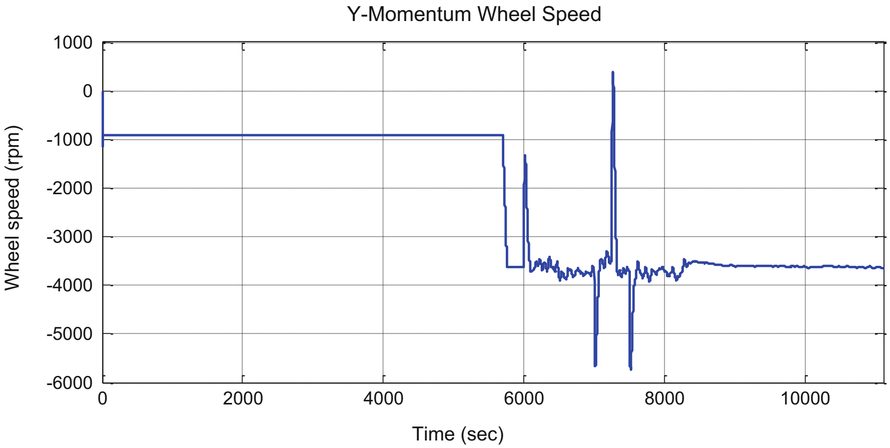

Fig. 11 Y-Momentum wheel speed during Y-Thomson detumbling and Y-Momentum control

until time 5700 seconds with the Y-Wheel speed at −1000 rpm. Then the Y-Wheel speed is ramped to −3700 rpm to absorb the Y-body spin, and at 6000 seconds, the Y-Wheel controller of Eq. (35) is enabled to control the pitch attitude to zero, and the magnetic cross-product controller of Eq. (36) is enabled to damp the roll/yaw nutation and maintain the Y-Wheel angular momentum at a wheel speed of approximately −3700 rpm. At 7000 seconds a pitch reference of +30° and 250 seconds later of −30° is commanded, before returning back to nadir pointing at 7500 seconds.

6.3 3-Axis Reaction Wheel Controllers

From the Y-momentum wheel mode, the X_B and Z_B reaction wheels can be activated and a 3-axis reaction wheel controller implemented using the estimated attitude and angular rates using the EKF of Sect. 1.5.3. The globally stable quaternion feedback controller of (Wie et al. 1989) can be modified to become an orbit referenced pointing control law. The quaternion and rate reference vectors can be generated from a sun orbit model for a sun-pointing attitude (to maximize solar energy generation on deployed solar panels), or it can be a zero vector for a nadir-pointing attitude or any specified constant attitude reference for a specific roll, pitch, or yaw requirement (see Fig. 12). The 3-axis reaction wheel control law (wheel torque vector) to be used for all these cases is:

$$\mathbf{N}_w(k) = K_{P1}\mathbf{I}\vec{\mathbf{q}}_{err}(k) + K_{D1}\mathbf{I}\widehat{\boldsymbol{\omega}}_B^O(k) - \widehat{\boldsymbol{\omega}}_B^I(k) \times \left(\mathbf{I}\widehat{\boldsymbol{\omega}}_B^I(k) + \mathbf{h}_w(k)\right) \tag{38}$$

with $K_{P1} = 2\omega_n^2$, $K_{D1} = 2\zeta\omega_n$ the pointing gains for a required controller closed-loop bandwidth and damping factor. $\mathbf{I}$ is the satellite moment of inertia matrix, $\mathbf{h}_w(k)$ is the measured angular momentum of the reaction wheels:

$\hat{\omega}_B^O(k) = [\hat{\omega}_{xo}(k), \hat{\omega}_{yo}(k), \hat{\omega}_{zo}(k)]^T$ is the body orbit reference angular rate estimate, $\vec{\mathbf{q}}_{err}(k) = [q_{1e}(k), q_{2e}(k), q_{3e}(k)]^T$ is the vector part of the error quaternion $\mathbf{q}_{err}$, where

$$\begin{gathered}\mathbf{q}_{err}(k) = \mathbf{q}_{com}(k) \bigoplus \widehat{\mathbf{q}}(k) \\ \begin{bmatrix} q_{1e} \\ q_{2e} \\ q_{3e} \\ q_{4e} \end{bmatrix} = \begin{bmatrix} q_{4c} & q_{3c} & -q_{2c} & -q_{1c} \\ -q_{3c} & q_{4c} & q_{1c} & -q_{2c} \\ q_{2c} & -q_{1c} & q_{4c} & -q_{3c} \\ q_{1c} & q_{2c} & q_{3c} & q_{4c} \end{bmatrix} \begin{bmatrix} \widehat{q}_1 \\ \widehat{q}_2 \\ \widehat{q}_3 \\ \widehat{q}_4 \end{bmatrix}\end{gathered} \tag{39}$$

with $\mathbf{q}_{com}(k)$ the commanded reference quaternion, e.g., a sun direction quaternion and $\bigoplus$ for quaternion division.

A nominal reaction wheel control mode can be, for example, do sun-pointing in the sunlit part of the orbit and nadir pointing, i.e., $\mathbf{q}_{com}(k) = [0, 0, 0, 1]^T$, in eclipse. The nadir-pointing attitude will ensure optimal antenna coverage for ground communication during eclipse and thermal stability to the imager telescope. Continuous momentum management of the reaction wheels can be done using a simple cross-product magnetic controller (Steyn 1995):

$$\mathbf{M}(k) = K_m \frac{\mathbf{h}_w(k) \times \mathbf{B}(k)}{\|\mathbf{B}(k)\|} \tag{40}$$

with $K_m$the momentum dumping gain.

The tracking of ground targets can also be accurately done by uploading the earth target's coordinates a-priory. A target tracking generator is then used onboard to calculate the commanded quaternion $\mathbf{q}_{com}(k)$ and angular rate vectors for the reaction wheel controllers as derived in (Chen et al. 2000). The geometry during target tracking to calculate the satellite to target vector in ORC is shown in Fig. 12. The 3-axis reaction wheel control law is similar to the quaternion feedback controller of Eqs. (38) and (39), but an integral term of the quaternion error $\vec{\mathbf{q}}_{ierr}$is added for improved tracking accuracy, where:

$$\vec{\mathbf{q}}_{i\,err}(k) \cong \vec{\mathbf{q}}_{i\,err}(k-1) + \vec{\mathbf{q}}_{err}(k) T_s \tag{41}$$

The ground target tracking control law then becomes

$$\begin{aligned}\mathbf{N}_w(k) = K_{P2}\mathbf{I}\vec{\mathbf{q}}_{err}(k) + K_{I2}\mathbf{I}\vec{\mathbf{q}}_{i\,err}(k) + K_{D2}\mathbf{I}\left[\widehat{\boldsymbol{\omega}}_B^O(k) - \boldsymbol{\omega}_{com}^O(k)\right] \\ -\widehat{\boldsymbol{\omega}}_B^I(k) \times \left[\mathbf{I}\widehat{\boldsymbol{\omega}}_B^I(k) + \mathbf{h}_w(k)\right]\end{aligned} \tag{42}$$

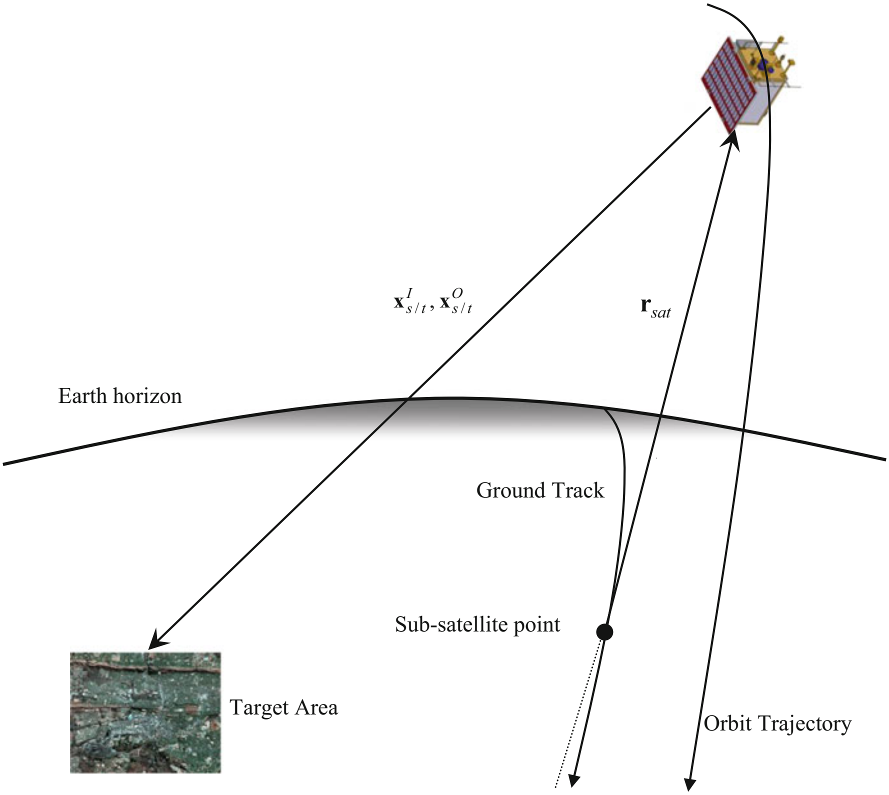

Fig. 12 Target tracking geometry

with $K_{P2} = 2\left(\omega_n^2 + 2\zeta\omega_n/\Delta T\right)$, $K_{D2} = 2\zeta\omega_n + 1/\Delta T$, $K_{I2} = 2\omega_n^2/\Delta T$, ω_n, ζ the dominant second-order closed-loop specifications, $\Delta T = 10/\zeta\omega_n$ the time constant for integral control, and $\boldsymbol{\omega}_{com}^{O}(k)$ the ORC target tracking angular rate commanded vector.

Figures 13 and 14 show the typical performance over an orbit of the 3-axis reaction wheel controllers of a LEO small satellite. Initially the attitude is controlled to nadir pointing (zero RPY). Between 600 and 1600 seconds, a ground target close to the sub-satellite ground track is tracked, with roll angle varying between +2° and – 4°, i.e., for an almost overhead pass. At 2000 seconds a sun-tracking control law is enabled to point the solar panels mounted on the zenith pointing satellite facet toward the sun. During eclipse (from 3099 to 5262 seconds) the sun tracking control law automatically revert back to nadir pointing to ensure improved antennae pointing for ground station communication.

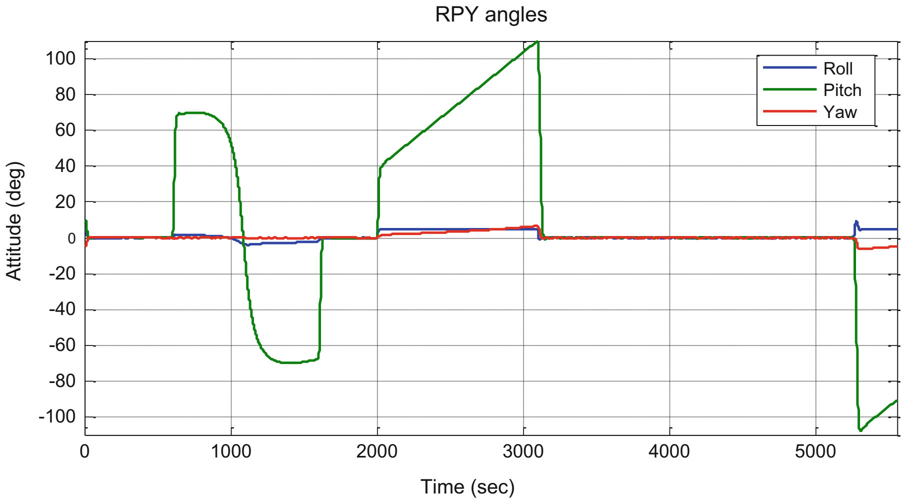

Fig. 13 Attitude angles during target tracking, sun tracking, and nadir-pointing control

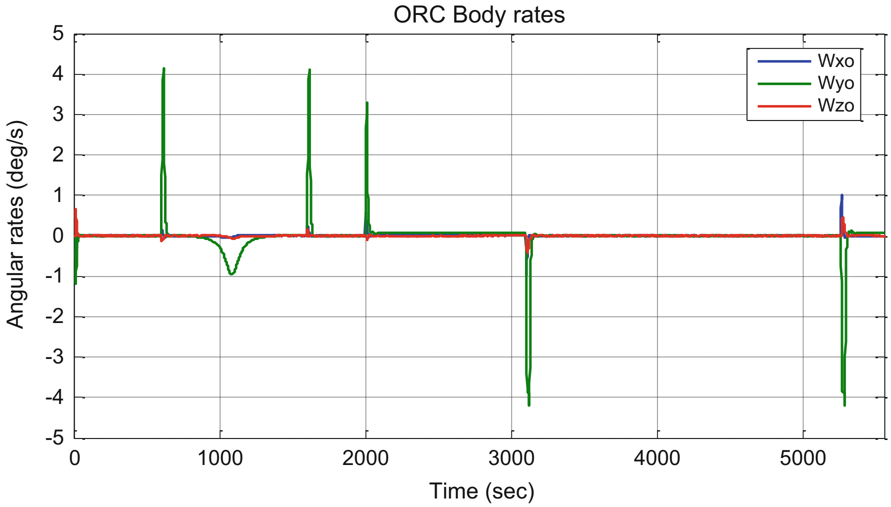

Fig. 14 Reaction wheel speeds during target tracking, sun tracking, and nadir-pointing control

7 Pointing Accuracy and Stability

The ADCS requirements for an earth observation (EO) satellite are mostly driven by the imager, the "main payload." These are determined by the Hi-Res camera as it will present the highest performance requirements for pointing accuracy, pointing stability, and platform agility. This section uses a hypothetical Hi-Res camera and satellite as an example to satisfy the following user requirements:

- Hi-Res ground sampling distance (GSD) of 1 m/pixel resolution on 7 μm square pixel dimensions
- Hi-Res swath of 12 km (assuming 12,000 active pixels per line)
- Agility of 30° roll and pitch rotations in 20 seconds
- Pointing control error of 200 m (1σ) at center of target
- Pointing knowledge error of 20 m (1σ) at center of target
- Pointing stability less than 0.1 pixel smear during time delay integration (TDI) imaging
- Pointing range in pitch and roll at ±30°
- 128 TDI stages (pixel rows) at the maximum integration setting
- 500 km near circular sun-synchronous orbit with 09 h30 am/pm local time at equatorial crossings
- 450 kg minisatellite with principle moments of inertia (MOI) $I_{XX} = I_{YY} = 270$ kgm^2 and $I_{ZZ} = 63$ kgm^2

7.1 Selected ADCS Hardware

7.1.1 Reaction Wheels

Four wheels in a tetrahedral configuration (see Fig. 15) with reaction wheel specifications:

- Maximum torque: $N_{max} = 0.2$ Nm
- Maximum angular momentum: $h_{max} = 10$ Nms (± 5000 rpm)

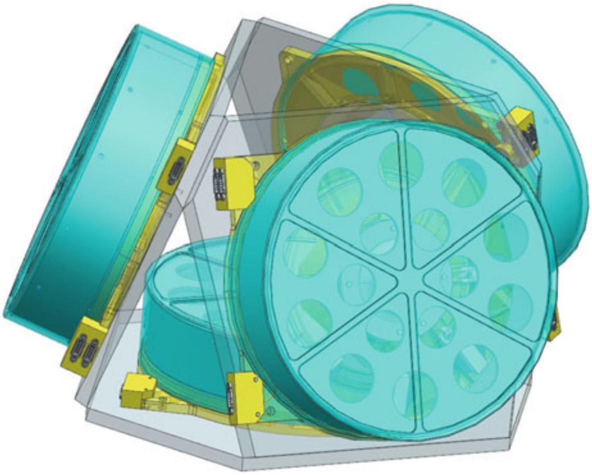

Fig. 15 Tetrahedral reaction wheel configuration

- Speed control accuracy: $\Delta\omega < 0.6$ rpm RMS
- Static unbalance <4.5 g.cm
- Dynamic unbalance <14.4 g.cm^2

7.1.2 Star Tracker

A star tracker with dual optical heads with 60° separation between boresight directions to prevent sun blinding at certain attitude pointing angles. The star tracker specifications are:

- Accuracy: 4 arcsec 1σ in boresight direction and 20 arcsec 1σ boresight rotation for 10 stars at 5 Hz.
- Exclusion angles: 30° sun and Earth
- Max tracking rate: 5 °/sec.

7.1.3 Angular Rate Sensor

A fiber-optic gyroscope (FOG) is selected to measure the angular rates per satellite axis. The FOG specifications are:

- Random walk <0.08 °/√hr → measurement noise = 4 milli-deg/sec (1σ)
- Bias drift <1.5 °/hr. = 1.5 arcsec/sec
- Bias stability <0.05 °/hr. = 0.05 arcsec/sec
- Update rate 10 Hz

7.1.4 Space GPS Receiver

The orbit position is measured accurately with a GPS receiver with the following relevant specifications:

- 3D position accuracy <10 m (1σ)
- Update rate 1 Hz

7.2 Jitter Analysis (Platform Stability)

7.2.1 Stability Requirement

Assume a maximum 10% pixel smear over the 128 TDI stages. For a 500 km orbit, $V_{sat} = 7.613$ km/sec and $V_{ground} = 7.06$ km/sec. Assume an imaging quality factor $Q = 1$, i.e., pixel ground size = GSD.

The exposure time for a 128 stage TDI sensor is therefore $t_{exp} = 128.\mathrm{GSD}/V_{ground} = 18.1$ milli-sec.

The GSD pixel angle: θ_{pixel} (500 km) = $\tan^{-1}$(GSD/500e3) = 0.4125 arcsec.

The stability requirement for roll and pitch pointing is then $\omega_{stability}$(pitch/roll) = $0.1\ \theta_{pixel}/t_{exp}$ = 2.28 arcsec/sec.

For yaw rotations the end pixels will be 6000 pixels from the 12,000 pixel line center; therefore a 0.1 pixel rotation at the end of a line will be $\psi_{pixel} = \tan^{-1}(0.1/6000) = 3.44$ arcsec and $\omega_{stability}(\text{yaw}) = \psi_{pixel}/t_{exp} = 189.9$ arcsec/sec.

The worst-case stability requirement is then for roll/pitch stability = $\underline{\text{2.28 arcsec/sec}}$.

The factors determining the platform stability during TDI integration will be discussed next.

7.2.2 Reaction Wheel Unbalance

Assume a four-wheel tetrahedral reaction wheel configuration with a wheel speed bias of $\omega_{wbias} = 1000$ rpm = 104.7 rad/sec = 16.7 Hz.

Static Unbalance

Assume for the tetrahedral configuration the static unbalance $mr = 4.5$ g.cm = 4.5e-5 kg.m and the worst-case unbalanced wheel disc CoM at 0.3 m from the satellite CoM.

The static unbalance forces in the X_BZ_B and Y_BZ_B plane for pitch and roll disturbance:

$$F_{su} = mr\omega^2 = 4.5\text{e-}5(104.7)^2 \sin(104.7t)\text{N}$$

The static unbalance angular accelerations will be:

$$\dot{\omega}_{x/y} = \frac{0.3F_{su}}{I_{XX/YY}} = 5.5\text{e-}4 \sin(104.7t)\text{rad}/\sec^2$$

The angular rate disturbance amplitude due to static unbalance will then be:

$$\left|\omega_{x/y\ static}\right| = \frac{\left|\dot{\omega}_{x/y}\right|}{\omega_{wbias}} = \underline{1.08\ \text{arcsec}/\sec} \quad (@16.7\text{ Hz})$$

Dynamic Unbalance

Assume for the tetrahedral configuration the dynamic unbalance mrd = 14.4 g.cm^2 = 1.44e-6 kg.m^2. The dynamic unbalance torque amplitude around the body axes causing attitude disturbances will be

$$|N_{du}| = mrd\omega^2 = 1.44\text{e-}6(104.7)^2 = 1.58\text{e-}2\text{Nm}$$

The dynamic unbalance torque around the roll and pitch axes will be

$$\left|\dot{\omega}_{x/y}\right| = \frac{|N_{du}|}{I_{XX/YY}} = 1.58\text{e-}2/270 = 5.9\text{e-}5\ \text{rad}/\sec^2$$

The angular rate disturbance amplitude will then be

$$\left|\omega_{x/y\ dynamic}\right| = \frac{\left|\dot{\omega}_{x/y}\right|}{\omega_{wbias}} = \underline{0.12\ \text{arcsec}\,/\,\text{sec}}\quad (@16.7\ \text{Hz})$$

Therefore the worst-case jitter will be due to static unbalance; this can be reduced by placing the RWs closer to the CoM of the satellite or by reducing the RW bias wheel speed.

7.2.3 Reaction Wheel Control Torque Disturbances

The brushless DC motor (BDCM) control of the reaction wheel speed will induce the following disturbance torques to the satellite body.

Nonlinear Friction

Stiction when crossing zero speeds. A typical stiction torque for a similar sized tetrahedral reaction wheel configuration is 4 milli-Nm. The wheel acceleration in a controller settling time of $10T_s = 1$ sec due to stiction, when the wheel stop and start, is (T_s = reaction wheel controller sampling time)

$$\frac{\Delta\omega}{\Delta t} = \frac{N_{stiction}}{I_{XX/YY}} = \frac{4e-3}{235} = 3.1\ \text{arcsec}\,/\,\text{sec}^2$$

$$\Delta\omega_{stiction} = \underline{3.1\ \text{arcsec}\,/\,\text{sec}}\,(\text{assuming a 1 sec RW controller settling time})$$

This angular disturbance clearly exceeds the stability requirement during imaging; therefore the RW speeds must be prevented from zero speed crossings, i.e., biased reaction wheels will be required in the tetrahedral configuration.

7.2.4 BDCM Torque Ripple

Assume 25% of the nominal torque (20 milli-Nm) during imaging as the torque ripple at the motor's commutation rate multiplied by the reaction wheel bias speed ω_{wbias}. The ripple torque will then be:

$$N_{ripple} = 5\ \text{milli-Nm@100 Hz}\,\{6\ \text{poles x }16.7\ \text{Hz@1000 rpm}\}$$

The ripple torque angular rate disturbance amplitude will then be:

$$\left|\omega_{ripple}\right| = \left(N_{ripple}/I_{XX/YY}\right)/628.2\ \text{rad/s} = \underline{0.006\ \text{arcsec}\,/\,\text{sec}}\quad (@100\ \text{Hz})$$

Reaction Wheel Control Torque

Assume a 1% of maximum tetrahedral torque increment every reaction wheel controller sampling time T_s:

$$\Delta N_{wheel} = 0.01 N_{wmax} = 2.0\ \text{milli-Nm in}\,T_s = 0.1\ \text{sec}$$

The ripple torque angular rate disturbance amplitude will then be:

$$\omega_{control} = \left(\Delta N_{wheel}/I_{XX/YY}\right).T_s = \underline{0.15\ \text{arcsec}/\text{sec}}$$

Reaction Wheel Speed Discretization

Assuming a speed control discretization step amplitude of $\Delta\omega_{wheel} = 0.6$ rpm = 3.6°/sec and reaction wheel moment of inertia I_{wheel} = 1.91e-2 kgm^2, then the wheel speed discretization will cause a body angular rate disturbance of

$$\Delta\omega_{x/y} = \Delta\omega_{wheel} I_{wheel}/I_{XX/YY} = 1.1\ \text{arcsec}/\text{sec}$$

This value is close to the roll/pitch stability requirement of 2.28 arcsec/sec for a 128 stage TDI image sensor. Neither the star tracker or FOG rate sensors can measure down to this low resolution. With only the reaction wheels controlled to an accuracy not worse than 0.6 rpm (1σ), the satellite platform stability requirement will be met.

7.3 Pointing Error Budget

The different contributions to a ground target's pointing error from a 500 km altitude are:

- Attitude knowledge error from the dual star tracker measurements
  Accuracy <4 arcsec (1σ) = 9.7 meter
- GPS position error projected to the ground
  Accuracy of satellite's in-orbit position <10 m (1σ) = 9.3 meter
- Timing accuracy (image timestamp correlation)
  2 milli-sec (1σ) worst case assumed due to software latency = 14.1 meter @V_{ground} = 7.06 km/sec.

Therefore the combined (1σ) geolocation measurement accuracy = **19.5 meter** (satisfies requirement)

- The attitude control accuracy <0.02° (1σ) = 174.5 meter

Therefore, the total (1σ) **pointing control error** = **194.0 meter** (satisfies requirement).

Other possible errors to consider:

- Maximum structural alignment variation (thermal) between main telescope and star tracker boresights <10 arcsec, thus <24.2 meter pointing error that can possibly be compensated for with a thermal model
- Atmospheric optical distortion for off-nadir angles and ionospheric errors for GPS signals

7.4 Satellite Platform Agility

Assume a four-wheel tetrahedral configuration with maximum total torque and angular momentum placed in the Y_B axis direction:

$$\mathbf{N}_{THmax} = \begin{bmatrix} 1.89 \\ 2.0 \\ 1.63 \end{bmatrix} \mathbf{N}_{Wmax} \quad \text{and} \quad \mathbf{h}_{THmax} = \begin{bmatrix} 1.89 \\ 2.0 \\ 1.63 \end{bmatrix} \mathbf{h}_{Wmax}$$

Then,

$$N_{THmax}(Y_B) = 400 \text{ milli-Nm}, \quad h_{TH\,max}(Y_B) = 20 \text{ Nms}$$

$$\omega_{ymax} = 0.7 h_{THmax}/I_{YY} = 0.0519 \text{ rad/ sec} \approx 3.0^{\circ}/\text{ sec}$$

$$\dot{\omega}_{ymax} = N_{THmax}/I_{YY} = \text{Acc} = 0.00148 \text{ rad/ sec}^2 = 0.85^{\circ}/\text{ sec}^2$$

For a bang-off-bang minimum-time rotation around Y_B, we assume 70% of reaction wheel angular momentum is still available to do the maneuver (20% of each reaction wheel's angular momentum is used to bias the tetrahedral configuration, and 10% is available to compensate for external disturbances). The bang-off-bang minimum-time angular rate rotation profile is shown in Fig. 16. The time to accelerate at maximum torque to ω_{ymax} is $t_a = 3.0/0.85 = 3.5$ seconds, and the pitch rotation angle to t_a is $\theta_a = 0.5\omega_{ymax}t_a = 5.25^{\circ}$. The deceleration phase of the rotation profile will take similar time and angle as the acceleration phase; thus the coasting phase for a 30° pitch rotation will take $t_c = (30^{\circ} - 2\theta_a)/\omega_{ymax} = 6.5$ seconds. Therefore, the minimum final time for a 30° pitch rotation will be $t_f = 2t_a + t_c = 7 + 6.5 = \underline{13.5 \text{ seconds}}$. Similar calculations for a 30° roll rotation (X_B axis), where the $\omega_{xmax} \approx 2.8^{\circ}/\text{ sec}$, $t_a = 3.3$ seconds, $\phi_a = 4.6°$, and $t_c = 7.4$ seconds, give a minimum final time $t_f = \underline{14 \text{ seconds}}$. Both these rotation times are less than the requirement of 20 seconds specified in the beginning of this section.

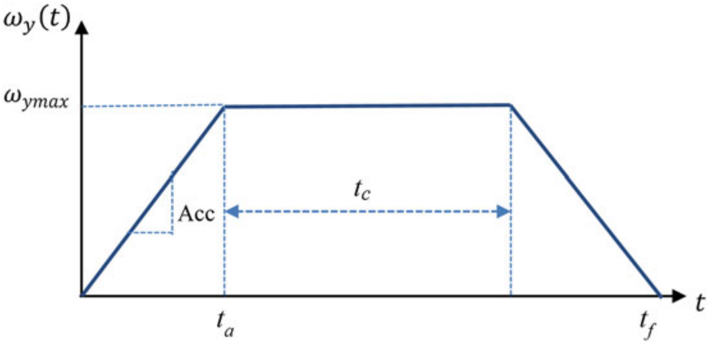

Fig. 16 Pitch angular rate profile during a minimum-time slew maneuver

8 ADCS Sensor and Actuator Hardware

The ADCS sensors typically used on small satellites are limited by mass, volume, and power constraints. Over the last couple of years, the available technology has improved and became more compact and lower power due to an increase in the density of semiconductor integrated circuits and advances in MEMS technology and nanomechanics. Therefore, most ADCS sensor and actuator types flying on larger satellites can now be found in miniaturized form for small satellite use. Although their performance in some aspects are still not the same as their larger and more power hungry bigger brothers, the gap is slowly closing, i.e., where the laws of physics do allow it. The next section will present some examples of these small satellite ADCS components that are available commercially and successfully used in various small satellite missions.

8.1 3-Axis Magnetometers

Fluxgate 3-axis magnetometers give the best noise performance, and their sensitivity and bias errors with temperature are better compared to MEMS type magnetoresistive and magneto-inductive sensors typically used in nanosatellites. The MEMS types with build-in bias and temperature correction circuitry and calibration equations have been used successfully on nanosatellites. For most magnetic control ADCS systems where accuracy is not a hard requirement, the MEMS type magnetometers are ideally suited with their inherent small size and low-power specifications. Table 3 compares the performance parameters of magnetometer types typically used on small satellites.

To reduce the influence of magnetic disturbances from the spacecraft bus, it is advisable to mount magnetometers on the external facets of the satellite and sometimes have them deployable; see Fig. 17 for a 3-axis microsatellite fluxgate magnetometer and a nanosatellite deployable 3-axis MEMS magnetometer.

8.2 Sun Sensors

The sun as a bright inertial object in the celestial sky is perfectly suited for accurate attitude vector measurements using a relative low cost, mass, and power-type sensing device. Sun sensors vary from planar photodiodes or solar

Table 3 Performance parameters of some 3-axis magnetometer types

Magnetometer type	Range (μT)	Scaling (mV/μT)	Resolution (nT)	Noise (pT_{rms}/Hz)	Axes error (°)	Linearity error (%)	Scaling error (%)	Temp coeff (ppm/°C)	Temp bias (nT/°C)

Table 4 Performance parameters of high accuracy sun sensors for small satellites

Sun sensor type	FoV (°)	Accuracy (° RMS)	Update rate (Hz)	Power average (mW)	Mass (g)	Size (mm^3)	Supply (VDC)	RadiationTID (krad)
NSS digital fine sun sensor	140	< 0.1	5	37.5	35	$34 \times 32 \times 20$	5–50	10
SolarMEMS digital two-axis SS	120	< 0.1	50	315	35.5	$50 \times 30 \times 12$	5	300

cells where the short circuit current is measured to get a value proportional to the cosine of the sun angle to the surface normal. Six of these sensors mounted with unobstructed hemispherical view each on the facets of a box-type satellite will always give the components of the sun direction vector from up to three sensors facing the sun. Due to earth albedo absorption and a non-ideal cosine response (due to reflections at low angles from the sensor surface), the sun vector accuracy from these coarse sensors is at best about ±5°, but mass and power are negligible. Higher accuracy sensors often make use of MEMS position-sensitive detectors (PSD) and optical windowing to give a sun direction vector measurement from the sun azimuth and elevation measurement angles. Table 4 gives some performance parameters of commercially available sun sensors and Fig. 18 show images of these sensors.

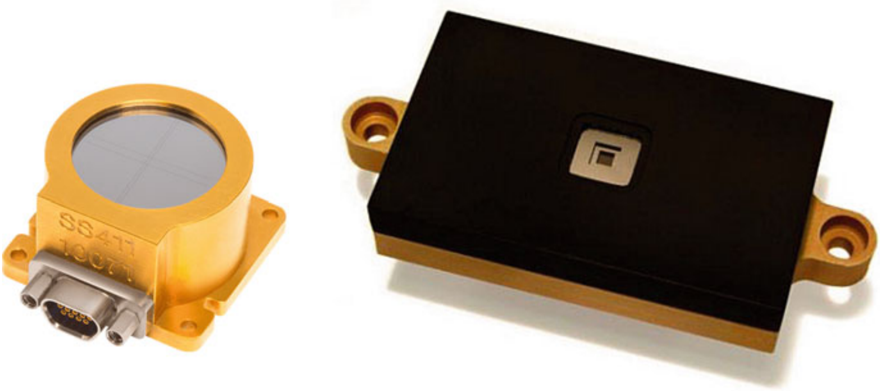

Fig. 18 Digital 2-axis sun sensors: Left, NFSS-411 (NewSpace), and right, SSOC-D60 (Solar MEMS)

8.3 Star Trackers

The most accurate attitude sensors used on small satellites are star trackers. They are sensors with very sensitive light detectors, typically charge-coupled devices (CCD); in some case these sensors are also cooled to reduce the thermal noise for an increased signal-to-noise ratio. The FOV of these sensors depends on the visual magnitude (M_v) stars that can be detected, e.g., for a CCD detector sensitive enough to see a 6.5 M_v star, a FOV of 15° will ensure at least three stars to be visible for more than 99% of the celestial sphere. The stars detected in the FOV will be slightly defocused to enable the star centroid to be accurately determined using a center of gravity method. The separation distances (angles) between all the measured stars are then matched to reference stars in an onboard star catalogue. For example, a unique match will be detected when a matching triangle can be found of three measured and reference stars. All other visible star separation angles will then be matched to generate the maximum number of measured stars in the SBC frame and reference stars in the ECI frame for star tracking.

After the initial processing intensive “lost-in-space” matching process, successive measurements will only be used to track their matched reference stars by searching in a small region around their previous position, assuming a slow rotating satellite. The tracking process is processing less intensive than star matching, and this enables most star trackers to generate vector pair solutions typically between 1 and 10 Hz for further attitude and rate determination use in an EKF estimator. Star trackers on larger satellites have typical RMS accuracies of less than 5 arcseconds in the boresight direction and 15 arcsec in boresight rotation. This performance is made possible by high-quality low distortion optics and very sensitive star detection. For nanosatellites the high CCD power requirement and large optics with sun and earth blocking baffles are inhibiting factors. However, a few nano-sized star trackers have already been developed and some

Table 5 Performance parameters of typical star trackers for small satellites

Star tracker	Accuracy (arcsec 1-σ)	Max track rate (°/sec)	Max update rate (Hz)	Power average (W)	Mass (g)	Size (mm^3)	Supply (VDC)	Baffle sun exclusion angle (°)
Sodern Auriga	6 (cross axis) 40 (boresight)	3	5	1.0	210	56 × 66 × 94	5	34
Adcole Maryland MAI-SS	4 (cross axis) 27 (boresight)	2	4	1.5	282	55 × 65 × 70 (no baffle)	5	45

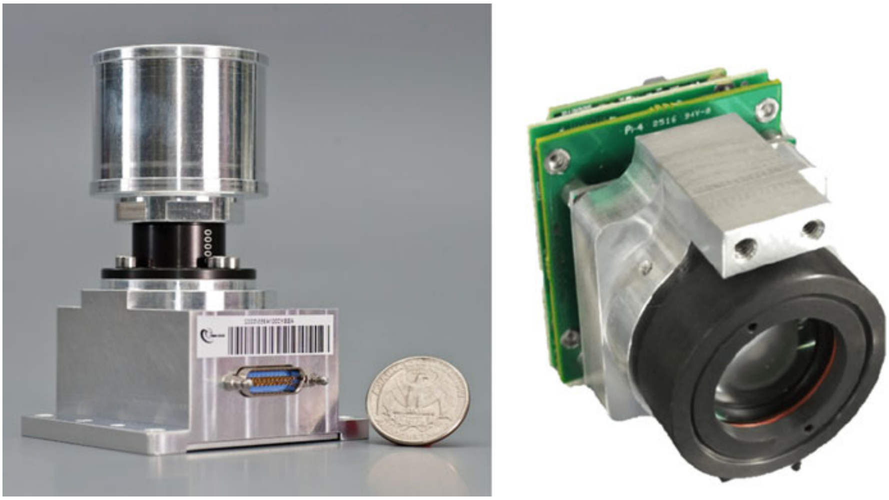

Fig. 19 Star Trackers: Left, Auriga (Sodern), and right, MAI-SS (Adcole Maryland)

also successfully flight qualified. See Table 5 for typical performance specifications of these small satellite star trackers; Fig. 19 shows images of these accurate sensors.

8.4 Angular Rate Sensors

Accurate measurement of the inertially referenced low angular rates of small satellites, during 3-axis stabilization, is possible using low measurement noise and low bias drift fiber-optic gyroscopes (FOG). The development of MEMS rate sensors is continuously improving, almost matching the performance of lower cost FOGs. To measure the initial high tumbling rates of nanosatellites, MEMS rate sensors can be utilized effectively. Table 6 gives a performance comparison between a tactical grade FOG sensor, high-performance 3-axis MEMS angular rate sensor, and an integrated circuit packaged MEMS rate sensor; it is clear that the performance gap is reducing. Fig. 20 show images of these angular rate sensors.

Table 6 Performance parameters of typical angular rate sensors for small satellites

Rate sensor type and model	Range (°/sec)	Noise (random walk) (°/√hr)	Bias drift (°/hr 1-σ)	Max update rate (Hz)	Power average (W)	Mass (g)	Size (mm^3)	Supply (VDC)
FOG 1-axis μFORS-3 U	± 499	0.08	3	1000	1.1	150	21 × 65 × 88	5
MEMS 3-axis STIM300	± 400	0.15	10	2000	1.5	55	39 × 45 × 22	5

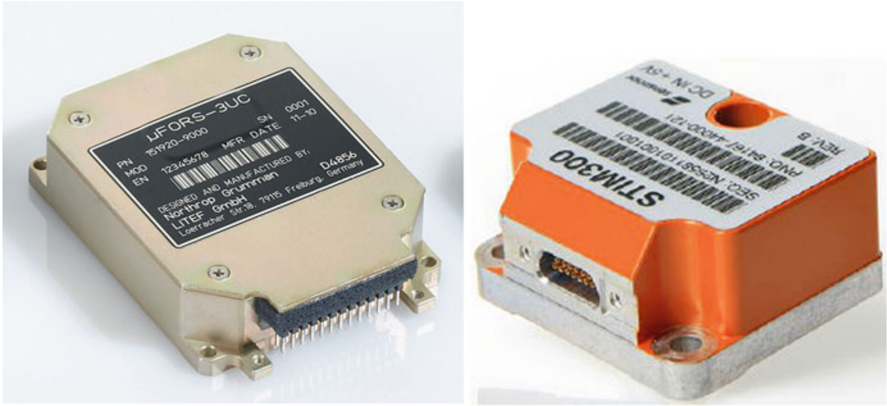

Fig. 20 Single axis angular rate sensors: Left, μFORS-3 U (Northrop Grumman), and right, STIM300 (Sensonor)

8.5 Magnetorquers

Actuators to generate magnetic moments for interaction with the geomagnetic field can easily be scaled for small satellite use. Magnetic torquer rods are preferred due to their smaller volume, power, and mass compared to torquer coils, but sometimes due to layout problems, air-core coils will be used. Torquer rods make use of a low remanence ferromagnetic core, e.g., MuMetal or Supra-50 alloys are suitable. Torquer rods will give a magnetic moment amplification of 80 to 120 compared to an air-core coil; therefore they use less current and power and a smaller enclosed area for a similar magnetic moment. The physical placing of the torquer rods are critical as they can influence each other, and the direction of the generated magnetic moment

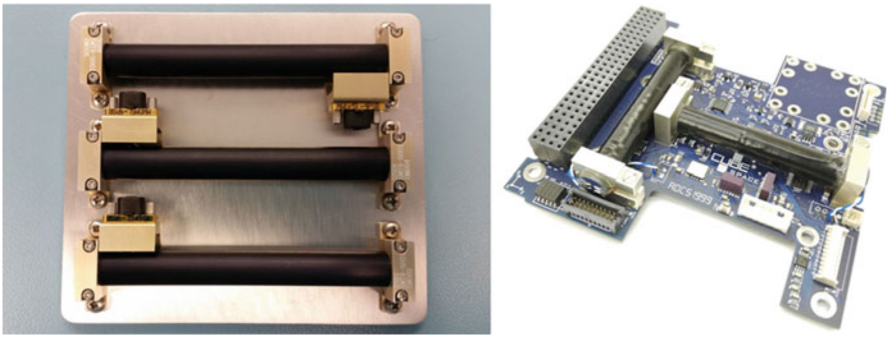

Fig. 21 Magnetorquers: Left, NMTR-X (NewSpace), and right, CubeTorquer (CubeSpace)

Table 7 Performance parameters of typical magnetorquers for small satellites

Magnetic torquer	Magnetic moment (Am^2)	Linearity (%)	Residual moment (Am^2)	Power max (W)	Mass (g)	Length (cm)	Supply (VDC)
NewSpace NMTR-X	1–100	$\pm$ 5	$<$ 0.5%	1.0	30 g/cm length	8–60	5
CubeSpace CubeTorquer small	0.48	2.5	$<$ 0.1%	0.8	28	6	5

can rotate, especially if they are separated by distances less than a rod length (except for a symmetric T-configuration, see Fig. 21). By pulse width modulation of the X_B, Y_B, and Z_B magnetorquer currents, a magnetic moment vector in any desired direction and size can be produced. Table 7 show typical performance parameters for these small satellite magnetorquers.

8.6 Reaction/Momentum Wheels

Reaction/momentum wheels are actuators that operate using the principal of preservation of angular momentum, to exchange the controlled angular momentum in the wheel disc's rotation speed to the body of the satellite. A reaction wheel assembly normally consists of a brushless DC motor (BDCM) with a shaft-mounted disc acting as a flywheel. The flywheel's speed is accurately measured with a shaft encoder to enable a feedback speed control system for accurate angular momentum control. The flywheel's size is chosen according to the momentum storage requirements of a satellite in a specific orbit. The BDCM torque is selected to meet the agility requirements during rotation maneuvers, i.e., how fast the satellite body must rotate during these maneuvers. Precise speed control with optimized low-power requirements and small volume and mass are the driving factors for the wheel choice on small satellites.

Table 8 Performance parameters of typical reaction/momentum wheels for small satellites

Reaction or momentum wheel	Max angular momentum (milli-Nms)	Max torque (milli-Nm)	Max speed (rpm)	Power const speed (W)	Mass (kg)	Size (mm^3)	Static/ dynamic unbalance (gmm/gmm^2)
Vectronic VRW-1	1000.0	± 25	± 6500	3.0	1.8	115 × 115 × 77	< 1/80
CubeSpace CubeWheel small	1.77	0.23	± 8000	0.15	0.06	28 × 28 × 26.2	< 0.03/0.5

The difference between reaction wheels and momentum wheels lies only in the application of the wheel's angular momentum to control the satellite's attitude. A reaction wheel operates in a near-zero momentum bias configuration, i.e., to limit the gyroscopic torques caused by an angular momentum vector during 3-axis attitude rotations. A momentum wheel operates around an offset speed to give an angular momentum bias to the satellite's body for gyroscopic stiffness. This means a momentum wheel will control the satellite's attitude actively in the wheel spin axis direction through momentum exchange (by varying the wheel speed) and passively through gyroscopic stiffness by keeping the attitude in the other two axes.

For a full 3-axis rotation capability, a minimum of three reaction wheels will be required, and the wheel speeds will be controlled around zero average speed. For redundancy reasons and to enable offset wheel speeds (to avoid the wheel torque disturbances at zero speed crossings), more than three reaction wheels can be used while still ensuring a zero average momentum vector applied to the satellite body. For example, four reaction wheels can be used in a forth skewed wheel, tetrahedral, or pyramid configuration (see Fig. 15 for a tetrahedral cluster).

Commercially available small satellite wheels are high-performance micro-mechanical devices, e.g., they are balanced to low static and dynamic specifications to limit wheel vibrations affecting the payload performance, they use special vacuum-rated bearings to ensure a long life in space, and they have to survive the launcher forces and vibrations. The typical performance specifications of these small satellite wheels vary according to their momentum storage capability; see Table 8 and Fig. 22.

8.7 Integrated ADCS Modules for NanoSats

A few complete ADCS solutions are commercially available for nanosatellite missions:

(A) The MAI-500 unit from Adcole Maryland Aerospace is a 0.6 U CubeSat-sized ADCS featuring two star trackers. It has a total mass of 1049 g and size of 100 × 100 × 62.3 mm. The average power consumption during nadir pointing is 2130 mW and specifies a pointing accuracy of 0.1°. See Fig. 23 for a photo of the MAI-500 unit.

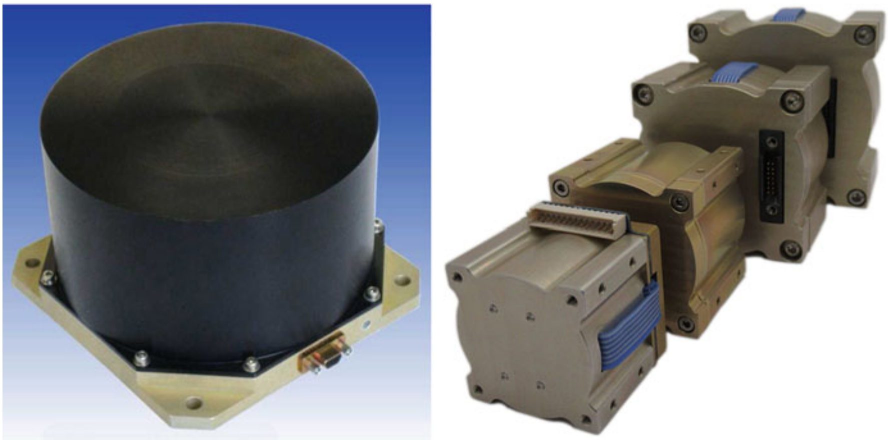

Fig. 22 Reaction/momentum wheels: Left, VRW-1 (Vectronic), and right, CubeWheels (CubeSpace)

(B) The Y-Momentum CubeADCS (CubeSpace) was originally developed for the QB50 mission. A 3-axis reaction wheel integrated ADCS bundle was since developed for higher accuracy pointing capability. These integrated ADCS units are currently flying successfully on several 2 U, 3 U, and 6 U CubeSat missions. An integrated 3-axis CubeADCS flight unit is shown in Fig. 24. It has a total mass of 554 g and size of 96 × 96 × 62 mm to fit into a 0.6 U CubeSat volume. The average power consumption is 571 mW. It is a 3-axis reaction wheel unit with nadir, sun, moon, and ground target pointing capability. It uses Y_B and Z_B magnetic torquer rods plus a X_B torquer coil, 3-axis MEMS rate sensors, coarse sun sensors, and deployable 3-axis magnetometer during low-power angular rate detumbling and safe mode control. For higher pointing ($< 0.1°$ 3-σ) and tracking performance, a CubeSense fine sun and nadir sensor and CubeStar star tracker with stellar gyro capability can be added. A space GPS receiver can also be seamlessly integrated to these units. Various state estimators including a full state and gyro-based extended Kalman filter are implemented to enable the quaternion feedback reaction wheel controllers to do autonomous attitude control.

(C) The iADCS100 (Hyperion) was initially developed to be the most compact high-performance ADCS for 1 U to 3 U CubeSats. The launching customer was the AALTO-1 satellite, launched in June 2017. The unit's layout is shown in Fig. 25. It has a total mass of 400 g, depending on the wheel momentum storage. The size of 95 × 90 × 32 mm will fit into a 0.3 U CubeSat volume. The nominal power consumption is 1400 mW. It is a three-reaction wheel unit with 3-axis target, nadir, and sun-pointing capability. It uses three magnetorquers and a built-in magnetometer for attitude detumbling and safe mode control. For ADCS sensors a ST200 star tracker, 3-axis MEMS rate sensors and plug-in sun sensors are used.

Fig. 23 MAI-500 ADCS unit for CubeSats (Adcole Maryland)

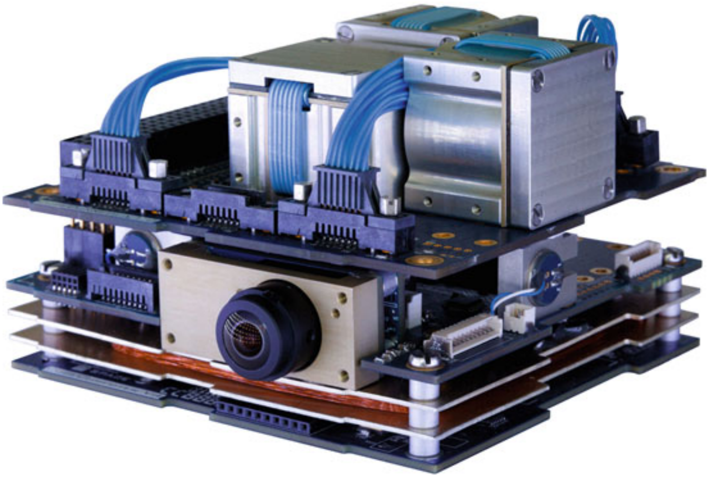

Fig. 24 CubeADCS 3-axis unit for 2 U to 6 U CubeSats (CubeSpace)

9 Future Directions

The ADCS of small satellites is constantly improving as nanotechnology and onboard processing capability enable the miniaturization of hardware and the implementation of more advanced software algorithms. As mentioned in the introduction, most nanosatellites are now launched with full 3-axis attitude control capability. The

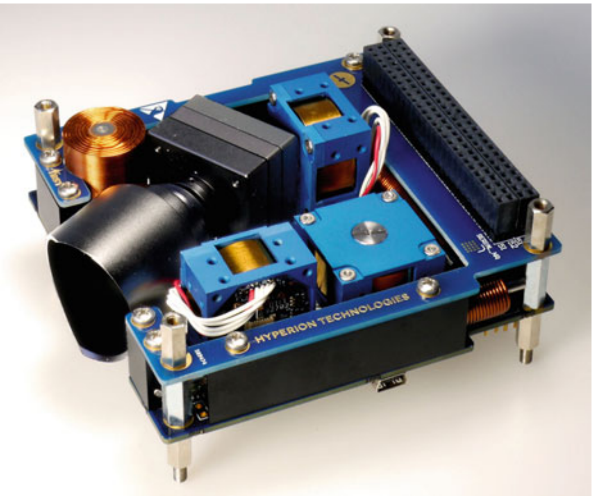

Fig. 25 iADCS100 integrated ADCS unit for 1 U to 3 U CubeSats (Hyperion)

pointing accuracy and stability of small satellites are approaching the performance previously possible only on large satellites. With the improvements in ADCS, more challenging applications, e.g., as found in space astronomy, can now be implemented on small satellites only limited by the payload mass, volume, and power requirements.

Research and improvements in small satellite propulsion systems (e.g., pulse plasma thrusters – PPTs) and accurate, agile actuators (e.g., control moment gyros – CMGs) are still required to further expand their future ADCS capability. However, missions requiring formation flying and large constellations of small satellites are becoming a current reality due to the lowering of costs and the increase in ADCS performance now possible.

Power Systems for Small Satellites

Joseph N. Pelton and Scott Madry

Contents

Abstract

The satellite power system is a vital component of all satellites and involves a number of parts. All of these parts play an important role in the success or failure of a small satellite mission. Since electrical power systems have been around since the beginning of the space age, and their function has been well established,

this part of a satellite design for this reason might be taken for granted. It also may be outside the expertise of cubesat builders with limited experience. This is a serious problem, as many telecommunications systems, on the ground or in space, often fail due to a power failure. This can be not only because the power generation or storage system fails but for other seemingly mundane factor such as a simple short in a wiring system that causes a satellite to fail due to a lack of critical power supply or even an electrical fire that destroys the entire satellite. Other sources of failure can come from as simple a problem as the leads from solar cells or photovoltaic cells failing due to contamination or oxidation that creates an overall power failure for a satellite. Experience over the years have confirmed the need to carefully design, manufacture, and test all aspects of a satellite's electrical power system in terms of safety, resilience, and lifetime performance. This important work is often overlooked or minimized in cubesat projects.

This chapter discusses all aspects of electrical power generation, an electrical power distribution system, power storage, and effective design of an electrical power system for all types of satellites that range from a femtosat (10 to 100 grams), a picosat (100 grams to 1 kg), a nanosat (from 1 kg to 10 kg) that includes cubesats, a microsat (from 10 kg to 100 kg), and a minisat (from 100 kg up to 500 kg in some definitions and from 100 to 1000 kg in others). The point is that power systems can command a good deal of the mass and volume of a satellite regardless of its size, and thus the power-to-mass ratio is important in satellites designs and especially so in the case of small satellites. Different approaches to power can thus be taken for different types of small satellites depending on their mission, lifetime requirements, and overall mass and volume. Finally, this chapter seeks to provide information developed by NASA and other objective sources about the suppliers of critical elements of an electrical power system for small satellites and especially with regard to solar power cells and power storage units.

1 Introduction

The overall design of a small satellite is largely driven by its power budget. This is because it is not atypical for one-third of the overall mass of a spacecraft to be related to its power supply and electrical systems. This is especially true if the spacecraft is being designed to have a sustained lifetime that lasts for a number of years. The application also drives the power requirements, and many satellites require significantly larger power systems than others. It is a mistake to look at the design of a small satellite's electrical power system as simply choosing which solar cells to select or which batteries to purchase. The equation is more complex than this. One should start with the key basics of the small satellite's mission; the smallsats intended lifetime; the orbital configuration in terms of whether it is a LEO, MEO, or GEO orbit; and other parameters. This will fundamentally drive your understanding of the mission objectives and parameters that will define what type of power system is required for your specific needs and budget.

If it is to be a telecommunications or networking mission in low Earth orbit with at least an 8-year lifetime and a particular throughput objective, then this can next allow a reasonable design process for the spacecraft. This initial set of objectives can next lead to developing a reasonable concept as to antenna design as required by the mission, as well as the power requirements, the fuel and thruster system to support the intended lifetime, etc. If it is to be a remote sensing or data analytics project, then there is a need to define basic objectives for revisit times, level of sensor resolution and types of sensors, data storage and data transmission, projected satellite lifetime, and more.

Again, these mission goals and objectives will lead to a clear system definition that can produce a better understanding of the type of satellite to be designed. This includes the power requirements needed to complete the intended mission. In short, one does not start with power requirements. Rather mission goals and resulting design features will serve to define the acceptable boundaries of the power system and clarify its various design features.

On one end of the scale, a short experimental project with a limited lifetime and minimal transmission requirements might result in a single-use primary battery that might be sufficient to provide the needed power until the battery is exhausted and solar cells or other power generation capabilities may not be needed at all. Operational missions with extended lifetimes will clearly require rechargeable batteries, on-board power generation, a process for discharging and maintenance of batteries, a monitoring function to observe the performance of batteries, solar cells, computers, and much more. The redundancy requirements must also be considered.

Overall, the mission objectives will drive the power system design. A radar satellite system that uses active sensing and thus the ability to release power from the spacecraft that can be reflected back to the space will clearly require more power and internal shielding than a passive system that simply analyzes light reflected back from the sun. Active RADAR satellites were famous in the early days of the space era for frying themselves due to the large power pulses required. Early Soviet military RADAR satellites were even powered by nuclear systems to meet these power requirements.

The key elements that designers of the mission will have to consider are (i) power generation; (ii) power storage; and (iii) overall electrical power grid and distribution requirements for the satellite payload (or payloads), as well as for the operation of the satellite bus. The power system design will tend to be different depending on the nature of the mission goals and objectives and clearly different for different types of satellites from the smallest of femtosats (or chipsats), up to the largest of minisats that might be as large as 500 kg or even 1000 kg.

Currently, a large percentage of small satellites have power generation capability and rechargeable batteries. cubesats on up tend to have such a capability. Even pocketqube systems at one-eighth the size of a 1-unit cubesat still have at least four solar cells and operate with a rechargeable battery. One chipsat or femtosat tends to have a single-use primary battery such as might be used in a wristwatch.

Thus, this discussion will start with a consideration of power generation and the predominant form that is used in most small satellites – namely, photovoltaic cells or, as they are more generally known, solar cells.

2 General Approach to the Design of a Small Satellite

There are actually several possible approaches that might be taken with regard to the design, assembly, integration, test, and launch of a small satellite project. One might be planning to design, build, and deploy a very large constellation of small satellites. In this case of an industrial applications project, one might create a vertically integrated system that creates all of the capabilities in-house and proceed to design and build perhaps hundreds or thousands of small satellites in-house. This is the case with SpaceX, Planet, and Spire, for instance. Another approach for an industrial satellite project would be to contract with an overall contractor that will obtain components, either to precise technical specifications or performance characteristic, and manufacture the small satellites for delivery for launch.

In the case of more individualized small satellite projects, one might obtain a complete kit for an entire small satellite from a vendor such as Pumpkin, or in the case of a larger and more sophisticated supplier, from some experienced entity such as Surrey Space Technology, Ltd. The other approach is to custom design and integrate all of the subsystems of a small satellite project in-house. The organization known as Innovative Solutions in Space (ISIS) operates a web-based Cubesat Shop. This is marketed as webshop for cubesats and nanosats and offers over 100 products associated with small sat projects. This website is broken down into the multiple parts or subsystems. These subsystems include antennas, attitude actuators, attitude sensors, cameras and payloads, command and data handling, communications systems, cubesat kits and buses, cubesat structures, ground stations, ground support systems, integrated attitude determination and control systems (ADCS), launch adapters, propulsion and pressurization, software services, solar panels and power systems, and training and simulators. Under these 16 categories, one can find multiple suppliers that correspond to each of these project subsystems. If one is new to the small satellite project area and wants assistance and guidance with regard to all these areas, the cubesat shop can be a useful source of information and guidance to legitimate and qualified suppliers from around the world (ISIS-cubesat Shop 2019).

3 Power Generation for Small Satellites

Although there are some small satellites that might use radioisotopes as a power source, such as planetary probes, and there are some missions that operate with a single-use non-rechargeable battery, these are only a minor exception to the general rule that most small satellites use solar cells to generate power and rechargeable batteries to store energy for the times when the spacecraft is in eclipse. The orbital parameters, including the period of solar eclipse, are vital parameters in the choice of these components.

4 Solar Cell Systems for Small Satellites

Solar cells, or photovoltaic cells, have been used to generate on-board power for satellite from the start of the space age. Consistent progress has been achieved over the decades to improve the efficiency of this technology in their ability to convert the energy from solar radiation into useful electrical power. At the start of the space age, these cells used amorphous silicon and typically had an efficiency of conversion of only about 10% to 13%. Today single P-N junction solar cells used in many solar panels for generating electrical power for homes and offices on Earth perform at comparable levels. Improved performance solar cells that use multiple junctions to capture energy at higher energy levels up to even the ultraviolet spectrum of energy are progressively more efficient, but also more expensive. A depiction of a positive-type to negative-type silicon junction that creates an electron flow is shown in Fig. 1.

The relatively higher performance of multi-junction solar cells that can capture energy at the higher energy green, blue, violet, and even ultraviolet spectra can clearly generate more electrical energy. There has been a careful study undertaken by NASA scientists to identify high-efficiency solar cells that use multi-junction photovoltaics and also solar cells that use high valence number and more efficient semiconductors using materials such as gallium arsenide, germanium, etc. to create

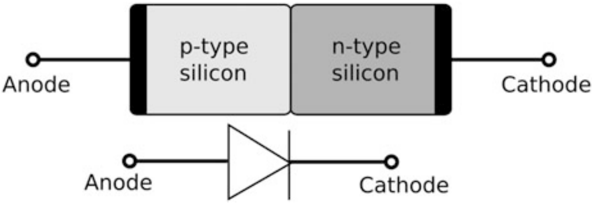

Fig. 1 Depiction of P-type/N-type silicon solar cell configuration. (Courtesy of Global Commons Raffa Maiden By Raffamaiden – BY-SA 3.0, https://commons.wikimedia.org/w/index.php?curid=21285768)

performance efficiencies that are generally in the 26% to 34% levels. The results of these comparative studies are shown in Fig. 2 (NASA, State of the Art, 0.3 Power 2019).

A brief listing of different solar cell manufacturers and some of the key performance characteristics of their solar cell offerings are provided in Annex 1 at the end of this chapter (Table 1).

The convenience of solar panel designs which have been optimized for assembly integration and testing is not the only attractive feature. These panels can come with integrated magnetorquers for orientation and temperature and magnetometer sensors. In larger 3-units, additional integrated features can be integrated into the solar panel design as well. These panels can be obtained for side, top, and bottom cubesat designs. A 1-unit side panel as manufactured by DHV is pictured below. This unit is provided with wiring and connectors and is provided for around $1800 (US) and is available on order in about 4–5 weeks (Fig. 3) (DHV Technology 2019).

More demanding nanosat missions with higher electrical power system requirements can employ not only cubesat panels but deployable solar panels to increase the available electrical power supply. Deployable solar panels are more expensive and are only recommended in cases where the smallsat mission has greater energy needs to perform its intended mission. Below is a series of deployable arrays by EXA (Fig. 4).

5 Electric Power System Design and Wiring

There needs to be a systematic way to supply power to components of a small satellite with associated battery packs. This is a critical part of a small satellite design, assembly, integration, and testing process. Power failures, degraded solar cell performance, wiring disconnects, circuit breaker mishaps, switch-related problems, and other aspects of a satellite's overall power system that can fail represent a large portion of satellite failures of all types – large, medium, or small. Once in

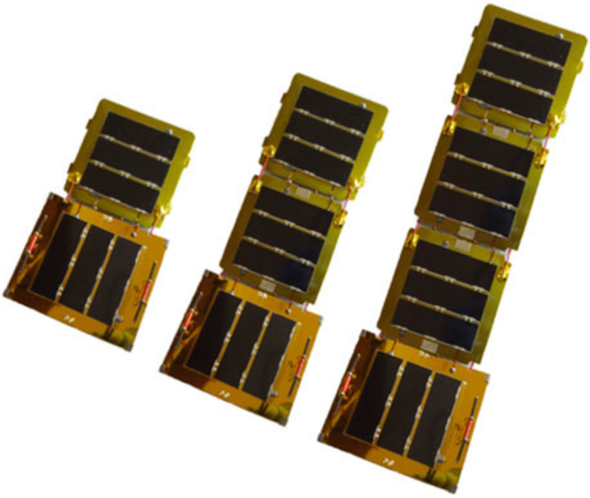
Fig. 4 Deployable solar array by EXA for high-power missions. (Graphic courtesy of EXA)



space, it cannot be understated that space is a hostile environment. Solar radiation and coronal mass ejections from the sun can and do lead to satellite failures by knocking out the power system. Circuit breakers and the ability to power down a satellite during a major solar storm event are something that large and more expensive satellites have as normal part of their operational routine. Small satellites should be operated with similar concern for these solar radiation and ion blast events from the sun.

One of the systems marketed via the cubesat store is the Crystalspace P1U EPS. This is a compact power supply with battery pack configured for both 1-unit and 2-unit cubesat configurations. This particular product includes a “fast maximum power point tracking boost converter.” This is able to charge integrated doubled battery pack and provide power distribution as required for cubesat configurations. Battery output in the electrical power system is fed through duplicated converters. Depending on the type of system ordered and solar array capabilities, these electrical power systems can provide voltage outputs starting at 3.3 V and up to 12 V. Pinouts and voltage outputs can be custom ordered in order to accommodate specific user needs (cubesat shop, Crystal Space 2019).

Another option is the Endurosat Electric Power System that also provides two battery packs and the following additional features: (i) three solar panel channels in order to provide a channel for each of the cubesats’ three axes and six panel connectors (typically USB connectors unless otherwise specified); (ii) input voltage (per solar panel channel) up to 5.5 V; (iii) input current (again this is for each of the three solar panel channels) up to 1.8 amperes; and (iv) a full guarantee of performance warranty and up to 5 hours of technical support (Endurosat 2019).

There are many other electrical power systems available such as the electrical power system including rechargeable battery packs from ISIS and many other suppliers that can be found on the web and those noted at the end of this chapter. It is important to work with suppliers if there are issues related to the US International Traffic in Arms Regulations (ITAR) or other similar restrictions in other countries such as the European Commission requirements. For the most part, these do not apply to the smaller-sized energy systems.

6 Assembly, Integration, and Testing (AIT)

The key elements of small satellite power systems include solar arrays or solar panels, electrical power systems with regulatory systems for power distribution that include battery packs, electrical wiring, sun sensors for maximum illumination, and magnetorques that can assist with sun orientation. The final missing ingredient is the process known as assembly, integration, and testing (AIT). It is important that well-trained personnel operating in clean rooms (or in some instances "clean enough rooms") carry out this important process. A faulty or somewhat loose wiring or USB plug connection can easily be shaken apart from a vital connection during the dynamic loads encountered during launch. Microsats or minisats for commercial systems are typically tested on shaker tables to simulate the vibrations and so-called pogo effects that can occur during rocket launch operations. After assembly is complete and the small satellite is completely integrated, careful testing is highly recommended. In the case of deployable antenna and power arrays, it is important to check out both of these deployments. Thus there needs to be a careful assessment of whether the antenna deployment and solar array deployments do not complicate or hinder either deployment process. Training of personnel to carry out all of these steps precisely and with quality checks along the way is important. In the case of large-scale small satellite constellations, many of these steps are now completely automated, but the test and assessment are still largely done by trained personnel.

7 Conclusion

The careful design and assembly, integration, and test of the electrical power system (EPS) are a key part of being able to create, launch, and operate a small satellite mission successfully. There are many elements of a satellite project, and it is easy to lose sight of an important step where there are so many parts to the puzzle. This article only addresses the design, assembly, integration, and test of the energy subsystem of a small satellite bus and its payload. It should be remembered that a successful program must also consider the ground stations and the mission control aspects of tracking, telemetry, control, and monitoring (TTC&M) of a mission. If there is a power failure in the ground segment, the mission could be lost in this way as well. Again power failures in the ground stations or the mission control are the most common types of problems that can and do occur in operational satellite systems.

The good news is that there are now many suppliers of small satellites. There are organizations such as Pumpkin and ISIS that can provide a complete cube satellite for launch and also assist with a launch services integrator that can arrange for a launch and launch registration and other administrative and regulatory arrangements from soups to nuts. Many cubesat and even smaller picosat (i.e., pocketqube) projects are training and learning exercises, and thus such projects tend to involve the design, assembly, and integration of all of the key subsystems in order to create an in-depth educational experience. It is important to consider the balance between gaining experience and education on one hand and assuring that "practical" quality assurances and mission goals are fully met on the other. Is this an educational, professional research, or business project? This is a fundamental question to be answered.

It is important to learn and understand about each and every subsystem and component that is essential to a small satellite programs' success. To recap, these elements include (i) antennas; (ii) attitude actuators; (iii) attitude sensors; (iv) cameras and payloads; (v) command and data handling; (vi) communications systems; (vii) cubesat kits and buses; (viii) cubesat structures; (ix) ground stations; (x) ground support systems and mission control; (xi) attitude determination and control systems (ADCS); (xii) launch adapters; (xiii) propulsion and pressurization; (xiv) software services; (xv) solar panels and power systems; and (xvi) training and simulators. Of all of these "parts" of a mission, a reliable, high-efficiency, and well-managed power system is well up there in terms of being a critical aspect of the mission with many single point-of-failure considerations and vulnerabilities.

Annex 1

Photovoltaic Cell and Solar Array Suppliers

There are a growing number of global suppliers of solar cells and complete solar arrays that include the solar cells with the integrated struts for ready deployment in space. Some manufactures such as Spectrolab can provide either individual solar cells or the fully integrated solar array. Research projects around the world are seeking to drive efficiency up about the current highest levels of around 45%. These research activities are exploring new high valence substrate and absorber materials, spectrum matching techniques, as well as lower-cost fabrication and new production techniques such as the IMM cell that uses metamorphic multi-junction manufacturing techniques. The following listing of multi-junction solar cell and solar array manufacturers is indicative of some of the well-known and tested suppliers.

Representative Photovoltaic Cell Manufacturers

Azur Space

This is a supplier of multi-junction solar cells that are typically triple-junction in design. These cells use a combination of gallium arsenide, germallium, and GaInP materials, and they achieve an efficiency of solar radiation to electrical energy output in the range of 28% to 30%.

Bharat Electronics Ltd. of India

Bharat Photovoltaics has developed its manufacturing capabilities in cooperation with the Indian Space Research Organization (ISRO). ISRO has licensed solar cell and solar panel technology from other suppliers in the USA and other countries and then partnered with Bharat Electronics Ltd. to create a lower-cost supply to the Indian market. Bharat can supply both solar cells and solar panels. These products include monocrystalline, polycrystalline, and thin-film solar cells. It also provides inverters, mounting systems, solar cables, as well as complete photovoltaic systems, terrestrial power systems, as well as satellite applications.

CESI/ENE

The CESI single-junction gallium arsenide solar cells that are deposited on a germanium wafer by ENE are thicker than some three-junction solar cells, but this lower-cost photovoltaic cell can provide a 20% efficiency under the AMO spectrum rating system. This type of cell has been used by the Surrey Space Technology Ltd for small satellite manufacture. Triple-junction solar cells with efficiencies around 27% are also available from these Italian and Belgium teams.

Emcore Corporation

Emcore also manufactures triple-junction solar cells in two different versions. The efficiency of solar energy conversion for these solar cells is typically in the range of

28.5% to 29.5%. Emcore cells are provided in standard sizes but can be provided to custom order in different sizes as well. NASA has used these cells on their own missions.

SolAero Technologies

SolAero Technologies is unique in that it is a collaborative effort with the US Air Force. SolAero Technologies and the USAF are currently developing a new type of cell known as the "metamorphic multi-junction (IMM)" solar cell. This special manufacturing technique has resulted in a lightweight and higher-efficiency cell that is in developmental testing. Current SolAero cell have an efficiency level in the 28% to 30% range. They offer at least four optional solar cell products with ZTJ cell having had extensive in-flight experience. The ATJ, ATJM, and BJT cells are particularly offered to support small spacecraft missions.

Spectrolab

This company has been one of the oldest and most comprehensive providers of solar cells as well as integrated solar arrays. There solar cells range in efficiency from 26% to 30%. The most common products by Spectrolab are the XJT Prime, XTJ, and UTJ solar cells. They are offered in standard and customized sizes. All of the Spectrolab's solar cells are also of the triple-junction design. The UTJ devices are rated at TRL 9 spacecraft applications.

Umicore

Umicore is another provider of triple-junction solar cells. It has been providing high-quality solar cells since the 1990s. Its solar cells with triple N-P junctions or bandgaps for its solar cells consist of indium gallium phosphide (InGaP), indium gallium arsenide (InGaAs), and germanium (GE) layer. These cells are made using a metal-organic chemical vapor deposition (MOCVD) process whereby the InGaP and InGaAs are deposited on germanium wafers. These solar cells have been demonstrated above 30% efficiencies under the AMO spectrum rating system.

Solar Panels and Array Manufacturers

Many of the companies that produce solar or photovoltaic cells also produce solar panels and arrays. In some instances, these panels also include magnetorquers, sun sensors, temperature sensors, and other features. Here are some of the typical providers of high-quality solar arrays from around the world. This is not an exhaustive list, but it includes many of the leading suppliers.

AAC Microtec and Clyde Space

The AAC Clyde Space photon solar arrays and solar panels are optimized to provide power to cubesat and multiple units of cubesats. These systems are designed to provide a high level of power generating efficiency by providing panels that can be position on the long sides of cubesats. If additional power is required, it is possible to have deployed, extendable solar arrays. These panels and arrays are designed to provide convenience in achieving reliable platform integration. Spectrolab XTJ Prime solar cells are typically included on AAC Clyde solar panels and arrays (AAC Clyde Space 2019).

Bharat Electronics Ltd.

See as noted in above information.

DHV Technology

DHV is one of the leading providers of solar panels and arrays. Its website maintains that it has participated in over 50 projects, that 35 satellites are currently utilizing its arrays and panels, and that this adds to some 1700 days of successful operation in space.

Endurosat

Endurosat makes several versions of solar panels. These are of a triple-junction indium gallium phosphide/gallium arsenide/germanium design and the solar cells used in these panels rated to 29.8% efficiency. The panels are of the 1-unit and 3-unit design, and their respective masses are 0.04 kg and 0.155 kg, and this includes a magnetorquer in the configuration. Maximum cell voltages are 2.33 V per cell (Endurosat, Solar Panels 2019).

EXA

The EXA DSA/1A (Titanium Deployable Solar Array for 1 U) is the entry-level product of a family of deployable solar arrays based on artificial muscles for cubesats in the range of 1 U to 6 U. The arrays are composed of five panels, 3 on top and 2 on the bottom, that are attached to the cubesat structure. Available on request are deploy and release contact sensors and also custom options such as sun and temperature sensors. Seven panel configurations are available for very high power missions.

GomSpace

GomSpace, which can undertake complete small satellites, is able to provide two different power systems for cubesats. These both use 30% efficient cells. These units are designed to include a magnetorquer, sun sensors, and gyroscopes. The customizable panels have a maximum output of 6.2 W and 7.1 W, respectively. Cubesat panels can be ordered with an integrated magnetorquer with only a slight mass addition. The 1-unit cubesat panel produces 2.3–2.4 W.

Innovative Solutions in Space (ISIS)

MMA Design, LLC

MMA's latest solar panel design is known as the rHaWK. It seeks to provide for high kW/m^3 solar electrical power production plus longer life, a high level reliability, through new manufacturing techniques significantly lower mass and volume. At the beginning of life, the MMA rectangular rHaWK solar panel can normally produce up to 90 kW/m^3 and at 28 °C over 150 W/kg. The efficiency rating for the solar cells used in the array is currently based on a configuration of the array at 29.5%. The lower-cost ZTJ cells produce 80 kW/m^3 and 130 W/kg at the beginning of life. MMA arrays have been used by both the US Air Force and NASA (MMA Design LLC 2019).

NanoAvionics

The solar panels provided by NanoAvionics are designed for 1-unit to 3-unit cube satellites. This array uses an epitaxial structure. These cells use a combination of gallium indium phosphide, gallium indium arsenide, and germanium for its structural makeup. Its solar panel efficiency is rated to be very close to 29%.

Small Satellite Antennas

Kiruthika Devaraj

Contents

Abstract

Antennas are an integral part of the satellite radio communication and navigation system that enables the transmission and reception of electromagnetic energy through free space. The small satellite size, volume, thermal, and material constraints pose a special challenge to the antenna system, and the antenna design is as much a challenge for radio engineering as it is for mechanical/structural engineering. Many new techniques including novel packaging solutions, deployment structures, 3D printing, and advances in the commercial printed circuit board technology have helped to tremendously reduce the volume and mass of antenna structures so they can be integrated on small satellites. Over the last decade, many novel and compact antenna solutions have been developed for small satellites that have enabled the small satellite radio communication systems to compete with much larger class satellites. This chapter presents an overview of the antennas that are most commonly used on small satellites and presents some recent examples of commercial small satellite antennas.

Gain · Beamwidth · Bandwidth · Cross polarization · Axial ratio · Omnidirectional · Isoflux · Tracking · Telemetry · Command (TTC) · Monopole · Dipole · Patch · Helical · Reflectarray

1 Introduction

Over the last 20 years, mission enabling technologies such as radio systems and antennas have become mainstream, and there has been a surge of activity in various types of small satellite missions – including Earth Observation satellites (such as Planet Labs Inc., Spire, Iceye, Capella Space), communication satellites (such as Starlink, Oneweb, Kepler communication, Lynk), and Internet of Things (IoT) satellites (such as Myriota, Astrocast, Fleet Space, Eutelsat, Swarm Technologies). The capabilities and performance of some of these small satellite communication systems are on par with larger form factor satellites.

Recent advances in 3D printing/additive manufacturing, material science, and commercial printed circuit technology have yielded a number of compact and highly performing antenna solutions that enable these newer classes of missions from a very small form factor platform. Some of these small satellite antennas have flown on over 300 satellites and established contact reliability on Planet's Dove satellites (https://www.planet.com/pulse/planet-openlst-radio-solution-for-cubesats/). Some other antennas have demonstrated impressively high gain, such as JPL's ISARA reflectarray with 33 dBi gain (Hodges et al. 2018). One of these antennas has even made it to deep space orbiting Mars and relaying data back to Earth on the MarCO satellite (Hodges et al. 2017).

1.1 Antenna Requirements

The requirements posed on the antenna subsystem can be split into internal performance requirements and external system requirements.

1.1.1 Performance Requirements

Frequency of Operation

Frequency of operation is set domestically in the USA by Federal Trade Commission (FCC) and internationally by the International Telecommunication Union (ITU) regulations.

Bandwidth.

Antennas need to maintain their performance (gain, beamwidth, and axial ratio) over a specific bandwidth. The actual use case will dictate whether a wideband or narrowband antenna is used. For instance, Tracking, Telemetry, and Command (TTC) radios traditionally are low data rate. Because of this, a narrowband antenna such as a dipole or patch antenna with ~1–3% fractional bandwidth is adequate. The payload radio, however, typically needs a high data rate. Depending on the fractional bandwidth requirements, which may be higher than 10%, broadband antennas such as deployable reflectors, horn antennas, or helical antennas are used.

Polarization

Radio waves passing through the Earth's ionosphere are subjected to Faraday rotation effects where the left and right hand circularly polarized waves propagate at slightly different speeds. Since a linear polarized wave is made up of two equal-amplitude left and right circular polarized components, a relative phase shift is introduced which ends up rotating the orientation of linear polarization. This effect is proportional to the square of the wavelength. While this effect is pronounced with very-high-frequency (VHF) and ultra-high-frequency (UHF) bands, it rapidly diminishes at higher frequencies such as X-band and above. Second, if a linear polarized antenna were to be used on a satellite, the satellite antenna orientation would need to constantly be maintained with respect to the ground antenna orientation during a ground station pass. This would add additional complications to the pointing and tracking requirements of the satellite.

To avoid the complications that linear polarized antennas pose, most satellites use left or right hand circular polarized antennas. These circularly polarized antennas need good cross polarization (cross-pol) discrimination between the two polarizations. Cross-pol is nominally specified as the Axial Ratio (AR) – which is the ratio between the semi-major and semi-minor axis of the polarization ellipse. A rule of thumb is for a single transmit system to have cross-pol levels of about 15 dBc (AR ~3 dB). Some special dual polarization transmit/receive systems that need a high signal to noise ratio for high order modulation (like 32APSK or higher) will need very high cross-pol discrimination of 25 dBc (AR ~ 1 dB), which helps improve the signal to noise ratio.

Efficiency

Satellite antennas require high efficiency so as to optimally utilize the radiation aperture. This requires, depending on the type of the antenna, a combination of the following:

- Low loss tangent materials
- Low surface roughness
- Low loss feed networks
- Optimal taper
- High cross polarization isolation
- Low spillover

Beamwidth and Gain

The mission system needs imposed on the antenna subsystem affect whether a broad beamwidth antenna with low gain, or high gain antenna with narrow beamwidth, is chosen. TTC antennas need wide coverage, so low/medium gain antennas such as dipoles or monopoles, and sometimes patch antennas are used. Payload antennas need high gain, so narrow beamwidth is acceptable since the satellite is either mechanically or electronically steering and continuously pointing and tracking the ground station during a pass.

1.1.2 External System Requirements

Some external requirements are imposed by the fact that these antennas are integrated on a small satellite platform. They also need to survive launch, operate in a space environment, and operate with other subsystems. These subsystems include:

High Reliability and Robustness

- The antennas need to survive the shock and vibrations of the launch environment.
- The antenna deployment mechanism, if any, should work with very high reliability since deployment failure could mean the end of a mission.
- Space poses extreme thermal and vacuum challenges and the antenna performance should not degrade under vacuum conditions or repeated extreme thermal cycling.
- The antenna should withstand space environmental effects including surface erosion from ultraviolet radiation and atomic oxygen, surface charging from space plasma, and structural damage from micrometeoroids. Active antennas should also withstand total ionizing dose and single event upsets from radiation.

Low SWaP (Size, Weight, and Power)

- Size: Small satellites have a very small volume available, so antennas are typically small form factor or need to be packaged in a small volume and deployed on orbit.
- Weight: Along with size, mass is also a limiting factor on small satellites because launch costs are constrained by mass and volume. Using light weight material is key to reducing total antenna mass.
- Power: For small satellite antennas, power is another constraint and certain steps could be taken to reduce total power consumption. For instance, a high efficiency power amplifier could be placed very close to the antenna or integrated into the antenna feed structure so as to avoid long cables and associated losses. The RF power could be reduced and a higher gain antenna could be used or vice-versa so that the effective isotropic radiated power (EIRP) stays constant.

Location Constraints

- Physical location: Antennas need to be physically located on the body of the satellite such that they are optimally utilized. For instance, on a low-Earth orbit (LEO) satellite, the GPS antenna should be mounted on the zenith facing side and the payload antenna should be mounted on the nadir facing side.
- Radiation surface: Depending on the frequency of operation, the entire satellite could become a radiator or ground plane, so antenna analysis and measurements should be done on the integrated spacecraft structure.

Other Constraints

- Multipaction: Under vacuum conditions, an electron avalanche effect called multipaction (multiple + impact) can occur, leading to intermittent disruption in communication subsystems and added noise. This occurs primarily in resonant structures such as cavity filters due to very high voltages of hundreds of thousands of volts in those structures. However, at RF frequencies, depending on the geometry of the structure and frequency of operation, this effect can occur at power levels as low as 5 W.
- EMI: In small satellites, electromagnetic interference (EMI) and self-interference issues need to be considered to ensure that one transmit antenna does not interfere with a sensitive receive system.

1.1.3 Feed Network

The feed network is an integral part of the antenna design, especially for high gain antennas that use antenna arrays. The feed network ensures that the electromagnetic signal is directed to and from the antenna with low attenuation and low phase mismatch. An ideal antenna design will incorporate broadband feed networks so that bandwidth is limited by antenna radiation patterns or gain variations and not by the resonant behavior of feed network. Several impedance matching and bandwidth enhancement techniques are available to enhance the fractional bandwidth of the feed network, which is limited theoretically by Fano's broadband matching theory (Fano 1948). Appropriate phase matching of the feed elements is also required to ensure the antenna meets the cross polarization requirements. For example, aperture coupling for patch antennas improves the bandwidth. For antenna arrays, quadrature hybrids and wilkinson power dividers provide phase matching as well as improved bandwidth.

When an antenna is chosen for a specific mission, its feed network should also be considered, such that the combined antenna/feed network pair maximizes the radiation efficiency and meets all the other performance and external requirements provided above. For instance, a large passive patch array might be less efficient compared to a passive reflect array if the dielectric transmission line losses dominate compared to reflectarray aperture losses. A reflectarray may be less efficient compared to a waveguide slot array, especially at high frequencies such as Ka-band, since the effects of feed positional or angular misalignments are more pronounced at higher frequencies. Some antenna arrays, such as radar antennas, may require specific amplitude and phase weighting to the individual elements so a very specific beam tapering or side lobe level can be achieved.

1.2 Antenna Types

A typical small satellite requires multiple antennas including Tracking, Telemetry, and Command (TTC) antennas, payload antennas, and Global Navigation Satellite System (GNSS) antennas. Additional antennas may be needed for certain missions like radar antenna for radar missions or antennas for intersatellite links. Each of these

Fig. 1 Four types of small satellites used on commercial satellites for the TTC systems

antennas has very different sets of requirements from each other. The TTC antennas are typically omnidirectional so that communication can be established with the satellite at all satellite attitudes or pointing modes. The GNSS antennas are typically hemispherical beams that allow for maximizing the number of available GNSS satellites. The payload antennas by contrast are narrow beam antennas with very high gain.

1.2.1 TTC Antennas

TTC radios and antennas need to possess very high reliability since their malfunction could mean the end of a mission. TTC antennas are typically omnidirectional so communication can be established with a satellite under all attitudes or pointing modes. If a single antenna cannot provide near spherical beam coverage, multiple spatially separated antennas are combined or switched to provide an omnidirectional pattern. The TTC frequency bands include VHF, UHF, S, X, Ku, and Ka bands. The data rates of a TTC radio are very low and bandwidth or cross-polarization requirements are not very demanding. At VHF and UHF bands, monopole and dipole antennas are typically used. At S, X, Ku, and Ka bands, patch, helical, horn antennas are used for TTC. Some examples of commercial TTC antennas used on small satellites are given in Fig. 1.

1.2.2 GNSS Antennas

GNSS antennas typically have hemispherical beam patterns. On LEO cubesats, GNSS antennas are mounted on the zenith facing direction so as to maximize the number of GNSS satellites in view of the antennas. Many small satellites have two GNSS antennas (which are most typically GPS antennas). They are often mounted

on opposite sides of the spacecraft, to get positional and timing knowledge under all spacecraft attitudes. Recently, commercial multiple-band GNSS antennas have been made readily available and provide improved positioning accuracy as well as redundancy in frequency. Two examples of GNSS antennas used on small satellites are provided in Fig. 2.

1.2.3 Payload Antennas

High gain antennas have a narrow beamwidth and require accurate pointing. When tight pointing requirements cannot be met, like with cubesats, a medium gain antenna with ~10–12 dB gain is used for downlinking payload data and high rate telemetry. Some medium gain antennas have an isoflux pattern to compensate for

slant range variations. NASA satellites Aqua, Terra, and Aura have isoflux payload antennas. On satellites that have very high data rate and bandwidth needs, it is necessary to use high gain, narrow beamwidth antennas as payload antennas. Whereas big satellites have been historically using large parabolic dish antennas, Fig. 3 provides recent examples of very compact, high gain payload antennas that have flown recently on small satellites.

2 Summary

Any small satellite antenna design should first and foremost start with the mission and satellite requirements. The system link budgets need to be appropriately allocated between the RF power amplifiers, satellite antenna, and the ground station. The satellite attitude control system, timing precision, and ground station tracking systems need to be designed appropriately to meet the pointing and tracking of the antenna beam. Once the antenna design requirements like frequency, bandwidth, gain, beamwidth, cross polarization, and sidelobe levels are established for the mission, an appropriate antenna type is chosen in collaboration with mechanical, structural, and reliability teams. Appropriate electromagnetic solvers such as ANSYS high frequency structure simulator (HFSS), Keysight Advanced Design Systems (ADS), TICRA GRASP, or CST should be used to simulate the antenna performance as a standalone unit and integrate on the satellite structure. The feed network needs to be co-designed with antenna to ensure appropriate impedance and phase matching to the antenna's elements. During fabrication, a good understanding of the material properties and the implications of manufacturing tolerances, stackup issues, and alignment errors will reduce mistakes and the need for multiple manufacturing iterations of the design. Some of these issues such as dielectric tolerances and surface roughness can be simulated a priori, and their effects can be understood before manufacturing begins. After fabrication, antenna characterization is done by measuring return loss with a vector network analyzer, while the antenna beam pattern is measured with a far-or near-field chamber. Gain, cross-polarization, and side lobes should also be measured for the antenna as a stand-alone unit, and after integration on a satellite. For deployable antennas, multiple deployment tests should be conducted and any variations in antenna performance should be measured. If there are large variations during the multiple deployment test, mechanical design tolerances should be revisited. Finally, the satellite should be operated under different operational modes by turning on various subsystems there no longer have EMI implications for the radio.

In conclusion, a broad overview of small satellite antenna design guidelines and recommendations are provided in this chapter, along with some recent examples of small satellite antennas that have flown on recent missions. Small satellite antennas represent both a strong mechanical and structural engineering challenge as well an electromagnetic engineering challenge.

Small Satellite Radio Link Fundamentals

Matt Ligon

Contents

Abstract

Small satellite radio systems often face link power budget, mass and volume constraints and restrictions. Additionally many small satellite systems are developed by student groups or start-ups with limited development resources. These challenges can be addressed utilizing commercial off the self (COTS) industrial solutions. Practical implementation of satellite links utilizing basic link theory and industrial standards and products is discussed.

1 Introduction

The subject of the theory and design of satellite data links is covered rigorously in many texts, papers, and university courses. However, most of the available reference material often burdens the reader with excessive complexity and information that may not be necessary for a practicing engineer to plan and implement a working small satellite communication system. This text intends to sacrifice rigor for clarity.

A thorough study of the subject of radio communications is a big undertaking for the novice. What is provided here is a *minimally complex* and focused discussion on the *key concepts* needed for a student or practicing engineer to understand the full picture of a satellite link at the system level. This chapter outlines the basic theory followed by practical examples of radio hardware and systems. This primer will hopefully provide a solid foundation with which the reader can continue their research into more specific areas of interest.

1.1 Intended Audience

1.1.1 Students

Radio and communication system theory draws on many academic domains. Depending on academic focus, students will specialize in a specific domains like RF engineering, digital signal processing, digital communication, electromagnetics, network design, etc. This chapter aims to aid students in their understanding of the satellite communication system as a whole and provide the broad context and to work with a large-complex system. Demonstration of mastery of these general concepts will be very helpful for a student applying for an internship or entry level position.

1.1.2 System Engineers

Satellite system engineers may not have the specific radio communications domain knowledge to effectively understand communication system design trade-offs and effectively communicate with the domain experts they work with. Mastery of the concepts presented in this primer will be beneficial to those who need to achieve competency in the multiple domains of satellite system design.

1.1.3 Engineers Working on Specific Subsystems of Radio Communication Systems

Engineers working on communication systems often have a limited scope of their work. For example, engineers may develop expertise in antennas or power amplifiers or baseband processing, and this document provides the larger context to the system as a whole.

1.1.4 Start-up Founders

Satellite hardware start-ups whose founders who did not personally have practical communication system understanding will benefit from this chapter and have a working background to be able to perform basic system feasibility studies and be more effective in their hiring process.

2 RF Link Basics

A concise review of basic RF link theory is presented here. In a later section, practical hardware options will be introduced and discussed. The purpose of this text is to provide a high-level view of the satellite link design process. A solid grasp of the “big picture” is very helpful for initial feasibility analysis and early planning.

When approaching the problem of implementing a practical system for data transmission over an RF link, *three fundamental questions* need to be considered:

1. How much “signal power” enters the receiver?
2. How much “noise power” enters the receiver?
3. What level of throughput can be achieved given the ratio of 1 and 2 *(known as signal-to-noise ratio or SNR)*?

2.1 Signal Power

> *Antennas and their design are addressed in this section. This can be a complex subject but for the purposes of discussion all that needs to be understood is that an antenna is a device that transfers “guided” RF energy (energy traveling in a waveguide or coaxial cable) into “free space” radiation or vice versa.*

The determination of how much signal power enters a receiver over a free space link is a *simple geometry problem*.

2.1.1 Transmitting with an Isotropic Radiator

First consider a conceptual (but not actually realizable) antenna known as an “isotropic radiator.” Such an antenna when fed some input transmit power P_T will produce a spherical wave front at distance R with P_T spread evenly across the surface of the sphere.

The surface area of a sphere is given by

$$A = 4\pi R^2 \left(\mathrm{m}^2\right)$$

The "power density" at some distance "R" is thus

$$\frac{P_T}{4\pi R^2} \left(\mathrm{W/m}^2\right)$$

Transmit Antenna

In reality it is impossible for a radiator to produce radiation that is equal power in all directions if such a property was desired. Also, it is often desired to focus the energy such that the power density in some direction is much higher than that of the *isotropic radiator.*

The ratio of the power density produced by an antenna relative to that of an "isotropic" radiator is the "antenna gain" (G_T).

> *An antenna with a gain >1 does not actually output more total energy than it receives at its input. It focuses the energy instead of radiating evenly in all directions. Antenna gain should not be confused with the term "gain" used in the context of amplifiers.*

The "power density" at some distance R given the actual antenna with a gain G_T is given by

$$G_T \frac{P_T}{4\pi R^2} \left(\mathrm{W/m}^2\right)$$

Receive Antenna

At the location of the receive antenna, it is now known what the power density of the incident field is from the preceding equation. The receive antenna can be described as having a "capture area" or "effective aperture," in this case "receive effective aperture" for the analysis (A_R).

The receive power is thus given by

$$P_R = A_R G_T \frac{P_T}{4\pi R^2}$$

2.1.2 Antenna Gain and Effective Aperture

Gain and effective aperture are two equivalent ways to describe how well an antenna focuses energy. Conceptually for the purposes of link analysis, it is easier to think of a transmit antenna in terms of gain and of a receive antenna in terms of aperture.

However, these properties are identical whether the antenna is used in either a transmit or receive configuration, a property known as “reciprocity.”

The relationship between gain and aperture is given by

$$A_E = \frac{\lambda^2}{4\pi} G$$

A derivation of this property can be found in Balanis (2005)

For certain types of antennas like reflector antennas or planar-phased arrays, the “aperture” is intuitive by inspection of the physical collector area. The “effective aperture” for a reflector is typically 60–70% of the actual area of the dish. For a planar-phased array, “effective aperture” can meet or exceed slightly the physical area. For other types of antennas, like a Yagi, the “aperture” is not obvious from the antenna construction.

The key takeaway from the aperture-gain relationship equation is that **for a given aperture, gain increases with increasing carrier frequency.**

2.2 Complete Link

The original receive power equation can be rewritten.

$$P_R = A_R G_T \frac{P_T}{4\pi R^2} \tag{1}$$

Using the aperture-gain relationship as two different equations utilizing either “aperture” or “gain”

$$P_R = G_R G_T \frac{\lambda^2 P_T}{(4\pi R)^2} \text{(this formulation known as Friis equation)} \tag{2}$$

$$P_R = A_R A_T \frac{P_T}{\lambda^2 R^2} \tag{3}$$

There is a **key insight** to be gained by examining the three different formulations of this equation, and these three different formulations of the same relationship describe three general classes of RF links:

1. Fixed aperture to fixed aperture
   Consider a point to point link between reflector antennas. The “aperture” of the antennas does not change with frequency. Equation (3) most directly represents this configuration. Note that “receive power” **increases** with increasing carrier frequency. This type of link is optimal for high throughput and benefits from high carrier frequencies. Links like these will often utilize carrier frequencies in the 10 s of Ghz to maximize throughput. A high throughput spacecraft radio system will generally fall under this category.

2. Fixed gain to fixed gain
   Consider a link between two low-gain antennas. Such a link is useful if communication needs to be maintained in any direction without pointing. Equation (2) most directly represents this configuration. Note that "receive power" **decreases** with increasing carrier frequency. An example of this sort of link would be radio or TV broadcast. Note that typical carrier frequencies for these purposes are no more than a couple of hundred Mhz.

   Ham radio operators operating in the "HF" band (3–30 Mhz) band routinely make contacts over thousands of kilometers with low-gain antennas and moderate transmit power levels. Long-range military communications also use similarly low-frequency links to reach extreme distances. The ionosphere aids this process by reflecting these signals allowing their path to avoid blockage by the curvature of the Earth.
3. Fixed aperture to fixed gain
   Consider a link between a ground-based dish and an omnidirectional antenna on a spacecraft. Such a link is beneficial because it does not rely on the spacecraft being able to point. Equation (1) most directly represents this configuration. Note that "receive power" **is independent** of carrier frequency. A low-speed TT&C (Telemetry, Tracking and Command) spacecraft radio will generally fall under this category since the spacecraft antennas are typically low-gain to provide attitude independent link closure.

> *The above simplified link equations do not include practical link impairments such as atmospheric absorption which is carrier frequency dependent.*

Later discussion will utilize these formulas in logarithmic form as it is more convenient to deal with the extremely large range of power levels dealt with and is the standard approach in practice.

> *An excellent discussion of the logarithmic representation of these sorts of equations and representations of system parameters can be found in Chapter 13 of the "Handbook of Satellite Applications" in the section Understanding Decibels* (Glover 2013). *It is recommended that the reader familiarize themselves with this section in order to follow later sections of this chapter which utilize logarithmic representations.*
> *Internet resources discussing the subject are also readily* available (Decibel Tutorial 2019).

2.3 Overview of Basic RF Satellite Link Calculations

Simple calculations using these concepts allow for quick feasibility and performance estimations for satellite link performance.

2.4 Concepts Not Discussed but Recommended for Further Study

- Antenna and wave polarization
  - Linear polarization
  - Circular polarization
  - Polarization matching
  - Atmospheric absorption

2.5 Noise Power

This section discusses how to determine the "noise power" that enters a radio receiver. As discussed in the introduction, it is the ratio of the signal power to the noise power that will ultimately determine the overall throughput that the link is capable of. The discussion will be limited to "thermal noise" or more specifically "Johnson-Nyquist" noise.

Examples of more complex forms of "noise" that may be encountered

- *Multipath reception, for example, GPS receivers in a dense urban environment receiving multiple copies of the signal at different power levels and phase shifts*
- *Self-interference from emissions from the spacecraft itself. For example, EMI or out of band emissions from other radios*

  SNR is often extended to SINR (signal-to-noise and interference ratio) to account for these sorts of issues.

2.5.1 Noise Power from Matched Resistive Source

Consider a matched resistive source (e.g., 50 ohm termination) connected to the input of the receiver. The power generated by the resistive source is generated by the thermal agitation of charge carriers.

The power entering the receiver (load) is given by

$$P_n = k_b T B \ (\mathrm{W})$$

P_n – Noise power (W)
k_b – Boltzmann constant ~ 1.38e−23 ($\mathrm{m^2 kg s^{-2} K^{-1}}$)
T – Temperature in Kelvin
B – Bandwidth over which power is measured (Hz)

Communication system analysis typically utilizes the bandwidth independent parameter **noise density**.

The total power is bandwidth times the noise density.

$$P_n = B N_0 \ (\mathrm{W})$$

N_0 – Noise density (W/Hz)

The “power density” of the noise can be calculated by dividing the power by the bandwidth

$$P_D = k_b T \text{ (W/Hz)}$$

Note that the power density for the transferred power from a matched resistive source is solely dependent on the physical temperature of the resistive device.

At room temperature (290 K), P_D= 3.73e−21(W/Hz) = −174 dBm/Hz

2.5.2 Noise Power in Real Receiver System

The previous section discussed how the noise power density from a resistive source is solely dependent on its physical temperature.

For a real receiver, it is customary and convenient to determine an “effective noise temperature (Te)” for the receiver system. This allows the calculation of the noise density by multiplying by k_b

$$N_0 = k_b T_E$$

2.5.3 Ideal Antenna

Consider an ideal antenna. Such an antenna has no losses, has a tight beam with no sidelobes and delivers all energy that it picks up to its feed with zero loss.

With an imaginary antenna like this, the “effective temperature” will be determined by whatever radiated sources it is pointing at. If we assume that the targets behave like “black bodies,” their physical temperature will be directly related to the output noise density by the $k_b T$ relationship. For the purposes of this discussion, it is assumed that the beam is narrow enough to only pickup radiation from the target (Table 1).

> *The sun is a convenient reference source for antenna characterization and performance validation* (Morgan 2018).

2.5.4 Real Antenna

A real antenna will suffer from sources of thermal noise other than the intended radiation that it is intended to receive. Consider a ground-based dish antenna used for communication with a spacecraft. Though it is pointed toward the “cold sky,” it will pick up energy from sources like the following:

1. Thermal radiation from the atmosphere
2. Thermal radiation from the earth picked up by sidelobes

Table 1 Temperature of some common radiative sources

Target	Temp (K)	$k_b T$ (dBm)	Notes
Deep space	2.7	−192	Cosmic background radiation
Earth	270	−174	Typical average earth temperature
Sun	5800	−161	Typical average sun surface temperature

3. Radiation from lossy (resistive) paths for the RF current
    (a) Losses on dish surface or antenna elements
    (b) Losses in the feed network and preselect filters

Resources on the subject can be found in (Lambert and Rudduck 1992; Gary 2019; Kraus 1988).

For the purposes of this discussion, a Te value of 100 K can be used which is typical for a ground-based dish pointing at the cold sky.

A space-based antenna which has a beam pointing toward the earth will have a Te value of around 300 K, the temperature from the earth and additional resistive temperature from loss in the antenna itself.

2.5.5 Low-Noise Amplifier

Any receiver system requires active and passive devices to condition the signal for reception. These contribute added noise. Dealing with this impairment is achieved by placing a **low-noise amplifier (LNA)** as close as possible to or integrated with the antenna feed. If the gain of the LNA is sufficiently high, the received signal and antenna/LNA noise will be significantly higher than any downstream noise sources and so can be discarded by them since the LNA will be the dominant source of amplifier noise.

Resources on the subject "cascaded noise" be found in (Kraus 1988; Noise Figure 2019).

The LNA noise performance is specified by a term called "noise figure."

The "noise figure" is the ratio of noise power out of the LNA to the thermal noise from a matched resistive source on the input. Since the thermal noise of a "matched resistive source" is temperature-dependent as discussed before, the noise figure is specified at a "reference temperature," typically 290 K.

The hypothetical 100 K antenna source is not delivering kb∗290 noise density, so the NF is not directly useful for the satcom example.

The "noise figure" can be converted to a "noise temperature" with the following equation:

$$T_N = T_{REF} * \left(10^{\frac{NF(dB)}{10}} - 1\right)$$

For example, if the LNA has a "noise figure" of 1 dB, the Te is 75 K.

Recall the hypothetical ground and spacecraft antennas and the 1 dB NF LNA. The total Te is simply the sum of the antenna Te and the LNA Te.

Ground receiver: Te = 100 + 75 = 175 K
Space receiver: Te = 300 + 75 = 375

The **key point** here in this particular link example is that the noise figure parameter has a larger overall effect on the performance of the ground-based system since the earth pointing antenna is picking up significant radiated energy from the earth. A high-performance earth-based antenna such as one designed for radio astronomy will benefit from exotic (and extremely expensive) cryogenically cooled LNAs, but an earth-pointing space-based communications antenna receives little benefit from a cryocooled LNA.

> *Most integrated dish systems will include the LNA with the feed, and the overall system will be specified with an aggregate Te including the effect of the LNA. This figure of merit is typically called G/T which is the antenna gain divided by Te.*

2.6 Overview of Noise Considerations

When analyzing satellite RF links, the received "noise density" needs to be determined. This is a combination of noise picked up from unwanted radiated sources as well as internally generated noise in the LNA. It is most convenient for satellite links to calculate overall noise sources for the purposes of analysis as an "effective temperature." The overall "noise power" is calculated by multiplying the "noise density" by the bandwidth of interest.

2.7 Concepts Not Discussed but Recommended for Further Study

- Noise figure cascade analysis. This analysis will inform whether or not noise contributions of elements after the LNA can be ignored.
- Detailed antenna temperature analysis.

2.8 Signal-to-Noise Ratio and Link Budgets

2.8.1 Introduction

The previous section discussed how to calculate received signal power and noise/noise density based off some simple properties of an RF link. This section will discuss how to "close the link" and create a "link budget." The goal is to ensure that given the link conditions and the choice of modulation and coding, sufficient signal-to-noise ratio is maintained to meet some requirement for throughput and error rate.

2.8.2 Modulation and Error Correction

The subject of signal modulation and error correction can be a very deep and complex topic. Fortunately the SNR and throughput relationship for various forms of modulation and coding schemes can be found in reference materials and technical documentation.

In this text, the discussion will be limited to two types of modulation. FSK (frequency shift keying) and APSK (amplitude phase shift keying) as almost all satellite point to point links will use one or the other. High-speed links will typically utilize PSK/APSK with complex error correction schemes for maximum throughput. Low-speed/low-power links will often use FSK or M-FSK due to the simple hardware and low power requirements.

> *Complex communication systems such as the multiplexed multibeam links of say the iridium communication system are beyond the scope of the discussion here.*

2.8.3 Modulation

Phase Shift Keying and Amplitude Phase Shift Keying

The most common form of modulation for medium- to high-speed radio links is PSK or APSK. With this form of modulation, the phase and/or amplitude of a carrier wave is changed to encode information.

BPSK (Binary Phase Shift Keying)

The simplest form of PSK is “binary phase shift keying.” In this scheme the phase of the carrier is shifted between 0° and 180° to encode either a 1 or a 0.

A section of the carrier with a duration of the symbol period is known as a “symbol.” In this scheme there is one bit encoded per “symbol.” In such a case, the “bitrate” is equal to the “symbol rate.”

> *Error correction will be discussed later which involves “redundant” bits. In such a case, the bitrate to symbol rate will change depending on the redundancy fraction.*

Figure 1 shows the symbol waveforms of a BPSK modulated carrier transitioning from a “0” to a “1.” This example is unfiltered which would in practice yield unacceptably wide spectral content. Appropriate symbol filtering prevents this

QPSK (Quadrature Phase Shift Keying)

The number of bits per symbol can be increased by encoding multiple bits in a single symbol. With “quadrature phase shift keying,” there are 4 symbol states, 45, 135, 225, and 315°, so 2 bits per symbol can be encoded. The number of bits per symbol can be increased to 3 by using 8 phases, this is known as 8-PSK (Fig. 2).

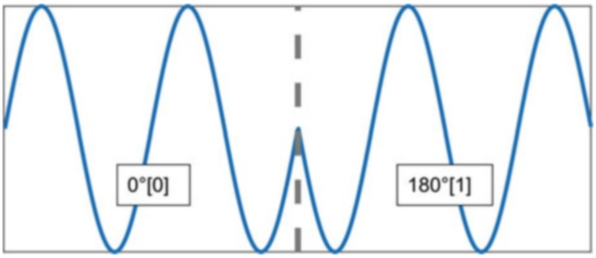

Fig. 1 Example of BPSK modulation format. (Image: Matt Ligon 2020)

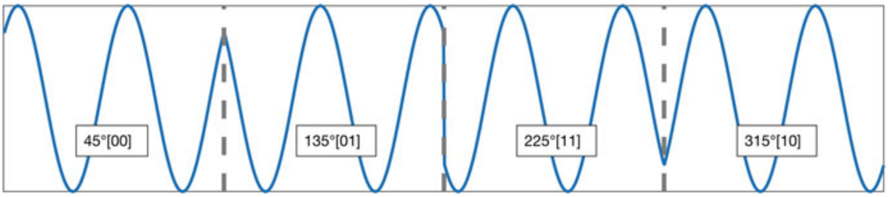

Fig. 2 Example of QPSK Modulated Signal. (Image: Matt Ligon 2020)

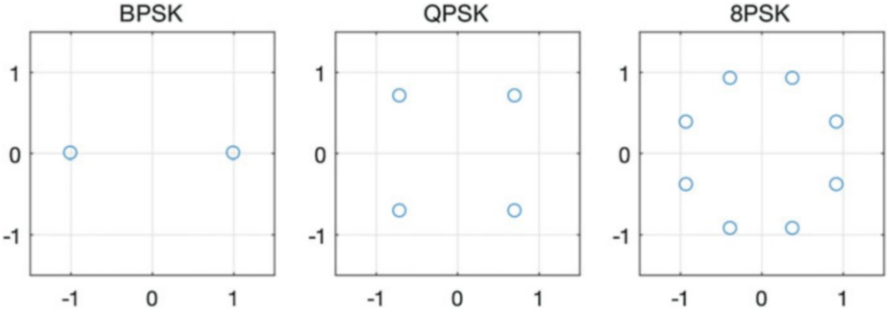

Fig. 3 Constellations for BPSK, QPSK, 8PSK,and 8PSK. (Image: Matt Ligon 2020)

PSK Constellation Diagrams

The common graphical representation for this type of modulation is to represent the symbols on a **constellation diagram**. Such a diagram is a polar plot that shows the amplitude and phase of each symbol.

Figure 3 shows BPSK, QPSK, and 8PSK represented on a "constellation diagram." Note that the 180d phase degree difference is clear from the BPSK plot and the 90d phase degree differences are clear from the QPSK plot and the 45d phase differences for 8PSK.

APSK Constellation Diagrams

Additional constant amplitude symbols could be added with reduced phase difference, 16-PSK, for example. This however is not an efficient use of the available phase-amplitude space. Instead to further increase the number of bits per symbol, amplitude is introduced as a variable resulting in what is called "amplitude phase shift keying." The 16 and 32 symbol constellations are shown below.

Higher-Order Constellation Diagrams

See Fig. 4.

Modulation Types and Required SNR

See Fig. 5.

With added noise, there is variability in the location of the received symbol. The size and spread of the received symbol "cloud" is dependent on the signal-to-noise

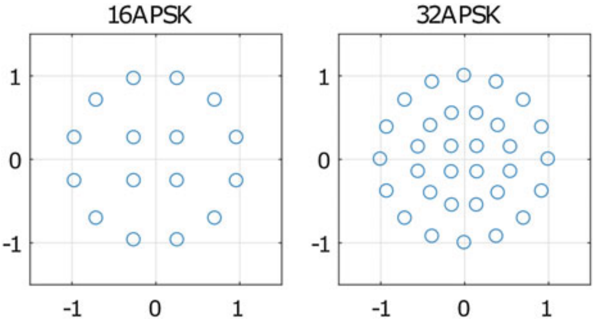

Fig. 4 16APSK and 32APSK constellation diagrams. (Image: Matt Ligon 2020)

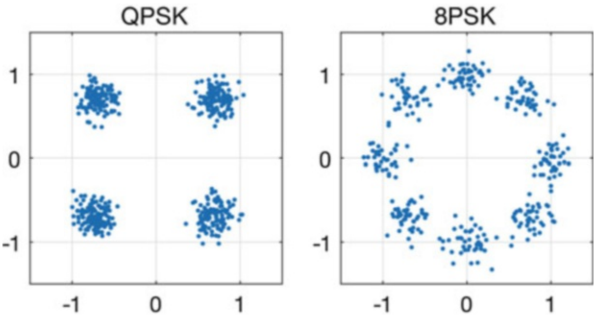

Fig. 5 QPSK and 8PSK constellations with 15 dB SNR. (Image: Matt Ligon 2020)

ratio. The “decision regions” or region that the received signal must fall to be interpreted correctly is smaller as the number of bits per symbol increases. This means that “higher order” (modulations with higher bits per symbol) require higher SNRs for correct interpretation of the received signal.

Alternate Constellation Configurations

These constellation schemes are not the only symbol arrangement used in commercial communication links. They are however particularly useful for satellite links with transmitters that are driven out of their nonlinear region because of their radially symmetric nature.

2.8.4 Error Correction

Due to the presence of noise, some fraction of the symbols will be interpreted incorrectly. Lower SNRs will result in a higher ratio of symbol errors. Practical communication systems deal with this problem by implementing “error correction.”

To put it simply, links that utilize “error correction” schemes add redundancy to the bitstream so that if a fraction of the bitstream is incorrect, the actual message can be reconstructed.

The subject of “error correction” is complex. Different schemes have different levels of performance which is related to the computing complexity of implementation. This text will not dive into the details of this subject, but the curious and mathematically inclined reader is encouraged to study the subject in more depth.

In this text, published specifications will be utilized to analyze practical RF links.

DVB-S2

The discussion of APSK modulation with error correction will be completed by referring to the DVB-S2 standard. The DVB-S2 standard defines packet framing, modulation types, and error correction schemes. The “DVB” refers to “Digital Video Broadcast” and was designed for the purpose of satellite digital television broadcast and backhaul. DVB-S2 is a very useful standard for general satellite data transmission as well.

Because of the considerable industrial investment in both the standard as well as the availability of inexpensive receiver hardware, it is a good option for inexpensive and low cost of development high-speed satellite links for CubeSats and SmallSats. DVB-S2 is by no means the only standard that can be used, but it is a high-performance well-documented standard that is useful as a reference. Traditional satellite systems commonly utilize standards defined by the CCSDS, for example.

Due to the sophisticated error correction implemented by DVB-S2, the processing requirements are high and require the use of FPGAs at high symbol rates. It is a useful standard for high throughput links but is not suitable for low-power low-speed links.

On the transmit side, DVB-S2 IP cores are commonly available for FPGAs. On the receive side, inexpensive commercial receiver hardware is readily available. For example, the TBS6903 PCI-E receiver card that can support 16APSK (5 bits per symbol) at 67.5MSPS (Mega symbols per second) can be purchased for 255USD.

The advantage of using a standard such as DVB-S2 is that there is thorough published information about the link performance and cheap to moderately priced commercially available receiver hardware. DVB-S2 supports QPSK through 32APSK and a variety of different coding rates (ratio of real bits total bits including redundancy). DVB-S2X further extends the available coding ratios as well as modulation types.

A key advantage of DVB-S2 is its implementation of error correction specifically **forward error correction** *based on concatenation of BCH (Bose-Chaudhuri-Hcquengham) with LDPC (Low Density Parity Check) inner coding* (DVB Fact Sheet 2018)

To reiterate, DVB-S2 is only a convenient standard that defines a specific implementation of modulation, framing, and error correction. These implementations are not exclusive to DVB-S2.

The DVB-S2 standard defines 23 MODCOD’s. A MODCOD is a combination of modulation and ratio of data bits to total bits.

Table 2 DVB-S2 MODCOD definitions

Mode	MODCOD	Mode	MODCOD
QPSK 1/4	1	8PSK 5/6	15
QPSK 1/3	2	8PSK 8/9	16
QPSK 2/5	3	8PSK 9/10	17
QPSK 1/2	4	16APSK 2/3	18
QPSK 3/5	5	16APSK 3/4	19
QPSK 2/3	6	16APSK 4/5	20
QPSK 3/4	7	16APSK 5/6	21
QPSK 4/5	8	16APSK 8/9	22
QPSK 5/6	9	16APSK 9/10	23
QPSK 8/9	10	32APSK 3/4	24
QPSK 9/10	11	32APSK 4/5	25
8PSK 3/5	12	32APSK 5/6	26
8PSK 2/3	13	32APSK 8/9	27
8PSK 3/4	14	32APSK 9/10	28

The following table from the DVB-S2 standard (ETSI 2014) specifies the relationship (Table 2).

Example

MODCOD 12 utilizes 8PSK with a code rate of ⅗. Each symbol encodes 3 "total bits" since 3 bits are encoded per symbol with 8PSK. The "⅗" refers to the ratio of "data bits" to "total bits" since extra bits are added for redundancy for the error correction.

If the symbol rate is 50MSPS, for example, that means there are 150 Mbps (3 bits per symbol for 8psk) including code bits and ⅗∗150 = 90 Mbps actual data rate at MODCOD:12

The important question however is how much signal-to-noise ratio is needed to support a certain MODCOD and subsequent data rate.

The DVB-S2 specification provides a table describing the ideal required SNR in the form of EsNo. EsNo is defined as the "energy per symbol" divided by the "noise density." In the table below, the specifications for a real demodulator have been added (Newtec AZ910) (Newtec 2019) to compare performance of a commercially available piece of hardware. In addition, the theoretical "Shannon capacity" has been added.

Shannon capacity and the Shannon-Hartley theorem will be discussed later, but for the purposes of the current discussion, understand that the "Shannon capacity" describes the theoretical maximum performance for a communications link.

ESNO or $E_S/N_0$is the ratio of **energy per symbol** divided by **noise density**.

Note that increases of "bits per symbol" known as spectral efficiency (η) requires higher EsNo, as discussed in the previous section.

Table 3 DVB-S2 modulation and required EsNo

MODCOD	Modulation	Code rate	DVB-S2 (bits/ symbol)	DVB-S2 theoretical EsNo req (dB)	Newtec AZ910 demod EsNo req (dB)	Shannon limit EsNo req (dB)	Shannon limit capacity (bits/ symbol)
1	QPSK	1/4	0.49	−2.4		−3.93	0.66
2	QPSK	1/3	0.66	−1.2	−0.70	−2.39	0.81
3	QPSK	2/5	0.79	−0.3	0.20	−1.38	0.95
4	QPSK	1/2	0.99	1.0	1.40	−0.07	1.18
5	QPSK	3/5	1.19	2.2	2.80	1.07	1.42
6	QPSK	2/3	1.32	3.1	3.60	1.76	1.60
7	QPSK	3/4	1.49	4.0	4.30	2.56	1.82
8	QPSK	4/5	1.59	4.7	5.10	3.02	1.98
9	QPSK	5/6	1.65	5.2	5.50	3.32	2.10
10	QPSK	8/9	1.77	6.2	6.60	3.81	2.37
11	QPSK	9/10	1.79	6.4	6.70	3.90	2.43
12	8PSK	3/5	1.78	5.5	6.30	3.86	2.19
13	8PSK	2/3	1.98	6.6	7.10	4.69	2.48
14	8PSK	3/4	2.23	7.9	8.40	5.66	2.84
15	8PSK	5/6	2.48	9.4	9.70	6.60	3.26
16	8PSK	8/9	2.65	10.7	11.10	7.21	3.67
17	8PSK	9/10	2.68	11.0	11.30	7.33	3.76
18	16APSK	2/3	2.64	9.0	9.60	7.18	3.15
19	16APSK	3/4	2.97	10.2	10.50	8.34	3.52
20	16APSK	4/5	3.17	11.0	11.50	9.02	3.77
21	16APSK	5/6	3.30	11.6	12.10	9.47	3.95
22	16APSK	8/9	3.52	12.9	13.30	10.21	4.35
23	16APSK	9/10	3.57	13.1	13.60	10.36	4.43
24	32APSK	3/4	3.70	12.7	13.60	10.80	4.30
25	32APSK	4/5	3.95	13.6	14.50	11.61	4.59
26	32APSK	5/6	4.12	14.3	14.90	12.14	4.80
27	32APSK	8/9	4.40	15.7	16.10	13.03	5.25
28	32APSK	9/10	4.45	16.1	16.50	13.20	5.37

With understanding of the concepts laid out, the definition **energy per symbol** is discussed below.

If the receive power is Prx and the symbol rate is Rs, it follows that the energy carried by each symbol is Prx/R. This is the **energy per symbol** or E_S

The discussion of “noise power” showed that it is a property of the antenna and receive system. How to simply determine signal power at the receiver was also discussed. By considering the additional variable of the symbol rate, “EsNo” can be calculated, and Table 3 can be consulted to determine the achievable MODCOD.

DVB-S2 and the Shannon Limit

In the previous section, the published behavior of a high-performance commercial standard called DVB-S2 was discussed. The level of performance of the standard can be determined by comparing it to what is known as the Shannon limit. Table 3 shows how many bits per symbol can be received given a certain EsNo. The Shannon limit will show what the maximum possible error free capacity of a "noisy channel" is.

The fundamental relationship between "C" channel capacity (bits per second), "B" bandwidth (Hz), "S" signal power (W), and "N" noise power (W) is given by the "Shannon-Hartley" theorem.

"Noise" in this context refers to "additive white Gaussian noise." Thermal noise has this property.

$$C = B\, log_2\left(1 + \frac{S}{N}\right)$$

The equation will now be reformulated.

Describe "S" as energy per symbol times symbol rate.

$$S = E_S R_s$$

Describe "N" as noise density times bandwidth.

$$N = N_0 B$$

Next it is asserted that $R_S = B$. In reality the ratio between the symbol rate and bandwidth for PSK/APSK is dependent on the implementation of the symbol filter. The discussion here will assume that they are equal.

Why is the minimum bandwidth dependent on symbol rate? This can be understood with a simple conceptual exercise. Imagine a stream of alternating ones and zeroes, 01010101, etc.

If this were to represent this with a sine wave where the peaks were ones and the troughs were zero, a sine wave with a frequency equal to the symbol rate would be needed. A lower-frequency wave would not be able to carry the information.

Rewrite the Shannon-Hartley theorem as follows:

$$\frac{C}{B} = log_2\left(1 + \frac{E_S R_S}{N_0 B}\right)$$

Assuming Rs = B yields

$$\frac{C}{R_S} = log_2\left(1 + \frac{E_S}{N_0}\right)$$

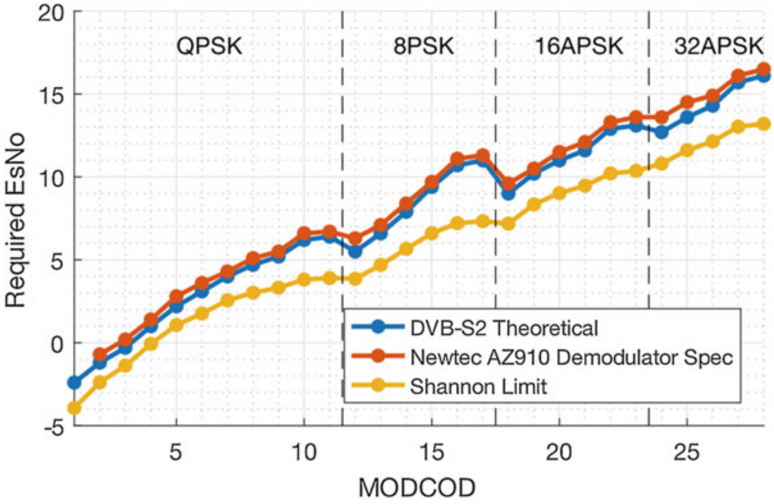

Fig. 6 EsNo required at different MODCODs. (Image: Matt Ligon 2020)

C(bits/s)/Rs(symbols/s) yields "spectral efficiency" η(bits/symbol):

$$\eta = log_2\left(1 + \frac{E_S}{N_0}\right)$$

Refer back to the DVB-S2 performance specification which shows the relationship between "spectral efficiency" and EsNo. The Shannon-Hartley theorem has been rewritten to show the theoretical maximum relationship between the two. The Shannon limit and the DVB-S2 performance are plotted in Fig. 6.

This plot shows the EsNo required for "quasi-error-free" operation of a theoretically ideal DVB-S2 channel, the specification for a commercial demodulator (Newtec AZ910), as well as the theoretical Shannon minimum EsNo required for a given MODCOD. It can be seen that the DVB-S2 implementation ranges from within 1 to 4 dB of the theoretical minimum.

Note the regions where the DVB-S2 plot has a larger deviation from Shannon. These are the regions where there is a smaller ratio of code bits to data bits. The error correction is less effective as the ratio of code bits to data bits tends toward zero. If there were no code bits, ***no error correction at all*** *could be performed.*
Since DVB-S2 is a standard intended for broadcast use, the performance is specified such that a consumer will experience a glitch rarely. This is referred to as "quasi-error-free."

Example DVB-S2 Link Budget

As an example the Planet Labs "Dove HSD" high-speed downlink system is studied. A thorough discussion of the system was published at the 31st Annual AIAA/USU

Table 4 Dove HSD key link parameters

Parameter	Value	Unit	Notes
Transmit power	2	W	
Tx antenna gain	10	dBiC	Circular polarized helical antenna
Symbol rate	70	MSPS	
Max distance	2050	km	Distance at 5d Elevation
G/T	29	dB/K	G/T for ground dish. G is gain, and T is "effective antenna temperature" Planet uses a mix of 4.5 and 5 m diameter dishes.

Conference on Small Satellites. It is recommended that the reader study the paper thoroughly for background on implementation details of both spacecraft and ground systems (Devaraj et al. 2017) (Table 4).

Recall the link equation from the previous section

$$P_R = G_R G_T \frac{\lambda^2 P_T}{(4\pi R)^2}$$

This equation shows how to determine the received power. EsNo needs to be determined to calculate the link throughput.

Recall the relationship between "effective temperature" and "noise density"

$$N_0 = k_b T_E$$

as well as the relationship between signal power, energy per symbol, and symbol rate

$S = E_S R_s$ or $P = E_S R_s$ to match the power symbol in the link equation

Expand the link equation

$$\frac{E_S R_s}{N_0} = \frac{G_R G_T \frac{\lambda^2 P_T}{(4\pi R)^2}}{k_b T_E}$$

and reformulated

$$\frac{E_S}{N_0} = \left(\frac{G_R}{T_E}\right)(G_T)(P_T)\left(\frac{\lambda^2}{(4\pi R)^2}\right)\left(\frac{1}{k_b}\right)\left(\frac{1}{R_s}\right)$$

The specific terms are discussed and given abbreviations and logarithmic units.

$$\left(\frac{G_R}{T_E}\right)[\mathrm{G/T}](\mathrm{dBi/K})$$

Gain of the receive antenna divided by the effective temperature. As discussed prior this G/T term is the standard figure of merit for a ground dish receiver antenna.

$$(G_t)[\mathrm{Gt}](\mathrm{dBi})$$

This term describes gain of the transmit antenna, which is a ratio of power density relative to that of an "isotropic" radiator. The "i" in the unit dBi refers to this.

$$(P_t)[\mathrm{Pt}](\mathrm{dBW})$$

This term describes gain of the transmit antenna. The unit dBW refers to the fact that it is a ratio relative to 1 W

$$\left(\frac{\lambda^2}{(4\pi R)^2}\right)[\mathrm{PL}](\mathrm{dB})$$

This term describes what is called "path loss." This is the reduction of energy density over distance due to the fact that the energy is spreading over a larger "spherical" wave front. The unit is dimensionless and is thus simply dB.

$$\left(\frac{1}{k_b}\right)[1/\mathrm{Kb}](\mathrm{K}\cdot\mathrm{Hz})/\mathrm{dBW}$$

As discussed in the "Noise Power" section, The k_bT term defines the noise power.

$$\left(\frac{1}{R_S}\right)[1/\mathrm{Rs}]$$

This is the symbol rate.

The link equation is now rewritten in logarithmic form. Note that the terms that have been inverted are now subtractions instead of additions.

$$\begin{aligned}\frac{E_S}{N_0}(dBHz) = {} & G/T(dBi/K) + G_T(dBi) + P_t(dBW) \\ & + PL(dB) + [1/Kb]((K\cdot Hz)/dBw) + [1/Rs](1/dBHz)\end{aligned}$$

A tabular link budget based on this equation is shown below. The numbers highlighted in red are summed together to yield the resulting EsNo (Table 5).

Table 5 Example DVB-S2 link budget

Parameter	Value	Unit
Distance	2.05E+06	m
Tx power	2.00	W
Carrier frequency	8.20E+09	Hz
speed of light	3.00E+08	m/s
wavelength	0.04	m
Boltzmann constant [Kb]	−228.59	dBW/(K·Hz)
Symbol rate	7.00E+07	Hz
Tx power dB [Pt]	3.01	dBW
Tx ant gain [Gt]	10.00	dBi
Path loss [PL]	−176.9531265	dB
1/Boltzmann constant [1/Kb]	228.59	(K·Hz)/dBW
1/symbol rate [1/Rs]	−78.45	1/dBHz
G/T [G/T]	29.00	dBi/K
EsNo	**15.20**	dBHz

Note that this link budget does not include any margin, atmospheric loss, antenna polarization mismatch, or other impairments. The resulting EsNo is a theoretical maximum given the basic link parameters

Referring to the DVB-S2 performance chart, it can be seen that an EsNo of 15.20 dB would allow the link to run at MODCOD 26. This is 32APSK with a ⅚ code rate with 4.12 bits per symbol. The example symbol rate is 70MSPS thus yielding a total throughput of 288.4 Mbps.

In reality that speed would not be achievable with the link. In practice the link needs to be run with sufficient margin. Other losses due to pointing inaccuracy, atmospheric attenuation, and other non-idealities need also to be considered (Table 6).

If a total of 5 dB is added to account for margin and impairments, the practical EsNo would be 10.20 dB. This allows the link to be run at MODCOD 19 (16APSK ¾) with 2.97 bits per symbol. At 70MSPS this is 207.9 Mbps.

The level of operating margin can be tuned to achieve maximum throughput

ACM (Adaptive Coding and Modulation)

DVB-S2 supports a wide range of “bits per symbol” depending on the available EsNo. The EsNo at the receiver is most significantly affected by the distance to the satellite. Planet’s Dove and SuperDove systems dynamically command the spacecraft transmitter to adjust the MODCOD to maximize throughput given the existing link conditions. It does not matter if the spacecraft is far away, has some hardware issue with its antennas or transmit chain, or if there is a pointing problem. By

Table 6 Example link budget with margin and additional losses added

EsNo	**15.20**	dBHz
Margin	−3.00	dB
Implementation loss	−2.00	dB
Design EsNo	**10.20**	dBHz

utilizing ACM a link can be maintained under adverse conditions albeit at a reduced data rate.

For **CubeSats and SmallSats**, ACM is very important function to have. Such spacecraft systems have limited power, are often experimental, lack reliable ADCS, and may not perform to the design specification due to rapid development and limited ground performance validation.

Comparison of Planet's SuperDove to DigitalGlobe WorldView-4 Satellite Downlink Performance

The example presented in the previous section was based on the HSD1 (high-speed downlink ver. 1) system implemented in the "Dove" spacecraft system.

Planet's latest CubeSat system "SuperDove" implements an upgraded radio system "HSD2" that utilizes 6× 76.8MSPS channels and can achieve over 1 Gbps.

Planet presented a paper on the implementation of this system at the 31st Annual AIAA/USU Conference on Small Satellites (Devaraj et al. 2019).

The DigitalGlobe WorldView constellation as well as their planned legion constellation operate at data rates of up to 1200 Mbps (DigitalGlobe 2012). Planet's SuperDoves can exceed this rate in peak operating conditions, but their overall average under good link conditions is about 900 Mbps.

The reader may be very surprised that a low-cost CubeSat a tiny fraction of the size and power budget of a WorldView class satellite is capable of similar data throughput rates. The answer to this question illustrates how SmallSats can "punch above their weight" compared to traditional satellite systems (Table 7).

The link budget shown above is from the WorldView-4 FCC filing. The data rate is 400 Mbps per polarization. With both polarizations the total throughput is 800 Mbps.

Examination of this link budget reveals several important insights into the design of the WV4 downlink system.

1. The radio system is designed to meet a 400 Mbps per polarization requirement in a worst-case condition. The system cannot speed up and take advantage of shorter slant ranges or better link conditions. **The system runs at a constant rate regardless of conditions. The system cannot fully take advantage of whatever link conditions are available:**
   (a) Rain loss accounts for 1.7 dB of the budget. The system cannot take advantage of dry conditions by speeding up.
   (b) A full **8.5 dB** of link margin is maintained under these worst-case conditions.

Table 7 WorldView-4 link budget from FCC Filing (DigitalGlobe 2012)

Frequency	8185	Mhz
Orbit height	770	km
Elevation	5	degrees
Data rate	400	Mbps
Bandwidth	200	Mhz
EIRP	57.1	dBm
Slant range	2718.88	km
Ground G/T	31.4	dB/K
BER	3.00E−05	
Required Eb/No (uncoded)	9.4	dB
Hardware implementation BER loss	−2.5	dB
Actual required Eb/No	**11.9**	
Spacecraft antenna diameter	19.7	in
Approx. HPBW	6.3	degrees
Gain of spacecraft antenna	29.1	dBic
Loss between HPA and antenna	−9.8	dB
Pointing loss	−1	dB
Transmitter Po	7.5	W
EIRP	57.1	dBm
Path loss	−179.4	dBm
Total loss (rain)	−1.7	dB
Required Eb/No	9.4	dB
Crosspol interference loss	−0.3	dB
Received C/N	23.4	dB
Implementation loss	−2.5	dB
Available Eb/No	20.4	dB
Downlink margin	**8.5**	**dB**

(c) The transmitter delivers 7.5 W of power, yet there is **9.8 dB** of loss between the transmitter and antenna.

(d) The antenna is **20 in** in diameter. If the power amplifier was placed right at the feed avoiding the 9.8 dB of loss, the antenna could have been approximately 6 in in diameter and produce the same transmitted power density. Additionally, a smaller antenna would require less accurate pointing.

The author has no additional information about the WV4 system other than what is publicly available from their FCC filings. The author's statements are based on some assumptions based on publicly available information.

The point is that designers of SmallSats and CubeSats **need not assume** that their subsystems will necessarily be hopelessly outclassed by traditional systems. Traditional systems typically include large safety margins for performance parameters due to their high-confidence, requirements-driven design approaches.

Small satellite radio systems with limited volume and power resources **should be designed to be able to operate at the maximum possible performance level given available link conditions.**

> *Of course the large difference in telescope aperture between a WorldView satellite and a Planet Dove result in great difference in optical resolution. The example here shows how non-primary subsystem performance need not be assumed to scale with size and cost of the satellite system. As a counterpoint a satellite which has a communications payload such as an Internet satellite will have radio hardware that operates as close as possible to the available theoretical link limit.*

2.9 Overview of Link Analysis

A link analysis for PSK/APSK, specifically as implemented with DVB-S2 was discussed. This information can be used as reference for implementation of a similar system. This discussion covered high-performance links which necessarily involve high power and compute requirements. The next section will cover simpler, lower-power systems for links that do not need high throughput.

2.10 Low-Power/Low-Speed Links and COTS Chip-Based Implementations

Integrated transceiver chips are an attractive option for low- to medium-speed satellite links with very tight power, volume, and cost budgets such as CubeSats; though they are intended for terrestrial use, their range can be extended with external amplifiers. Additionally external frequency conversion can be done to support channel carrier frequencies unsupported by the chip. An example of a CC1110-based satellite radio is the “OpenLST” an open source project released by Planet in 2018 (Klofas 2018).

> *There are several complexities associated with frequency conversion in this context. Feasibility/difficulty is dependent on specific implementation. Additional detail on the subject is out of scope for this discussion.*

The transmit power can be increased with the addition of an external power amplifier which can be selected to meet link requirements.

These integrated chips typically have internal LNAs with relatively high noise figure (and equivalently high effective temperature). A low-noise amplifier with a lower $T_E$can be added to the receive chain and will dominate the overall noise performance as long as its gain is sufficiently high.

A higher reliability system based on FSK or other modulation types could be implemented by utilizing an SDR (software-defined radio). Examination of the published performance of commercial COTS chips however is useful for performance estimation.

2.10.1 FSK-Based Implementations

Typical transceiver chips utilize “2-ary non-coherent frequency shift keying” (2-FSK) to modulate data. With 2-FSK, bits are encoded by shifting the carrier frequency up or down. The size of this shift is called the *deviation*. 2-FSK utilizes two tones to encode data so there is one “bit per symbol.” An excellent reference source for details on FSK can be found on the Atlanta RF website (Texas Instruments).

The primary configuration options for FSK are baud rate (which just means symbol rate), deviation, and receive filter bandwidth.

Higher rate links will need larger deviations and larger bandwidths. Larger bandwidths lead to higher receive noise power, and thus higher signal power is needed as well. With reduced received signal power, the bandwidth must be sufficiently small so that SNR can be sufficiently high. Coherent FSK has higher performance and not dependent on the receiver bandwidth, but the significantly higher processing power required may make it unsuitable for a simple low-power link.

> *Using spread spectrum techniques, reduced bandwidth is not needed with reduced receive power. This is pointed out here so that the reader does not assume that the lower rates necessarily require lower receiver bandwidths at a fundamental level.*

Depending on the device, there is a minimum receiver bandwidth; this will limit the ability for the chip to operate efficiently at very low speeds.

The Texas Instruments CC1110 has a minimum filter bandwidth of 58 khz, whereas the minimum on the CC1125 is 3.8 kHz. The minimum baud rate for the CC1110 is 1.2 khz. The CC1125 does not have a minimum baud rate but does have reference specifications for as low as 300 Hz operation (Texas Instruments).

Doppler Shift

The discussion of narrow channels necessitates a discussion of **Doppler shift** caused by the relative velocity between transmitter and receiver. For example, at 500 Mhz and 500 km orbital altitude, the range of Doppler shift is about +/−10 kHz.

If the carrier frequency offset caused by Doppler prevents reception, **Doppler compensation** must be performed. Based on the orbit geometry, instantaneous expected Doppler can be calculated, and the ground side radio can be tuned to compensate.

Receivers must tolerate some level of carrier frequency offset as frequency references are not perfect. If the offset is small relative to the bandwidth of the signal, it can likely be ignored, though the receiver bandwidth may need to be widened. If the offset is significant, say for the minimum 3.8 khz

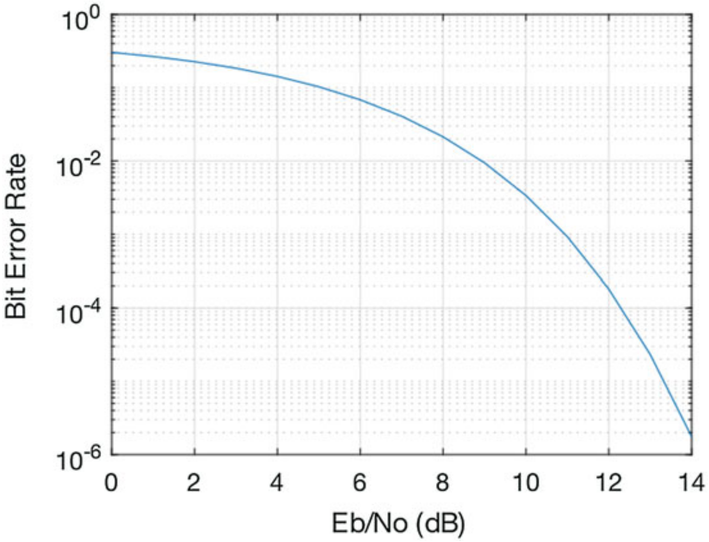

Fig. 7 Theoretical performance of non-coherent 2-FSK. (Image: Matt Ligon 2020)

filter bandwidth of the CC1125, accurate Doppler compensation is an absolute necessity.

The scaling is linear with frequency, so at 2 Ghz the shift would be about +/−40 kHz. Links operating at higher carrier frequencies are more affected by Doppler.

2.10.2 Link Throughput Estimation

In order to estimate the throughput of a chip-based link, the datasheet published performance can be referenced. The datasheets for CC series transceivers list "sensitivity" for different data rate configurations. The theoretical performance of 2-FSK shown in Fig. 7 can also be referenced.

In datasheets for most CC devices, "sensitivity" is the input power level required to achieve lower than a 1% bit error rate. The difference between a 1% BER and, for example, a 10^-5 BER can be determined by referring to the theoretical 2-FSK "waterfall curve" shown in Fig. 7.

A few example link budgets are shown here which show the level of received power for some reference links.

From the datasheets for the CC1125 and CC1310, the "sensitivity" specifications are plotted. Additionally the power required for an ideal 2-FSK receiver at 1% BER is plotted as well as the Shannon limit. These theoretical curves are plotted assuming that the receiver temperature is 900 K. This is representative of the high noise temperature of these chips due to their relatively high noise figure. The performance can be increased with the addition of a higher-performance LNA.

Referring to the example links, the "low-power downlink" (Table 8) could comfortably operate at 1 kbps; the high-power uplink (Table 9) could run

Table 8 Low-power downlink example. 70 cm UHF low-power downlink at 2050 km range

Parameter	Value	Unit
Distance	2.05E+06	m
Tx power	1.00	W
Carrier frequency	4.70E+08	Hz
wavelength	0.64	m
Tx power dB [Pt]	0.00	dBW
Tx ant gain [Gt]	0.00	dBi
Path loss [PL]	−152.12	dB
Rx ant gain [Gt]	10.00	dBi
Rx power [Pr]	−142.12	dBW
Rx power [Pr]	**−112.12**	dBm

Table 9 High-power uplink example. 10 W from 2 m dish 2 Ghz uplink at 2050 km range

Parameter	Value	Unit
Distance	2.05E+06	m
Tx power	1.00	W
Carrier frequency	2.00E+09	Hz
speed of light	3.00E+08	m/s
wavelength	0.15	m
Tx power dB [Pt]	10.00	dBW
Tx ant gain [Gt]	30.50	dBi
Path loss [PL]	−164.70	dB
Rx ant gain [Gt]	0.00	dBi
Rx power [Pr]	−124.20	dBW
Rx power [Pr]	**−94.20**	dBm

comfortable at 200 kbps. The moon link (Table 10) may barely operate at 300 bps when using these sorts of chips, and the very narrow bandwidth would require accurate Doppler compensation.

2.10.3 Spread Spectrum

As discussed prior, the FSK-based CC chips minimum filter bandwidths limited their performance at very low rates and also increased Doppler sensitivity. The utilization of spread spectrum techniques as implemented in an SDR, for example, allows for low bitrate operation at high symbol rates.

Direct Sequence Spread Spectrum

Most commonly, spread spectrum is achieved by encoding a bit with a “spreading code.” The coded data will be increased in length by the size of the code

Table 10 Moon to earth example. Moderate gain (10 dBi) low-power (1 W) tx to 5 m earth dish at 8 Ghz

Parameter	Value	Unit
Distance	3.84E+08	m
Tx power	1.00	W
Carrier frequency	8.00E+09	Hz
speed of light	3.00E+08	m/s
wavelength	0.04	m
Tx power dB [Pt]	0.00	dBW
Tx ant gain [Gt]	10.00	dBi
Path loss [PL]	−222.20	dB
Rx ant gain [Gt]	50.00	dBi
Rx power [Pr]	−162.20	dBW
Rx power [Pr]	−**132.20**	dBm

and thus requires a proportionally higher symbol rate and bandwidth to transmit.

Recall that increasing the bandwidth will reduce SNR. In fact spread spectrum signal power may be up to tens of dB below the noise power. The signal can be retrieved from the noise however because the spreading codes are known. By correlating the received signal with the codes, the data can be retrieved.

The codes used are orthogonal to each other, that is, when correlated with each other, the result is zero.

Shannon Limit Revisited

Shannon theorem shows that maximum channel capacity is achieved with increasing bandwidth, but this reaches an asymptotic limit.

This limit is given by

$$C \approx 1.44 \frac{S}{N_0}$$

Recall that

$$N_0 = k_b T_E$$

The signal power S can now be solved for which is the required signal power level given a receiver temperature Te. In Fig. 8 this has been plotted for Te = 900 K.

The slope of the Shannon limit closely matches that of the trend of the transceiver chips and roughly ranges from 15~20 dB away from the chip sensitivity specification. Recall that a DVB-S2 implementation utilizes highly computationally expensive forward error correction to operate close to the Shannon limit.

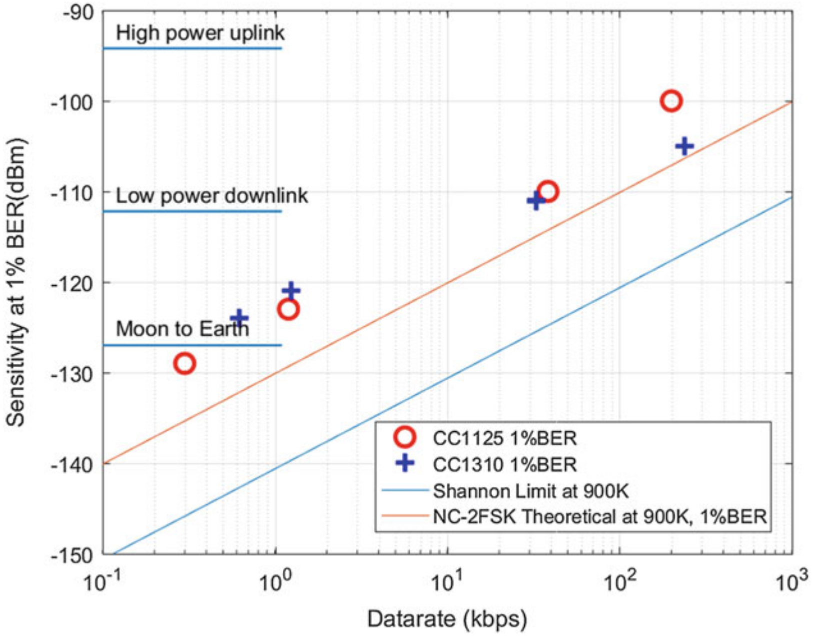

Fig. 8 CC1125 and CC1310 published sensitivities at 1% BER. (Image: Matt Ligon 2020)

2.11 Interference and EMI

The above discussion has assumed that thermal noise was the only noise source. In practice, interference from earth sources can be significant. At 450 Mhz, which is Planet's allocated UHF receive band for Dove and SuperDove, noise power is regularly 20 dB and above the thermal noise floor over large regions of land. Though this band is set aside for earth observation communications, it appears that the widespread usage of nearby bands and their leakage emissions adds up to a significant degree when seen on a wide scale by a spacecraft. At the 2.056 Ghz band that is allocated for earth observation, such interference is minimal, and the system can operate in a thermal noise limited regime.

Another very likely source of interference is self-generated noise from the spacecraft itself. Noise from high-speed clocks, data lines, switching power supplies, as well as leakage energy from transmitters can jam receivers. The effort involved in preventing and or mitigating these sorts of problems is not insignificant and can present an expensive challenge.

3 Conclusion

Satellite radio links utilizing both sophisticated and simple modulation schemes can be planned utilizing basic link theory and published information from industrial standards and products. Standards such as DVB-S2 and CCSDS provide detailed performance information for high-speed, high-performance satellite links. FSK and spread spectrum performance can be estimated from published specifications for commercially available integrated solutions.

Small Satellites and Structural Design

Joseph N. Pelton

Contents

Abstract

The cost to orbit for 1 kg of mass, using an Atlas launch vehicle, is currently around $20,000 and represents the high end of the range of launch costs. The latest technology represented by a SpaceX Falcon launcher, an ISRO Polar Satellite Launch Vehicle (PSLV) or a small satellite launcher such as the Electron all are significantly less costly. Nevertheless launch cost even by the most efficient launchers into low Earth orbit (LEO) remains quite expensive. In the case of very large space craft such as a high throughput satellite for telecommunications with mass of 5000–10,000 kg, the savings that might come from a highly efficient structural frame that reduces the overall mass by 100 kg, or alternatively allows the payload to be 100 kg larger, might be worth

J. N. Pelton (ed.), *Handbook of Small Satellites*,
https://doi.org/10.1007/978-3-030-36308-6_12

something like $2 million dollars per satellite launched. Even for small satellites such as a 3 unit cubesatellite, a very light weight, high strength frame that is thermally stable, and is not adversely affected by high radiation levels, clearly has good value. At this size, however, it is more common to use a lower cost material such as aluminum alloy.

Frame designs for small satellite are getting increasingly more sophisticated. It is possible that a primary frame or even a secondary structure such as a solar cell panel to allow the inclusion of an additional heat sensor, star tracker, or other safety feature or capability to be integrated into the harness design.

Some designs might even allow the addition of a passive de-orbit device that allows the small satellite to more quickly deorbit. In short, some design features for primary or secondary structures are optimized by determining and adding features that reduce both the mass and available usable volume of a small satellite.

The addition of new additive manufacturing capabilities to the arsenal of capabilities available to those who design and manufacture small satellites can increase the performance, cost-effectiveness, or safety of a project.

This article addresses all aspects of a small satellite's design in terms of its mass, strength, volume efficiency, thermal and radiation protective qualities, reliability, and overall structural aspects and efficiency as measured by all of these factors. It analyzes what aspects have been improved over time and what the prospects are for the future to increase structural design and performance. This article analyzes the status and future direction of research related to primary structure related to small satellites. This primary structure is key to a satellite surviving launch and deployment, its operational integrity throughout the spacecraft lifetime up to its end of life. Also considered is the nature and performance of its secondary structures. The structural integrity of these secondary systems are also necessary to support the successful operation of subsystems or components such as solar panels, thermal blankets, radiation shielding, instrument mounts to be properly anchored so as to operate reliably, and so on. Progress is being made on primary and secondary structure design and performance. In many instances, the design of the small satellite and its structural elements are being integrated with essential elements of the spacecraft to reduce mass, increase volume for payload systems, or otherwise increase efficiency. These innovations are sometimes known as multifunctional elements when structures, panels, wiring harnesses, sensors, and other devices are integrated together in the design.

1 Introduction

The first satellites that were launched were, in fact, small satellites. They were virtually all small platform carrying experimental packages to test out new space technologies. The first emphasis was on testing radio, sensors, and experimental devices and the buses or platforms that carried them were not of particular or special concern. This was particularly the case with regard to the rocket systems of the U.S.S.R. that had developed very powerful rocketry. Some of the earlier soviet satellites in the Sputnik and especially the Molniya series resembled craft that looked more like washing machines than delicately engineered spacecraft designed to reduce mass. In the USA, which had less capable launchers, the design focus was different. The US designers of spacecraft, very early on, began to conceive of satellites buses that had the greatest strength but also required the least amount of mass. The shift from all governmental space operations to commercial systems in US programs, such as Relay (RCA), Telstar (AT&T), Syncom (Hughes), and Early Bird (Intelsat and Hughes), led to research and development to create spacecraft buses that were structurally sound but as light in mass as possible (Pelton 1974).

This led to the development of carbon-epoxy composite structures for the primary structure of a satellite. This type of composite for the primary structure was found to be very strong and the lightest in mass in comparison to such materials as steel, titanium, or metal alloys. These very strong fibers were also extremely resistant to thermal expansion and shear characteristics and still retain compressive strength in both longitudinal and transverse dimensions. As will be discussed later, these primary structural elements can be designed to incorporate other key elements of the satellite's design such as wiring harnesses, sensors such as sun or thermal sensors, etc. Table 1 shows these characteristics for a commercial available carbon fiber/epoxy resin material that is readily now available. Such composites are not only used for the design and construction of spacecraft, but also automobiles, aircraft, and other products where aspects such as strength, durability, and light weight are desirable construction qualities (Carbon/Epoxy Composite 2019).

The use of carbon fiber/epoxy resin composite materials, because of their light weight, thermal stabilities, longitudinal and transverse strength qualities, and durability, became quite common for satellite structure. Indeed this type of composite has been used in the structural elements in the manufacture of a very large number of satellites. Indeed these types of carbon/epoxy are finding their ways into components for aircraft, automobiles, and many dozens of other products. The smallest satellites such as cubesats, pocketques, or chip satellites

Table 1 The strength, shear, and thermal expansion characteristics of carbon/epoxy resin composites

Property	Units	Value
Coefficient of thermal expansion – longitudinal	$\times 10^{-6}\ \mathrm{K}^{-1}$	2.1
Coefficient of thermal expansion – transverse	$\times 10^{-6}\ \mathrm{K}^{-1}$	2.1
Compressive strength – longitudinal	MPa	570
Compressive strength – transverse	MPa	570
Density	$\mathrm{g\ cm}^{-3}$	1.6
Shear modulus – in-plane	GPa	5
Shear strength – in-plane	MPa	90
Ultimate compressive strain – longitudinal	%	0.8
Ultimate compressive strain – transverse	%	0.8
Ultimate shear strain – in-plane	%	1.8
Ultimate tensile strain – longitudinal	%	0.85
Ultimate tensile strain – transverse	%	0.85
Volume fraction of fibers	%	50
Young's modulus – longitudinal	GPa	70
Young's modulus – transverse	GPa	70

The above characteristics are those of RS Stock No. 764-8700, RS Stock No. 764-8703, RS Stock No. 764-8716, and RS Stock No. 764-8707, but they are generally indicative of carbon fiber/epoxy resin composite materials

typically end up not with composites but more likely something like a metal alloy such as a light weight but relatively strong aluminum alloy which is sufficient to the design, since these smallest of satellites tend to be volume limited and not mass limited.

2 Optimized Design of Small Satellites and Structural Design

An optimized design might not be used to reduce the mass of the small satellite but to add additional features or capability. Altering the mass of a small satellite's structural features can thus be seen in the context of an opportunity cost. A better primary structure in terms of lower mass, greater volume, acceptable longitudinal or transverse strength, and or thermal qualities might also be evaluated in terms of allowing additional capability to be added to a small satellite design. Less mass associated with structural design could be reinvested to increase a small satellite's performance, safety features, reliability or ability to de-orbit at end of life.

Indeed a good satellite designer, despite its mass and dimensions, always considers the aspect of "opportunity cost." This is to say that if I can reduce the cost, performance, or mass of a satellite in one aspect of its design, can I produce or can I reinvest that additional mass or volume, etc. to achieve a better result. If I have less mass associated with structure can I increase another capability such as power or processing speeds to produce better overall results in terms of performance of the mission objectives. Systems engineering and assessing opportunity costs are a closely related activity, especially in the world of small satellite design.

The best small satellite structural design is not just limited to its mass, strength, and thermal qualities. The other crucial element is the extent to which it allows the efficient assembly and performance of all the components essential to a small satellite's performance. When one acquires a solar cell panel, that panel could be designed as a structural element of the small satellite and it might also integrate a magnetotorquer or sun sensor or thermal sensor into its design so that the ultimate payload might be more capable. In short, the design of a small satellite such as a cubesat involves volume efficiency as well as mass efficiency. Of the two, volume efficiency is more important, but not if volume efficiency risks reliability and resilience.

3 Small Satellite and Kits and Standardized Structures

There are several ways that one might approach the design, manufacture, test, and deployment of a small satellite. One might start with the idea of doing the entire design and manufacture of a small satellite on a vertically integrated basis either in-house or through a general contractor. This entity will design and try to optimize all aspects of small satellite design, particularly if it is for a large-scale constellation where thousands of small satellites are to be launched. In this case, the idea is to have a structure that is high in longitudinal, transverse, and shear strength, thermally stable, as low in mass and volume as possible, and perhaps adaptable to accommodate elements such as wiring and sensors, and hopefully also low in cost of manufacture and assembly.

The other approach is to acquire subsystems and components from reliable suppliers who specialized in a particular area such as solar panels, magnetotorquers, digital processors, thermal blankets, sun sensors, star trackers, or suppliers of payload systems for telecommunications, networking, remote sensing, data relay, etc. Even prime contractors tend to obtain particular components rather than manufacture every aspect of a satellite.

In the world of small satellites and especially very small units such as at the level of cubesats or qubesats and most particularly when the project is a one off or very limited number of satellites, the ordering of components or kits from specialized suppliers can make a good deal of sense.

Suppliers such as Pumpkin or Innovative Solutions in Space (ISIS) for instance can provide small satellite structures from 1 units up (Pumpkin for instance can provide 1 unit, 6 unit, and 12 unit structural frames). These kits for a cube satellite tend to be manufactured in materials such as an aluminum alloy. The skeletonized structural frame pictured in Fig. 1 by Pumpkin is fabricated from a strong alloy known as Aluminum 5052-H32. This alloy is described as having corrosion resistance and good workability to create a skeletal structure and resistance to metal fatigue and ability to be easily welded. Despite its modest weight, it at least has moderate strength. Since it is used in gas tanks, aircraft fuel lines, appliances, and

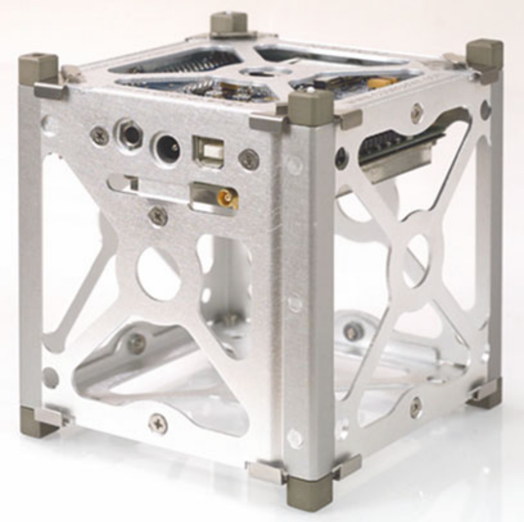

Fig. 1 A skeletal cubesat frame from an aluminum alloy. (Graphic courtesy of Pumpkin)

other applications, its cost is not high. Only in larger microsats and minisats is it common to go to carbon/epoxy composites. See Fig. 1.

The same is true of femtosats (i.e., chipsats) and picosats (i.e., pocketqubes). The systems engineering task in terms of designing the structural elements of these types of small satellites is finding ways to conserve available volume much more than mass. The logic of using kits or assembled units at the level of femtosats and pocketqubes is increasingly clear because the designers of such types of small satellites have already been forces to conserve mass and volume while also meeting structural requirements for strength, shear, thermal integrity, etc. Supplier of kits and launch intergrators for PocketQubes are limited. These include Alba orbital, KSF Space, and GAUSS Srl (see Fig. 2).

The following are some of the suppliers of primary structural systems for satellites at the cubesat level (typically 1 unit up to 6 units and now in some cases up to 12 unit structures). The trend line is that continuing progress has been made in the development of new standards and cost effective structures. Recently, 12 unit structures have been developed by several providers and on the other end more options are beginning to occur with regard to pocketQube units that are 5 cm × 5 cm × 5 cm small satellites that are available for quite small experiments. The fact that the International Space Station is now equipped with dispensing systems that can handle everything from pocketQubes to 12 unit cubesats and thus small satellites from 200 mg to around 90 kg has helped this standardization of structural systems and help lower the cost of such types of smallsats (NASA State of the Art 2018).

- Endurosat
- GOMspace

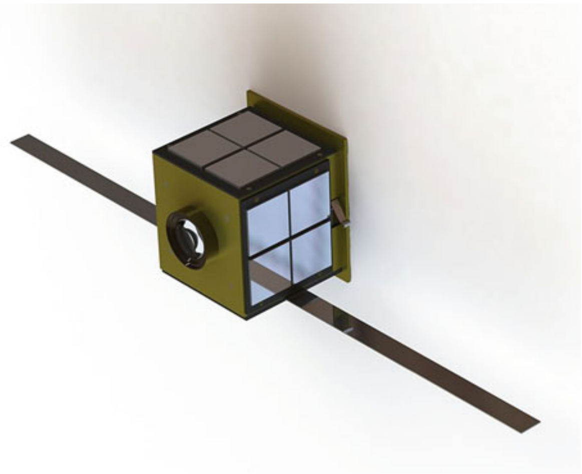

Fig. 2 A pocketqube picosat with camera. (Image courtesy of Alba orbital)

- Innovative Solutions in Space (ISIS)
- NanoAvionics
- Pumpkin
- Radius Cubesat Structures

There are of course other providers and the above list is not intended to be exhaustive. This is the current list of global suppliers for cubesat structural suppliers that appears in the NASA State of the Art of Small Satellite Technology report in their section on Structures, Materials, and Mechanisms (NASA State of the Art 2018).

4 Small Satellite Structure and Additive Manufacturing

One of the key newer elements in the manufacture of small satellites is the introduction of additive manufacture to the building of everything from cubesats to minisats. Additive manufacture can provide a number of advantages to this process.

There are several ways that so-called 3D printing can provide advantages in this regard. If the outside structure and wiring harness for a small satellite are integrated, this can expand the size of the internal volume to accommodate a larger payload. In some designs, the external panels could embed wiring, sun and heat sensors, and even magnetotorquers. This can not only make a small satellite more efficient in terms of payload size, it can also speed up production in the case of small satellites for large-scale constellations (Becedas and Capparros 2014).

The development of suitable standards for materials that can be extruded from additive manufacturing and more adaptable 3D printers with double extruders are now able to cope with the design and manufacture of composite-based satellite structures. This type of double extruders can facilitate the ability to embed functional features into the structure. This can for instance include wiring or sensors and thus create so-called multifunctional structures.

Yet another aspect of additive manufacturing with regard to small satellites that could create yet another benefit is with regard to the minimization of orbital space debris at end of life in terms of its destructive forces on one hand. This new form of manufacturing technique can easily allow for new design possibilities, shapes, and geometries. Such shapes and designs were difficult to achieve in a cost-efficient manner without using 3D printing techniques. These new shapes and geometries might be also designed to facilitate additional atmospheric drag, facilitate release of gases at end of life, or enable ease of repurposing as reusable modules. This type of approach might be compatible with experimental design concepts that have been explored by the US Defense Advanced Research Projects Agency (DARPA) in the context of so-called Satlets.

On the other hand, there is the possibility of using additive manufacturing to create more efficiency shielding techniques for small satellites against potential collision with debris or micro-meteorites as will be discussed below.

5 MicroLattice Structures as a Part of Small Satellite Panels

There are other structural materials other than composites that can make sense for small satellite and their structural design. One of these new possibilities involves the use of metallic lattices or even so-called metallic “micro-lattices” These lattices can play a role in the interior design of structural panels for small satellites. The creation of very light weight but strong metallic lattice structures is one of the possible structural components that are made possible and cost efficient with additive manufacturing techniques. In lieu of foam or other such materials, metallic micro-lattices can be stronger, more resilience, waste less material, and even cost less when fashioned by a 3D printer optimized for this type of design.

With the latest additive manufacturing technique, a metallic micro-lattice could be intentionally designed for a specific need. It is possible to create “negative Poisson rates.” This could allow, for instance, the increased resistance capabilities of a structure, or even to help its protection against collision with a micro-meteorite. This type design could also add to the shear resistance of a small satellite structural panel (Gong et al. 2014).

The capability to make lighter and lighter structural elements via 3D printing continues to improve. The micro-lattice variant that has been designed by Boeing is rather amazingly shown to be 99% air and 1% metal (The lightest metal 2015) (see Fig. 3).

Spacecraft that design orbital space debris shielding in order to lessen the impact energy of debris or micro-meteorites create several layers of shield separated by gaps that could be filled with micro-lattice rather than foam. This may be more the case for microsats and minisats where volume considerations are not quite a severe.

The current approach that is used in most small satellites is typically based on the employment of honeycomb panels. Such honeycomb panels have limited impact

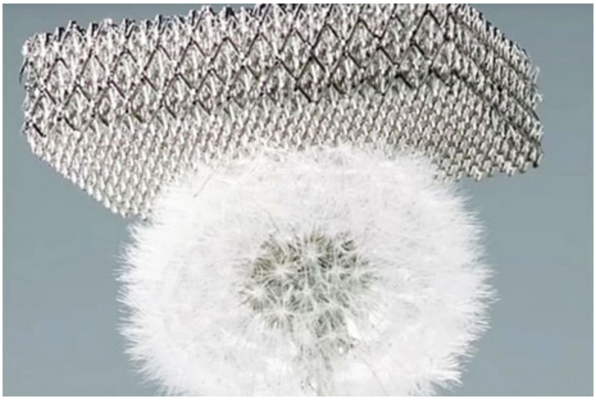

Fig. 3 A super low mass micro-lattice variant suspended on top of a dandelion. (Graphic courtesy of Boeing)

mitigation characteristics. Further the volumetric demands of these honeycomb panels would be challenging to include within the limited volume of a true small satellite such as 1 unit CubeSat standard. The use of metallic micro-lattices is for the future design of debris collision mitigation system. This approach may prove most promising for larger small satellite designs that might be manufactured so that they could be deployed for a large scale LEO constellation.

6 Conclusion

The materials used for the primary structure of truly small chipsats, pocketQubs, cubesats, and up to six unit cubesats will most likely remain metallic materials such as aluminum alloys similar to those discussed in this article. On the other hand, larger small satellites such as microsats and minisats in the range of 10 kg up to 1000 kg may tend to use carbon/epoxy composites. The challenges for the future is the extent to which primary structural elements or even secondary structural elements such as solar cell panels will be designed as highly space efficient components to include harness wiring, sun sensors, thermal sensors, or other quite small units such as magnetotorquer in order to maximize volume for the smallsat payload.

Efficient system engineering will continue to seek to improve small satellite design. This will mean eliminating the inefficiencies of the spacecraft “bus” so as to increase the payload that supports the prime mission for which the spacecraft is being deployed. The idea of considering each and every one of the components of a spacecraft bus as “excess mass” and an impinging occupier of internal volume must be seen as an ‘opportunity cost’ that is taking away power, mass, or volume that could be devoted to the real purpose of a small sat mission. The design of new and improved materials that can be lower in mass and volume, while maintaining longitudinal, transverse and shear strength and be resistant to change as thermal conditions should rise or fall is a clear objective.

The new capabilities that come from additive manufacturing offer a way to pursue these objectives and also reducing the cost of fabrication and material consumption. There are research studies that are seeking to use these new manufacturing techniques to improve the production of multifunctional components or systems, reduce mass, preserve volume for the payload, preserve structural strength and thermal stability, and as find better ways to cope with problems and issues that arise from orbital debris or micrometeorite collisions, as well as to better ways to protect small satellites against collision or to allow these small satellites to be recycled for use within new spacecraft.

Research in materials, structural design, additive manufacturing, thermal and radiation protective materials, multifunctional systems, micro-lattices, recycling of satellite components, and more can help make small satellites better. These innovations can create cubesats that are more cost-effective, more resilient, and better prepared for hazards in outer space include orbital debris collisions, thermal variations, coronal mass ejections, and other design and operational issues.

Small Satellite Constellations and End-of-Life Deorbit Considerations

Vitali Braun

Contents

Abstract

Space missions come with a huge potential to provide global services such as navigation or telecommunication. With decreasing cost to insert satellites into orbit and the further miniaturization, the currently observed launch traffic involves more and more small satellites. Global broadband Internet services delivered by large constellations consisting of thousands of small satellites have been proposed by several companies. Some of the first satellites were already launched. Space debris mitigation guidelines have reached international consensus more than a decade ago and are applied to current space missions. What do they imply for small satellites? And are they still valid for large constellations? If an increasing number of satellites are continued to be inserted into a constrained orbital region, would there ultimately be an issue with sustainability? Research over the past few years has provided some reassuring output that a way toward a sustainable use of outer space does exist – under the current mitigation guidelines and even with operational small satellite large constellations. But there are clear

limits, and the international community is faced with an increasing level of responsibility to preserve the commonly shared resource space for future generations.

Keywords

End-of-life · Sustainability · Long-term evolution · Mega-constellations · Disposal · Space debris

1 Introduction

Having achieved the objectives of their satellite mission and barring any mishap before that, any owner or operator is facing the challenge in the inescapable transition from the operational to the disposal phase, assuming that any potential extension of the operational phase has already been applied before. The disposal phase is the time interval during which a satellite completes its disposal actions, with the main objective of permanently reducing its likelihood of a future accidental breakup and to achieve a required long-term clearance of the *protected regions* it had been crossing or operated in ISO (2019). Possible disposal actions range from doing nothing at all; maneuvering the satellite such that it doesn't interfere with any protected region in the near future; targeting a faster orbit decay, for instance, by maneuvering to a lower altitude orbit in the low Earth orbit (LEO) region; targeting an atmospheric reentry with a well-defined impact footprint on the Earth's surface (controlled reentry); to attempting a retrieval of the satellite and a subsequent recovery on Earth, the latter surely being the most expensive option.

Certainly, the *do-nothing-at-all* option after the operational phase results in the lowest direct cost associated with a single satellite mission and may even come with a strong incentive in an intensely competitive market or where missions are selected on a lowest price scheme only (Schaub et al. 2015; Adilov et al. 2013). This is also the case when a satellite is essentially operated until it no longer responds. But any satellite launched into Earth orbit will immediately find itself in company with other active missions, derelict spacecraft, spent upper stages, as well as space debris sharing the very same environment. Leaving a nonoperational satellite in that environment results in an additional potential collision partner for other active satellites, which would be perceived by them as a further operational burden. Even worse, a satellite, after end-of-life and remaining in space for years, or maybe even decades or centuries, may suffer a breakup resulting in hundreds to thousands of fragments lethal to other missions, with Titan Transtage breakups near the geosynchronous region being prominent examples. Left in orbit and potentially approaching an atmospheric reentry in an uncontrolled way, a satellite may also pose a risk to people or infrastructure on ground even many years after its operations have ceased.

In this chapter, today's space environment is described with a focus on orbital regions of interest based on certain applications satellite missions have been designed for. The historic evolution of the space environment and the number of objects on orbit serves as an indication how individual actors, policy decisions, applications, and events (like explosive breakups) continue to shape that environment. With the proliferation of space debris, we put the safe operation of satellites in space and the valuable services they provide at risk. Space debris environment evolution models provide the means to study possible future scenarios. In many different recent studies, the impact of future launch traffic on the space debris environment, involving small satellites and potential large constellations thereof, has been addressed and will be summarized herein.

The rationale for space debris mitigation actions results from such analyses, and environment evolution models allow to evaluate the efficacy of different mitigation strategies. This ultimately leads to the discussion of methods to assess the impact of a given mission on the space debris environment. Perceiving the near-Earth space environment as finite, it is only reasonable to address the idea of a *capacity*, essentially leveraging a satellite-specific environment criticality index to a maximum number of objects a certain environment or orbital region can accommodate during a time period in a sustainable way.

Given that our society today heavily relies on the complex infrastructure in space and assuming that this technological dependence is very likely to intensify in the future, we clearly have to address the sustainable use of the resource space in order to ensure that future generations may likewise benefit from space.

2 The Space Debris Environment

In March 1958, the satellite Vanguard 1 was launched into low Earth orbit (LEO). Having a mass of only about 1.5 kg, the small satellite conducted a very successful scientific mission improving our knowledge in the areas of geodesy and atmospheric research. Operations ceased in May 1964 when Vanguard 1 turned to a derelict spacecraft in an 4000 km × 650 km orbit with a remaining orbital lifetime of a few centuries. Today, it is the oldest human-made object in Earth orbit, sharing that environment with about 19,800 objects (space-track.org 2019), which consist of active and derelict satellites, rocket bodies, and other space debris. But Vanguard 1 is not the only example of a historic signature in today's orbits, which is why understanding our current space environment and, maybe even more importantly, discussing any potential future scenarios are inevitably linked to events and decisions in the past which shaped that environment.

The evolution of the number of on-orbit objects is shown in Fig. 1. After more than 5800 launches and 530 debris-generating events (ESA Space Debris Office 2019), the catalogued orbital population today is clearly dominated by nonfunctional objects, with only about 10% thereof being active satellites (Union of Concerned Scientists 2019). While fragments from explosive breakups of rocket bodies have had the major share in the orbital population since 1961, the situation has distinctly changed after the Fengyun-1C anti-satellite test in 2007 and the collision between Kosmos-2251 and Iridium 33 in 2009, adding in total more than 5700 debris

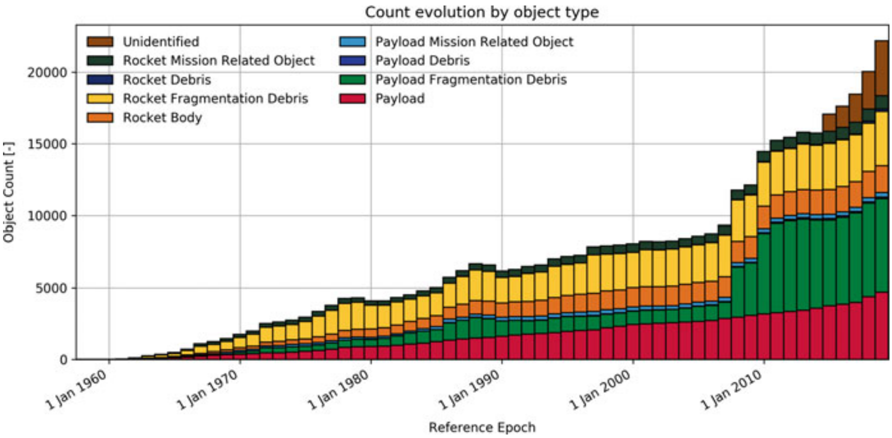

Fig. 1 Count of number of objects in orbit for different object types (https://discosweb.esoc.esa.int, as of August 23, 2019. ©ESA 2019)

fragments. There is one more notable feature in Fig. 1, namely, the objects labelled as *Unidentified* which appear as part of the population since 2015. Those are not new objects but mostly the result of a combination of data coming from two different entities: the satellite catalogue (SatCat) maintained by the US Air Force's 18th Space Control Squadron (18 SPCS) and the catalogue provided jointly by the JSC Vimpel Interstate Corporation and the Keldysh Institute of Applied Mathematics (KIAM). Many of the objects in the Vimpel catalogue are correlated to the ones from the SatCat, but there is a remaining subset of objects, mainly in higher altitude orbits, which have not found their way into the US catalogue. Moreover, as their origin could not be determined, they remain categorized as unidentified for the time being which, in fact, is also true for a few objects in the US catalogue.

Evidently, no single catalogue can ever claim completeness, and the object count evolution in Fig. 1 is only referring to the subset of objects we are able to monitor continuously via ground-based observations, limited by observability constraints and sensor sensitivity. The numbers in Fig. 1 are often referred to in literature as on-orbit objects larger than 10 cm, which more or less reflects on current sensor limits. Space debris models, such as ESA's Meteoroid and Space Debris Terrestrial Environment Reference (MASTER), provide a comprehensive picture of the environment given the evidence we have. In its latest version (available from https://sdup.esoc.esa.int), the MASTER model counts about 34,000 objects larger than 10 cm at the reference epoch of November 1, 2016. By modelling known debris-generating events and calibrating them with actual measurements (Braun et al. 2019), MASTER provides us with estimated object numbers as if we were unaffected by observability and sensitivity limits.

Being designed to fulfil a specific mission, operational satellites have been launched to orbits that accommodate best for the given mission objectives. As those satellites and their associated rocket upper stages are the main source for any debris generated, it does not come as a surprise that the distribution of space debris more or less follows the one of their progenitors, at least for larger objects sizes. Figure 2 shows the spatial density, that is, the number of objects per volume element of one cubic kilometer, as a function of the orbital altitude in LEO for objects larger than 10 cm according to MASTER. The most congested altitude band is between 700 and 900 km. It is the preferred region for Earth observation satellites and a typical choice for Sun-synchronous orbit missions. Clearly visible are the two distinct peaks in the collision fragments from the Fengyun-1C (at about 850 km) and the Kosmos-Iridium (slightly below 800 km) events, both of which occurred in the very same congested region. The spatial density shows a steep decline toward lower altitudes due to increased atmospheric drag which acts against the direction of motion, thereby lowering the objects' orbital altitude over time and effectively acting as a natural sink mechanism for the space debris environment.

The increasing number of objects in Earth orbits has a major impact on the operation of satellites. Over the past few years, collision avoidance has become a standard process for any maneuverable satellite in LEO, for example, ESA's Space Debris Office reports on 27 collision avoidance maneuvers (CAMs) in 2018 conducted by 8 satellites (Braun 2019). Taking the entire LEO satellite fleet operated by the European Space Operations Centre (ESOC) into account, an average number of one to two CAMs are required per year and per spacecraft (Braun 2019). An ESA study concluded that each avoidance maneuver can be associated with an overall cost of approximately EUR 25,000 (Krag et al. 2018). Extrapolating this number to about 580 alerts above the maneuver threshold, assumed to occur annually in LEO, results in a potential yearly damage of EUR 14.5 million (Krag et al. 2018).

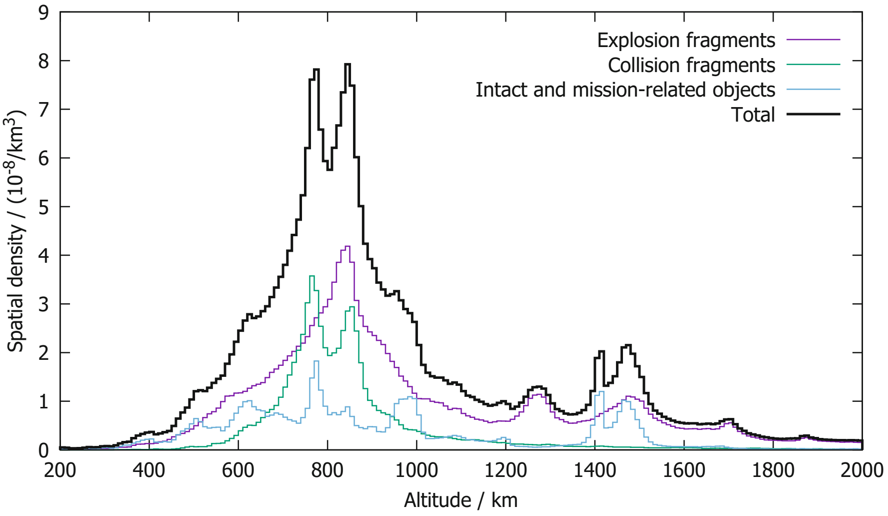

Fig. 2 Spatial density in the LEO region for objects larger than 10 cm according to the MASTER model on November 1, 2016. (©ESA)

The consequences of a collision can be manifold. A widely accepted criterion to assess whether an impacting object is lethal or not is the energy-to-mass ratio for that event: if the kinetic energy of the impactor divided by the mass of the target satellite is above 40 J/g, it is generally considered a catastrophic collision resulting in a complete fragmentation of the target satellite (McKnight 1991). For instance, an aluminum sphere of 10 cm diameter hitting a 1500 kg LEO satellite with a typical impact velocity of 10 km/s results in an energy-to-mass ratio of about 50 J/g. The higher the impact velocity, the smaller a lethal object can be. This became quite evident in August 2016, when Sentinel-1A was hit by an impactor of about 1 cm in size (Krag et al. 2017) into its leading solar array wing. A picture taken by an onboard camera confirmed a 40 cm impact feature that also explains the permanent power loss of about 5% for the mission. The MASTER model estimates about 900,000 objects larger than 1 cm, and a flux analysis for the Sentinel-1A orbit reveals that the annual probability of an impact with objects larger than 1 cm is about 6%. The Sentinel-1A mission survived this impact without major consequences. Certainly, if the main body would have been impacted, the outcome could have been significantly worse, ranging from the loss of components over subsystems up to the entire mission. However, it is not only the individual mission affected after such an event. The Sentinel-1A event resulted in a total number of seven tracked fragments, which also appeared as chasers (or secondary objects) in the regular collision avoidance screenings of other ESA satellites. With even higher numbers of fragments, the effects will be non-negligible in the operations of other missions: the fragments of the Fengyun-1C and the Kosmos-Iridium event combined make up about 40% of all conjunction events (where the collision probability went above 10^{-6}) for the satellites screened by ESA's Space Debris Office since 2015.

The effect of collision fragments triggering new collisions and potentially leading to a self-sustained growth in the object numbers has been described by Kessler and Cour-Palais (1978) and became known as the *Kessler syndrome*. It basically means that if in a certain region a critical density of objects is reached, the self-sustained cascading effect would further increase the density without even adding new objects into that orbital region through new launches. This has been confirmed by more recent long-term environment evolution studies (e.g., Liou 2011), where even a future no-launch scenario resulted in an overall orbital population growth due to mutual collisions. The time when this tipping point had been passed was estimated to be in the 1990s (Bastida Virgili and Krag 2011). It is therefore likely that the conditions for a self-sustainable growth are already met in the altitude band between 700 and 900 km and remediation measures, such as active debris removal, might be required to stabilize that region in the future.

The threat posed by the space debris environment, as outlined above, has been recognized as critical by the international community during the 1990s. With officially establishing the Inter-Agency Space Debris Coordination Committee (IADC) in 1993 and culminating in the adoption of the United Nations Technical Report on Space Debris in 1999 (United Nations (UN) 1999), the way toward an international consensus on space debris mitigation had been paved.

3 Space Debris Mitigation

The IADC Mitigation Guidelines (IADC 2007) have been endorsed by the UN General Assembly in 2007 and formed the required international consensus as the basis for subsequent standardization (e.g., ISO-24113:2011) and adoption into national laws (UNCOPUOS 2019a). The main intent is to reduce short- and long-term space debris generation via dedicated mitigation measures. As of today, the only discrimination made is between launch vehicles and spacecraft, which means that all mitigation measures apply equally, whether the mission is public or private, whether it is a large scientific satellite or a tiny *femtosat*.

For satellites in any orbital region, the mitigation guidelines entail to limit the release of debris and minimize the breakup potential during normal operations, to limit the probability of accidental collision with known objects, and, after end-of-life, to passivate the satellite and limit its presence in either the LEO or the GEO protected regions. The *LEO protected region* is defined as the spherical region that extends from the Earth's surface up to an altitude of 2000 km, whereas the *GEO protected region* is a segment of the spherical shell defined by the altitude band between 35,586 and 35,986 km (geosynchronous altitude ±200 km) and latitudes between ±15 degrees with respect to the equatorial plane (IADC 2007).

Even though there are some small satellites (<500 kg) that are launched into geosynchronous orbits, those typically have a few hundreds of kilograms of mass. The vast majority of satellites, especially with a mass below 100 kg, are launched into the LEO region. For instance, for the nano-/microsatellites in the range between 1 and 50 kg, less than 2% of those are expected to go beyond the LEO region in the projected period from 2019 to 2023 (SEI 2019). Therefore, the focus in the following will be on LEO missions.

The disposal phase for any satellite mission in LEO consists of two major steps: limiting its presence in LEO to a maximum of 25 years followed by a passivation of the spacecraft. The so-called *25-year rule* has been accepted based on long-term environment evolution analyses (see also next paragraph) showing an acceptable future trend in the orbital population. For satellites without any maneuvering capability, and therefore lacking the means to avoid collisions, it is understood to set the starting point of that 25-year period already at the time the object is inserted into the environment, whereas for maneuverable satellites that period starts only after the end of the mission. Several options to accomplish the removal of a satellite from the LEO protected region exist and are given in order of preference in ISO (2019):

1. Retrieving it and performing a controlled reentry to recover it safely on the Earth
2. Maneuvering it in a controlled manner into a targeted reentry with a well-defined impact footprint on the surface of the Earth to limit the possibility of human casualty
3. Maneuvering it in a controlled manner to an orbit with a shorter orbital lifetime that is compliant with the 25-year rule
4. Augmenting its orbital decay by deploying a device so that the remaining orbital lifetime is compliant with the 25-year rule

5. Allowing its orbit to decay naturally so that the remaining orbital lifetime is compliant with the 25-year rule

Unless any of the first two options is selected, a passivation of the satellite is required. In general, this implies that the satellite design already foresees measures to permanently deplete all remaining onboard sources of stored energy, such as discharging batteries and making sure they do not recharge again, venting pressure vessels and safe or stop any moving parts like momentum wheels or flywheels.

With retrieval or targeted reentries being very uncommon disposal options for small satellites, the general approach is to launch them into sufficiently low orbits which would comply with the 25-year rule through natural orbital decay. Alternatively, if there is maneuvering capability or the option for orbital decay augmentation after end of mission, for instance, via drag sails, higher altitude orbits can be selected. A more detailed set of recommendations, specifically for small satellites, is provided by IAA (2019). Figure 3 shows the destination orbits (by perigee and apogee altitude) of small satellites with mass below 50 kg. Obviously, the more recent launches tend to put small satellites into lower orbits, but this cannot be attributed to the parallel development of space debris mitigation guidelines alone: it is rather the fundamental change in how small satellites are being launched. The first missions had to find opportunities for piggyback launches, where the primary payload would determine their orbit. It shouldn't come as a surprise that many of those first missions had been injected into typical orbits Earth observation satellites

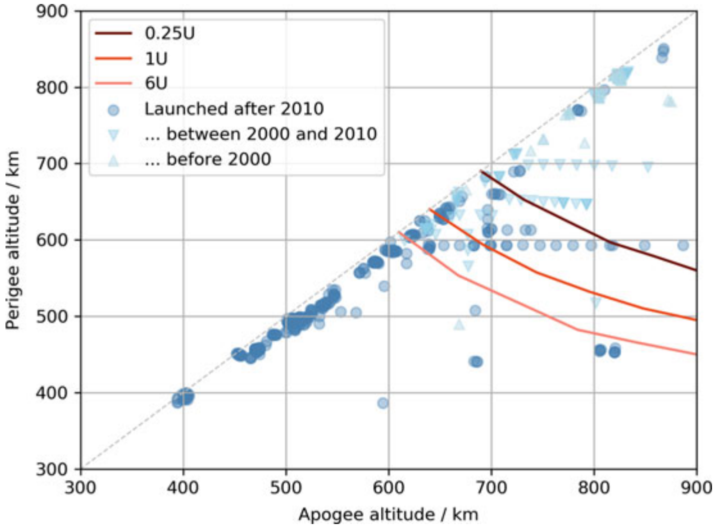

Fig. 3 Destination orbits according to ESA's DISCOS database for on-orbit satellites (as of September 2019) with mass below 50 kg. Altitude limits for a natural orbit decay within 25 years (simulated with ESA's DRAMA/OSCAR tool) indicated for 0.25 U, 1 U, and 6 U CubeSats, for randomly tumbling EOL attitude and a mass of 0.25, 1, and 6 kg, respectively. (©ESA)

occupy, for instance, in Sun-synchronous orbits around 800 km. With ride shares and especially dedicated small satellite launches becoming a reality in the last few years, the picture has clearly changed. From a space debris mitigation perspective, this can be called a positive trend (if launch providers apply the available mitigation standards and guidelines), which is also confirmed by ESA's latest environment report (ESA Space Debris Office 2019): for satellites with a mass below 10 kg, the LEO lifetime compliance has increased from 70.9% to 77.6% over the course of 10 years (2000 vs. 2010). Moreover, looking at the small satellites below 50 kg, as displayed in Fig. 3, it can be said that for all launches since the year 2000, about 26.4% of the satellites currently on orbit have a lifetime beyond 25 years. For those launched since 2010, that number drops to 16.0% and for objects launched since 2015 even to 6.7%. Figure 3 indicates the altitude limits for three different types of CubeSats below which a compliance with the 25-year rule through natural orbital decay can be expected. For near-circular orbits, this threshold is typically around 600 km but depends on the specific satellite design, its assumed attitude mode after disposal, and the applied solar activity forecast method the estimated lifetime is susceptible to. There are many uncertainties in the lifetime estimation process and thus in the compliance verification of any end-of-life disposal plan. Nevertheless, commonly accepted methods and processes on how to perform such analyses have been established, for instance, on ISO level (ISO 2016), and form the basis for tools used by agencies, industry, and academia worldwide in early mission design phases, such as NASA's DAS (Liou et al. 2019), CNES' STELA (CNES 2019), or ESA's DRAMA software (ESA 2019).

The preference of lower altitude orbits comes with another advantage in view of the small satellite failure rates that are still rather high with 42.6% of all launched small satellites between 2009 and 2016 showing either partial or total mission failure (Jacklin 2019). With access to space becoming more affordable, many new entrants come with a generally lower experience in space hardware compared to traditional entities. In addition, shorter design and development cycles do not necessarily imply a positive effect when it comes to reliability. It does not mean that granting everyone access to space is something bad – rather the contrary. But from a perspective of a sustainable space debris environment, it is preferred to have such missions in altitudes where they would naturally comply with guidelines and failure can thus be an option. In other words, if reliability is difficult to assess for any newly developed system, a recommendation could be to go to higher altitude orbits only after a certain design has been proven to work, for instance, via a precursor mission or a checkout in a low altitude orbit.

While the reported failure rates apply to single small satellite missions, the situation might be completely different for small satellite constellations. If a constellation operator can demonstrate a subset from the envisaged constellation working flawlessly, it might be reasonable to assume that the entire fleet would operate with a high success rate, given the identical satellite design. But what is a sufficiently high success rate given that today's mission to deploy large constellations typically targets orbital altitudes around 1000 km? Any satellite failing at those altitudes would remain in the environment for centuries or even millennia. It is therefore crucial to address the environmental impact any large constellation deployment may have and to carefully design the required end-of-life strategy (IADC 2017).

4 Small Satellite Constellations and the Future of the Environment

The concept of satellite constellations has been around since the beginning of space flight, where a group of similar satellites would be used to achieve a certain objective in areas including navigation, telecommunication, meteorology, Earth observation, and reconnaissance. While most of the historic and operational constellations would typically consist of dozens up to a few hundreds of satellites, a rather recent development is to provide low-latency global broadband Internet services through a space-based infrastructure consisting of thousands of small satellites. A very high number of satellites, in a large constellation, are required to obtain a global broadband coverage, whereas the low-latency requirement would demand a deployment in lower altitudes. The most prominent examples include:

- Project Kuiper by Amazon, proposing a constellation of 3236 satellites in LEO according to a filing with the FCC on July 4, 2019.
- The first six satellites were launched in February 2019, but this system has currently declared bankruptcy.
- SpaceX's Starlink constellation consisting of 4425 up to 11,943 satellites, with a first batch of 60 satellites launched in May 2019.

Even though the potential impact of satellite constellations on the space debris environment has been subject of study long before the announcement of any of the abovementioned large constellations (e.g., Anselmo 2001), the current space debris mitigation guidelines are based on the outcome of long-term environment evolution projections without foreseeing any distinct constellation deployment in the models. It was therefore only reasonable that concerns had been raised on whether the recommended mitigation practices were sufficient to limit the growth of the on-orbit population given that thousands of new satellites may become part of that environment very soon. Therefore, several investigations were initiated, mainly involving researchers with capabilities to run long-term environment evolution studies, and coordinated on IADC level, in order to show how a potential future with large constellations in orbit might look like and to provide further technical input to the ongoing policy and guidelines discussions on long-term sustainability. It is important to understand that one does not even get close to predicting the future of the environment with any of the available models. However, if reasonable assumptions are being made and there is an international consensus on the modelling approach, then it is possible (and in fact being done) to base policy decisions on the outcome of such studies. They do not provide credible estimates on the exact total number of objects the population is going to have at a certain point in time, but they allow studying the relative effects when certain mitigation measures are introduced. As an example, the 25-year rule reached consensus after the simulation results obtained by different entities had shown a limited growth of the environment – compared to a reference scenario without disposals in LEO that showed an exponential increase in object numbers indicative of a collisional cascading runaway situation.

Before discussing the outcome of the recent studies on the effects of large constellations, it is important to understand the modelling approach and the assumptions typically made in such simulations in order to ease the interpretation of the results and to be aware of the various uncertainties and the sensitivity of certain parameters.

The first step is to select a reference population representing the current space debris environment. At IADC, as an input to the studies on large constellation, it was agreed to select the MASTER reference population from January 1, 2013 for all objects larger than 10 cm (about 20,000 objects in LEO). The size threshold means a trade-off between those objects relevant for the simulation, i.e., being lethal in a sense of potentially causing catastrophic breakups, and the required computational resources. For the selected objects in that population snapshot, the orbital evolution can be computed until any given point in the future. Typically, projection spans between 100 and 200 years are foreseen.

As new satellites are certainly going to be launched in the future, the next inevitable step consists of defining a launch traffic model. Figure 4 shows the launch traffic to the LEO protected region until 2018. While civil and defense missions were

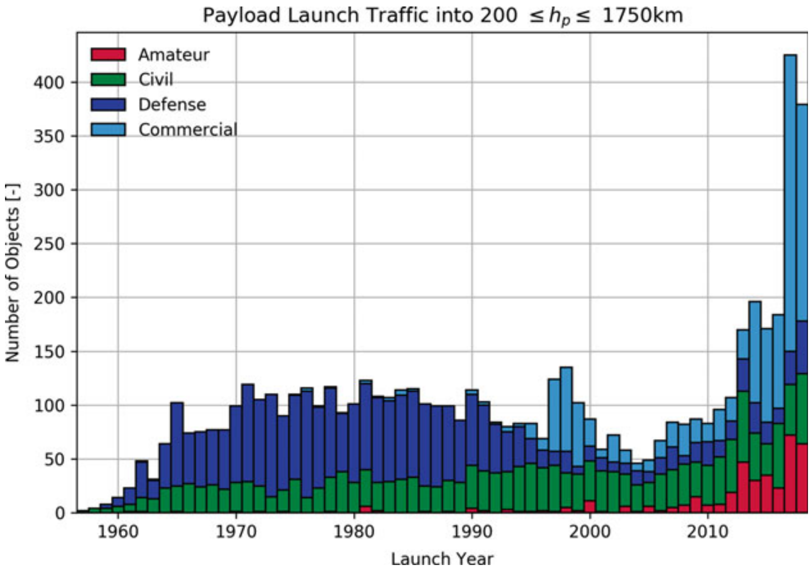

Fig. 4 Payload launch traffic to the LEO protected region (ESA Space Debris Office 2019. ©ESA 2019)

predominant until the early 1990s, amateur and especially commercial missions initiated the paradigm change toward what is referred to as *NewSpace* today. A researcher in 1985 might have perceived a very comfortable situation observing that there was a launch record of roughly 100 satellites per year into LEO for the past 15 years and even a more or less stable share between defense and civil missions. It would have been a reasonable assumption back then to say that things might remain like this for quite some time and therefore to assume a stable launch rate of 100 satellites per year for the future evolution studies they had envisioned. The same researcher 30 years later would be faced with a certain issue: seeing the commercialization, the trend toward smaller satellites, new launch opportunities (ride shares and dedicated small satellite launches), and the announcements made on a possible deployment of large constellations, it is a rather daunting task to make any launch traffic projections, especially for a 100-year time horizon. In past IADC activities, it was generally assumed that the launch record of 8 years may be concatenated to cover the projection span. For instance, when using the IADC 2013 population, the launch record from 2005 to 2012 would be taken such that all launches in the future resembled the very same activity, with only a decent jitter applied to the orbital elements of each payload newly added to the simulation. However, the launch activity between 2005 and 2012 was substantially different from what we see today, especially if market forecasts (e.g., SEI 2019) are taken into consideration, which rather confirm the trend of several hundreds of satellites launched into LEO in the coming few years. In order to account for this effect, many researchers have augmented their models to follow the 2005–2012 cycle and superimpose a trend derived from recent small satellite launches and current market forecasts.

The launch traffic model adds objects to the environment generally assumed to be operational for a certain period, where either they would have no orbit control and thus follow a natural orbit evolution due to external perturbations or they would perform station-keeping and/or collision avoidance maneuvers. In the latter case, it can be assumed that a satellite would successfully avoid any potential collision while it is operated. After its operational phase, that satellite would join the set of objects that are susceptible to collisions and at any simulation step be evaluated by the breakup event model. As an example, the model would check whether at any given time step two objects share the same volume element in space. If this is the case, a collision probability for that encounter would be obtained, and, based on the result, a collision may be triggered or not. In the former case, a breakup model (very common is NASA's Standard Breakup Model EVOLVE 4.0 (Johnson et al. 2001)) would generate fragments of a given size, area-to-mass ratio, and velocity increment, which are subsequently added to the population. The breakup event model would also be used to trigger explosive fragmentations, generally applied to the subset of on-orbit rocket bodies. Again, one may take the history of on-orbit explosions and extrapolate a trend for the future, but then it is also reasonable to assume that passivation would be successfully applied to all future launchers and at a certain point no explosive breakups would occur any more. The latter approach is sometimes preferred to better isolate and compare mitigation measures in a collision-driven growth of the environment.

With the assumptions made above, one simple reference scenario can already be created without any post-mission disposal (PMD) measures so that both satellites and rocket bodies are left on their orbits after their mission. Mitigation activity is added to the model and includes passivation, PMD, and active debris removal (ADR) measures. An exemplary simulation output is shown in Fig. 5. Without any mitigation measures, a nonlinear increase in the number of objects in LEO can be observed, which effectively means that catastrophic collisions would occur more frequently over time – a prerequisite for a collisional cascade. With passivation alone, the number of objects after 200 years is already halved, but a nonlinear trend is still discernible. Adding PMD (with a success rate of 90%) on top leads to a still growing population. Finally, a complete remediation of the environment could, in theory, be achieved by ADR depending on the rate of objects being actively removed from the environment. In Fig. 5, an example is given for five satellites being actively removed per year.

Having established a reference scenario for the background population without any deployment of large constellations, the effect of inserting thousands of small satellites into distinct altitude bands can now be studied relative to that scenario. A generic large constellation was devised in Bastida Virgili and Krag (2015), with a total of 1080 active satellites at 1100 km altitude, and distributed in 20 orbital planes with an inclination of 85 degrees. The full set of model parameters from that study is given in Table 1.

Several operational and end-of-life options were considered to see what the impact on the environment might be, measured in the total number of objects and the cumulative number of catastrophic collisions after 200 years. In addition, the obtained graphs provide additional information whether there is an indication of a runaway situation or not. It was observed that the PMD success rate appears to be the most sensitive parameter, as shown in Fig. 6 for the mean environment evolution trends from a detailed Monte Carlo analysis. The impact of a large constellation can

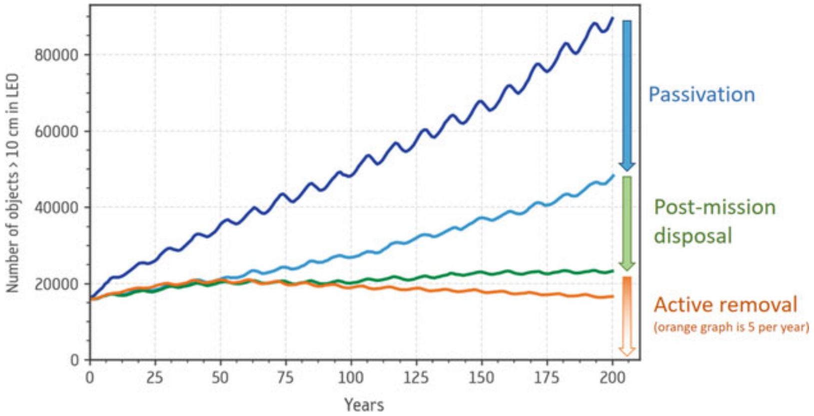

Fig. 5 Example for the evolution of object numbers (>10 cm) in LEO over 200 years for different mitigation strategies. (©ESA)

Table 1 Simulation parameters for a generic small satellite mega-constellation in Bastida Virgili and Krag (2015)

Parameter	Value
No. of satellites	1080
Orbital altitude	1100 km
No. of orbital planes	20
Orbit inclination	85 deg
Mass per satellite	200 kg
Average cross section	1 m^2
Full operational capability	2021
First launch	2018, with 20 launches/year until 2021
Operational lifetime	5 years
Replenishment	12 launches/year
No. of satellites per launch after 2021	18
Upper stage behavior	Immediate reentry after satellite release
Mission-related objects released	None
Collision avoidance	Yes
Constellation lifetime	50 years
End-of-life strategy	Lowering only perigee altitude such that remaining lifetime is <25 years
Background population	MASTER reference population from May 1, 2013; launch traffic 2005–2012
Background population PMD success rate	90%
Explosions	None

essentially be separated into three parts: a steep increase in the on-orbit object population during the constellation buildup and replenishment phases; followed by a period of a decreasing population while the remaining satellites after disposal are still on their decaying orbits; and, finally, a long-term, gradual increase in the population due to collisions involving long-lived, failed constellation satellites.

Assuming a 100% success rate for the disposal of constellation satellites, it is even possible to return to an environment where there would be basically no sign that a constellation ever existed (magenta graph). Applying the same PMD success rate as for the background (90%), a notable difference is observed after 200 years, but the trend (green graph) is very similar to the background population, and also the growth rate is on the same order, so that one could call such a scenario acceptable. In fact, later studies (e.g., Bastida Virgili et al. 2016a) introduced a Wilcoxon rank sum test to show that the null hypothesis of a nonexistent long-term impact had to be rejected (at a 5% significance level) for PMD success rates below 95%. Further reducing the PMD success rate leads to an increase of the object growth rate in LEO after the constellation lifetime, as shown for the 50% case in Fig. 6 (blue graph). In that case, it is already very obvious that the constellation has a long-term impact on the environment. It should be emphasized that Fig. 6 is only showing the mean trends.

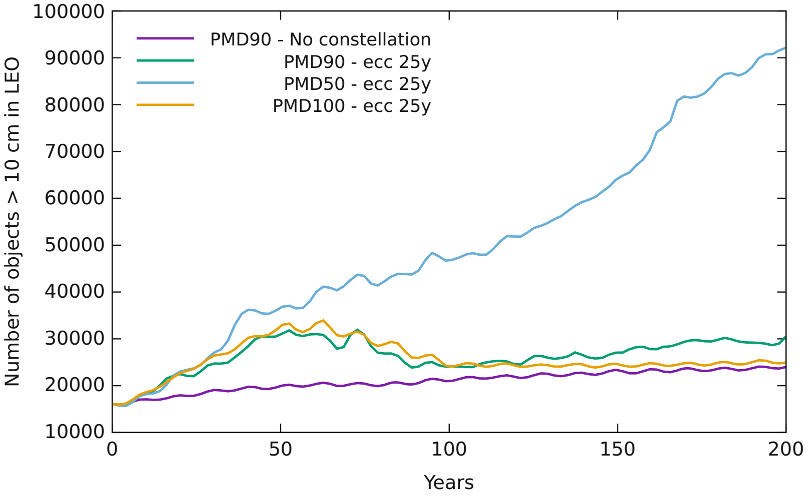

Fig. 6 Evolution of the number of objects in LEO varying the PMD success rate for constellation satellites. (Bastida Virgili and Krag 2015. ©ESA, 2015)

Other representations included the assessed uncertainty from the different Monte Carlo runs and showed that variations from that mean can be quite high, even though they do not contradict the interpretation given here (Bastida Virgili et al. 2016a). A high PMD success rate is therefore required, as otherwise many failed satellites will end up stranded in the constellation's operational altitude and suffer from collisions at some point. Another finding was a positive correlation between the constellation lifetime and the PMD success rate: increasing the former demands to be more successful in the disposal phase in order to end up in similar scenarios after the constellation has ceased.

More detailed analysis followed later, after the initial identification of significant parameters for the long-term impact on the environment had been made, e.g., (Bastida Virgili et al. 2016a, b). Combining the results of different environment evolution models, it was confirmed that the highest priority for any large constellation should be on the PMD success rate. The effect of further reducing the remaining orbital lifetime after disposal, for instance, from 25 years to 10 years, was discernible, as the interaction with lower altitude satellites and the potential for a collision would be reduced. A trade-off between PMD success rate and the residual lifetime would be always biased toward the former. As an example, a 90% PMD success rate combined with a 25-year remaining lifetime strategy resulted in the same number of objects in LEO over the projection period as a scenario with 85% PMD success rate and disposal orbits with a 5-year remaining lifetime (Lewis et al. 2017). However, the failure rate is typically not selectable by the constellation operator and may be even unknown at the beginning when the constellation is being built up. One option is to insert the first satellites into low orbital altitudes and have an initial checkout phase followed by a transfer to the operational orbit. In that case, any early orbit failure will leave a satellite stranded at altitudes that are highly affected by residual drag, thereby leading to a quick natural removal from the environment.

Satellites being part of the background population would experience a non-negligible impact of such a large constellation operated at much higher altitudes, as the disposed constellation satellites would start crossing their operational orbits. The efforts in terms of collision avoidance would clearly increase, with an example being the five- to tenfold increased flux estimated for the International Space Station (ISS) during the constellation's operational lifetime (Lewis et al. 2017; Peterson et al. 2016). Adding high numbers of small satellites into lower altitudes below 600 km only exacerbates this effect (Bastida Virgili et al. 2016b).

Similar results for slightly different constellation parameters were also obtained by other researchers (e.g., Kitajima et al. 2016). In essence, one may conclude that the more general results obtained for the space debris environment evolution in earlier studies, e.g., (Anselmo 2001), were confirmed by the more recent analyses that put a focus on the impact large constellations may have: a full adherence to the currently existing mitigation guidelines (incl. the 25-year rule) may avoid a destabilization in the long-term evolution of the environment, if accepted PMD failure rates for constellation satellites would be limited even further. This would also be in line with the currently recommended end-of-life disposal reliability of 90% in ISO-24113 as a bare minimum. Further measures that have an influence on the environmental impact already during the design phase are to decrease the constellation satellites' cross section and to increase the individual constellation satellite's lifetimes (Lewis et al. 2017). Nevertheless, an impact on the environment will always exist, at least on the short-term during the operational phase of the constellation with an increase in collision avoidance efforts for all other operators.

Even though these findings provide some reassurance that the environmental impact of small satellite large constellations can be addressed and significantly reduced through careful mission design, there is an important caveat: the conclusions drawn from the investigation of the environmental impact of a single constellation to not always lend themselves to be applied if multiple large constellations are being operated. Moreover, even the increase of the number of intra-constellation satellites beyond the about 1000 satellites (as used in most analyses) may lead to different conclusions. For instance, in a constellation of 4000 satellites, the influence of whether conducting operational collision avoidance for the constellation satellites or not is much more pronounced than in a 1000 satellites case (Kitajima et al. 2016). This is understandable, as quadrupling the number of satellites in the constellation and applying the same PMD success rate mean that after any given time interval, the expected number of failed satellites at the constellation's operational altitude is four times higher. In other words, a linear increase in the constellation size may result in a nonlinear increase in the number of self-induced catastrophic collisions (Lewis et al. 2017). This finding has been also confirmed for non-constellation traffic: the expected increase in small satellites being launched into near-Earth space requires us to rethink the "big space" paradigm. Certain altitude bands (around 800 km) appear to show a future increase in spatial density even if no further launches would occur (Somma et al. 2019). Also other altitudes, as the ones proposed for large constellations, show the tendency of a limited capacity in terms of a maximum number of satellites that could be inserted for a given time interval. A notion of the need to control the growth of the number of objects in the environment is thereby attained.

5 Environment Control: The Concept of Capacity

The current set of space debris mitigation guidelines apply to single satellites and launch vehicles. Although their formulation is based on technical input gathered from long-term environment evolution studies, there is no dynamic way of accounting for significant changes in the environment that were not foreseen in those studies, like the substantial transformation of launch traffic with increased commercialization of the space sector or the current adherence levels to mitigation guidelines as opposed to expected ones. Moreover, it was noted earlier that a linear change in the behavior of an individual object has a nonlinear response when the number of individuals is high enough. Recognizing that each satellite may leave a certain footprint during its presence in the space debris environment, it seems only reasonable to come up with a metric or index formulated such that relevant aspects of the satellite's mission affecting the environment evolution are captured. Applying such an index globally, one may take this approach one step further and come up with the concept of environment capacity: if a certain environment evolution trend for a given period appears to be acceptable to the international community, one can compute the cumulated index and thus obtain the available resources to the community over the same period.

Several authors have studied ways of classifying intact satellites with respect to their environmental criticality. The *Figure of Merit* (FOM) developed in Utzmann et al. (2012) allows ranking objects according to their preference for active debris removal. Similar ranking schemes have been devised and extended to be applied in other areas such as the *Criticality of Spacecraft Index* (CSI) in Rossi et al. (2015), which has been later modified to assess parameter sensitivities of certain large constellations designs (*Criticality of Constellation Index* (CCI) Rossi et al. 2017); the ranking scheme to evaluate the Italian satellites' disposal strategy compliance in (Anselmo and Pardini 2015); the *Environment Criticality* (EC) index in (Kebschull et al. 2017); or the *Environmental Consequences of Orbital Breakups* (ECOB) in (Letizia et al. 2017). Most of those formulations are based on a very simple relationship for the index:

$$Index = Probability \times Severity,$$

where the *probability* quantifies the likelihood of a collision (and subsequently a catastrophic breakup) for a given orbit subject to the background space debris population, whereas the *severity* provides an estimate of the potential breakup consequences.

Providing flux estimates for any given target orbit, the MASTER model has been used in many formulations, e.g., for the EC or the ECOB index, to come up with a value for the probability at distinct epochs but also to compute an integrated value over the mission lifetime (or the entire on-orbit time) capturing both the evolution of the target orbit and the background population.

The severity term generally quantifies the impact a fragmentation of the target satellite would have on the environment, including active satellites. For instance, if a breakup is likely to occur in densely populated orbital regions, the severity term will correspondingly be higher compared to cases with breakups in regions with low activity. More complete solutions, like for the ECOB index (Letizia et al. 2019), take also into account that fragment clouds evolve over time and thus affect different orbital regions and active satellites in the future.

The application of an index, or any other comparable risk metric, will capture the impact of a single mission on the environment. It will discriminate between large and small satellites, it will favor missions in naturally compliant orbits over high altitude ones, etc.

Having established the formulation of the index for single satellites, it is straightforward to compute the *cumulative index* for the entire on-orbit population of intact satellites. The strength of this cumulative index, when carefully constructed, is that it quantifies the notion of space as a limited resources discussed earlier. In such a representation, the state of the environment can be evaluated, and different mitigation strategies may be compared with respect to each other. An example for the cumulative ECOB index is shown in Fig. 7. It compares three

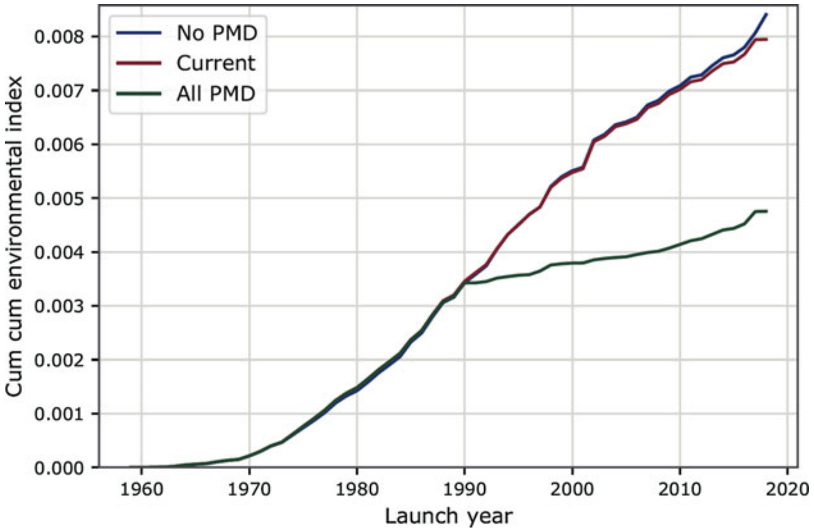

Fig. 7 ECOB cumulative index as a function of time for different mitigation scenarios. (©ESA, 2018)

different strategies that were assumed to be applied since 1990 in order to see how the environment would have evolved until today. The *No PMD* scenario would see satellites just left in their operational orbits after the end of mission; in the *Current* scenario, the actual environment as it evolved until today can be found, whereas the *All PMD scenario* shows an evolution where all satellites launched after 1990 would have been disposed of after their operational lifetime. In essence, if end-of-life mitigation measures would have been applied since the 1990s as they are recommended today (of course, they did not exist back then), the cumulative index would have been only half of what it is now. Interestingly, the current situation is very close to the *No PMD* scenario. In other words, a low level of adherence to the mitigation guidelines does not differ too much from a scenario where operators just do not dispose of satellites after their end of mission. It may also indicate that the satellites being disposed are not necessarily the most critical ones in the environment.

In this sense, the formulation of an index can be used as a metric to describe the environment capacity. Without loss of generality, an example is being discussed in Letizia et al. (2019), where it is assumed that the international community could agree on a long-term environment evolution trend with a rigorous implementation of space debris mitigation guidelines and an associated PMD success rate of 90% corresponding to what they could define as a sustainable use of the resource space. It is possible to compute the cumulative index for such a scenario, which had a value of 2.4 over 100 years in Letizia et al. (2019). All missions that are supposed to be launched over the next 100 years are thus thought to consume at most an index of 2.4. If started in 2020, a certain index for all satellites launched in that year could be obtained, along with what remains for the subsequent 99 years by just subtracting what was consumed in 2020. This way, an important feedback mechanism could be introduced, where mitigation measures were directly translated to lower consumption and thus an increased capacity to launch more satellites.

Even though such an approach does not currently exist, it does not seem unrealistic that consensus might be reached in the future. In fact, the International Telecommunications Union's (ITU) registration process for frequency allocation works in a similar fashion, where registration is expected between 7 and 2 years before the date of *bringing into use*, and may serve as an inspiration for a capacity register (Letizia et al. 2019). Any mission designers might check their satellite's index estimate via a publicly available service and compare to similar missions followed by the capacity allocation for a possible launch.

Recognizing near-Earth space as a valuable resource where a sustainable consumption is desired, and given the free access to space according to the *Outer Space Treaty*, the space debris problem is another area that relates to the *tragedy of the commons*. One important aspect in this context is in which order entities would be allowed to harvest from that resource. In Letizia et al. (2019), the *first-come, first-served* approach is elaborated in analogy to the ITU registration process, but discussions have just begun, and the outcome remains to be seen. The likely slowdown in the deployment of smallsat constellations as a result of the Covid-19 virus, may help to resolve the issue of the equitable use of the global commons.

6 Conclusion

Many important services modern society relies on are delivered by satellite technology from near-Earth orbits. It is noble common goal to maintain these benefits or even to further expand for generations to come, but then issues related to sustainability need to be addressed. The increasing traffic in Earth orbits has given rise to concerns of a potential instability due to a collisional cascading effect, also referred to as the Kessler syndrome. This is not an issue in the far future – it needs to be addressed now, observing that research indicates repeatedly that a certain tipping point condition may have been already reached in altitudes around 800 km.

International consensus on space debris mitigation has been reached on UN level more than a decade ago, followed by an ongoing process of the adoption of those guidelines into standardization processes and national laws. In order to minimize the potential to generate space debris, any satellite or launch vehicle needs to limit its presence in the LEO and GEO protected regions. While current levels of adherence to post-mission disposal (PMD) guidelines are at about 60% for payloads (excluding naturally compliant ones, the PMD adherence level drops to merely 20% (ESA Space Debris Office 2019)) and about 80% for rocket bodies (ESA Space Debris Office 2019), it is encouraging to observe that especially small satellites are being increasingly inserted into sufficiently low orbits, where the remaining on-orbit lifetime is below 25 years.

For small satellite constellations, where plans to launch thousands of satellites into significantly higher altitudes at about 1000 km have been announced, a strict adherence to mitigation guidelines is required. Many researchers have confirmed that any impact of such a single large constellation on the environment can be minimal to negligible, if a high PMD success rate (>95%) would be attained. In case of multiple large constellations, also this could not be sufficient. Moreover, this is clearly beyond what is observed in LEO today and may serve as a serious constraint in a competitive market. Even though a certain trade-off may be possible when reducing the remaining on-orbit lifetime way below the required 25 years, the PMD success rate would still be the driving parameter: an exemplary analysis showed that 5 years remaining lifetime could allow for a trade-off with the PMD success rate to 85%. It has also been shown that a careful design of the constellation operations may address end-of-life issues already at relatively low additional cost, including the minimization of the satellite's cross section or the insertion into low altitude orbits. While there are ongoing discussions on whether more stringent requirements are required for large constellations or whether small satellites should be treated differently, the current analyses indicate that the existing set of guidelines need to be strictly applied by everyone.

Satellite collisions, which are expected to be the main driver of the object population growth in the future, are not only a subject of matter after the end-of-life measures have been taken. With increased space traffic in a highly dynamic environment, where there are difficulties to track and catalogue all potentially lethal objects, it is in the self-interest of any satellite operator to become even more responsible toward safe operations in space including collision avoidance measures.

The recent case of the close approach between ESA's Aeolus and SpaceX's Starlink satellite (Foust 2019) was indicative of the common need for more accurate data and methods but also procedures and protocols being established and exchanged within the community. Addressing this need, the recent adoption of the *Guidelines for the Long-term Sustainability of Outer Space Activities* by the UN's Committee on the Peaceful Uses of Outer Space (UNCOPUOS 2019b) can only be reassuring.

Given that responsible space operations and full adherence to mitigation guidelines are granted, potentially with a few large constellations in space with sufficiently low environmental impact, this may nevertheless be insufficient to keep space sustainable. With too many satellites being launched, as can be the case with space infrastructure being commercialized and maintained to a high degree by profit-maximizing firms (Adilov et al. 2013), runaway conditions may still be reached. One example is in the launch of multiple large constellations, where not all of them find their business case achieved. A worst-case scenario in a potential bankruptcy could mean that all of the already launched satellites of that failed constellation would remain in space for centuries.

In a constrained environment, such as the LEO region, traffic needs to be controlled in order to guarantee sustainability. Where that limit is may be debatable, but the recent proposals to establish a rating scheme appear promising. With the likelihood of a collision and the impact such an event would have on operators and the environment in general factored into a single index, any space mission can be evaluated already before its launch. Moreover, a cumulative index could support the establishment of a capacity register for any given orbital region and thus limit the number of missions launched in a given time period as a consequence. This may be perceived as a step to constrain the freedom to access space guaranteed by the *Outer Space Treaty*, but recognizing space as a limited resource, noting that the Outer Space Treaty also calls to avoid harmful interference, and acknowledging that any satellite operated in space is actually consuming part of that commonly shared resource, it seems only reasonable to agree with Hegel: freedom is the recognition of necessity.

Spectrum Frequency Allocation Issues and Concerns for Small Satellites

Morio Toyoshima and Attila Matas

Contents

Abstract

Many small-satellite missions have been launched and many more are planned. Small-satellite projects and missions are becoming very active because of some of their advantageous features, such as low latency. As the development cycle and the mission duration for small satellites are short, the relaxation of the regulation and easy deployment are discussed. The current situation with regard to the regulatory aspects for nanosatellites and picosatellites, especially in terms of frequency allocations, is described in this chapter.

1 Introduction

The number of small-satellite missions has increased recently. More than 200 launches were conducted in 2018 and more than 400 nanosatellite launches are forecasted in 2019 (Erik Kulu 2019). As the number of launched small satellites increases, there are some frequency-allocation issues for small satellites. This chapter describes the current situation for spectrum-allocation issues and concerns for small satellites.

2 Characteristics of Small Satellites

Small satellites have advantages such as being faster to build and deploy, lower in cost, and having less path loss as well as transmission delay. Figure 1 shows an 1U-size CubeSat which is standardized with the dimensions of 10 cm × 10 cm × 10 cm. The faster development duration can be less than 1 year. The cheaper development cost can be less than tens of thousands of dollars for simple CubeSats. Faster implementation can be done by using modular and standardized CubeSat equipment, and miniaturized equipment can be used based on the latest technology. On the other hand, there are some drawbacks, such as limited launching opportunity, none or little orbit control, small or unreliable power source, limited lifetime, limited mission types, and limited regulatory certainty. Small satellites, however, provide a means for testing emerging

Fig. 1 An example of 1U-size CubeSat

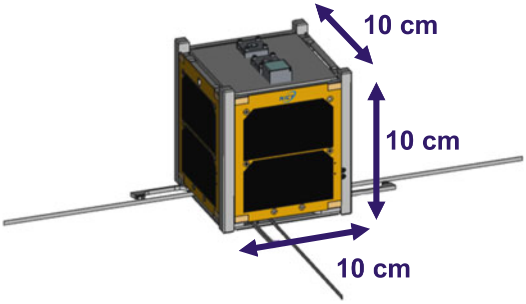

Table 1 Typical characteristics of small satellites

Denomination	Mass (kg)	Max. bus power (W)	Typical cost (USD)	Max. dimensions (m)	Development time (years)	Mission duration (years)
Smallsat (Minisat)	100–500	1000	30–200 M	3–10	3–10	5–10
Microsat	20–100	150	10–150 M	1–5	2–5	2–6
Nanosat (1U-6U CubeSat)	1–20	20	100 k–10 M	0.1–1	1–3	1–3
Picosat	0.1–1	5	50 k–2 M	0.05–0.1		

Note: There are various definitions of small-satellite categories that are used and development times and mission durations vary to a degree around the world

technologies, offer opportunities for new satellite operators that might not otherwise have considered or been able to afford the use of satellite technologies, and operation or demonstration in a variety of practical space-based applications according to the satellite mass categorized as shown in Table 1 (Report ITU-R SA.2312 2019). Moreover, small satellites are easy to be launched with a larger host satellite as piggy-back.

3 Definition of Small Satellites

There is no regulatory definition for small satellites in the International Telecommunication Union Radio Regulations (RR). There are only definitions for geostationary (GSO) and non-GSO satellites. Most of small satellites will be launched in the low earth orbit (LEO); therefore, small satellites belong to non-GSO satellites (ITU-R WP7B 2019; Matas 2018). The characteristics and spectrum requirements of satellite systems using nano- and picosatellites in ITU-R were studied and reported in ITU-R SA.2312 characteristics, definitions, and spectrum requirements of nanosatellites and picosatellites, as well as systems composed of such satellites and ITU-R SA.2348 current practice and procedures of notifying space networks currently applicable to nanosatellites and picosatellites (Report ITU-R SA.2312 2019; Report ITU-R SA.2348 2019). The small-satellite community was interested in relaxation of the RR and easy deployment of their non-GSO satellites. The regulatory aspects for nanosatellites and picosatellites in Resolution 757 at World Radiocommunication Conference 2012 (WRC-12) of the ITU resolves to invite WRC-18 to consider whether modifications to the regulatory procedures for notifying satellite networks are needed to facilitate the deployment and operation of small (nano- and pico) satellites and to take the appropriate actions. But the quick decision made at WRC-15 was that there was no need for any special regulatory procedures to facilitate the deployment and operation of nano- and picosatellites.

4 Small Satellite with Short Duration Mission

Small satellites with short duration mission (SDM) are discussed in terms of technical characteristics and spectrum requirements in ITU-R Study Group 7 – Working Party 7B (ITU-R WP7B) (Report ITU-R SA.2312 2019) and the results of these studies are presented in the Report ITU-R SA.2425 studies to accommodate spectrum requirements in the space operation service for non-geostationary satellites with short duration missions and Report ITU-R SA.2426 technical characteristics for telemetry, tracking, and command in the space operation service below 1 GHz for non-GSO satellites with short duration missions (Report ITU-R SA.2425 2019; Report ITU-R SA.2426 2019). WRC 15 decided about a new RES 659 Studies to accommodate requirements in the Space Operation Service (SOS) for non-GSO satellites with SDM and invited the ITU-R to study the spectrum requirements for tracking, telemetry, and command (TT&C) in the SOS for the growing number of non-GSO SDM satellites. A new term "short duration mission (SDM)" as stated in the Resolution 659 is used for the first time in the ITU-R, which refers to a non-GSO satellite system having a limited period of validity of not more than typically 3 years. There is currently no particular regulatory definition for non-GSO SDM satellites. The ITU-R Study Group 7 – Working Party 7B (ITU-R WP7B) developed at the CPM19- Report to the WRC-19 (CPM Report 2019) four methods to satisfy WRC-19 Agenda Item 1.7 (*to study the spectrum needs for telemetry, tracking, and command in the space operation service for non-GSO satellites with short duration missions, to assess the suitability of existing allocations to the space operation service and, if necessary, to consider new allocations, in accordance with Resolution 659 (WRC-15))* and two new reports (Report ITU-R SA.2425 2019; Report ITU-R SA.2426 2019) how to satisfy this action item:

1. Method A proposes no change to the RR.
2. Method B1 proposes a new SOS (Earth to space) allocation for non-GSO SDM systems in the frequency range 403–404 MHz.
3. Method B2 proposes a new SOS (Earth to space) allocation for non-GSO SDM systems in the frequency range 404–405 MHz.
4. Method C proposes to use the SOS allocation in the frequency band 137–138 MHz for downlink and the band 148–149.9 MHz for uplink and to provide appropriate associated regulatory provisions in the RR for non-GSO SDM TT&C links.

Since the existing RR does not take into account the short development cycle and the short lifetimes of non-GSO SDM, a simplified regulatory regime and recording procedures for non-GSO SDM is required. Based on missing regulatory regime for non-GSO SDM, the ITU-R Study Group 4 – Working Party WP4A developed a method as described in the CPM19 Report to the WRC-19 (CPM Report 2019) Agenda Item 7-Issue I – to address this issue that consists of modifications to the existing regulatory procedures for Advanced publication information (API) and Notification of satellite networks and systems that are not subject to Section II of

RR Article 9, to facilitate the recording of non-GSO SDM systems in the MIFR. The most important aspects of the new draft Resolution Simplified regulatory regime for non-GSO SDM satellite systems proposed by the ITU-R WP4A are:

- SDM satellites, operating under any space service not subject to ART 9 Section II (ITU Radio Regulations 2016), shall follow the RR with the exceptions stipulated in this resolution.
- The application of the simplified regulatory regime shall have no impact, as compared to networks not applying the simplified regulatory regime, on the regulatory sharing status of the allocations to services, both terrestrial and space.
- SDM satellites using spectrum allocated to the amateur radio service shall operate under ART 25 (ITU Radio Regulations 2016).
- The total number of satellites in a SDM satellite constellation shall not exceed 10 (t.b.d. by WRC 19) satellite;
- The maximum period of operation and validity of frequency assignments of a SDM satellite shall not exceed 3 years from the date of bringing into use (DBIU), which is equal to the satellite launch date, without any possibility of extension.
- SDM satellite systems shall have a single launch date associated with the first launch (in the case of systems with multiple launches).
- SDM satellites for which the regulatory regime in this resolution is applied will not accrue any special or additional rights under the RR over those satellite systems not applying this regime.

5 Frequency Allocation for Small Satellites

Main purposes of small satellites are used for amateur satellite, space operation, Earth observation satellite, space exploration satellite, weather monitoring satellite, and so on. There are some instances where 1U-6U satellites are used for commercial purposes and such uses and spectrum allocations are consistent with the processes related to such services for telecommunications, remote sensing, RF Geolocation, etc. As an example, the frequency band for nanosatellites is shown in Fig. 2 (Erik Kulu 2019). As can be seen from W-band and laser/optical in Fig. 2, the higher frequency bands will be used more in future small-satellite missions. The typical frequency allocated for small satellites are shown in Table 2 (Matas 2016). For the allocation of frequencies, the world on the Earth has been divided into three "radiocommunication" regions as described in provision No. 5.2 of the ITU Radio Regulations (Timmerman 2018): exclusive allocations, which are favored in cases that involve broad international use of equipment; shared frequency allocations, which are applied to maximize the use of the available spectrum when two or more radiocommunication services can effectively utilize the same frequency band. A shared frequency band can be allocated to more than one service (primary or secondary). Stations of a secondary service shall not cause harmful interference to stations of primary service, cannot claim protection from harmful interference from stations of a primary service, and can claim protection, however, from harmful

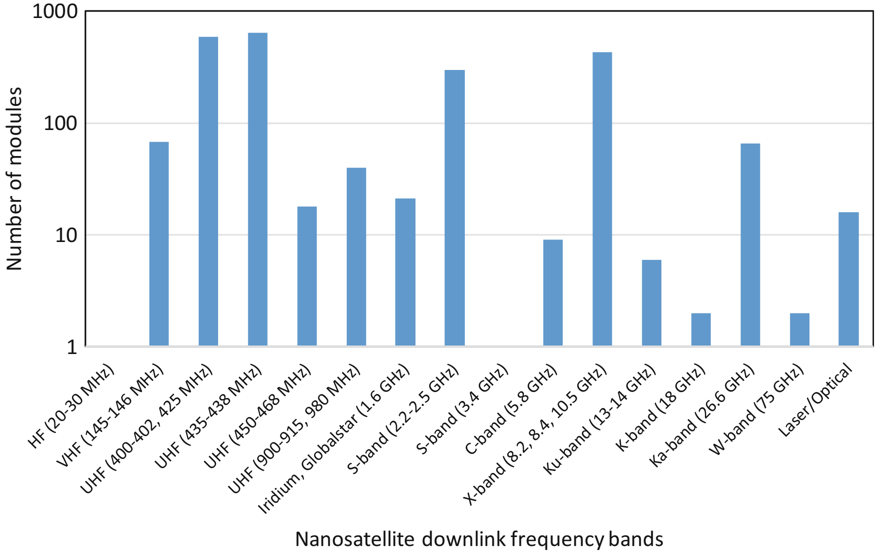

Fig. 2 An example of frequencies allocated for nanosatellite downlink bands

interference from stations of the same or other secondary service(s) to which frequencies may be assigned later (Timmerman 2018).

According to No. 4.4 of the RR (Timmerman 2018) Administrations of the Member States shall not assign to a station any frequency in derogation of either the Table of Frequency Allocations in this Chapter or the other provisions of these Regulations, except on the express condition that such a station, when using such a frequency assignment, shall not cause harmful interference to, and shall not claim protection from harmful interference caused by, a station operating in accordance with the provisions of the Constitution, the Convention, and these Regulations.

The determination of whether or not a frequency assignment to a transmitting station is capable of causing harmful interference to the stations of another administration operating in accordance with the Radio Regulations does not lie only on the side of the administration operating the transmitting station that may be producing the interference and other administrations should have information about a use under No. 4.4 to assess its interference potential or identify the source of harmful interference. For this reason, an administration intending to use a frequency assignment to a transmitting station under No. 4.4 has to notify to the Bureau this frequency assignment, pursuant to Article 11 (Timmerman 2018), if possible prior to bringing it into use.

When notifying the use of frequency assignments to be operated under No. 4.4, the notifying Administration shall provide a confirmation that it has determined that these frequency assignments meet the conditions and that it has identified measures to avoid harmful interference and to immediately eliminate such in case of a complaint (ITU Rules of Procedure 2018).

Table 2 Typical frequency allocated for small satellites

Frequency band	Service	Symbol	Type of allocation
401–403 MHz	EESS (E-S)	EW	Primary
401–402 MHz	SOS (S-E)	ET	Primary
449.75–450.25 MHz	SOS (E-S) SRS (E-S)	ET EH	No. 5.286-only subject to No. 9.21 (other No. 4.4)
1215–1300 MHz	ESSS (active), SRS	Ex, EH	Nos. 5.330–5.335A protecting RNSS and RL
1427–1429 MHz	SOS (E-S)	ET	Primary
2025–2110 MHz	EESS (E-S, S-S) SOS (S-E, S-S) SRS (E-S, S-S)	EW ET EH	Primary
2200–2290 MHz	EESS (S-E, S-S) SOS (S-E, S-S) SRS (S-E, S-S)	EW ET EH	Primary
2290–2300 MHz	SRS (S-E) (deep space)	EH	Primary
8025–8400 MHz	EESS (S-E)	EW	Primary
8400–8500 MHz	FX, MOB SRS (S-E)	EH	Primary
8550–8650 MHz	(EESS), (SRS) (active)	Ex, EH	Primary
9300–9800 MHz	(EESS), (SRS) (active)	Ex, EH	Primary
9800–9900 MHz	(eess) (active) (srs) (active)	Ex EH	Secondary
10.6–10.7 GHz	(EESS), (SRS) (passive)	Ex, EH	Primary
13.25–13.75 GHz	(EESS), (SRS) (active)	Ex, EH	Primary
22.21–22.5 GHz	(EESS), (SRS) (passive)	Ex, EH	Primary
22.55–23.15 GHz	(ISS), (SRS) (E-S)	ES, EH	Primary (No. 5.338A)
23.6–24 GHz	(EESS), (SRS) (passive)	Ex, EH	Primary

Notes: *EESS* earth exploration-satellite service, *SOS* space operation service, *SRS* space research service, *EW* space station in the earth exploration-satellite service, *ET* space station in the space operation service, *EH* space research space station, *ES* station in the inter-satellite service

Amateur-satellite service (EA) can be used for small satellites. Amateur service is defined as a radiocommunication service for the purpose of self-training, intercommunication, and technical investigations carried out by amateurs, that is, by duly authorized persons interested in radio technique solely with a personal aim and without pecuniary interest in RR 1.56. Amateur-satellite service is also defined as a radiocommunication service using space stations on earth satellites for the same purposes as those of the amateur service in RR 1.57. The frequency allocation for EA is shown in Table 3 (Timmerman 2018).

Table 3 Frequency allocations for amateur satellite service

Wavelength	Frequency band (MHz)	Applications
10 m	28,000–29,700 (primary)	This band is used primarily in conjunction with an input or output in the 144 MHz band
2 m	144–146 (primary) Satellite: 145.794–146	These bands are in heavy use by numerous amateur satellites for inputs and outputs
70 cm	435–438 (secondary) RR No. 5.282	
23 cm	1260–1270 (secondary) Earth-to-space only RR No. 5.282	These bands are used as alternatives to the 144 MHz and 435 MHz bands because of congestion
13 cm	2400–2450 (secondary) RR No. 5.282	
9 cm	3400–3410 (secondary) Regions 2 and 3 only RR No. 5.282	
5 cm	5650–5670 MHz (secondary) Earth-to-space only RR No. 5.282	These bands are used for experimental amateur satellites
	5830–5850 MHz (secondary) Space-to-earth only	
3 cm	10.45–10.5 GHz (secondary)	These bands are used for experimental amateur satellite communications
1.2 cm	24–24.05 GHz (primary)	
6 mm	47–47.2 GHz (primary)	These bands are used for experimental amateur satellites
4 mm	76–77.5 GHz (secondary)	
	77.5–78 GHz (primary)	
	78–81 GHz (secondary)	
	81.0–81.5 GHz (secondary) RR No. 5.561A	
2 mm	134–136 GHz (primary)	
	136–141 GHz (secondary)	
1 mm	241–248 GHz (secondary)	
	248–250 GHz (primary)	

6 International Frequency Coordination, Notification and Recording in the ITU Master International Frequency Register

An Administration shall send to the Bureau a general description of the network for the Advanced Publication Information (API) not earlier than 7 years and preferably not later than 2 years before the planned DBIU of the satellite network or system as shown in Fig. 3 (Matas 2016). A clear majority of the non-GSO small satellites operates in the frequency bands not falling under formal ART 9

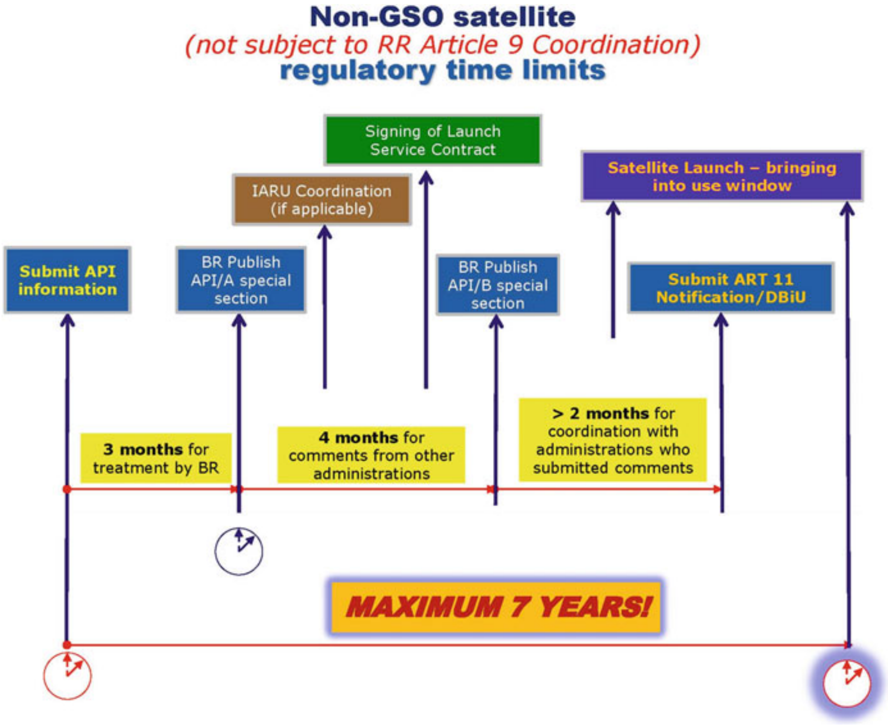

Fig. 3 Basic international frequency coordination procedure for small satellites

coordination procedure. Shortest regulatory limit for non-GSO not subject to coordination from API up to Notification/DBIU is no more than 9 months. The API is published after 3 months through International Frequency Information Circular (IFIC) at the ITU. Following to the publication of the API, comments from other administrations are accepted for 4 months. The international frequency coordination is then conducted with administrations who submitted any comments. The regulatory time-limit represents crucial information for bringing a satellite network into use and submitting notices for recording in the Master International Frequency Register (MIFR). The notified DBIU of any assignment to a space station of a satellite network shall be no later than 7 years following the receipt of the API.

Requirements for administrations to notify satellite frequency assignments and associated orbital positions for recording in the MIFR, declaration of bringing satellite into use, and protection of these assignments from harmful interference are the key pillars of the ITU RR international orbit/spectrum regime.

7 Conclusion

The current situation of the regulatory issue for small satellites was described. There is no regulatory definition for small satellites in ITU-R RR, but in general small satellites belong to non-GSO satellites because most of them are launched into the LEO. A non-GSO satellite system having a limited period of validity of not more than typically 3 years can be referred as SDM. As it is expected that the number of small-satellite missions will increase, the new frequency bands are allocated for non-GSO SDM systems, which corresponds to the relaxation of the regulation for small satellites because of the short development cycle and the SDM. Higher frequency bands will be used more for small-satellite missions in the future.

Flight Software and Software-Driven Approaches to Small Satellite Networks

Robert Harvey

Contents

Abstract

There is a growing market for satellites that fall into the "Microsat" and "Nanosat" classifications. Many of these satellites are designed and manufactured by small groups such as in academia, startups, or small incubator teams inside larger organizations. These environments tend to be fast-paced and will likely eschew traditional aerospace life cycles and design paradigms in favor of rapid prototyping, consumer electronics parts, and even on-orbit testing. Microsats

R. Harvey (✉)

have somewhat different flight software implications and requirements than traditional satellites. This chapter discusses some of the flight software aspects of Microsats, along with design trades, processes, and the role of the flight software group in small organizations. Certain aspects of the flight software are called out for Microsats, including satellite safe modes, configuration updates, on-orbit software upgrades, and security. The flight software life cycle for Microsats is discussed in the context of a shifting and multiple-launch schedule. The intent of the chapter is to lay out guidelines for new flight software engineers such that while building out new Microsats, they also lay the groundwork for launching their product at scale.

Keywords

Planet · FSW · Flight software · Satellite telemetry · Satellite constellations · Cubesat, Microsat

1 Introduction

At the time of this writing, Planet Labs Inc. ("Planet") operates one of the largest satellite constellations in history (chapter ▶ "Planet's Dove Satellite Constellation"). Planet's approach to satellite design and operation is a departure from traditional methods, including a focus on using consumer-off-the-shelf (COTS) components, leveraging the Cubesat form factor and launching early and often with primary and secondary payload opportunities. In the beginning, this approach to satellites was largely unverified and certainly not applied to scale. This novel approach has implications for the flight software (FSW) and the flight software engineer, not least of which is that the flight software engineer may be working on an aggressively small team and the lines related to traditional functional roles may be blurred. The intent of the chapter is to lay out the challenges that can face new flight software engineers when working toward Microsat missions and provide a way of thinking that can ensure mission success for Microsat designs that may eventually be launched at scale. The content that follows is based on the author's experience at Planet; it is not based on any extended experience in the traditional aerospace fields. This does not reflect the opinions of Planet Labs.

2 Flight Software and Microsats

Is flight software for Microsats different than flight software for traditional satellites? There is an argument that Microsats are inherently the same as other satellites (although generally smaller) and therefore the flight software should have the same properties as any previous flight software system, regardless of design heritage. There is assuredly much truth in this. Microsat flight software systems must address power, thermal, and guidance concerns. They are responsible for telemetry and system limit checking, as well as enabling the payload to execute on its mission. There is a vast heritage of documentation and design for traditional flight software that should be considered and potentially used for any Microsat mission.

However, these similarities are most pronounced when the flight software is considered as a decomposed system, looking internally at the functional blocks inside the flight computer itself. Taking a step back, some differences start to become apparent: items such as shorter development life cycle, the blurred role of the flight software engineer, the global software ecosystem for the mission, the abbreviated and sometimes opportunistic launch schedule, the tight integration of subsystems, and the contract manufacturing process. These items will create a different environment for the flight software engineer than traditional satellite design.

For a fleet of Microsats, the differences become even clearer. In this model it is likely that iterative hardware design is taking place and every launch opportunity diversifies the satellite hardware in orbit, which must be handled by flight software. This is magnified by "tech demos" and the desire to test features in space whenever possible (definitely not traditional). In the case that many identical satellites are launched at once, the reality is that Microsats degrade at a faster rate and have less redundancy which means that the functional capabilities degrade and become diversified over time across the constellation (months to several years). This also must be addressed in flight software.

The concept of operations for Microsats is also different. In a fast-paced launch environment and especially with tech demos, it is likely that flight software is not completely ready prior to launch. The reality in this case is that on-orbit software updates must be common, reliable, and generally not exciting. It is also likely that FSW resets may be common and may even be the preferred way to achieve a known state in the satellite. This is a far cry from very expensive satellites where a reset may be decided by committee and can result in expensive downtime.

The methodology for building Microsats is also different from regular (and more costly) satellites. Traditional aerospace design will use a tremendous waterfall life cycle, from requirements down through testing and deployment. The waterfall life cycle itself is often a large living artifact, being copied from program to program and tweaked as appropriate for dates and details of the new program. This development process is intended to ensure contract value to the customer, enforce milestones for product maturity, ensure compatibility between components developed by different vendors, and keep complicated projects on track. In contrast, the reality for Microsats is that they tend to be built in agile and limited resource environments such as academia, space startups, and even small incubator groups in much larger organizations. The designs are less complicated and the risk posture is completely different. Requirements are often eschewed for rapid prototyping, and design documentation is often replaced with whiteboard conversations. The feeling of moving rapidly motivates the (small) team and often is completely necessary to meet an aggressive launch date with a new product design.

It is unfortunately the case that aggressive timelines tend to erode standard SW engineering practices. There could also be pressure to deliver an initial (suboptimal) working design in order to secure funding. The resulting pitfall for Microsat projects unfortunately is that you will eventually be successful and you will pay for your shortcuts later. There is then an appropriate balance in Microsat development methodology that is somewhat difficult to achieve, namely, to be lightweight, fast, robust, and future-proof.

Regarding whether Microsat flight software is different than traditional flight software, Microsat FSW components may be very similar to regular satellite programs, but the path to achieving mission success with Microsat FSW can be quite different. Being aware of the above points, especially early in the development cycle, can contribute to initial mission success, long-term company success, as well as a smoother running organization. Some of these points will be discussed as appropriate in the rest of this chapter.

3 Role of the Flight Software Team

In the lightweight planning world of Microsats, it is insightful to consider the reality facing the flight software team. In small team environments, team members will likely be stretched across multiple disciplines, and the "flight software team" could be a somewhat loosely defined organization. These members of the flight software team could have diverse experience with respect to developing software, sometimes being non-SW subject matter experts with some coding background. It should be noted that the earlier the team subscribes to standard software engineering practices, the more robust the system will be to on-orbit testing, modification, new hires, and feature requests. Standard practices would include coding for unit test, modular design, re-factoring when needed, consistency in coding standards, and continuous integration (CI) methods.

It is very useful to define the scope of work for the flight software team as early as possible. Microsats are limited in volume, and it is often the case that much of the avionics must be compressed into a few printed circuit boards in order to provide room for the payload. This generally limits the ability to buy pre-built subsystems which can be integrated into the satellite bus. The result is that many subsystems end up being homegrown, and inevitably they require some form of software. Consider Fig. 1 which shows a somewhat generic diagram for a Microsat system.

The satellite block on the left contains the avionics (top) and the payload (bottom). The avionics are controlled by a flight control computer (FC) which must deal with power, attitude control, GPS, and the tracking, telemetry, and control (TT&C) radio. Note that many of the blocks are indicated with their own Microcontroller (uC). The payload as shown has its own processor (payload computer) and is shown integrated with a high-speed radio and the payload sensor through a field-programmable gate array (FPGA). The flight control computer is the device first thought of when discussing the responsibilities of the flight software team. This is also the device that will have a functional block representation that is similar to flight computers pretty much everywhere. As can be realized quite rapidly when looking at the diagram, there are a multitude of other processors besides the FC that could require software, and this can easily fall into the flight software group

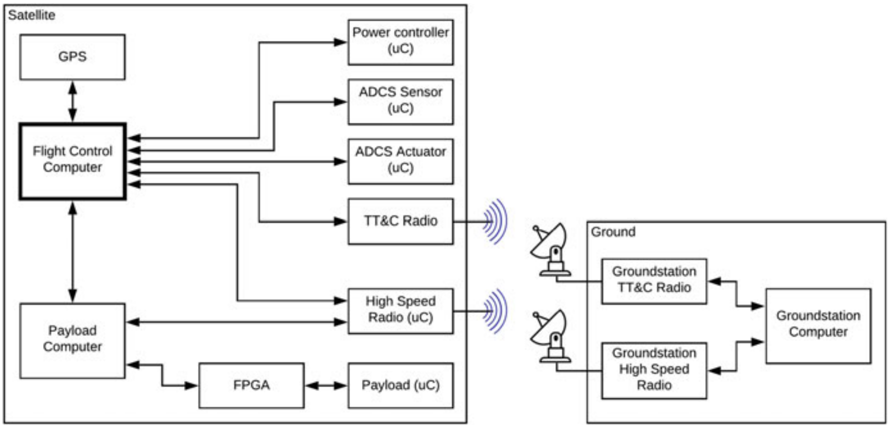

Fig. 1 Example satellite and ground system. (Image © 2019 Planet Labs Inc., licensed for one-time publication)

purview (every block in the diagram could be an independent software project). There are some things that are less obvious but still impactful to FSW. All of the devices with software must be software upgradeable post-launch. This includes devices that have third-party software on them! So even without primary responsibility for device software, there is still a requirement to develop a way to upgrade software on that device.

It might seem that the payload system is developed by the payload team in isolation, but this is not the case. There are likely to be common device drivers (especially for sensors and I/O) and also common telemetry, message protocol, and transfer routines. In some cases, the Microsat design does not have a clean boundary between payload and avionics, and the various software components need to coexist on a processor. This places a requirement on the flight software team to build portable, robust code and to possibly consider multiple processor architectures when architecting the code layout, repository, and build system. It may also be an opportunity to speak with the payload engineers about coordinating software engineering practices.

It is also the case that FSW responsibility may extend to the ground system (GS). If custom radios are being used, the code might be similar between the satellite and the ground, or maybe the communication link is the proprietary technology being developed. In the case that the GS is from a third party, it is still likely that communication libraries for message serialization/deserialization and telemetry ingestion will have common components with the satellite FSW.

There is another reality for the flight software engineer that must be considered. The tools to test out the satellite at the board level and full-build level do not write themselves. In a very small team, sometimes the best way to test out the hardware is with the actual flight software, and who better to write the interface and testing tools than the flight software team? This is not a bad scenario, but it needs to be taken into account, and it needs an owner (flight software team or not). It should be noted that it is rare for the on-orbit control procedures to map well to test procedures which implies care in separating one from the other. If there is a dedicated test team available, there may still be a FSW role to develop software components to interact with the satellite, even if the test code is decoupled from it.

The above paradigms may seem daunting for a small team. In a completely custom Microsat design, the processor and FPGA count can easily hit a dozen. Software work may not be confined to just satellite components. Early knowledge of this should be considered an opportunity:

- To ensure that all work is considered in the schedule
- To check the work against available staff
- To drive interconnect design, code architecture, and code reusability
- To revisit subsystems that might be available off the shelf

The important takeaway here is that the FSW role is not confined to the "flight computer": there is a larger software ecosystem that can include multiple processors, multiple systems, and multiple disciplines. In a lightweight planning environment, the details of all this work may not be captured, and not accounting for this work can lead to a stressful environment.

4 Flight Software Life Cycle

Planet has launched satellites on more types of rockets than almost any commercial company (chapter ► "Planet's Dove Satellite Constellation"). The reality is that the life cycle for any given Microsat iteration (and launch) will be overlapping with other launches, sometimes aggressively so. This obviously impacts not only flight software but other development groups as well. Figure 2 shows a single mission life cycle on the top and then multiple instances of this overlapped for three launches at the bottom.

At a high level, the top sequence is similar to any satellite program. A Microsat program will of course have differences: the requirements phase may be abbreviated, the day-to-day planning may be laid out using established Agile methodologies (likely more familiar to the technical team), the integration and test phase may be limited by access to flight simulation capabilities, and it is almost for certain that the overall time frame will be significantly shorter.

An impactful time for flight software (and everyone else) is when the first printed circuit boards for flight hardware arrive in-house (start of board verification). There is a collision of disciplines who will want to check out the boards. Flight software will presumably have been developing software on development boards or possibly non-form factor in-house boards. Electrical engineering will first do initial board bringup for smoke test, power rails, etc. Almost immediately after this, there will be the request to "talk" to the board (assuming it has a processor on it). Does the

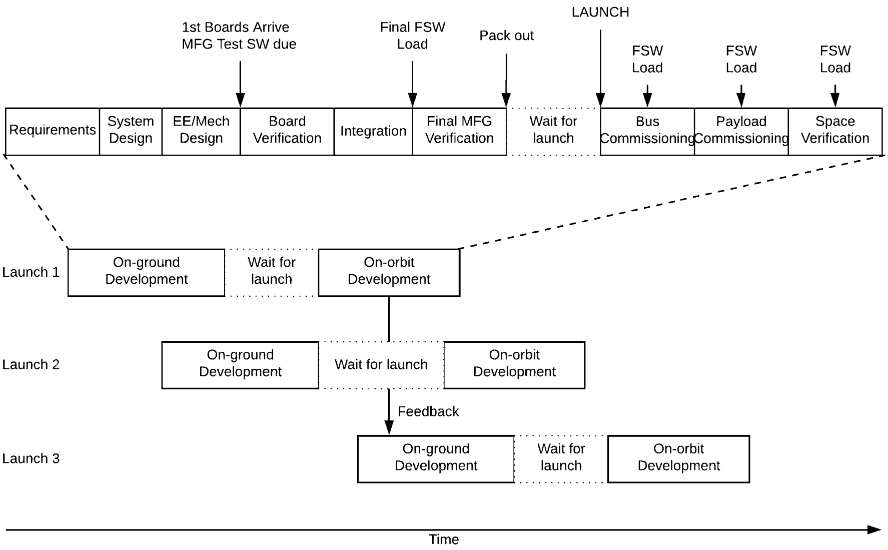

Fig. 2 Flight software life cycle. (Image © 2020 Planet Labs Inc., licensed for one-time publication)

software exist to do this? Be very mindful of this period in the life cycle, and consider carefully what the expectation will be from a software standpoint and then plan for it. This includes both satellite software and test harness software. Is the flight software team responsible for both? How can the flight software be ready if this is the first time that flight hardware has been available? In many cases the flight software needs specific flight hardware in order to be written, especially for drivers. The flight software engineer should also be cognizant of critical path timing not accounting for development work on the actual flight hardware. Note also that there is a distinction between test software and full flight software support for a given device or system on the satellite. A device or subsystem may be identified as not requiring full software support at launch, but the hardware will have to be validated on the ground regardless.

The launch date (or more accurately the pack-out date) will be a huge driving factor in schedule. The Microsat or possibly small fleet of Microsats will likely be a secondary payload for the targeted launch meaning that the actual launch date will be determined by a third party and potentially occur at a point which creates an overly aggressive schedule. The Microsat team will have to meet the payload integrator's window for delivery which may mean prioritizing development to ensure that critical systems are complete and robust while other systems are pushed off to a future on-orbit flight software or payload software upgrade. This may strike some readers as a disastrous or at the least irresponsible situation. How could one possibly launch a satellite without a full software suite that has been rigorously tested on flight hardware on the ground? This is the reality of Microsats.

The goal of any flight software team should be to optimize around this reality. This will involve a heavy focus on the on-orbit flight software update design including a bootloader and security capabilities as well as prioritizing the truly mission-critical components as early as possible (see section "Satellite Safe Mode").

Once pack-out has occurred, the flight software team will likely be working with the satellite operations group to prepare for new concept-of-operations (con-ops) procedures. There will also be ongoing development for flight components that have not had full software support implemented yet (potentially newer sensors or payload). Once launch has occurred, there will be possible flight software upgrades, for issues related to bus commissioning, payload commissioning and then infant mortality, experience with slow decay of components and workarounds, etc. Note that any schedule for the program should include work after the launch and not just terminate at launch. This is important when multiple launches are in play, discussed next.

There is an argument to say that many of the above issues are just schedule related. If there is time to do everything correctly, then the satellite and software will be fully featured, and you will be done at pack-out. Except for on-orbit component failures, this could possibly be true for a launch or two. In a growing company which is iterating on satellite design, building out on-orbit capability, and trying to maintain service-level agreements (SLAs), this is most assuredly not true. Consider the bottom part of Fig. 2. Multiple launches are occurring in order to prove out hardware design and meet SLAs, on-orbit and on-ground development is overlapped, and many iterations of hardware are in play. Consider that critical feedback from an on-orbit satellite design becomes available in the middle of board verification for a future launch and new boards must be created to account for it (note that time frames are shown such that the feedback can skip a launch). This is new, unplanned work for multiple teams, but the schedule is fixed by the third-party launch date. Possibly there is a critical problem with an on-orbit satellite component that must be addressed immediately by the FSW team, but there is also an ongoing and critical board bringup underway. The on-orbit issue will take precedence, especially if the mission is jeopardized. Or potentially a launch date happens to occur just before the pack-out for a subsequent launch, meaning that there is a requirement to support on-orbit commissioning while at the same time the on-ground manufacturing phase is at a critical juncture.

The point is that multiple-launch schedules can interact with each other in somewhat unpredictable ways, and the time to be allotted for development is hard to calculate. With vagaries in launch dates and idiosyncrasies in Microsat hardware, it is rare for software development work to be complete at pack-out even if the schedule is closely monitored, unless there are multiple teams available to handle the different phases in the various ongoing life cycles (unlikely in a small company). Being able to decouple software development work from the launch schedule is actually a very important opportunity. Planning out a robust system architecture with emphasis on mission safety and on-orbit flight upgrades will help enable this.

5 Flight Software and Processor Selection

In the Microsat development process, the flight software team should be participating in design discussions related to processor and sensor selection. Anything related to software should be considered from the standpoint of software toolchains, open-source versus closed-source code, space heritage, code reusability, and complexity. There are also questions related to processor load and memory sizing that the FSW team should be involved with. Note that when viewed as a software development problem, a Microsat project has much in common with other systems which are operated remotely and need to be robust against power loss and possible frequent software updates. This includes Internet of Things (IoT) projects and even some automotive projects. Much of the following will look familiar to people who are experienced with those systems.

Any processor selection should be judged against a list of requirements. The requirements should be carefully selected to meet the mission goals and maintain mission safety. In many cases, there is no obvious choice even after the requirements have been assessed. This means judging which requirements are most favorable to the teams and mission. Selection of a particular processor can also be intertwined with other devices, such as sensors (which might support a particular bus). Figuring out the requirements for processors can be somewhat daunting; the following bullet items lay out some informational groundwork for the process:

- **Space heritage** – Electronic devices which have already been proven to work well in space are ideal choices if they are available and meet the mission requirements. This can reduce early and unexpected mortality for Microsats. It can also reduce the cost of performing radiation testing on critical devices. The difficulty with space heritage parts is that they are either very expensive or difficult to identify because of export restrictions and a lack of public documentation. NASA has a published list of radiation tested parts that can be interesting to look over (NASA n.d.). Note that “space heritage” is sometimes blindly assumed to be a positive thing, but it is possible that a device has space heritage but performed poorly.
- **Off-the-shelf software** – Selecting parts that have readily available third-party software that can be applied to the mission can save time and allow the flight software team to focus on other flight software projects for the satellite. As mentioned in **Role of the Flight Software Team**, there will always be multiple software targets in the spacecraft. The organizations behind the off-the-shelf software presumably have already spent time debugging and verifying the software and possibly also time validating the associated hardware component(s). There are possible difficulties here, the first of which is that the third-party software may only be sold or compatible with hardware which may not fit in the satellite (Microsats tend to have a very constrained volume, and the payload generally dominates with the avionics packed around it). The second is that often only a particular component of the third-party software is desired, but it is very difficult to decouple from the complete system or the underlying protocols. Often this frustration will just lead designers to create the software “in-house.”

- **COTS, or not** – There are radiation-hardened and radiation-tolerant electronic parts that may be worth considering, especially in the safety-critical domain. These will tend to be much more expensive and generally of a much older electronics vintage (less capable) than regular consumer-off-the-shelf (COTS) parts. In Microsats, it may be possible to use a radiation-hardened MCU or FPGA, but it will be unlikely to be able to use a full rad-hardened subsystem due to cost and bulk. As Microsats will generally be majority COTS based anyway, this option may not be useful, but it is worth considering. If there is a safety-critical area where a rad-tolerant part is being considered, it may be useful to consider some of the safety-critical automotive MCUs and components that are now available. Note that the effect of radiation on COTS components is an intense area of study (Sinclair and Dyer 2013) and may require its own team.
- **Common build systems** – There will be multiple processors in the design, with the possibility of multiple manufacturers, different CPU cores, and different build systems and environments. It is very advantageous to limit the number of build tools and environments that are required to build all of the software targets for the satellite. This should only be done as appropriate, but it is much better to select a single, slightly suboptimal solution for multiple use cases and then to try and drive down on optimal and unique processors at every opportunity. Note that this is a “soft” requirement, in that it is intended to allow for smoother development, higher efficiency across the team, and possibly a lighter load on the team when it comes to supporting build and artifact publishing infrastructure. Over the long term, this can be a very appropriate choice.
- **Debug capabilities** – The software team should understand the debug options available for the processors that are being selected. At the least, this should include JTAG support which can be used for debugging as well as boundary scan verification during manufacturing. There may be other debug options that are desired, potentially some kind of embedded trace module. The debug options for very high-speed devices and memory could be more complex, but this should be considered when choosing these devices.
- **Board support packages (BSP)** – A significant portion of the work in flight software is in writing drivers. Processors which have a comprehensive board support package for a board that might have similar characteristics to the flight hardware can be very beneficial. Note that there are two levels for drivers, there are the peripherals that are pinned out of the chip (UART, I2C, ADC, etc.), and then there are the drivers for all the sensors and actuators that are connected to the processor. The availability of a hardware abstraction layer (HAL) is also beneficial since this can make porting between operating systems and processors easier (see section “Flight Computer Software Design”).
- **Processor speed** – It is necessary to select a processor that is powerful enough to execute all its required functions in a timely manner. This will be a function of the processor’s clock speed, as well as memory access timing and any hardware acceleration that is relevant (floating point units, cryptographic cores, DSP instructions, etc.). It is highly valuable to run processor intensive algorithms on third-party development boards to try and benchmark throughput requirements

for possible processor candidates. Also be aware that repeated access to devices on a communication bus, and the addition of new devices, can add up and impact available throughput which can be aggravated when sensors are unavailable (failed or disconnected) and device access time-outs start accumulating. This can cascade and cause throughput problems if not handled appropriately. Once there is an idea of the computation-intensive operations and the bus operations, the processor requirement should probably be increased 50–100% for future growth. Note that the above statements are more relevant for the flight computer and processors which are more embedded in nature. The payload compute system may have a different set of requirements, likely involving fast read/write memory and bus support. Also be aware of any circumstances which may require the control loops to run at a faster rate. This will require more processor capability.

- **Peripheral and bus options** – An audit of the available processor pins should be completed. This is more of an electrical engineering (EE) and system design role, but it is worth mentioning. The iterative nature of Microsats is generally accumulative, in that devices and capability will likely be added as opposed to swapped. This will require more general-purpose I/O (GPIO) pins and more traffic and addressable parts on the various communication buses. Do not select a processor that is immediately maxed out for peripheral capability and bus I/O. It is also useful to try and limit the types of communication buses that need to be supported, regardless of their availability on a given processor.
- **Open source versus closed source** – Buying closed-source code from a vendor may be an option for accelerating development. It may also meet some requirement for reliability or real-time responsiveness. Note that there is a difference between buying source code from a third party and compiled code (libraries). Not having the actual source code can make it difficult to debug and fix critical issues in a timely manner. Source code from a third party may come with build environment and seat licensing issues that can complicate development and notably also server-side continuous integration. Open-source code is becomingly an increasingly valid method for building out Microsat capabilities and systems.
- **Avionics versus payload** – It should be recognized that the requirements for the payload computer and the flight computer are different. Although it might be initially desirable to combine the two functions into a single processor, it may be better to keep them separated and optimized for each function. The flight computer must be reliable and continuously active. It is directly responsible for satellite safety and this should not be compromised. The payload computer could be shut off for extended periods and reset if there is any detected problem. An error in the payload memory will not cause the satellite to spin up or generally cause harmful behavior, especially if the flight computer is monitoring telemetry from the payload system and can take appropriate action. The avionics will likely require a less complex processor than the payload which is easier to make robust. It is also undesirable to impact the avionics system with a payload software change. There are other differences which are addressed in the next bullets.

- **Internal versus external memory** – Larger processors will tend to have more complicated memory which is located externally to the chip. It may be possible to select a smaller processor for the flight computer that has some form of internal memory that would be more robust to layout and manufacturing issues. The payload system will likely have much different memory requirements, including very fast read/write access and very large data storage requirements. It should be noted that large, fast, and complex memory devices such as solid-state drives (SSDs) are much more prone to failure than simpler flash implementations (Costenaro et al. 2015). It is important to realize that a memory device that is chosen for high-speed data collection and large storage capability may not be an appropriate place to have operating system or program memory. Note that complex memory devices may be performing maintenance operations under the hood with their own microcontroller (such as wear leveling). This will have its own failure modes and again could be less robust than a simple flash implementation.
- **Error-correcting code (ECC) capability** – There are many COTS processors and memory devices with ECC. These devices are generally able to correct for a single bit flip and detect a double bit flip. This type of technology can protect against single-event upsets (SEU) which are one likely type of radiation damage expected in low earth orbit (LEO) (Sinclair and Dyer 2013). Note that this is particularly desirable for devices which are continuously on where boot CRC checks and a reloading of random-access memory (RAM) are not taking place. Some automotive safety-oriented processors will also be able to check memory in I/O registers and throughout the memory pipeline, not just RAM and flash. The use of ECC may not make the system "radiation-tolerant," but it is a readily available technology that can mitigate these kinds of errors, and it should be incorporated where possible.
- **Operating system (OS) selection** – Processor selection will be tied to the operating system selection. In most cases, this will be a real-time OS (RTOS). The flight software team should be comfortable with the RTOS capabilities and maturity with respect to the processor. Although possible, it is generally not a good idea to start off a new program with a port of an RTOS to a new processor. Certain processors may force a more limited set of RTOS options onto the team which must be weighed against the perceived benefits. If multiple processors require an RTOS, it will be beneficial to select the same RTOS as appropriate. Note that the payload system may benefit from a different OS, maybe even an OS without full RT support such as Linux. This might enable a better development experience on the ground for the payload team and provide a much more feature rich environment that is similar to a laptop or desktop. For limited processors, it may make sense to forgo an OS entirely and generate a bare-metal implementation. This can initially be simpler and faster to get to a testable product. However, care should be taken as bare-metal projects tend to suffer from a lack of software structure and code entropy can take its toll as multiple developers work on the program. There is also an assumption that a tasking infrastructure is not needed which can become problematic as more sensors are added and delays start to pile

up in the processing chain. In many cases, a bare-metal decision may just be putting work off to a later date when the code will need to be re-factored and potentially rewritten for an RTOS.

The above talking points will hopefully be useful but are not comprehensive. For any device selection, there are the standard questions about end-of-life (EOL) time frame, supply chain, second source, environmental limits, and process technology. There may also be the need to radiation test critical devices. These are issues for the larger team.

The above conversation is focused on processors, but other devices (such as sensors) which must be accessed through software should also be evaluated for software impact. It is appropriate to standardize the possible sensors in the satellite design. It should not be the case that there are two different kinds of temperature sensors on different boards that could possibly be the same device. This doubles the software work and will siphon off time that could be spent on other tasks.

When assessing processors and devices, the flight software team should always remember to advocate for homogeneity where possible because this can have a direct impact on the flight software team workload. Also be careful of selecting a processor for a very specific reason such as an embedded security feature. These decisions can influence the general software architecture and may make porting to new processors very difficult.

6 Software Build System Architecture

As mentioned in previous chapters, the flight software team will likely be responsible for multiple processors on board the spacecraft with each requiring a different software image. They may also be responsible for ground software and/or dictionaries that are used in ground systems communicating with the spacecraft. There will also be multiple generations of spacecraft that will need to be supported, which will likely require different software or configuration. This is a difficult situation to manage from a build and release standpoint, and defining an appropriate software build architecture early on in development can be very helpful. Figure 3 demonstrates a possible build architecture that can support multiple platforms over multiple generations. On the left are the inputs to the build system; build artifacts are generated as the flow moves down and to the right. The first takeaway is that the inputs on the left are likely managed by different teams which means that a process needs to be negotiated between teams that allows for smooth integration of new information (data format, release management, release notes, etc.).

6.1 Build Process Inputs

The following bullet points define the input blocks on the right side of Fig. 3:

- **Satellite HW Specification Database** – The electrical engineering (EE) team will be designing multiple boards for each satellite. As new generations of

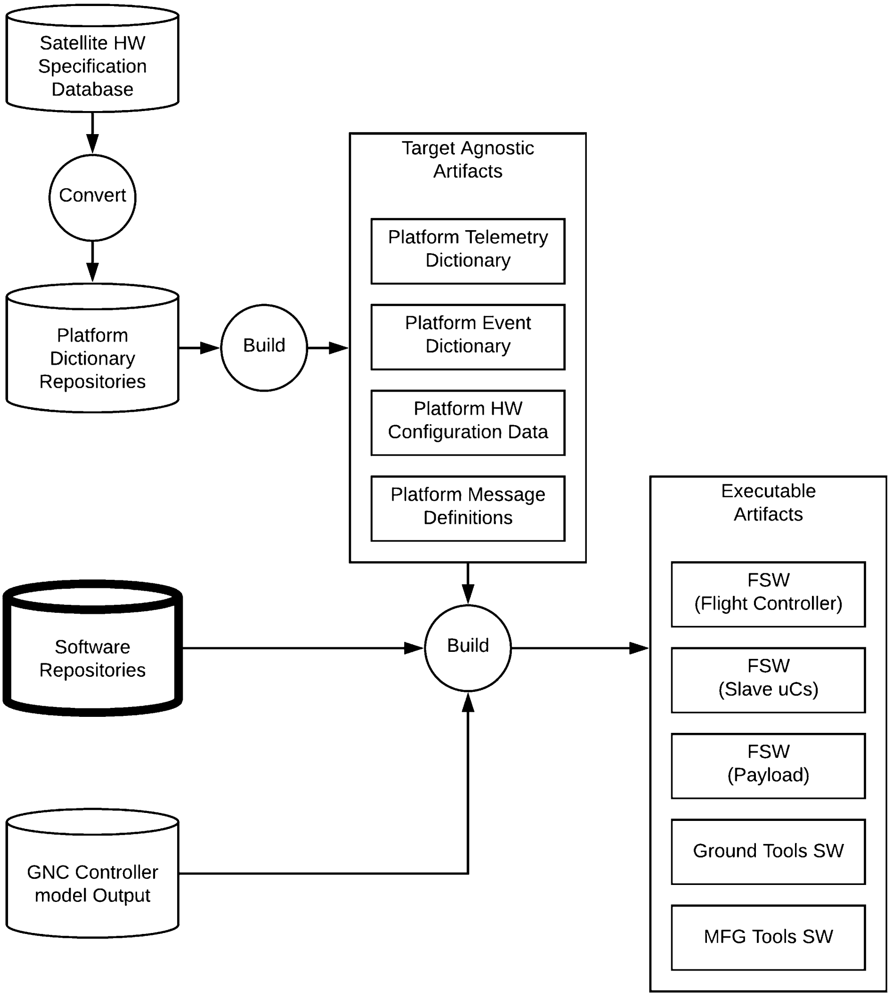

Fig. 3 Flight software build architecture. (Image © 2011 Planet Labs Inc., licensed for one-time publication)

satellites are created, the board designs will change, and this information must be transferred to the software team in some kind of reliable way. In order to fully describe what the software must do, this database can be very detailed. It should contain the list of all processor GPIOs and their functions, topology for communication buses and device addresses on the buses, a list of sensor devices (make and model), mapping of power rails to devices, power rail control information, and even resistor values where appropriate for sensor reads. This documentation will likely be contained in a format that is easy to integrate and use with EE tools. It will have to be exported to the platform dictionary repository. The necessity of this information being maintained correctly and at this level of detail is often noted when the team must go back in time and investigate older designs that may be having on-orbit issues. Note that a documentation system that does not allow easy detection of small changes will be hard to use in any event.

- **Platform Dictionary Repositories** – Each satellite variant (platform) will have a unique set of characteristics that should be maintained in the platform dictionary repository. This will include the definition (configuration) of the satellite hardware, imported from the EE HW specification database as shown in Fig. 3. Each platform will also have a unique set of telemetry channels and event descriptions that must be described and maintained. The intent behind the platform dictionary is to have a code-agnostic, single source of truth for the platform information. This information can have its own set of tools, rules, and schema to ensure that the data is consistent. It should be possible to generate the platform information for each satellite variant at any time. This system can also be used to define protocols and message structure.
- **Software Repositories** – The software repositories contain code, build instructions, and other collateral that is required to build the flight software and potentially other software as well. This may be one or multiple repositories depending on how the flight software team structures the code base. The software repositories are combined with the output of the platform dictionaries at build time to create the executables that can be loaded to the various processors in the satellite ecosystem.
- **GNC Controller Model Output** – A common model in satellite design is to use a third-party tool to build all the guidance, navigation, and control (GNC) models and then export the models as C code which can be integrated into the flight software. The GNC design will generally be owned by the GNC group and not FSW. The integration of the auto-generated code and the FSW must be well understood, since the inputs to the guidance algorithms must be well-conditioned, correspond to the right frame of reference, and have the right units. The output must also be understood so that actuators can be driven appropriately. The GNC model output may differ for satellite iterations and variants, and the GNC output should be versioned and described. Note that it would be possible to store the model code in the same repository if desired.

6.2 Build Process Artifacts

The intent of the build system is to generate artifacts that can be used to run and improve the satellite ecosystem. There are two kinds of build artifacts generated in Fig. 3, target-agnostic artifacts and executable artifacts which are target specific. Note that the target-agnostic artifacts can be used as input for building the executable artifacts, but they can also be exported to other teams for ingestion in other build environments. The target-agnostic artifacts may tend to be in declarative languages such as JSON or YAML, which can be consumed by multiple groups operating in different coding languages and operating environments. It might be the case that the artifacts target certain coding languages and some output artifacts can be consumed directly by those languages (like C headers or Python libraries). The point of having the target-agnostic artifacts is that an update to a platform dictionary can be rolled out and tracked across multiple systems with only a single change, not by having to coordinate independent changes in multiple code bases. The rollout to a live system must be orchestrated, and the satellite ecosystem must support more than one active platform. When operating and building satellites for any length of time, it will be the case that multiple platform definitions will always be in play. Note that the idea of target-agnostic artifacts (or artifacts that are published and used by multiple systems) is hardly new. The CCSDS has published documents related to this concept for many years (CCSDS 1987, 1992).

6.2.1 Target-Agnostic Artifacts

- **Telemetry dictionary** – Each satellite platform will have a unique set of telemetry channels that are used to monitor and control its operation. Telemetry information that is created on the satellite will generally not be self-describing due to file size concerns and may also be in binary format. The telemetry dictionary is used to convert machine-generated telemetry points into human-readable data points. It is also used to describe the relationship between the telemetry point and the hardware (source device or subsystem), provide design context if appropriate (description), and also give the units. The telemetry dictionary can be used to convert telemetry in real time (during a radio pass), potentially into graphical displays for operators. It can be used by back-end tools to display historical data, and it can also be used by developers to understand how to build out automation. These scenarios will all involve different tooling and coding languages which is why the dictionary must be code agnostic. The telemetry dictionary will exist across the ecosystem and should be immediately indexable by satellite platform type with multiple telemetry dictionaries existing at once. Note that it is possible for some telemetry channels to be common across satellites (attitude parameters, for instance). This is generally dependent on the subsystem. How one handles the common parameters is up to the designer, either by generating a new (but duplicated) list or by using some kind of inheritance.
- **Event dictionary** – The event dictionary has much in common with the telemetry dictionary. The distinction here is that telemetry is considered time series data (like system voltages), whereas events are one-time data (like a configuration change, limit check warning, etc.). Events tend to have more complex data structures associated with them which makes it appropriate to build out a separate event system from the telemetry system. The manner in which the event dictionary is used is similar to the telemetry dictionary except it will have to describe the more complicated data structure for each event.
- **Hardware (HW) configuration data** – Each satellite variant should start with a hardware configuration which will enumerate the bus layout, the individual device hardware, and the device configuration. This will come in large part from the EE interconnect information. It will also include physical data related to the satellite such as sensor and actuator mounting alignments. The HW configuration information can be pulled into the FSW build process in a similar way that device trees are used in an

operating system (OS). A device tree is generally a binary blob that an OS knows how to parse that describes how it is connected to external hardware (like clock source, pin assignments, etc.). There is another important job for the HW configuration information which is to be imported into the mission operations center (MOC) satellite database with an entry for each new satellite. This database is critical to satellite operations, especially at scale. The MOC database will contain this hardware information; it will detail which software version is on each processor and what the backup software version is. It will detail the current operational mode for each satellite, and it will provide information about security keys, power models, calibration data, etc. Very importantly it will also track degradation of satellites over time which can be tracked against the original HW configuration. The full extent of the MOC database will not be described here, but when flight software is loaded on-orbit and needs to adjust based on new or degraded hardware on a particular satellite variant, it is likely that information will come from the MOC database.

- **Message definitions** – Communication with the satellites will be through a defined interconnect. It is useful to create and store the message definitions such that they can be used to generate message serializers and deserializers on both the satellite and the ground. These serializers/deserializers will be pulled into the flight software as part of the build process. They can also be exported to groundstation code and manufacturing code as appropriate.

6.2.2 Executable Artifacts

The executable artifacts are more recognizable than the target-agnostic artifacts. The need to address multiple deliverables is discussed in **Role of the Flight Software Team**.

- **Flight software for flight computer** – This is the software image for the flight computer. This will likely also include the bootloader image for the flight controller.
- **Flight software for slave microcontroller(s) (uC)** – As mentioned in a previous section, there will be many microcontrollers and possibly microprocessors in the Microsat design that require software. The build process will have to generate all of these software products, and it is likely that the build products will require different tools and possibly different build environments. This may include bootloader images for some of the processors.
- **Flight software for payload** – The payload computer and system will require software. This software may or not be in the same code repository as the avionics flight software. Depending on how the payload processor is architected, this could include bootloader images.
- **Ground tools software** – This would include ground-side radio software, groundstation software, possibly data analysis software, and maybe components that are interoperable with mission control.
- **Manufacturing tools software** – This includes software that might be needed to interface with the satellite while it is on the production line, potentially using a different (and protected) interconnect definition that is only appropriate on the ground.

It should be noted that Fig. 3 shows the build inputs and artifacts but does not indicate where the artifacts are stored. Artifacts will have to be published to some location that makes them available to satellite operations and manufacturing personnel while still meeting any security considerations. The above build architecture is fairly complex, and it may be appropriate to leave out certain pieces until they are needed or to implement it in a different fashion. Ultimately, there will need to be a server level build option which can reliably, repeatedly, and automatically execute the build, unit test, and publishing pipeline steps. However, it is still useful to understand why the design is laid out this way in order to avoid future problems.

7 Flight Computer Software Design

The flight computer is responsible for maintaining the satellite in a power-positive, ground-responsive, and thermally survivable envelope. It is also responsible for enabling the payload to succeed in its mission, through execution of time-sequenced flight control commands, attitude adjustments, orbital maneuvers (if applicable), and power sequencing of payload components. The flight computer must enable the Microsat to downlink its payload data as appropriate. In general, there is the same command and telemetry requirement as all flight computers. There is a significant amount of existing and comprehensive literature about satellite design that should be considered when developing the flight computer architecture (Brown 2002; Wertz et al. 2011). There are also third-party vendors who offer flight software products specifically for Microsats who may be able to supply part or all of the flight computer components, allowing the team to focus on other components such as the payload and its software.

NASA has open-sourced a comprehensive flight software suite called the “Core Flight System” (NASA 2014, 2019). There is a wealth of experience behind this effort, and it is very informative to investigate. There are many similarities between the content of this section and the CFS, which is to be expected since they solve some similar problems. The CFS is actually a superset with respect to functionality since many different kinds of missions can be supported (including deep space), whereas the content here is for LEO Microsats. The CFS may be appropriate as a candidate for Microsat FSW. If one can use the CFS, many capabilities may come for “free” at a later date when they are required. The downside to the CFS is that it can be complex, and the initial learning curve will be steep. In the case that only certain components are desired from CFS, it is a little difficult to separate them out from the larger system. The CFS is also currently ported to certain operating systems which may not be appropriate for the processor that was selected for the flight computer, or the processor may be not be sized appropriately. Note also that the CFS does not necessarily solve certain software problems on the satellite, such as the infrastructure for supporting the local communication bus or integration of sensors and actuators (highly dependent on hardware design). This will somehow have to be integrated into the CFS system. The build system and artifacts for CFS may not match well with other processors or programs that the software teams are working on, including server-side continuous integration (CI) and build. Integrating custom over-the-air protocols may also be more work. However, it might be the case that third-party groundstations are going to be used, and these use some kind of standard protocol schemes, such as those defined by the Consultative Committee for Space Data Systems (CCSDS). The CFS may be able to support some of these protocols natively. In any event, this should all be evaluated from the point of the satellite ecosystem and requirements.

Figure 4 details a possible software architecture for the flight computer. This is a static view of the software that demonstrates the hierarchy between components. The blocks that are on the bottom are generally independent of the ones on top. It should be noted that many of the blocks here are consistent with the NASA CFS diagrams and should be consistent with almost any flight computer design. This is the architecture for the flight computer, but note that there are many components in the diagram that would also be applicable to microcontrollers or other processors in the satellite. This is an opportunity for code reuse and modularity that should be taken advantage of.

Figure 4 has several layers which are described below:

- **Applications** – The application layer as defined here represents the high-level functions that the flight computer must perform. These are generally mappable to requirements such as thermal management, power monitoring, spacecraft attitude tolerances, and time maintenance and distribution. The flight computer must be able to provide enough telemetry for each of these applications to be monitored against its design and performance envelope. Note that at the software level, the code for an application may be split among a task, an interrupt service routine, and potentially an asynchronous messaging handler while still sharing common data. The “Command Processor” is the externally facing consumer of messaging which can provide protocol related capability and is a gateway to the internal messaging bus. The “Power” application will monitor the power state of the system and effect brownout or safety related actions as appropriate. It will also be used to command various parts of the satellite to power on and off. The “Thermal” application will maintain the satellite in its thermal envelop by monitoring temperatures and activating thermal control systems as appropriate. The thermal application will be subject to any restrictions that are being enforced by the power application. The “Runtime Sequencer” will accept arrays of instructions from the ground that represent sequences of future states of the spacecraft. The runtime sequencer will ensure that the satellite state is executed as defined in the timing of the sequences by issuing commands to the other applications. The sequences represent the steps that the spacecraft must execute to complete some phase of the mission (like pointing at a groundstation for downlink). Note that the runtime sequencer should ensure that satellite changes are atomic. It must also be robust against sequence interruption and failure.
- **Services** – Services as defined here are software constructs which enable the applications to perform their jobs. Some of these may not have related requirements but are dictated by software design. This includes internal messaging

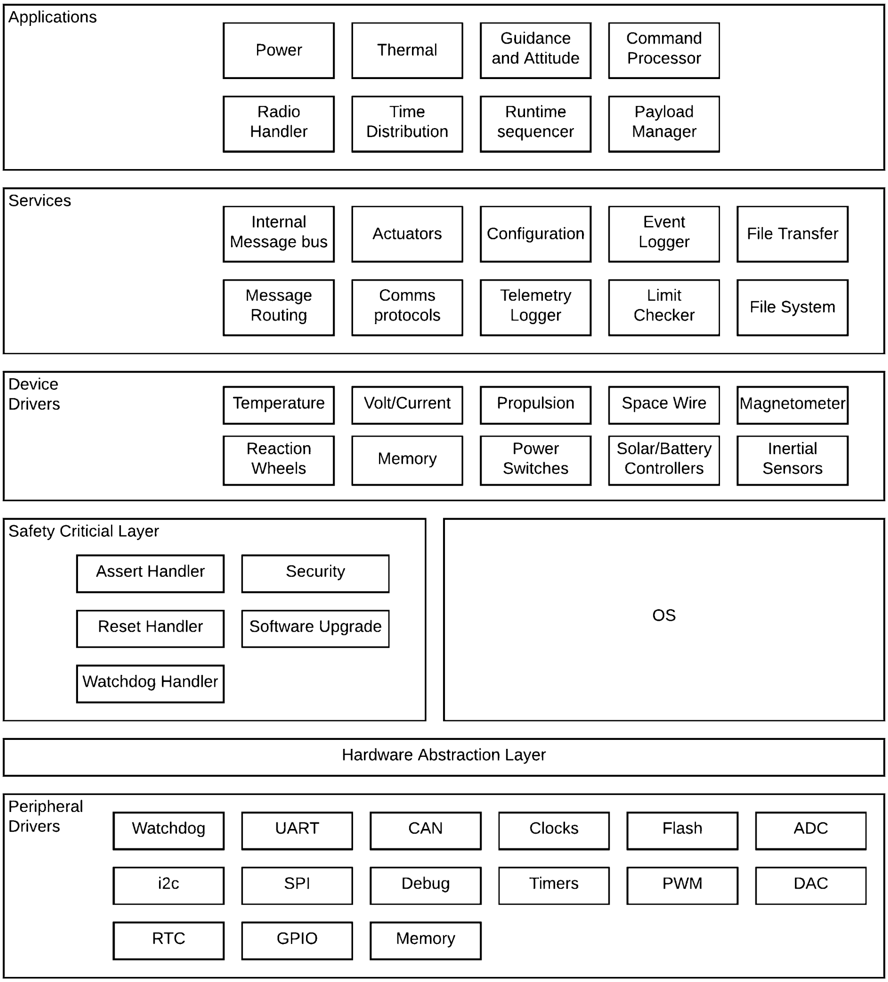

Fig. 4 Flight computer software architecture. (Image © 2011 Planet Labs Inc., licensed for one-time publication)

buses, configuration services, telemetry and event logging services, file system implementations, etc. Note that it is important for these services to be independent of the satellite-specific content. It is not appropriate to build a telemetry or configuration service that is unique to the telemetry or configuration for a given spacecraft variant. This will allow easy portability to new satellite systems.

- **Device Drivers –** Device drivers will be required for all components that are accessed through the various communication buses (such as SpaceWire, UART, I2C, SPI, etc.). They will have command sets and register definitions which are not local to the processor. These are distinct from devices which are natively supported by the processor chip architecture (see peripheral drivers below). Note that the intent would be that these device drivers are portable to other processors. The device drivers will often have to be written by the flight software team. The device driver layer is shown over the OS, but it is possible that applications may be written to bypass the OS and access these devices directly. This is highly dependent on the OS and possibly memory ramifications (allocation/deallocation, direct memory access, etc.).

- **Safety-Critical Components and OS** – This layer has somewhat less of a strict definition to it, in that the relationship between the safety specific components, the OS, and other components may be more complicated than the simple layer approach shown. The safety-critical components are called out explicitly because they are some of the most important software features in the spacecraft. These must be well-designed, robust, tested, and extremely well understood. These features are discussed in further detail in sections "Satellite Safe Mode" and "Security".
- **Hardware Abstraction Layer (HAL)** – This layer is self-explanatory. It abstracts the OS and the higher-level features from the specifics of the hardware implementation. A good HAL means that porting the flight computer software over to a new processor will be easier (e.g., if the flight computer chip is end-of-life (EOL), design changes require a more powerful processor or potentially for a different satellite product). The HAL may be tightly integrated into the peripheral driver layer.
- **Peripheral Drivers** – The processor will require drivers for all peripherals that are to be used to control and monitor the spacecraft. These are generally the peripherals which are part of the processor and have associated internal registers and pins. This code will generally be processor type specific and can many times be available in board support packages or third-party code repositories.

The flight computer architecture as presented here is only one possible example. When designing the system, the flight software team should always look to minimize or eliminate blocks when appropriate (e.g., by standardizing on an external communication bus and external sensors). They should also be looking to share code wherever appropriate among various processors.

8 Flight Software and System Design

There are many aspects of the satellite system design and larger ecosystem that impact flight software or can be impacted by flight software. The following details some specific cases that will be helpful when building out flight software. It is also useful to call out some topics which deserve special attention, including satellite safe mode, software upgrades, and security.

8.1 Satellite Safe Mode

Microsats are generally not designed with the same redundancy and reliability as traditional satellites. This is obviously the result of the much reduced cost. However, they still require the concept of a “safe mode” that the satellite can enter when a fault occurs or for a general mission safety condition. An understanding of the satellite safe mode should be built up very early in the design process, and components related to the safe mode should be prioritized and worked on first in order to give them maximum runtime on the ground prior to launch.

The safe mode should involve a minimum number of subsystems and should allow those systems to have authority over as much of the rest of the satellite as possible. An absolute minimum set of subsystems would be the flight computer, the power control board, and the TT&C radio (assuming no subsystem redundancy). Focusing on these subsystems is extremely important.

Two common failures with Microsats are electronic latchups and processor memory corruption. Latchups can often be cleared by removing power from the device and then reapplying it. This creates two design considerations; first, the ability to remove power from the satellite and its subsystems should extend as far upstream as possible in the power infrastructure. Second, it is very useful to ensure that the flight computer firmware can control power to as many subsystems as possible (as opposed to systems being driven by a non-switchable high-level power bus). This may allow the flight computer to detect and assert a fix, instead of having to force a satellite-wide reset or maybe wait for a planned low-power state (brownout) event if the latchup is exceptionally bad. It is also a good idea to ensure that the flight software is able to actively bring the satellite into a power-on reset (POR) state after a software reset. This means actively asserting all devices under control into a known state, either through direct I/O pin manipulation or setting registers in devices which are connected via communication buses. The flight software should also be capable of actively shutting down power to subsystems in a benign and orderly way. The firmware should be able to make assessments of which buses it believes are healthy.

From an operational point of view, it should be possible to try and address a device failure first through flight computer commands, then through a flight computer reset, and then possibly through a full satellite reset. It should be the case that the flight computer can request (or force) a full satellite reset in some way. From a recovery standpoint, it may also be useful to be able to use the TT&C radio to reset the satellite in response to a radio message, assuming that this can be done as a secure operation.

Watchdogs should be implemented on the satellite in order to try and bring the satellite back into a known state if there is a fault that renders one or more of the safe-mode subsystems unreliable. Processor internal watchdog capabilities should always be used if available. It may be desirable to implement an external hardware watchdog of some kind. All critical systems should have a recurring requirement to “pet” the watchdog and push off its reset function. In the case that a watchdog triggers, the faulty system should be considered completely unreliable, and the watchdog system should not use that system for recovery (by design). It is useful to have some watchdog countdown timer implementation that is reset after every contact with the ground. Note that any system that can reset the satellite should not have a pathological condition where it continually resets the satellite and the time between resets is very short.

The processor assert handler also plays a role in the safe mode of the spacecraft. The assert handler can be called from either hardware or software. The triggering of an assert could be from an unexpected operational request or from undetected memory errors. The assert handler should be designed using the same concepts as the watchdog implementation, and the result of triggering an assert could be a reset of the processor or possibly of the spacecraft. The various possible asserts should be categorized and actions taken as appropriate.

From the flight software perspective, the reset sequence for the satellite should be considered carefully. As noted above, resets of the flight computer and other processors can be a useful tool for trying to bring the satellite into a known state. As such, the path that the reset sequence takes as it executes will be an integral part of the safe mode implementation. A processor will likely go through some kind of bootloader code before starting the application. What happens if this bootloader code remains active for any period of time or stays active because of an application failure? The flight computer bootloader may be one of the most important pieces of software that the flight software team will write. It may have to contain hardware initialization code to ensure that the satellite is properly and safely configured. It may have security requirements or it may have to deal with the TT&C radio. The bootloader will have to ensure that an application that it intends to launch is integrity checked and possibly authenticated, and it must understand what to do when this fails. The bootloader is very importantly one of the few software components that is generally not updated in space. There are other considerations as well for flight software, for instance, the flight computer should prioritize and initialize the most critical systems first and then proceed down through the less critical systems.

Memory errors are another common form of radiation-induced error on spacecraft. Processors and FPGAs should be capable of detecting and/or fixing memory errors at some level (for instance, with ECC). When an uncorrectable memory error has occurred, the processor should immediately be considered suspect. One of the safer approaches is to tie an uncorrectable ECC error into some kind of hard reset circuitry which could be triggered through the absolute minimum amount of software (maybe through only an interrupt service routine with no application code). Another approach is to disable the watchdog monitoring code (ensuring watchdog will fire) and then to try and capture as much information about the state of the processor as possible before attempting a reset through software. This can dramatically aid debug work. This is a less robust approach, but it also allows for the possibility of shutting down high-power systems that might be active in a benign way.

The safe mode should have a very well-understood outcome for guidance and control. The simplest model is to shut down all active guidance, stop all actuators, drop into a low-power mode, stop executing on pre-stored command sequences, and await instructions from the ground. This will put the satellite into a tumbling state, which would have to be understood from a systems standpoint (total possible spin-up, pathological solar panel pointing, etc.). The next level up would be to assert some basic form of guidance to at least keep the satellite from tumbling. Care and thought should be put into this kind of design because at some level, an algorithm such as this will have to assume that certain sensors and actuators are functioning correctly. If these sensors and/or actuators have failed or are somehow calibrated incorrectly (for instance, through memory corruption), then the impact of applying a guidance mode could be disastrous. This kind of design would expand the boundaries of the critical systems required for safe mode.

8.2 Atomic Configuration Updates

It should be possible at any given point to have a clear understanding of the configuration of the satellite. More importantly, the satellite should never end up in a state where only partial configuration has been applied. This places a requirement on the system design to ensure that configuration changes are atomic. The potential for partial configuration changes could occur during interrupted radio links or if the satellite is executing pre-stored command sequences and some form of fault occurs that aborts the set of command sequences before they are completed. The satellite may then not execute a command sequence that was intended to restore some background state for the spacecraft.

Configuration is used in two senses here; there is the concept of “configuration data,” such as calibration data, satellite sensor frame data, security settings, payload settings, current orbital parameters, guidance parameters, etc. This tends to be longer-term data which is updated from the ground during a radio link pass. There is also the way in which the satellite is “configured” at runtime, such as varying power rail settings for payload and heaters, satellite pointing mode for solar panels, etc. This generally comes from the satellite flight software design and the ongoing execution of pre-loaded sequences to execute on the mission. Both of these types of changes should be atomic in nature and should be revertible (if appropriate) at reset or fault.

This idea of atomic configuration updates may seem obvious, but configuration information can be spread across multiple systems and subsystems. It may also be the case that certain configuration data is required to be updated more often and considered less critical, creating the desire to implement different messages for different configuration parameters. It may also be the case that different system owners have devised different schemes for how they ingest configuration requests.

The amount of configuration data for a satellite, even a Microsat, is considerable. It is unlikely that the whole configuration state can be applied at once, even if desirable. A system-level breakdown of configuration data into manageable and appropriate groupings is appropriate, ideally with each element in the group then being atomic in nature.

For configuration data, it is appropriate to create wrapper logic around configuration set commands that can atomically apply new configuration (once verified) and which more importantly can assert a known or default state at reset or fault. Verification of the data should involve a cyclic redundancy check (CRC) or potentially security-related verification (HASH) depending on how security is implemented and should also include bounds checking where appropriate.

For runtime configuration of the satellite (pre-loaded command sequences), it is useful to define a higher-level “manager” application that will ingest the request for state change and act on it as appropriate (as opposed to executing some low-level command directly). This manager function can then also contain the logic for reset or fault cases and can restore default or safe state as appropriate.

8.3 On-Orbit Software Upgrades

As stated previously, the philosophy for Microsats should be that software upgrades while in orbit should be reliable, possibly often and not exciting. As mentioned in **Flight Software Life Cycle**, there are many reasons why the flight software may not be ready at the time of launch. It is also the case that since full space simulation may not be possible on the ground, lessons learned during actual on-orbit testing can only be incorporated using on-orbit flight upgrades. Verification of payload may be even more tied to on-orbit testing, and updates to the payload software should be expected.

Planning out software upgrades to the satellite is one of the most important system design questions to be answered by the flight software team. This includes the flight computer, peripheral microcontrollers, and the payload system.

Processors should always be able to maintain at least two different images for software, with one being active and the other idle and available for update. This means that memory architectures should be sized appropriately for two images, as well as multiple copies of configuration data, redundant security information where appropriate, and room for a bootloader. Payload data should (if possible) be kept in a separate memory device than the flight software. It will have a different use profile and will likely require a much larger memory device which may be less tolerant of the space environment. When updating flight software, it is useful to enforce a design where both flight software images get updated in a ping-pong fashion such that one is just ahead of the other in version. The advantage of this is that it reduces the “staleness” of the software in orbit. The impact of stale software can be a tedious, long road of sequential updates that must be executed by the satellite operations group to bring the satellite up to date if a flight system must be reverted to a backup copy of software that is extremely old.

Software upgrades will be somewhat sporadic with respect to the mission life cycle and could potentially cause large peak loads on radio links and internal bus links between processors. It is important to ensure that these links are sized appropriately for software upgrades and avoid the tendency to only focus on the steady-state operation of the satellite with respect to bus and communication design. It should not be the case that the processor selection and flight software design result in software image sizes that are beyond or barely within the transfer capability of the satellite uplink. It should also be taken into consideration how long the satellite may be unable to focus on its mission while in the software upgrade mode. When uplinking software updates to the satellite, the design should be robust against losing the radio link, subsequently being able to resume the upload at a later time without resending data.

In the software upgrade design, it is possible to consider both atomic upgrades of the software and partial upgrades. An atomic upgrade would replace the entire image with an uplinked version. This version can be tested and validated on the ground for each satellite variant as appropriate. It is also possible to have a partial update scheme, using a package manager or virtual container for high-level operating systems or by uplinking a “binary diff” file that can be applied to static content on the satellite, integrity checked, and then loaded into nonvolatile memory. Partial upgrades can reduce bus traffic but have two downsides. The first is that a series of partial updates applied to various satellite iterations can be hard to test, track, automate, and revert. This can be very painful for satellite operations. The second is that a partial upgrade does not protect against corruption of the existing content on the satellite (for instance, through memory corruption). It is useful to be able to minimize the software cross section that cannot be updated atomically in orbit, in particular for unrecoverable radiation damage. In most cases, it should be possible to update everything except the bootloader.

8.4 Accountability in Operations

In a fleet of Microsats, the level of automation in satellite operations will be quite high. There will likely be a computing infrastructure that is monitoring the satellite fleet and generating data analytic reports that are fed into the various organizations in the company. The monitoring capability will be tied into an automated escalation and alarm system. Generally there will not be live personnel monitoring the satellite system 24/7. This automated monitoring will benefit from satellite data that is easy to machine parse and which is consistent in time stamp. For simple time-series values such as voltage, current, spin rates, etc., the monitoring is straightforward, and there can be a threshold set for both warning and fault levels. However, it is also useful to find alternative solutions for cases where the automation must perform complex processing on the received data in order to arrive at a conclusion; this includes having to apply some kind of waveform processing to time-series data, for instance, trying to estimate battery charge state from historical current and voltage levels (which may be sparse or incomplete).

The need for hardware-related telemetry on a satellite is more obvious than the need for system-level telemetry and monitoring. In a Microsat ecosystem, there are multiple systems in play, and each of them may be rapidly evolving, including mission control software, groundstation software, radio software, and satellite software, not to mention possible changes in groundstation hardware and cloud-computing infrastructure. When operating a fleet of Microsats, it is likely that there are legitimate reasons for some payload windows to fail; this includes technical reasons and also operating reasons such as aggressive time windows, operating close to the edge of the power envelope, etc. The point is that there will always be a high level of general noise that can make a new failure difficult to detect and isolate. Once detected, it can become a very daunting exercise to figure out why certain operations have not taken place if the observability of the system is poor, especially if they are finally noted as a general downward trend in system-level performance. Observability is then extremely important to be able to track down and diagnose issues that arise in the program.

In general, the flight software team and all other developers should embrace this idea of system "observability," the notion that at any given time, it is possible to trace how the satellite got into a particular fault state or failed to execute on its payload mission for some interval. This "observability" should also be designed such that it is easy to integrate into the automated monitoring system. An example of why this is important is measuring fleet-wide system performance against a customer service-level agreement (SLA) for a remote sensing type of mission. First, it is important to understand that there are a very large number of reasons that payload remote sensing data does not make it to the customer. Consider Fig. 5, which lays out how a payload acquisition request results in product being delivered to the customer. For convention, the left half of the diagram is labeled as "Reaction Time" which is the time between payload data request and payload data acquisition. The right half is labeled "Latency"; this is the time between payload data acquisition and delivery to the

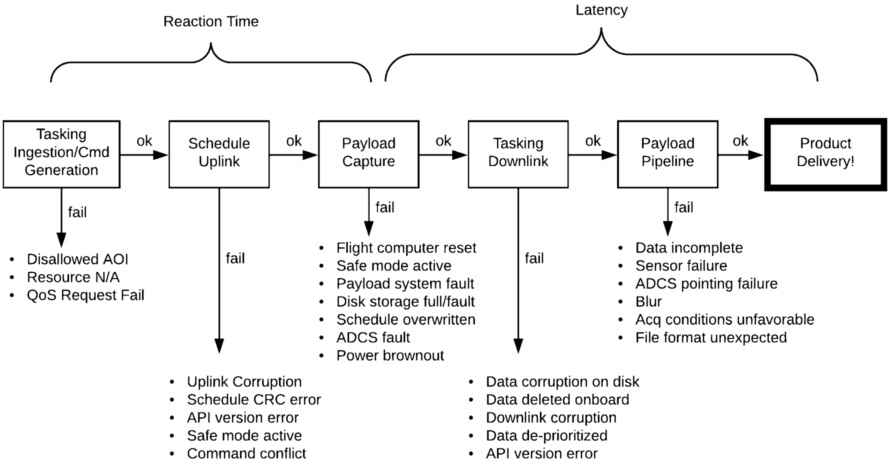

Fig. 5 Accountability for payload delivery. (Image © 2011 Planet Labs Inc., licensed for one-time publication)

customer. Both the reaction time and the latency may have SLA-related limits. For each step in the process, there are some example failure conditions listed.

The leftmost block is the initial task request, which may fail due to an inappropriate area of interest (AOI), satellite resource conflict, or potentially a failure due to an unmeetable quality of service request. Once declared acceptable, the request is turned into a series of command sequences that must be uploaded to the satellite, which is the next block in the sequence. There are multiple reasons that this can fail as well, including the satellite being in safe mode, potentially a command conflict, or the radio pass just happens to fail for equipment or planning reasons. This pattern continues to the right until data delivery to the customer. At the system level, each step of the process will have a non-zero failure percentage that must be observable and monitored. As can be seen from the rest of the diagram, there are many fault paths for the payload sequence (and many that are not shown). The intent for the system monitoring should be twofold: first, the customer facing team must be able to answer the question of why a particular payload sequence was not acquired, and, second, it must be possible to rapidly track down which step in the process has degraded. And then use that information and the observability built into the design to understand why the SLA may be at risk.

The reality here is that it can be very difficult to estimate the impact of what appears to be a small change, but (by design) it should be very easy to monitor it once it is deployed. Changes are always being made to the system, and this must be built in to the monitoring expectation. Early on in the design process and at regular intervals, the team should audit the event and telemetry streams and ensure that high-level functions in the end-to-end satellite ecosystem can be monitored easily. Each team should also be on the lookout for changes which may derail payload delivery and ensure that those events are reported and ingested into the automated monitoring.

8.5 Security

A critical aspect of the satellite ecosystem is the security posture and security implementation. The security posture for a mission will vary depending on the perceived value and lifetime of the mission. An academic mission of a single Microsat may have a less rigorous posture than a large satellite fleet that has ongoing launches for replenishment (and a longer window for security practices to become stale). The security posture will also be dictated by regulatory bodies such as NOAA in the USA. In any event, a satellite mission should have a security plan that comes from the security posture (requirements) which allows the security to be implemented in a way where risks are properly assessed and appropriate measures taken to achieve the desired level of security.

There is a reality that security design on a Microsat may not be given as much priority as other components and subsystems in the spacecraft. This is especially true in the early phases when basic systems are being developed, resources are short, and there is a significant chance that the early Microsat will not even reach full mission status after launch. There is then a likelihood that security features will be implemented “over time” as the design and potentially the company become more mature. From a flight software standpoint however, it is very beneficial to understand the eventual security capabilities early in the design process and identify the possible impacts to the flight software design. The use of standard security paradigms can greatly aid this process, and they should be considered (this will also help to avoid creating security vulnerabilities). The literature around security practices and possible implementations can be daunting, but an applicable and good starting point for a Microsat satellite design is to understand the IP security (“IPsec”) open standard Wikipedia article and then the various standard documents themselves (Kent 2005; Kent and Seo 2005). A good satellite-based security document to read after IPsec is the “Space Data Link Security Protocol-Summary of Concept and Rationale” published by CCSDS (CCSDS 2018). This document can reinforce some of the IPsec concepts through a satellite-based example. When choosing a security paradigm, the encrypted and authenticated option should be preferred. Note that an interesting aspect of the CCSDS implementation is the concept of the “authentication bit mask” which allows for selective exclusion of some fields in the message authentication code (MAC) which can make the application of authentication slightly more flexible.

The CCSDS publishes many security-related documents which are worth reading: the “Security Guide for Mission Planners” (CCSDS 2019a) is a good overview of security for the whole mission. It also lays out how the various CCSDS security documents are interrelated. The “Report on the Application of Security to CCSDS Protocols” (CCSDS 2019b) also has great information on security for satellites.

Returning to the flight software team, the goal of the team should be to break down security requirements into capabilities and then come up with a schedule to implement them, preferably as soon as possible. Availability of these capabilities can provide security to the Microsat even when the security plan is not completely fleshed out. At a high level, these capabilities will relate to requirements for hardware and software cryptographic capability, tamper detection, the storage of crypto keys in nonvolatile memory, and implications for the design of communication protocols. It is easy to fall into the trap of building out mission functionality first and then being in an awkward position trying to implement security on top of the resulting implementation. It is best to try and avoid this.

Before examining possible security capabilities, it is worth mentioning some concepts that can impact the flight software security design at a fundamental level. The first is the concept of a security boundary and a cryptographic module, and the second is the notion that the endpoints of a security paradigm may terminate in different places on the ground.

In the context of satellite security design, establishing the security boundary means having a clear understanding of how data and commands transition from a trusted to an untrusted domain and vice versa. A cryptographic module defines the perimeter within which cryptographic processing is performed, such as command and telemetry decryption and encryption. From a flight software standpoint, establishing the security boundary and cryptographic module on the satellite will help identify which devices on the satellite must have cryptographic capability and access to keys and which do not. This may also impact how devices are interconnected.

With a less stringent security posture, the security boundary could be defined as being at the physical satellite boundary itself, potentially at the interface where the satellite feeds data to/from the radios. The cryptographic module could encompass all the devices except for the radios, so keys could be freely shared among all devices, and one or more devices would be responsible for key management and cryptographic operations. This model imposes fewer design constraints in terms of satellite design and may be adequate for a satellite with a less stringent security posture.

With a more stringent security posture, the security boundary could again be defined as being at the physical satellite boundary itself, but with a singular subsystem (device or devices) forming the cryptographic module responsible for key management and cryptographic operations. While this may impose more design constraints, it should (hopefully) provide for tighter control around the security processing on the satellite. Having the security code separate from other satellite functionality should also support easier auditing of the security operation. Note that security boundaries and cryptographic modules also apply to ground systems that perform encryption and decryption of satellite data.

It is important to understand that the endpoints for security capabilities may vary depending on the purpose. Figure 6 indicates some possible security paradigms. Note that these concepts are also discussed in CCSDS references (CCSDS 2011, 2019b). The point here is that there are security links that can terminate at the local groundstation and also security links which can potentially terminate in dedicated or cloud-based servers for the mission operations center (MOC) and payload processing. It is therefore inappropriate to focus on a security paradigm which is only designed for the over-the-air (OTA) datalink, for instance, and it must be the case that secure messages can be routed from a groundstation through the ground network to the appropriate downstream endpoint (mission control or payload processing). In the diagram, “Mission Operations Center” represents the server or cloud-side processing system which automatically manages the satellite constellation. The following describes the links in Fig. 6:

1. **Mission Operations Center and Satellite** – The connection shown here is that of a traditional “bent pipe” where the groundstation merely relays packets back and forth (both telemetry and command). The groundstation may implement some form of data link security and may have the authority for message retries.
2. **Groundstation and Satellite Radio** – It may be the case that the round-trip delay between the groundstation and mission operations center is inappropriate for certain operations, and there is a desire to implement some autonomy on the groundstation itself. A prime example of this is adaptive coding and modulation (ACM) where it is desired to keep the feedback loop driving the radio as tight as possible. Automatic repeat request (ARQ) can also be done locally at the groundstation.

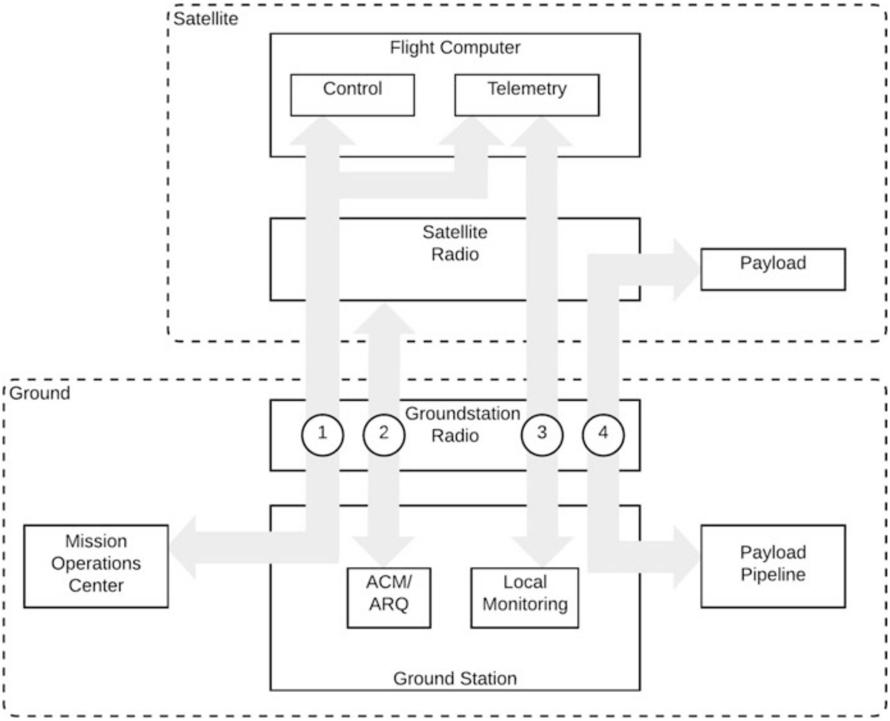

Fig. 6 Security routing endpoints. (Image © 2011 Planet Labs Inc., licensed for one-time publication)

3. **Groundstation and Satellite Telemetry** – This is a more uncommon case, but there may be a reason for satellite telemetry information to be available at the groundstation. This would typically just comprise telemetry received directly from the satellite.
4. **Satellite Payload-to-Payload Pipeline** – The payload data will likely be delivered directly to a cloud-computing endpoint or potentially a customer endpoint for pipeline processing. The ground system will have to understand how to route this information to the payload endpoint. Note that it may be the case that the payload does not have to be encrypted at all. This will depend on business and regulatory conditions.

8.5.1 IPsec Concepts and Capabilities

The concepts behind the IPsec model represent capabilities that will very likely need to be implemented on the satellite. Note that implementing simple models for these capabilities while still following best practices for the actual encryption and authentication can go a long way in securing the satellite. The following list gives some context around the capabilities that may be useful to the flight software team:

- **Security association (SA)** – The security association is an agreement between two entities about how they will use security capabilities and practices to communicate in a secure fashion. The security association for an early stage Microsat can be simple, potentially decided entirely in advance with no runtime negotiation and based on pre-loaded symmetric keys. The pre-loaded keys can be used directly for encryption and authentication purposes. There should be a security association entry for each security relationship in the system (as shown in Fig. 6). At a minimum, the SA should have a version and detail a minimum set of cryptographic algorithms to be used (encryption, MAC), key attributes, and a list of valid key IDs. Alternatively for satellites desiring more flexible key rotation, the SAs on board the satellite may be updated using a form of key exchange to generate fresh traffic protection keys (CCSDS 2011). Consideration needs to be given to the number of message round trips required for the establishment of an SA as this adds latency to the process.
- **Security header** – The security header is added to the data content and is intended to indicate how the corresponding data should be decrypted and also to allow for authentication of the data. The name "security header" is presented to be generic, in that the header can be designed as appropriate for the Microsat system. It should have similar parameters as the Encapsulating Security Payload (ESP) from IPsec (Kent 2005) where necessary, such as the Security Parameter Index, the initialization vector (IV), a sequence number, and an ICV or MAC. The CCSDS document for the Data Link Security Protocol (CCSDS 2018) has both a "security header" and a "security trailer" which when combined have similar fields to the ESP. Since authentication is generally a good idea, combining the CCSDS "security header" and "security trailer" may be an appropriate choice to consider. Note that the IPsec definition is tied to IP and the CCSDS design reference above is tied to a data link layer. It may be appropriate to create a security header that is agnostic of protocol or communication layer.
- **Security Parameter Index (SPI)** – The SPI is included in the security header and indicates which SA the content is intended to be used for. For a Microsat, this can be as simple as a scalar value which indicates which security association (SA) to use. It is potentially useful to also include a version into the field in addition to the SPI.

8.5.2 General Concepts and Capabilities

- **Software cryptography** – From a software standpoint, the types of cryptographic algorithms must be understood and implemented. It is useful to try and identify cryptographic libraries which are appropriate for the processor in the device selection phase. There is no reason that this should be done in-house. Note that software cryptography can create a large burden on the processor that must be accounted for. It is also an idea to ensure that there is headroom to grow on the processor in the case that the cryptographic algorithms must change. Cryptographic libraries can be very comprehensive and will likely contain many more algorithms than the satellite system needs, consider removing unused routines from the software, and also remove security algorithms that are no longer considered secure.

- **Hardware cryptography** – In the design and device selection phase, there should have been some consideration of hardware security capabilities. This would be either hardware implementations of cryptographic algorithms (like the advanced encryption standard AES) or maybe hardware acceleration with floating point libraries or digital signal processing (DSP) blocks. Note that hardware cryptographic capabilities are not upgradeable so if the hardware is unable to provide sufficient protection at a later date (for instance, if the key length or cryptographic algorithm is insufficient), then the update will have to be moved to software, or a new processor must be selected and integrated. A way of reducing the risk of this would be selecting cryptographic algorithms and key lengths that are thought to be secure for the expected lifetime of the satellite constellation. For constellations with a design lifetime of many years, designing in crypto agility can be challenging due to emerging quantum computing capabilities.
- **Key storage** – The flight software must be able to store the permanent keys that are provisioned at manufacturing, and it must do this in a reliable way. In the flight software work, the store will likely be one of the larger efforts. The key store must be persistent, potentially duplicated for redundancy, and protected against write failure. Note that in a Microsat, security keys are likely maintained in flash, and flash is generally fairly robust when not written to. It is a really good idea to not use a flash storage device that implements a flash translation layer (FTL) under the hood. This could mean that the memory storage device is actually moving the keys around for wear leveling, and a radiation event could be detrimental if it disrupts this write operation. The key management scheme should be tied into the SA that is discussed above, with each SA being associated with at least a pair of keys. For more complex security schemes, there will likely be a hierarchy of keys such as master keys and traffic encryption keys (CCSDS 2011) and also the notion of key life cycles and cryptoperiods. This will have to be reflected in the key storage design.
- **Protocol definitions** – It is important to ensure that the security header can exist in the protocol definitions from the start. When using third-party communication designs, this will likely not be a problem. However, in a home brew system, there may be some data overhead concerns if the maximum radio packet size is small. Care should be taken as well to ensure that the security implementation (encryption) does not interfere with any message routing implementations.
- **Replay protection** – Protection against the replaying of previously sent commands is almost as important as the authentication of commands. IPsec achieves this through the use of a sequence number associated with each SA that is incremented on each packet sent. The receiver tracks the sequence number for each SA and enforces ordering to reject replayed (repeated) packets. There should always be replay protection built into the design.
- **Fallback plan** – There should be a well-understood design for the security system if there is some kind of degradation or compromise. This may be a fallback security key or key store or potentially a different algorithm suite that is not normally used. It should be predictable to the satellite operations group when the fallback plan is activated.

Having the SW/HW cryptographic capabilities, the key storage, the SA, and the security header design will allow for implementation of a reasonable first level of security. If these aspects are handled correctly for the initial (or early) Microsat design, then the flight software team may only have a supporting role when the system is scaled up to many satellites. The bulk of the extra work will be in key management on the ground, both inside the mission operations center and the manufacturing process.

Security must be understood in all aspects of operation, including software upgrades and during resets and faults. Security must be active during the software upgrade process, and a failure in the upgrade should not result in a compromised security position (there should never be a possibility that the security is not active). The security design should also be robust against loss of time on the satellite, and as in any system, the security will only be as good as the weakest link.

9 Conclusion

When developing Microsat software, it is important to properly understand the scope of work involved for the flight software team and also the development life cycle when multiple launches are taking place. This will enable the flight software team to develop appropriate architecture and build philosophies that allow critical software components to be delivered in a timely fashion. The flight software team should ensure that on-orbit software upgrades and an appropriate safe mode are well established as early in the design process as possible. The environment in which the flight software team operates can be challenging for long-term planning and development. Where possible the flight software team should look to the future and ensure that they try and position themselves for future success at scale. This includes focusing on items such as building observability into the design, identifying security capabilities, and being involved early on in the processor and device selection process. A successful Microsat company could end up with a very diverse set of satellite hardware in orbit, both from ongoing developmental improvements and from random degradation of hardware once it gets into the space environment. The flight software team should plan for the implications of this reality and help ensure that the company can successfully operate a diverse fleet of satellites.

Network Control Systems for Large-Scale Constellations

Jeroen Cappaert and Sreeja Nag

Contents

Abstract

Network control systems for large-scale constellations of small satellites are of critical importance to the successful and safe operation of smallsat systems – especially in the case of remote sensing networks but also for other applications. As the level of complexity of the space segment and the ground segment of these networks increases so does the level of complexity of the network control systems that are used. Today small satellite constellations such as those represented by

Planet and Spire represent the two largest small satellite constellations in operation, but in the near future, there are many new constellations that may require network control of many thousands of smallsats. There are challenges associated with initially deployment, configuration of spare satellites, operation of large constellation, and de-commissioning and de-orbit of smallsats that require a high level of sophistication and technical expertise. All of these levels of complexities and methods to create effective network control systems for large-scale constellations are addressed in this chapter.

1 Introduction

In recent years, there has been a proliferation of smallsat constellations. There are now over a dozen companies now having fully operational constellations and commercializing their telecommunications, networking, automatic identification system (AIS), remote sensing, and RF geolocation products. These small satellite constellation operators now have a special focus on how to achieve the most efficient and optimal use of their spacecraft assets. Most modern smallsat constellations are no longer operated on an on-demand basis. Instead most of these smallsat systems collect or communicate data on the basis of software programming. Thus most of these spacecraft operate at their own pace. Further in the case of remote sensing and other systems, there is a trend toward processing of data on-board the satellite to greatest extent possible. If it is possible to pre-process the data on-board before bringing it to the ground, it can lead to greater efficiencies at several levels.

The goal of a network control system for a smallsat network thus typically becomes to translate direct customer demands into the operational plans for the satellite networks without commands or specific requests for data coming from the ground. This process is called, especially for remote sensing satellite systems, asset tasking. This method of optimizing the usage of the space and ground segment assets via network control software is key to the successful operation of smallsat networks (see Fig. 1). As such, network control is now central to achieving mission and business success. In short optimized network control systems are key to determining achieving the highest return on investment and the most efficient asset allocation in orbit and on the ground.

2 Smallsat Constellations

A Euroconsult study has projected that, over the next 10 years, about 8600 smallsats will be launched, at an average of 835 per year as of 2023. They also project that this will grow to an average of 880 launched per year by 2028.

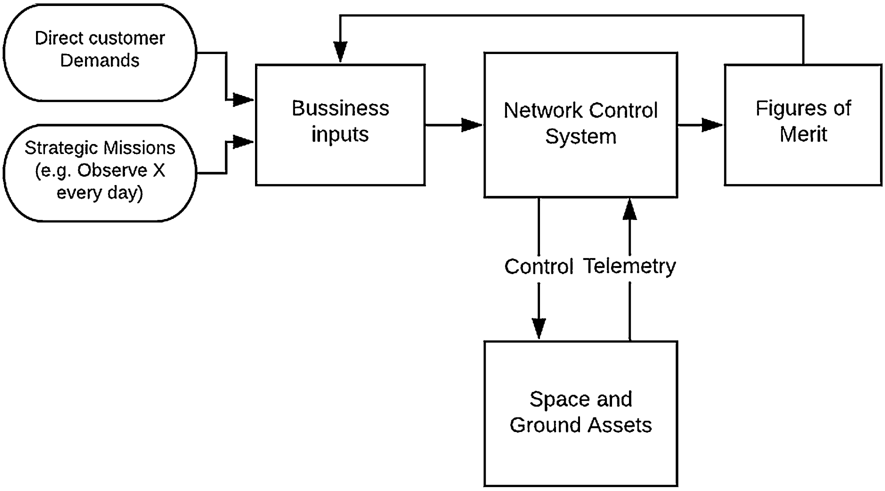

Fig. 1 Network control as part of business process

According to the Euroconsult study, 322 smallsats were launched in 2018. Of these launches about 40% were for constellations (Euroconsult 2019).

Proposed constellation sizes range from 10s of satellites to 100s and 1000s. A few operational constellations already exist today in the range of 10s and 100s of satellites (e.g., Planet, Spire).

This trend toward the use of more efficient software, optimized network control systems, and the use of pre-processing where possible is not restricted to smallsat networks. These same dynamics are also driving fundamental change in the way large networks of satellites are operated.

In the past it was feasible to manage and control a few satellites by means of an on-the-ground team of operators. It was even for larger networks of perhaps 20 in number by means of simple automation and a scripting process followed by manual operators on the ground. This approach however becomes increasingly unwieldy for larger constellations. Human errors – sometimes called cockpit errors – become more likely as network operations grow in size. There is a threshold – of perhaps a constellation of 50 satellites – that forces a change to a completely different level of automation.

A constellation of 50 or more, such as was first demonstrated by the Iridium and Globalstar constellations, requires a different approach. At this level of complexity, the satellites can no longer be thought of as individual assets. This is because the complexity of interaction is increasing exponentially, which can be shown analytically (Alderson and Doyle 2010). A network of this size has to be considered as a holistic combine. It becomes necessary for space assets to be continually optimized. Automated network control can then be programmed to provide maximum product value.

One must start from a purely practical perspective to consider what satellite operators are able to achieve. It is very challenging for operators to constantly monitor and in real time resolve anomalies that occur within a constellation larger than perhaps 20 satellites operating in low Earth orbit (LEO) and truly impossible at a level of 50 satellites. This is because the complexity of interaction is increasing exponentially. If one considers the case of a modern smallsat constellation, the complexity becomes very great indeed. Such a constellation could have:

- Greater than 100 satellites. These might be distributed in many orbital planes.
- There could be ground station at 50 or more locations.
- There might be well over 1000 satellite contacts per day.
- The level of communications throughput and data download might be collectively measured in gigabytes per second.
- Satellites might have varying data requirements and have been programmed to provide multiple services or data products.

With this amount of complexity, manual control essentially becomes impossible. Automated and programmed systems are needed for network control. This then allows operators to focus on providing the needed responses and inputs to the system. The role of human operators thus becomes that of balancing business priorities and re-acting to specific issues or anomalies that might require attention.

3 Network Control System Functionality

All these elements of optimized systems operations are shown in Fig. 2 with the many parts of a network control system depicted. There are many aspects to consider. These elements include but are not limited to the following (Cho et al. 2018).

- **Satellites**: a typical smallsat constellation and the satellites deployed in it are built up over time. This may include the use of rideshare launches. In such cases the constellation can be less “managed” than traditional constellations that can utilize dedicated launches.
- **Ground stations**: Smallsat operators typically rely on a ground station network that is not monolithic in nature. Rather these ground stations may well be constituted by multiple owners and service providers. The result of this diversity of providers and terminals is a ground network that has capabilities that might widely differ. For example, on some stations there might just be a downlink available, while other stations can send commands as well as receive data.
- **Mission control**: The mission control centers can also differ. One facility could be a traditional physical mission control center. Others might be designed as completely cloud-based distributed control center. Such a facility could have limited on-shift operators.
- **Schedules**: Scheduling is also key concept that drives asset allocation. Transit and payload schedules are traditionally generated centrally from the mission control

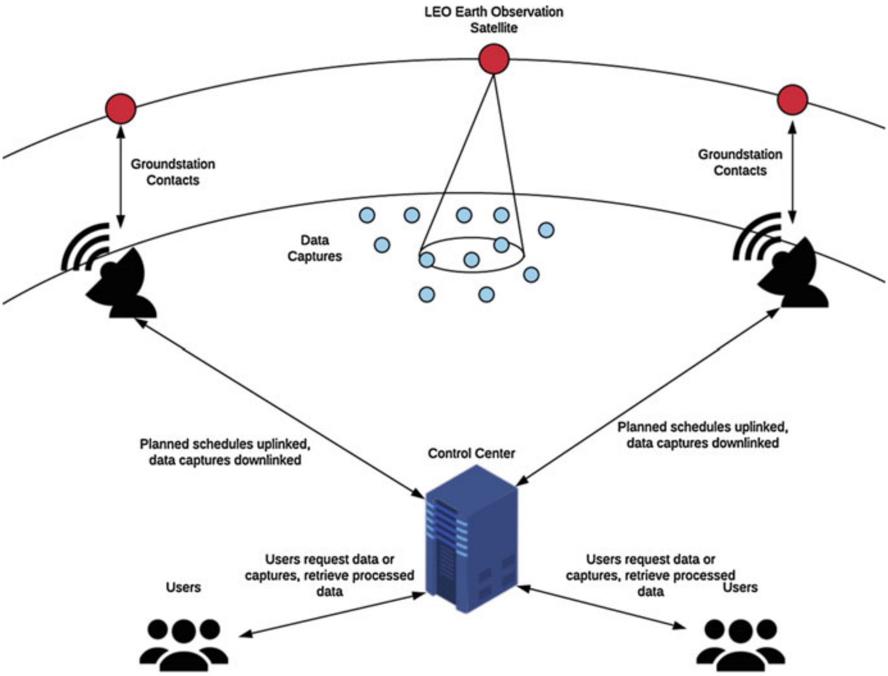

Fig. 2 Illustration of the elements of a network control system and need for flexible network control

center. In modern systems, however, network control varies depending on whether spacecraft are programmed with on-board satellite autonomy.

- **Customers/users**: Internal users and customers have varying needs. These may vary by season or other variables. Factors that might vary include changing number of measurements per day or once per day, week, month, etc. There can be some form of a one-off on-demand requirement such as a measurement at a specific time and place. Users could also specify multiple interfaces as to where and when to retrieve data.

Smallsat constellations come in various forms and sizes and now comprise many applications, but generally the goal of network control can be generalized to the following:

- Optimize both the ground and space segment assets so as to provide the maximum return on investment.
- Ability to exploit the satellite system to allow maximum flexibility to respond to customer demands and changing market needs.

In the case of a communications constellation, the goal is typically to determine how to route given volumes of throughput optimally. Alternatively, the objective for an Earth observation constellation is to schedule data collections efficiently as well as to find the best route to relay data to the ground. Both problems are highly interconnected to routing efficiency. The use of network control systems t to achieve routing efficiency is considered in the rest of this analysis.

3.1 Figures of Merit

A figure of merit provides a way to best gauge the performance of a network control system and is especially key for Earth observation services. The rationale for establishing a figure of merit typically considers one or more of the following criteria.

- **Revisit time**: This is the time between subsequent observation and/or coverage of the same geographical area. This is key for both networking and Earth Observation services. It's an important aspect as it defines the intervals during which coverage or service is not provided.
- **Refresh time:** This is the time between subsequent observations of the same asset (e.g., in the case of asset tracking like automatic identification systems (AIS), automatic dependent surveillance (ADS-B), or machine-to-machine (M2M) communications).
- **Latency**: This represents the time between an observation and data delivery to customer or the time to provide data networking connectivity. Sometimes this also includes the time required to command a spacecraft to take a certain measurement.
- **Coverage**: This provides a precise measure of the geographical coverage of a satellite constellation. This defines the percentage of the Earth's surface (or an area of interest) that is covered. Similarly, asset coverage can be defined as the ratio of assets that is covered (ships, buildings, airplanes).

3.2 Constraints

A network control system thus needs to be flexible and responsive in order to take into account various operational constraints. The principal constraints include:

- **Energy constraints**: It is important to ensure that the stored energy in the spacecraft battery is always sufficient to meet power needs of the mission and the spacecraft bus as well as meet the associated needs during the times of solar eclipse. All scheduling of spacecraft activities needs to take into account the satellite's power budget. There also needs to be some reasonable margin. In short scheduling of service must always respect power availability plus some margin.
- **Thermal constraints**: There are also thermal constraints that must be considered in the provision of services. Each of the spacecraft's subsystems must be used only if the temperature expected in that interval is within an acceptable range. If a

particular payload observation or communication windows are found out of range, then this service capability must be cancelled.

- **Data balance or storage capacity**: There must be care taken to ensure that the storage space remaining on the spacecraft is more than adequate to meet mission objectives. This includes the capability to always be aware of the storage capacity and downlinking capabilities in terms of data rate and windows that are available for such data transfers.
- **Subsystem compatibility constraints**: There can be competing power, thermal, or other constraints that must be considered. This means that network control systems must be programmed so that non-compatible subsystems are not used at the same time or that all operational requests are compatible for the times they are in use. For example, high-power transmitters and a sensitive receiver might operate effectively at the same time. Other payload elements might have competing pointing, thermal, or other requirements.
- **Geographical constraints**: In some cases there are constraints related to operating over certain geographical areas. For example, one might want to operate payloads only over land, deserts, oceans, or arctic regions. Additionally, an operator might want to restrict service in polar regions so as to recharge batteries. Thus the geographic constraint would hinge on whether is above highly trafficked areas or not.
- **Regulatory constraints:** It is also important to make sure that all operations are conducted within the limits of space operation frameworks and applicable licenses. Satellite communication services are restricted in many ways, but there are also constraints on Earth observation satellites and other applications. Those who are launching communications satellite systems might have to coordinate with other operators on a non-interference basis. This can result in the need to duty cycle radios, implement communications blackout windows, or point away for geostationary satellites, which have protected status, to reduce the risk of interference. Additionally, operators must take care not to exceed power flux density limits set by the ITU since many satellites might be communicating at the same time. Any network control systems need to take these constraints into account.

3.3 Challenges

Some of the main challenges for a satellite network control system are examined below.

3.3.1 Heterogeneity

Smallsat constellations, which include hundreds or more satellites, are deployed in different generations. Thus these satellites may have different capabilities. Thus these networks might contain satellites that are in some ways heterogeneous in design. This is due to the iterative development process over time. Constellations are built up piecewise as hardware is developed and improved. Geosynchronous satellites might have lifetimes of 15 to 18 years, but constellations with LEO satellites may be replenished much more often than traditional satellite systems. This results in a constellation that can be composed of dozens of hardware versions, some of which might be minor, while others might be more significant.

Another reason for differences in hardware of satellite design, or even operational frequency bands, can be a satellite operator purchasing satellites from other networks. Sometimes acquisitions can come from completely different satellite networks (e.g., Planet and the initial SkySat constellation).

Smallsat systems can also be different, not just in terms of hardware differences, but there can also be a variety of software versions across the constellation. A single satellite might be composed of subsystems each running their own software version and each being software-upgradeable. This is a manageable issue, but it requires considerable discipline to make it work. Unique software configurations might arise as well as satellites experience key issues and/or major anomalies. There may be the need to create workaround solutions that are unique to one satellite or a particular cluster of smallsats. Every satellite tends to develop a unique "personality," based on the specific hardware and software features and potential anomalies or workarounds in place (Open Networking Foundation 2012).

Any network control system needs to take into account these differences when scheduling its assets.

3.3.2 Orbital Patterns

While some smallsat constellations are actively managed and station is kept to special parameters, many are not. Other constellations are more irregular and rely on available rideshare opportunities. For example, see Fig. 3a–c. These figures provide a comparison between the Spire, Planet, and Iridium orbits. The difference in launch strategy results in satellite to ground station transit patterns that are quite different for these three constellations. Satellites might see a ground station a few times an hour regularly for a while, only to have hours-long contact gaps later.

This usually results in figure of merit distributions with a long tail. For example, Fig. 4 shows the latency distribution of the Spire constellation and ground network. While latency is normally very good, due to the orbital configuration, sometimes

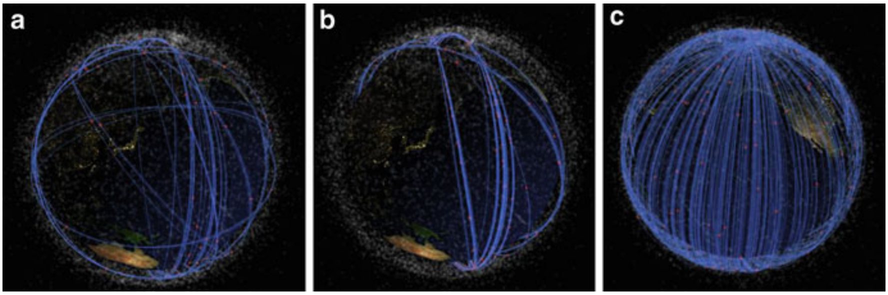

Fig. 3 (**a**) Spire's LEMUR constellation. (**b**) Planet's Flock constellation. (**c**) Iridium

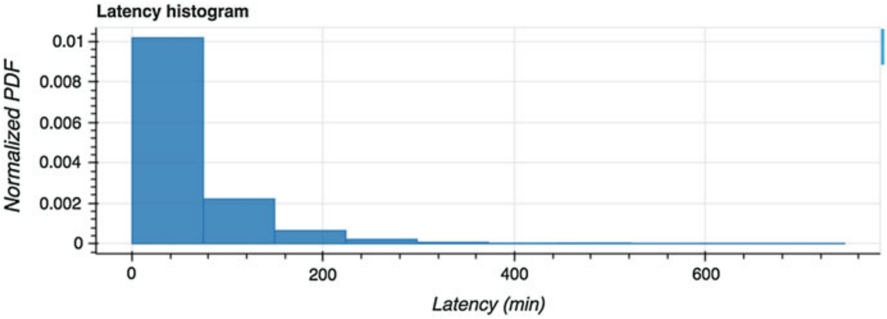

Fig. 4 Latency patterns for the Spire constellation (Graphic courtesy of Spire)

there are large contact gaps between satellites, resulting in a few periods with long latency that skew the average latency.

3.3.3 Multi-customer Nature

Many modern constellations no longer serve one type of customer or might even operationally produce more than one type of data from multiple payloads. The need to manage and control the competing priorities between various data types can be difficult. These challenges become even greater as various data types are added, the volume of data transfer grows, and latency requirements differ. Additionally, within a single data type, multiple different service levels could and often do exist. For example, captures relating to emergencies (e.g., imagery for natural disasters, ship data following collisions, etc.) could have higher priority needs than “standard” captures. Any network control system thus needs to be flexible so it can consider various data types and different tiers of data. One might end up with a latency-data volume curve as shown in Fig. 5, where various tiers of data volumes are downlinked at various latencies as well as different data speeds.

4 Network Control Subsystems

- On Fig. 6 an example is shown of what a constellation network control system might look like. The various components are discussed (Cho et al. 2018) below.

4.1 Satellites

4.1.1 On-Board Automation

The main goals of the on-board automation include at least the following four objectives:

- **Checkout and commissioning of satellites:** The efficient deployment and commissioning of multiple satellites in a constellation is a demanding task.

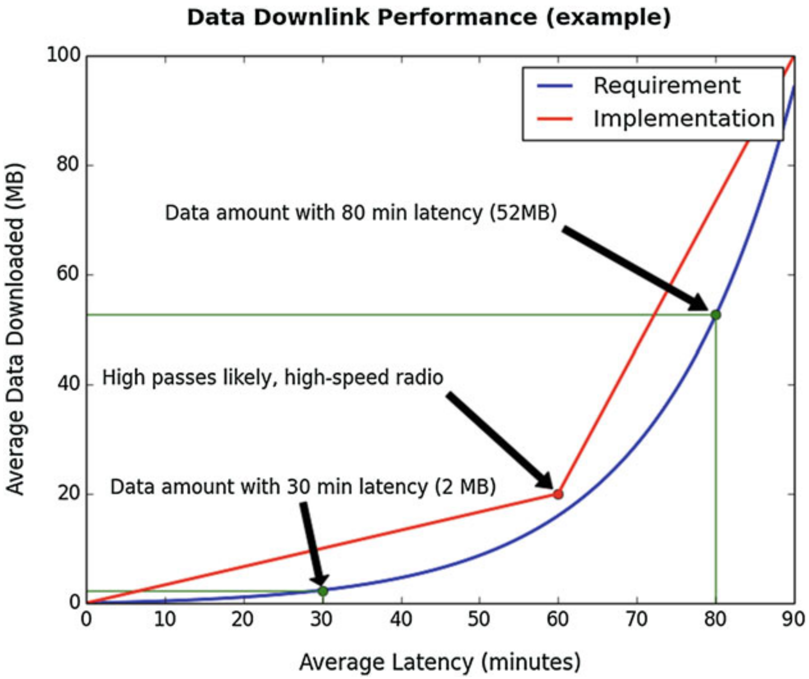

Fig. 5 Example of latency-volume curve (Graphic courtesy of Spire)

This can mean the deployment, checkout, and commission of multiple satellites that are deployed from one launch vehicle. Thus the managing satellite commissioning for many, many satellites across dozens of vehicles over a wide span of time is cumbersome. For example, Planet moved to a fully automated commissioning system which was probably essential since they were involved with the launch, checkout, and commissioning of 88 satellites associated with a single launch by a Polar Satellite Launch Vehicle (Doan et al. 2017).

- **Tasking payloads and communication radios.** For many small satellite constellations, there is a formal process to create "tasking schedules." These are typically generated by the mission control system on the ground and synchronized periodically with the spacecraft for a specific time interval (e.g., 24 h). Various levels of automation might exist on the spacecraft. Such automation serves to make this task easier and more efficient. In the case of automation, a task list might be quite simple. There might just be a list of commands with timestamps (e.g., "turn on payload one"). Alternatively there might be a higher-level list of subtasks (e.g., "complete a payload collection on payload one and prepare the data for downlink"). In some of the more advanced network control systems, more autonomy might be given to the spacecraft. In this case there might be a more flexible task provided. This might result in a tasking such as "Complete 10 payload windows with optimal geographic distribution in the next 24hrs."

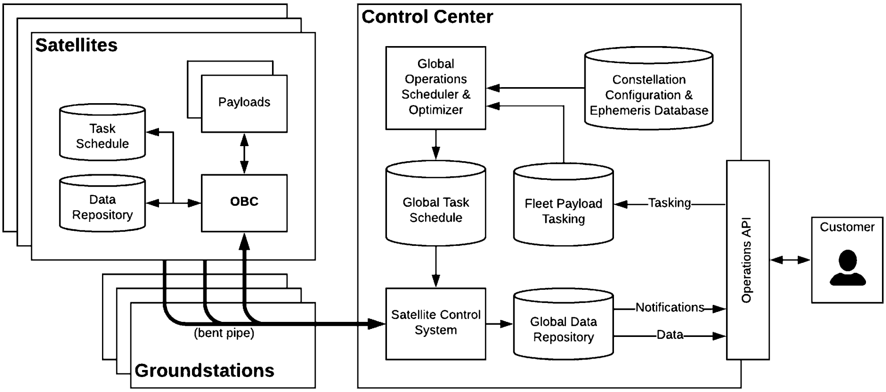

Fig. 6 Components of typical network control system

- **Managing spacecraft data.** In the case of different payload data types, there might be a need for different types of data handling. Data might exist in various forms and conditions. These might include ring buffers, databases, and plain text or binary files. For example, native data type will be allowed to determine the best storage tool. In the case of IoT message, it might be best to create a database. In the case of raw radio frequency collection, this process might work better with binary files. Data size and data latency are among the factors that contribute to these decisions. In the case of data with low latency requirements, it is best to avoid large files that would take a long time to download. The on-board computer can also apply data compression where appropriate and pre-process the data to prepare it for downlinking. Thus it is best to encode large files in advance of downlink.
- **Collect telemetry, monitor system health, and recover where needed.** Lastly, it is the task of the on-board computer to monitor health for all subsystems. It is also tasked with the responsibility to collect system telemetry and perform fault detection and isolation and recovery as required. Traditionally the on-board computer would be tasked to "flag" any faults and transmit them to the ground in order to alert operators. In more advanced systems, especially in the form of 0 recurring and simpler faults, this might be programmed to be handled through an automated recovery process. The latest systems employ modern machine learning telemetry systems. This allows longer-term trending of telemetry data and a greater ability to identify indicators of impending system failures.

4.2 Ground Stations

In most systems, the ground stations act simply in bent-pipe mode. This means that data is transmitted directly to the control center without buffering or processing. The advantages of this architecture would be in the form of enhanced security. This is to say that no data would ever be left unencrypted on a ground station. It would also decrease latency in that data can be streamed directly to the control center without having to wait to complete a satellite pass.

4.3 Control Center

4.3.1 Configuration and Ephemeris Databases

As indicated above, each satellite usually ends up having what might be called a unique personality. This then results in the need for a per-satellite configuration database. Such a detailed database can keep track of things like (i) satellite frequency configuration, (ii) licensing jurisdiction, (iii) status of subsystems, (iv) status of watchdogs, (v) timestamps of the last time maintenance procedures were executed, (vi) software interface versions, (vii) ADCS control modes, (viii) telemetry alerting limits, and other data peculiar to an individual satellite. Whenever tasks are scheduled and executed, the satellite configuration database is used to determine how to interact with a specific satellite. This would include decision as to what software interfaces to use. This key database would also contain the ephemeris information for satellites.

In addition, the database can contain ground station characteristics. This would alert the scheduler as to which satellites are compatible with which ground stations.

4.3.2 Operations Scheduler and Optimizer

To make the best use of all assets, a globally optimal ground system transit and on-board tasking schedule needs to be generated.

The block diagram shown in Fig. 7 shows how an optimizer fits into the large satellite control process. The input for the optimization process is derived from business-level goal functions. These might take the form of "Collect X MB of data at Y min of latency" or "optimally cover a specific area of interest." Business objectives can also change over time. Thus, the goal functions are not necessarily static. High-level functions need to be translated into actionable satellite operations interface variables. This is where figures of merit are employed. Thus figure of merit

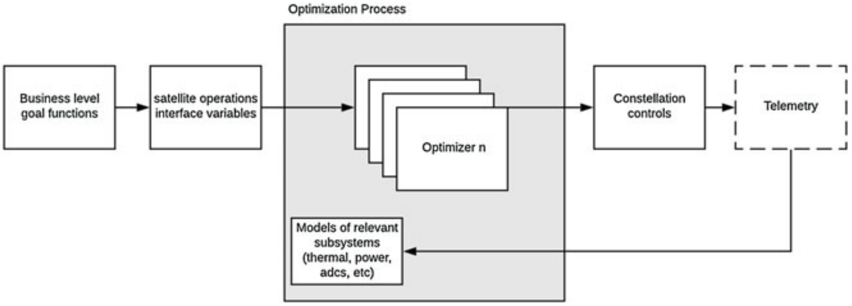

Fig. 7 Example of optimization process

conditions are then fed into the optimization process. The output from this process will be translated into constellation control parameters. These then become specific tasking schedules, the setting of telemetry limits, etc. This ultimately becomes a circular process after these parameters are executed and telemetry data collected. This informs the control center on the level of success achieved compared to the initial goals.

4.3.3 Optimization Strategy

On-Board Optimization

One option is for the ground to output contact schedules as well as a set of objectives for each spacecraft which in theory it can autonomously pursue. Each spacecraft would in this case need its own optimizer. This would include its own thermal and power models, priority maps, etc. This optimizer would need to computationally be programmed to run efficiently on the on-board computer.

Some advantages with this approach are relatively simple ground-based scheduling; more resiliency against unpredictable hardware behavior that was not foreseen during scheduling, such as an instrument failing to turn on; and ability to react to evolving phenomena to observe.

On the other hand, there are disadvantages with this approach: less fine-grained control with a less deterministic outcome that might potentially result in performance further away from a global optima and the higher levels of on-board autonomy, requiring more complex satellite side code.

Ground-Based Optimization

This approach entails an entire schedule (as optimized on the ground) to be uplinked to each satellite. This would be expected to be followed under nominal operations. This has the advantage that it provides very fine-grained control over what the constellation is asked to do with a deterministic outcome.

Hybrid Optimization

A third option would be a hybrid optimization that bridges the above two approaches. This approach generates a globally optimal schedule on the ground. Yet there is also enough intelligence on the satellite to intervene when operational conditions deviate from assumptions made during the generation of the ground-based schedule.

Such an intervention might, for example, allow satellite to throttle back instrument usage if the amount of data throughput is backing up. It might also activate an instrument to expend energy stored in excess of what was expected.

Algorithms in Literature

A number of planning and scheduling algorithms have been published, and at a very high level, in open literature for single large satellite missions. Key examples are represented by Automated Scheduling and Planning Environment (ASPEN) for EO-1 satellite. Another example is the Advanced Spaceborne Thermal Emission and

Reflectance Radiometer (ASTER) that is utilized on the Terra satellite as well as the high-resolution imagery from the IKONOS commercial satellite. It is also used for scheduling observations for the geostationary GEO-CAPE satellite or image strips over Taiwan by ROCSAT-2.

Stochastic algorithms have been proposed and computationally simulated for single spacecraft (Xhafa et al. 2012) and multiple payloads (Jian and Cheng 2008) and comparative merits documented for satellite fleets (Globus et al. 2002). While they offer accurate solutions, the cost of initial condition dependence, exponential time to converge, and large training sets make them very limited in mission applications. (Abramson 2012; Robinson 2017) have developed a coordinated planner that can handle a continuous stream of image requests from users by finding opportunities of collection and scheduling air or space assets to maximize collected utility. Agent-based autonomous scheduling has been implemented on NASA's Deep Space 1 (Schetter et al. 2003).

Some analysts have (Bunkheila et al. 2016) demonstrated the ability to provide for the scheduling of the scan of single LEO orbiting satellite by dividing the areas of interest and choose the sequence of strips of coverage by this method. This is based on various distance functions for an ideal orbit. It fixed scanning times based on roll and pitch angles and is therefore able to compute the temporal feasibility of pointing without modeling the Attitude Determination and Control (ADC) system or its uncertainties.

Simulation studies have optimized the scheduling for single Cubesat downlink to a network of ground stations (Spangelo and Cutler 2012) or multiple payloads' downlink to existing stations (Jian and Cheng 2008), within available storage and energy and access time constraints. Studies have also combined single satellite scheduling with information sharing across satellites for a weak consensus on feasible charging, downlink, and observation schedules (Kennedy et al. 2015) using fixed view imagers.

Scheduling observations for constellations of large satellites with payload repointing has been formulated for the French Pléiades constellation (Lemaitre et al. 2002) (Damiani et al. 2005) and COSMO-SkyMed constellation of synthetic aperture radars (Bianchessi and Righini 2008). Schedulers for Cubesat constellations such as the 200+ Dove spacecraft fleet operated by Planet Labs, Inc. (Boshuizen et al. 2014) assume static orientation of the sensor in orbit and only schedule duty cycles for payload power. Accounting for full reorientation in multi-spacecraft missions imposes computationally expensive constraints on scheduling spacecraft slews between payload operations. It is only recently that scheduling with slew-time variations has shown reasonable convergence using hierarchical division of assignment (He et al. 2019) and step-and-stare approaches using matrix imagers (Shao et al. 2018) and dynamic programming to account for utility maximization with ADC modeling (Nag et al. 2018). Planet Labs has published a preliminary scheduler used to operate their agile Skybox spacecraft fleet (Augenstein et al. 2016). Spire uses a similar approach for their RF sensing fleet. Agile observation schedulers that can recompute science value real time and autonomously reschedule observations across a constellation have demonstrated utility in simulation (Nag et al. 2019).

EOS is well suited for the mixed integer linear programming (MILP) approach because to perform any activity at any time instant (or not) can be modeled as a binary integer (e.g., ROCSAT-2 scheduler), and CPLEX can solve such formulations efficiently. However, MILP allows for only linear constraints and a single objective function, and there is no guarantee of reaching an optimum in linear time. The first drawback can be addressed using linear bounds to otherwise nonlinear variables (under-constrained formulation). The lack of a single, linear objective can be addressed using a Lagrangian sum of multiple objectives or a convex function representation of the objective. However, such approximations take away from accuracy and cutting plane bounds need not always be reliable. As examples, MILP has been successfully formulated for EOS for PLEIADES and the SPOT series, GEO-CAPE, and adapted as Constraint-based Interval Planning in the EUROPA planner for Deep Space 1. Constraint programming is not restricted to integer variables and linear equations/inequalities. Variables can be intervals or anything in the finite domain and constraints can be arithmetic or symbolic.

EOS can also be framed as an orienteering problem because it is a selective traveling salesman problem (TSP) where agents are required to visit as many checkpoints as possible within a time frame, each associated with a weight. The target captures can be assigned weights and orbital or subsystem constraints set up to represent travel times between captures and the objective is to maximize the weighted sum. The prize-collecting TSP not only minimizes travel time but also penalizes for unvisited cities. However, the interplay between orbital access to required captures by fast-moving LEO satellites and ACS-dependent slewing times causes the time for the traveling salesman to go from one capture to another to be highly dependent on the absolute time either capture is accessed. Variable time further adds to TSP solution complexity.

While dynamic scheduling across the full state space is known to generate an astronomical number of paths, unsolvable in polynomial time, branch-and-bound-like approximations to the dynamic programming (DP) approach have demonstrated a practically suboptimal resolution of the NP-hard non-restricted problem. DP has also been applied to the dynamic scheduling problem after it is decomposed into several simple, static problems defined by a rolling horizon, which is automatically appended with waiting tasks as current tasks are completed.

4.3.4 Asset Profiling

To be able to optimize assets, one must know the capabilities of these assets. While a good first guess is to use an analytical approach based on theoretical performance of assets, the asset performance changes over time (e.g., degradation), there can be variability in the actual performance between satellites, and different satellites might have different constraints (e.g., performance differs between different orbital planes). Because of these issues, it’s possible to integrate automated asset profiling into the optimization process. Based on real satellite telemetry, expected figures of merit are determined that can then be fed into an optimizer. Using machine learning techniques, it’s also possible to anticipate asset performance over time. It’s also possible to alert on sudden changes in performance characteristics (e.g., a drop in

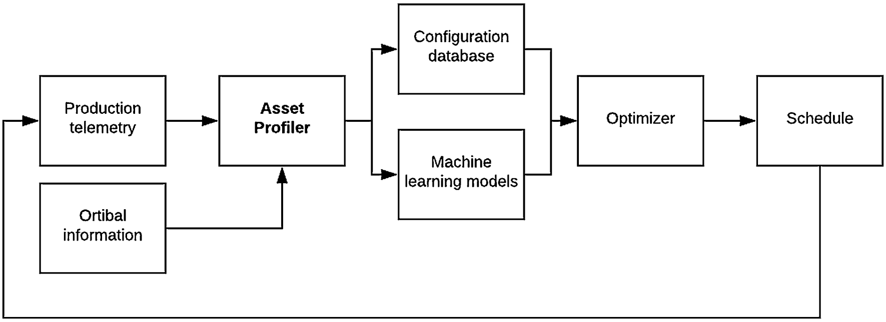

Fig. 8 Example of asset profiling process

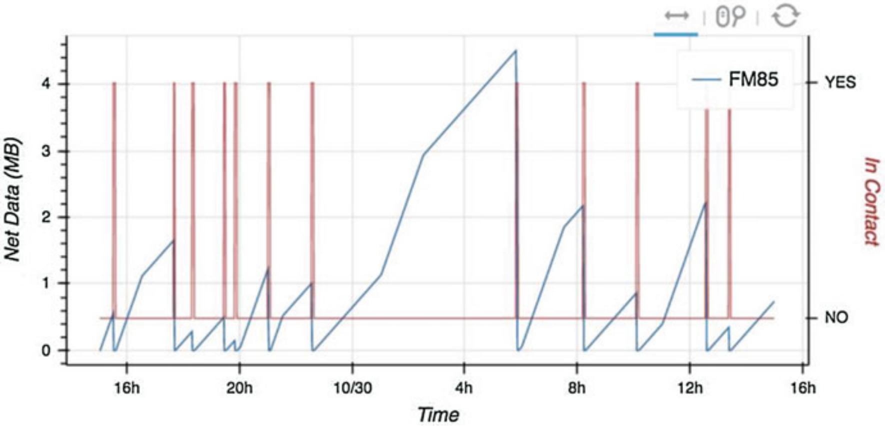

Fig. 9 Example of asset profiling model

downlink volume or collected observations). Figure 8 shows an example of asset profiling integration.

An example of a plot that could be obtained by an asset profiler is shown in Fig. 9. This example shows a model of the payload data generation rates on-board a satellite. As time goes by, the data volume on board increases until the satellite is in contact with a ground station and the data buckets are emptied. These models can be used to determine which satellite is most in need of a ground station contact, to optimize for data latency.

4.4 Operations Interfaces

While in a large-scale operations system, satellite operators cannot directly interface with each satellite all of the time, certain interfaces are required to ensure they can input priorities into the system, react to issues, and monitor health.

4.4.1 Priority and Request Management

Typically, any network control system will have a method of interfacing with the inputs of the optimization process. It is the task of operators to translate business priorities into actionable goal functions for the constellation. This may take the form of defining constellating wide figures of merit (e.g., system data throughput, or data collected under a certain latency target). When ad hoc requests come in, operators normally have override mechanism to command the satellites as needed outside the process.

4.4.2 Health Monitoring and Incident Management

Given the level of automation present, the main job of satellite operators is not to directly command or task assets but rather to monitor the constellation for any anomalies that might occur and manage those appropriately. To be able to do this effectively, an incident management system is required that can link back to operational data, on-ground test results, and any other information that can help resolve the issues at hand. Operators can then feed this information back to engineering development teams as new satellite versions are being developed.

5 Network Control with Intersatellite Links

If intersatellite links are present on a constellation, the concept of operations is changed quite drastically. It should be noted that the presence of intersatellite links doesn't necessarily imply a real-time connection between satellites and the ground. One particularly interesting concept is the delay- or disruption-tolerant network. This type of system has been designed for networks lacking continuous connectivity (Nag et al. 2019). This approach significantly decreases the latency associated with data getting from source to destination while tolerating intermittent connectivity.

Similarly, the advent of software-defined networks (concept shown in Fig. 10) has provided an abstraction toolset that can simplify the design of networked constellations. Some of the benefits include isolating multiple virtual networks, isolating various data flows (e.g., TT&C vs. data), more efficient sharing of spectrum, and enabling a more flexible network control structure. Additionally temporospatial SDNs enable additional benefits such as advanced packet routing and usage of orbit and attitude knowledge in data routing (Barrit and Eddy 2015).

Various proposed data routing algorithms are also available in literature for intersatellite-link constellations, e.g., Fig. 11 (Bunkheila et al. 2016).

6 Machine Learning and AI Applications

A few uses of machine learning and AI applications in network control systems have already been mentioned above, such as telemetry trending or asset profiling, but these are far from the only applications, and as larger constellations are deployed,

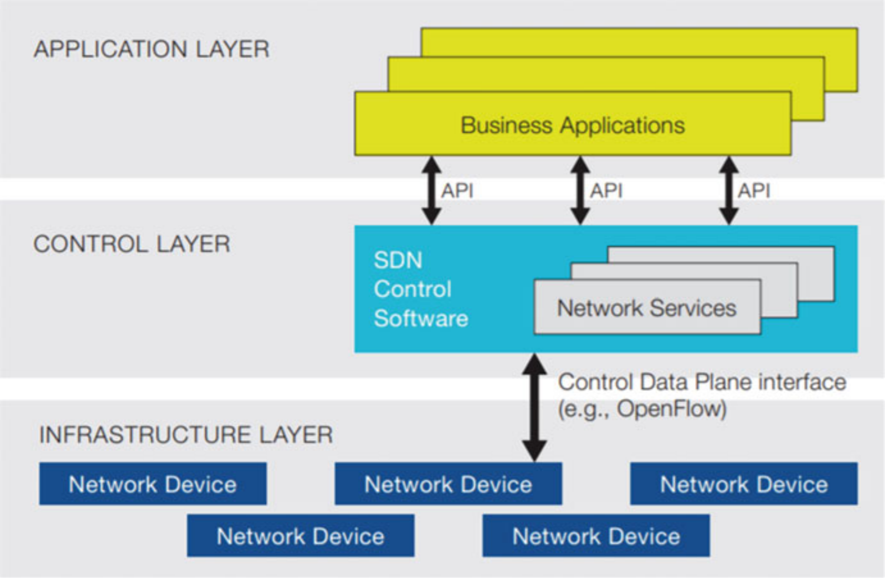

Fig. 10 Software-defined networking concept (Open Networking Foundation 2012)

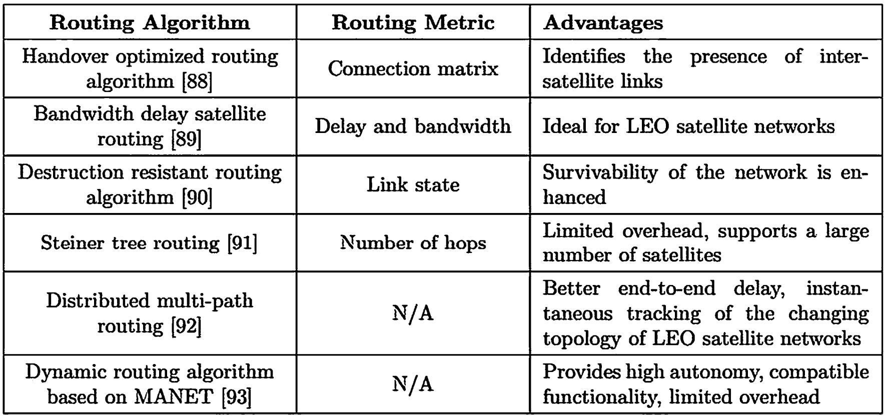
more and more useful applications appear. This is particularly true in the area of remote sensing and Earth observation.

Machine learning and AI applications are driving innovations in on-board data processing or simply pre-processing. Mechanically, this explosive growth in launches of private and public satellites has induced an exceedingly rapid growth for space-generated data. ESA observation satellites reached requirements of close to 150 terabytes per day in 2018. This volume and definition of data has contributed to the across-the-board rise in users for space-generated data. The volume and reliability of this data have tremendously improved. Further the speed of delivery has been reduced to almost real-time capabilities for certain data categories. This process has created considerable issues in the management of the data flows, with delays, defaults, and crucial data reaching the user a long time after it ceased to be operationally useful.

However, the latest technological developments in chip-making have made possible the pre-processing of data directly at the satellite level. Thus data analytics in space has progressively reduced the amount of data to be downloaded back to ground stations.

This factor process of on-board processing of data improves constellation efficiency greatly. It also reduces the demands on staff, equipment, and other the infrastructure on the ground and also reduced the power speeds required for the satellite transmissions. Moreover, it allows the raising of the speed at which critical information is transmitted to users by allowing the satellite to prioritize independently which data will be downloaded first, thus decreasing latency for truly relevant



Routing Algorithm	Routing Metric	Advantages
Handover optimized routing algorithm [88]	Connection matrix	Identifies the presence of inter-satellite links
Bandwidth delay satellite routing [89]	Delay and bandwidth	Ideal for LEO satellite networks
Destruction resistant routing algorithm [90]	Link state	Survivability of the network is enhanced
Steiner tree routing [91]	Number of hops	Limited overhead, supports a large number of satellites
Distributed multi-path routing [92]	N/A	Better end-to-end delay, instantaneous tracking of the changing topology of LEO satellite networks
Dynamic routing algorithm based on MANET [93]	N/A	Provides high autonomy, compatible functionality, limited overhead

Fig. 11 Available routing algorithms for intersatellite links (Radhakrishnan et al. 2016)

information, as well as allowing the satellite to autonomously direct sensors and make time-critical decisions.

In parallel, many new machine vision chips have stimulated interest by allowing smaller platforms to accomplish many more analytics. This increased capability includes the ability to run complex pattern determination and identification programs. There is an increasing consensus across the space ecosystem that this development is potentially a game changer for many current space-based products. Many feel it is likely to create profoundly disruptive applications that will largely exceed the capabilities of current space-based platforms in generating large sets of “smart,” directly actionable data.

For example, the ESA-supported HyperScout-2 mission carried a Myriad 2 neural networking chip (Esposito et al. 2019). Spire’s LEMUR2 satellite is carrying a Nvidia Jetson AI computing device in an ESA-supported demonstration mission. The range of potential applications is wide and includes cloud detection and removal from imagery, RF fingerprinting, RF IQ analysis and de-interference, pattern detection, and many others.

7 Conclusion

Network control systems are often-neglected systems but are becoming more and more important as operators move from manual operation of a few satellites to operating large constellations where optical asset allocation is very non-transparent.

As complexity increases, more tools are required to offload operations from a team of operators to a true network control system. Part of the complexity of finding the optimal asset utilization for a constellation is the heterogeneity of a lot of smallsat networks. Modern network control systems leverage the appropriate tools to distribute the right levels of automation and autonomy between space and ground assets.

For constellations with intersatellite links, existing tools such as disruption-tolerant network (DTN) and software-defined networking (SDN) can be leveraged to enable packet routing, as compared to algorithm development from scratch.

Lastly, the application of machine learning and the use of newly developed AI-oriented chipsets provide a large opportunity to increase the on-board autonomy of spacecraft.

RF and Optical Communications for Small Satellites

W. G. Cowley

Contents

Abstract

All satellites require communication links. This chapter compares the use of radio frequency (RF) with optical links for small satellites. Even in the case of small satellites, free space optical (FSO) links now offer very useful options. FSO communications have some unique advantages and disadvantages compared to RF satcom. The latter will always have a role, but for throughput, security, and licence-free operation, FSO communications are increasingly worth considering. This chapter provides an overview of these two options, making comparisons where possible. The last section reviews some recent developments in both areas.

1 Introduction

A major issue with small satellite RF communications is the difficulty of obtaining licenced spectrum. Given that the RF spectrum is a finite resource with increasing demands from both terrestrial and space applications, this is a critical constraint for many projects. In some cases, such as cellular communications and high-capacity communication satellites, the recent use of spot beams that allow frequency reuse has provided some relief to spectrum availability. This is not usually an option for small satellite satcom.

FSO communications offer advantages of orders-of-magnitude higher data rates, increased security, and licence-free operation. However the very low-divergence optical beams require high pointing accuracy, and in any earth-space scenario, weather effects (such as cloud obstruction) must be taken into account. As shown below, even in clear skies, the fading effects of Earth's atmosphere can cause significant loss. Fading can be mitigated to a larger extent than obstruction, which requires spatial diversity for robust communications. With respect to FSO pointing, this requirement is often the most demanding aspect of the payload and may also impose significant constraints on the platform's attitude control and dynamic response.

This chapter is set out as follows. The next section starts with an overview of first RF and then FSO communications payloads, describing the chief characteristics of each, plus how they have evolved in the last couple of decades. Selected topics, including antennas, performance metrics, and atmospheric impairments, are explored in section "Key Issues". Finally section "Small Satellite Examples" describes some case studies of both RF and FSO payloads with the aim of illustrating topics covered earlier in the chapter. Other comparisons of RF and FSO satcom may be found in (Hemmati et al. 1996; NASA n.d.; Kaushal and Kaddoum 2017).

2 Communications Payload Overview

Figure 1 shows a block diagram for either RF or FSO communications payloads. Despite their differences, they share most functions. The rest of this section describes these building blocks for each type of comms payload and outlines various realization options. In addition the likely boundaries between analog and digital representation of the signals are summarized.

2.1 RF Payloads

RF communication techniques are fairly mature but still evolving in small satellites. For very tight mass and power constraints (e.g., CubeSats) with low data rates, the use of simple modulation schemes such as frequency-shift keying (FSK) operating in the VHF or UHF bands has been traditional. Power and mass requirements are very modest for LEO applications requiring only kbit data rates. The functions shown in blue in Figure 1, such as modulation, demodulation, and amplification, were originally implemented with analog or low-complexity digital electronics and are moving progressively to become software-based or use application-specific integrated circuits (ASICs). These small satellites use simple antennas such as quarter-wave monopoles, either singly or phased to provide circular polarization (CP) (see section "Antennas and Pointing").

Figure 1 also applies to the ground components of a small satellite communication system. Of course it is much easier to achieve antenna gain and higher transmit powers on the ground, so many (RF and FSO) satellite links take advantage of this and can be designed with simpler space segment requirements. For all satcom, balancing the link budget, usually in both directions, is an art which also requires system-wide trade-offs. Several satcom link budgets described in this chapter may be explored with a software app available at (lowsnr.org n.d.). For the low-frequency CubeSats described above, the corresponding ground station (GS) equipment usually includes a tracking Yagi antenna system, ideally with a low-noise amplifier mounted at the antenna to achieve the best signal to noise (SNR) ratio. The indoor equipment of this GS may consist of a commercial UHF transceiver connected to a PC which carries out the low-bandwidth modulation and demodulation functions in software.

New approaches for small satellite RF communications payloads are likely to provide more functions implemented in software (or firmware) rather than dedicated

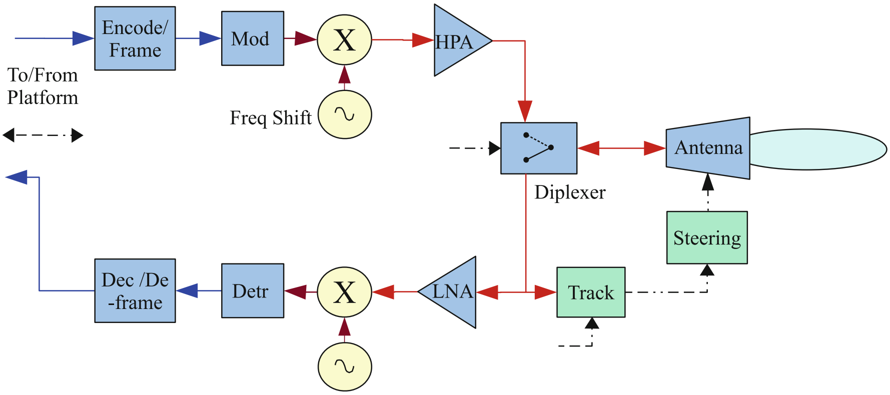

Fig. 1 Generic RF and FSO communications payload assuming a common antenna. RF payloads may not require green functions, and FSO payloads may not require yellow functions

electronic hardware, better use of allocated RF bandwidth, and the migration to higher frequency bands. Many of the operations shown in Figure 1 now use a "discrete time" (or sampled) representation of the signal, with sufficient sampling rate to avoid aliasing. Thus digital signal processing (DSP) functions such as filtering, frequency shifting (shown in yellow in the figure), decimation, interpolation, modulation, demodulation, encoding, and decoding are used where possible, giving better performance, more flexibility, and greater functionality. This approach is called software-defined radio (SDR). Some processing of the signal, such as amplification and filtering of the signal at the carrier frequency, must still be handled in "continuous time" with analog electronics. The recent advent of specialized application-specific integrated circuits (ASICs) which include hybrid analog and digital stages allowing signal digitization and synthesis functions (plus frequency shifting to intermediate frequencies) (e.g., Analog Devices n.d.) is very attractive in terms of power efficiency, flexibility, and performance.

CubeSats are no longer limited to low frequencies; small RF payloads are commercially available up to Ka-Band, e.g., (SWIFT-KTX n.d.). Advances in microelectronics now allow much smaller and more power-efficient RF electronics operating at microwave frequencies. Whereas it used to be challenging to manipulate signals above ≈ 1 GHz with low power and mass constraints, the rapid growth of consumer electronics has made this much easier. Similarly, modulation and coding options for small satellite RF links have grown significantly over the last decade, allowing more efficient use of allocated bandwidth. Powerful forward error correction (FEC, also called channel coding) algorithms can provide up to ten times improvement (i.e., 10 dB) in power consumption or data rate, so this option should always be considered on new designs. Coding and modulation options are discussed further in section "Performance Limits, Modulation, and Coding".

2.2 FSO Payloads

FSO payloads use lasers for inter-satellite links (ISLs) or to provide communications between satellites and ground. Similarly to the RF case, advances in optoelectronics and the large development of terrestrial fiber-based communications have greatly improved the prospects of FSO for small satellites. Most links transmit in the infrared or optical bands, with wavelengths around 1550 nm (as used in most optical fiber) becoming increasingly common. This band is called "eye-safe" as lasers cause less damage to the retina, e.g., (Kaushal and Kaddoum 2017). Other common wavelengths include 1064 and 850 nm. For these payloads the "antenna" is some form of telescope. While the typical transmit power of small satellite RF or FSO payloads is similar (e.g., 0.1 to 10 W), the large difference in data rate arises from the high antenna gain in the FSO case due to the many orders of magnitude change in wavelength. Indeed, at least in the transmit case, it's frequently not possible to use the whole antenna gain from a modest optical aperture on a small satellite, and laser divergence must be increased to make the link acquisition feasible.

Digital functions such as framing and FEC are similar for FSO and RF payloads and are shown by blue signals in Figure 1. The payloads differ more in the red paths, which use either coaxial cable or waveguide for RF and often fiber for optical signals. Given a single antenna, the simplest diplexer in RF systems in a solid-state or mechanical switch, allowing bi-directional communications by a time division multiplex (TDM) approach. In the FSO case, the use of two wavelengths is very common, with the diplexing carried out by dichroic optical components such as mirrors and filters.

Key technology options for FSO payloads include the selection of wavelength (s), optoelectronic device families, modulation method, and antenna pointing options. The simplest FSO LEO downlinks rely on the platform attitude control system (ACS) to steer the laser downlink and simply turn the laser signal on or off to transmit bits of information, i.e., on-off keying (OOK). The detection scheme for these systems is likely to be noncoherent, often called "direct detection" where the received signal is delivered to some type of photodiode. Section "Performance Limits, Modulation, and Coding" explores FSO detection options a little further.

Unfortunately, the pointing accuracy of the small satellite attitude control system (ACS) is not usually sufficient to make efficient use of the laser downlink. For example, suppose the ACS allows the laser to be pointed to an optical GS (OGS) with a standard deviation error of 1/3 of a degree and the laser beam divergence is arranged to be 1 degree, or $\approx$17 milliradians (mrad), giving a 3σ confidence that the laser signal reaches the OGS. In this case the number of photons per bit at 100 Mbit/s, from LEO with 1 W laser power, into a 20 cm OGS aperture is only $\approx$1 (lowsnr.org n.d.).

For this reason, optical payloads normally control their own pointing in order to make use of lasers with smaller divergences (say from 1 mrad to 10 μrad). This pointing control can take many forms. It may use the satellite platform for coarse pointing and implement, say via controlling steering mirrors, a fine pointing system that can direct the laser with suitable precision. If the satellite's knowledge of its absolute pointing is ill-defined relative to the desired laser divergence, it is not sufficient to provide a fine steering method that relies on the performance of the host ACS. Instead it is common to make use of some reference signal, such as an uplink beacon. The optical comms payload may also need to provide its own coarse pointing facility. Bear in mind that in the case of the LEO downlink to OGS, say from an Earth observation satellite, the downlink pointing to a specific OGS will be constantly changing during a pass. In addition the satellite may be subject to transient attitude disturbances due to its own ACS actuators and thrusters. Pointing and tracking are discussed further in sections "Antennas and Pointing" and "PAT Schemes for Small Satellites".

3 Key Issues

This section explores some specific issues related to RF and FSO communications payloads for small satellites. Where possible the similarities and differences between the optical and radio approaches are described.

3.1 Performance Limits, Modulation, and Coding

In the RF case, Shannon determined a number of fundamental performance limits for digital communications. For the last 60 years, there has been steady progress in approaching these limits by the use of FEC. In a digital communication system, the relevant performance metric is called energy per information bit to noise spectral density *(E_b/N_0)*. Most satellite channels have a high free space loss (FSL) due to large link distances and are limited in performance by the thermal noise added at the receiver input, so they can benefit substantially by using FEC methods. Early approaches added parity bits to the information bit stream and thereby increased the overall bandwidth requirements. In the 1970s it was realized that FEC could be applied at the level of modulation symbols and the benefits of error correction (called coding gain) could be obtained without necessarily increasing the RF bandwidth. Given the importance of conserving bandwidth, it is useful to assess the performance of an RF link in terms of the required E_b/N_0 to achieve a required spectral efficiency (i.e., information bits per second per Hz of RF bandwidth).

Figure 2 shows a summary of these fundamental limits, plus some practical examples of actual performance, with FEC (selected DVB-S2 modes, shown with "X" symbols) and without FEC ("+" symbols). The solid curve is the capacity limit derived by Shannon, and the dashed plots illustrate modulation-constrained bounds, up to 16-point constellations. The figure shows the fundamental trade-off between spectral efficiency and E_b/N_0. Good codes are approaching the capacity limits and may provide about 7 to 10 dB improvement compared to uncoded transmission. For comparison, if the standard satcom convolutional code performance is plotted on this figure, it's about halfway between the coded and uncoded examples shown. These results assume coherent detection with ideal (or almost ideal) pulse shaping (achieved through filtering) to minimize bandwidth. Modern radio systems often

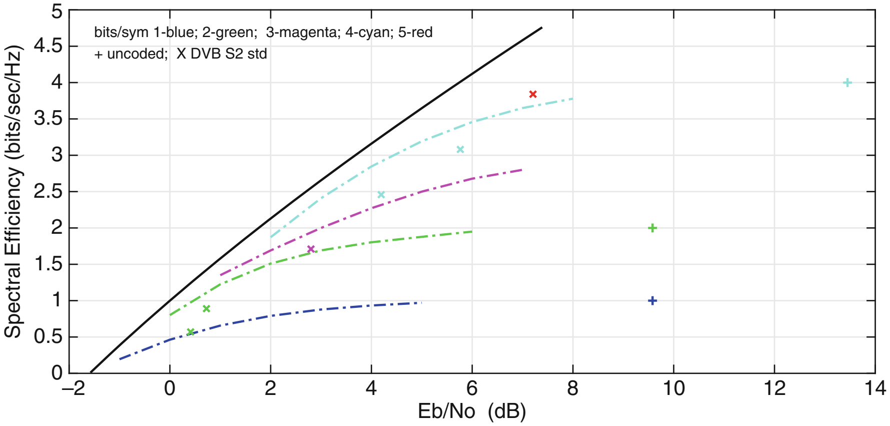

Fig. 2 Spectral efficiency versus E_b/N_0: bounds (solid and dashed lines) and actual performance (symbols)

vary in both the amplitude and phase of the RF carrier wave to carry multiple information bits per transmitted symbol, thereby achieving a higher spectral efficiency. This is called quadrature amplitude modulation (QAM).

Most of the coding gain in Fig. 2 comes from an iterative approach called low-density parity-check (LDPC) codes, or from closely related "turbo" codes. Perhaps the first such code on a small satellite was the turbo code used on "FedSat" in 2002 (eoPortal web pages 2002). Iterative coding methods may be extended to handle some other impairments, e.g., section "RF Payload Using SDR". In space, computational requirements must be considered, but efficient designs are becoming available (e.g., Turbo and LDPC Codec Designs n.d.).

Compared to the RF case, there's a very wide range of modulation and detection options, plus device technologies which are employed in FSO communications. This chapter provides a brief summary, and the reader is referred to (Kaushal and Kaddoum 2017; Aviv 2006; Hemmati and Caplan 2013; Hemmati 2009) for further information. Both noncoherent and coherent approaches are used, although the former are considerably simpler to realize. For example, the incoming light may be simply focused onto a reverse biased diode, whose junction contains an undoped (or intrinsic) layer between the p-type and n-type semiconductor regions. When a photon of sufficient energy falls on the junction, an electron-hole pair is produced which leads to a current pulse. These PIN diode photodetectors have many advantages but suffer from the need for electrical amplification of the tiny output currents, which invariably leads to the addition of significant electrical noise. A related approach relies on an avalanche effect when one or more photons arrive. Avalanche photodiodes (APDs) can avoid most of the electrical noise addition but with lower bandwidth as the gain multiplication increases. Better results can be obtained with these noncoherent (or direct detection methods) by amplification prior to detection, after coupling the received signal into a suitable optical fiber. The amplification can be achieved via semiconductor optical amplifiers or by using doped fiber amplifiers. For example, erbium-doped fiber amplifiers (EDFAs) are widely used in many areas for optical amplification in the region of 1550 nm. By mixing the input signal with a "pumping" laser at a shorter wavelength, it is possible to amplify the input signal by stimulated emission of photons from excited erbium ions in the fiber. This type of device may also be used in FSO transmitters to amplify the output of a small semiconductor laser to the power levels required by the optical link budget.

Coherent optical detection involves the "mixing" of a reference laser with the incoming optical signal. As in the RF case, the mixing process results in the modulated signal being shifted in the frequency domain, either to 0 Hz (homodyne) or to an intermediate frequency (heterodyne), say within radio wavelengths. The coherent approach opens the door to standard RF modulations, such as PSK, and can produce excellent results. Needless to say, the provision of stable optical references, and detection methods that preserve phase information, adds considerable complexity. A somewhat simplified approach is to use differential PSK (DPSK) detection, where a delayed version of the input signal is used as the "reference" signal. For example, this scheme is used in the LCRD (Edwards 2019).

In the optical case, in addition to the impact of additive noise, it may be necessary to take into account statistical fluctuations if a small number of photons are received per bit. This effect is called shot noise. For a given bit rate, the shot noise issue can be mitigated by using pulse position modulation (PPM) with more bits (and more photons) per optical symbol. Section “PAT Schemes for Small Satellites” mentions an example of a “photon-counting” OGS using M-ary PPM, where M represents a large number of possible pulse positions.

Accounting for various noise sources in FSO receivers can be difficult, and approaches used in link budgets vary. A common approach is to use the received photons per bit (PPB) as the key performance metric for satellite communications. A summary of measured PPB results ranging from about one to hundreds may be found in (Caplan 2007; Rohwer et al. 2010). Unamplified direct detection methods, such as PIN diodes, will require thousands of PPB. Direct detection and PPM, either with optical pre-amplification or photon counting, can give excellent results.

3.2 Antennas and Pointing

For RF links, two antenna issues must be addressed. The first is stowage and deployment of the physical antenna, and the second is how to point it in the required direction. As noted above, at lower frequency bands, it is often convenient for LEO satellites to use wire antennas that are released from a stowed configuration via a simple “burn wire” approach. These low-gain antennas largely avoid the need for antenna pointing. Rotation of the electric field vector, caused either by Faraday rotation in the lower frequency bands or antenna misalignment, can add additional loss with linear polarization but can be overcome by CP. Microstrip antennas also offer options for small satellites. Single patch radiators may provide 5 to 7 dBi gain.

Antennas become more demanding as the required gain increases. In general, antenna pointing options include relying on platform attitude control, mechanical steering of antenna structures, and phased array approaches. A classic example of steered RF antennas in LEO was provided by the first-generation Iridium constellation, (Rohwer et al. 2010) which used mechanically steered Ka-Band antennas for cross-link and feeders, plus phased array L-Band antennas, giving spot beams to user terminals. At the time (two decades ago), the multi-beam phased array antenna was a significant advance.

Particularly in CubeSats, the physical volume of the stowed high-gain antenna is an important issue. Whereas the traditional approach in the microwave bands has been parabolic antennas which are unfurled during commissioning, recent innovations include deployable meshes of patch antennas and the “reflectarray” recently used on the Mars CubeSats (see section “High-Gain CubeSat Antennas”).

Antenna deployment is not a problem for optical payloads, but as noted in section “Antennas and Pointing”, pointing is a critical issue. As mentioned above, it’s common to separate the solution into fine pointing and coarse pointing mechanisms. An uplink beacon from the OGS is the most frequent approach to assist fine pointing the satellite downlink. This requires a control system whose input often originates from a “four-quadrant” photodetector that measures the angular offsets in the received uplink beacon. The error signal is used to control actuators to align the transmitted optical signal with the received beacon. Some FSO links operating over paths with significant relative motion have the added complexity that the flight time of the signal is large enough that its transmit laser must be directed to a future receiver position. This is called “point-ahead” tracking.

The design of sensors, actuators, and control loops that can provide the required pointing accuracy, both for initial acquisition and then tracking, is a demanding aspect of the optical communications payload design and requires multidisciplinary expertise. A few aspects of this area are described below, and section “PAT Schemes for Small Satellites” contains examples showing recent progress in this area. As mentioned in section “Communications Payload Overview”, FSO satellite links are usually “full duplex,” i.e., operating in both directions at once, although the data rates may be highly asymmetric, or even zero if a received beacon is only used for transmit pointing. This requires a very high degree of optical isolation (e.g., 140 dB) so that the transmit signal does not “blind” the receiver. Beacon signals are typically modulated in some fashion, possibly with low-rate data, so that they can be separated from background optical signals. The acquisition phase typically needs a larger field of view. After splitting the common optical path into receive and transmit components, it is common to use most of the incoming signal for data reception but extract a portion for acquisition and/or tracking. Imaging arrays can be employed instead of four-quadrant detectors for this function, with trade-offs between extra complexity and better tracking or faster acquisition to be considered. Acquisition requirements will vary widely according to the application scenario. For rapid lock, it’s clearly very desirable that the received signal will be within the acquisition field of view (FOV); otherwise a search strategy must be employed. Acquisition must usually be achieved in two directions before data transmission commences. Searching for the signal at both ends of the link should be avoided! Finally, the bandwidth of pointing control loops depends on the dynamics of the host satellite and the degree of isolation between the platform and the optical payload. Careful simulation of the electromechanical system, using a model of the platform vibrational behavior, is normally undertaken to ensure transmit signal pointing jitter will be (say) within 10% of the beam divergence.

3.3 Fading and Obstruction

Satellite links between space and Earth must consider the effect of various impairments. In the lower frequency bands, the attenuation from the atmosphere is negligible, but mobile devices with low-gain antennas may suffer from fading due to ground reflections and/or signal attenuation caused by path obstruction. For point-to-point RF links, there’s little atmospheric loss below Ku Band. However Ka-Band systems can suffer tens of 10 dBs attenuation due to rain and clouds. Fade statistics depend on frequency, elevation angle, and geographic region. For example, at 20 GHz, with 40 degrees link elevation, attenuation does not exceed 10 dB for more than 1% of the time, or 30 dB for 0.1% of the time in the worst of eight ITU-R rain regions, e.g., (Mitchell 1997). While attenuation due to rain is the main impairment, other weather effects include attenuation by water-bearing clouds, small losses in antenna gain due to wet surfaces, and depolarization effects which degrade the performance of systems using orthogonal polarizations. Above Ka-Band the atmospheric effects increase greatly due to absorption by water vapor or oxygen molecules. For example, the latter attenuates strongly near 60 GHz.

Mitigation approaches for RF fading include increased fade margin, adaptive power control, and adaptive modulation. Satcom systems subject to significant RF attenuation will need to consider system issues such as latency requirements, onboard storage, the number of ground stations, and possible use of ISLs to achieve suitable performance.

The atmosphere is more of a problem for optical links. Clouds and fog may obstruct the signal completely, so the statistics of cloud cover are important when considering OGS locations. For example, using multiple OGSs across Europe can reduce the outage probability to about 10^{-3}, but an intercontinental network can achieve any required availability (Giggenbach et al. 2015). These will require good terrestrial optical fiber connections. Interestingly, rain may only cause modest attenuation in optical links, compared to the higher RF bands. For this reason hybrid RF and FSO systems have been proposed, mainly for terrestrial scenarios, where an adaptive modulation and coding strategy can be used to adjust the relative use of the RF and FSO links depending on weather conditions, to maximize throughput.

Even in clear-sky conditions, FSO links suffer from attenuation and fading issues, e.g., (Kaushal and Kaddoum 2017; Hemmati and Caplan 2013). The wavelength used will lie within an atmospheric “transmission window” where molecular absorption (by water vapor, carbon dioxide, or ozone) will be only a fraction of a dB per km. Rayleigh scattering becomes more significant at shorter wavelengths below 1000 nm. These effects are heavily dependent on the amount of atmosphere traversed, so the OGS height and elevation angle of the optical link can make large differences. While these effects are usually categorized simply as attenuation, a more serious effect is due to slight changes in temperature and pressure of air cells within the optical path. Differences in the refractive indices of these cells cause scintillation effects which are observed as rapid intensity variations over millisecond time scales. These variations result from cancellation or reinforcement of the laser signal as it propagates through multiple cells. This fading can cause serious impairment to FSO links. Figure 3 shows an example of variations that are well modelled by a lognormal distribution.

In addition, for satellite communications these turbulence effects vary depending on whether uplinks or downlinks are considered. In the former case, beam spreading or beam wandering effects due to turbulence occur at the start of the transmission path, so the impact is much worse than in a downlink along the same satellite-ground path. Unsurprisingly, mountain locations are popular for large OGSs as the atmospheric effects are significantly reduced.

Mitigation strategies for fading include spatial diversity (e.g., using a large enough telescope in the OGS to “average out” some of the short-term variations),

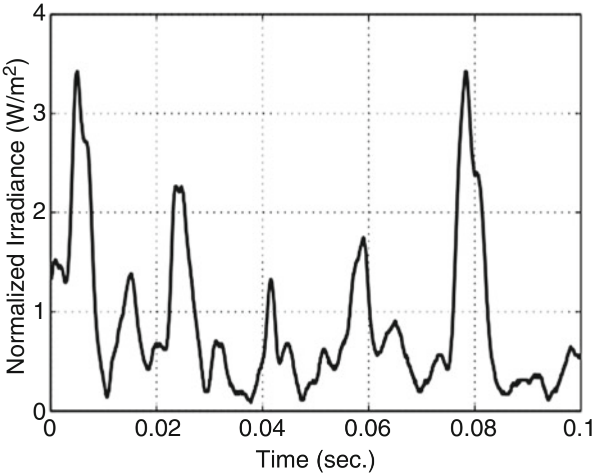

Fig. 3 Example of FSO fading over a 1.5 km 1550 nm horizontal path, using a 13 mm aperture, from (Letzepis et al. 2008)

multiple-input and multiple-output (MIMO) techniques, interleaving combined with FEC and adaptive optics which aims to correct the wave front distortions.

4 Small Satellite Examples

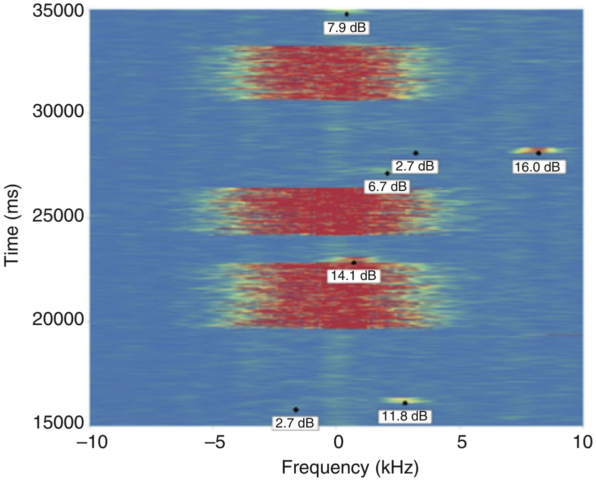
This section considers some specific examples which illustrate recent developments and current status of topics discussed above. See also (NASA n.d.; Gao et al. 2018).

4.1 RF Payload Using SDR

This case illustrates a scenario of uplinking short messages from very large numbers of low-cost ground terminals to a LEO CubeSat constellation. This is ideally handled by VHF or UHF communications where both the terminals and the satellites use low-gain antennas with few pointing requirements and terminals must be very low power.

The application scenario is not new, but the approach used in this example is novel and illustrates the benefits of recent signal processing and coding advances. Based in Adelaide, Myriota is a startup originating from the University of South Australia. The author was involved in early stages of this research several years ago. Given the limited communications capacity of existing "Internet of Things" (IOT) providers, this project set out to maximize the spectral efficiency for the IOT scenario and simplify terminal access requirements. It uses an extension of iterative channel coding approaches to handle short uplink messages that are completely unsynchronized in time and frequency. The resulting system caters for many more

Fig. 4 Reception of weak ground terminal signals from LEO CubeSat



terminals than traditional methods and is much more robust in terms of interference and noise. Figure 4 shows an example spectrogram with seven successfully decoded messages, plus large interferers. The low-SNR messages are ≈1 kHz wide and have a duration of 250 ms. The company has shown it is often possible to decode messages which suffer from significant interference overlap. [See (Haley et al. 2018) for details.]

At present Myriota delivers an uplink-only service to customers by capturing signals in LEO and performing signal processing on the ground. They are migrating some of this processing to a custom CubeSat constellation. Myriota is also able to downlink data to terminals. This is currently used for network management and will be offered for customer data in the future.

4.2 High-Gain CubeSat Antennas

Parabolic antennas have been deployed from large communication and remote sensing satellites for many decades, but their use in CubeSats has only occurred in the last decade. The RainCube (Chahat et al. 2016) project has deployed a Ka-Band mesh reflector from a 6 U CubeSat. This 0.5-m-diameter dish is part of a 35.75 GHz nadir-pointing radar designed to measure precipitation from LEO. This project required a suitably high-gain antenna (≈42 dBi) to achieve the small beamwidth (≈1.2 degrees) to give adequate radar resolution. Achieving the required antenna surface accuracy at Ka-Band from a 1.5 U stowed volume is impressive. A Cassegrain design was used, with a telescoping circular waveguide to the feedhorn. RainCube has been in use since mid-2018. The deployment can be seen at (NASA/JPL n.d.).

Other approaches have shown it is not essential to use a parabolic reflector. An S-Band antenna design using an array of patch antennas is illustrated in (Warren et al. 2015). The patches lie on flexible membranes which are flattened by a tensioning scheme during deployment. This design avoids the need for a feed assembly deployed away from a reflecting surface. It uses under 2 U of stowage space to give an antenna area of 1.53 m^2 and provided a gain of 30.5 dBi at 3.6 GHz during ground tests. The “reflectarray” approach has been successfully used in ISARA and Mars CubeSat (Hodges et al. 2017, 2018) missions. It uses flat panels which reflect the signal transmitted from a feed assembly. By varying the size of square patches on the flat panels to change their phase, this design can form a beam and steer it in a required direction. Furthermore the flat panels can be very conveniently stowed in unused space around the CubeSat before launch. Using this approach the Mars CubeSats, shown in (Hodges et al. 2017; Rohwer et al. 2010), successfully provided X band communications back to Earth during the descent of the Mars lander.

4.3 LEO FSO: OSIRIS

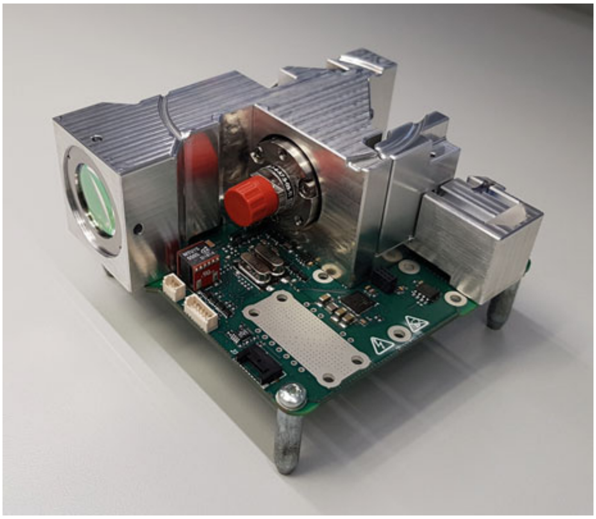
The Institute of Communications and Navigation at DLR has extensive experience in both terrestrial, aeronautical, and satellite FSO communications. They have conducted several FSO trials with international partners, including the author’s university. DLR has recently been developing their own optical payload, called OSIRIS, for small satellites. This section provides a short summary of this work which illustrates a steady evolution in FSO terminal capabilities.

Four versions of the OSIRIS terminal have been developed. The first was flown as a secondary payload on the University of Stuttgart “Flying Laptop” 110 kg satellite launched in 2017. The payload tested two laser sources (100 mW laser diode and 1 W EDFA) and supported data rates up to 200 Mbps. This LEO satellite provided an excellent pointing accuracy of better than 0.5 mrad to an observation target on the ground. The OSIRIS payload uses satellite pointing thereby saving significant complexity and only weighs 1.3 kg. The transmit beam divergence was nominally 1.2 mrad. References (Fuchs et al. 2018, 2019) contain more details of calibration and downlink experiments.

The second version of OSIRIS was launched as a secondary payload on the BiROS satellite. In this case the beam divergence was reduced, aiming for a bit rate of 1 Gbps. With a very small increase in mass, the design includes a sensor that measures the offset in reception of an uplink beacon, with the aim of sending this to the platform ACS to obtain the required pointing accuracy. While most of the payload functions have been demonstrated, at this time it has not been possible to achieve downlink data reception, as the optimization of the satellite ACS to achieve the required accuracy could not be continued due to the primary mission of BiROS.

Two more versions of OSIRIS are in the pipeline. Version 3 is aiming for 10 Gbps and is planning to fly on the ISS in 2020. It includes a coarse pointing assembly (CPA), plus FEC and automatic repeat request (ARQ) in the downlink. Version 4 is designed for CubeSats and was first shown at the IAC of 2018. The target mass is 300 gms, with a data rate of 100 Mbps and output power of 100 mW. It will use the CubeSat ACS for coarse pointing, to an accuracy of +/− 17 mrad and includes fine pointing using an uplink beacon. Figure 5 shows a prototype of this terminal.

Fig. 5 Prototype of the OSIRIS payload, version 4 s



4.4 PAT Schemes for Small Satellites

Section "Antennas and Pointing" introduced issues associated with achieving suitably accurate pointing of FSO satellite terminals. The following examples illustrate recent developments in pointing, acquisition and tracking.

In the Lunar Laser Communications Demonstration (LLCD), NASA and MIT have shown the feasibility of high-rate FSO links over lunar distances. In 2013 the LLCD demonstrated reliable communications at 622 Mbps in the downlink and 20 Mbps uplink on the Lunar Atmosphere and Dust Environment Explorer (LADEE) satellite. This ≈7 kg terminal may be seen in exploded form at (Weatherwax and Doyle 2014; Hemmati et al. 1996). The figure shows a 10 cm reflector telescope in the upper right-hand side. A two-axis gimbal allows coarse pointing over a large angular range. Between these two an inertial reference unit (IRU, shown in blue in the figure) is used to stabilize the telescope and other optical components from satellite vibrations. This approach was developed under a NASA Small Business Innovation Research scheme and has subsequently been used on several FSO projects. Highly sensitive angular rate sensors, based on magnetohydrodynamics, plus digital control systems and voice-coil actuators allow the MIRU to isolate the optics from satellite vibrations above several Hz. Variations at lower frequencies are handled by sensing the received power after nutation of the receive fiber using piezoelectric actuators. The overall scheme was designed to meet the demanding 4.2 urad RMS pointing error requirement. Further details, including a photon-counting OGS, can be found in (Weatherwax and Doyle 2014; Scozzafava et al. 2007; Boroson et al. 2009).

Recent projects from MIT and JPL illustrate further progress in pointing, acquisition, and tracking for small satellite optical payloads over shorter distances.

NASA's TeraByte InfraRed Delivery (TBIRD) demonstrator aims to deliver up to 200 Gbps from a LEO CubeSat, using COTS parts where possible (Chang et al. 2019). Their approach uses a quadrant detector of the uplink beacon signal for both spatial tracking and low-rate communications (e.g., to allow an ARQ system for the high-rate downlink). To minimize payload complexity, this single receive sensor provides pointing feedback to the satellite bus for fine attitude control. The uplink uses 2 PPM with pulse shaping to provide a discrete spectral component which helps the tracking algorithm avoid background perturbations.

TBIRD uses a transmit beam divergence of approximately 130 urads and requires a volume of under 2 U with a mass of slightly over 2 kg. Clearly the approach relies on recent improvements in the ACS of small satellites, especially in the area of star trackers and reaction wheels. After acquisition of the uplink beacon, the FSO payload provides feedback to the TBIRD ACS at 30 Hz. TBIRD is due for demonstration in 2020 and is only one part of NASA's ambitious optical communications program (Edwards 2019; Park et al. 2019). A related recent CubeSat project funded by NASA and developed by The Aerospace Corporation is called the Optical Communications and Sensor Demonstration (OCSD). This resulted in 1.5 U CubeSats that used platform pointing and relied on very good platform ACS, from accurate star trackers, to avoid the use of an uplink beacon. In this case a more powerful 4 W, 1064 nm laser was employed. Over the course of the project, the laser divergence was reduced as the platform ACS accuracy improved (Todd et al. 2019).

An MIT project also aims at low-cost FSO downloads from LEO. The Nano-Satellite Optical Downlink Experiment (NODE) project uses only 200 mW of optical power, to 30 cm "amateur" telescopes in the OGS. With a larger divergence of $\approx$1.3 mrad, they aim for 10 Mbps. The NODE payload is less than 1 kg in a 1.2 U volume (Clements et al. 2016; Cahoy 2018).

5 Summary

RF satcom is progressing well with the use of higher frequencies, better spectral/power efficiencies, low-volume deployable antennas, and further payload miniaturization. Particularly in the last decade, even greater progress has been achieved for FSO payloads, where significant reductions in power, mass, and volume have been achieved. In addition the standardization of FSO, transmission formats are making progress (e.g., Edwards et al. 2017). Scarcer RF spectrum, longer links, and higher throughput will increasingly favor FSO solutions.

Hosted Payload Packages as a Form of Small Satellite System

Joseph N. Pelton

Contents

Abstract

In recent years there has been an enormous amount of attention that has been given to small satellites. Much of the focus of that publicity has related to very large constellations of small satellites such those proposed by OneWeb, SpaceX, Boeing, Thales Alenia, Planet, Spire, and others. Many of these constellations involve the launch of hundreds or even thousands of satellites. The rapid buildup of these small satellite constellations has to some extent overshadowed another important concept that has been effectively used in recent years as an alternative to free-flying small satellite projects.

This important alternative is known as a "hosted payload." The concept is simply to place a smaller "payload" on board of a satellite platform. This allows a small and typically quite efficient payload to carry out its intended function not as

a free-flying small satellite but as an adjunct to a larger space platform. In this type of configuration, a hosted payload derives its power, stabilization and orientation, and tracking, telemetry, and command services from its larger host platform. In some cases there might be only one hosted payload on another satellite. In other cases there might even be a number of hosted payloads all flying on a single satellite platform, rather than as free flyers.

Such a hosted payload arrangement can provide a number of advantages that can be derived from such an arrangement. These advantages can include (a) improved launch arrangements and associated improvement in launch costs, reduced regulatory requirements related to frequency coordination, registration of satellite launching notification to the United Nations, etc.; (b) economies of scale and cost reductions associated with the ability to share the power system, thermal controls, TT&C system, and stabilization, pointing, and orientation system of the larger spacecraft platform; (c) reduced operational cost associated with maintaining a small satellite in order or in some cases maintaining a large network of satellites in orbit (Note: this advantage includes not having to be concerned about avoidance of conjunctions with other satellites since this function is carried out by the larger satellite operator); and (d) not having to be concerned with the end-of-life disposal of the hosted payload(s), since these functions will also be carried out by the spacecraft operator that manages the larger satellite or in some cases an entire satellite constellation.

This does not mean that there are only positive benefits derived from carrying out a mission or even providing an ongoing space service by means of a hosted payload approach. If there is a failure (i.e., partial or total) of the host satellite or even a system failure that applies throughout an entire network of the host platform satellites, this is clearly a problem for the hosted payload. This failure of the host satellite or the constellation of host satellites would clearly be a very serious nature. There can be more complex types of problems beyond a host satellite not achieving orbit or total failure. There could be problems such as partial loss of a capability. This might be a problem with the solar arrays that require a cut back or even total loss of power supply to the hosted payload. In the case of a hosted payload mission, it is prudent to anticipate potential problems and seek to spell out in a contractual document an equitable solutions to possible problems before they occur.

The following article seeks to present examples of the various types of ways that hosted payload systems have been used to carry out missions that might have otherwise been undertaken by small satellites. It explains the types of organizations that operate in this area, including the Hosted Payload Alliance, that promotes this approach to governmental and military organizations that have been a frequent adopter of this approach over the past decade. It provides information about the possibility of use of hosted payloads on an entire constellation such is now the case with the Aireon hosted payloads that are currently operational on all 66 of the satellites in the Iridium Next small satellite constellation.

1 Introduction

The idea of combining space missions and flying an experimental package on another larger satellite has been implemented in practical ways for many years. In the 1960s NASA combined unrelated experiments that flew on the Applications Test Satellite (ATS-1) Intelsat included a Maritime Communications Satellite (MCS) package in the Intelsat VA satellites that was designed to provide maritime services. This continued to provide services for mobile services in the L-band even after the creation of Inmarsat organization. Likewise the Marisat program that was built and deployed by the Communications Satellite Corporation to provide maritime communications services to the US Navy was designed to provide additional commercial maritime communications services in different frequencies. Thus for many decades, there have been combined missions on satellites to achieve economies in the design, launch, and operation of satellite systems through the use of hosted payloads. Many of the early instances involved governmental agencies or defense agencies.

The last 15 years has seen increasing interest in the efficiencies that hosted payloads can bring to governmental, military, commercial, and experimental space programs. The Hosted Payload Alliance (HPA) is a strong advocate for the use of this approach. The US Government Accountability Office undertook a formal review of Department of Defense hosted payload projects completed and planned and reported its findings as follows: “GAO and others have found that using commercial satellites to host government sensors or communications packages – called payloads – may be one way DOD can achieve on-orbit capability faster and more affordably. Using hosted payloads may also help facilitate a proliferation of payloads on orbit, making it more difficult for an adversary to defeat a capability. Since 2009, DOD has used three commercially hosted payloads, with three more missions planned or underway through 2022” (United States Accountability Office 2018).

Commercial organizations, such as Intelsat General, SES World Skies US Government Solutions, etc., provide particular assistance to use the hosted payload approach for military and governmental agencies. Perhaps most impressive of all has been the deployment of Aerion payloads on all of the Iridium Next satellites to provide a comprehensive global ability to provide Automatic Dependent Surveillance-Broadcast (ADS-B) aeronautical surveillance via these specially equipped systems (Space-Based ADS-B: Making Global Air Traffic Surveillance a Powerful Reality n.d.).

The early experience with hosted payload was most typically just one-off efforts. These were often efforts to provide technology verification of a new space technology or service. This hosted payload approach provided a cost-effective way to provide an in-orbit testing of how this new technology might work. It was found that one way to conduct an in-orbit experiment was to put a package on another larger satellite "host" platform. This was simpler than putting together a complete satellite platform, arranging for its launch, registering the launch with the United Nations, meeting due diligence requirements of the launching state, and perhaps carrying out RF interference coordination negotiations.

Often such add on packages, if they were small enough, could fit within the mass margin available for already contracted launch services. This often proved to be the case for commercial systems deploying a new telecommunications or remote sensing satellite to orbit. This advantage alone could provide a great cost savings. The Maritime Communications Subsystem (MCS) package on the Intelsat VA and the Marisat launches arranged by Comsat for services to the US Navy as well as to provide commercial maritime mobile satellite services may have been the first two times that a hosted payload was designed to provide an ongoing commercial service. This provided a very cost-effective type of approach. Thus designing a "package" that could ride on a host platform was clearly confirmed as viable way to provide commercial space applications even in the 1980s (Pelton et al. 2004).

Today, the 66 operational Aireon packages on Iridium Next, a low Earth orbit (LEO) constellation for mobile satellite communications, represent the largest such network deployed as a hosted payload constellation. The small satellites represented by Iridium Next, with an even smaller hosted payload on board, provide economies of scale to the Aerion system and its operation. This arrangement also provides incremental revenue to the Iridium LLC Enterprise (see Fig. 1).

Of course in some instances, the hosted payload (or payloads) can fly on quite large satellites deployed in orbits that include LEO, MEO, GEO, and even other types of orbits. Such hosted payloads might typically be in the range of 1–50 kg, but the host platform might be a smallsat or even run up to the largest of all satellites such as the Alphasat or Inmarsat XL that is well over 10,000 kg in mass.

2 Hosted Payloads for Technology Verification and Service Verification

The most common use of hosted payloads for many years has been for technology verification. At least for the years 2013–2018, technology verification represented about 20–25% of the reasons for all small satellite launches. Projections for the future suggest that there will be much greater growth in terms of applications and services if use of hosted payloads follows the pattern of overall small satellite usage (Overall Distribution of Small Satellite Launches by Usage n.d.).

In a number of instances, it was a combination of technology verification and in-orbit lifetime testing. In light of the high cost of satellite launches and the difficulty of in-orbit repair or retrofitting, the designers of satellite systems like to

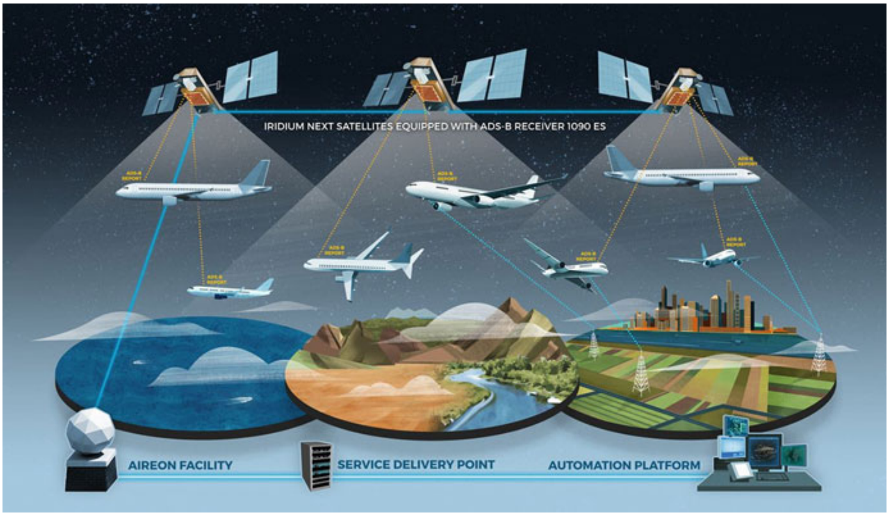

Fig. 1 The Aireon ASD-B hosted payload packages are now providing aeronautical surveillance service to commercial aircraft. (Graphic courtesy of Aireon)

be confident in the viability of all the technologies that are implemented on a spacecraft. Operators of satellite systems such as those that provide telecommunications services have used the current generation of satellite to test next-generation technology.

In one related type of mission, the Intelsat system flew an experimental router developed by Cisco on the Intelsat 14 that was in this case funded by the US Air Force as arranged by Intelsat General. In this case Cisco leased three transponders to conduct experimental with flexible reassignment of capacity using the IRIS router to reallocate capacity to meet needs for video downloads and other high bandwidth requirements. The type of experiment is central to future moves of communications satellite designs to encompass onboard processing and the building of so-called "smart" satellites. Intelsat on an earlier mission has also flown Ka-band packages prior to widespread operational use of this band in the 28 GHz uplink and 18 GHz downlink (Cisco Router Sent Into Space Aboard Intelsat Satellite 2009).

It is not necessarily the case that onboard hosted payloads by commercial telecommunications carriers are related to the future mission of the satellite organization. SES Americom, another satellite communications, signed an agreement with the US Air Force to host an experimental missile warning sensor on a communications satellite launched in January 2011 (Brinton 2009).

The future of telecommunications satellite services may well require exploitation of the Q-band (33–50 GHz), V-band (50–75 GHz), and W-band (75–110 GHz). Currently there is a Q/V experimental package known as TDP5 (named after Italian scientist Aldo ParaBoni) that is flying on the joint Inmarsat and European Space Agency (ESA) spacecraft. This spacecraft is known as Inmarsat XL (but is also known as the European Space Agency's Alphasat). The purpose of the hosted

Fig. 2 The Q/V Aldo Paraboni experiment launched as a hosted payload that rides aboard the Alphasat project by ESA (Graphic courtesy of ESA)

payload experiment was to test telecommunications satellite services using advanced digital multiplexing techniques and precipitation attenuation mitigation techniques in the Q/V bands (Brinton 2009) (see Fig. 2).

This Alphasat and Inmarsat XL satellite joint mission represented one of the world's most complex hosted payload undertakings. This satellite was designed primarily as a high-capacity mobile communications satellite. Yet, under the agreement with ESA, some 20% of the satellite resources were devoted to the four hosted payload experimental packages aboard. The Alphasat part of the joint project first flew for a 3-year period as funded experiments. This was, however, renewed for an additional 3-year period through the end of 2019 (ESA Artes Alphasat programmed to be extended n.d.).

In the case of the even higher satellite transmission frequency experiments undertaken by the Italian Space Agency to testing satellite transmission in the W-band, and known as the WAVE project, a different approach was taken. In this case the decision was taken to launch the experiment as a free-flying nano-satellite rather than taking the hosted payload approach. This experiment lasted only 3 months. Thus it did not have the opportunity of a 6-year in-orbit test which was possible with the Alphasat Q/V hosted payload experiment (Experimental Missions in W-Band: A Small LEO Satellite Approach, Researhgate n.d.).

3 The Hosted Payload Alliance

In April 11, 2011, seven commercial space industries, led by Iridium, formed what is called the Hosted Payload Alliance. The initial members of the Hosted Payload Alliance, who also the formed the steering committee, consisted of the following companies: Boeing Space and Intelligence Systems, Intelsat General Corp., Iridium Communications, Lockheed Martin Space Systems, Orbital Sciences Corp. (now

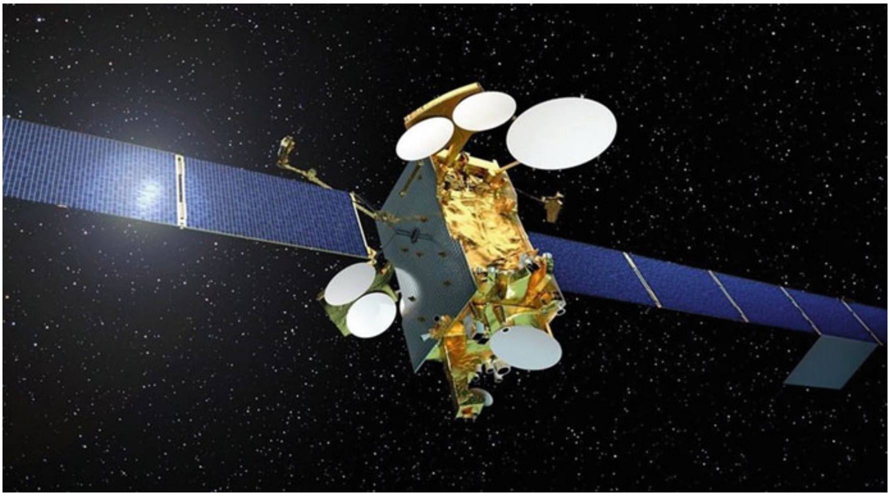

Fig. 3 The SES-14 satellite launched in 2018 with the GOLD hosted payload aboard. (Image provided courtesy of NASA)

Northop Grumman Innovation), SES World Skies US Government Solutions, and Space Systems/Loral (Seven Satellite Firms Form Hosted Payload Alliance 2011).

These aerospace companies had past experience with working with governments as contractors and providing new and sometimes unique solutions to governmental entities. Intelsat formed Intelsat General to work specifically with the US government and the US Department of Defense on providing dual-use facilities to meet special needs and transponder leases for dedicated communications services. This evolved into finding ways of meeting requirements for placing hosted payloads onto Intelsat satellites. The IRIS hosted payload by CISCO that became a hosted payload on the Intelsat 14 and funded by the US Air Force was launched in 2013. SES World Skies US Government Solutions was also formed to accommodate special needs of the US government. This led to the 2015 award to SES World Skies US Government Solutions of a contract for a NASA experiment to fly on the SES-14 satellite.

In this case the technology was not for a practical application but for research as to the effects of solar and thermal radiation on the Earth. This hosted payload experimental package was known as GOLD. This rather contrived acronym stood for Global-scale Observations of the Limb and Disk (GOLD) instrument. This research payload was launched in January 2018 and helped confirm the cost, schedule, and operational efficiency of hosted payload projects (Foust 2018) (see Fig. 3).

The Hosted Payload Alliance (HPA) is not directly involved in the individual arrangements for contracting with commercial contracts to carry research packages into orbit, but this organization has provided useful assistance to the process of bringing such arrangements into the mainstream of thinking of such arrangements by governmental officials. The HPA holds annual conferences that reports on the various projects that have taken place, provides a website and press releases that explains project successes and milestones, and helps share information with regard to contractual language, insurance and liability matters, and procedural and regulatory matters of interest. The Hosted Payload and Small Satellite Summit serves a quite useful forum to bring together potential experimenters and commercial satellite operators that can offer platforms for tests, experiments, demonstrations of technology, and even the opportunity for providing an ongoing space-based services, as is the case with the Aireon hosted payloads.

In the annual summit meeting of the Hosted Payload Alliance and Major James Crane of the US Military's Hosted Payloads Office, he has stated the following conclusions: "Ultimately, the benefits of hosted payloads are staggering. Their ability to increase access to space, slash the cost of military space missions and fundamentally shift the way the military approaches satellite and spacecraft acquisitions is simply too important to let concerns about risk and control keep hosted payloads on the ground" (Presentation of Major James Crane, DOD Hosted Payloads Office n.d.).

Despite these findings by the US Government Accountability Office and the Hosted Payload Office including the approval of "an IDIQ contract called HoPS" (known as the Air Force's Hosted Payload Solutions Program), the number of hosted payload projects has not greatly increased. Some observers have suggested that having programs and projects over which military units retain complete control and involve much larger budgets are still a factor that limits the number of hosted payload undertakings.

4 "NewSpace" and Economics in Launch Services and Spacecraft Design

Another key aspect that will likely control the extent to which the number of hosted payload projects will be undertaken relates to progress that is achieved by so-called "NewSpace" aerospace companies seeking to develop lower-cost launch capabilities. This is particularly the case in the area of new launch services providers and their ability to deliver reliable and easily schedulable launches for small satellite missions at ever lower costs. There have been studies done of various hosted payload projects that have found that the combined costs for developing and launching hosted payload packages run around $250,000 per kilogram. This would equate to about $1,250,000 for a 5 kg project or $12,500,000 for a 50 kg project.

These cost figures are difficult to relate to a free-flying satellite experiment or service providing spacecraft. The lack of comparison comes from the fact that an independent spacecraft must also provide for a power supply, a positioning and orientation system, thermal controls, and a tracking, telemetry, and control system, plus a platform structure and thermal controls. Further there would be additional staffing and operational costs associated with a free-flying satellite.

What is clear is that if the cost of launching a free-flying small satellite were to be significantly reduced, then the relative advantages of hosted payloads would be somewhat diminished. There are now all sorts of ambitious efforts to create much lower-cost launching systems. These newer designs include reusable rockets (i.e., first stages and fairing covers); new types of lower-cost materials for fabricating rocket stages (i.e., Rocket Labs); new use of additive manufacturing for creating rocket launcher engines; lower-cost launching operations from truck-mounted systems or from high-altitude carrier planes; and more. Also some of these new launcher companies are located in countries with lower salary costs such as Argentina, Brazil, China, India, Israel, Russia, etc.

Some of these new commercial launch services companies are estimating that the cost of their commercial launch services for small satellites will drop down to around $40,000 to $50,000 per kilogram or even lower. Even so, these prices will remain well above the capabilities of reusable launchers such as the Falcon 9 rockets at around $10,000 per kg and potentially as low as $5,000 per kg. Others are projecting that the cost of designing and manufacturing spacecraft will also fall. This assumes not only that satellites will be designed and manufactured for less but also that satellites will be designed with increasing skill so as to do more within less mass and volume (Andraschko et al. 2019).

Indeed these economies have already been achieved. Companies such as Blue Origin, SpaceX, Launcher One, Vector, and Rocket Labs are offering lower prices and greater launching rates. There are another 40 new start-up launcher companies that are promising greater economies and better results. Some have suggested that instead of rockets that can be launched repeatedly for 20 times to 30 times, in the future, this could go to repeated launches up to 100 times. If this can be accomplished with lower-cost launching sites, and if the manufactures of these rocket launchers are can be reliably done in countries with lesser labor costs, the prices could continue to fall. In such a price or cost environment, the emphasis toward the use of hosted payloads might shift from cost savings to an emphasis on less orbital debris and less “space junk” to be removed from orbit.

5 Mission Consolidation Efficiencies

The greatest emphasis that is placed on hosted payload projects is on the cost savings that can be achieved. It is logical in that there are clear savings in many ways. There are clear savings in terms of launch costs and all of the paper work and regulatory hurdles associated with a launch. Then there are also demonstrable cost savings associated with the sharing of power systems; tracking, telemetry, and command systems; pointing and stabilization systems; structures; thermal systems; etc. Once the satellite is launched and operational, there are savings due to the fact that the “spacecraft bus” is managed by the platform host operator rather than the organization associated with the host payload sensor or telecommunications package.

The benefits extend beyond the cost savings that can be derived. The additional benefits that should logically be considered include the following: (i) the operator of the host platform is responsible for removal of the satellite for orbit and the proper discharge of batteries or outgassing of fuel tanks to avoid explosions or other such misadventures; (ii) in the case of reliability, lifetime testing, or demonstration of new services, the period of the test can likely be much more extended. In the case of the Q-/V-band, telecommunications services and precipitation attenuation mitigation testing on Alphasat were able to go for 3 years and then extended for another 3 years. In the case of the W-band nanosat free flyer, the test was for only 3 months.

Further the record of dependability or reliability with nanosats and cubesats systems are much worse than that associated with large spacecraft. A reliability assessment of cubesats by NASA scientists and engineers has indicated the reliability problem with cubesats as follows: "There has been an exponential increase in CubeSats launched since 2003. There were only 105 launched from 2003 through 2012, 79 in 2013, and 118 in 2014. Yet mission success rates average, 45 percent and 77 percent for academia and industry, respectively. Missions were deemed a success if the CubeSat operated on orbit for 60 days or longer" (Venturini n.d.).

There are a number of design, manufacture, testing, and launching techniques that have served to increase the reliability of nanosats and cubesats, but nevertheless the success in terms of reliability is far less than with more sophisticated satellite systems, and the time of successful operation is significantly longer. The initial launch of 60 minisats for the SpaceX constellation resulted in 5 satellites that did not properly activate. This results in concerns about the reliability of such smallsats but also in the ability to deorbit smallsats that do not activate and cannot be reached for commands (O'Callaghan 2019).

6 Legal, Regulatory, Liability, and Insurance Considerations

The types of legal, regulatory, liability, and insurance considerations associated with a hosted payload system are clearly different than in the case of a free-flying nanosat or cubesat. For the most part, they tend to be less of an issue because the main operator of the satellite and the associated launching nation have most of the responsibilities for getting the national license to launch, filing the launch notification to the United Nations, and to carry out the technical intersystem coordination under the International Telecommunication Union (ITU). Nevertheless someone seeking to launch a hosted payload has the responsibility to provide the needed technical information required for various filings to the organization that is launching the host payload satellite. If the hosted payload or series of hosted payloads on board a constellation of satellites are providing services to various countries, they still must obtain so-called landing licenses to operate in those countries. In some instances, there will be new regulatory issues to address.

If remote sensing data is obtained by a hosted payload but such data is not downloaded within that country, and processed data is only sold via the Internet, there could be questions as to whether some form of national approval might be required. This is not a question unique to a hosted payload. The fact that such operation is conducted via a hosted payload does not exempt a satellite service provider from national or international regulatory policies.

There are questions about insurance coverage. Can separate launch insurance be obtained for a hosted payload and if so would it be for the cost of replacing such a payload or could it cover the cost of lost revenues from the services it is seeking to provide?

There are a number of possible questions of liability. If the host platform satellite operator partially loses power so that it cannot continue to provide power to the hosted payload, does the guest payload owner have standing to sue the host platform satellite operator to recover from its losses? Does the host platform satellite operator sign an agreement in advance to provide a proportionate part of the remaining power? In the case of the Inmarsat XL-Alphasat project, for instance, Alphasat has claim to 20% of the mission resources. In the case of the International Space Station, each one of the partners in the project signs a "franchise agreement" that spells out each country's rights and claims to resources. What is clear is that legally binding contractual agreements that spells out rights, responsibilities, and proportionate claims on resources should be agreed in advance of a launch of a host platform satellite and the hosted payload.

7 Framework for Hosted Payload Contractual Arrangements

The above discussion indicates both the need for a clear contractual arrangement that would spell out the responsibilities of the host platform satellite owner and/or operator as well as those of any hosted payload. Fortunately there are precedents of such agreements that provide useful models that might be used. This agreement should cover not only what the rights, duties, mutual responsibilities, and sharing of resources under nominal conditions as well as in the case of difficulties and system failures. It should also cover the possible issue of dangers or harm that the satellite in question, including its hosted payload(s), might somehow cause to another satellite or the injured party in the case of a deorbiting accident. Some of these events might seem quite remote or almost impossible to consider ever happening, but mutually protective language in the case of such partnerships seems prudent to address in advance.

8 Conclusion

The popularity of hosted payload agreements seems likely to continue to grow. There are not only the advantages of cost savings related to launch services, satellite manufacturing economies, and operating costs but other clear advantages as well. The development of new launch capabilities and efficiencies, improved forms of satellite design and manufacture, as well as rising concerns with orbital space debris will likely impact the degree to which the use of hosted payload systems will grow in the future.

What is clear is that the so-called "small satellite" revolution has many implications for the future. Small satellites and new launch services have showed the world new ways to exploit space systems and technologies. Some of these new ways include hosted payloads and small missions based on new ways of sharing space resources. Other concepts include the idea of high-altitude platform systems (HAPS) and shifting of services to Internet-optimized networks and fifth-generation broadband cellular services that utilize a range of terrestrial, cellular, HAPS, and satellites deployed at various altitudes.

High Altitude Platform Systems (HAPS) and Unmanned Aerial Vehicles (UAV) as an Alternative to Small Satellites

Joseph N. Pelton

Contents

Abstract

The advantages of a high altitude to provide telecommunications, broadcasting, surveillance, remote sensing, and military related services have been known for a long time. For many years the options have largely been limited to ground-based antennas on towers or mounted on top of buildings or mountains or satellite systems. Other options such as balloons, aerostats, or other alternatives such as kites have all

https://doi.org/10.1007/978-3-030-36308-6_19

largely proved to be unreliable. Such systems have not proven reliable in maintaining power and altitude, especially in violent rain and wind storms.

In recent years the idea of an intermediate altitude option to ground based towers or satellites has been re-explored in the form of what have been formally designated by the International Telecommunication Union (ITU) as High Altitude Platform Systems (HAPS). The ITU designated service for radio communications from HAPS has been specified to operate in the altitudes of 20–50 km. The practical uses of the altitudes known as near space or as the "Protozone or "Protospace" (i.e., the stratospheric region from 20 km to 160 km) have in recent years grown from essentially nil to a wide range of new applications.

This range of altitudes, sometimes described as near space, the "Protozone" or "Protospace," is usually referred to as the area above commercial airspace and most military aviation (i.e., 20 km) and below the altitude where one can sustain a satellite in orbit for a long periods (i.e., 160 km). This area has slowly but steadily emerged as an area of interest for many new and innovative uses. These applications of the Protozone include high altitude platform systems (HAPS), dark sky stations, possible use by robotic air freighters, hypersonic missiles, and hypersonic craft performing so-called "space tourism" or even hypersonic transportation systems.

The uses of a reliable high altitude platform system that could maintain a relatively stable platform for a sustained period of time might be used for telecommunications and networking, broadcasting services, stratospheric atmospheric research, remote sensing, surveillance, and other military uses.

This chapter discusses the various efforts that have been undertaken to develop HAPS technologies and systems as well as the various practical, military, and research applications that have been envisioned for so-called "near space" or "protospace" or "the Protozone." A range of different technical approaches have been proposed and tested. These have included flown platforms using both pilots and automated systems (i.e., balloons, airships, dirigibles, and zeppelins, and even powered kites), platforms that are jet powered, platforms that are solar powered and automated, and even platforms that use microwaves transmitted from the ground and converted to electrical power to power such stratospheric platforms for a sustained period of time at a stable altitude and position. Several initiatives have been seriously pursued, and space research organizations such as NASA and JAXA have carried out serious experimental projects in this area. Also some aerospace companies are prepared to offer commercial HAPS capabilities to carry out a number of difference "Protozone-based services."

Such high altitude platform systems (HAPS) are seeking to prove that they can be reliable in service, stabile in their altitude and positions, have adequate power, and be cost competitive with low Earth orbit satellite services. Today billions of dollars are being spent on deploying large scale satellite constellations using small satellites. The question is whether HAPS-based networks can offer viable competitive service? This chapter seeks to provide useful information that might help to answer that question.

Aerostat · Broadband telecommunications services · Broadcasting services · Defense-related services · Drone · High Altitude Platform Systems (HAPS) · Hypersonic transportation · Near space · Protospace · Remote sensing · Stratosphere · Surveillance · Unmanned Aerial Vehicles (UAVs) · Unmanned Aerial System (UAS)

1 Introduction

The basic concept of a High Altitude Platform System (HAPS) is relatively straight forward. The idea is to create the equivalent of a geostationary satellite but position it over a 1000 times closer to Earth. This means that when path loss is considered a High Altitude Platform System at 35 km rather than at 35,870 km altitude can concentrate its power, with a comparably designed antenna with the same gain, a million times (i.e., 1000^2 more effectively) than a geostationary satellite. This is a huge advantage in terms of effective power and at 35 km the coverage is enough to cover a country like Cuba or even the island of Hispaniola with high efficiency. Clearly an island country with modest national dimensions could find a high altitude platform system (HAPS) or a so-called Unmanned Aerial System (UAS) or Unmanned Aerial Vehicle (UAV) of interest not only telecommunications, networking, or broadcasting purposes, but for many other purposes. UAVs or HAPS can usefully provide platform higher than a tall building, tower, or mountain top but lower than an orbiting satellite (see Fig. 1).

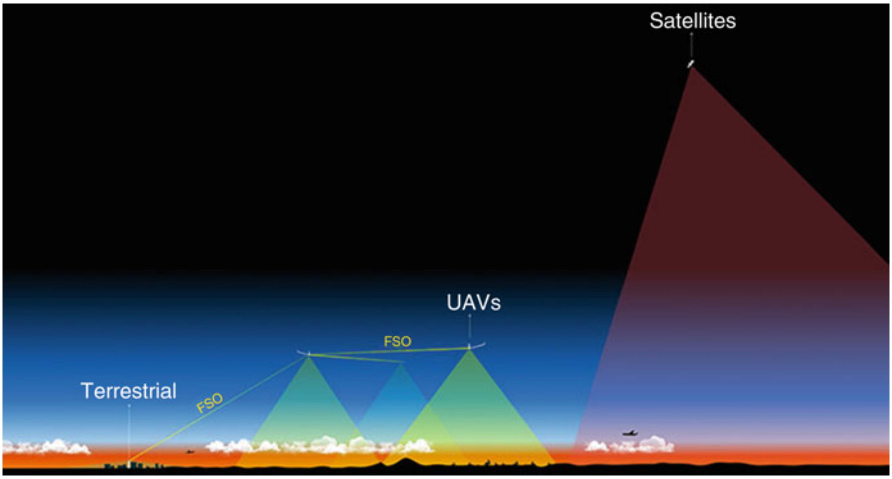

Fig. 1 The gap in coverage that a UAV or HAPS can provide vis a vis terrestrial towers and satellites

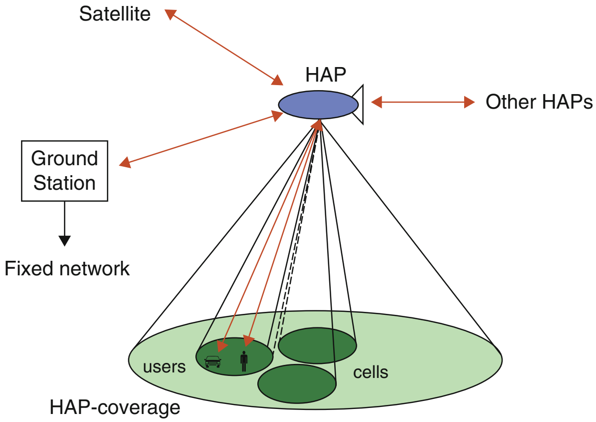
Fig. 2 Schematic showing the basic architecture of a High Altitude Platform System (HAPS)



Such a high altitude platform can be used for aerial surveillance for forest fires, agricultural- or forest-related diseases, urban planning, pollution infringements, illegal fishing, or other criminal activities, as well as for a wide range of communications related activities. Today the term of art that is more often used is UAS which stands for Unmanned Aerial System. This is because the UAV is actually just part of an overall system including the ground operations that controls the vehicle and the payloads on the vehicle. In some senses a UAS could be considered a drone, but for the most part a UAS involves more sophisticated automated aircraft that can fly to much higher altitudes and support larger payloads and missions. UAS capabilities such as the Golden Hawk or Predator, for instance, represent very sophisticated pieces or equipment that costs millions of dollars. These types of UAS as developed by the US Defense Advanced Research Projects Agency (DARPA) for military purposes should not be considered the same a "toy drones" costing thousands of times less (UAVs 2019).

And with the proper design a HAP system can connect with satellites, ground stations, other HAPS, and users located in cells to extend coverage that just one HAPS can provide (see Fig. 2).

The concept of a UAV or HAPS in terms of geographic coverage and effective power performance vis a vis a geosynchronous satellite, or even a low Earth orbit (LEO) satellite, is clearly shown in Figs. 1 and 2. The key problem is how does one stabilize a HAPS in a volatile atmosphere in a relatively stabile 3-axis location? Further how is sufficient power, performance, and continuity of service provided over a long term period of operation?

2 History of the Development of Higher Altitude Platforms (HAPS) or Unmanned Aerial Systems (UAS)

2.1 Aerostats

The first attempt at higher altitude platforms were a much lower altitudes and these systems were called aerostats. These were tethered systems that were deployed to provide communications services provide for border security or other forms of

Fig. 3 A docked aerostat not in service that is used primarily for surveillance. (Graphic courtesy of Internet global commons)

policing and armed security systems. These systems have often found to be unstable and strong storms and winds have tended to blow them away from their ground tethers. More recently the concept for aerostats has tend to move to smaller tethered balloon that can carry aloft very small packages such as Ethernet data links or sensor and surveillance equipment, and these smaller systems are easier to maintain in place more reliably. Some aerostats have been equipped with a pumping system that could add or subtract air from the system to control altitude (Aerostat definition 2019). Such aerostats operate at much lower altitudes and are not for activities that would be considered in competition with small satellite constellations. The prime uses of these systems today are for border security and military surveillance (see Fig. 3).

The idea of using UAS or HAPS for telecommunications or remote sensing was in the 1990s and 2000s considered to be a possible major alternative to GEO satellites. This was before the possibilities of large scale constellations of low Earth satellites populated by small satellites that could work to flat panel ground antennas that use phased array electronic beam tracking of satellites. Many different projects were actively undertaken.

2.2 Jet Powered High Altitude Aircraft

There was the Angel Technology Corporation. It studied the possibility of a series of jet propelled craft that would fly in "halo" flight path to provide telecommunications and remote sensing services at very high stratospheric altitudes with a replacement craft cycling up before the other descended. This project had Burt Rutan, the aerospace designer, as the prime craft designer, and also involved Arthur D. Little and Peter Diamandis. It was acquired by Raytheon when it declared bankruptcy.

2.3 Beamed Microwave-Powered High Altitude Platforms

Another project, known as Stationary High Altitude Relay Platform (SHARP), involved plans to create an experimental aircraft that would be powered by microwave energy beamed up from the ground that could be converted to electrical power to maintain this platform at high altitudes for a very long period of time. This project which was initially conceived by had a number of engineers and scientists involved. A commercial version of this system was incorporated to create this system, but it also ended in bankruptcy. This project was not able to solve a number of technical, operational, and cost issues as well as the basic safety issue of transmitting high intensity microwave beams up from the ground with possible danger to airline passengers (Schlesak et al. 1988).

2.4 Solar and Battery Powered HAPS-UAS Platforms

Yet another approach that has been pursued is that of solar powered platforms that uses solar energy to power electric engines to drive propellers to key a platform aloft and which includes batteries to keep the platform operational at night. NASA has developed such a solar powered system in conjunction with Aeroenvironment Inc. In September 11, 2019, a Tokyo company HAPSMobile Inc. (“HAPSMobile”), which is a subsidiary of SoftBank Corp. (TOKYO:9434) and minority-owned by AeroVironment, Inc. was able to complete a successful test flight of a commercial system prototype known as the HAWK30 solar-powered high-altitude platform system (HAPS). This test flight was conducted at the NASA Armstrong Flight Research Center (AFRC) and flew to an altitude sufficient for this platform to provide telecommunications, remote sensing, or surveillance services over an area of many thousands of square kilometers (HAPS Mobile Successfully Completes…., Sept 2019) (see Fig. 4).

Fig. 4 Solar-powered HAPS platform. (Graphics courtesy of NASA)

2.5 Dirigible-Based HAPS Systems

General Al Haig and associates undertook trying to design a US-based network of very large dirigible-based system that would operate at an altitude of around 20 km (13 miles) high that would be able to provide telecommunications, networking, and broadcasting services. This project also failed due to both a lack of overall financing and technical design issues (Mike Miles 1998).

The dirigible-based HAPS program that made it the farthest from concept to implementation was the Japanese HAPS system. The concept was to be a network of 15 dirigibles that would be able to provide complete coverage of Japan for communications services. This project was jointly undertaken by Japanese space specialists at what was then known as the Communications Research Laboratory (CRL) and now known as the National Institute of Information and Communications Technology (NICT) and the National Aerospace Center (About NICT 2019).

There were many issues to address. One of these issues was the annual major wind reversal that would blow the HAPS dirigibles off course and maintaining the network in place would be quite difficult in terms of the very strong change in winds. The ultimate solution found was to let all of the 15 HAPS dirigibles to be blown to a new position and then have the last dirigible be flown around to assume the first position in the national coverage configuration. In Fig. 5, there is an artist graphic image looking down from a satellite to see HAPS dirigibles below.

Another key issue was obtaining frequency allocations for suitable frequencies that could be used for this HAPS system for telecommunications services to Japan. The solution found was a so-called “reverse allocation” of the Ku-band spectrum used for satellite communications. In this case, the up link would be as 12 GHz and the down link would be at 14 GHz. Japanese calculations were that this use of the spectrum could result in about a 6% efficiency penalty for Ku-band satellite services in the region.

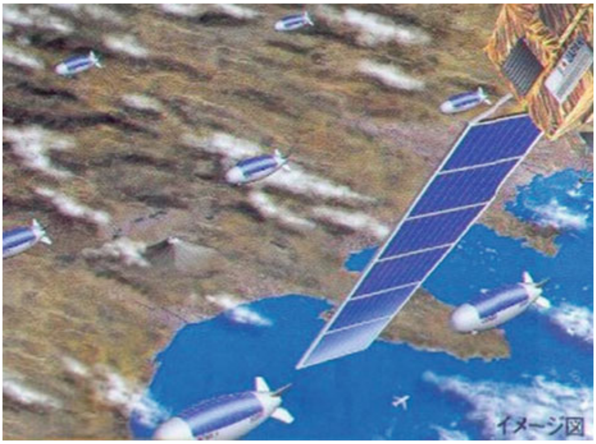


Fig. 5 Artist representation of Japanese 15 HAPS system of a dirigible network that was never deployed. (Graphic courtesy of Japan’s NICT)

After years of planning, design, and initial implementation efforts, it was ultimately decided not to deploy this system for Japan.

3 Cost and Efficiency of HAPS Networks for Communications Service

There are a number of reasons why HAPS systems for telecommunications and broadcasting services have ultimately not been deployed in a systematic way such as been the case for communication satellites. There remain technical design issues, questions of reliability, and resilience of operation. Some of the largest issues have revolved around the cost of building, deployment, sparing, and cost effective operation of these networks. The cost efficiencies of GEO satellites and the new planned LEO small satellite constellations are continuing to increase and the reliability of satellite networks have achieved a 99.999% performance.

The most efficient high throughput satellites in GEO orbit have now achieved up to a 300 Gigabit/second throughput capabilities. The largest of the small satellite will also provide very efficient, reliable, and cost efficient services. There are no specific or reliable numbers for the cost of service or satellite or HAPS system costs at this time, but they can be reasonably closely estimated for purposes of rough order of magnitude assessments. These rough estimates are provided in Table 1.

Although the costs for HAPS service might seem high in the Table 1 chart, it must be noted that the HAPS services would be highly targeted to the needs of say an island country. Further, when it is realized that there are 527,600 minutes in a year, the cost of a very broadband gigabit/second of throughput for a minute drops to about $0.00006 for the highest efficiency GEO satellite, to $0.0003 for a LEO System, and to $0.065 for a HAPS network. It turns out that all three of these transmission media represent a very small part of the cost of an overall telecommunications or broadcasting service. For instance, the cost of a billing, advertising, and marketing program, or other cost elements are likely to be much higher than the cost of any one of these three types of transmission systems. If one figures the cost of a 100 megabit/s data stream on a HAPS network, the per minute cost would drop to $0.0065.

Nevertheless the bottom line is that high throughput GEO satellites or large scale small satellite constellations will for the most part outperform HAPS networks for telecommunications and broadcast services, particularly if there are high throughput broad band services requirements. Further they likely would be able to provide a higher level of service both in terms of bit error rate and continuity of service as well as providing interconnectivity to the rest of world for international services with much greater ease and efficiency.

4 The Future Prospects for HAPS Services

All of the various transmission systems addressed in this Handbook such as GEO, MEO, and LEO satellite system and HAPS or UAS networks are developing new and better technology and certainly the cost and performance figures in Table 1 will

Table 1 Cost efficiencies for satellites and HAPS networks

Rough economic comparisons of the transmission efficiencies the current technologies of GEO, LEO, and HAPS Systems

System type	Estimated system cost	Coverage (Sq. Km)	Beam throughput	Beam performance index
Geo system (3 sats) 200 beams 15 years lifetime	\$1.25 billion	5×10^5 sq. km/ beam Total coverage: 1×10^8 sq. km	1.5 gigabits/s	\$33 for each gigabit/s/km^2 of throughput for each year of lifetime
LEO System (1000 sats) 40 beams 7 years lifetime	\$4 billion	1×10^4 sq. km Total coverage: 1×10^8 sq. km	200 megabits/s	\$170 for each gigabit/s/km^2 of throughput for each per year of lifetime
HAPS (20 beams) 10 years and 10 HAPS	\$50 million	5×10^2 sq. km Total coverage: 1×10^5 sq. km	100 megabit/s	\$37,000 for each gigabit/s/km^2 of through for each year of lifetime

Note: These theoretical comparisons are distorted in many ways by such factors as the fact that satellites cover the entire globe. This includes regions that have no or minimal service requirements (i.e., oceans, deserts, arctic regions). It is likely that global satellite systems provide active revenue services from an area that is less that 10% of the Earth surface. In contrast a HAPS system would be directly targeted to a compact island area which may in many instances have narrowband requirements. This targeting efficiency is not taken into account in the above beam performance index. This analysis was prepared by Joseph Pelton and all rights are reserved. This chart is licensed to Springer for this presentation in the *Handbook of Small Satellites*

likely continue to advance apace. Currently there are stratospheric systems that are being developed to provide for higher efficiencies in terms of altitude stability, improved power systems, and intersystem links between HAPS systems. One such example is the so-called Stratobus HAPS which is designed for providing both telecommunications service to its service area but also to interconnect to other HAPS as pictured in Fig. 6.

5 Applications for HAPS and UAS Systems at Stratospheric Altitudes

The biggest and most successful applications for satellites have been telecommunications and broadcast services and this is likely to be the case for High Altitude Platforms. There are many applications in the age of broadband 5G cellular services, over the top data streaming and other networking services that could well be met by

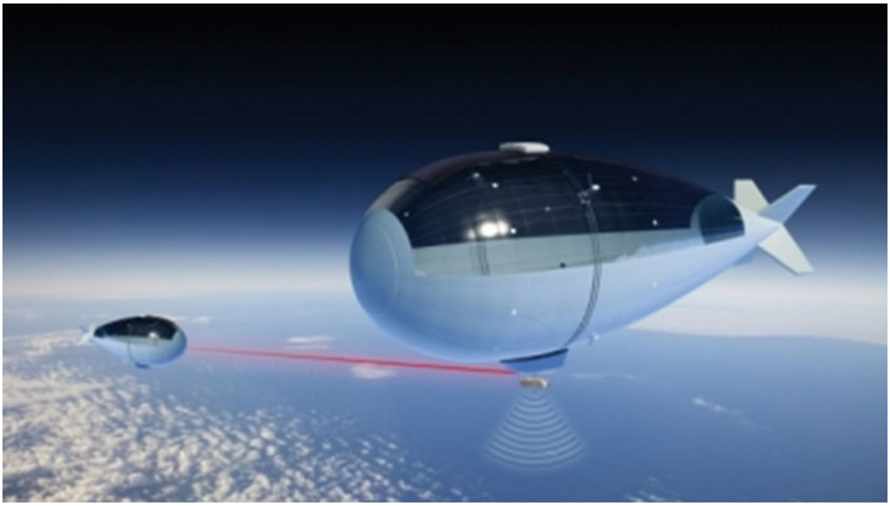

Fig. 6 Stratobus High Altitude Platform System (HAPS). (Graphic courtesy of Thales Alenia)

HAPS/UAS systems – particularly in areas of the world that have limited networking services now in place. There are billions of unserved or underserved people in the world that could utilize these systems to gain access and do so at reduced costs.

But Unmanned Aerial Systems (UAS) and HAPS are a multifunctional type capability that are capable of many diverse applications that go beyond telecommunications, broadcast, Over-The-Top streaming services, and networking services. Some of these applications are discussed below and, indeed in some cases, they are being actively employed in various parts of the world today.

(a) **Border Security**

One of the active uses of HAPS/UAS systems today is border security. Areas where illegal border crossings are at issue and frequently occurring have resorted to deploying UAS with sensing devices, telescopes, telephoto cameras, and other capabilities to detect such crossings. There are companies such as Verus Technology Corporation, Tekever, and Israel Aerospace Industries that are developing and selling such systems around the world for border security and related applications. The IAI system that has been installed in Argentina for border security and includes UAS systems has been described by Major General (Ret) Gadi Shamni, Executive Vice President of Land Systems at IA as follows: ". . ..it is a novel approach to border control and grappling with multiple challenges faced by many countries. IAI's land systems offer a range of strategic and tactical solutions targeting multiple threats. We combine technological expertise, advanced communication solutions and innovative operational concepts into a comprehensive solution (IAI/ELTA, Dec. 20, 2017)."

(b) **Surveillance and Military Operations**

Perhaps the most extensive use of UAS capabilities around the world is for surveillance and military operations. These are primarily sophisticated drone systems that are designed to operate at various altitudes. Northrop Grumman is perhaps the largest manufacturer of systems that can be controlled to obtain imaging of particular areas. This can be simply systems to collect information. Or it can be a system to support logistics for troop operations and alert war fighters of terrain issues or location of hostile forces. Or it can be even be used as a platform from which to fire weapon systems against land or air systems.

(c) **Monitoring of Pollution, Illegal Fishing, Smuggling, and Police Activities, etc.** After border security and military activities, various policing and monitoring operations are now common uses of UAS capabilities. These systems are particularly well suited, of course, for monitoring very wide and vast areas for particular activities. Thus, monitoring of areas for illegal fishing, for smuggling operations, or for spotting polluting activities are very well suited for UAS that are equipped for these activities. Since satellite systems do not typically provide real time imaging and analysis, UAS operations are particularly apt to uses where immediate actionable data can be produced. In some cases, however, information from UAS sensors can be cross indexed with satellite data such as automatic identification systems (AIS). Thus, AIS data from satellites on ship locations could be cross referenced from ships seen from high altitude platforms to spot smugglers or illegal fishing operations.

(d) Remote Sensing
There can from UAS systems be helpful for many purposes related to remote sensing. Again it is possible to combine sensing information from satellites and UAS systems by comparative analysis of older satellite data with real time information from high altitude platforms. Some of the more such applications include smart farming to determining improved data for watering and fertilizing of plants, soil acidity, or basic levels, etc. These systems can also be used for crop and tree disease detection, forest fire spotting, or even analytics of terrain to assist with resource detection for mining or other operations.

6 Stratospheric Tourism

There are some new ways that balloon or dirigible technology can also be employed that may produce innovations that may produce benefits and applications along the lines outlined above. One of the more innovative new concepts is the idea of providing lifts by tourists and even wedding parties to stratospheric altitudes. There are at least two companies that are currently providing this type of offering. These are Worldview and Zero-to-Infinity which are both offering booked high altitude accessions and for much cost less than those now providing so-called space tourism accessions (Zero-to-Infinity, Simplifying Access to Space 2019; Worldview 2019).

The development of these systems has led to some innovations and others will perhaps follow. The dirigible accent systems used by the Worldview enterprise has developed a secondary escape system in the event of a problem with the primary accent system. This is shown in Fig. 7. In the event some of the remote sensing,

Fig. 7 Stratospheric Tourism and new ascent system with escape system. (Graphic Courtesy of Worldview)

surveillance, or monitoring operations should be designed in the future to include human operators these safety features could prove quite important.

7 Dark Sky Stations

Another innovation that is under study and involves new capabilities with balloon or dirigible systems is the so-called dark sky station. This idea is the creation of a balloon buoyed station in the stratospheric that could be used for upper altitude research, Earth observation, and also possibly serve as a platform for ion engine systems to insert nanosats into Earth Orbit. It is an idea that has been championed by such organizations as JP Aerospace (JP Aerospace 2019). This type of capability represents yet one other application for use uses of the Protozone and gives additional urgency to the idea that space traffic management rules and regulations, or at least best practices, include procedures for satellites and space craft in Earth orbit, but would also seek to address who safety systems and traffic controls would apply to the upper stratosphere above commercial air space and military air space (Fig. 8).

8 Space Traffic Management (for Orbital Space and the Protozone)

There are now a growing number of uses that are now occurring or are envisioned for the regions above 20 km and below 160 km that seem to require space traffic management systems to be put in place. This is a matter of both technological

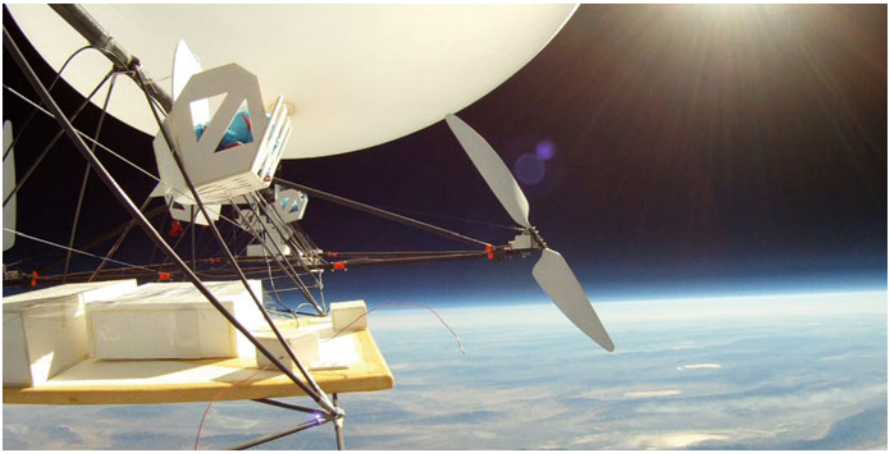

Fig. 8 Dark Sky Station. (Graphic courtesy of JP Aerospace)

capabilities for monitoring of traffic and velocities of things traveling on near space or the protozone and also regulatory controls or at least best practices until actual regulatory systems are put into place. Current uses of this near space region include HAPS or UAS platforms or vehicles, robotic aircraft carriers, dark sky stations, hypersonic space planes for space tourism or in time point to point transport, and a variety of military applications that include surveillance planes, hypersonic missiles, and other types of crafts. To utilize a region of the stratosphere where there are stable platform operating with little or no velocity and hypersonic vehicles operating at say Mach 6 is to invite disaster. Efforts have been undertaken by the UN Office of Outer Space Affairs (OOSA) and by the International Civil Aviation Organization (ICAO), but no specific regulatory processes have been agreed or explicit provisions of international law enacted involving space traffic management for the Protozone. This will be one additional reason to inhibit the development of the use of HAPS or UAS in the upper stratosphere. Thus, most uses will likely be at lower altitudes (i.e., below 20 km) and above national territories, where national aviation regulatory agencies such as the FAA in the USA, EASA in Europe will provide for air safety and traffic regulation.

9 Frequency Allocations and Access to Spectrum

The other key issue that will likely impact the deployment and use of HAPS and UAS is procedures and regulatory process for the allocation of frequencies associated with the control of such systems and the operation of radio signals for telecommunications, networking, broadcasting, platform operational controls, or data relay. For many years, the oversight of the use of radio signals was largely divided between terrestrial, ocean, and air-based regulatory controls and outer space. The addition of the need to control a regulatory process for the Protozone or near space adds yet another level of complexity. Figure 1 at the beginning of the chapter shows that there is a new region of significant size and volume now needs regulatory and safety controls. This need is increasingly being recognized as new applications are developed.

10 Conclusion

The idea of using high altitude platform systems (HAPS) or unmanned aerial systems (UAS) is not a new idea. For nearly 50 years there have been meteorological balloons, aerostats, and high altitude military jets for surveillance purposes. Only in the past decade or two have there been a surge of ideas from space planes and hypersonic transport to dark sky stations and HAPS and UAS for telecommunications and other services (Pelton 2017).

In some ways it may turn out that these stratosphere platforms could provide a competitive option to large scale small satellite constellations, but in many ways it may turn out that these systems might serve as complementary tools to be used in combination with each other. There are a number of economic, technological, operational, and regulatory issues to be addressed and resolved before there will be greatly expanded uses of the so-called Protozone or near space regions about 20 km, but such increased applications now seem quite clear. This chapter sought to provide some historical background, a review of some of the alternative technological approaches, and some brief analysis of regulatory concerns that comes from expanded use of HAPS and UAS for telecommunications, remote sensing, and military applications.

Launch Systems and Small Satellites

Retrofitting and Redesigning of Conventional Launch Systems for Small Satellites

Abstract

The small satellite revolution has dominated news in the space industry for the past decade. This change in the space industry has been variously described as the “NewSpace” or “Space 2.0” revolution. Certainly a major aspect of this revolution has come from the popularity that arose from the launch of hundreds of cube satellites as well as other types of micro- and minisatellites. This new way of looking at how to design satellites, miniaturize components, and use off-the-shelf components and even new way to construct satellites on assembly lines and to test their reliability using type approvals has changed the satellite construction industry. Another key part of this Space 2.0 revolution has come in the space launch industry. We have seen the development of new rocket launchers that represent new ways of designing, manufacturing, integrating, and testing of launch vehicles as well. The conventional suppliers of rocket launchers have also reacted by reinventing themselves as well.

This Space 2.0 revolution with regard to launch vehicles has frequently led to innovations as well – both for new entries in the launch industry and for established launch providers. We have seen such changes as use of new materials, new avionics and other subsystems, as well as new construction techniques and testing systems. In some cases there have been efforts to create alternatives to launching from conventional launch facilities such as launching from carrier vehicles or even balloons or air towing systems. This ongoing effort to create new launchers to support the burgeoning market represented by “cubesats”on up to “microsats” and “minisats” for smallsat LEO constellations keeps expanding. In short all launch services providers – new and old – have seen the need for change, innovation, cost reduction, and better performance.

This chapter focuses on how the “conventional suppliers” of launchers have adapted to the changing space industry and have responded as effectively as possible to the challenge represented by new and more entrepreneurial providers of new launch systems.

In short, this chapter focuses on the “conventional” or “established” launch providers and explores some truly important changes that are now afoot. It is clear that the established providers of rocket launchers intend on innovating and responding to the competitive challenges that the “NewSpace” or “Space 2.0” revolution has brought to the launch services industry. Currently there is some “protection” to the “conventional” launch providers offered due to the fact that national launches, particularly those for strategic or defense-related missions, are restricted to national flag industries.

There is now an effort around the world to innovate, to redesign, to reconfigure, and to adapt the space launch process. In some cases, it is a matter of changing existing launch vehicles or upgrading launch system adapters to accommodate the growing need to launch these much smaller craft and to launch many more smallsats at one time. The move is on to reduce costs, accommodate more small satellite launches, and accommodate new types of commercial space systems customers that are new to the world of space and have new types of expectations.

This chapter addresses these creative adaptations, redesigns, or totally new innovations from the established space launcher industry. This creative adaptive process is addressed in three different parts:

(i) The use of large-scale launcher system residual capacity to provide for a piggyback ride for space
(ii) The creation of new launch configurations to create a way to accommodate multiple minisatellites such as smallsats of the 100–500 kg class
(iii) Other innovative launch configurations that range from getting payloads into space via hosted payload systems, multiple smallsat carrier systems that accommodate a number of "smallsats" or even small experiments that fly on board the International Space Station as installed on the NanoRacks experimental station

In addition to the information provided in this chapter and the ones that follow in this section, there is supplemental information on launch systems that can be used for deploying small satellites in Appendix E on Global Launch Systems.

1 Introduction

The "smallsat" revolution, as reported in the press, has been about much more than designing and building small satellites. This revolution, which is sometimes known as "NewSpace" or "Space 2.0," is really much broader in scope. It really represents the idea of disruptive technologies that can replace conventional ways of doing things and making things better in every aspect of the aerospace industry.

This can involve inventing new ways of doing things that are either faster; lower in cost; more efficient; easier to design, build, and test for quality and safety; more efficient to operate; or more environmentally sound or sustainable for the future.

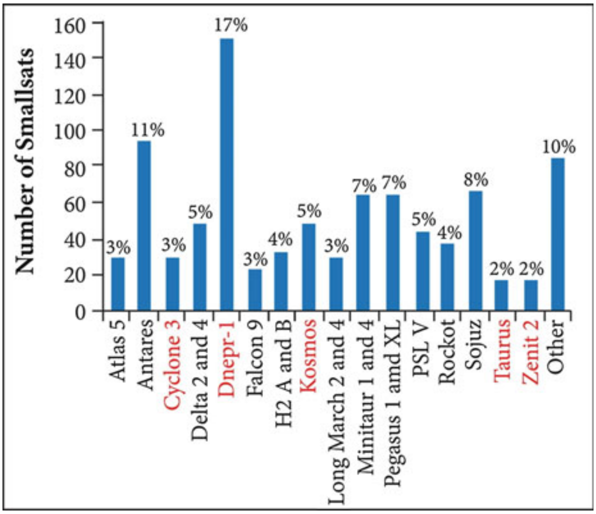
The essence of "disruptive ideas" is to be really creative and not do things that are 2% or 3% better, but 50% or even twice as good as before. It also involved doing things in totally new and "outside the box" ways. The military-industrial complex, the defense department officials, and large-scale aerospace companies have for decades been innovative and managed to incrementally improve technology and designs over time. The conventional approach to improvement in the aerospace industry, however, has been in the form of gradual improvements and incremental change. “NewSpace” or “Space 2.0” has a drive to breakthrough innovation that is disruptive to the status quo approach of doing things.

The thought process that came from Google, Amazon.com, Microsoft, and start-ups from the world of Silicon Valley and other innovators around the world that have come from the computer industry has sought radical change. There has been a push for truly disruptive ways to change the way things are done. The entrepreneurs from the world of computers, IT systems, artificial intelligence, and robotics thought not about small improvements but big changes. The “NewSpace” innovators have thought up ways to shrink satellites by a factor of ten to even a hundred times. They have sought to make them in new and more creative ways, using different materials and production processes. And once this process started, it certainly did not stop there.

Suddenly there was a new breed of thinkers who were not only seeking to improve how satellites were designed and built, but some of the “NewSpace” innovators were examining new and more efficient ways to launch satellites. They even questioned whether rockets had to be launched from expensive ground-based launch facilities. The precise start of “NewSpace” revolution is hard to fix in time, but the establishment of the Ansari X-Prize to create commercially a private space plane was a key milestone in the move to find new, better, faster, and lower-cost ways to launch things into space.

This challenge has now become abundantly clear to the conventional launch industry and to the space agencies of the world. Yet even here the record of small satellite launches up until 2014 has been dominated by conventional launches and proven systems as shown in Fig. 1. It is only in the last 5 years that new launch options have begun to appear. Even in cases where national policy restricts launches to national carriers, changes have occurred. New entrants such as SpaceX, Blue Origin, and others are making inroads.

Fig. 1 The launch record for small satellite through 2014. (Graphic courtesy of the global commons)



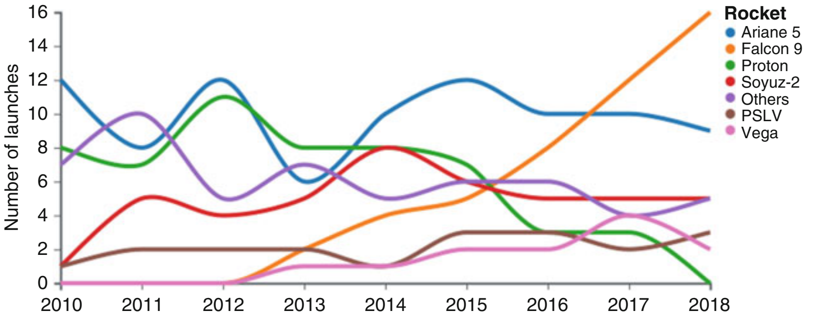
Thus space agencies such as NASA, ESA, JAXA, Roscosmos, the Chinese National Space Agency, and ISRO, among others, recognized that the world of rocket launchers was changing.Likewise, the large aerospace companies such as Arianespace; the Airbus Group; Lockheed Martin; Boeing; the United Launch Alliance (ULA); Northrop Grumman; BAE Systems; Khrunichev, the Russian Proton rocket manufacturer; and the Chinese Long March company have all recognized that the twenty-first century market for rocket launches has significantly changed and is not in their favor. There will be a significant shift from the launch of large spacecraft into GEO into a much more diversified need of many different types of satellites into many different orbits. There will be a significant increase in the launch of various types of small satellites ranging from femtosats, to picosats, to nanosats, to microsats, and to minisats. Meeting such diverse demand for "smallsats," which ranges from under 100 g up to 500 kg, will be difficult. This will be especially true if the demand is to support a very high volume of such small satellite launches. Further, this will be additionally complicated if a resupply of small satellite constellations is required on the order of every 7 years or so. Change, adaptation, and new rocket development will be the name of the game. New concerns with the sustainability of space, orbital debris removal, and cleaner fuels with less particulates will only complicate this adaptation process.

Of the existing set of commercial launchers, only the Indian Space Research Organisation (ISRO) with its Polar Satellite Launch Vehicle (PSLV) seemed to be well positioned to respond to the competition posed by newer and more agile and perhaps significantly more cost-efficient commercial launch providers.

There have been many adjustments in the past decade to accommodate the needs of the changing launch market by the traditional providers of launch services. This has included adjustments in pricing, revamping of launch vehicles and new launch rockets designs, and reconfiguration of the launch and deployment options available to those seeking to launch small satellites.

2 The Changing Launch Market

According to the US FAA Office of Commercial Space Transportation, the global space economy as of the end of 2018 was $245 billion, but global launch services represented only $5.5 billion or only about 2% of the total. It is perhaps even more important to stress that only about one-third of this amount is globally competitive since there are national guidelines and strategic concerns that restrict launch selection to national launch providers. Thus this part of the global space economy is less than 1% of the total, yet this part of the international space launch marketis increasingly subject to competition (FAA-AST). The last decade of this competitive profile is shown in Fig. 1. This shows that the Falcon 9 has ascended (not a pun), while Ariane 5 has lost its predominant role, and the Russian Proton has been the largest loser in this competitive process (Space Launch Market Competition) (See Fig. 2).



Rocket	Origin	First launch	2010	2011	2012	2013	2014	2015	2016	*2017*	*2018*
Vega [c]	Europe	2012	N/A	N/A	0[c]	1	1	2	2	*4*	*2*
Soyuz-2	Russia	2006	1	5	4	5	8	6	5	*5*	*5*
PSLV [b]	India	2007[b]	1	2	2	2	1	3	3	*2*	*3*
Proton-M	Russia	2001	8	7	11	8	8	7	3	*3*	*0[a]*
Others[d]	-	-	7	10	5	7	5	6	6	*4*	*5*

(a) Two commercial launches planned in 2018, Eutelsat and Yamal, were pushed to 2019
(b) First launch of the competitive PSLV-CA and PSLV-XL versions (2007 and 2008)
(c) Maiden flight of Vega was non-commercial
(d) Atlas + Delta excluding U.S. military missions and GPS Related Launches, Dnepr, Rokot, Zenit

Fig. 2 The changing scene of launch providers in the global competitive market (Ibid., Space Launch Market Competition). (Graphic courtesy of the FAA-AST)

The result is a rather chaotic market. The "conventional" launch providers are seeking to adjust, reengineer, and re-envision their launch systems to maintain their dominant positions in the market. This is for at least two primary reasons. The first reason is the new competition from the new launch providers such as SpaceX and their Falcon 9 and Big Falcon Rocket, Blue Horizon, New Glenn, Rocket Labs, LauncherOne, and others are bringing to the competitive launch market. These new entries are forcing a move to provide more cost-effective and responsive launch options. The second reason is that the market is changing and there is a new and expanding market for both quite small satellites (i.e., cubesats, nanosats, and micro-sats) up to 50 kg in size and minisats in the 50–500 kg class. Both of these markets are currently projected to rise sharply in the future.

2.1 Global Competitive Commercial Launcher Market

The market study conducted by SpaceWorks has charted the growth of the smallest satellites in the 1–50 kg range, and they have found a healthy growth in this type of “smallsat,” but they are projecting a rise that will continue to expand and reach perhaps 700 a year in volume by 2024, if the higher end of the projections are correct. This would mean that some 2,600 such nanosats and microsats would be launched between 2019 and 2024 (SpaceWorks) (See Fig. 3).

Studies by Northern Sky Research of minisatellites up to 500 kg in size show a similar rapid increase. These projected launches of new constellations range from a few dozens of satellites on the low end up to SpaceX’s ambitious plans to launch many thousands of satellites on the high end. These satellite constellations are to be launched to support the establishment of large-scale constellations for telecommunications, networking, data collection and analysis, automatic identification services (AIS), remote sensing, and even frequency monitoring and strategic information gathering. Other uses include technology demonstration and component testing, military monitoring and other strategic applications, and scientific experimentation not only in Earth orbit but also in deep space. The Northern Sky Research studies indicate that the theoretical total of satellites launched to support new constellations could add up to 20,000; their more cautious projection is that some 7,000 or so will be launched by 2027 and provide a breakdown for the various purposes for which these small satellites will be launched (See Fig. 4).

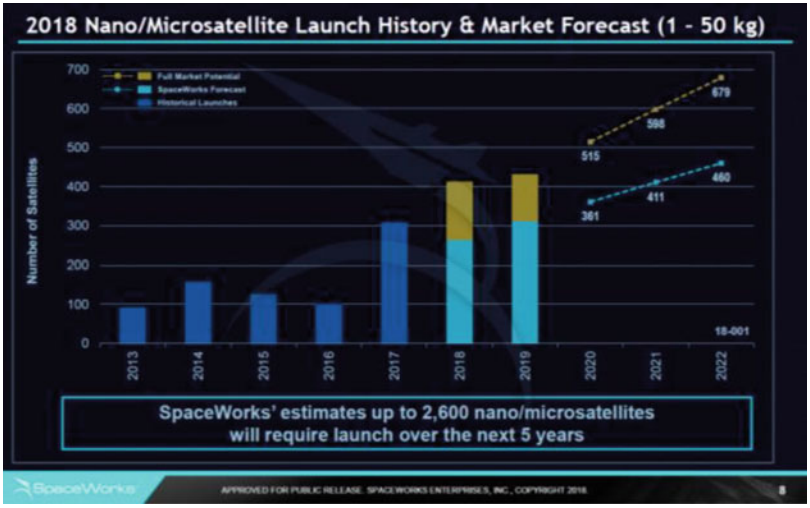

Fig. 3 SpaceWork’s estimates of 2,600 nano-/microsats to be launched by YE 2024. (Graphic courtesy of SpaceWorks)

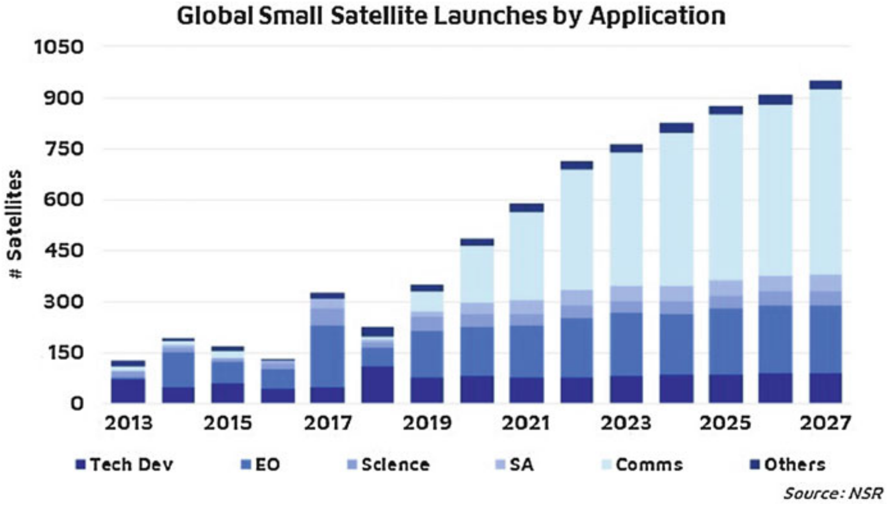

Fig. 4 Northern Sky Research projections of microsat and minisat launches. (Graphic courtesy of Northern Sky Research)

The Northern Sky Research study notes that more than a little amount of caution should be exercised in light of the current "effervescence" in the small satellite market. The satellite market has seen similar enthusiasms in the 1980s when 17 new Ka-band satellites were filed and only 2 were actually built. Also there were multibillion dollar bankruptcies constellations in the late 1990s for the Iridium, Globalstar, Orbcomm, and Teledesic systems. The Northern Sky Research study states their caution in the following manner in their report on small sat markets: "In the past decade, a vast number of new players have entered this space with diverse business models targeting a multitude of applications. Yet the question remains: has the growth in the small satellite market increased beyond sustainable business cases?" (Small Satellite Markets).

Regardless of whether there are 20,000 satellites launched in the next 8 years or 7,000, this is still an enormous number to contemplate. Currently there are only about 1,500 operational satellites in the Earth's orbit. What is sobering is that there are also over 20,000 pieces of space debris larger than the size of a baseball that might potentially collide with all of these new smallsats. Further, almost all of these new satellites are to be deployed in the most congested areas between the altitudes of 400 and 1200 km. Further LEO satellite networks must be resupplied about once in every 7 years. This means we need to consider not only the new deployments but also their replacement satellites as well.

This sharply rising demand to launch "smallsats" in the coming decade ahead very likely means that this demand will be met by both revisions and innovations in conventional deployment systems by conventional launch providers plus new commercial entries into the launch services market as well. The changes that are occurring with regard to the launch of small satellites will be addressed under the four different types of deployment systems that are now evolving within what is called here the conventional commercial launcher companies and instrumentalities.

There is additional information provided in Part 13 on various types of launch vehicles currently available in the global launch vehicle market with regard to conventional launch services providers discussed in this chapter as well as new launch service providers. Also Part 4.3 provides information on new smallsat launch options for cubesats and the new Kaber system that can launch smallsats up to 100 kg in size.

2.1.1 The Use of Large-Scale Launcher System Residual Capacity to Provide for a Piggyback Ride for Space

One of the key strategic issues facing the launch vehicle industry today is what is the best strategy going forward in a rapidly changing market? Is the best way forward to continue to develop large but very cost-efficient launchers that are partially reusable but with "adaptors" that allow a variety of different types and sizes of satellites to be launched? Or should there be a fleet of different types and sizes of launchers that can be more closely fitted to the needs and deadlines for launch for the customers seeking to deploy satellites – especially for large-scale constellations with hundreds or perhaps thousands of small satellites to be launched?

The Indian Space Research Organisation with their PSLV launch in mid-February 2017 deployed a Cartosat-2D Remote Sensing Satellite for India satellites, plus 88 3-unit "cubesats" for Planet Labs, as well as 8 cubesats for SPIRE as well as for other customers. This record-setting launch put some 104 different free-flying satellites into LEO with one PSLV Mark 2 rocket, and it shows that a combination of dispensing and adaptive structures can make larger-scaled rocket systems quite responsive to small satellite operator needs as well as those deploying larger satellites (Foust 2017) (See Fig. 5).

Clearly there are a growing number of "NewSpace" developers of truly small launcher companies such as Virgin Orbit, Rocket Labs, etc. that are tailoring their launchers to deploy small satellites. It seems likely that they can be much more geared to providing customized services and flexibility of schedule while also providing very cost-effective launch services. The question is whether their services will be reliable, responsive, and truly cost-effective in the new launcher market. Further, there are new entries such as SpaceX and Blue Origin that seem to bank on their innovative designs and reusability of first-stage launchers to drive down costs. In short, the best way forward is not certain in today's global launch industry even among established service providers who have been in this business for many decades.

It is these types of questions that are central to the strategic thinking of many of the established rocket launching organizations. The remainder of this section addresses some of the strategies that seem to be emerging from these carriers to the extent that these approaches have become known. These are presented in alphabetic order and not in any order of importance or significance.

Fig. 5 The Indian PSLV Mark 2 launch in February 2017 with a record number of satellites deployed into LEO. (Graphic courtesy of ISRO)

3 Ariane 5 and Ariane 6 by Arianespace

The Ariane 4 and Ariane 5 vehicles were for many years the predominant rocket launching system in the world and provided the majority of commercial launches, particularly for the launch of telecommunications satellites into GEO and for remote sensing satellites into polar orbits. The Ariane vehicles offered many options for smaller satellite piggyback launches with its SPELDA adapter. The high cost of the Ariane 5, currently in the $165 million to $220 million range, is no longer considered cost competitive. The strategy of Arianespace until fairly recently was to develop an Ariane ME launcher that would span the time until the new Ariane 6 could be designed and deployed. More recently it was decided to cancel the development of the Ariane ME and press ahead to develop the solid-fueled Ariane 6 more rapidly. Furthermore, the current focus seems to be to develop the Ariane 6 so that it more or less duplicates the launch capability of the Ariane 5 but to create a new launcher that is significantly less costly to launch and operate so that launch services can be offered at substantially lower cost.

The Ariane 6 will have two versions, the A62 and the A64. The A62 will have two solid boosters and will be capable of launching 5 metric tons to geosynchronous transfer orbit. The larger A64 will have four rocket motors and will be capable of transferring 11 metric tons to geosynchronous transfer orbit. These large boosters will have adapters to accommodate a wide range of satellite sizes and missions (Ariane 6: The Next-Generation Launch Vehicle).

One of the key Ariane 6 design feature is that it has adopted a modular configuration. Thus the Ariane 6 has core stages that are powered by liquid propellant modules. These core stages can be supplemented by either two strap-on solid boosters for the A62 or four strap-on solid boosters for the A64. The other feature that has been used to reduce cost is to utilize what is called a “series production” for its rocket engines. This approach allows a technology-sharing approach for the smaller new Vega C rocket that also uses the P120 engine. This is the same P120 engine that will be used in Ariane 6’s solid strap-on rocket motors. This allows net savings for the Vega C and the Ariane 6 series.

The Ariane User Manual that is currently online indicates that these vehicles can be configured to launch into a variety of orbits that include LEO, highly elliptical orbit (HEO), SSO, MEO, polar orbit, sub GTO, GTO, and escape orbits (Ariane 6 User Manual).

The other key strategic move is that Arianespace has become one of the key investors in the OneWeb constellation, which will perhaps be the first of the large constellations to market. Thus Ariane will be guaranteeing its launch manifest to deploy a large portion of the OneWeb satellites to orbit. The initial OneWeb launches will utilize the Soyuz launcher as arranged by Arianespace. These Soyuz vehicles will utilize the French launch site in Guyana to deploy six of the OrbWeb satellites at a time. Later launches with utilize the Ariane 6 that will deploy a much larger number of the OneWeb satellites with timing and numbers still to be determined.

4 Indian Space Research Organisation (ISRO) Polar Satellite Launch Vehicle (PSLV)

One of the standout space agencies of the world in terms of developing new, reliable, and cost-efficient launching capacity that continues to be highly competitive with regard to “NewSpace” disruptive new launchers is that of the Indian Space Research Organisation (ISRO) and their Polar Satellite Launch Vehicle. This development of a reliable launch vehicle has proceeded steadily by upgrading and enhancing the lift of this vehicle by addition of solid rocket engine boosters and other enhancements.

The first and smallest of the launchers, the PSLV-G, was first launched in September 1993. The PSLV-CA was first launched in April 2007. The PSLV-XL was launched initially in October 2008. Most recently the PSLV-DL was first launched on January 24, 2019. This medium and upper medium launch vehicle represents one of the lowest cost launch options available to the commercial launch market with the price of the PSLV rockets ranging between $21 million and $31 million as of 2019 (Polar Satellite Launch Vehicle).

These PSLV rockets have launched spacecraft to the Moon and to Mars and have also orbited some 50 spacecraft for India out of 43 successful missions with only two launch failures and one partial failure. They have deployed well over three-quarters of their total spacecraft since 1993 for overseas commercial customers. This includes the record launch in February 2017 when they launched an Indian remote sensing satellite and two other Indian small satellites and well over 100 cube satellites that included 88 3-unit cubesats for Planet Labs and 8 3-unit cube satellites for Spire plus some others for overseas customers (India launches).

5 JAXA HII, HIIA, and HIIB

The International Space Station is a project of the United States, Russia, Europe, and Japan and involves a cooperative agreement between these countries space agencies, i.e., NASA, Roscosmos, the European Space Agency (ESA), the Canadian Space Agency (CSA), and JAXA, the Japan Aerospace Exploration Agency. Japan has played a number of key roles in the International Space Station program since the original international agreement was signed in 1988. This participation has included the construction of the Japanese Experimental Module (JEM), known as Kibo, support to the station-keeping of the ISS, via the Japanese Data Relay Test Satellite, and the H Transfer Vehicle (HTV) (Kamigaichi, n.d.).

The most recent launch was the HTV-6 that was launched to the ISS on the HIIB launch vehicle in December 2016 to carry cargo to resupply the ISS. This HTV capsule was the sixth mission to the ISS. This capsule can carry supplies, equipment, and also small satellites (i.e., cubesats and microsatellites) for redeployment via the Japanese Experiment Module, Kibo. With the new agreement to extend the lifetime of the ISS to 2024, Japan has agreed to develop the upgraded HTV-X transfer vehicle that may include a return capsule rather than being incinerated in the Earth's atmosphere (HTV-X Concept (JAXA) 1 (c)) (See Fig. 6).

The continuing problem that applies to Japanese launch vehicles is their high cost. One response that has been made to control costs has been the decision by JAXA and the Japanese government to turn the operation and construction of the HII vehicles over to the Mitsubishi Heavy Industries company and to seek to control the cost of the solid fuel boosters provided by US supplier Northrop Grumman-Orbital ATK (China's Long).

Fig. 6 The conceptual model for the Japanese HTV-X transfer vehicle

6 Long March 1 to Long March 9

Long March vehicles represent a wide range of capabilities from the smallest Long March 1 to the very heavy lift Long March 5, which is currently the largest of the Chinese rocket systems. This vehicle currently serves a largely Chinese market. The many launches associated with Chinese governmental programs are sufficiently large to support a very active domestic space program without major commercial launch services business.

The Chinese top heavy lift launcher, the Long March 5, has a diameter of 5 meters and a height of 57 meters. This vehicle is competitive to the launch capacity of the Ariane 5, Atlas 5, Delta 4, Falcon High Thrust, and Soyuz vehicles.

The July 2017 launch failure of this heavy lift launch vehicle for China has delayed the construction of the Chinese space station and its Chang'e lunar missions. Nevertheless, a redesign of this launch vehicle has been completed. This includes the new liquid oxygen and liquid hydrogen YF-77 engines, two of which power the Long March 5 first stage. This change is believed to be primarily aimed at correcting the turbopump issue that was reported to be the cause of the 2017 failure. China announced early in 2019 via its "Blue Book of China Aerospace Science and Technology Activities" that it would pursue perhaps the world's most active national space program. The ambitious objective was to launch 50 spacecraft through over 30 launches including three Long March 5 missions (Jones).

In addition to the planned ambitious launch agenda for the Long March 5, China has also now developed the Long March 6 and Long March 7 vehicles. These are smaller than the Long March 5. The Long March 6 is optimized to support the launch of 1080 kg to sun-synchronous orbits at an altitude of 700 km that can particularly support remote sensing missions (Archive of Long March 6). The Chinese Long March 7 is designed to lift up to 13,500 kg to low Earth orbit (LEO) (Archives Long March 7 Launch Vehicle).

Finally, the Chinese Academy of Launch Technology has announced plans for the very large capacity super heavy lift Long March 9 rocket as well as less specific plans for the Long March 8 that would be a partially reusable lift system that would recover the first stage and would be designed primarily for launch to sun-synchronous polar orbits.

The new Long March 9 rocket as currently announced would be more or less equivalent in lift capacity to the Saturn V used in the US Apollo program. This rocket would also parallel the lift capacity of the new Space Launch System (SLS) of the United States currently being developed by NASA for planetary missions. The SLS currently has an estimated first launch date around 2021 or 2022. This massive new Chinese launch vehicle is expected to have a weight exceeding 4,000 metric tons and would stand 93 meters high, which is the equivalent of a 30-story building. According to reports from the Chinese Academy of Launch Vehicle Technology (CALT), this rocket will be powered by newly developed 220 ton hydroxyl engines. It will reportedly have a lift capacity of 140 tons to low Earth orbit. With a suitable dispensing system, this type of super heavy lift system could deploy thousands of minisatellites for a low Earth orbit (LEO) constellation with a single launch (Berger).

7 Northrop Grumman Innovation Systems (Formerly Orbital ATK) (Antares, Cygnus Capsule, Minotaur, and Pegasus)

Northrop Grumman, through its subsidiary Northrop Grumman Innovation Systems (formerly Orbital ATK), provides a number of space launch vehicles that are capable of launching small, medium, as well as larger payloads to orbit. The smallest of these launchers is the Pegasus® rocket. This smaller rocket is very cost-efficiently launched from the company's "Stargazer" L-1011 carrier aircraft. The Pegasus has proven to be the industry's small space launch workhorse, having conducted 43 missions from six different locations worldwide since 1990. This launch vehicle launched one of the world's first small satellite constellations, the Orbcomm system for global store-and-forward messaging. Northrop Grumman's Antares space launch vehicle provides medium-class space launch for payloads weighing up to 8,000 kg. Omega™, Northrop Grumman's newest rocket, is currently in development for the US Air Force's Evolved Expendable Launch Vehicle (EELV) program. This is a new class of intermediate- and large-class launch vehicles.

The Minotaur® is a ground-launched rocket. This rocket combines Pegasus upper stages with larger decommissioned Peacekeeper first-stage rocket motors. The Minotaur can be used to boost larger payloads to orbit. Currently active are the Minotaur IV, V, and VI rocket configurations that are available to provide increased lifting capacity for government-sponsored payloads. Minotaur-C is a commercial Minotaur option for NASA and launch nongovernment-sponsored payloads (Space Launch Vehicles). Minotaur II designs also provided stage elements for the Antares launcher development.

The Taurus is yet another option from Northrop Grumman Innovation Systems, but this is being phased out of operation.

8 Rokot

Rokot is a Russian/USSR-developed rocket that derived from a USSR intercontinental ballistic missile that was originally known as the UR-100N (or the S-19 Stiletto). This launcher is marketed by the Eurockot Launch Services GmbH company that is based in Bremen, Germany. This launch vehicle is manufactured at the Khrunichev Space Center. It typically launches a payload of some 1950 kg into 200 km low Earth orbit (LEO).

There were three launches in 2019 of the Rokot (that translates as "Boom" in Russian) from the Plesetsk launch site. These launches were of communications and Earth observation satellites which were larger spacecraft, but the first of these launches of a Gonets-M satellite included piggyback launches of two small satellites that included an amateur radio satellite and an experimental small satellite for Geodesy measurements.

One of the more significant Eurockot launches was the Swarm of three small satellites for the European Space Agency (ESA) in September 2013. This Swarm network is measuring theEarth's magnetic field and the changes to the magnetic poles that may be currently beginning a reversal process. The cost of this launch was approximately $36 million or (27 million euros).

The status of the Rokot launch is currently under redefinition and will likely be redefined for any future missions (Eurokot).

9 Soyuz Launch Vehicle (See also Vega)

The Soyuz rocket system is manufactured by the Progress Rocket Space Center, which was formerly known as TsSKB-Progress. This is a Russian joint-stock company under the jurisdiction of Roscosmos State Corporation responsible for the Russian government space program. It is the developer of the famous Soyuz-FG rocket used for manned space flight, as well as Soyuz-U used for launching unmanned probes. Since 2013, both Soyuz-U and Soyuz-FG are gradually being replaced by the modernized Soyuz-2 launch vehicle (Soyuz) (See Fig. 7).

Soyuz rockets are now the only vehicle being used to ferry crews to and from the International Space Station. In addition, there are now commercial launches being operated from the Arianespace Soyuz CSG launch facilities that have now been

Fig. 7 Soyuz launch vehicle. (Graphic courtesy of the global commons)

Fig. 8 Soyuz with large payload and 3–200 Kg minisats and Vega with 5–200 Kg minisats. (Graphic courtesy of Soyuz)

configured at the Kourou launch center in French Guiana for Soyuz-2 commercial launches. There are also launch facilities at Kourou Launch Center for the new Vega vehicle. Figure 8 shows typical configurations for both Soyuz and Vega launches that include possible ways to provide lift to orbit for various 200 kg small satellites (Soyuz at the Guiana Launch Site).

10 United Launch Alliance (ULA)

United Launch Alliance (ULA) is a US launch provider that largely represents a joint effort of Lockheed Martin and Boeing, but other contractors now contribute to this overall effort. The Boeing-manufactured Delta 4 and Delta 4 Heavy are currently being phased out of service due to high costs. Recently, the marketing of the Atlas 5 has been transferred from Lockheed Martin to (ULA), and that is expected to help lower costs by having a single entity being responsible for marketing and launch arrangements. The main initiative to create a new heavy lift and cost-efficient launch vehicle is the development of the new Vulcan® rocket, with engines developed by Blue Origin, into service with the initial “trial launches” to be offered to commercial customers at reduced rates as it is being flight qualified. This represents a case of “conventional” launch providers, i.e., Lockheed Martin, and new entry companies, i.e., Blue Origin, joining forces (Foust 2018).

One of the objectives of the new Vulcan and Vulcan Centaur is to create a new cost-efficient launch vehicle designed toaccommodate deployment of microsatellites and minisatellites (typically in the 10–500 kg class).

11 Vega Small Launcher

Vega accommodates the launch of small satellites. Specifications related to minisatellites (200–400 kg),microsatellites(50–200 kg),ornanosatellites (<50 kg)have been set forth intheAuxiliary Passengers User's Manual for the Vega. There are many different options now spelled out with regard to auxiliary or "piggyback" launch options. These include the so-called Small Spacecraft Mission System to accommodate cubesats, nanosats, microsats, and minisats. The SSMS includes the PiggyBack HEXA 1, the PiggyBack HEXA 2, as well as other options.The rideshare table for Vega spells out at least six options. Vega C (consolidation) can send up to 2,300 kilograms (5,070 lbs) to low Earth orbit (LEO) – 60% more than Vega. The object of a new Vega Lite that is under study would provide an even smaller launcher. It would be designed to compete with Vector, Virgin Orbit, and Rocket Labs. The Vega C and Vega E configuration is designed to compete with such launch options as Taurus and Taurus XLS, Minotaur IV, Minotaur-C, Rokot, and Soyuz-2-Iv (Elizabeth Howell).

12 Innovative Launch Arrangements from the "Conventional" Launch Industry

The "conventional" satellite industry has sought to respond to the challenge that "NewSpace" launch companies have posed to business models. The high-cost systems such as Delta 4 and Delta 4 Heavy are being phased out, as they cannot be upgraded to make them competitive with SpaceX. Several launch service providers have tried to exploit the cost advantages of proven military missile technologies, such as the Northrop Grumman Innovation Systems, formerly Orbital ATK, has done with the Minotaur and Taurus vehicles.

There have also been efforts to launch from aircraft rather than traditional launch centers, adopting new avionics systems, attempts at more vertical integration, and development of reusable vehicles. There have also been many attempts to create launch configurations and small satellite dispensers. These range from the various configurations discussed above with regard to Ariane, Soyuz, Vega, to the amazing Indian Polar Satellite Launch Vehicle that in February 2017 put over 100 cubesats into LEO orbit. The Vulcan development by ULA even has simply adopted the Blue Origin engines to seek a new competitive pathway forward.

The bottom line is that the small satellite revolution that has demanded new, more creative, and lower-cost launch arrangements has forced the traditional launch companies to make changes by a wide range of innovations in launch design, manufacturing, components, and testing. Indeed, innovation has found ways to use the International Space Station and the Japanese Experiment Module and the Canadarm as innovative ways to deploy cubesats and microsats.

There has also been cooperation and strategic shift involving complicated cooperative arrangements with spacecraft manufacturers. The launch of constellations in LEO or larger satellites in MEO or GEO has now been planned to include hosted payloads so that some of the "new smallsats" are actually piggyback payloads that are riding inside of the satellites to be launched. In other cases, there have been new efforts to develop systems that operate in the stratosphere or what has been called "subspace" or the "protozone" to provide communications, remote sensing, or other services that do not require a launch into orbit at all.

The world of the space launch industry has changed, but not all of the innovations have come from the new entries like SpaceX, Blue Origin, Virgin Orbit, Rocket Labs, Virgin, or the 40 or so start-up companies that are seeking to create new launcher capabilities for small satellites as addressed in a separate chapter in this handbook.

13 Strategic and Risk Elements for the Space Launch Industry

And there is some risk in the space launch industry in becoming overly focused on the immediate challenges of the day. There are creative minds at work to examine new and even breakthrough ideas for the longer-term future. If there are major discontinuities with perhaps on the order of ten thousand small satellites to be launched in a year and then a lull for 7 years, this is clearly a large corporate challenge to face. But there is also the question of what disruptive technologies might come next.

It has been posited that in 50 years, the proposition that putting people and products and cargo on top of a controlled bomb may turn out to be considered odd, foolish, environmentally unsound, or at least un-clever. There are scientists and engineers who are looking into what might be done with rail guns, mass drivers, tether lift systems, and even the so-called space elevators or space funiculars. There are other ideas that involve lighter than air craft and dark sky platforms from which ion engines could fly small satellite systems to orbit.

And the challenge is not just better ways to access orbit, but also there is a need to develop new technologies to get space junk safely down from orbit. The current UN guideline for removal of spacecraft within 25 years of end of life of a satellite seems badly out of step with the idea of multiple mega-constellations of many thousands of satellites with an average lifetime of 7 years. The replenishment of the constellations every 7 years without removing the dead satellites creates untenable situation. The math simply does not work. Clearly, the launch industry of today that is busily innovating to cope with today's challenges must look to longer-term challenges as well.

14 Conclusions

The future of launch vehicle development seems divided into three types of markets. These are (i) launches of large satellites into GEO to support commercial video and global telecommunications and enterprise requirements; (ii) minisatellite constellations with masses typically in the 100–500 kg range for very large constellations in LEO and MEO orbits; and (iii) cube satellite (or nanosat) systems that are typically in the 1–10 kg range.

Exactly how the launch industry might best respond to these different needs is still not clear. The next 5 years, however, should give much definition to what types and range of sizes for launch vehicles will respond to these different needs in terms of launch schedules and types of spacecraft to launch.

The idea of very large high lift launchers that deploy hundreds or thousands of minisatellites might represent one option. The other option could be smaller but highly cost-efficient launchers that could be launched more nimbly. This is the market that many of the new commercial "NewSpace" rockets seemed to be aimed at servicing. "NewSpace" or "Space 2.0" initiatives are forcing the global space launch services industry to change and change quickly. Will the traditional launch providers regroup and win out over the new competition? Or will the disruptive technologies of the newest launch providers that are deploying a wide range of new technologies and systems in a new and powerful ways win out? Or will there be forms of mutual accommodation and thus new ways whereby the new systems will merge with the old? The move by the established United Launch Alliance to integrate the rocket motors being developed by Jeff Bezos' Blue Origin into their new Vulcan rocket seems to be yet another example of the "new" now merging with the "established" launch service providers. Another example might be the One Web System as it emerges from bankruptcy under new financing. This was originally planned to be deployed by a combination of Ariane 5, Soyuz, and LauncherOne vehicle by Virgin Orbit.

New Launchers for Small Satellite Systems

Carlos Niederstrasser and Scott Madry

Contents

Abstract

The “smallsat” revolution has created a new and immediate need for additional launch capabilities for a variety of small payloads, ranging from 1-U CubeSats to larger smallsats of various different designs and applications, ranging up to 500 kg or even larger. An important component of this new market is the variety not only of types of satellites and organizations building them but also the new, very large constellations that will be launching hundreds and even many thousands of small satellites that will drive many of the new launcher needs. Part 4.1 has covered the traditional and existing launch capabilities, such as Soyuz, Ariane, Delta, Atlas, the Polar Satellite Launch Vehicle, Long

March, etc. Other articles in this section also discuss several of the new launch options available and their smallsat capabilities and rideshare options as well. These launch options include (i) the SpaceX Falcon launchers; (ii) Blue Origin and their New Glenn launcher; (iii) the new Vulcan launcher that will be a part of the launch services offered by the United Launch Alliance; and (iv) the Ariane 6. In this chapter, the main objective is to consider the many new entrants into the launch industry in recent years that have specifically targeted this emerging new launch market but, in most cases, have not yet flown. The new launch vehicles that are being proposed and built for small satellite launches and how they will accommodate these many small satellite systems and their launch requirements are discussed.

1 Introduction

The previous chapters have covered the basics of smallsat launchers and the several, existing conventional launchers that provide services for the growing smallsat community. This chapter presents the very large number of new entrants into the smallsat launch market (USU Smallsat Conference website 2019). It is important to remember that the launch market, while the most visible (and loudest) part of space activities, is actually a very small part of the total space business. As shown in Fig. 1, the launch market in 2015 was some US$5.1 billion, and while this is a large number, it is only 1/3 of the satellite manufacturing market, and it is dwarfed by the space services, ground segment, and government operations aspects of the global space business. Launchers get much of the attention and press coverage, but the launch market remains a small part of the overall space market, and even with the several new entrants, this will not substantially change in the near term.

Although there are many kinds and definitions of smallsats, those developing the launchers and payloads must meet all of the regulatory, liability, telecommunications, and frequency requirements imposed on those who launch rockets and satellites into orbit. The regulatory aspect of both launching and operating satellites cannot be underestimated, even as the global space regulatory context changes. Launchers and satellites, no matter how small, must still be properly licensed by their national authorities.

2 New Launch Options for Smallsats

Launching a CubeSat or smallsat into orbit is the single largest item of expenditure for most CubeSat projects. Getting even small amounts of mass into Earth orbit requires a very large amount of energy, and today that is provided by chemical rockets that are very costly and also quite dangerous.

There has been explosive growth in the smallsat market, and this has shown a 23% increase between 2009 and 2018; this trend is seen to continue to grow through 2024 (Space News 2019). Some 322 satellites were placed into orbit in 2018, in a total of 44 individual launches. It is interesting to note that smallsats are made up 69% of these launches, as measured by satellites, while accounting for only 4% of the total launch mass. This is a major change in progress and one that likely will accelerate in the near future. The current generation of space launch vehicles was sized for payloads of several thousand kilograms, as the world moves into an era of ever smaller and smaller satellites.

2.1 The Second Small Launcher Revolution

There are approximately 80 new small satellite constellations that are being proposed for a variety of commercial services in the near future, consisting of thousands of new satellites. These include telecom/data/Internet of Things (IoT) systems, as well as remote sensing and data analytics systems. All of these, as well as the hundreds of other “Silicon Valley” space startups, CubeSat kits, and student projects, will require launch services.

The growth in the smallsat market, combined with the success of SpaceX, has led to a dramatic increase in the number of launch vehicles being developed to service this particular niche. This new trend has been further encouraged by several new government programs such as the European Union's Horizon 2020 and the American DARPA Launch Challenge.

Small launch vehicles are not new. In fact, many of today's heavy launch vehicles – Atlas V, Delta IV, Falcon 9, and Ariane 5 – all trace their origins to smaller rockets. Today's Atlas V has a direct heritage going back to the Convair Atlas SM-65 ICBM designed in the 1950s. This was the first US operational ICBM missile and the origin of the Atlas rocket family. It also was used for the first four American orbital astronaut launches in Project Mercury. It was 23.11 m tall, with a 3-m diameter, and carried a payload of some 1680 kg (Fig. 2).

Fig. 2 Atlas 2E Ballistic Missile on display at the San Diego Aerospace Museum, Gillespie Field, El Cajon, California. (Graphic courtesy of US Air Force)

Before embarking on larger launch vehicles, SpaceX and Arianespace both cut their teeth on smaller launchers like the Falcon 1 and Ariane 1, respectively. As the need for payload performance grew, largely driven by the increasing size and complexity of commercial, GEO telecommunications satellites, so too did size and capability of the rockets. Both governments and private industry found it more economic to field ever-larger launch systems, and satellite developers matched these capabilities with ever-larger designs in a positive feedback loop that led to mighty launchers such as the Ariane 5.

Of the small launchers in the early days of the Space Age, only the Scout has retained its small size. Even as the Scout became obsolete due to aging technology, a small niche remained for vehicles able to lift less than 1000 kg to LEO. In 1995, the Conestoga became the first fully commercially developed rocket to ever be launched; unfortunately its first and only flight resulted in a launch failure (Fig. 3).

Fig. 3 The Conestoga, the first truly commercial space launcher. (Graphic courtesy of Conestoga)

In 1990, Orbital Sciences Corporation deployed the Pegasus rocket, which used a Lockheed L-1011 wide-body airliner as the first stage, getting the Pegasus up to about 10,000 m altitude. Also developed largely on a commercial basis, Pegasus has gone on to become the workhorse of the small launch vehicle market, with 44 flights flown to date. Subsequently Pegasus was joined by Taurus, Athena, and the Minotaur I, which utilizes excess government military ICBM motors, recycled for commercial launch services (see Fig. 4).

The perceived need for small launchers in the 1980s and 1990s, which resulted in the development of Conestoga and Pegasus, was largely driven by new, large LEO telecommunications constellations such as ORBCOMM and Iridium. Ultimately the demand from these constellations and larger constellations like Teledesic failed to materialize, due to a variety of economic and regulatory factors. The resulting low launch rates, and competition from rideshares on larger vehicles, destined this generation of small launchers to high-priced niche markets. This created a significant barrier to low-cost new entrants. Twenty years later, the growth of CubeSats and new constellations such as Planet, OneWeb, and Starlink is creating a perception of new demand for small rockets. Planet is now considered the world's "largest constellation of Earth-imaging satellites" (Planet 2019) with over 400 satellites launched to date. SpaceX has filed an FFC license request for more than 30,000 satellites, and OneWeb has outlined plans for a constellation of more than 2,000 satellites, as described in other chapters in this volume. Others, including Sony, Amazon, and Apple, have recently made statements regarding creating their own satellite constellations.

Traditional rideshare and secondary payload opportunities, discussed elsewhere in this volume, fundamentally force the payload provider to compromise; the primary customer for these rockets controls all mission parameters such as schedule, destination orbit, safety requirements, etc. The smaller satellites simply "tag along" and accept whatever restrictions are placed on them by the primary customer. This lack of flexibility may be acceptable for small technology demonstrations or CubeSat academic projects, but it is not practical when launching an operational asset or fielding a large constellation.

Fig. 4 The Orbital Sciences L-1011 jet aircraft releases the Pegasus rocket carrying the Space Technology 5 spacecraft with its trio of microsatellites (2006). (Graphics courtesy of Northrop Grumman Innovation)

The expected growth in small satellite launch requirements, and the commercial and very visible success of SpaceX, has led to a new wave of proposed vehicles with payload capacities as small as a single 3-U CubeSat (roughly 5 kg) and as big as 1,000 kg, reaching the lower end of today's medium-class commercial launch vehicles. All of these new entrants are looking for an answer to the same "chicken and egg" question that confounded the small rockets of the 1990s – in order to be successful, large constellations need low costs, but costs can only be kept low if the launch rate is high and remains stable over time.

2.2 New Launch Vehicles

Today, there are over 140 different entities worldwide hoping to develop new small launch vehicles. A full review of these is provided annually, and the trends are all pointing toward a robust market (Niederstrasser 2019). Many of these newcomers are driven by purely commercial goals with visions of hundreds, if not thousands, of satellites launched every year. The coming of age of "New Space," friendly capital markets, and the successes of SpaceX and Planet have led many new entrepreneurs to start down the tortuous path of space rocket development. Others, seeing the appeal of government contracts as agencies like NASA, the DoD, and ESA, also have set their eyes on smaller satellites for their operational launch needs.

In the past 10 years, governments have started to encourage this new trend. The US Department of Defense and NASA are funding a variety of small launch vehicles while looking not just for traditional launch services but also for "launch on-demand" capabilities that are not currently offered. US programs like the new DARPA Launch Challenge (DLC) and NASA Venture Class Launch Services (VCLS) aim to provide enough incentive and guidance to these new fledging companies to bring them from PowerPoint presentations to actual launch systems. The DLC mirrors the prizes of the early aviation age and the successful, modern XPrize, with its goal to launch payloads with just a 14-day notice to a previously unspecified orbit. The successful team stands to win a US$2 million reward on the initial launch and US$10 million reward on the second launch within 2 weeks. To many of the small launch vehicle contenders, DARPA's interest makes a lot of sense. "[DARPA's] seeing the same scenarios or requirements that a lot of us are seeing — the need for more responsive access," said John Garvey, president of launch services at Vector, one of the three companies selected as a finalist in the DLC (Masunga 2018) (see Fig. 3). Showing the inherent risk in this endeavor, however, Vector has since entered into a bankruptcy phase due to financial issues (Fig. 5).

Government interest in small launch vehicles is not limited to the United States. ESA's Future Launchers Preparatory Programme or FLPP (ESA 2018) and studies funded through the European Union's Horizon 2020 (Oving et al. 2017) have both contributed the needed investment in the European market. Individual countries have also taken a new interest in small satellites. For instance, the United Kingdom has been actively exploring potential launch sites for many of the new entrants and

Fig. 5 Infographic describing the DARPA Launch Challenge. (Credit: DARPA)

announced the selection of at least four sites across the country to field both vertically and horizontally launched vehicles (Moore 2018).

Another new player in the area of small launch vehicles is China. China has had a robust government launch industry for many years, and in the past few years, they have increased their investment in small launch vehicles. Efforts in this area are led by government organizations, state-owned enterprises, and also new commercial companies claiming to be the first commercial space companies in the country. This is all part of a bigger space effort in China. The Beijing-based consulting firm Future Aerospace stated that there are over 60 private Chinese aerospace firms now in existence (Space Daily 2018), but the exact commercial nature of these is unclear. Commercial Chinese launch systems face a significant policy and regulatory barrier, as US payloads are prohibited by law from utilizing Chinese launch services, but this limitation does not apply to payloads from most other countries. So even if the US launch companies are not in direct competition with Chinese firms for American payload launches, they will see significant competitive pressure from their new Chinese counterparts, if they can demonstrate initial success.

As of October 2019, there are currently eight operational systems with payload capabilities of less than 1000 kg to LEO that are available on a semicommercial or commercial basis. The oldest and most successful of these is the Pegasus XL, originally fielded by Orbital Sciences Corporation, now part of Northrop Grumman. Five of these eight operational systems are Chinese, and although it is expected that they will be offered commercially outside of China, this has not yet happened. The newest non-Chinese rocket in this category is the Electron, developed by Rocket Lab, based in the United States and New Zealand. After a failure on its maiden flight in 2017, Electron has launched eight times with 100% success rate, and has recently added a second launch pad in Virginia, and is adding another second pad to its

China Rocket Co., Ltd.	Jielong 1	China	17-Aug-2019

existing launch facility in New Zealand (see Fig. 6). Other systems like the Israeli Shavit or the Iranian Safir also fall roughly into this performance class, but are not listed in Table 1 due to their limited availability outside of their country of origin.

Beyond these operational systems, there are over a hundred of new systems currently under development worldwide. Some are little more than paper and PowerPoint designs by three people in a garage, while others are well-established startups or subsidiaries of multinational corporations with hundreds of millions of dollars in funding. All of these share the aim to dramatically increase the ease of access to space for small satellites. As has been previously stated, this is a trend that is not limited to the United States. While the United States continues to have the largest share of new vehicles under development, China has a significant number of new entrants as well. Spain and the United Kingdom are also well represented due to significant recent investments in the industry made by their respective governments. Other efforts come from countries as varied as Brazil, India, Singapore, South Korea, Turkey, and many others.

3 Design Developments

With so many vehicles under development, it is not surprising that each new entrant is trying to find a distinguishing characteristic that will allow them to differentiate their products and services from their competitors in what is shaping out to be a very crowded field. One of the key areas of differentiation is the way the rocket is launched. Until 1990, every single space launch rocket ever flown had launched in the same fashion – from a ground-based launch pad somewhere on terra firma. In 1990, Pegasus became the first launch vehicle to be dropped from an airplane, rather than take off from land. At least one commercial Russian launch has been made from a military submarine, in 1998, when a converted submarine ballistic missile was launched in the Barents Sea carrying two small German satellites, TUBSAT-N and TUBSAT-N1 (Space Today Online 2003). In 1999, a Zenit launcher from Sea Launch became the first to take off from a floating, sea-based platform, taking advantage of a launch at the equator. New vehicles under design are still dominated by traditional, land launch-based concepts, but a significant number of them are being designed to be launched from a sea platform or from an airplane first stage. Other previously untried methods, such as balloons and electromagnetic rail guns, are also under consideration.

For example, the Spanish firm Zero 2 Infinity, founded in 2009, proposes utilizing a stratospheric balloon system to lift the rocket (dubbed rockoon) to approximately 30 km altitude, where it would then ignite its engines and commence its ride to orbit. The expected benefit of such an arrangement derives from the rocket being above most of the Earth's atmosphere at ignition, thereby significantly reducing drag and required fuel. Like other air-launched systems, it also offers the benefit that it can be launched from virtually anywhere with limited ground infrastructure and support. This can result in a fundamentally different vehicle configuration. The Zero 2 Infinity Bloostar uses concentric toroidal stages rather than the traditional cylindrical tandem stages (see Fig. 7). A total of 13 methalox engines are arranged in three stages, with engines dropping off in turn in groups similar to traditional staging. The system is designed to place 140 kg into LEO and 75 kg into sun-synchronous polar orbits for remote sensing applications. The company claims multiple launch customers, but the system has not launched at this time.

Even less traditional systems are also under development. A number of systems impart most of the vehicle's kinetic energy at the start of the launch rather than through a traditional chemical rocket system. SpinLaunch is proposing the use of spinning "kinetic energy-based launch system" that would impart initial acceleration to hypersonic speeds. Other companies are looking at electromagnetic rail guns or gas guns to provide the initial acceleration. None of these systems are near production at this time.

Fig. 7 Zero 2 Infinity Bloostar rocket prototype deployed from a stratospheric balloon. (Credit: Zero 2 Infinity)

Beyond the launch method, new entrants are looking at a variety of new technologies and propellants as they develop their systems. Additive manufacturing, or 3D printing as it is colloquially known, is utilized by a large number of the new launch systems. The use of 3D printing of engines can lead to engines that are simpler with a significantly lower number of moving parts and hence could potentially increase vehicle reliability and reduce cost. Some companies, like Relativity Space, are taking this a step further, as they 3D print the bulk of their entire rocket rather than using traditional rolling and welding techniques for tanks and other pressure vessels. The search for safer, more environmentally friendly, or higher-performing propellants has some companies moving away from the traditional chemical rocket propellants to new combinations like hydrogen peroxide and kerosene, fuming nitrous acid and turpentine, and other undisclosed, proprietary propellant mixes.

4 Performance and Cost

Although this chapter addresses small launch vehicles in general, not all new entrants have the same performance. Over half of the new small launch vehicles have payload capabilities in the 150–500 kg to LEO range, similar to what is available with older systems such as the Pegasus or Minotaur I. Other systems are aiming for larger capability of 1000–1500 kg to LEO, bringing them closer to the domain of “medium lift” rockets such as the now retired Delta II. On the other end of the spectrum, several new vehicles are aiming to service the very small market, with some planning to carry under 10 kg to LEO, sufficient for just one or two CubeSats. This broad range of payload capabilities illustrates the uncertainty in the small launch vehicle market. There are widely differing opinions on which class payloads are likely to experience the most growth and will become niche markets.

This market uncertainty is also evident in the proposed launch costs for the new vehicles. Although common wisdom would seem to dictate that lower cost should be the primary goal for a new system, this is not true for the majority of companies trying to enter the market. The primary advantage of dedicated small launchers (compared to traditional rideshares) is operational flexibility. Some have equated this difference to a bus versus a taxi. In a rideshare (bus) service, the secondary payload provider has a very little say on the exact schedule and ultimate orbital destination, being held captive to requirements of the primary payload. With a dedicated (taxi) services, the small satellite is the primary payload and thus has a significantly greater say on operational requirements such as schedule and orbital destination. As a result the cost per kilogram for most of the new small launch vehicle entrants is in the neighborhood of $20 k/kg to $40 k/kg, which is significantly higher than the cost per kilogram on larger rockets such as the Falcon 9 ($2.7 k/kg for the reusable variant). That is not to say that low cost is not important for many of the new providers. Indeed, some of the newer technologies, such as the additive manufacturing discussed previously, are aimed at reducing vehicle costs.

Future cost containment is also important to continued market success of the vehicle, since many efforts in the past have seen their costs grow significantly after the initial launch. To contain cost growth, it will be important for new vehicles to have high flight rates. Many of the new entrants are aiming at 50 flights per year. As a reference, the most prolific launcher in 2018 was the Falcon 9 with 20 launches. This, once again, points to the “chicken and egg” problem previously referenced. To achieve the desired flight rates, the new vehicles will have to rely on the mega-constellations, and for these constellations to be successful, low launch costs will be key. Unfortunately, for small launch vehicles, mega-constellations often have dozens of satellites in the same orbital plane, which makes multiple-satellite launches on large rockets more efficient. The ability to achieve high flight rates is another large market unknown facing the companies and entrepreneurs entering this field.

5 Funding the Revolution

Even amid all these market uncertainties, capital for new rocket developments has been plentiful. With the noted exception of Pegasus, every successful launch system before the 2010s relied almost exclusively on government funding and the promise of government purchases for its development and initial deployment. Today, national governments continue to be an important source of funding, but they are not the only source. Some of the new entrants are entirely founder-funded, relying on the deep pockets of their founders. Others are funded through venture capital, prizes, and other mechanisms. Somewhere between $1.5 billion and $2.5 billion has been invested in the small launch industry over the past 10 years.

The variety of funding available is as broad as the vehicles themselves. In addition to national governments, local governments such as the Gobierno de Aragon (Spain) and government development funds like the Saudi Industrial Development Fund contribute capital as investors in the company. Beyond government entities, private equity is also playing a significant role in the industry, demonstrating a growing investor confidence in this emerging field. Investors range from specialized seed investors, such as Space Angels, to well-known venture capital firms such as Khosla, Huaxing Growth Capital, and Sequoia Capital. Whether traditional venture capitalists are ready for the higher risks and longer development time cycles of launch vehicles remains to be seen. One of the most advanced efforts, Vector Launch, Inc., filed for bankruptcy after Sequoia Capital declined to provide additional funding to the company (Gladstone 2019).

Beyond government and venture capital, some efforts have been funded by billionaires hoping to leave their mark in the growing space industry. Jeff Bezos (Blue Origin) and Elon Musk (SpaceX) are well known for their investments in large launch systems. Other billionaires such as Microsoft founder Paul Allen and Indian actress Deepika Padukone have invested in smaller launchers. Billionaire investment does not come without its pitfalls however. Stratolaunch, an effort to launch rockets from the world's largest airplane, suffered a significant setback when its primary funder, Paul Allen, passed away. The executor's of Mr. Allen's estate did not have the same interest in space ventures as Mr. Allen, and Stratolaunch was sold to other investors and changed its mission from space launch to hypersonic vehicle testing.

Regardless of the funding source, the need for significant amounts of capital is the one constant among launch system development. Rocket Lab is reported to have raised $288 million over several rounds (Foust 2019). This largely mirrors reported development costs for SpaceX's Falcon 1 or Orbital Sciences' Pegasus. The credibility of an organization that states they can develop a new launch system for significantly less than that needs to be assessed carefully. Thus it is not surprising that, even as new players emerge, a number of efforts have already collapsed under the immense technical and financial challenges of developing a new launch system. The aforementioned Vector Launch is only one of several firms that have filed for bankruptcy or ceased operations.

6 Conclusion

The "smallsat" revolution now underway has created a strong requirement for new launch systems that are specifically designed for smaller payloads. There is also an increasing interest in "launch on-demand" services. There is likely to be significant growth in the smallsat launch services market over the next several years. This will be serviced by an interesting mix of new and existing launch providers like SpaceX, Blue Origin, United Launch Alliance, ISRO, Ariane, rideshares on other launchers, deployments from the International Space Station, and new, small launch entrants like the Electron. Indeed there are a very large number of new smallsat entrants, over 140 at this counting, but most of these will not survive to see their first launch. Many more nations are entering this new market, with China taking a large role at present. Small launch vehicles are within the technical capabilities of a wide range of nations, including Brazil, Israel, the United Kingdom, and Iran, among others. There are new and innovative approaches being taken, including launches from balloons and also new fuel types being considered. Additive manufacturing is rapidly maturing and will play an increasingly large role in the construction of both satellites and rockets. The requirement for "launch on-demand" and dedicated smallsat launch options will likely make several new small launch systems successful, but the overall picture remains uncertain and perhaps will not be clear until a decade or so from now.

Smallsat Rideshares and Launch Aggregators

Scott Madry

Contents

Abstract

The "smallsat" revolution has created a new and immediate need for additional launch capabilities for a variety of small payloads, ranging from 1U cubesats to larger smallsats of various different designs and applications, ranging up to 500 kg, and indeed some definitions even include satellites up to 1,000 kg as "small." An important component of this new market is the wide variety of types of small satellites and the expanding nature of organizations building them. One of the most critical factors in sizing the launch market for small satellites is the rapidly expanding number of the proposed very large constellations. Many of these constellations envision the launching of hundreds and even many thousands of small satellites that will drive the size of launcher market and dominate new launcher offerings. Earlier chapters in this section have covered the traditional and existing launch capabilities and how they might be configured to launch small satellites – particularly for small satellite constellations. Thus, the first chapter in

this section has considered well-established launchers such as Soyuz, Ariane, Delta, Atlas, the Indian Polar Satellite Launch Vehicle (PSLV), etc. The second chapter in this section covers the new small launch options. In this chapter, the focus is on the several existing and available rideshare launch vehicle options and how they can accommodate small satellite launch needs. It will also consider the new and rapidly evolving business of "smallsat launch aggregators" which provide the service of working with cubesat and other component manufacturer needs for the services of an experienced integrator who can manage all of the regulatory and engineering processes and who will work with the launch provider or even make all of the arrangements for the launch.

1 Introduction

The previous chapters have covered the basics of smallsat launchers, the several, existing conventional launchers that provide services for the growing smallsat community, and the many new small launchers in development. In this chapter, the focus is on rideshare options that are currently available and the future expansion of these options as additional launch aggregators emerge. In short, it addresses the new market of smallsat aggregators. It is important to remember that the launch market, while the most visible, and certainly the loudest part of space activities, is actually a very small part of the total space market. As shown in Fig. 1, the launch market is typically on about 2% or so of a $300 billion plus overall space market. It is typically only about a third of the satellite manufacturing market, and it is dwarfed by the space services, ground segment, and government operation aspects of space. Launchers get much of the attention and press coverage, particularly when they fail, but the launch market remains a vital but small part of the space market, and this will not substantially change in the near term as new launcher developments make launchers more cost-efficient and more broadly available for smallsats.

There are many kinds and definitions of smallsats, and the boundaries are shifting as the new industry grows and matures. Smallsats, nanosats, cubesats, microsats, minisats, and more are being produced by more and more entities around the world. The number of proposed large-scale constellations keeps accelerating. All of these

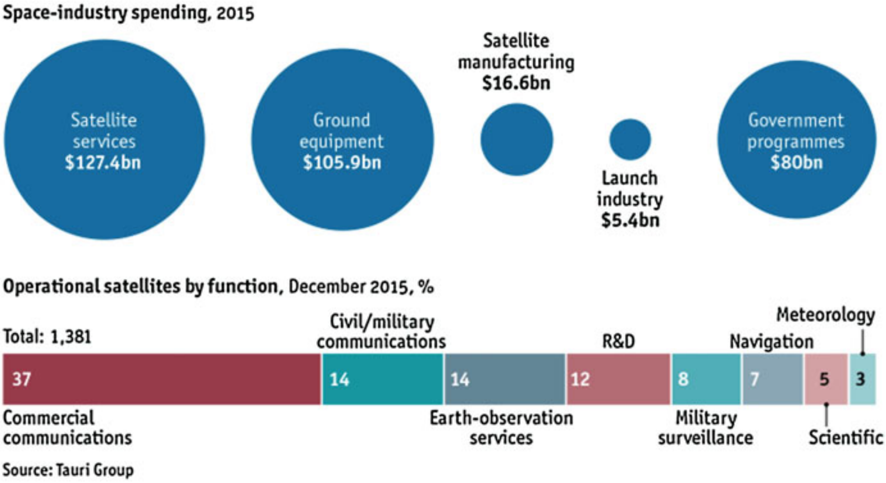

Fig. 1 Overall space industry spending. (Image courtesy Tauri Group/Satellite Industry Association)

ultimately require launchers, and they also must meet all of the regulatory, liability, and telecommunication requirements to be launched into orbit. It is a time of new opportunity but also of some confusion and turmoil.

While we have a very large number of new small launch entrants, there is an equally interesting and active new market consisting of companies who will act as an integrator and provide a middleman service for cubesat and smallsat developers, and these often arrange for smallsat launches. Most university cubesat builders have little to no experience in what is actually required in getting their project launched and have no knowledge of the requirements for integrating a payload into a launch manifest or the regulatory, telecommunications, power, and safety requirements of individual launch providers. This has created the new market of cubesat and smallsat launch aggregators, who provide this service, in addition to arranging the actual launch. The launch can also be the most expensive aspect of a cubesat project, and it requires skills well beyond those needed to build a cubesat at a university or startup. National policy, intellectual property requirements, ITAR restriction, and more place burdens on smallsat developers that can be confusing and smallsat aggregators can provide the needed skills and perspective to navigate this aspect of launch.

The original source of launch services for cubesats and smallsats was piggyback launches and launches provided by decommissioned military ballistic missiles. At first, many cubesats were launched on decommissioned Russian rockets through companies like Eurockot and Kosmotras, and the launch costs were about US$50,000 per single U cube on Kosmotras. Kosmotras was founded back in 1997 to use the Ukrainian Dnepr rocket launch systems, which was based on the SS-18 ICBM rocket that was no longer in military service due to international missile treaties. This vehicle could serve very well as a commercial satellite launch vehicle and did so for many years and at a very low cost. The company was a joint Russian

(90%), Ukraine, and Kazakhstan venture that launched commercial payloads from both the Baikonur Cosmodrome in Kazakhstan and the Yasny facility in Russia. The three-stage system successfully launched 21 commercial missions, including a 2014 flight that launched a total of 33 smallsats, a record at that time. This was the first aggregated smallsat mission, which launched various satellites for commercial and educational customers from 17 countries around the world (https://spaceflightnow.com/2015/02/06/customers-assured-of-dnepr-rockets-nearterm-availability/) (see Fig. 2).

Several successful launches were made, including low-cost smallsat payloads brokered by Kosmotras, but with the deteriorating Russian political and military situation with Ukraine, the venture no longer operates. But it led the way in demonstrating that there is a market for commercial smallsat launchers and for smallsat aggregators.

Eurockot Launch Services, GmbH, was founded in 1995 as a joint venture between the ArianeGroup and the Russian Khrunichev State Research and Production Space Center. It was founded to launch payloads from the Plesetsk Cosmodrome in northern Russia and has provided several commercial launches, starting in 2000, using the Russian Rokot vehicle. Plesetsk is some 800 km north of Moscow and is used primarily for remote sensing payloads launched into

Fig. 2 Dnepr rocket launching the German TanDEM-X satellite from Baikonur. (Image courtesy DLR. https://www.dlr.de/media/en/desktopdefault.aspx/tabid-4986/8423_read-15607/8423_page-2)

polar, Sun-synchronous orbits (SSO). The Rokot is a Russian SS-19 liquid-fueled ICBM, converted to commercial use. There have been 26 successful (out of 28 attempted) launches through 2018, but the venture is now “under redefinition” according to its website and is no longer accepting new missions. These two retired Cold War intercontinental ballistic missile systems, converted to peaceful uses, led the way for others to follow.

2 Cubesat Launches from the International Space Station (ISS)

The ISS has proved to be an excellent point from which to launch cubesats and smallsats, and this has now become a common occurrence. The Japanese Kibo module, because of its external airlock, can be used to launch cubesats, as shown in the images below (see Fig. 3).

The JEM Small Satellite Orbital Deployer (J-SSOD) is a JAXA-developed device that allows cubesats to be loaded on a Japanese HTV-3 ISS replenishment vehicle for deployment from the Kibo airlock. It was the first of such system and was first used in 2012, when 12 cubesats were successfully deployed using this system. It can load six Us at a time per airlock operation. Cubesats are loaded and launched from within the pressurized compartment and can be tested and checked out by the ISS crew before deployment. The Japan Manned Space Systems Corporation (JAMSS) provides smallsat launch services through the ISS and the Japanese H-llA launchers, starting in 2014. They provide all interface coordination, safety requirements and documentation review, logistical services, and technical consulting for cubesats up to microsats up to 50 kg (https://digitalcommons.usu.edu/cgi/viewcontent.cgi?referer=https://www.google.com/&httpsredir=1&article=3264&context=smallsat). Over 30 smallsats have been launched so far, dating back a decade to 2009 (Fig. 4).

Fig. 4 The J-SSOD on the ISS deploying three 1U cubesats. (Images courtesy JAXA)

3 NanoRacks "Concierge to the Stars"

The American company NanoRacks was founded in 2009, and they have developed a variety of commercial capabilities for the ISS. In 2013, after successfully launching a cubesat using the J-SSOD, they requested permission to develop their own commercial cubesat launch capability, and the NanoRacks CubeSat Deployer (NRCSD) was launched to the ISS in January of 2014 on an Orbital Sciences (now Northrop Grumman Innovation) Cygnus vehicle, preloaded with a total of 33 small satellites. This was the first commercial cubesat launch capability on ISS, and it has several advantages, including a larger 48U capacity. It is a self-contained cubesat deployer system that mechanically and electrically isolates cubesats from the ISS, cargo resupply vehicles, and ISS crew, thereby reducing the regulatory and safety complexity and cost of launching from the ISS (http://nanoracks.com/wp-content/uploads/NanoRacks-CubeSat-Deployer-NRCSD-Interface-Definition-Document.pdf). It can be launched from Earth, already loaded with cubesats, by several different vehicles to the ISS, and is then grabbed by the ISS arm and placed in the correct orientation for the remote launch of the satellites by the ISS crew. The smallsats never enter the station's pressurized modules, and so the system is far simpler. NanoRacks acts as the payload integrator and handles all safety

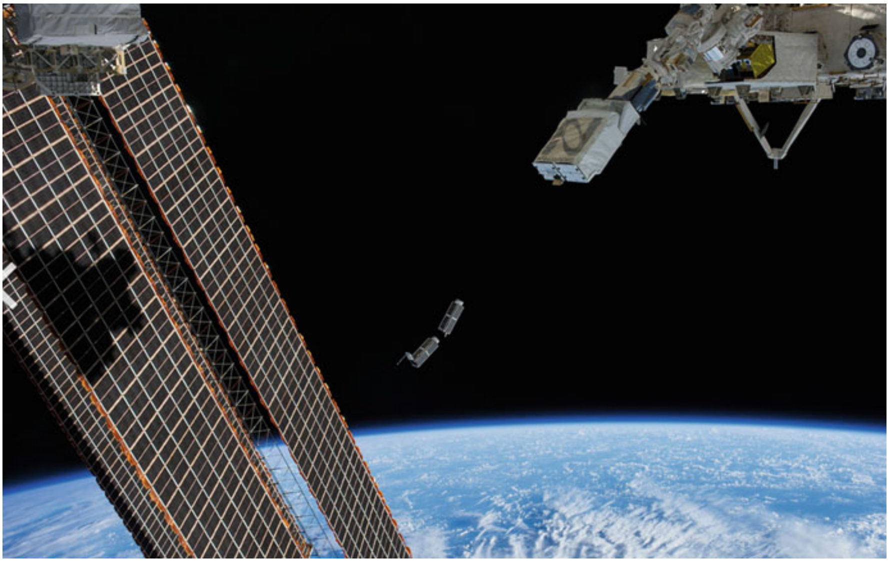

Fig. 5 Two 3U Planet Dove satellites being launched on January 25, 2014, from the ISS by the NanoRacks CubeSat Deployer, attached to the Japanese remote manipulator arm. (Image courtesy NASA)

documentation, regulatory approvals, and NASA requirements for its customers as part of its launch business services. As of this writing, NanoRacks has facilitated over 580 payloads, including many experiments as well as smallsats to the ISS, including the launch of multiple cubesats (Fig. 5).

Cubesats can be launched to the ISS aboard any of the various resupply options and loaded into the Kibo airlock for launch or launched using the NRCSD externally. Of course, this limits the satellites to the ISS orbital inclination and altitude (51.6° and approximately 400 km). Another limitation to using the Kibo airlock is that, because the payloads are taken aboard the living spaces of the ISS, all cubesats must meet the very strict ISS safety and documentation process, which is complex and very detailed, and adds cost and complexity to the cubesat development process. The NanoRacks system avoids this limitation.

NanoRacks is now working with Boeing to develop, launch, and operate a new airlock from the US segment of ISS, providing similar capabilities from the American part of the station specifically for smallsat deployment.

In order to get around the ISS orbital altitude and inclination limitations, NanoRacks has developed the External Cygnus Deployer (E-NRCSD) system. This innovative approach uses an NRCSD, loaded with up to 36U of cubesats, which is launched to ISS on a Cygnus resupply vehicle, and which remains attached to the Cygnus during its stay there. Once the Cygnus is loaded with trash and separates from the ISS, instead of simply deorbiting immediately, it is boosted up to a 500 km orbit, well above the ISS orbit, and the satellites are then deployed

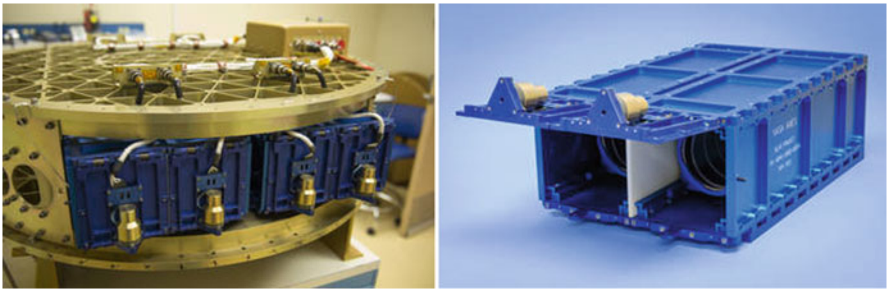

Fig. 6 The NASA Ames NLAS dispenser. (Images courtesy NASA)

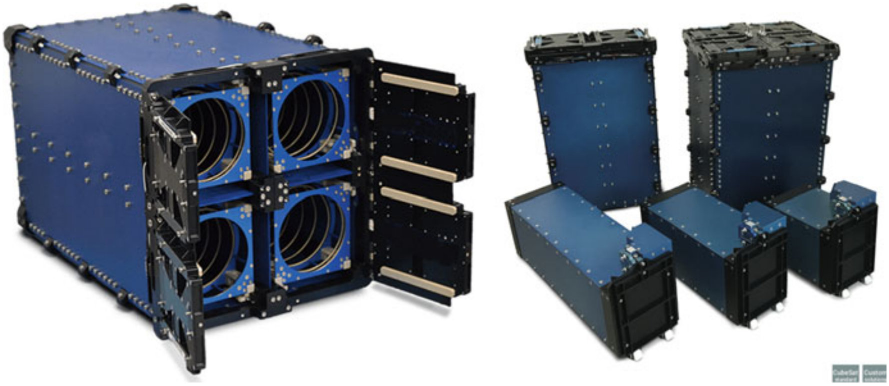

Fig. 7 The ISIS Quadpack CubeSat Deployer in various sizes. (Image courtesy ISIS)

remotely from there. This system has flown three times in 2016 and 2017, successfully launching multiple satellites.

NanoRacks has not stopped at servicing the ISS. They have signed agreements with ISRO of India to provide similar systems to launch into polar, Sun-synchronous orbit from the Indian Polar Satellite Launch Vehicle (PSLV), and they have also signed an agreement with Blue Origin to market microgravity research payload services on the New Shepard suborbital vehicle.

There have been several other cubesat deployment systems developed, including the NASA Ames Nanosatellite Launch Adapter System (NLAS) shown below. The system includes four dispensers for up to 24U, an adapter frame to mate with various launch vehicles, and a sequencer to control the system. It can accommodate from 1U to 6U payloads, and multiple adapters can be mounted on the same vehicle (see Fig. 6).

The Quadpack is an unpowered European 12U cubesat deployment system developed by ISIS in the Netherlands. It is a system develop outside of US-ITAR trade restrictions and so avoids US export limitations. It has flown multiple payloads dating back to 2014 on Falcon 9, Soyuz, Indian PSLV, and Dnepr launch vehicles (see Fig. 7).

3.1 The Payload Orbital Delivery System (PODS)

Space Systems Loral has developed the PODS system to provide frequent and cost-effective access to near GEO for smallsat payloads. This concept uses commercial GEO satellites built by SSL to carry smallsat payloads to near GEO for deployment. It provides power and can accommodate smallsat payloads of up 75 kg.

3.2 Beyond the ISS: Shared Missions

There have been multiple opportunities for smallsat and cubesats to ride as small, parasite, or shared payloads on larger launches with a prime customer. For traditional launch vehicles like Ariane V, Delta, Soyuz, etc., the added mass of a few cubesats is minimal, but there must be an interface system for power, deployment, etc. In the early years, each launch provider developed their own, unique adapter structure, and this was done for the ESA Vega, Ariane V, Delta, and more. What was needed was a standardized adapter system that could be used on multiple vehicles.

3.3 ESPA: The EELV Secondary Payload Adapter

Establishing standard payload interface capabilities has been an important step forward in making commercial, shared launch missions practical. The ESPA adapter was originally developed in the 2000s to launch secondary payloads on US Defense Department space missions from Atlas V and Delta IV Evolved Expendable Launch Vehicles (EELV). The adapter design has become a de facto standard and is now also used for many government and private spacecraft missions as well (https://arc.aiaa.org/doi/abs/10.2514/6.2001-4701) (Fig. 8).

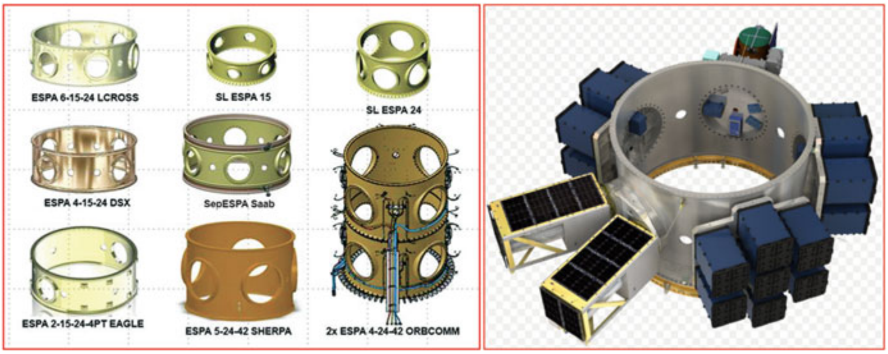

Fig. 8 Multiple ESPA rings were used on a recent launch of the SpaceX Falcon 9 that carried the Orbcomm OG-2 constellation of data networking satellites. (Images courtesy Spaceflight Industries)

3.4 Spaceflight Industries

Seattle, Washington-based Spaceflight Industries was founded in 2010. Its business is to aggregate cubesats and other small, secondary payloads to fly as secondary payloads on various different commercial launchers from around the world. It also operates a geointelligence company, BlackSky, which operates high-resolution remote sensing satellites and provides custom imagery data analytics.

In order to facilitate their rideshare business, Spaceflight has developed its SHERPA system, which provides the structure, power, data, and other required interfaces for multiple satellites. SHERPA is a commercial additional development of the ESPA system but which also contains an optional kick motor to allow for orbital changes and which also provides power for the satellites after separation from the booster rocket. The first SHERPA multi-payload adapter ring was to fly on a test flight aboard a Falcon 9 rocket in 2016, but this was delayed, and it was used to fill a Falcon 9's entire launch capacity on a December 2018 mission. This mission flew a total of 64 individual satellites for 51 customers from 14 countries, all of which flew on a Falcon 9 rocket into a Sun-synchronous orbit. It was the third launch of this Falcon 9. All satellites deployed nominally (see Fig. 9).

There are at least four versions of the SHERPA, either existing or in development, including small, unpowered systems with a small sail to passively decrease the release orbit and a large system with a kick motor designed to put satellites into a Geo Transfer Orbit (GTO). As of this writing, there are no new announced missions for the SHERPA.

European launchers have also kept pace with offering rideshare capabilities, and ESA has the P-POD deployment system for their Soyuz rocket's ASAP-S platform. This can accommodate several small payloads for each mission, and over 50 smallsats have been launched on both the Soyuz and Vega launchers, with more to come. Several of these have been a part of the ESA "Fly Your Satellite" program (https://www.arianespace.com/mission-update/a-trio-of-miniaturized-satellites-are-ready-for-launch-on-arianespaces-next-soyuz-mission/), where students are given the opportunity to build and fly cubesats as a part of their participation in the ESA Academy (Fig. 10).

NASA has a similar program, called the CubeSat Launch Initiative (https://www.nasa.gov/content/about-cubesat-launch-initiative). Since its beginning, some 85 missions have flown on 22 Educational Launch of Nanosatellites (ELaNa) flights on multiple launchers, including from the ISS, with 34 more on the manifest. These have included the first elementary school cubesat and the first built by a tribal college, among others. NASA provides the launch, but does not fund the development or building of the satellites themselves (Figs. 11 and 12).

4 The New SpaceX Rideshare Program

The rapidly evolving world of smallsat launchers like Rocket Lab and smallsat aggregators like Spaceflight Industries were quickly changed in August 2019, when SpaceX Chief Elon Musk announced that SpaceX will now offer monthly "Rideshare"

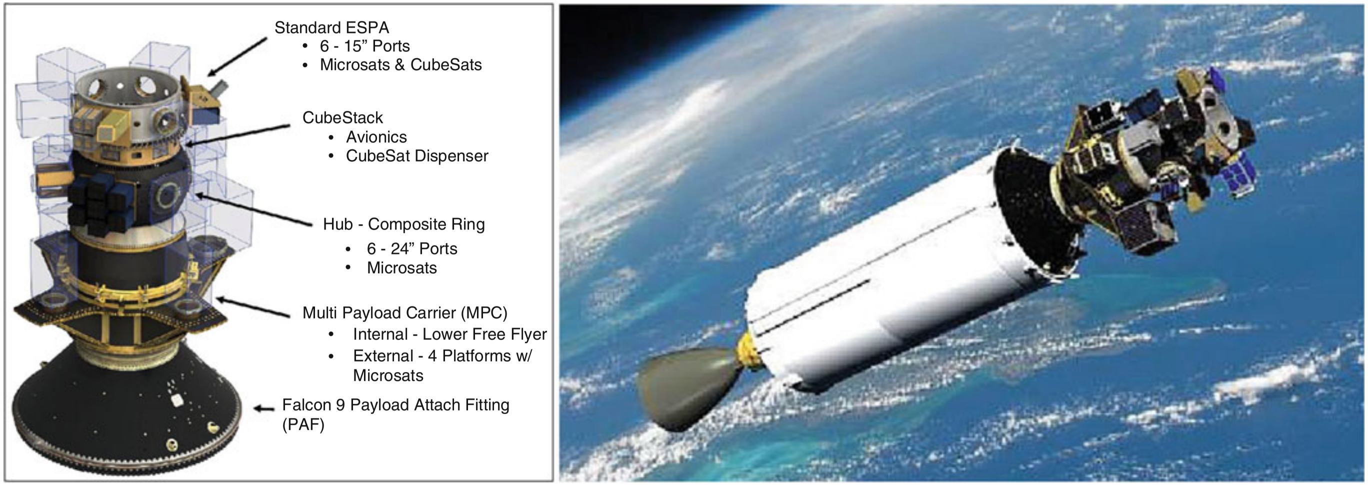

Fig. 9 The Spaceflight SHERPA bus with multiple payloads, attached to the SpaceX Falcon 9 upper stage. (Images courtesy Spaceflight Industries)

Fig. 10 Image of the potential smallsat mass available on the Soyuz and Vega launchers. (Image courtesy Arianespace)

Falcon 9 scheduled smallsat and cubesat launches to Sun-synchronous orbits (https://spacenews.com/spacex-revamps-smallsat-rideshare-program/). Always the disruptor, Musk has decided to take a major share of the smallsat launch market using his existing Falcon 9 launch schedule. He has announced a regularly scheduled, three launches per year offering, from Vandenberg, into polar Sun-synchronous orbit (SSO), that will charge only US$1 million for up to 200 kg, with launches starting in March of 2020. This is less than half of the cost originally stated by SpaceX and is a significant reduction in price over existing operators, at US$5,000 per kg if the full 200 kg is filled or just $10,000 per kg if only half of the 200 kg allocation is filled.

Musk has observed that airlines do not wait to fill an airplane before departing; Musk also announced that the launches would proceed on schedule, even if some customer's payloads were not ready, with those requiring a later launch paying

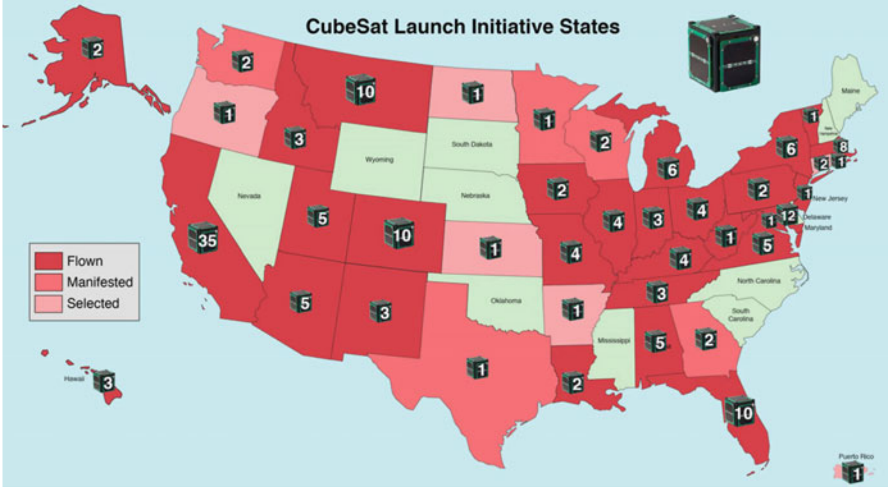

Fig. 11 Number of satellites per state launched by the NASA CubeSat Launch Initiative. (Image courtesy NASA. https://www.nasa.gov/content/about-cubesat-launch-initiative)

a small fee to roll over to the next launch (https://spacenews.com/spacex-says-rideshare-missions-will-launch-on-time-even-if-partly-empty/). The first scheduled launch will be a previously launched Falcon 9 to Sun-synchronous orbit in March of 2020. Launches will proceed on a quarterly basis thereafter. SpaceX will also routinely offer extra space on their many upcoming Starlink LEO launches and on other commercial launches with excess capacity. While SpaceX has said that they intend to continue to work with smallsat aggregators like Spaceflight Industries, this very low-cost and regularly scheduled smallsat launch service is very bad news for the many new, smallsat launch entrants and aggregators. SpaceX will likely command a significant fraction of the smallsat launch market with their proven launchers, regular schedule, and very low cost. They have also recently announced the return of polar Sun-synchronous orbit (SSO) flights out of Cape Canaveral, offering such missions from Florida for the first time in many years.

Arianespace has also entered this market and will offer a Vega smallsat launch in the first quarter of 2020 and also now has longer-term plans for a reusable launcher. Blue Origin likewise is seeking to bring a reusable launcher to market. India is developing a new Small Satellite Launch Vehicle that will be sized for small satellite payloads as well. This will be offering 500 kg to LEO and 300 kg to SSO. This will be a solid rocket design intended to provide very low-cost smallsat services either directly or through aggregators. The problem is that most of the new small launchers, including those by Vector, Virgin, and Rocket Labs, will have prices that are typically in the $30,000–80,000 per kg. With launch price offerings in this range, there may be an ongoing struggle by small satellite launcher organizations as discussed elsewhere in this handbook to be competitive with those who are developing reusable launch systems.

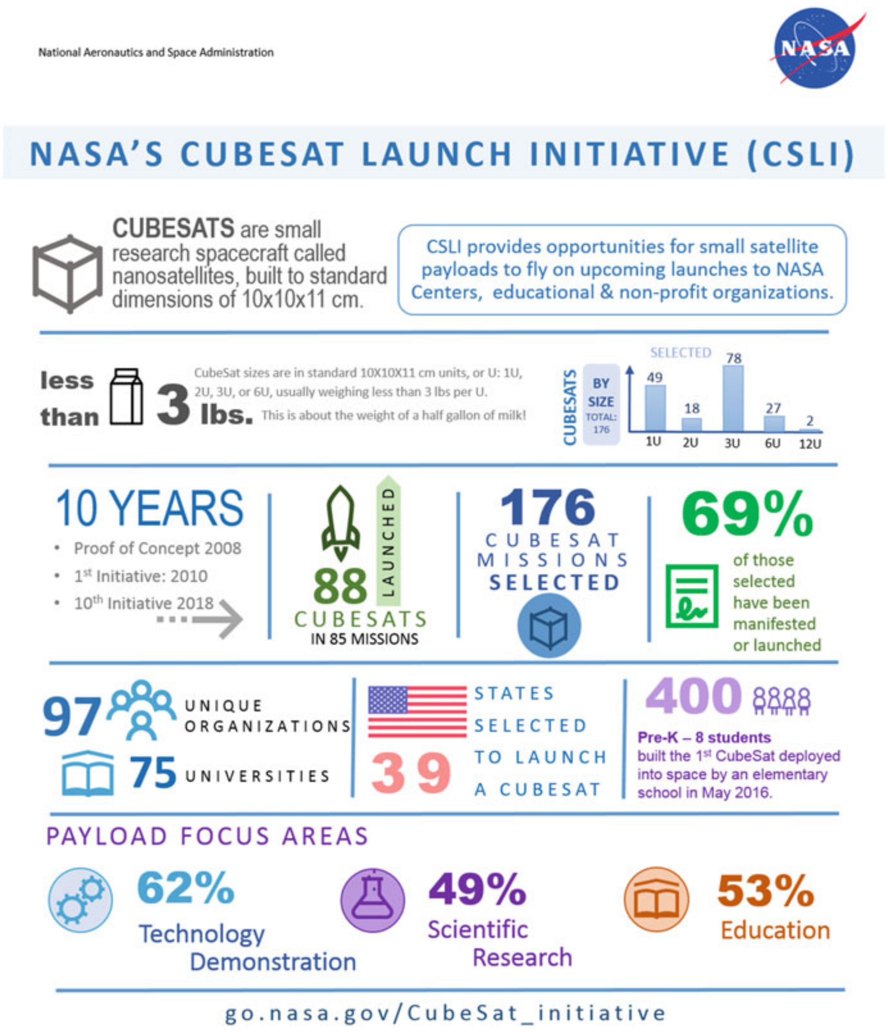

Fig. 12 The NASA CubeSat Launch Initiative. (Image courtesy NASA)

5 Conclusion

There will be explosive growth in the smallsat launch services market over the next several years. This need will be provided by a mix of existing launch providers like SpaceX, Ariane, Rocket Labs, Blue Origin, ISRO, Vector, Virgin, and perhaps many other startups that are seeking to support this market as discussed elsewhere in this handbook. Rideshares on other launchers which are managed by smallsat aggregators and new small launchers are still largely in development. Building a cubesat is quite different from navigating the complex and difficult process of finding a launcher and meeting all of the safety and regulatory requirements. Smallsat aggregators provide a useful service for novice cubesat builders, by providing this expertise, and this market will continue to grow and expand in the future. This is driven by the complex regulatory and documentation requirements for smallsats that most university and startups lack.

Large space agencies like NASA and ESA will continue to make rideshares available as an educational opportunity, but these slots will be limited. The International Space Station will continue to be a launch port for these through existing and new smallsat launch mechanisms. SpaceX has disruptively altered the existing mix by offering regularly scheduled launch opportunities potentially priced as low as US$5,000 per kg. It will be difficult for other providers to match this, with the possible exception of Blue Origin and Ariane, and possibly others, which will also be providing reusable launchers in the future. At this point, one must wait and see how the market continues to develop. No matter who provides these services, there is likely to be a robust and dynamic smallsat aggregator and launch market extending into the future, and even if only a few of the many, new small launch systems in development actually become active, there will be many launch opportunities available.

Frequent and Reliable Launch for Small Satellites: Rocket Lab's Electron Launch Vehicle and Photon Spacecraft

Morgan Bailey

Contents

Abstract

With frequent orbital launches of the Electron rocket and the successful deployment of customer satellites to orbit, Rocket Lab has established itself as one the key technology innovators of the global small satellite launcher industry. Rocket Lab seeks to address major barriers currently associated with small satellites, including long lead times to launch, reaching of precise orbits, and cost reduction. These are solutions the small satellite industry has been promised for decades, but now they are a reality with Electron and other innovations now being achieved. The Electron launch vehicle is a dedicated small launcher designed to serve the small satellite market with dedicated, high-frequency launch opportunities. Having crossed the threshold into commercial operations, Rocket Lab is well positioned to identify and address the persistent and evolving challenges faced by

1 Introduction

Rocket Lab's mission is to make space accessible by delivering a rapid-response orbital launch service for small satellite customers that is both frequent and reliable. Before Rocket Lab began orbital launches in January 2018, commercial and government small satellite operators alike did not have access to timely, cost-effective, and responsive access to orbit. Historically, small satellite operators were forced to choose between infeasibly high costs for a dedicated launch or accept the limitations of flying as a secondary payload on a rideshare launch. The infrequency of launch opportunities also poses a challenge for resiliency in space. All satellites are vulnerable, be it from natural, accidental, or deliberate actions. The ability to deploy new satellites to precise orbits in a matter of hours, not months or years, is critical to government and commercial satellite operators alike. It means uninterrupted weather monitoring, communications, navigation, early warning, and security systems – serving billions of people every day.

Realizing the potential of small satellites, Peter Beck founded Rocket Lab in 2006 to deliver this level of frequent and reliable access to space with the Electron launch vehicle. Following on from orbital launch in January 2018 (see Fig. 1), the Electron launch vehicle has now deployed 47 satellites across seven orbital launches (as at 31 December 2019). Rocket Lab has delivered a 100% mission success rate for small satellite customers.

2 Electron Launch Vehicle Overview

The Electron launch vehicle was designed from the outset for reliability, performance, and a high flight rate. Electron is a two-stage launch vehicle with an additional Kick Stage (see Fig. 2) designed to circularize the orbit of small satellites. Capable of launching payloads of 150 kg (330 lbs) to a nominal 500 km sun-synchronous orbit from a choice of two dedicated Rocket Lab launch sites, Electron provides unrivalled flexibility and launch schedule control for small satellite customers.

Electron's full structure, including propellant tanks, is made from carbon composite for a strong and lightweight flight structure. The all carbon-composite construction of Electron decreases mass by 40%, resulting in enhanced vehicle performance over traditional materials such as aluminum. The payload fairing on Electron is a split clam shell design and includes environmental control for the

Fig. 1 Electron's first orbital launch "Still Testing," 21 January 2018. (Graphic courtesy of Rocket Lab)

payload. The fairing is 2.5 m in length with a 1.2 m diameter and a total mass of 44 kg. It uses a pneumatic locking system and spring separation.

Electron's first stage is powered by nine of Rocket Lab's flagship Rutherford engines, with the second stage powered by a variant of the Rutherford engine which provides improved performance in vacuum conditions (Table 1).

Rocket Lab excels at producing high-performance miniature avionics and flight computer systems. Avionics flight hardware is custom designed by Rocket Lab and includes flight computers and a navigation suite incorporating an initial measurement unit (IMU), GPS receiver, and S band transmitter which transmits telemetry and video to ground operations. Guidance and control algorithms are developed with flexibility in mind, and the combination of flight hardware, software, and guidance and control algorithms is fully tested and validated using Hardware-In-The-Loop (HITL) testing frameworks.

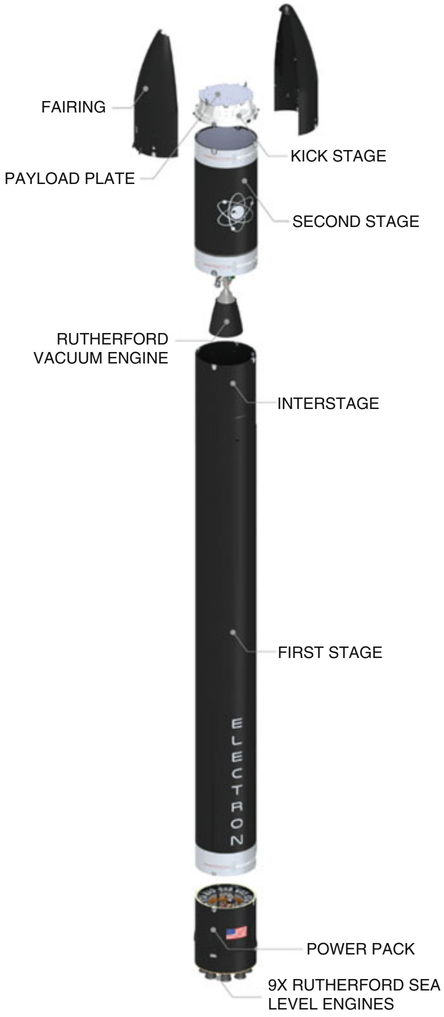
All aspects of the Electron vehicle are designed for ultimate manufacturability to allow for a high launch cadence and to provide an unprecedented frequency of launch opportunities.

3 Rutherford Engine

Rocket Lab's flagship engine, the 4900 lbf Rutherford, is an electric turbo-pumped LOx/RP-1 engine specifically designed for the Electron launch vehicle (see Fig. 3). Rutherford adopts an entirely new electric propulsion cycle, making use of brushless DC electric motors and high-performance lithium polymer batteries to drive its turbo-pumps.

Rutherford is the first oxygen/hydrocarbon engine to use additive manufacturing for all primary components, including the regeneratively cooled thrust chamber, injector pumps, and main propellant valves (see Fig. 4). Additive manufacturing of

Fig. 2 Electron launch vehicle design. (Graphic courtesy of Rocket Lab)



engine components allows for ultimate manufacturability and control. All aspects of the engine are designed, developed, tested, and manufactured in-house at Rocket Lab.

4 The Kick Stage

The small satellite industry is experiencing incredible growth, with more spacecraft operators than ever before demanding frequent access to space. Today large constellations are already taking shape on orbit, with many more planned. With the influx of traffic in low Earth orbit comes the responsibility of small satellite operators

Table 1 Summary of Electron's key technical elements and performance parameters

Specification	Value
Length	17 m
Diameter	1.2 m
Stages	2
Vehicle mass (lift-off)	13,000 kg
Payload mass	150 kg (sun-synchronous orbit)
Payload diameter	1.08 m
Standard orbit	500 km (sun-synchronous orbit)
Propulsion – stage 1	9 × Rutherford engines (LOx/kerosene)
Propulsion – stage 2	1 × Rutherford engine (LOx/kerosene)
Material/structure	Carbon fiber composite
Standard launch site	Mahia, New Zealand

and launch providers alike to ensure space remains safe and accessible for the benefit of all on Earth. Rocket Lab plans to launch more frequently than any other launch provider in history, so the company is carefully considering its role in the solution for the sustainable use of space and the reduction of debris in orbit. Traditional launch methods leave large rocket stages on orbit for years and often provide limited control over where a small satellite is deployed, adding unnecessary risk for all satellites.

Rocket Lab's Kick Stage (see Fig. 5) enables a sustainable small satellite launch system and a safer LEO for all. After Electron's second stage reaches an elliptical orbit, the Kick Stage separates (see Fig. 6) and a 3D-printed engine named Curie ignites and circularizes the payload's orbit.

Fig. 4 Electron’s nine first stage Rutherford engines in flight. (Graphic courtesy of Rocket Lab)

Fig. 5 Electron’s Kick Stage during final prelaunch fit-out. (Graphic courtesy of Rocket Lab)

The Kick Stage is capable of delivering multiple payloads to a range of different orbits on the same mission. Thanks to the Curie engine’s ability to reignite in space, the Kick Stage can move to different orbits to deploy multiple satellites to different, precise locations. A cold gas reaction control system supports this further for precision pointing on deployment (see Fig. 7).

Not only does this put satellites in their perfect orbit, but it makes them faster and easier for operators and regulators to identify and catalogue them. Once the payloads are deployed, the Kick Stage can perform a deorbit maneuver to lower its orbit, making it possible to renter the Earth’s atmosphere and burn up in just days, not months or years. This design enables Rocket Lab to launch missions that leave no part of Electron in orbit once payloads are deployed.

Fig. 6 The Kick Stage immediately following separation from Electron's second stage during the "Still Testing" mission in January 2018. (Graphic courtesy of Rocket Lab)

5 Electron Performance Capability

Electron missions are customized to suit customer's individual mission requirements, allowing the flexibility to reach a customer's desired orbit when and where required. Rocket Lab can tailor the vehicle to specific mission requirements including a range of sun-synchronous altitudes in circular or elliptical orbits at inclinations between 39° and 98°.

Electron's performance to various orbits can be seen in Figs. 8 and 9 below.

6 Photon

After establishing itself as the global leader in small satellite launch, Rocket Lab introduced the next evolution of its mission services – the in-house designed and built Photon satellite platform.

Rocket Lab now delivers an all-inclusive spacecraft build and launch service that enables small satellite customers to focus on delivering their service from orbit and generating revenue, rather than building their own satellite hardware. Small satellite customers simply bring their payload or idea and Rocket Lab takes care of the rest, including complete satellite design, build, and launch as a bundled and streamlined experience.

Photon is an advanced and planned evolution of the Rocket Lab Kick Stage (see Fig. 10). Operating a high-powered iteration of the flight-proven 3D-printed Curie propulsion system, Photon can support missions with up to a 5-year on-orbit life span. Equipped with an S-band communication system, a high-fidelity attitude control system, and a robust avionics suite, Photon is the complete spacecraft solution for a range of LEO missions, from constellation development, through to technology demonstrations and hosted payloads. Photon enables small satellite

Fig. 7 13 CubeSats for the NASA ELaNa-19 mission in December 2018 being integrated onto the Kick Stage in preparation for launch. (Graphic courtesy of Rocket Lab)

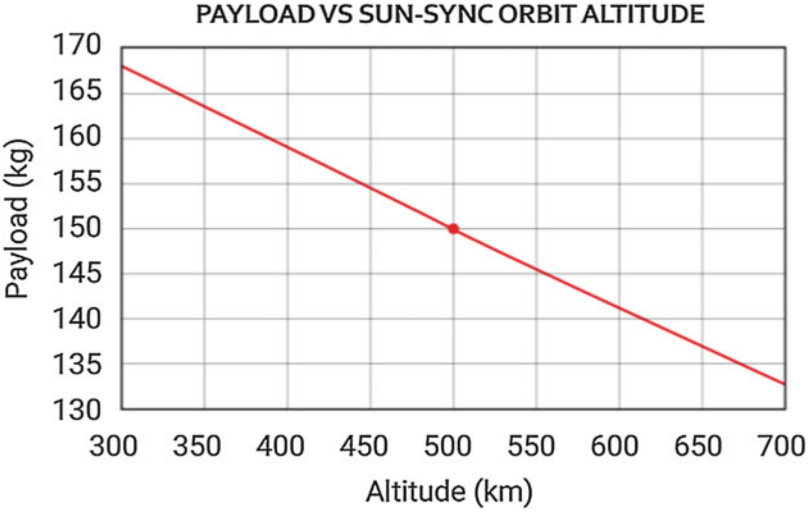

Fig. 8 Performance to circular sun-synchronous orbit

operators to focus on their core purpose – their payload applications – without the needless distraction of developing or procuring a spacecraft.

See Table 2 for full Photon specifications.

7 Launch Sites

Historically, the ability for small satellite operators to access launch frequently and on short notice has been hampered by more than just a lack of launch vehicles. Launch sites are a major contributor to launch queues, slowing the path to orbit for

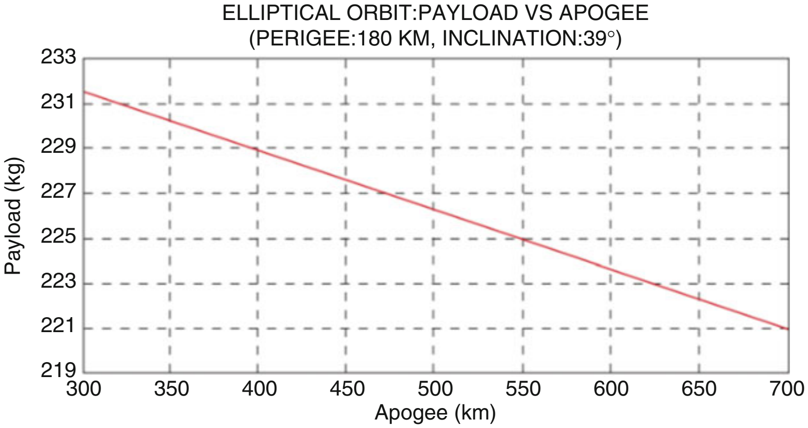

Fig. 9 Performance to a 180 km perigree at 45° inclination elliptical orbit

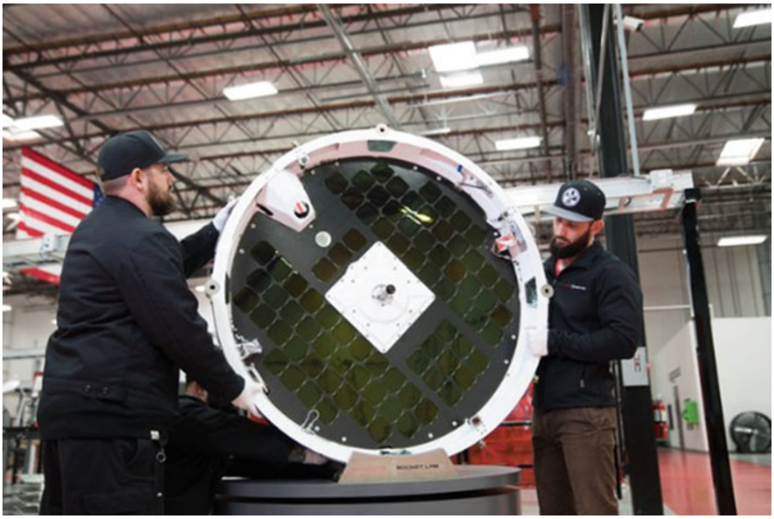

Fig. 10 Photon in production at Rocket Lab's Huntington Beach Headquarters. (Graphic courtesy of Rocket Lab)

satellite customers. Large launch vehicles with dedicated payloads take priority on crowded launch ranges, often forcing smaller missions down the launch schedule. The high volume of air and marine traffic over United States' launch sites also causes friction between launch, sea, and air operators all vying for safe, clear routes. This growing traffic jam also creates increasing challenges for regulatory and licensing authorities such as the Federal Aviation Administration (FAA).

To combat this issue and free small satellite operators from the queue, Rocket Lab operates two dedicated launch sites offering customers unmatched schedule flexibility.

Table 2 Summary of Photon specifications and performance versus the Kick Stage

Specification	Kick Stage	Standard Photon	Performance Photon
Payload mass	Up to 200 kg	Up to 170 kg	Up to 160 kg
Payload volume	Electron payload fairing		
Payload power (peak)	N/A	100 W	TBS variant(s) 1000 W
Payload energy	N/A	TBS	TBS variant(s) 300 Wh
System voltage	N/A	28 V unregulated; regulated options available	
Pointing accuracy	N/A	5°	50 arcsec
Pointing stability	N/A	1°/s	2 arcsec/s
Slew rate	N/A	5°/s	
Specific impulse	220 s		290 s
Payload data interfaces	LVDS, Ethernet, CAN RS422/435 Space Wire		
Payload data storage	N/A	8 GB	32 GB
Communications	N/A	S-band space/ ground	Space-ground via GEO
Telemetry and command data rate	N/A	Up to 512 kbps	S-band: Up to 512 kbps GEO relay: Up to 200 kbps
Payload data rate	N/A	Application-dependent	
Design life time	Hours	LEO >5 years	
Navigation accuracy	5–10 m		

7.1 Launch Complex 1

Established in 2016 and located on New Zealand's Mahia Peninsula, Rocket Lab's Launch Complex 1 is the world's first private orbital launch range (see Fig. 11). This FAA-compliant site can accommodate a launch rate of 120 flights per year. From the site, it is possible to reach orbital inclinations from sun-synchronous through to 39°. This enables a dedicated launch option with a wide spectrum of orbital inclinations. New Zealand's remote island location and low volume of marine and air traffic creates ideal conditions for frequent launch opportunities, enabling the highest possible launch cadence of any pad in the world.

Launch Complex 1 supports on-site payload integration with two separate and secure cleanrooms located in the Integration and Control facility <200 m from the launch pad (see Fig. 12).

Payload integration and encapsulation operations procedures are designed to minimize complexity and increase mission reliability.

Cleanroom specifications:

- Certified ISO 8 cleanliness level (Class 100K)
- Overhead crane for payload integration operations
- Standard 110 V AC @ 60 Hz and 230 V @ 50 Hz Power
- Secure area including 24/7 security guards, building access control, video monitoring, and an area warning system

Fig. 11 Launch Complex 1 on New Zealand's Mahia Peninsula. (Graphic courtesy of Rocket Lab)

Fig. 12 A DARPA payload in the LC-1 cleanroom during integration procedures. (Graphic courtesy of Rocket Lab)

Both cleanrooms offer a private customer viewing area and workspace that looks into the cleanroom during operations, giving customers full oversight of operations while minimizing the number of personnel required in the cleanroom itself (see Fig. 13).

Fig. 13 The dedicated customer room and viewing area that looks directly into the cleanroom. (Graphic courtesy of Rocket Lab)

To date, Launch Complex 1 has been host to eight Electron launches that have deployed small satellite payloads for NASA, DARPA, the Unites States Air Force, and a range of commercial customers.

7.2 Launch Complex 2

In Q4 2019, Rocket Lab will complete construction of Launch Complex 2, the company's second launch site. Located at the Mid-Atlantic Regional Spaceport on Wallops Island, Virginia, LC-2 is tailored specifically for government missions and can support up to 12 launches per year (see Fig. 14).

In addition to the pad itself, Rocket Lab is developing a Launch Vehicle Integration and Assembly Facility in the Wallops Research Park to support the simultaneous integration of up to four Electron vehicles. The facility will also contain a control room with connectivity to LC-2, as well as dedicated customer facilities. This new facility, combined with the purpose-built gantry located at LC-2, will provide significant and dedicated vehicle processing capability and flexibility to meet Rocket Lab's high launch cadence.

8 Responsive Launch Capability

Responsive space launch, the ability to rapidly and frequently deploy satellite infrastructure, is crucial in maintaining strategic, commercial, and scientific advantages in space. The U.S. Space Transportation Policy (2013) clearly states that the

Fig. 14 Launch Complex 2 under construction in September 2019. (Graphic courtesy of Rocket Lab)

United States Government shall "pursue research and technology development activities regarding alternative launch capabilities to improve responsiveness, resiliency, and cost effectiveness for future space launch alternatives."

Responsive space access is of strategic importance for government small satellite operators and commercial constellation operators alike. As reliance on services from small satellite constellations dedicated to internet connectivity, marine tracking, weather, and communications grows, the ability to promptly, accurately, and decisively deploy assets to orbit becomes vital.

Rocket Lab's Electron launch vehicle and Photon satellite bus were designed from the outset to deliver timely spacecraft deployment, restoration, and sustainment in orbit.

Truly responsive space access requires three things – responsive launch vehicles, responsive launch sites, and responsive satellites. With the Electron launch vehicle, two dedicated launch complexes and the configurable Photon satellite platform, Rocket Lab has demonstrated all three aspects.

Rocket Lab's rapid response launch architecture has been designed to support 24-h, on-call launch capability.

The mission flow for a rapid-response launch is a modified and streamlined version of the proven, standard Rocket Lab launch capability.

Preassembled Electron launch vehicles can be stored at Rocket Lab's USA and New Zealand launch complexes ready for call up 24/7 (see Fig. 15). Rapid checkouts and stage mates can be carried out in hours, with vehicle interfaces, fluid, and electrical connections designed for quick connect/disconnect.

Small satellite payloads can be pre-integrated onto Electron's Kick Stage payload plate and stored securely in a flight-ready state at Rocket Lab launch sites, ready for

Fig. 15 A preassembled Electron launch vehicle awaiting launch at LC-1. (Graphic courtesy of Rocket Lab)

deployment at any time. Electron's standardized, modular design sees satellites integrated onto the stand-alone payload plate which can then be mounted to any Electron vehicle, enabling rapid responsive launch capability. Alternatively, Rocket Lab can take urgent delivery of a spacecraft and conduct a rapid spacecraft integration and encapsulation within hours.

Rocket Lab goes one step further with the creation of the common Photon satellite bus. Small satellite operators simply provide their sensor and Rocket Lab looks after satellite build, launch, and ground segments. Photon removes the need for operators to build their own spacecraft and is an end-to-end solution for increasing flexibility for quick-reaction launches without sacrificing reliability.

While payload and vehicle operations are being carried out, concurrent mission delivery analysis and licensing takes place, with trajectories, Monte Carlos, and Hardware-In-The-Loop (HITL) testing carried out by a 24/7 call-up rapid response team.

This mission flow minimizes launch timelines and increases flexibility without significantly increasing technical complexity or cost.

9 Reusability

In an effort to create further efficiencies and increase launch cadence, Rocket Lab has confirmed plans to recover and reuse the first stage of the Electron launch vehicle. Work on Rocket Lab's Electron first stage reuse program began in late 2018 at the end of the company's first year of orbital launches. The plan to reuse Electron's first stage will be implemented in two phases. The first phase will see Rocket Lab attempt to recover a full Electron first stage from the ocean downrange of Launch Complex 1 and have it shipped back to Rocket Lab's Production Complex

Fig. 16 A render of Electron's first stage during reentry. (Graphic courtesy of Rocket Lab)

Fig. 17 A rendering of Electron's first stage with chute deployed for reentry, awaiting air capture by helicopter. (Graphic courtesy of Rocket Lab)

for refurbishment. The second phase will see Electron's first stage captured midair by helicopter before the stage is transported back to Launch Complex 1 for refurbishment and relaunch (see Figs. 16 and 17).

On Rocket Lab's tenth launch, currently scheduled for November 2019, Electron will carry critical instrumentation and experiments to provide data that will inform future recovery efforts; however, Rocket Lab will not attempt to recover the stage on this mission. Rocket Lab plans to begin first stage recovery attempts in 2020.

10 Conclusion

Rocket Lab has brought frequent, reliable, and dedicated launch capability to the global market, freeing small satellite operators from launch queues and rideshare limitations. With the introduction of the Photon satellite platform, the completion of Rocket Lab's Launch Complex 2, and plans to recover Electron's first stage for reuse, Rocket Lab is poised to deliver increasing flexibility and responsiveness to government and commercial customers.

The Evolution of Medium/Heavy-Lift and Reusable Launch Vehicles and Its Implications for Smallsat Access to Space

Clay Mowry and Michael Grasso

Contents

Abstract

The advent of reusable commercial medium−/heavy-lift launch vehicles will drive growth in the small satellite (smallsat) industry by enabling low-cost access to space for constellation operators in geosynchronous orbits (GEO) and non-geosynchronous orbits (NGSO). Innovations in reusability, high-performance engines, and larger payload fairings are changing the economics of launch, providing significant value to smallsat operators. Reusable, medium−/heavy-lift launch vehicles like Blue Origin's New Glenn and SpaceX's Falcon offerings offer smallsat operators affordable access to space and significant value in the form of decreasing time to market, rapid fleet refresh, and solution scalability.

This article describes how the evolution of space launch capabilities will impact the smallsat industry. Specifically, it describes the developments in the launch services market, smallsat operator launch preferences, and the enabling role played by heavy-lift vehicles.

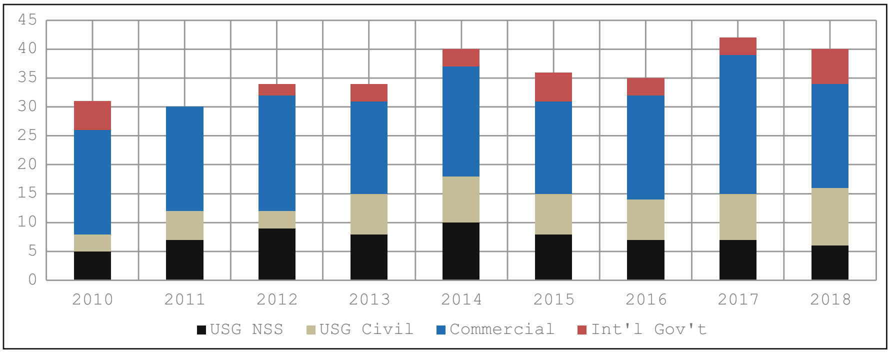
1 Introduction

Demand for commercial launch services has changed considerably from 2010 to 2020. Compared to the prior decade, there were more launches of large high-throughput satellite (HTS) geostationary systems and constellations of smallsats supporting a range of applications from communications to remote sensing. Moreover, several companies announced plans to deploy non-geosynchronous (NGSO) mega constellations of hundreds and, in some cases, thousands of spacecraft to service burgeoning connectivity markets. In fact, in the last 2 years, SES, Iridium, Telesat, OneWeb, and SpaceX deployed test and/or operational spacecraft for their respective NGSO systems. During the same period, changes to US Government policy further added to medium−/heavy-lift launch demand. For example, NASA drove additional demand by outsourcing the delivery of cargo to the International Space Station (ISS), and the US Air Force began competing launch services contracts. These policies increased the size of the addressable market and allowed for greater competition among established providers and new entrants. These shifts in US Government policy coupled with the evolution of commercial satellite architectures have changed the global launch services landscape.

Within the launch market, there are four categories of launch customer verticals addressable by US medium−/heavy-lift providers: (1) commercial, (2) US government civil (USG civil), (3) US government national security space (USG NSS), and (4) international civil/military. From 2010 to 2018, the number of addressable launches for US medium−/heavy-lift providers averaged 36 per year. (Note: Certain Ariane 5 missions to GTO count as dual launches.)

There was modest growth at approximately 3% year-over-year during this period. Growth is attributed to demand from the commercial and USG civil verticals. For reference, the total number of addressable launches to US-based commercial medium−/heavy-lift launch providers comprised about 40% of all global orbital launch events over the last decade. The other 60% of launches include those for governments with their own launch capabilities (e.g., Russia, China, France) and launches on small and light-lift vehicles (e.g., Minotaur, Pegasus).

As shown in Fig. 1, the commercial vertical was the largest in terms of volume of launches, representing roughly half since 2010. This vertical is primarily comprised



Source: Blue Origin

Fig. 1 Launch market for US-based commercial medium−/heavy-lift providers (2010–2018)

of operators of commercial communications satellites that operate in GEO, and each weighs between 3,000 and 6,000 kg.

Launch demand from commercial operators in particular is in the midst of a large transformation that could be defined by the proliferation of non-geosynchronous orbit (NGSO) constellations, primarily in LEO and MEO, and smallsats in GEO. Over the next decade, several companies plan to deploy large constellations of smallsats in LEO to provide global broadband connectivity services. Many of these constellations are so large that they require a significant increase in commercially available launch capacity to ensure that they can to deploy their targeted number of spacecraft to close their business cases and meet regulatory guidance. In fact, the growth of NGSO constellations in the commercial market could ultimately comprise a majority of future launch demand in the 2020s and beyond encompassing initial deployment, evolution, and replacement missions. In 2019 alone 120+ NGSO smallsats belonging to SpaceX and OneWeb were deployed. The numbers for 2020 were projected to increase sharply, but planned deployments were curtained by the effects of the Covid-19 virus and the One Web bankruptcy.

Beyond LEO, operators are moving forward with plans to operate “Micro GEO” satellites weighing 300 to 1,500 kg and targeting niche connectivity applications. Start-up providers like Saturn, Astranis, and Ovzon are seeking to provide service to underserved areas of the world and for smaller national satellite communications projects, using satellite form factors that are 4 to 20 times smaller than traditional GEO satellite platforms and employing software-defined payloads. These spacecraft can offer significant and targeted bandwidth that can meet new and existing customer needs. Astranis’ spacecraft, for example, have ~7.5 gigabits per second of throughput capacity (Via Satellite 2019). These systems will require shared launches on medium−/heavy-lift vehicles to achieve greater cost savings. Micro GEOs may also require much more frequent refresh, especially when compared to large HTS and classical GEO systems, as their lifespans are expected to be about half that of legacy systems (~7 years instead of 15 years). Their size, refresh requirements, and need for fast time to market may ultimately drive demand for new launch approaches, specifically for direct injections into GEO versus more classical transfer orbits. Eliminating electric orbit raising time and extending life on orbit are two major advantages of GEO direct missions, the benefits of which are enhanced given the size and expected lifespan of these small spacecraft.

2 Access to Space for Smallsats

Over the last decade, commercial interest in smallsats increased because they were considered relatively inexpensive, flexible, and easily upgradeable platforms (Avascent 2015). In swarms or constellations, smallsats also offer the advantage of disaggregation to large platforms. This changed operational risks and provided other commercial benefits (e.g., coverage, revisit, redundancy). Smallsat constellations are now viewed as complements to larger satellite systems and, in some cases, as substitutes.

The increasing capability of smallsats coupled with their attractiveness for commercial and government applications has accelerated demand for launch services to accommodate them. This has driven more interest and investment in (1) medium−/heavy-lift launch vehicles with bulk deployment capabilities, (2) small−/light-lift launch vehicles with targeted deployment capabilities, (3) ridesharing systems, and (4) managed services offerings.

These investments have increased the number of launch options available to smallsat operators. Today, they can launch on dedicated and multi-manifested/rideshare missions; they can buy launches directly from service providers or from brokers and third-party aggregators; and they can even outsource the space segment entirely to managed services providers, such as condosat operators like Loft Orbital.

Historically, satellite operators have used medium−/heavy-lift expendable launch systems for the initial deployment of satellite constellations to LEO and MEO orbits (refers to satellite constellation operators whose individual spacecraft have a mass of more than 100 kg). There are operators of satellites that weigh less than 100 kg, such as Planet and Spire, who have used a combination of medium-, light-, and small-lift vehicles to initially deploy, refresh, and augment their constellations. Smallsat constellation operator launch preferences are dictated by their manufacturing throughput, risk posture, time-to-market requirements, fleet size, and spacecraft mass/size (refers to satellite constellation operators with individual spacecraft mass of more than 100 kg).

Iridium, Globalstar, Orbcomm, O3b, and OneWeb all selected medium−/heavy-lift launch vehicles (Soyuz, Delta II, Falcon 9, Zenit, and Ariane 6) as the price per satellite and per gigabit deployed on orbit is lower compared to using small launch systems. Deployment schemes are derived from constellation architectures, including the number of planes, number of satellites per plane, and the mass and volume of the satellites.

With larger mega constellations, the use of larger, reusable heavy-lift vehicles can dramatically reduce capital expenditures for constellation operators by lowering launch costs, typically the largest single cost associated with deploying the broadband satellite system. For example, New Glenn's payload capability of up to 45 metric tons delivered to LEO, combined with a 7 m fairing that is twice the volume of the largest launch system operating today, will reduce per satellite launch costs and lower capital expenditure requirements for constellation operators like Telesat and OneWeb. Telesat's Chief Executive Officer Dan Goldberg stated that they selected the heavy-lift New Glenn because "Blue Origin's powerful New Glenn rocket is a disruptive force in the launch services market which, in turn, will help Telesat disrupt the economics and performance of global broadband connectivity" (Henry 2019).

Moreover, for many operators, time to market with an operational constellation is critical. Deployments that maximize the amount of spacecraft deployed in one launch event will dramatically reduce the time between concept development and commencement of operational services. Time to market for connectivity providers and imagery companies may further drive demand for new launch business models and procurement approaches.

3 Bulk Deployments, Multi-manifesting, and Ridesharing

Access to space for smallsat operators typically involves a trade-off between price and control over schedule/orbit. Many operators, especially those in early stages of system development and financing, sacrifice control over schedule/orbit for inexpensive launch services. This section explores three launch approaches that smallsat operators have adopted to deploy their smallsats and constellations.

3.1 Bulk Deployments

While the Geneva-based International Telecommunication Union's (ITU) 2019 report on global broadband deployment stated that more than 50% of the world's population now has access to the Internet, a large portion of those users are underserved, and more than three billion people remain unconnected. Satellites are a low-cost way to provide service to rural and underserved areas of the world where deploying fiber-optic cable is cost-prohibitive.

Demand to launch the initial population and replenishment of fleets of NGSO broadband constellations is expected to increase dramatically over the next decade to meet the growing demand for Internet connectivity around the world. Bulk deployments are launches that take nearly the entirety of launch vehicle's performance to deliver large quantities of spacecraft. For example, SpaceX is currently bulk deploying its Starlink constellation on Falcon 9, as is Arianespace for OneWeb on Soyuz 2. Satellite operators, particularly those planning to offer broadband services, will require medium−/heavy-lift launchers for bulk deployment of their systems. These commercial operators will need access to low-cost launch systems that have the capability and availability to ensure continuity of coverage and service quality.

These NGSO spacecraft are expected to weigh between 100 kg and 1,000 kg, which necessitate launch systems with the most performance to orbit and fewest volume constraints. NGSO mega constellation operators intend to operate in multiple planes at varying altitudes and inclinations (e.g., mid-inclination LEO, SSO). Some operators will operate their satellites at low altitudes (sub 700 km) to ensure low latency and rapid reentry. While demand for constellation bulk deployments will grow, it could be variable on a year-by-year basis depending on refresh cycles. These operators require medium/heavy commercial launch services that offer low costs, high availability, and sufficient performance (mass/volume) to meet customer needs and regulatory deployment, service, and coverage requirements.

3.2 Multi-manifesting

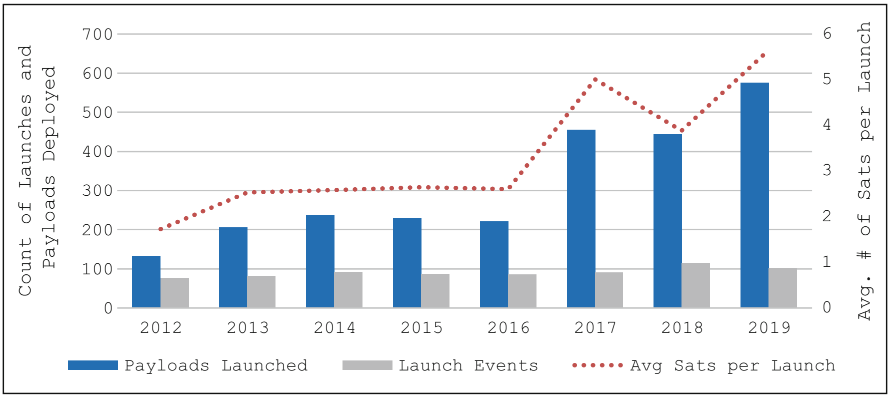
Overall payload mass launched has continued to grow, both in the form of larger satellites and in the form of multi-manifested payloads. The increase in multi-manifested payloads has been influenced primarily by new NGSO satellite constellation launches, the growth in availability of capable smallsat platforms, increasing diversity in GEO broadband spacecraft, and a proliferation of rideshare options on existing and new launch systems.

Satellites planned for GEO will continue to be launched alongside co-passengers. Multi-manifested missions, like those launched on Ariane 5, will continue to be popular means to reaching orbit. In the near future, operators of micro GEO satellites and flexible light GEO spacecraft (FlexLight), which are characterized by their ability to reconfigure in orbit and offer flexible coverage, will seek multi-manifested approaches to reach orbit. Example FlexLight platforms include Thales Alenia Space's Space Inspire, Airbus' OneSat, and Boeing's 702X platforms. (Note: Industry experts also refer to these FlexLight satellites as software-defined satellite (SDS). Such approaches can help ensure low-cost access to space for operators of large and small spacecraft in GEO.

3.3 Ridesharing

The market for rideshare launch services has grown significantly over the last decade. The onset of capable, smallsat form factors and the availability of affordable launch services for auxiliary payloads have increased the number of satellites launched globally. While the number of launches globally experienced modest growth, the number of payloads launched into space annually has increased dramatically. In fact, the annual number of payloads launched has more than doubled over the years 2012 to 2019 (Fig. 2).

Ridesharing capabilities and multi-manifesting are responsible for the democratization of access to space as well as new companies and business models, which is driving an unprecedented expansion in the quantity of satellites deployed over the last decade.



Sources: Blue Origin and Space Activities in 2019, Jonathan McDowell, Rev 1.3

Fig. 2 Launches and count of payloads deployed (2012–2019)

Rideshare is an approach to deploying multiple payloads into orbit on a single launch by leveraging excess capacity. Rideshares are defined as missions for non-primary payloads on a particular launch campaign (ULA 2015). For launch service providers, rideshare is a means of asset utilization.

There are several types of rideshares. There are launches of auxiliary payload rideshares, where one or more secondary payloads share a launch with a primary payload customer. There are dedicated rideshare missions, where there is no single primary payload that has priority rights; under this approach, mission capacity is shared between several satellites. Lastly, there are propulsive rideshares, where an auxiliary platform with propulsion is co-manifest alongside primary payloads. These propulsive systems offer independent orbit-tailoring and dispensing capabilities.

Ridesharing offers many advantages to satellite operators. It gives them access to an abundance of available flight opportunities across multiple vehicles. For certain missions, ridesharing on larger launchers may even enable some degree of weight and volume flexibility over smaller vehicles. But, perhaps most important, there is a perception of affordability versus dedicated launches. This perception is exacerbated when operators compare launches on smaller systems whose price per kg of payload to LEO, for example, can be eight times more expensive than options on medium—/heavy-lift rideshare alternatives.

At the same time, there are drawbacks to ridesharing. Historically, there has been limited price transparency, though SpaceX's SmallSat Rideshare Program has challenged this notion directly by publicly announcing a $1 M per 200 kg price tag for capacity on Falcon 9 to SSO and mid-inclination LEO. There is also less orbit control, meaning satellite operators may need to trade a more optimized orbit that could be achieved on a smaller rocket for a less ideal orbit on a rideshare mission. Again, some companies, such as smallsat propulsion providers and on-orbit transfer companies (e.g., Momentus), those that offer last mile delivery with altitude raising systems, believe this drawback can be solved affordably by adopting their respective products and services. Rideshare missions also have less schedule control, as they tend to be subject to vehicle availability and delays with the primary payload. Lastly, some rideshare missions have relatively inflexible contract terms and conditions, which can prove burdensome to satellite operators.

4 Conclusion

A key market-defining enabler of smallsat launch, whether bulk deployments, multi-manifested missions, or rideshare, is reusable medium−/heavy-lift launch vehicles. These systems offer unparalleled cost savings relative to expendable alternatives and have superior availability, as they are not constrained by manufacturing throughput or ultra-specialized supply chains. Moreover, vehicles with high-performing upper stage engines and large payload fairings will further enable smallsat operators to deploy systems that offer superior services and products to their respective customers.

On November 23, 2015, Blue Origin's New Shepard suborbital rocket became the first launch vehicle to climb above the 100 kilometers Kármán line, the internationally recognized border between the Earth's atmosphere and outer space, then return to safe land vertically. That same New Shepard booster and capsule repeated the achievement four more times with limited maintenance before being retired. SpaceX's Falcon 9 medium-class launch vehicle first flew to space and landed successfully a month later in December 2015. Subsequent Falcon 9 and Falcon Heavy boosters have flown to space and back three times. Blue Origin is now completing design of the New Glenn heavy-lift system, which baselines a minimum of 25 reuses per booster. Following these successes, ESA announced their own reusable rocket engine development program dubbed Prometheus, and the French and German space agencies CNES and DLR have started work on a reusable first stage flight demonstrator named Callisto.

These medium−/heavy-lift reusable boosters were developed with the goal of dramatically lowering the cost of access to space for satellite operators and space agencies, allowing a thriving space economy to grow and flourish. For mega constellations their large architectures require both increased heavy-lift performance and more payload fairing volume to efficiently deploy and replenish constellation planes.

Design, Engineering, and Manufacture of Small Satellites for Constellations

Kits, Components, and the Design, Manufacture, and Testing of Small Satellites

Joseph N. Pelton and Rene Laufer

Contents

Abstract

The "NewSpace" revolution has changed the world of satellite applications, science, and experimentation. The design, manufacture, testing, and operation of small satellites in the age of "NewSpace" (or "Space 2.0") have altered dramatically – especially so in the past decade. Today is a time when small satellites (i) are still shrinking in size; (ii) are being designed and built more economically; (iii) are being tested more efficiently; (iv) are being subtly upgraded through multiple generations with minor improvements; (v) are being produced at a much more rapid pace: and (vi) are definitely being launched at lower cost. All of these shifting factors that might be called "efficiency factors" make the field of small satellite design and construction fairly dynamic.

Nevertheless construction standards for cubesats and now pocketQubes help to acquire smallsat components and structural elements from a competitive global market via the Internet with increased efficiency and competitive costs. There are also Internet sites that provide useful description of qualified suppliers and their products with clarity and useful background information.

Clearly the small satellite market is divided into truly diminutive units (i.e., femtosats, picosats (including pocketQubes), and nanosats (including cubesats)) that are typically for academic experiments and investigations and the larger smallsats for commercial services (3U cubesats and up to microsats and minisats). Although the suppliers of kits, components, and smallsat sensors are largely attuned to academic institutions and student small satellite experiments and proof-of-technical-concept missions, some of these same suppliers can also support commercial market satellite programs as well.

This chapter is focused on providing some advice and guidance on more effective ways to design, obtain key parts and components, integrate, test, and arrange for the launch of what is often called the academic smallsat market. Nevertheless, this chapter may also provide useful information to commercial smallsat programs, especially those whose spacecraft are of the 3U to 6U cubesat variety.

1 Introduction

It might be assumed by some that because a smallsat project involves a very small device, fitted into a standardized unit, it is also simple. The line of logic is that since this smallsat is being designed to accomplish a student's experiment or investigation at the lowest possible cost, this somehow translates into something that is much less "complex" than a full-sized satellite. In short, "small" means less complicated. This is, of course, very far from the truth. The key functionality of a satellite must be shrunk to fit into a very small structure, and thus, if anything, the design, manufacturing, and testing process may be far more demanding.

A small satellite must have a power supply; antennas for communications; sensors for various functions; thermal controls; processors to control the functioning of the satellite and to process signals related to tracking, telemetry and command. It must also have radio telecommunications/data relay capabilities plus the essential; experiment or test of concept that is the prime purpose of the smallsat mission. It must have a structure, wiring, power converters, filters, and other features, such as torquerods and possibly micro-thrusters, fuel, passive deorbit systems, deployment mechanisms for solar arrays, antennas, and other components. The ability to design, build, and test a small satellite is actually a demanding task. Squeezing all of these parts into a very small volume and keeping the mass low are not in any way simple (see Fig. 1).

This project required 3 months to design and construct by well-qualified engineers and technicians at SSTL who worked as volunteers in cooperation with volunteers from Amateur Radio United Kingdom. This project contained an amateur

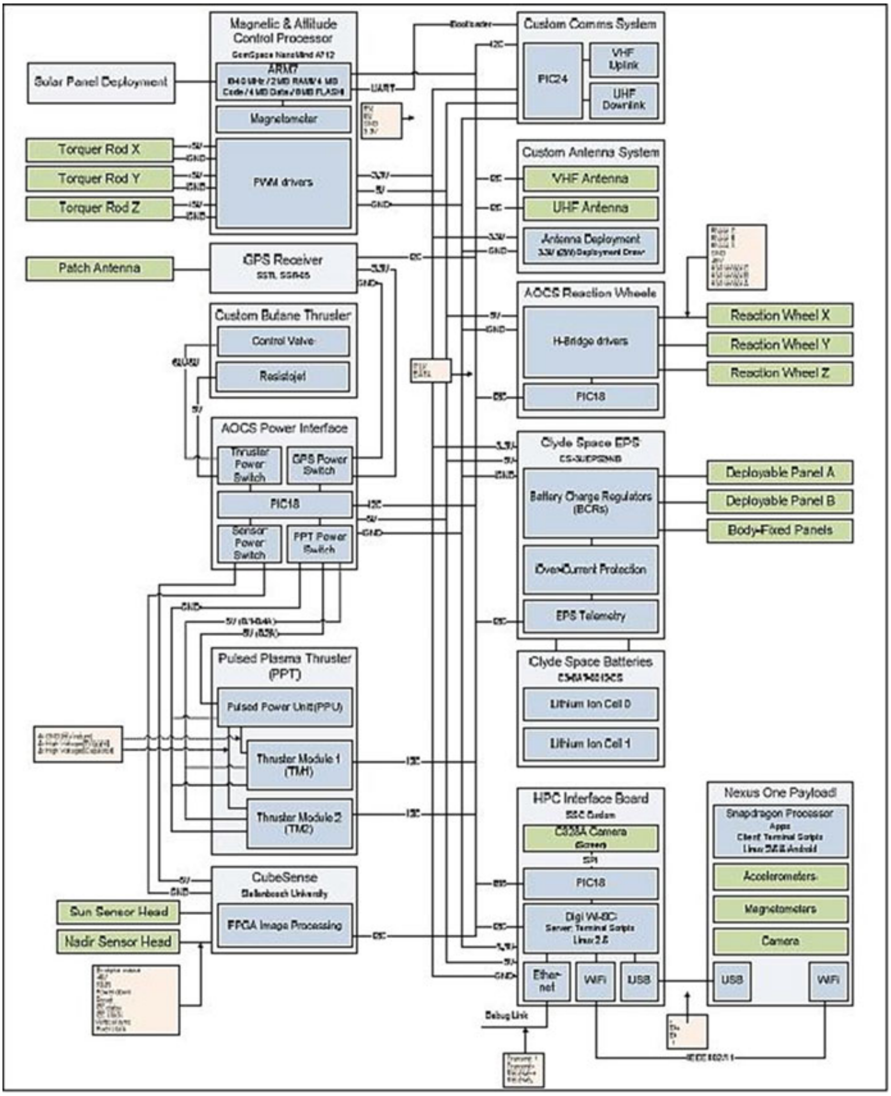

Fig. 1 Schematic diagram of the STRaND-1 3U cubesat designed by SSTL and Amsat-UK (STRaND-1 2019). (Graphic courtesy of SSTL and USSC)

radio AX-25 packet radio downlink that operates in the 437.568 MHz band. In some ways it is like a cell phone in the skies. This project was designed and built at the Surrey Space Technology Limited (SSTL) and launched on an Indian Polar Satellite Launch Vehicle (PSLV-C20). This smallsat project is perhaps somewhat more complex than others in that it did include custom butane and pulsed plasma thrusters and other special features such as both X, Y, and Z axis torquerods and X, Y, and Z axis reaction wheels. In this project a Pumpkin© brand solid chasis, a battery supplied from Clyde, Ltd.©, and a solar cell deployable array from SSTL© were the sources of key components (STRaND-1 Smartphone Cubesat 2019).

The design and assembly of all the key components and integrating them together are no small feat. After the integration is complete, component parts and the overall satellite have to be tested for qualification and readiness for launch (see Fig. 2).

The fact that the task of designing, building, integrating, testing, and launching of cubesat projects around the world has been accomplished many times over provides clear advantage to those embarking on new smallsat projects for the first time. Today’s smallsat experimenters can benefit from those that have gone before, thus providing very useful information. Someone starting a cubesat project does not have to, in effect, reinvent the wheel.

Nor does one have to develop from scratch a 3-axis stabilized free-flyer cubesat as the only way to undertake an experiment in space. One can deploy smaller units such as pocketQubes that are essentially one-eighth in size (i.e., 5 × 5 × 5 cm), and these

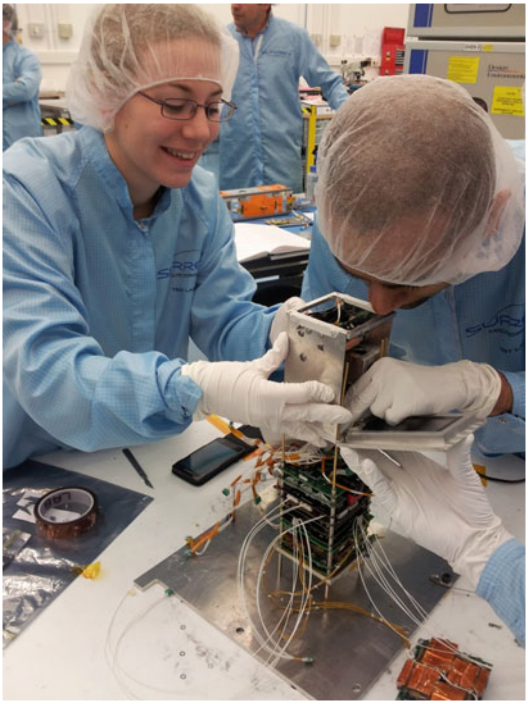

Fig. 2 The assembly and integration of the STRaND-1 smartphone cubesat. (Graphic courtesy of the Surrey Space Center)

do not have to be three-axis stabilized. It is also possible to design experiments that fly on a larger "mothership" that supplies power, stabilization, and telecommunications as well as tracking, telemetry, and command functions.

There are also arrangements that can be made via nanoracks for small orbital experiments to be designed that are flown up to the International Space Station where these mini-projects can be placed in the nanorack experimental bay and never actually launched as free-flyers. Under this approach astronauts can start and stop experiments and even monitor results that can be reported to the ground. This is the type of project sponsored by the National Center for Earth and Space Science Education and the Arthur C. Clarke Institute for Space Science Education. This is the simplest approach by far, and even students at the primary and secondary levels of education can plan and execute space science educational projects of this type.

2 Kits and Components

There are many websites online that are devoted to assist those seeking to undertake smallsat projects or related activities. Perhaps the most notable is the cubesat.org website that features several dozen suppliers of cubesat kits and key components that are accessible via the web in many areas such as structures, batteries, solar cells and solar arrays, sensors, materials and deployment mechanisms, processors, torquerods, reaction wheels, integration services, and assistance with launch services. This website is accessible at http://www.cubesat.org/new-index.

This website describes in one paragraph the offerings of many smallsat-related suppliers and features only companies with a clearly established and creditable track record of quality product and services.

NASA by means of its NASA Ames Research Center has started a program known as SmallSat Parts On Orbit Now (SPOON). This program is seeking responses and updated information with regard to smallsat programs, products, and services from educational organizations, research labs, not-for-profit organizations, and even industry sources via a specific request for information process. The stated purpose of this solicit of information is to assist organizations planning smallsat projects and to promote competition.

NASA has designed its "SPOON" project to seek information that is considered "state-of-the-art" and at what they define as a Technology Readiness Level 5.

This SPOON directory of information is organized into the following specifically defined areas:

> **NASA SPOON Database**: Structures, Materials & Mechanisms; Complete Spacecraft Platforms; Communications; Propulsion; Power; Command and Data Handling; Attitude Determination & Control; Thermal Systems; Software (Architectures, Methodologies); Guidance, Navigation and Control; Spacecraft Integration; Launch and Deployment; Optoelectronics; and Deorbit Mechanisms. (NASA SPOON Database 2018)

The European Space Agency, like NASA, has also been active in the small satellite arena. ESA has sponsored or engaged in a number of small satellite programs. These activities have included the use of small satellites for its "In-Orbit Technology Demonstration" Program. Recent projects have included (i) GOMX3, (ii) GOMX4B, (iii) Simba, (iv) Picasso, (v) Qarman, (vi) Radcube, (vii) Pretty, (viii) AMS-Sat, (ix) Hera, (x) RACE, and (xi) Proba-V cubesats. It has had two pocketQube projects involving telecommunications and networking projects known as Astrocast and Pocketqube. It has also chosen a number of smallsats for its Fly Your Satellite (FYS) Program, and it has included Oufti-1, e-st@r-II, and AAUSat-4 in its first edition program. Also, it has supported the launch in its second edition program of the following smallsats: LEDSAT, EIRSAT-1, CELESTA, 3CAT4, UoS3, and ISTsat-1. Finally it has undertaken five interplanetary small satellite projects (Walker and Hager 2018).

Under the ESA Fly Your Satellite Program, extensive support is offered to university-based student experimental projects that are qualified to meet the program standards. Under this program for qualified projects, ESA offers:

- Direct support from ESA specialists
- Introduction to ESA verification processes and related documentation
- Participation in ESA workshops and training courses
- Access to ESA environmental test facilities
- Training opportunities to get acquainted with ESA standards and best practices (see Roger Walker and Philipp Hager presentation, June 2018)

Other space agencies also have various programs to support small satellite missions that they are undertaking themselves or to support small satellite initiatives by educational institutions or industry projects. This includes those that are seeking to design and build small satellites or to develop new launch systems to support small satellite launches. A search of the sites of these other space agencies is recommended.

3 Testing

The support that is offered involves not only help with the design and construction of small satellites. There is also support with regard to the testing, independent verification and validation, and qualification of small satellites for launch. This "qualification" of cubesats is important to those constructing and launching the small satellites in order to reduce the number of "dead on arrival" missions and to extend their operational lifetime from a few days to months or even years. Careful review of the cubesat and its design and safe configuration is likewise important to avoid accidents involving the launch operations.

There are a number of issues that are of particular concern. Sometimes industrial wiring rather than space-qualified wiring might be used in cubesat projects. The flow of electricity and wiring resistance to electrical current are different in space, and this can lead to the failure of small satellites and could even lead to electrical fires. The NASA and ESA safety reviews, verification testing, and testing documentation can avoid unfortunate design and construction errors. Other areas of particular testing and design review are concerned with the stabilization and pointing systems, batteries, mechanical deployment systems, active and passive thermal controls, any fuels or pyrotechnics that might be included in the cubesat design, and all electronics, electronic switching, power converters, and processor systems.

A significant number of cube missions have been launched via the International Space Station. In this case there is a particular concern with safety and whether the cubesat might represent a fire or other type of hazard. For this reason NASA has created a special unit to review the safety and design of all cubesats to be launched via the International Space Station.

The elements that might be included in a spacecraft can be quite extensive. The following represents a listing of the elements that would normally be included in an independent verification and validation plan that would seek to ensure that a spacecraft would be not only safe to launch but also be as resilient as possible and thus achieve its expected lifetime or operate for its nominal mean time to failure (Table 1).

In the case of femtosats, picosats, and nanosats, the quality, verification, and safety testing may be less exacting. The thought process is that if the small satellite can be designed, built, tested, and launched for a cost that is perhaps hundreds or even thousands of times less than a conventional large spacecraft, then there are practical risks that can be taken into consideration with regard to not undertaking the most expensive and time-consuming thermal/vacuum tests or not manufacturing the smallsats in the most exacting and expensive clean rooms. Thus Planet Inc. manufactures their Dove 3U cubesats in what they call their "clean enough" room and avoids thermal/vacuum testing. Each smallsat project thus tends to be designed, built, and tested according to a strategic business plan that makes judgments as to the degree to which they might use commercial off-the-shelf components with regard to digital processors, battery systems, and solar arrays, as well as to which verification tests they will do and the specifications that they will use for clean room assembly. The key question is whether verification tests are focused on the "payload" or the "bus." Thus is the testing most directed toward the smallsats' mission that is to undertake remote sensing, telecommunications or networking services, weather observation, etc., or is the testing zeroed in on the functional platform which allows the payload to perform its tasks?

There is no single set of guidelines as to how exacting the specifications for components for small satellites must be or to the degree to which components should be assembled and tested in the highest quality clean room. The ability to use small satellite missions to provide proof of concept includes testing the use of lower-cost components or new manufacturing conditions to produce spacecraft at lower cost. In the case of commercial systems where there are hundreds or even thousands of spacecraft being produced, the important question of cost savings in manufacturing and testing programs comes from several key factors. As the volume of production

Table 1 Elements of a spacecraft verification testing program (Bukley et al. 2018)

Elements that are included in a spacecraft test plan
Typical components and subsystems to test
Guidance navigation and control
Propulsion
Attitude control, 3-axis stabilization, and pointing systems
Thermal control system
Communications, telemetry, command system, and data handling
Processors, redundant systems, and switching systems
Power systems
Active and passive thermal control systems
Structure, deployment mechanisms, and control sensors and actuators
Payload components and systems (if there is a standardized and flight-proven bus platform, then more emphasis can be placed here)
Adequacy and reliability of the ground control systems and global access of TTC&M systems to satellite network
Areas of testing and test measurement specifications
Thermal range (heat and cold extremes)
Vibration testing (intense vibration at launch, pogo effects, and low-frequency sinusoidal vibrations)
Acoustical systems
Radiation levels
Reliability, precision, and clean room specification for manufacture and assembly
Design reviews and oversight of manufacturing and testing
Functional elements of test plan
Test objectives, frequency, and locations
Test equipment requirements
Step-by-step procedural detail and process
Test methodology and protocol
Input/output value limits and pass/fail criteria

goes up, these questions become increasingly important. Some of the most key factors are:

- Can various components be used that are off-the-shelf products which have not been flight and/or endurance tested and thus acquired at much lower cost and still produce minimal on-orbit failures?
- Can key components or kit structural elements be acquired at low cost from competent suppliers that have developed smallsat elements and products with demonstrated space flight resilience and yet reasonable cost because of their economies of scale? (This is key for particular projects, experiments, or missions that only involve one or a few spacecraft.)
- Can a “good enough” clean room with technicians that have only modest training and assembly skills be used to produce smallsats for the project in question?

- Can quality, verification, and safety testing be limited to only a relatively small number of tests that can be conducted with equipment that is not greatly expensive and does not require long-term endurance testing?
- Can some of the components requiring high precision and resilience be produced by the use of additive manufacturing (i.e., 3D printing)?

Several of these questions apply not only to those producing smallsats, but going forward, these questions might also apply to those producing and testing large spacecraft and launch vehicles as well. Currently the production of small satellites is expanding into new sectors. Thus smallsats are not only being produced at schools and universities and by startup firms that have invented new approaches to the design, manufacture, and testing of the cubesat-sized spacecraft that they are building but also companies from the well-established aerospace world.

One such example is the SENSE 3U cubesat produced by the Boeing Corporation for the US Air Force and launched in 2013. Indeed it can be a large established aerospace corporation that is producing many of the smallsats currently in production around the world (see Fig. 3).

AirBus plays a key role into the production of OneWeb satellites. Boeing has begun the production of the m-Power MEO satellites for SES that represents the second generation of the O3b constellation. Its subsidiary Argon ST along with Sierra Nevada has built the second generation of the Orbcomm system. Thales has filed to deploy its own large-scale constellation and manufactured the second generation of the Globalstar constellation as well as Iridium Next. Boeing has also filed to deploy its own constellation of small satellites as well. The Sierra Nevada Corporation and SpaceX are not exactly established aerospace corporations, but they are no longer seen as startup firms as well. If SpaceX accomplishes its goal, it will become the largest producer of small satellites as well as the largest manufacturer of satellite transceivers on the ground.

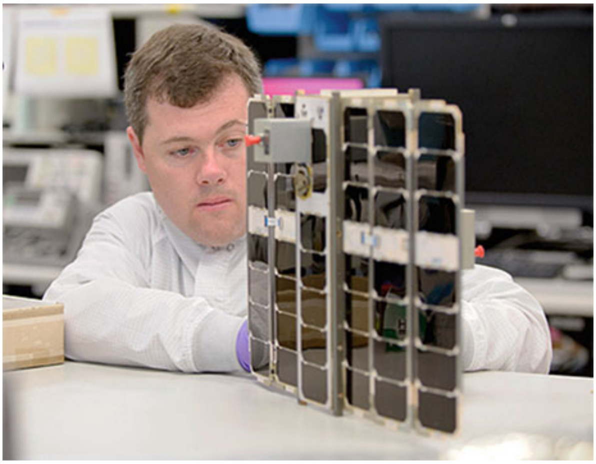

Fig. 3 The SENSE smallsat supplied to the US Air Force by the Boeing Corporation. (Graphic courtesy of the US Army) (Satnews 2019)

What we do know is that way that spacecraft are designed, manufactured, tested and launched have made a dramatic shift in the past decade. The shift to production of smallsats has altered almost every aspect of how to make and deploy satellites, how they are operated, how new generations are deployed, how old satellites deorbited, and how arrangements are made for sparing and reliable operations ensured.

The smallsat was designed to collect meteorological data and transmit it back to Earth via an S-band link to support US Air Force operations and to test the ability of this 4 kg satellite to perform reliably for this purpose in contrast to much larger and more expensive satellites.

4 The Pocketqube Option

The popularity of the cubesat appropriate to experimentation, proof of concept, and other missions that can be achieved with very small satellites has now produced the inevitable result of what is now called the pocketQube.

The pocketQube, as noted elsewhere, is the consequential idea of a picosatellite that is one-eighth of the size of cubesat and is a 5 × 5 × 5 cm cube that can be used to carry out experimentation and proof of concept in even small packages than a cube satellite. The standardization in its volume and a maximum mass of 250 g allows ease of arrangement for launch and also allows kits and components to be developed so that economies of scale can once again be achieved by those that develop key components. These components can be structural frames, batteries, solar arrays, torquerods and other components needed for this new entry into to the smallsat arena.

Alba Orbital, who has pioneered this field, offers a complete kit on the web for the current price of $10,299.00 as of August 2019 and explains its offering in the following terms:

> Satellites have traditionally been expensive with even lower cost solutions like Cubesat costing six figure amounts, limited to those with larger budgets. The PocketQube Kit addresses these problems and widens access to space for smaller budget organisations. The PocketQube Kit is ideal for a wide range of groups who are interested in building a low cost Satellite. For example Science, Technology, Engineering and Maths (or STEM) educators, from K-12, High School up to University. The Kits is also ideal for Governmental customers looking to begin a program. (Alba Orbital 2019)

In the age of miniaturization and microelectronics, no one can truly predict where the process of shrinking of smallsats will end. Today, however, the pocketQube concept has increasingly become a popular idea for student experimentation and low-cost launch arrangements. The Unicorn 2 picosat from Alba Orbital that is now offered via the web is shown in Fig. 4.

Other competitors will offer alternative systems in the future, but Alba Orbital has to date been the prime entry in this area of offering the kit for the complete picosatellite as well as assistance to arrange for launch services. The offerings related

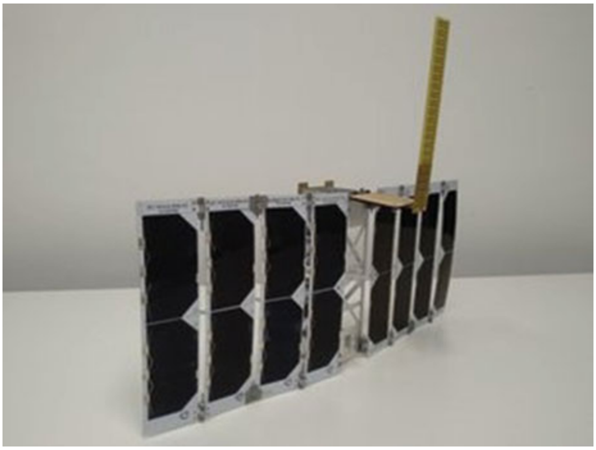

Fig. 4 The Unicorn 2 nanosat of 250 g mass is essentially solar cells and electronics. (Graphic courtesy of Alba Orbital)

to pocketQubes will undoubtedly become even more cost-effective, and perhaps configurations will become even more creative. One of only a few pocketQubes has actually flown into space to date, but dozens are queued for launch. The question that has increased in scope and vigor with regard to cubesats will perhaps reach a crescendo with regard to pocketQubes. There should be an altitude limit attached to tiny smallsats that have no active or passive deorbit mechanism. The idea of restricting nanosats and picosats to a maximum altitude of perhaps 250 km to ensure their return to Earth and safe deorbit is a topic of consideration, and this is likely to receive increased discussion and perhaps international support in the future.

5 Swarm Configurations

The problem with very smallsats is that when they get to be quite small, they lack the power and antenna gain to communicate over long distances. The latest idea centers around extremely small satellites, the size of stickers or even postage stamp. Such small satellites are commonly known as “chipsats.” These can include micro-level sensors that can be deployed to take measurements within a field or dispersed system to take readings and then communicate back to a “mothership” satellite the data that a swarm collects. The data relayed by the chipsats to the mothership can then be communicated back to Earth or a spaceship. Various chipsats are now being developed, and these tiny small satellites (i.e., femtosats) can include sensors able to collect data and report this information as collectively acquired by the swarm (IFL Science 2019; http://www.cubesat.org/new-index).

These types of chipsats are still too experimental to be standardized into kits or uniform components, but in time this seems very likely to be the case. As noted above the problem that would also apply to swarms of chipsats is how are the chipsats recollected and returned to the mothership so as to not leave debris behind (Fig. 5).

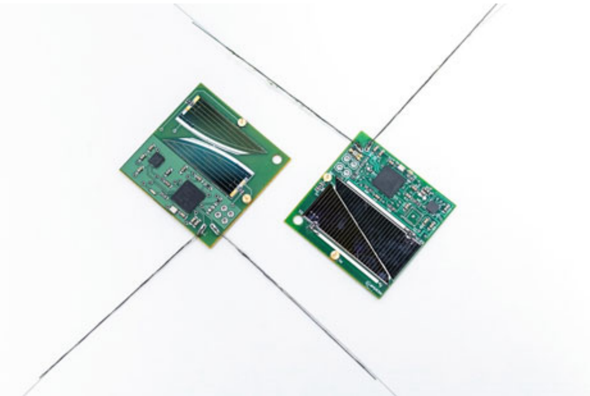

Fig. 5 Stamp-sized "chipsats" that can collect information as a swarm and report data to a "mothership." (Graphic courtesy of Stanford University)

6 Conclusion

The field of small satellites has continued to leap ahead as innovative ideas and new approaches to the design, manufacture, testing, launch, and utilization of small satellites have continued to race ahead. Conferences focused on smallsats, cubesats, and now even pocketQubes and chipsats contribute to the scientific, engineering, and practical knowledge associated with the smallsat field of study.

The whole area of innovation in the field has almost the field of constant innovation and spin-off ideas and creativity. The idea of cubesats for student experimentation, concept development, and learning about spacecraft design has led to a growing number of new ideas. The idea of nanosats and increasingly efficient cubesats has evolved to innovative picosats and pocketQubes. This drive toward increasing efficiency and innovation has in turn led to femto-satellites and even more recently toward chipsats and the idea of swarm systems linked to a "mothership" to collect data and transmit the information back to Earth.

There have also been innovations in terms of testing and verification processes, and as increasing knowledge and manufacturing systems developed, the production efficiencies also have increased. This has now led to a number of commercial ventures that can produce key components and even integrated systems at reduced cost. Today there are a number of smallsat kits and component parts that are accessible through such websites such as www.cubesat.com or pocketQube systems via www.albaorbital.com.

The remarkable development of smallsat technology and systems has made these capabilities available to an ever-widening circle of participants and at ever-decreasing cost. Innovations such as smallsat kits and components can be globally accessed via a growing number of reputable websites. Students at colleges and universities and in schools even down to primary level can be involved in space studies and experimentation. The authors were recently able to see student's space experiments in operation in a public school just outside of Cape Town, South Africa, which was active on the International Space Station.

The more effective use of a variety of smallsat systems and technologies plus improved and more cost-efficient launch systems has opened the doors to many more uses, applications, and scientific inquiries. Space agencies, research institutes, and commercial organizations have found an ever-expanding way to use smallsat efficiencies to explore and probe key areas of space sciences, demonstrate and test new technology and systems, and examine new space applications. This is an important new tool that continues to evolve, improve, and become more capable and cost-efficient.

Resiliency, Reliability, and Sparing Approaches to Small Satellite Projects

Joseph N. Pelton

Contents

Abstract

The design, manufacturing, testing, and sparing approaches that have been used in the space industry have been built up over the course of over 60 years of experience. That experience has come largely from two sources, namely, civil and military space agencies and the aerospace industry serving the operators of increasingly sophisticated space application systems primarily for telecommunications, remote sensing/Earth observation, and GNSS networks. These systems largely had in common that they were complex, big-budget programs that were expected to have a long life despite the harsh conditions of outer space and launch operations. This has led to a design and testing process based on the emphasis of high reliability. This included such concepts as in-orbit spares, providing for redundancy of components that

represent a single point of failure and a very elaborate testing program to qualify all of the subsystems and fully integrated spacecraft against all types of possible flaws that could lead to failure. This approach has led to extensive quality assurance and lifetime testing for each spacecraft and key components. This testing program and the adding of redundancy for key components have extended the manufacturing time for spacecraft. It has also added significantly to the cost. This approach was believed to be necessary because there was no repair capability in space and of the high cost of launches, the expectation of quite long lifetime for spacecraft, plus the need to take this type of approach to obtain launch and operational insurance from underwriters.

The rise in recent years of the “NewSpace” industries, sometimes known as “Space 2.0,” has led to a revolution in how to design, manufacture, and operate spacecraft in Earth orbit. These new players in commercial space have questioned almost everything about commercial spacecraft design, manufacture, deployment, operations, and approach to reliability. They have asked basic questions about the long accepted “conventional approaches” as to how one should design, build, test, and launch spacecraft and even the orbits in which they should operate. Thus there are now a number of new ideas about the architecture of satellite systems and new concepts about how to design, manufacture, undertake quality and lifetime testing, launch, deploy, operate, and provide for operational spares in orbit. When there are hundreds or even thousands of operational spacecraft, the ratio of spares to operational satellites can be greatly reduced down to less than 10%.

The focus on this article is on how small satellites, and especially new small satellite constellations in LEO and MEO orbits, might be designed, built, tested, and deployed with new approaches to resiliency, reliability, and sparing. This approach started in a low-key way when much lower-cost satellites were using off-the-shelf components. This process began with the building of Amsat Oscar satellites and then the efforts of what is now known as Surrey Space Technology Limited. The next stage of thought came with the LEO systems designed by Iridium and Globalstar systems, but the most important breakthroughs came in the era of cubesats and the successful rise of small satellite projects such as those represented by Planet Labs, Spire, Skybox, and other small satellite projects born out of Silicon Valley-based entrepreneurs who have dared to think about satellite design and reliability in totally new ways.

This chapter examines these new ways of thinking and analyzes the pros and cons of these new ways of building and operating spacecraft and assesses how different approaches for different types of systems might still be appropriate. In short there may be more than one approach that can be used for different types of spacecraft that have different goals and aims.

1 Introduction

The world of spacecraft design, manufacture, reliability and assurance testing, launch services, and launch insurance for the space industry is in many ways different from most enterprises carried out on Earth. This is true for a number of obvious reasons.

Once a spacecraft is launched, there are no service personnel available to make repairs or to provide new fuel for thrusters or to replace batteries or solar cells that no longer function. Secondly the space environment is challengingly and in many ways quite lethal. The satellite can potentially be heated by the sun or if shielded become quite cold. There is also potentially damaging space weather in the form of solar radiation, coronal mass ejections of high speed ions, or even bombardment by micrometeorites, cosmic radiation, and now even collisions from orbital space debris. Space is a hostile and dangerous environment for satellites and getting more dangerous. Thirdly, for many decades at least the cost of launch services remained quite high with modest improvement in the cost per kilogram to launch a satellite, and reliability and possible launch failure are always a concern. Fourthly most satellites were ordered in limited numbers, and thus these handcrafted spacecrafts were expensive to build and test for reliability.

In sum, the design, production, reliability testing, launch, and operation of each satellite have become increasingly expensive for the conventional satellite industry as these satellites became bigger, more powerful, yet more cost-efficient. Large and more capable satellites represented a challenge to operate as their tracking, telemetry, and command systems grew to require millions of lines of code and launch insurance costs mounted as well. The development of larger, more powerful, and cost-efficient spacecraft, however, always seemed to make sense in that the high-powered beams allowed the ground systems to become ever smaller and less costly. Low-cost VSAT dishes for broadcast satellite services and even handheld transceivers that grew to number in the millions also provided the cost justification for this technology inversion. More technology and power in the sky for a few complex and powerful satellites made sense if there could be millions of low-cost dishes at every home or apartment building, or this allowed millions of handheld satellite phones to be sold at lower cost.

At various times there were questions about this main line thrust of satellite development to design and build bigger, more capable, yet more cost-efficient spacecraft that could also have lifetimes that extended to 15 years or even 18 years. Volunteer scientists built low-cost amateur radio satellites called OSCARs that were launched at low costs. In the 1990s there were various ideas that promoted the ideas of producing capable but smaller satellites that could be produced on manufacturing lines with greater efficiency and lower cost of production and lower cost of testing once the production line had proved a reliable product. The Iridium satellites, largely designed and engineered by the Motorola Corporation (Thomas n.d.), and the Globalstar network, largely designed and engineered by Space Systems/Loral and Qualcomm, had a major impact on how low Earth orbit constellations and small satellite for mobile communications would be designed, engineered, manufactured, launched, and operated (Globalsatr n.d.).

In some ways the so-called Teledesic satellite network that was backed by Bill Gates and Craig McCaw and first organized in 1994 eventually went bankrupt at the turn of millennium. This never-launched system was conceived as a disruptive technology that would re-envisioned many aspects of the conventional model for global satellite communications.

In terms of design, rapid prototyping and manufacture, use of inter-satellite links, reduced transmission latency, large-scale deployment in LEO orbit, and sparing philosophy, the Teledesic system was designed to create a whole new model for how satellite networks were designed, manufactured, tested, deployed, and operated.

In every key aspect including resiliency of design and sparing this system, as conceived some 20 years ago, is almost an exact a model for the large-scale LEO constellations of small satellites now being implemented today. Certainly some design aspects were found in the Globalstar and Iridium mobile satellite systems that were deployed in the late 1990s. Teledesic, in terms of overall design concepts, however was the "true intellectual parent" of the OneWeb and Starlink megaLEO satellite systems that are currently being deployed and will also serve as precursor in many ways of many other systems yet to come (Lloyd's Satellite Constellations-Teledesic n.d.) (Fig. 1).

The design of the Teledesic system was revolutionary in a number of ways. These included several new concepts in terms of resilience and reliability. Teledesic, which was to be a Ka-band system, envisioned assembly line manufacture but also with

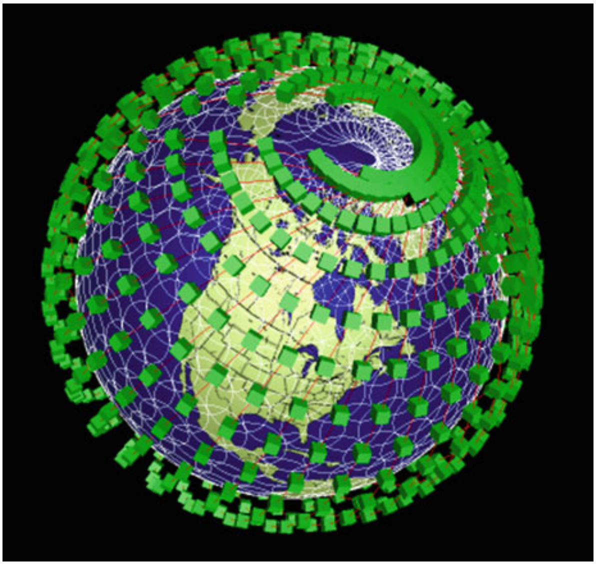

Fig. 1 Proposed 840 Teledesic satellite system plus 80 spare satellites. (Graphic Courtesy of Lloyd's of London)

high levels of reliability. The large number of satellites in the constellation included the idea that the incremental cost of deploying 80 additional satellites as system spares (i.e., 9% of the total) would not be large in proportion to overall cost of manufacturing and launching the overall system. Secondly it envisioned the design would include eight inter-satellite links that could then interconnect to eight adjacent satellites. With this degree of network flexibility, it would not be difficult to work around any satellite failure in the large-scale network. After more system design, studies were done and efforts were made to reduce cost; it was decided in time to reduce the number in the network to 288 satellites. Ultimately the innovative project as first envisioned by Dr. James Stuart as the "calling" telecommunications satellite project was abandoned (Teledesic, Astronautix Encyclopedia n.d.).

The low Earth orbit (LEO) systems that were deployed, namely, the Iridium and Globalstar satellite system for mobile communications and Orbcomm for store and forward data relay services, all thought in terms of putting up spares that could be inserted into operational service. Further, Iridium included the capability of inter-satellite links (ISLs) to increase reliability by working around satellite failures in the network. This feature also greatly reduced the costs in potentially eliminating the need for a large number of TT&C facilities located all over the world. It must be noted that in the case of Iridium, the additional cost to the satellite manufacture of the ISLs largely offsets the cost savings by eliminating the need for a large network of ground-based tracking, telemetry, and command (TT&C) facilities. Thus the main advance was in terms of near instance restoration of services when a satellite might fail.

The final historical note about LEO constellations and reliability comes from what some call the cubesat revolution. The student experimenters that began building small sats in the 1980s and 1990s often did not have huge budgets and then thus tried to find both lower-cost ways to construct their cube satellite experiments, but they also focused on miniaturization of components, sensors, power sources, structures, and antennas to also save on launch costs. These cubesat projects led to commercial start-up ventures that managed to design application satellites that were quite cost-effective.

Thus new commercial ventures such as Planet Labs, Skybox, and Spire found ways to design and build small satellites for a fraction of the cost of commercial operators of more conventional remote sensing and Earth observation companies. In some cases it was lower-cost wiring, batteries, and processors, and in other cases it was miniaturized sensors. These new small satellite system operators conceded that their small satellites were perhaps not as reliable as the larger and more conventional satellites for remote sensing. Their practical answer was to say that they would launch more satellites in their assembly lines that would in essence never shut down. The idea is that they could on their continuous production lines achieve three goals: (i) continuous improvement with frequent new generations of their small satellite measured in weeks or months rather than years; (ii) they would be able to get more frequently updated information for improved analytics; and (iii) they would consider each new small satellite a potential "spare" that would add resiliency to their overall network.

Although small satellites for remote sensing have led the way, the telecommunications satellite industry has followed their lead to pursue small satellite innovations. In this case the motivation has been the pursuit of new markets with low-latency satellites that are better suited for Internet-based services, Internet of Things (IoT) services, broadband 5G services, and better services to rural and remote areas. Another driver is the shift from broadcast satellite service to OTT (over the top) digital streaming via broadband networking. The need for power and antenna gain has not allowed communication satellites the same miniaturization advantages, but the other advantages seem to all apply.

These other gains that apply for small sat networking satellites include more efficient high-volume manufacturing, additive manufacturing techniques, more efficient deployment of small satellites from new reusable launch vehicles, and new sparing concepts used in all of the very large-scale constellations.

This change in satellite system design has happened quite quickly over the past 10 years. There are now three main types of satellite systems that are now available for the largest space systems market of telecommunications including broadcasting and networking. There are high-throughput satellites (HTS) with extraordinary data streaming and broadcasting efficiency deployed in GEO orbit such as operated by Intelsat, EchoStar, Eutelsat, and Telesat.

There are the MEO orbit satellite networks as represented by SES's O3b and its latest mPower network that is being manufactured by Boeing (Henry 2017) (See Fig. 2). And then there are the high- to medium-speed LEO constellations that vary everywhere from the Kepler and Capella true small sat constellations to the much larger mini-satellite LEO systems such as those currently being launched such as OneWeb, SpaceX's Starlink, and others to be deployed.

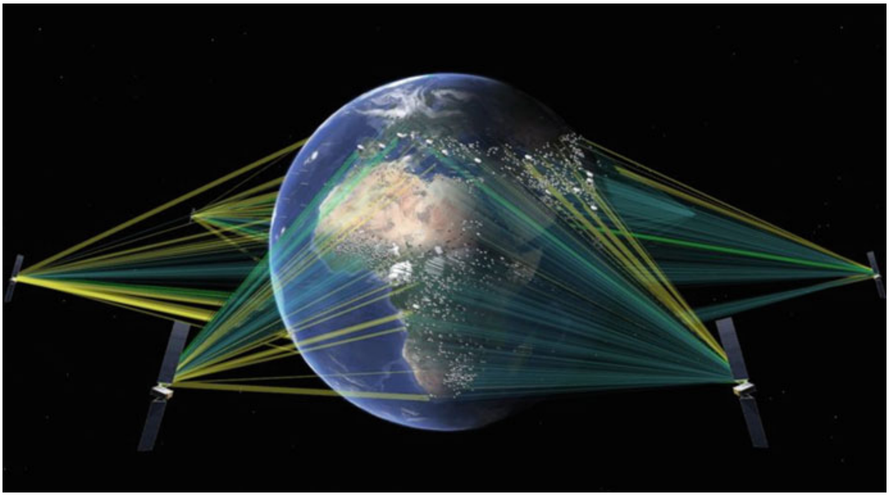

Fig. 2 The new O3b MEO "mPower" network with fiber-like throughput speeds. (Graphic courtesy of SES)

What is important to note, in terms of reliability and resilience, is that these various types of satellite systems entail different approaches to coping with risk and spacecraft or system control failures. Nevertheless each has a technical logic and business and economic viability to them. The strategies for GEO and MEO systems are closely aligned with the conventional approaches to quality and mission assurance, while the LEO systems largely represent a new approach of letting the large number of satellites in the constellation to be the protective margin for service reliability. This may or may not also be augmented with inter-satellite links designed to provide additional protective margins for systems control and network redundancy.

Each of these approaches will be discussed below. In addition the added complication of orbital debris and debris removal, especially in the large-scale LEO constellations, will be discussed as an additional element of risk.

2 Reliability and Resilience for GEO and MEO Networks

The traditional approach to providing for the reliability and resilience largely continues to apply to GEO and MEO systems. This is because the number of satellites that are procured at one time, for such networks, continues to be a rather small number that is typically in the range of 4–10 spacecrafts. This limited number of procurement limits the ability to take advantage of the economies of large production runs and achieving a number of spare satellites at the incremental cost of last satellites in the production run and economies of scale achieved at the end of a production run and the economies associated with launching a number of satellites together to low Earth orbit (LEO).

There are efficiencies of production and benefits of proven efficiencies that can be realized by manufacturers creating standardized platforms that have proven reliability. Thus manufacturers tend to create three-axis stabilized spacecraft platforms often optimized for satellites of a particular size, mass, and power performance. Thus a satellite operator might be purchasing say four, six, or eight spacecrafts at a time, but the payload may be integrated with a proven platform bus that has been successfully flown on scores of other missions. Thus the specialized remote sensors or telecommunications antenna system for a particular mission may fly on a proven bus that has performed reliably on many previous missions. This provides both a cost bonus and risk reduction benefit.

There is a need for reliability testing for the new payload and for the payload as integrated with the platform to ensure that the risk of an in-orbit failure is as low as possible. The testing process breaks down into what systems and subsystems that are to be tested, the type of testing that is to be done, and when and where this test evolves into a test plan for the satellites. The key components and subsystems that are typically to be tested, the types of tests, and test plan components are noted in Table 1 (Bukley et al. 2018).

The reliability, performance, sophistication, and operation of satellites in Clarke orbit (GEO orbit) and MEO orbits are in many ways quite similar. These typically are high-performance satellites with sophisticated instrumentation, relatively high-power systems with high-performance sensors or telecommunications antenna capable of supporting high-precision spot beams designed to achieve very high levels of frequency reuse. Thus all of the testing procedures and quality and mission assurance tests noted in Table 1 above would be all likely included in acceptance testing for both MEO and LEO satellites. Nevertheless there are some differences that are worthy of note.

Radiation level testing: The satellites in MEO orbit are more likely to be subjected to much higher levels of radiation. GEO satellites are generally above the highest levels of radiation exposure from the Van Allen belt. GEO satellites still have to be concerned about radiation flares from the sun that occasionally occur, but radiation from the upper Van Allen belt is more or less a pattern of a continuous

Table 1 Key elements in a test plan, types of tests, and component tests

Elements that are included in a spacecraft test plan
Typical components and subsystems to test
Guidance navigation and control
Propulsion
Attitude control, three-axis stabilization, and pointing systems
Thermal control system
Communications, telemetry, command system, and data handling
Processors, redundant systems, and switching systems
Power systems
Active and passive thermal control systems
Structure, deployment mechanisms, and control sensors and actuators
Payload components and systems (if there is a standardized and flight-proven bus platform, then more emphasis can be placed here)
Adequacy and reliability of the ground control systems and global access of TTC&M Systems to satellite network
Types of tests and manufacturing specifications
Thermal range (heat and cold extremes)
Vibration testing (intense vibration at launch, pogo effects, and low-frequency sinusoidal vibrations)
Acoustical
Radiation levels
Reliability, precision, and clean room specification for manufacture and assembly
Design reviews and oversight of manufacturing and testing
Test plan components
Test objectives, frequency, and locations
Test equipment requirements
Step by step procedural detail and process
Test methodology and protocol
Input/output value limits and pass/fail criteria

degree of exposure. Thus the design of MEO satellites will typically include more of a glass-like coating of the photoelectric cells in the solar array to extend lifetime. The electronics and circuit breakers and switches will need to be designed to protect against high levels of radiation exposure.

Thus the exact orbit and its nearness to the Van Allen belts and the need for protective shielding or precautions against high level of radiation from high energy protons in these belts must be taken into consideration.

The inner belt is shaped like a toroid (i.e., like a doughnut). This first belt is largely concentrated between 960 and 6000 km or (600–3700 mi). The outer belt (another toroid) is largely concentrated between 15,000 and 20,000 km (or 9300 and 12,400 miles) above the planet. In short radiation from the Van Allen belts is highly concentrated and can be quite harsh at some altitudes and much more benign in other regions (see Fig. 3).

Thus LEO satellites are often deployed at altitudes under 1000 km, and MEO satellites tend to be orbited in the range between 6000 and 15,000 km. If they are deployed in the range between 15,000 and 20,000 km such as the case with the NAVSTAR GPS satellite system, additional radiation protection and shielding for the solar arrays and the electronics are highly advisable.

Further digital processing chips and electronic components should be tested against higher radiation levels. Of course the added shielding increases spacecraft mass and thus boosts launch costs (Howell 2018).

Deorbit requirements: There is another mass penalty associated with MEO satellites that is actually much larger than that represented by shielding to protect solar cells, electronic components, switches, and processors. This penalty comes from the fact that MEO orbits create a real challenge for deorbiting at the end of life. LEO satellites are easiest to bring down to splash in the oceans or more likely burn

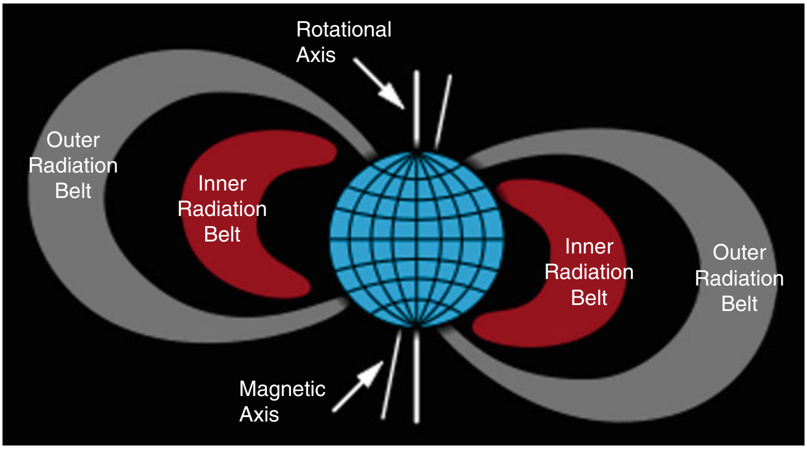

Fig. 3 The Van Allen belts represent high-radiation areas and a threat to spacecraft. (Graphic courtesy of NASA)

up in the atmosphere. GEO satellites can be raised to a higher parking or “graveyard” orbit where they can remain for literally millions of years.

MEO satellites, however, must add quite a bit of additional fuel (about 40% additional to that provided for regular station-keeping) in order to actively deorbit them. These types of spacecraft in terms of their orbital configuration are in the reverse of a “Goldilocks” orbit in that they are either too high to deorbit back toward Earth or too low to go into a graveyard orbit above geosynchronous orbit. In terms of number of satellites to create a global network (i.e., about 15–20) or altitude that does not to have too much path loss or latency, MEOs were first thought of the perfect compromise between extremes, but in terms of excess fuel to achieve deorbit, these types of satellites represent the extreme example. If strict new regulations are enacted for mandatory deorbit guidelines, it will be MEO orbit satellites that will have the greatest challenge to meet without there being a large financial and operational challenge.

3 Testing Apparatus

One area where MEO orbit satellites can have an advantage over GEO satellites is that they can often be much more compact than GEO orbit satellites. These satellites because they are twice to even four times closer to Earth can have the equivalent of 4–16 times the effective antenna gain or sensor performance of a GEO satellite. This means that the satellite can be less massive and have smaller solar arrays or smaller antennas than a larger GEO satellite. This means that smaller and less costly thermal vacuum chambers can often be used for testing. In general verification and validation assessments, lifetime or stress testing or performance can be done at lower costs.

4 Reliability and Resilience for Small Satellite Networks

The “NewSpace” revolution has been disruptive to many aspects of how spacecraft systems are designed, manufactured, launched, and operated. Core to these changes is the idea of small satellites that are less costly to design and built with components that sometimes include off-the-shelf components and are manufactured via such techniques as additive manufacturing. They also might be less extensively verification and validation testing after the manufacturing process has been proven to be precise and completely consistent against proven standards. This small satellite production in large quantities for constellation numbering in the hundreds or thousands allows the paradigm to shift from a few satellites elaborately tested for absolutely highest of standards of reliability and resilience to a process of having a large array of satellite serving to verify system reliability.

5 Small Satellite Constellation Design as Self-Sparing Network

The predominant approach to satellite applications for many years was to have a limited number of operational satellites and an even more limited number of designated in-orbit or possibly on-ground spares ready for launch. The idea of large-scale constellations includes a sufficient number of satellites that the entire constellation represents a sparing capability for itself. The Iridium and Globalstar mobile satellite system did deploy satellites intended as in-orbit spares but leveraged the capability of these spares in various ways. The Iridium system introduced the concept of inter-satellite links (ISLs) so that adjacent satellites could work around the "hole" created by any satellite failure until the replacement satellite was maneuvered to the correct orbital position. Further it developed a system of deploying spare satellites in a slightly lower orbit that could efficiently be lifted to the proper position and thus reduce fuel expenditure and increase the speed of restoration of full service capability.

The shift from LEO constellations with 50–70 satellites to megaconstellations with many hundreds and potentially thousands of satellites creates a large enough network that individual satellites are no longer of great consequence. Particularly in networks for remote sensing such as Planet Labs, the idea of reliability is geared simply to such measures as moving up the regular deployment of satellites. The existing large number of satellites will respond to any satellite failure. There is no longer any scarcity of spare capacity since the entire constellation is the spare.

This approach has been summarized in the following manner: "For this type of alternative design architecture, the replacement of failed satellites with a ready supply of spares [within the existing network] is the key to achieving system reliability. This approach is seen as the alternative to stringent testing and flight-qualified components with proven long-life capabilities in a stringent space environment"(Pelton 2018).

In networks such as SpaceX's Starlink that envisions the ultimate launch of around 12,500 spacecraft, there will be more or less a constant deployment of satellites including spare satellite capacity. When there is a campaign of launching 60 satellites at a time that only represents 0.5% of the entire network, the calculus of sparing dramatically changes.

6 Inter-satellite Links (ISLs) to Augment Reliability

Of course networks such as Starlink represent the extreme for large LEO networks. Another strategy that was introduced by Iridium and was proposed by Teledesic was the use of inter-satellite links (ISLs) to work around satellite failures that might create a gap in complete global network coverage.

The addition of inter-satellite links to large-scale LEO networks is clearly a way of extending the reliability of a large satellite network. If adjacent satellites either to the side or with regard to leading or lagging orbits can connect to users, then the outage would not be apparent to the user community. If there is a spare satellite in a slightly lower orbit that can be raised to the orbital location where the failure occurs within hours of the failure, the problem would be seamlessly addressed. The biggest problem might be finding a way to deorbit the failed satellite.

7 Radiation and Space Weather Concerns

There is always a concern with spacecraft being exposed to solar flares and coronal mass ejections (CMEs). Fortunately for LEO systems, these are best protected by the Van Allen radiation belts and the Earth's natural electromagnetic protective fields. Thus while there should be some concern for shielding and protection against a high-level CME event, this is not a key concern for LEO constellations deployed below 1000 km. For constellations that are launched in orbits about 1000 km, perhaps more concern should be given to radiation testing.

8 Lifetime Concerns

Spacecraft that are deployed in LEO orbits tend to have shorter lifetimes than satellites deployed in GEO or MEO orbits. This is because of their nearness to the Earth's atmospheric drag; high orbital speed; strict mass budgets that limits redundancy for key components, subsystems, or vital components; and no allowance for additional fuel, batteries, or other expendables. Mean time to failure in the range of 6–8 years might be a typical expectation. This shorter lifetime can be seen as an advantage in terms of being reasonably able to use more off-the-shelf components, processors, batteries, and structural elements that are lower in cost yet still have a reasonable lifetime expectations.

On the other hand, the shorter lifetime for quite large constellations, particularly those that might have thousands of spacecraft deployed in a network, represents a disadvantage. If satellites have a lifetime of 6–8 years before they need to be replenished with new satellites, it is a major if it takes up 1–2 years before the launch campaign is finished. GEO and MEO systems can be quickly deployed, and lifetimes in the 12–18 years range are common. The full lifetime of the GEO and MEO networks can be realized and exploited, but for megaLEO systems the deployment period eats into the period of useful system exploitation.

9 Deorbit Concerns

The deorbiting issue of satellites at the end of their practical life that is well synchronized with the deployment of the next generation of upgraded satellite represents a number of practical, technical, economic, and reliability and resilience concerns. The number of crucial questions that are concerned here includes:

How long can a system operator extend the operational lifetime of retiring satellites without risking the possibility of collision between retiring spacecraft and the new generation of satellites?

Are the deployment approaches now being used to launch large number of small satellites such as the spinning release of 60 satellites at a time (in the case of a Falcon launch vehicle for the Starlink system) sufficiently safe in the case of a replenishment of a LEO network, or is a controlled dispenser needed?

Are the current voluntary guidelines from the IADC for deorbit of satellites some 25 years after end of life now obsolete and perhaps highly dangerous in light of the likely replenishment schedules of LEO constellations occurring every 6–8 years and launch campaigns that might take 1–2 years to complete?

10 Concerns About Orbit Space Debris

The concerns of the new very large-scale constellations and the accelerated chances of orbital collisions continue to rise. Current estimates of the likelihood orbital collision between two space objects as developed by NASA and ESA estimate the current odds are now between once every 5 years and once in every 10 years. These assessments were developed prior to the latest plans to launch perhaps over 20,000 new spacecraft in the next few years with a high concentration in low Earth orbit (LEO).

The Aerospace Corporation has undertaken an analysis of the additional concern that a deorbiting spacecraft from one of the new LEO constellations might possibly hit an aircraft. This assessment found that there was indeed a finite possibility that such a collision could occur with a greater than 1% per year in the event that all of the proposed constellations were deployed as now envisioned.

11 Conclusion

The world of “NewSpace,” “Space 2.0,” and the so-called small satellite revolution has brought many changes to the space industry. These new approaches to designing, manufacture, launch, and operation of application satellites have been disruptive in many ways. One of the many significant changes has come in how the resilience and reliability of space systems are planned for and implemented. The new manufacturing and testing methods associated with small satellites including the use of more off-the-shelf components and large production runs with automated processes have tended toward satellites with lesser standards of reliability being launched, but the sheer volume of the spacecraft that are planned for launch is seen as a means of increasing the reliability of the overall networks that have significantly larger elements to ensure continuity of service.

There are several aspects of small satellite design and manufacture that can assist with reliability and rapid restoration of services. The elements include (i) inter-satellite links (ISLs) that can allow routing of service around failed satellites, particularly in the case of telecommunications and networking services; (ii) additive manufacturing techniques that can increase reliability of component parts; and (iii) super redundancy of satellites deployed in megaLEO constellations in order to allow the "network to be the spare" rather than designated spare satellites.

These new approaches to sparing and reliability of small satellite constellations have tended to shift the emphasis of concern from "sparing philosophy" to concerns about space traffic management, space situational awareness, and the prevention of collisions between the large number of satellites that are being deployed into huge constellations. The particular concern is the disposition of satellites in large constellations at the end of life and the new deployment of spacecraft for the next generation of satellites. In the age of GEO and MEO constellations, this was a relatively straightforward and not particularly high-risk type of operation. The experiences with the Globalstar, Iridium, and Orbcomm networks have already shown that deorbit operations involve risk elements that raise significant concern. The move to large-scale constellations with thousands of spacecraft raises a new level of concern about the deorbit and replacement process and the risk of collisions occurring.

There are also concerns about the reliability of command and control systems and systematic control of such networks without spacecraft conjunctions and potentially catastrophic collisions occurring. The resiliency of TT&C networks and the ability to execute commands on a continuous and uninterrupted basis represent a concern that is perhaps not fully addressed.

Some of these concerns can and will be addressed through improved technology and artificial intelligence in satellite control systems. Other aspects of the concerns for orbital safety and the long-term sustainability of outer space activities will need to be addressed in new regulatory guidelines and processes. These might be by means of bottom-up development of best practices. In time these safety measures will likely require new processes associated with internationally agreed methods of space traffic management and perhaps globally mandated methods for orbital debris removal and improved systems to achieve sustainability of space services and operations in Earth orbit – particularly in low Earth orbit.

Ground Systems and Small Satellites

Evolution of Satellite Networks and Antenna Markets

Arunas G. Slekys and Safieddin (Ali) Safavi-Naeini

Contents

Abstract

The VSAT (very small aperture terminal) was first developed for commercial use by Hughes Network Systems in the mid-1980s and implemented on the first commercial satellite network for Wal-Mart, operating over a GEO (geostationary) Ku-band satellite. In over 30 years since, there have been dramatic advances in satellite, networking and ground system technologies, solutions, and services, the scope of which go well beyond what can be addressed in this Handbook. The modest objective of this chapter is to provide key insights into the evolution of satellite networks and associated ground systems that today serve all global

market sectors. It identifies applications for which the transformative potential of electronically steerable phased arrays (described in chapter ▶ "Electronic Beam-Scanning Technology for Small Satellite Communication Systems and Their Future Development") is poised to displace mechanically steered parabolic antennas as large-scale, small satellite constellations are launched. The net result will be an expansion of global satellite markets and diversification of ground systems, as VSATs and flat panel, phased array solutions supplement each other to fuel the expansion.

The world of small satellite constellations in LEO and MEO orbits will extend the reach of satellite communications, particularly in underserved portions of the world. By eliminating mechanical steering, flat panel antennas with electronic tracking will open up new addressable mobility markets through lower cost and compact packaging, whether for airborne, maritime, train, or land vehicle applications. This is not a matter of ground satellite systems being replaced, but supplemented in a very significant way.

1 Introduction

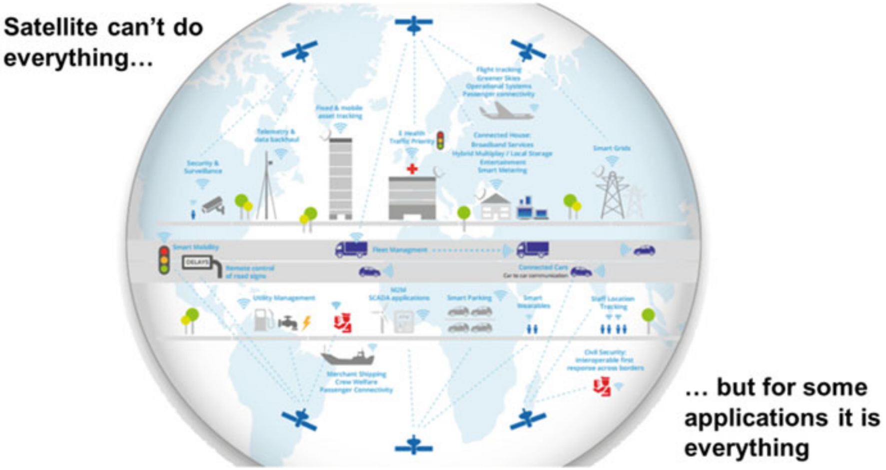
That decision to implement the first enterprise satellite network by Walmart was hailed by Fortune magazine (Fortune 2005) as "one of 20 most strategic business decisions of the twentieth century" because it gave them an "informational competitive advantage." In particular, it gave Sam Walton, the owner of Walmart, the ability to review progress of his many distributed stores by utilizing the then new medium of video-conferencing with his management team, including sharing up-to-date sales, marketing, and inventory information. Only satellites could reach all of his locations across the country, mostly in rural America, and unlike terrestrial technologies, offering uniform quality of service delivery at costs that are independent of location.

Fast forward more than three decades and these core benefits of satellite networks remain as key drivers in enterprise and government markets globally. Most significantly, advances in satellite architectures and technologies have lowered cost per bit of high-speed service delivery to be competitive with terrestrial, thereby expanding addressable markets to include the billions of consumers unconnected worldwide. Latest market data (Northern Sky Research 2019) shows the total installed base of VSATs globally is approaching seven million sites, with approximately four million being consumer and the aggregate growing at almost 15% CAGR. Today's largest consumer satellite Internet service, on just one VSAT system, i.e., HughesNet™, spans the Americas with over 1.4 million subscribers.

Invention of the VSAT began the transition from when only large corporations or broadcast networks could afford the large dishes and the extensive real estate required to receive signals from the early C-band and Ku-band GEOs, to today's world of multi-spot beam, Ka-band, high-throughput satellites (HTS) in which everyday consumers can enjoy the benefits of high-speed Internet access at affordable costs. For example, in the mid-1960s, Intelsat I (http://www.boeing.com/defense-space/space/bss/factsheets/376/earlybird/ebird.html) required a 30-meter Standard A parabolic antenna to receive one TV signal. Just two decades later, this had dramatically changed. The first VSAT emerged as a large briefcase-size box weighing several kilos connected to an external 1.5- to 2-meter fixed parabolic antenna, providing typically a maximum user uplink data rate of 9.6 kbps and costing approximately $10,000.

Today's GEO satellites can transmit over 200 TV channels into a half meter parabolic antenna and receiver or deliver up to 1 Gbps of two-way Internet data throughput via the latest generations of compact VSAT installations, including modems/routers and a range of fixed/mobile/transportable antennas, virtually all being mechanically steerable parabolics.

As illustrated in Fig. 1, today's burgeoning multi-billion dollar satellite industry is a core part of a rapidly evolving networking architecture that connects people, enterprises, and things worldwide, delivering video, voice, and Internet access/data services to millions of locations.



- Consumers
- Service providers
- Large and small enterprises across all verticals: Oil and gas, utilities, retail, news, lotteries, hospitality, banking, film production, forestry, sporting events, insurance
- Government and defense: Border patrol, NASA, FEMA, EPA, FBI, NATO
- Emergency services organizations, police, fire, medical

2 Satellites Enable High Availability Connectivity

By virtue of operating over wireless channels in space, satellite networks uniquely provide a robust alternative path to terrestrial links, whether fixed (fiber, cable, landlines) or wireless/cellular. High availability, fault-tolerant solutions result when both networking categories are configured together, with either as primary or backup, making them critically important when disasters strike for both emergency preparedness/response and maintaining enterprise or government operations. As a case in point, during the aftermath of Hurricane Maria which hit Puerto Rico and the US Virgin Islands in November 2017, satellite connectivity proved invaluable in recovery operations as terrestrial infrastructure was devastated (Fig. 2).

Hughes and partner, Response Force 1, supported the San Cristobal Hospital in Ponce by deploying VSATs and solar generators, helping to keep it operational and enabling leadership teams to order supplies and medications as well as evacuate patients in critical condition. They also supported businesses, such as wholesalers, pharmacies, retailers, and others to ensure operations could continue, including processing insurance claims, credit card payments, and government-issued food stamp (debit card) purchases – which was critical as cash was difficult to come by following the storms. And not to mention working with federal agencies to reconnect airports in St. Croix, St. Thomas, and San Juan in order to schedule first responder flight cycles to the islands (Fig. 3).

3 Mobility Solutions: From Emergency Response to Telemedecine, Mobile Education, and Banking

In virtually all the application areas illustrated, VSATs and related satellite systems/gateways from the earliest versions to the most advanced have employed primarily parabolic, mechanically steerable antennas operating over Ka or Ku band GEOs, in either fixed, transportable, or mobile configurations. Figure 4 illustrates just one example (C-COM Satellite Systems 2019) of a transportable antenna offering, a category that evolved to serve a wide range of markets by virtue of rapid, self-pointing capability, typically 90 seconds or less, and not requiring specially trained experts – in this case with solar panels and battery backup for rapid deployment virtually anywhere.

Transportable configurations span a wide range of applications globally, from satellite newsgathering, to mobile telemedicine, remote oil/gas and military field operations, cellular towers on wheels, and more, which the reader may find at various vendor websites. Figure 5 shows examples from various countries of mobile clinics configured for different categories of medical care, from basic checkups and nutritional guidance to breast cancer screening – bringing much needed telemedicine services to the public living outside urban areas.

Mobility applications as opposed to transportable have proven extremely challenging when employing mechanically steerable antennas, and all require some form of movable and stabilized platform, including accurate GPS and gyro positioning.

Fig. 2 Terrestrial infrastructure can struggle to withstand the forces of nature. (Graphic courtesy of Hughes Network Systems)

Fig. 3 Satellite connectivity at the airfield of San Juan Airport. (Graphic courtesy of Hughes Network Systems)

- Portable and scalable
- Transportable case includes battery, 2-4 foldable solar panels (125W)
- Single sealed lead acid battery holding up to 100Amp/Hr, expandable
- Direct AC (110 or 220VAC) and DC (12VDC) outlets
- Recharged via solar panels, vehicle DC or AC;
  can operate for 2 days: typical load(Antenna+Ctlr+modem+BUC+IPphone+laptop)

Fig. 4 Example of transportable self-pointing parabolic antenna. (Courtesy of C-COM Satellite Systems)

Fig. 5 Examples of mobile telemedicine vehicles. (Graphic courtesy of C-Com Satellite Systems)

Whether operating over GEOs, MEOs, or LEOs, and whether for airborne, maritime, or train services, such configurations are bulky and relatively expensive, on the order of 100 thousand or more US dollars, and as a result have been limited to low volume commercial and military markets.

Figure 6 shows an example of an airborne, mechanically steerable Ku/Ka dual-band antenna designed for commercial aircraft. Besides the high cost of retrofit, the relatively large radomes to house such antennas increase flight drag and add to fuel costs. Despite these barriers, the market demand is unabated, and Euroconsult estimates that more than 23,000 commercial aircraft will offer connectivity to passengers by 2027 (up from 7,400 aircraft in 2017).

A discussion of electronically steerable phased arrays as a game-changing alternative to the mechanically steerable parabolic follows in chapter ▶ "Electronic Beam-Scanning Technology for Small Satellite Communication Systems and Their Future Development," highlighting its advantages in reducing size, weight and power requirements and with lower cost. This is especially important for airborne applications through reduced radome sizes and hence corresponding drag, not to mention opening up the potential for personal vehicle applications.

4 Emerging Hybrid Architecture: From GEOs, MEOs, to LEOs, SmallSats, and 5G Wireless

Today, with over 7 billion wireless and over 4 billion Internet subscribers, we are on the brink of creating a truly interconnected global society with unprecedented opportunities to advance social and economic development in all nations. But to

realize this dream, the most pressing question now is how can we create the best delivery ecosystem on a planet-wide scale to realize the greatest promise of the Internet itself: To be always available, easy to use, affordable, and transparent to users? The answer lies in marrying new generations of satellite with both terrestrial fixed and wireless technologies such as 5G. This is already happening in the marketplace – and rapidly advancing beyond GEOs to include MEOs, LEOs, and an emerging plethora of SmallSat constellations. Figure 7 summarizes Euroconsults' forecast of total satellites of all types to be built and launched by 2026, approaching 3000 and representing approximately $300B of investment. The latest filings and

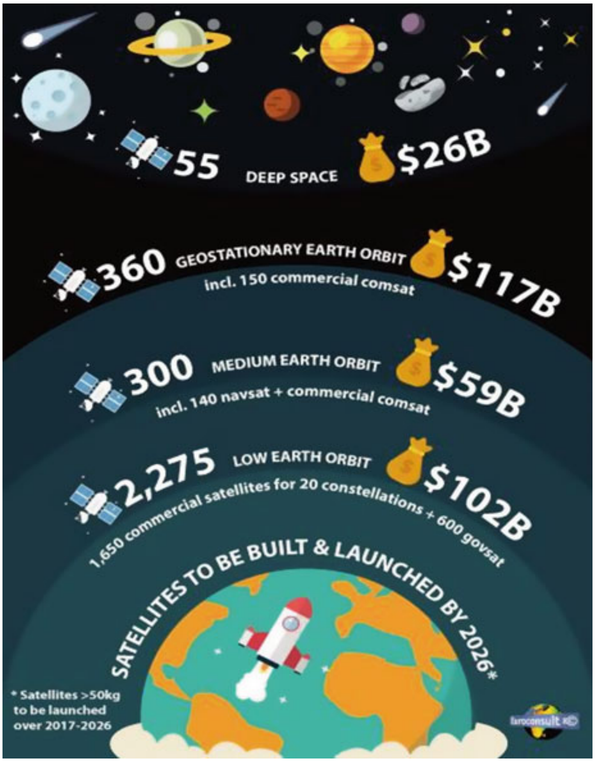

Fig. 7 Satellite launch forecast. (Courtesy of Euroconsult)

launch schedules may actually change substantially due to new small satellite constellation launches on the plus side or Covid-19 virus impacts on the negative side. According to Researchandmarkets.com, the overall global supply of satellite capacity – including GEO, MEO, and LEO constellations – will grow from 1.3 Tbps in 2017 to almost 10 Tbps by 2022, an eightfold increase in just 5 years.

No visionary could predict these advances, not even Arthur C. Clarke, who in 1945 had postulated that geostationary orbiting platforms could provide all types of services to mankind everywhere, with receiving parabolic antennas of about 1 foot in diameter! Indeed, the communications satellite is a machine that has changed the world for the better – one of the major engineering achievements of the twentieth century.

4.1 The Affordability Challenge

In countries and regions where individual subscriptions to satellite service are too expensive for the average resident, hybrid solutions of wireless and satellite technologies are emerging to power community Wi-Fi hotspots and shared VSAT services that make access affordable. The main advantage of these solutions is that people can use their own devices, usually handheld mobile phones, a category today that accounts for 48% of web page views worldwide (https://www.statista.com/topics/779/mobile-internet/). This simple example of marrying cellular and satellite technologies has helped bring connectivity to numerous "mobile first" markets in Asia and Africa, providing cellular operators a cost-effective path to expand their addressable markets beyond higher density urban areas. It's estimated that by 2022 nearly 12% of global mobile traffic will be via the emerging 5G wireless technologies (https://www.nsr.com/geo-vs-non-geo-who-wins-the-90-billion-consumer-broadband-opportunity/?utm_source=NSR+Email+List&utm_campaign=509a5de80e-VBSM18.BL1&utm_medium=email&utm_term=0_524993cda3-509a5de80e-259555657), which in ex-urban and rural regions with limited or no terrestrial services will undoubtedly include combined sat/cell hybrid approaches.

At the satellite systems level, the industry has advanced from single CONUS-coverage Ku-band GEO satellites with a few Gigabits of capacity, to multi-spot beam GEO architectures with from tens to 100s of Gigabits of capacity – so-called high-throughput satellites (HTS) – and on the near horizon, numerous constellations of MEOs, LEOs, and the newest category of SmallSats or Microsats. Table 1 summarizes the key variables of GEO/MEO and LEO satellites extracted from Reference (Architectures for Next Generation High-Throughput Satellite Systems 2014), which is an excellent treatise on the subject of satellite architectures.

This architectural evolution has led to new designs for systems, gateways, and a plethora of high-speed user terminals which are beyond the scope of this handbook. The reader may reference any number of manufacturer's websites to learn about their respective system and service offerings, including advancements such as wideband channels with DVB-S2x modulation, high-density gateways with lights-out operation, web acceleration/caching, advanced compression, and hardware security – which all taken together result in more efficient management of satellite bandwidth and, hence, low OPEX/CAPEX for operators, greater flexibility in creating competitive service plans, and a media-rich customer experience.

4.2 The Internet of Things (IoT) Explosion

On the immediate horizon is the Internet of Things (IoT) and its associated cellular/wireless 5G technology, arguably one of the most exciting and revolutionary technological developments of the Internet age. IoT is a network of cyber-physical devices comprising embedded electronics, sensors/actuators, software, and connectivity, enabling such devices to collect and exchange data over the Internet. These devices interact with physical environments, whether in homes/offices or externally on land, sea, or airborne, and their data collected by sensors are processed intelligently in order to derive useful inferences and enable controlling them. For example, an actuator is a device that is used to effect a change in the environment, such as adjusting the temperature controller of an air conditioner, which could be on an airplane, in cruise ship, or in an apartment.

Table 1 Satellite system parameters

			LEO		MEO		GEO	
			Up to 20 deg elevation	Over 400 km wide nadir cell	Up to 20 deg elevation	Over 400 km wide nadir cell	Up to 20 deg elevation	Over 400 km wide nadir cell

IoT applications are essentially unlimited, spanning industrial processes, logistics, eco-sustainability, energy efficiency, remote assistance, and environmental monitoring, with estimates of as many as 50 billion devices by 2025. As for any networks, performance indicators, such as scalability, reliability, data throughput, latency, and energy consumption are important system design considerations. In particular for IoT – representing networks of networks – the range of metric values is especially wide, given there will be literally billions of devices which can each be served timely with very low data rates, while aggregations can require substantial capacity.

Introduction of 5G wireless links will provide for high data rates with low end-to-end latency, which are particularly important properties for such time – critical applications as autonomous cars and intelligent transportation systems. Coverage of 5G networks will in the foreseeable future be limited to urban and higher density areas, due to cost constraints of terrestrial buildout. This presents the opportunity to marry satellite and 5G terrestrial wireless networks to create a unified framework for seamless IoT coverage as illustrated in Fig. 8.

Such an architecture is rapidly evolving and with the following advantages:

(i) **Global Coverage**: Constellations of GEO (Geo-stationary) satellites employing Ka-band spot beam technology are rapidly covering the globe and already delivering high speed, affordable Internet access to millions of subscribers either unserved or underserved by terrestrial broadband technologies,

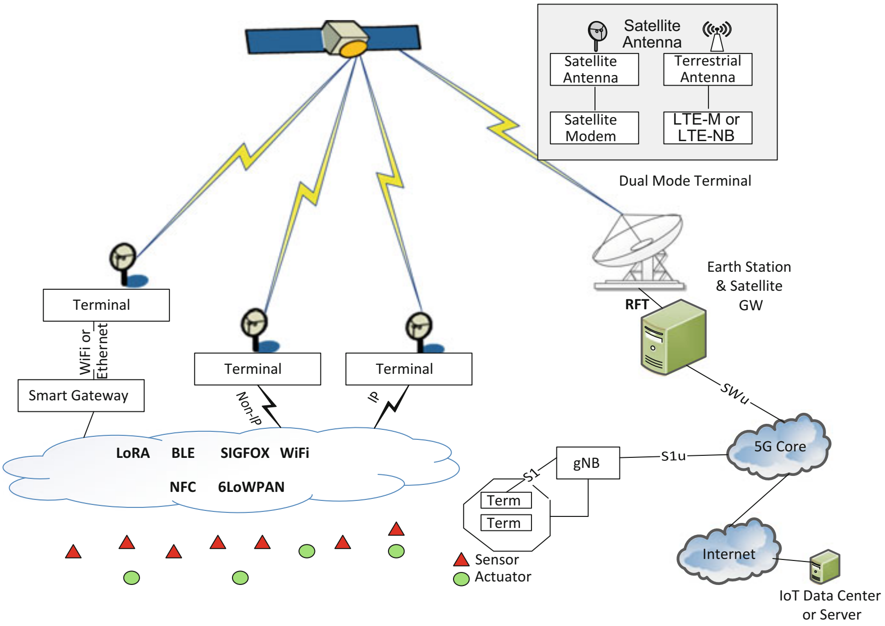

Fig. 8 Hybrid satellite and 5G architecture. (Graphic courtesy of Hughes Network Systems)

whether fiber, DSL, cable, or wireless. Soon to be launched LEO (low –earth –orbiting) satellites such as by OneWeb, Telesat, and Amazon will augment capacity globally in the next few years, and orbiting at approx. 1000 km result in much lower latency than GEO's at 40,000 km.

(ii) **High Reliability/Availability**: The high reliability of satellites is well proven, with service quality levels typically at or above 99.9% and with in-orbit operational lifetimes of 15 years as the norm, meaning IoT networks can be readily configured as a combination of terrestrial 5G and satellite with either providing primary or backup connectivity or as a hybrid simultaneous cellular-satellite solution.

(iii) **Longevity**: As already noted, satellite network operational lifecycles today are typically 15 years, and since all of these constellations are expected to be backward compatible, technology life cycles of 20+ years in future can be anticipated.

(iv) **Deployment Flexibility**: Besides ubiquity, satellite coverage can be targeted and dimensioned via spot beams much like terrestrial cell sites to deliver a specified capacity to serve a given collection of sensors. Furthermore, low power/low data rate sensors can be easily deployed and operate using solar power options in rural or remote areas. For higher-throughput control or aggregation applications, such as backhauling of cellular traffic, VSAT terminals with up to 1 Gbps can be rapidly deployed at a low cost that's distance insensitive, unlike terrestrial options requiring middle and last mile physical infrastructure.

(v) **Isolation**: The fifth value proposition comes from a satellite IoT network generally being offered as a proprietary, closed system, enhancing reliability, and offering greater security.

(vi) **Multicasting**: The final benefit is multi-casting. This refers to broadcasting a message to a group or subgroup of subscribers as a single billable event. Multicasting of a single broadcast to reach multiple units when combined with satellite's flexible coverage and capacity dimensioned beam sizes yields the most cost-effective network designs, mitigating overall capital, and operating costs (CAPEX and OPEX).

Given the ubiquity and capacity of space-based communications, satellite technology will play a critical role in supporting the development of the IoT sector and realizing the full potential of interconnected devices, having created a broadband superhighway in space – easily handling the potential billions of forecasted IoT devices.

5 Conclusion

As the above examples show, incredible progress has been made by the satellite industry in just a few short decades, and yet we find ourselves in a sense "back to the future," at the dawn of yet a larger and more profound era. And nobody, not even

Arthur C. Clarke, could have predicted the significant scale of satellite markets growing and expanding as new satellite technology in space and on the ground is deployed. The one certainty is that there will be progress, fueled by the combined creativity and partnerships of people and businesses across the expanding spectrum of technologies – terrestrial and satellite alike – to make these advances happen.

In particular, the following article in ▶ "Electronic Beam-Scanning Technology for Small Satellite Communication Systems and Their Future Development" on phased arrays and related market opportunities describes the disruptive potential of these new generation antenna systems that are poised to displace parabolic, mechanically steerable technology as large-scale small satellite constellations become deployed in the 2020s.

Electronic Beam-Scanning Technology for Small Satellite Communication Systems and Their Future Development

Safieddin (Ali) Safavi-Naeini and Arunas G. Slekys

Contents

Abstract

The rapid development of a new antenna technology known as electronic beam-scanning systems, phased arrays, flat panels, and other phraseologies has opened up new vistas for antenna solutions of twenty-first-century satellite communications. This technology has the potential to be applied in the deployment and use of MEO, LEO, and small satellite constellations, in addition to supporting ground

systems of GEO/MEO/LEO satellite networks. In particular, it holds the promise of expanding the addressable market for mobility applications of satellite networks by virtue of reducing size, weight, power, and cost compared to mechanically steered antennas. Development of this technology for space antennas and ground systems is still evolving. This chapter describes the nature of electronic beam-scanning antennas, the technology challenges, their applications, and state-of-the-art solutions.

1 Introduction

Satellite communications (SATCOM) is uniquely positioned to extend the global digital economy to every corner of the world, in the ocean, high in the sky, and to the remotest villages, including the 60% of the world's population that still does not have access to the Internet. Unlimited demand for ubiquitous access to information and connectivity everywhere and anytime for the widest variety of applications – ranging from commercial and personal communication to environmental monitoring (remote sensing), navigation, science, and defense – has stimulated significant innovation and growth in satellite communications systems, components, and network technologies.

As noted in Part 6.1, GEO systems have been the main industry drivers to date, with associated antenna solutions based primarily on mechanically steerable parabolic technology, i.e., high gain reflector and dual-reflector antennas with focal plane arrays having multi-beam radiation capability. The largest volume applications have been for fixed configurations, with mobility versions limited to transportable or on-the-pause kits, which are assembled in the field and typically employ rapid, self-pointing functionality. But they are not usually mobile in the context of handheld cellphones, although Inmarsat and Thuraya have managed to offer this type service from GEO platforms in L- and S-bands. Mobility applications in the much higher-frequency Ku- and Ka-bands in particular have proven extremely challenging, requiring some form of movable and stabilized platform, including accurate GPS and gyro positioning. Hence, whether operating over GEOs, MEOs, or LEOs, and whether for airborne, maritime, train, or other land mobility services, such configurations have typically been bulky and relatively expensive, i.e., on the order of tens to hundreds of thousands of US dollars, and have been limited to low volume commercial markets. Nor are such large antenna systems suitable for small satellite systems because of their significant size, weight, and power consumption requirements.

Enter the opportunity for flat panel, phased-array antenna solutions, which are poised to revolutionize the industry – no matter if it's for GEOs, MEOs, and LEOs or for small satellites in low earth orbits (typically 500 km to 1,200 km, etc.) and even for lower altitude applications such as high-altitude platform systems.

2 General Characteristics of Antenna Systems for Small Satellite Constellations

With remarkable advances in low-cost and lightweight structures, including the miniaturization of RF/microwave electronics and component technologies, small satellites (mini-, micro-, nano-, pico-, and femto-satellites) with ranges of weight from less than 100 g to around 500 kg have become the fastest-growing new sector of the industry. By virtue of their low-cost, small mass, and much easier launch requirements, they are being rapidly deployed in an increasing number of applications from earth science to geo-mapping, as well as a wide range of data communications in support of the exploding world of Internet of Things (IoT)/5G broadband cellular devices. Smaller members of this family, namely, CubeSats, are being increasingly used for remote sensing, earth observation, and scientific research. Microsatellites and minisatellites are being introduced in mega-constellations (SpaceX, Telesat, OneWeb) to deliver broadband Internet access worldwide.

As a case in point from SpaceX (May 15, 2019): "Each of the Starlink satellites weighs around 500 pounds (227 kilograms). Stacked together inside the payload shroud of a Falcon 9 rocket, the 60 satellites weigh 15 tons (13,620 kilograms), making the cargo for the May 2019 launch the heaviest ever lofted into orbit by SpaceX" (https://spaceflightnow.com/2019/05/15/spacex-releases-new-details-on-starlink-satellite-design/).

Antennas are key elements of all satellite systems, providing the necessary RF communication links between the satellite and the ground stations for both command/control and telemetry, navigation, and payload. Inter-satellite links (ISL) have also become quite important for small satellite networking, allowing for more accurate orbital placement and maintenance of moving satellites and requiring high gain antennas with low SWaP (size, weight, and power), and, above all, beam-forming and tracking.

Small satellites have traditionally been used for disaster monitoring, scientific and technology demonstrations, earth observation, and search and rescue missions. Telecommand, telemetry, and tracking systems typically use narrow band signals at VHF/UHF, S-, X-, Ku-, and Ka-bands. These antennas should cover a wide angular range (often a full hemisphere or very broad beam) in a reliable manner: monopoles, helices, patches, complex slots, and deployable systems (Gao et al. 2018).

Antennas for broadband communications should be high gain and with narrow beams directed toward the ground station. Although high-precision Attitude

Determination and Control Systems (ADCS) are becoming available for small satellites; currently the only viable solution is to lower the gain and to widen the beam. A number of deployable, inflatable, and foldable structures have been proposed and developed (Gao et al. 2018; Rahmat-Samii et al. 2017).

Emerging LEO mega-constellations and convergence of space and terrestrial communications (Integrated Space and Terrestrial Network or ISTN) are having significant impact on radio communication requirements of small satellites and their ground segment. Several mega-constellations are in the formation stages, with their primary goals to provide both mobile and stationary users on land, sea, and in the air with broadband Internet access. The 5G rollout has started with promises of extreme bandwidth, connectivity, low latency, and reliability. However to extend its reach to all corners of the world, it must use space communication as a truly ubiquitous infrastructure. Depicted in Fig. 1, realization of the ISTN (Integrated Space and Terrestrial Network) concept and architecture as the next major evolution of global network topology depends on highly intelligent radio links and antenna technologies with agile beam-forming capability. Antenna array technology with built-in intelligence is the only viable solution to materialize such a vision.

Almost all current small satellite antennas are fixed beam systems, which are obviously not optimal for many emerging and future applications. For low-frequency, low-speed telemetry and telecommond functions, fixed antenna with appropriate pattern may have an acceptable performance. However, as mentioned before, the increasing complexity of operational scenarios while both ends of the link are mobile requires fast beam-forming and tracking capability. To address serious constraints on the size and weight of the antenna for small satellite systems, multifunctional design approaches with integrated radio front-end appear to yield highly promising solutions.

Based on the aforementioned facts, to meet the requirements of future missions, small satellite antennas must have agile beam-forming/tracking capability with the following characteristics:

- Light weight
- Small size and conformal geometry
- Low power consumption
- Stable performance over a wide range of temperature and other environmental factor variations
- Material and fabrication methods should resist launch condition and be qualified for space applications
- Low-cost

3 Phased-Array Antenna Systems for Small Satellite Communications

As mentioned earlier, communications between the satellite and ground networks and satellite-to-satellite links underpin the worldwide ISTN network. Extremely high data throughput of all classes of satellites, including the smallest, requires

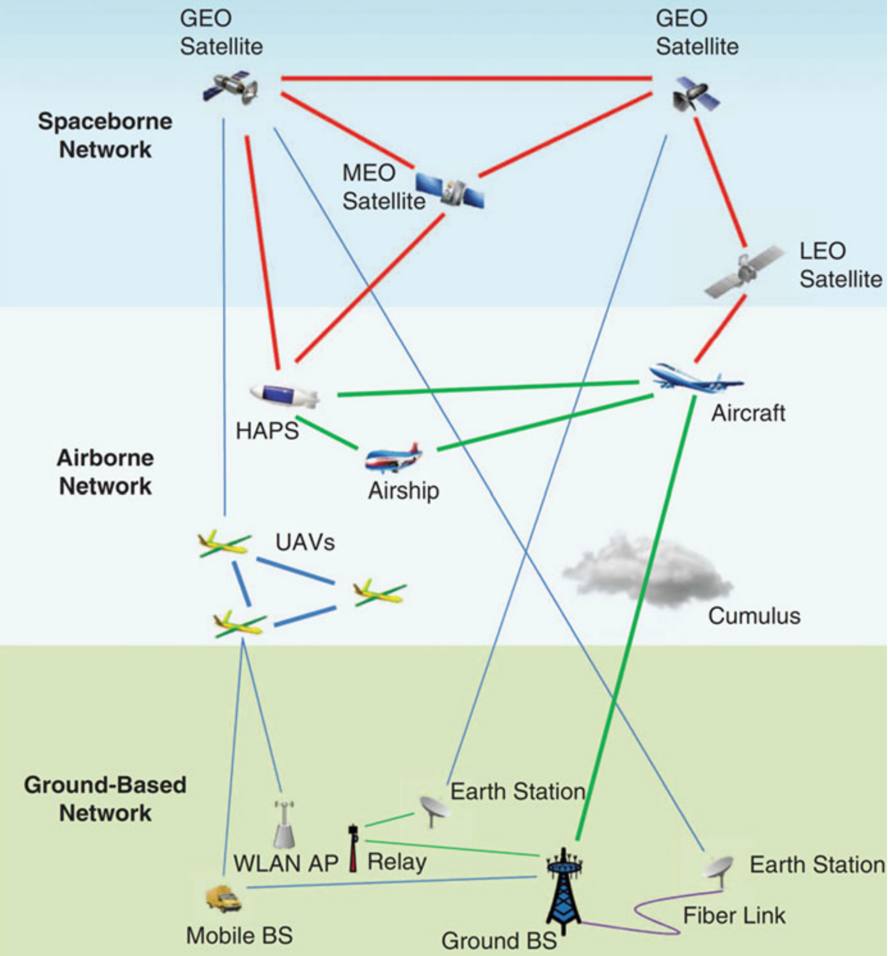

Fig. 1 Integration of space and terrestrial networks: evolution toward Integrated Space and Terrestrial Network (ISTN). (Courtesy of X. Huang et al. 2019)

wideband antenna systems with high gain and beam-steering capability over the hemisphere, in low-profile (conformal) configurations, with low weight and power.

Mechanically steered reflector antennas (Imbriale et al. 2012), which are still most widely used in satellite systems, are large and heavy structures with complex gimbal mechanisms, which are slow and consume considerable power. Vibration generated by mechanical rotation of the antenna induces error in high-precision sensors and can change the location and orientation of the satellite.

Phased-array antenna with electronic beam control capability has attracted considerable attention as the most promising technology for a wide range of applications including satellite to ground, aircraft to satellite (aeronautical satellite communication), and inter-satellite links.

By adaptive antenna beam-steering using intelligent electronics and signal processing schemes, phased-array technology will eliminate the need for motorized, mechanical steering systems, thereby realizing considerable savings in antenna size, weight, and power consumption. These specifications are critical to airborne and fast-moving, vehicle-mount SATCOM terminals for which flat/low-profile and lightweight antennas are desirable for reducing vehicular/aircraft drag and increasing radio communication efficiency. Indeed, connected mobility applications are expected to be the primary demand drivers for flat panel antennas, accounting for 92% of their estimated cumulative global revenues (est. $9.1B) by 2026 (Northern Sky Research 2017).

Migration toward high-throughput systems is not limited to large satellites and GEO links. There is a growing trend toward broadband data communication in smaller satellites down to nanosats (King et al. 2012), operating at Ku-band (18 to 27 GHz) and Ka-band (27 to 40 GHz).

3.1 Challenges

Despite all the unique advantages of millimeter-wave (mmW) technology, such as extreme communications bandwidth and measurement resolution (angular, distance, and time), commercial (mass market) exploitation of this spectrum is still quite limited due to current device technology cost, complexity, and performance limitations (limited signal power and noise performance). High propagation and scattering losses (Sulyman et al. 2014) as well as considerable mmW attenuation in typical operational environments (man-made objects, foliage, etc.) cause severe signal decay and dispersion in this range of frequencies.

3.2 Solution

To deal with the aforementioned radio link impairments and active device performance limitations, intelligent multi-antenna systems – such as phased arrays with integrated beam-forming devices for phase/amplitude control – have become the most promising solutions (Roh et al. 2014) to deliver enough signal power at the receiving point and to provide sufficient quality of communications. Phased arrays are still quite costly and complex structures and until very recently have been primarily and almost exclusively developed for defense and scientific (space) systems. Aggressive CMOS and SiGe technology scaling and progress in commercial high-density multifunctional integrated circuits and ASIC technology in mmW (Roh et al. 2014; Jeon et al. 2008; Tabarani et al. 2018), however, coupled with advances in high-precision multilayer circuit and packaging technologies (Meniconi et al. 2013; Litschke et al. 2005; Chen et al. 2006), are rapidly removing these barriers and opening new and exciting possibilities. During the last decade (Han et al. 2015; Gu et al. 2015; Vaccaro et al. 2010; Hong et al. 2014), there has been significant growth in worldwide efforts by research organizations and companies targeting low-cost commercial technologies for mmW multi-antenna beam-forming.

Mobile SATCOM terminals, in addition to cost/complexity constraints, should also meet a number of additional requirements such as size, weight, and power consumption or so-called SWaP, which require unique solutions. Mobile SATCOM has become a driving market force behind the commercialization of high-performance, phased-array technology.

Antenna arrays with beam-forming capabilities for mobile SATCOM, mainly in Ku-band (12/14GHz), have been proposed and developed by research institutes (Baggen et al. 2013; Mousavi et al. 2008; Schippers et al. 2008; Hoehn et al. 2013) and industries (Johnson et al. 2015; GILAT 2014; Henderson and Milroy 2005; ThinKom 2014; Phasor Soluions 2015) over the last decade. A comprehensive European Ka-band phased-array initiative (Baggen et al. 2013) resulted in active sub-array modules. Although the modules are still somewhat complex and expensive for mass market applications, recent progress in semiconductor technologies, digital systems, and multilayer planar technologies will undoubtedly reduce the cost. A number of Ku-band, phased-array development activities have been reported by industries over the last 5 years. The technical details and the achieved performances have not been reported in details. However, some general remarks can be made based on their published data and patents.

The existing industrial developments can be broadly divided into two approaches: (1) RF beam-forming and (2) digital beam-forming. A Ku-band phased-array with digital beam-forming has been reported in (Phasor Soluions 2015). Each antenna element is connected to its own transceiver chip, which down-converts the signal to bits. Although the signal combining at bit level is simpler than that at RF level, the overall system architecture is quite complex, and extension to very broadband applications is quite difficult. A Ku-band reconfigurable holographic beam-former has been reported in (Johnson et al. 2015), using originally MEMS and then liquid crystal to control the transmission properties of a metasurface. The technical details and specifications have not been reported yet. The developed system has a medium bandwidth.

The beam-scanning and phase adjustment can also be performed by a mechanical movement based on Variable Inclination Continuous Transverse Stub Array (VICTS) (Henderson and Milroy 2005) idea. A Ka-band beam-scanning array has been developed based on this idea (ThinKom 2014). Although VICTS is a mechanically steering system (not an electronic scanning array), the physical motion of the aperture is limited to the rotation of three plates (feed, aperture, and polarizer) around a common vertical axis inside the fixed system package. Therefore the structure is fairly low profile, and the antenna structure as whole does not have any apparent mechanical movement. The system has been deployed in commercial applications by Gogo Inc.

Extensive research activities and industrial efforts in three sub-areas, (a) phased-array antenna in microwave band, (b) mmW multilayer antenna elements and small arrays (Baggen et al. 2013; Mousavi et al. 2008; Lier and Melcher 2009; Ehyaie and Mortazawi 2010), and (c) advanced single- and multi-channel mmW front-end integrated circuits (Tabarani et al. 2018; Hashemi et al. 2005; Koh and Rebeiz 2008; Jeon et al. 2008) with beam control capabilities, are gradually reducing the cost and complexity of phased arrays and will eventually result in the rapid deployment of this technology in price-sensitive commercial applications. As the most promising approach, the modular and scalable system architectures can significantly reduce the cost and complexity of the overall system. This approach is further described in the next section.

4 A Cost-Effective, Modular, and Scalable Phased-Array Architecture

In this section, after a quick review of phased-array theory and its main characteristics, a modular and scalable phased-array technology as the most cost-effective solution for intelligent antenna and radio system is described.

4.1 Review of Phased-Array Theory: Choice of Antenna Element and Array Configuration

The choices of the antenna element and the array configuration are intertwined, and both are linked with the general specifications of the system. The total radiated field, $\mathbf{E}(\mathbf{r})$, from an array made of M identical and identically oriented antenna elements with the far field, $\mathbf{E}_e(\mathbf{r})$ (assuming that the element radiated power = 1 W), is given by:

$$\begin{aligned} \mathbf{E}(\mathbf{r}) &= \mathbf{E}_e(\mathbf{r}) \sum_{m=1}^{M} |I_m| \exp(j\psi_m) \exp\left(j\widehat{\mathbf{k}} \cdot \mathbf{r_m}\right) \\ \widehat{\mathbf{k}} &= \widehat{\mathbf{x}} \sin\theta \cos\varphi + \widehat{\mathbf{y}} \sin\theta \sin\varphi + \widehat{\mathbf{z}} \cos\theta \end{aligned} \tag{1}$$

where $|I_m|$ exp $(j\psi_m)$is the relative excitation amplitude and phase of the element number "m," located at $\mathbf{r_m}$. The unit vector $\widehat{\mathbf{k}}$ is along the direction of radiation (look angle: polar angle θ and azimuth angle φ). It is obvious from (1) that the radiation and circuit properties of an array system depend on the element as well as the configuration of the elements and the feed circuit. Polarization of the far field, to a large extent, is determined by the element pattern, $\mathbf{E}_e(\mathbf{r})$. However, special arrangement (e.g., "sequential rotation" method) of the elements in the array can improve the polarization of the array beyond that of the element.

The antenna elements should have sufficient (impedance/gain/axial-ratio) bandwidth, good polarization purity (polarization can be improved over the scan range by complex excitation of the element orthogonal ports), and high radiation efficiency.

It is important to maximize the isolation (minimize the coupling) between the elements. A quick analysis reveals this. The so-called active impedance of the antenna element, which is the input impedance of the antenna in an array environment, is different from that of the same element in isolation. The active impedance of the element number "q" is given by:

$$Z_{a,q}\left(\widehat{\mathbf{k}}\right) = Z_{qq} + \sum_{m=1,\, m\neq q}^{m=M} Z_{qm}\left|\frac{I_m}{I_q}\right| \exp\left[j\left(\psi_m - \psi_q\right)\right] \tag{2}$$

where $Z_{a,q}\left(\widehat{\mathbf{k}}\right)$ is the active impedance of the antenna number "q" when the beam is scanned to the direction $\widehat{\mathbf{k}}$ and Z_{qm}s are the mutual impedances between various elements. The key point here is the dependence of the active impedance on the scan angle. To see this, note that to move the beam toward the direction $\widehat{\mathbf{k}}$, the phase of each element should be set to:

$$\psi_m = -\widehat{\mathbf{k}} \cdot \mathbf{r_m} \pm 2N\pi \tag{3}$$

where N is an integer. Therefore as the beam is scanned to new direction, $\widehat{\mathbf{k}}$ and consequently ψ_m will change (see Eq. 2), and as it is obvious from (2), the active impedance of each element will change accordingly. This change, in general, has a negative impact on the performance of the active feed circuits, which are often optimized for a particular load (antenna) impedance. However, if the couplings between the antenna elements (Z_{qm}) are small, the active impedance variation, which is generated from the summation term in (2), can be neglected. There are a number of methods, which can be used to minimize coupling between the array elements. The easiest way is to increase the element spacing. However, half-wavelength spacing is the most common choice. Larger spacing decreases the coupling but limits the scan range.

The same array may be required to work at two different frequency bands. The elements should work at two disjoint frequency bands. The element spacing (in the case of array with regular grid) is chosen such that grating lobes are suppressed over the scan range. This usually leads to choosing the element spacing equal to half-wavelength at higher-frequency band (smaller wavelength).

Choice of the most optimal array configuration for a given set of requirements is a major initial step in development of a cost-effective electronic beam-scanning system. Referring to (1), this includes determination of the minimum of number of the antenna elements, M, and their locations $\{\mathbf{r_m},\quad m = 1, 2, \cdots M\}$, and the element normalized (with respect to the current required for unit power radiation by each element) excitations $\{|I_m| \exp\,(j\psi_m);\quad m = 1, 2, \cdots M\}$, which would provide the required EIRP (transmit side) and G/T (gain divide by the system noise temperature of the receiver array) over the scan range, while meeting the standard (e.g., FCC or IUT) radiation spectral density mask, over the entire range of operational frequencies. Certain level of polarization purity is to be maintained over the same range of frequencies and scan angles.

The transmitter array's most important performance characteristic is EIRP $(\widehat{\mathbf{k}})$ [Watts or dBW]:

$$\text{EIRP}\left(\widehat{\mathbf{k}}\right) = \left[\text{Gain of the Array}\left(\widehat{\mathbf{k}}\right) \times \text{Total Radiated Power}\right] \tag{4}$$

$$\text{Gain of the Array}\left(\widehat{\mathbf{k}}\right) = \text{Gain of the Element}\left(\widehat{\mathbf{k}}\right)\frac{\left|\sum_{m=1}^{M}|I_m|\exp\left(j\psi_m\right)\exp\left(j\widehat{\mathbf{k}}\cdot\mathbf{r_m}\right)\right|^2}{\text{Total Radiated Power}} \tag{5}$$

as a function of radiation direction $(\widehat{\mathbf{k}})$. In the case of active array, the element excitations, $\{|I_m|\exp(j\psi_m);\quad m=1,2,\cdots M\}$, can be controlled by a beam-forming MMIC (containing variable gain amplifiers and tunable phase shifters).The excitation coefficients should be optimized to maximize EIRP without violating the radiation mask over the entire scan range.

On receive side, to determine G/T, G, or gain of the receiving array can be calculated by (5), but $\{|I_m|\exp(j\psi_m);\quad m=1,2,\cdots M\}$, should now be replaced by the normalized complex gain and phase of the low-noise amplifier and tunable phase shifter of the receiver front-end MMIC. Furthermore, all the feed line losses up to the point where G/T is calculated or "referred to," which is often the input of the low-noise amplifier, should subtracted from G. The system noise temperature, T, is the sum of the effective antenna noise temperature, T_a [°K], and the receiver system noise temperature, T_{rcvr} [°K], or:

$$T = T_a + T_{rcvr}\quad\left[{}^\circ\text{K}\right] \tag{6}$$

Effective antenna noise temperature depends on the external noise sources (often represented by their brightness temperature) around the receiving antenna, the receiving antenna pattern $G\left(\widehat{\mathbf{k}}\right)$ as a function of look angle, antenna physical temperature, and the insertion loss of the transmission line between the antenna element and the low-noise amplifier. The dependence of T_a [°K]on the external noise sources is given by:

$$\frac{\int_{4\pi} T_B\left(\widehat{\mathbf{k}}\right)G\left(\widehat{\mathbf{k}}\right)d_2\widehat{\mathbf{k}}}{\int_{4\pi} G\left(\widehat{\mathbf{k}}\right)d_2\widehat{\mathbf{k}}} \tag{7}$$

where $T_B\left(\widehat{\mathbf{k}}\right)$ is the brightness temperature around the antenna. It is quite interesting to note that the part of the antenna noise temperature given by (7) actually changes with the scan angle because of change in the antenna receiver beam and gain$G\left(\widehat{\mathbf{k}}\right)$. The fact that by proper shaping of the receiver antenna beam, $G\left(\widehat{\mathbf{k}}\right)$ (reducing side-lobe levels toward the warm ground or other sources of noise or interference), the effective antenna noise temperature and therefore the total system noise can be reduced. This simply points to another important advantage of phased array as compared to fixed beam systems.

The receiver system noise temperature, T_{rcvr} [°K], is mainly determined by the noise figure of the receiver front-end. Therefore *G/T* is essentially a measure of SNR (signal-to-noise ratio) at the receiver front-end.

An example of an optimal array (square grid) of half-wavelength-spaced microstrip patch elements, optimized for 40 dB gain (boresight), and satisfying FCC mask is shown in Fig. 2. Note the loss of gain (aperture efficiency) due to tapering and also gain reduction as the beam scanned to off-boresight angles. The array can be implemented in a modular fashion (2 × 2 or 4 × 4 sub-arrays).

Regarding the antenna array configuration, there are a number of optimal nonperiodic (irregular) array geometries, which result in less number of the antenna elements and are most often used for fixed beam system. The optimal array topology for a wide-scan beam, which can satisfy radiation mask, is still an open research question (Haupt 2007; Rocca et al. 2014; Chirikov et al. 2013). Most of the existing optimization efforts lead to non-modular topologies, which are obviously not cost-effective and therefore of no interest to mass market applications. Although so far the most feasible module geometries are square/rectangle and triangular/hexagonal, nonuniform sub-arraying and non-regular shape modules (polyomino tiling) are also being investigated as possible alternatives for further reduction of the number of elements.

Although separate transmitter array and receiver array provide highest performance in terms of transmit/receive channel isolation (full duplex communication systems), impedance/gain bandwidth, pattern/polarization, and angular scan, there are cases where transmitter array and the receiver array must share the same aperture. Two important approaches to achieve this are (1) interleaved array configuration, wherein the transmitting and receiving array elements are placed between each other, and (2) dual-band transceiver arrays, consisting of multi-band radiating elements. Although interleaved array with fixed beam, particularly for half-duplex communications, has been demonstrated successfully, high-performance full-duplex phased array with wide-angle beam-scanning capability at higher microwave and millimeter-wave range of frequencies is quite costly and complex.

4.2 Cost-Effectiveness of Modular Architectures

As compared to a non-modular structure, modular architecture has a significant production cost advantage. Fabrication of a large array of few thousands of antenna elements at millimeter-wave, incorporating beam-forming active devices in one batch, with high positioning and alignment accuracy in the range of tens of micrometers (microns), at a reasonable cost for commercial applications is quite challenging. However, providing such level of accuracy for smaller modules (a small number of antenna elements) over small areas (few cm square) is quite feasible.

Furthermore, embedding tens of thousands of active and passive devices in complex, large-area multilayer circuits and antenna structures with high precision is another formidable task. A third problem with the conventional non-modular approach is its inherent lack of flexibility. Very often, any change in the current

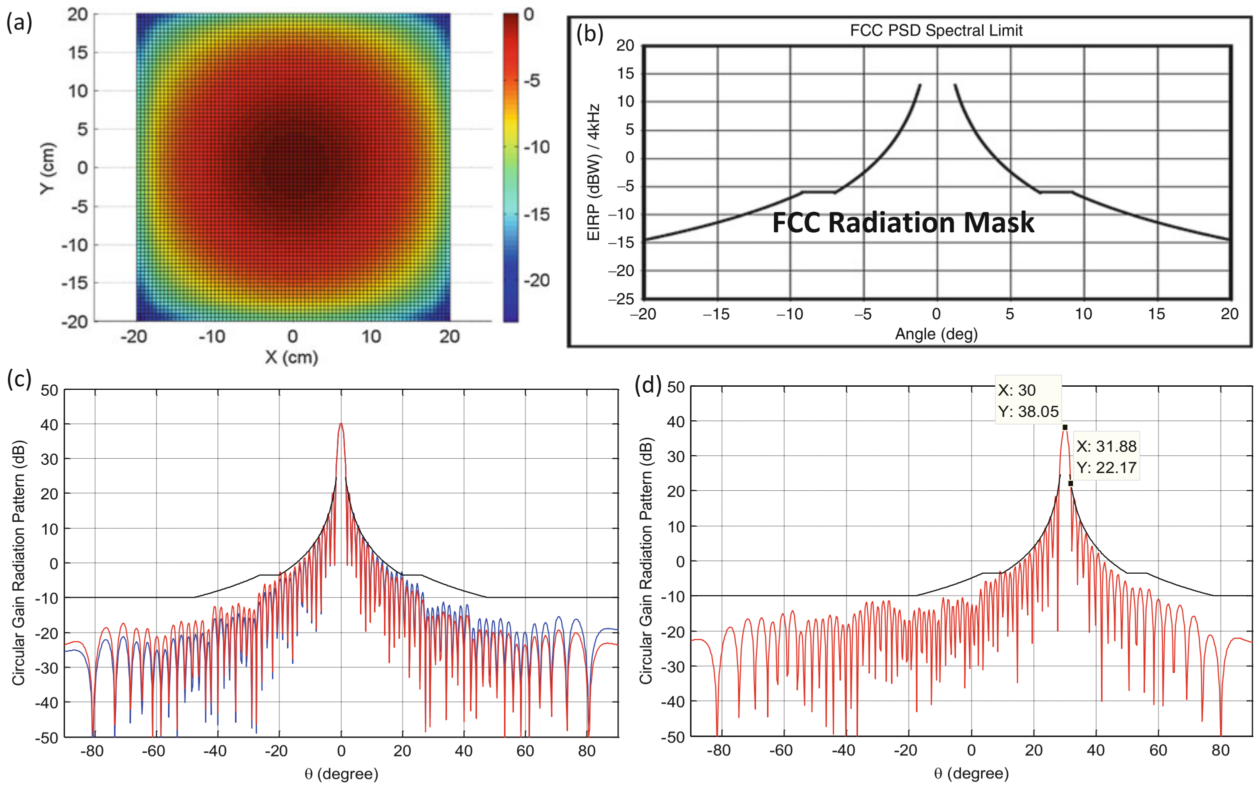

Fig. 2 (**a**) Amplitude distribution of an 80 × 80 array of half-wavelength spaced patch elements, (**b**) FCC radiation spectral density mask, (**c**) gain pattern at boresight, and (**d**) gain pattern at 30° scan angle. (Courtesy of University of Waterloo-CIARS (Centre for Intelligent Antenna and Radio Systems))

design parameters (array size, configuration, number of elements) for a new market will require a complete redesign of the entire array system and a new costly and time-consuming development cycle. This usually results in the considerable modification of the beam-forming algorithm and calibration as well, thereby with significant increase in the production cost.

In a modular architecture however, the entire phased array is built from a number of small and identical modules (small sub-arrays) or building blocks, allowing for the aforementioned challenges to be overcome in a convenient manner. The low-profile Ku-band receiving phased-array system (Fig. 3) reported about a decade ago (Mousavi et al. 2008; Fakharzadeh et al. 2009; Bolandhemmat et al. 2009) was one of the first modular systems developed for commercial mobile SATCOM. The entire phased array (1,000 elements) consisted of a few tens of sub-arrays, each passing the combined signal to one low-noise amplifier and an electronically controlled phase shifter (RF beam-forming). The system uses low-cost devices and fabrication methods and does not require any factory calibration. A highly intelligent algorithm performs calibration (removing phase/amplitude unbalance between the channels) and beam-forming, without any initial knowledge of device and antenna characteristics ("Zero Knowledge" algorithm (Mousavi et al. 2008)). The combination of low-cost but tunable sub-array modules and a highly intelligent algorithm results in a very cost-effective approach.

The Ku-band transceiver phased array reported in (Phasor Soluions 2015) follows a modular approach, but using digital beam-forming and much larger modules. A 256-element Ka-band phased array for mobile SATCOM is reported in Low et al.

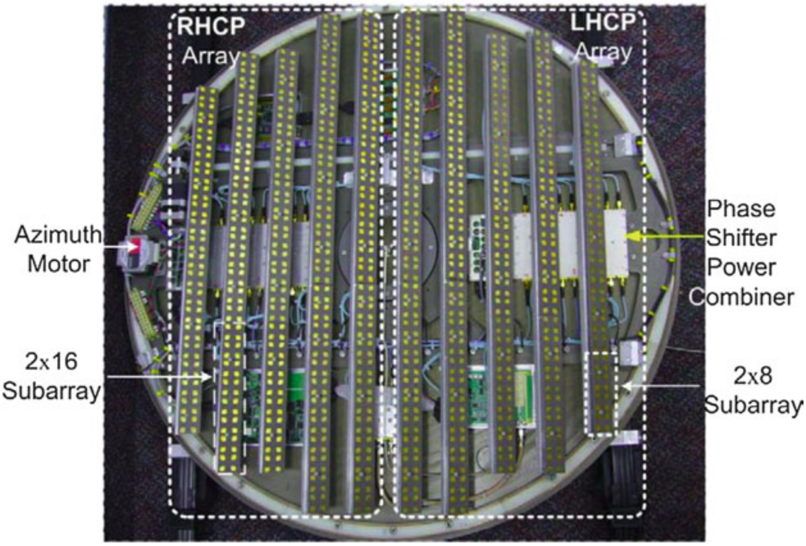

Fig. 3 Ku-band phased-array developed by the University of Waterloo-CIARS. (Courtesy of Intelwaves Technologies (Mousavi et al. 2008))

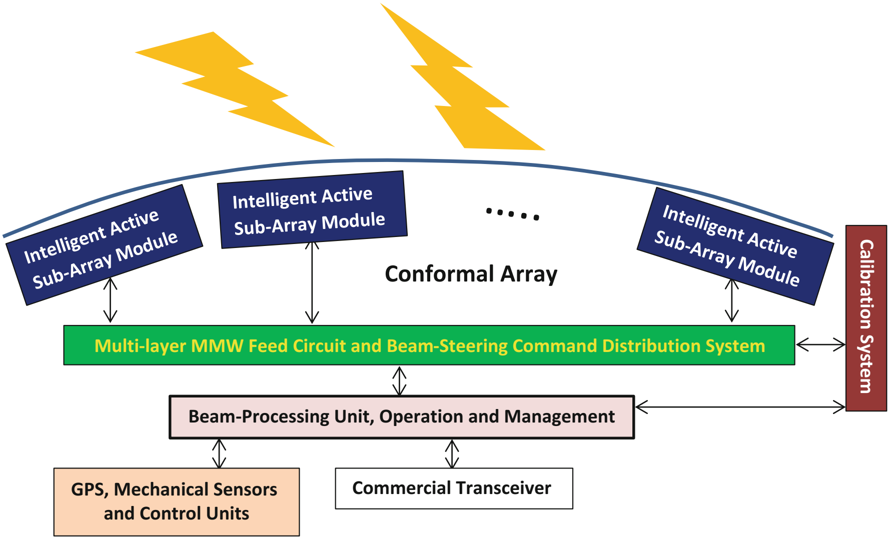

Fig. 4 A modular and scalable system architecture for intelligent antenna/radio system. (Courtesy of UW-CIARS (Abdel-Wahab et al. 2019))

(2019). The array has a 3-dB beamwidth of 7° and 34.5 dBW EIRP at broadside. The design concept can be extended to a larger array. A highly modular architecture presented in Abdel-Wahab et al. (2019) uses highly intelligent and small sub-array modules, incorporating active beam-forming devices with built-in intelligence, as a building block for a wide range of phased-array systems with different numbers of elements and configurations. The system architecture is shown in Fig. 4.

Each intelligent sub-array module (building block) consists of a small number of elements (2 × 2, 4 × 4, or 8 × 8) together with their beam-forming devices and a local beam-forming processor and memory which stores calibration data related to a particular building block or sub-array module.

A peculiar feature of the modular architecture of Fig. 4 is that the antenna beam-forming algorithm can be implemented in a distributed manner. Built-in intelligence and the local processing power of each module allow for parallelizing the beam-processing algorithm in such a way that a significant part of the beam-steering process can be carried out in the module local processor. Therefore, modularity extends to the beam-forming algorithm as well. This architecture significantly simplifies the beam-steering command distribution network, which constitutes one of the challenges in large-scale, high-performance phased-array systems.

The same architecture can be implemented in beam-steering reflect-array and transmit-array configurations.

The architecture illustrated in Fig. 4 is highly cost-effective. Intelligent active sub-array modules can be considered as autonomous RF beam-forming modules, with fully software definable functions, which can be used for almost all communications or sensing applications within its operational range of frequencies. The

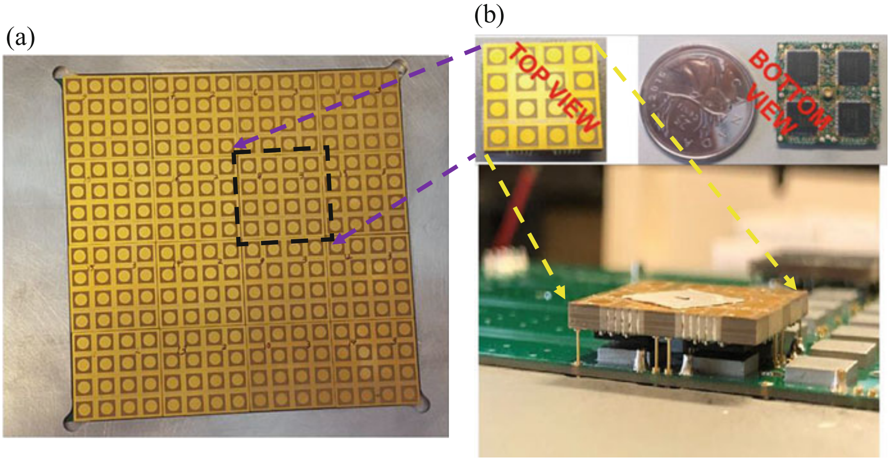

Fig. 5 (**a**) A modular architecture for 256-element Ka-band phased array made of 16 intelligent sub-array modules (4 × 4), (**b**) LEGO-like assembly process. (Courtesy of UW-CIARS, C-COM Satellite Systems)

modules are therefore standard "agnostic." The fundamental production cost advantage of such a modular approach as compared to conventional non-modular technologies stems from the flexibility/programmability of the modules, which can be used for a large number of applications and therefore can be mass-produced. Modules constitute more than 70–75% of the system cost and hence present economies of scale to bring down the cost significantly. The only part of the system which should be customized for various applications is a passive backplane feed circuit, which either distributes the RF signal among the modules (in transmit mode) or collects RF signals (in receive mode).

A highly modular array architecture and its LEGO-like assembly process are shown in Fig. 5.

The radiation pattern as the beam is scanned, EIRP, and *G/T* of the 256 element array is shown in Fig. 6.

4.3 Feed Circuit and System Integration Technologies

In this subsection, phased arrays with RF beam-forming are considered due to their lower cost and complexity, which are of paramount importance for small SATCOM applications.

To enhance system radiation efficiency and bandwidth, the insertion loss and dispersion of the feed circuit must be minimized. Although metallic waveguides have significantly lower insertion loss as compared to planar lines (strip line, microstrip line, coplanar waveguides, etc.), their cost, complexity, volume, and weight are not acceptable for many commercial mobile applications. On the other

hand, the printed planar lines, which are the most popular type of signal transmission technology for small circuits, become quite lossy in large-scale feed circuits at millimeter-wave frequency bands of interest in HTS systems. A promising solution which combines the advantage of the two methods is substrate integrated waveguide (SIW) (Li and Luk 2015; Xu et al. 2010; Abdel-Wahab et al. 2011, 2015), which can also be considered as a planar waveguide technique. Figure 7 illustrates an 8 × 8 40 GHz dielectric resonator antenna array fed by an SIW.

For large-scale system integration, a multilevel (hybrid) scheme combining various types of feed techniques, such as the three aforementioned technologies, is a highly efficient approach. Shown in Fig. 8 is a typical hybrid scheme, where the first level (intelligent 4 × 4 or 8 × 8 sub-array modules) is implemented in a multilayer planar technology (polymer based, LTCC, or MCM). These are the essential building blocks of the entire system. The second level is an SIW signal

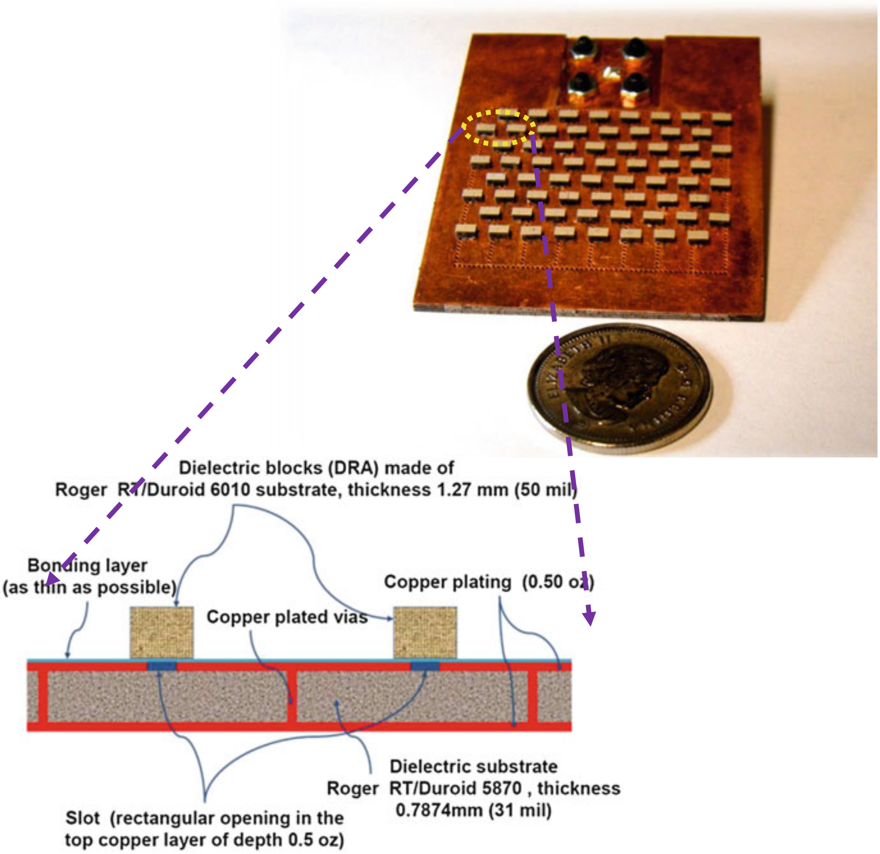

Fig. 7 An 8 × 8 40 GHz dielectric resonator antenna array fed by SIW

splitter (transmitter array) or a signal combiner (receiver array), which splits/combines the signals between/from a certain number (e.g., 4, 6, or 8) of intelligent modules. The choice of SIW is dictated by its lower insertion loss as compared to planar lines for long feed circuits in higher microwave and millimeter-wave range of frequencies. In lower frequencies (L-/S-/C-bands), low-loss planar lines such as air-filled strip lines can also be used in place of SIW for the second level of the feed circuit. For large-scale arrays (few thousands of elements), a third-level feed circuit is needed, which contains the longest segments of the feed lines located between the SIW (second-level feed) and the system RF input/output. Such long feed lines should be realized by the lowest insertion loss technologies. A possible choice is reduced height metallic waveguide. To reduce height, weight, and eventually production cost of air-filled metallic waveguide, metallic 3D printing offers new possibilities and may soon provide a viable alternative to planar circuits at higher microwave and millimeter-wave range of frequencies.

4.4 Active Beam-Forming Device Technology

Active cost-effective beam-forming techniques commonly use multi-channel Si-based MMIC devices, with phase shifting, amplification, and polarization switching capabilities. To maximize the performance within the acceptable target cost range, MMIC architecture should be optimized for the particular active sub-array module configurations.

Commercially available nano-metric CMOS and SiGe processes like 65 nm CMOS and 130 nm SiGe are currently among the most optimal options for implementing microwave/millimeter-wave active beam-forming architecture such as the one shown in Fig. 9.

The MMIC front-end architecture needs to be compatible with the system functions and performance requirements and fully scalable in order to meet the requirements for various scales of the phased-array systems. A number of MMIC architectures for phased-array transmitter/receiver on the chip and wafer (Jeon et al. 2008; Hashemi et al. 2005; Koh and Rebeiz 2008; Jeon et al. 2008; Natarajan et al. 2011; Cohen et al. 2013) have been presented for 8−/16−/32- and 256-element arrays.

The system SWaP (size, weight, and power consumption) requirement is determined, to a large extent, by MMIC power consumption and RF efficiency particular on transmit size. Recent advances in microwave/millimeter-wave power MMIC technologies and downward trend in the power consumption per channel have allowed for effective thermal management of medium-size to large-size active arrays using state-of-the-art, well-designed thermal structures. Worldwide efforts aiming at thermal management of high-power electronics have resulted in a number of highly efficient and low-profile heat transfer and thermal dissipaters using forced air, liquid cooling, and more recently miniaturized heat pipes (Ababneh et al. 2019). Thermal management is a critical issue which should be taken into consideration from the early design stage.

Large-volume microwave/millimeter-wave component testing (on-wafer and packaged) is quite costly, complex, and often not reliable. Production time and cost must be minimized. This problem has been subject to intensive research recently (Kissinger et al. 2010; Kim et al. 2013).

On-chip/off-chip built-in and self-test concepts as described by above researchers not only help with minimizing the MMIC factory level testing/verification but also assist with improving the performance of MMIC in the system, where the work environment of MMIC can be quite different from that of the factory or test lab.

Choice of circuit topology for each MMIC circuit block has to take overall cost/complexity and power consumption requirements into consideration while meeting the performance requirements. As an example, if the system contains an internal calibration system, then given the fact that a robust intelligent calibration algorithm can effectively correct the errors in an analog circuit, a simple analog phase shifter can be considered a good option instead of a digital phase shifter, minimizing cost, complexity, and power consumption.

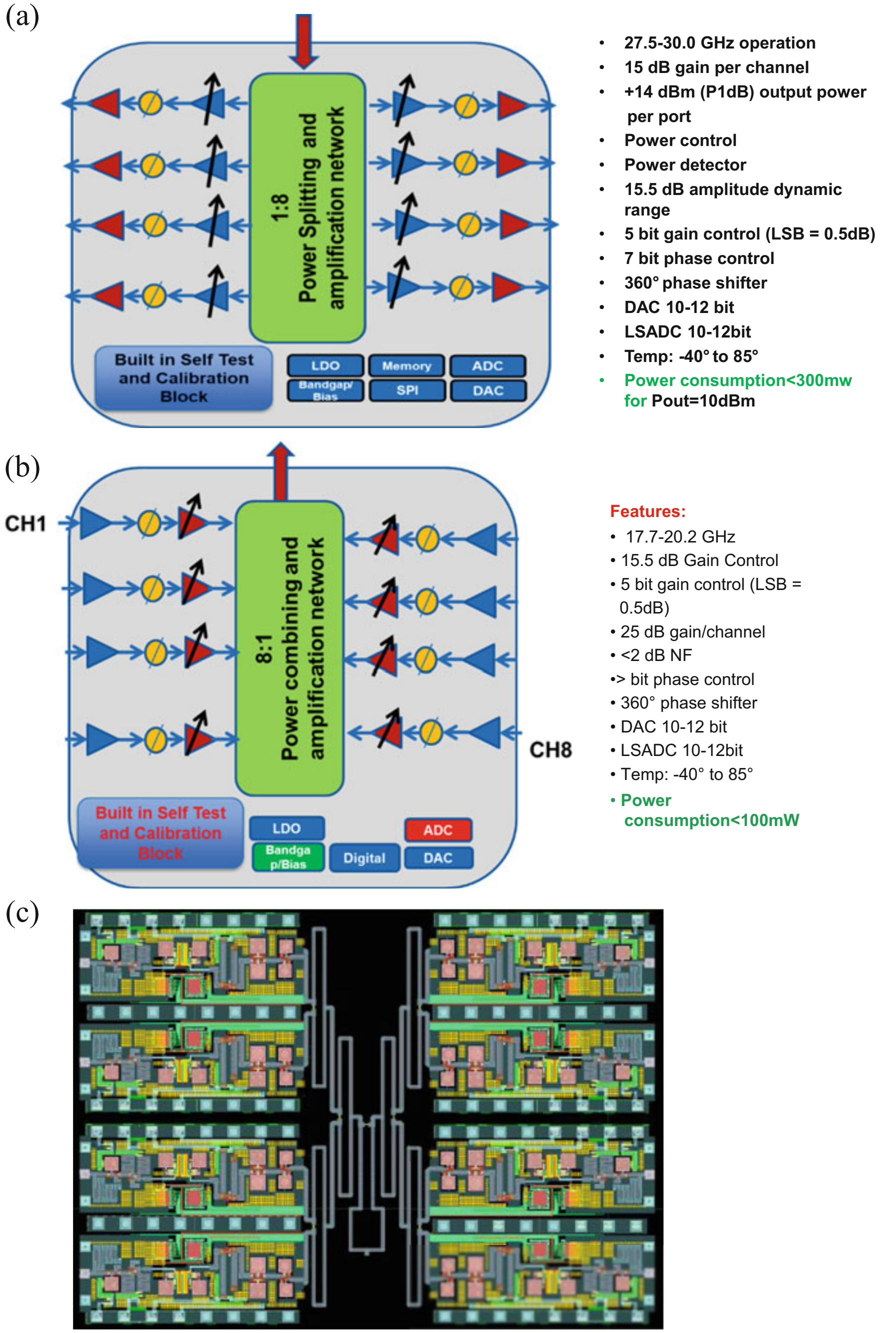

Fig. 9 Typical Ka-/K-band transmitter and receiver 8-channel MMIC architecture: (**a**) transmitter MMIC, (**b**) receiver MMIC, (**c**) 8-channel MMIC layout. (Courtesy of UW-CIARS)

The number of beam-former channels (phase shifter/amplifier) that can be implemented on one MMIC is another important design decision. Given the level of maturity of a certain semiconductor fabrication process, increasing the number of channels beyond a certain point makes the fabrication process more error-prone, reduces the yield, and increases the power consumption and the generated heat per die. Ease of interconnecting the MMIC inputs/outputs to the module feed circuit is another important consideration, which will relate to the type of the feed circuit technology and MMIC packaging technique. These show interplay between various subsystem designs/development.

Similar considerations apply to design of the receiver MMIC. The same approach can be applied to receiver intelligent modules (sub-array building blocks) which are required for active phased-array systems. The most essential system goal on the receive side is to maximize *G/T*. The array gain (*G*) is determined by the size of the array. *T* is the system noise temperature and, as described earlier, is contributed by antenna noise, losses preceding the first stage of the low-noise amplification (antenna radiation efficiency and the insertion loss of the feed circuit between the antenna element and MMIC ports), and the electronic noise generated by the MMIC and other circuit elements (noise figure of the low-noise front-end). In the absence of external noise sources, the dominant factors are often the feed circuit loss and the MMIC noise figure. The feed circuit loss can be minimized by minimizing the length of transmission line between the antenna input and MMIC. The MMIC noise figure depends on the technology minimum noise figure, the low-noise amplifier design, and the antenna active impedance presented to the MMIC. Very often the MMIC noise figure sets the lower bound to the system temperature. For example, with a typical required *G/T* greater than 12 or 14 dB, and the phased-array physical area constraints dictated by major Ka-band application markets, then a noise figure often less than 3 dB or even 2 dB is required for the K-band receiver front-end MMIC, which is fortunately quite within reach of the current state of the art. For some highly critical applications where a much better noise performance is required, a hybrid approach is adopted, wherein the low-cost (CMOS or SiGe) front-end MMIC can be assisted by an additional stage of an ultra-low-noise amplifier using discrete devices such as pHEMT. A unique advantage of a fully active array is the inherent capability to generate pure polarization at any scan angle. The radiated field polarization of any antenna element will change with look angle. In the case of critical applications where a pure polarization is needed at any arbitrary beam pointing direction, each antenna array element can be fed at two orthogonal radiation mode feeding points ("orthogonal ports"). By proper choice of the phases and the amplitudes of the two MMIC channels which excite these two orthogonal ports, any polarization at any scan angle can be generated. The excitation phases/amplitudes are a function of the scan angle. Therefore the polarization and the radiation beam direction essentially become software definable.

A number of techniques to deal with the scan angle dependence on the antenna active impedance have been developed recently. Proper antenna design methods call for choice of the orientation of the neighboring elements and enhancing the isolation between neighboring elements through parasitic structures; engineered surfaces and defect ground plane; and MMIC built-in intelligence and reconfigurable architectures. All have been successfully applied to this problem.

4.5 Passive Phased-Array Technologies

Passive phased arrays, wherein the phase shifting and amplitude control are realized by passive tunable structures, are attractive solutions for low-cost communications and sensing applications where the EIRP and *G/T* requirements and radiation beam characteristics are less demanding. Cost, complexity, and power consumption of active phased-array systems can be significantly reduced if the active beam control circuits could be replaced by reasonably low insertion loss passive phase shifters, whose insertion loss does not change with the phase shift. A number of passive millimeter-wave phase shifters (MEMS-based (Chakraborty and Gupta 2016) and ferroelectric-based structures, liquid-crystal (LC) phase shifters (Strunck et al. 2015), MMIC phase shifters (Yang and Yang 2011; Ellinger et al. 2010), photonic-based phase shifters (Yi et al. 2011; Zhang and Pan 2018), and more recently, high-dielectric movable slab phase shifters (Abdellatif et al. 2014)) have been proposed and developed in recent years. Among these, MMIC phase shifters and moving, high-dielectric constant (such as BLT) slab phase shifters can be considered as feasible approaches for low-cost, large phased-array systems. To date, none of the other approaches can meet the insertion loss requirement (both average loss and phase shift-dependent loss variation) or size constraints (the phase shifter structure footprint must fit underneath the array element or one unit cell of a 2D phased array at higher microwave or millimeter-wave frequencies), in a cost-effective manner. MMIC phase shifters, due to their cost and complexity, are often used in active phased-array systems. The new BLT phase shifter (Abdellatif et al. 2014; Al-Saedi et al. 2018) appears to be an interesting solution for modular passive phased-array applications. BLT (barium lanthanum titanate) is an exceptional material with very high-dielectric constant but very low loss tangent. This technology can potentially result in a low-cost, miniaturized, and low-insertion loss phase shifter with very low phase shift loss dependence for high-performance phased-array systems.

4.6 Internal (On-Board) Calibration

An important advantage of active phased-array systems, as compared to fixed beam antenna systems, is their inherent capability to effectively deal with phase/amplitude imbalances, component failures, and/or large variation in component characteristics over time, through well-designed internal or on-board AI-based calibration and diagnosis techniques. Phased arrays are highly resilient (fault-tolerant) structures and can continue to work, with reduced performance, even if a large number of their active beam-forming devices fail (graceful degradation).

Responses of both active devices and passive components will necessarily change with temperature, mechanical deformation, and other unpredictable environmental factors. Robust and intelligent (AI-based) beam-forming and system identification algorithms can deal with these changes as long as they can be estimated in a timely manner.

On-chip microwave and millimeter wave self-test techniques, as mentioned before, can be extended to real-time monitoring of MMIC critical performance measures. One approach is to measure amplitude and phase of the high frequency signal at critical points of the beam-forming MMICs to assess the chip performance and model its behavior. MMICs for phased-array applications commonly include temperature sensors for reporting the junction temperature, which is used to adjust MMIC parameters and to maintain its performance over a wide range of temperatures. Loop-back test strategies and built-in self-test are other strategies currently being implemented to adaptively control the performance of a MMIC.

Maintaining phase/time synchronism between intelligent modules is another major challenge. A backplane feed network (signal splitter in the case of transmit-array and signal combiner in the case of the receiver array) collects or distributes module RF signals over a large area (tens of cm). Low-cost production processes do not provide the tens of microns range of positioning accuracy or tight angular tolerance needed in millimeter-wave phased arrays. The inevitable phase/amplitude imbalances between the mmW signal paths from the input to the system of each individual antenna should be compensated for. The phase/amplitude balancing is particularly critical for the transmit array, which must satisfy the radiation spectral density mask. A number of statistical methods, orthogonal code-based techniques (Silverstein 1997), and external (remote or on-board) sources (Lier et al. 2000; Fadamiro et al. 2018) have been proposed for calibration of phased-array systems. These methods often require either far field or highly complex near-field measurements, which are not feasible for mobile satellite communication.

A promising approach followed by a number of research groups is to integrate electromagnetic field probes (small test antennas) either in the feed circuit (see SANTANA project (Baggen et al. 2013)) or in the radiating aperture, or at some small distance from the aperture. Using field probes integrated into the aperture offers the most cost-effective approach with minimal or almost no impact on the feed circuit. In a typical scheme shown in Fig. 10, the probe can pick up the near-field aperture signal directly. When the array elements are excited individually or in particularly formed groups, the detector probe near field can be used to accurately estimate the element amplitude/phase imbalances generated by all errors and uncertainties from the input to the system to the radiating aperture. Such techniques can be used not only to fully calibrate the phased-array system but also to characterize each MMIC active channel (amplifier/phase shifter chain connected to a particular antenna element input) inside the array environment. By using such an internal (on-board) calibration technique, the impact of the beam-scanning and the array environment on the gain and phase response of each MMIC can be measured and accounted for in the beam-forming and polarization adjustment during the system operation.

5 Conclusions

The rapid development of new phased-array or electronic beam-scanning technology is changing the landscape of radio and antenna solutions for all satellite communication systems, whether GEO, MEO, LEO, or future small satellites. Recent advances in low-cost, multilayer circuit/antenna technologies, microwave/millimeter-wave integrated circuits, low-cost powerful digital systems, and highly intelligent beam-forming and system identification/calibration algorithms are paving the way for the next evolution toward integration of space, air, and terrestrial networks. The development of low-cost active and passive phased-array ground systems for 5G/6G cellular and small satellite constellations will offer many opportunities for new satellite services, particularly in the under-served regions of the world. The new large-scale small satellite constellations that are being deployed will be heavily dependent on this new ground segment capability to provide their data-based and 5G/6G-oriented broadband cellular services. It is hoped that the technical background provided in this chapter can assist in the understanding of the expanding market for ground antenna systems and particularly for flat panel antennas that will support the rapid increase in small satellite constellations.

Ground Systems to Connect Small-Satellite Constellations to Underserved Areas

Christoffel J. Kotze

Contents

Abstract

Access to broadband Internet is increasingly becoming compulsory in order to participate in many aspects of modern economic systems. Currently more than a third of the global population does not have access to any form of Internet connection and thus by default is excluded from any activity for which it is a prerequisite. One of the primary reasons for the exclusion of any population from Internet access is the lack of available communication infrastructure; this is particularly relevant in remote societies. Satellite technology by its very nature is not geographically constrained making it ideal to deliver broadband

to remote communities. Opportunity presents itself with the recent announcement of mega-constellations featuring hundreds or even thousands of small satellites, which significantly bolster not only the available bandwidth but also the ability to provide it at low latency as it will operate in lower orbits.

In the world of satellite services, the focus tends to be on the space systems in orbit, but in the case of large-scale LEO constellations, the design and implementation of the ground systems will be of critical importance. The purpose of this chapter is to investigate what is practically required at ground level to allow a remote community to successfully engage small-satellite broadband Internet in a reliable, cost-effective, and technically and operationally feasible manner.

Broadband apparatus for remote communities (BARC) · Broadband · Digital divide · Electrical power supplies · Flat-panel antennas · Last-mile problem · Mega-satellite constellations · Small satellites · Technical assistance · Electronic tracking antennas · Wi-Fi access

1 Introduction

The Fourth Industrial Revolution (4IR) is a term used to describe the collective effect on society by rapid simultaneous developments across diverse fields. The new capabilities of this cyber revolution serve as a driver of novel innovation with the potential to positively affect virtually all aspects of society (Schwab). In addition to drivers such as the evolution of cloud technology, connected sensors, and advanced data analytics, it is the sustainable and cost-effective availability of broadband Internet that glues all the components together and enables technology convergence. Though there has been an encouraging acceleration in Internet penetration in recent years, a significant percentage of the global population has still not been connected. Data released in June 2019 indicates that out of an estimated world population of just over 7.7 billion, Internet global penetration is less than 53%. If this estimate is correct, this still leaves 3.3 billion people unconnected (InternetWorldStats 2019). Currently not one of the global macro regions has complete Internet penetration, though in most cases the connected portion of the population is significantly higher than the unconnected; Africa represents the only regional exception (Fig. 1). A 2014 study identified four primary conditions that need to be met before a user will adopt a broadband Internet, namely, it is readily available, accessible, affordable, and relevant to the community or the individual concerned.

Considered the primary preventative factor for adoption of broadband is the “availability” of an Internet service to the target population. The availability of the necessary infrastructure to create the end user community to the connection mesh, often referred to as the so-called last-mile challenge, is the first step in achieving connectivity. In addition to the communication infrastructure, practical use of the Internet also requires ancillary services such as electricity and the necessary

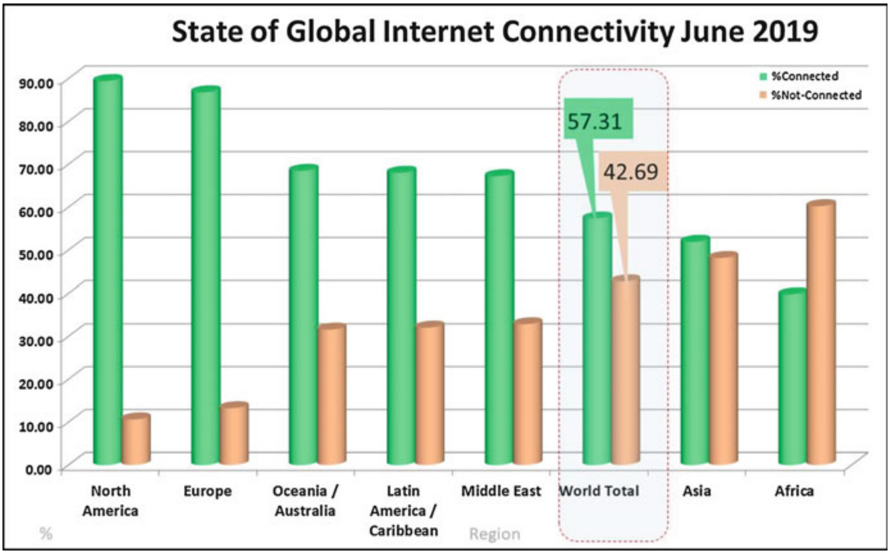

Fig. 1 Regional Internet connectivity expressed as % of the population. (Graphic courtesy of the author)

hardware to engage the service if it is available. A World Economic Forum study indicates the absence of infrastructure as the primary reason for Internet access exclusion of more than a third of the global population, citing 31% not having 3G coverage with 15% without electricity (Biggs 2018a). This chapter aims to explore some of the challenges faced by remote rural communities when it comes to the implementation of broadband Internet and how it can be mitigated.

The term “digital divide” is used to generally differentiate between two groups; on the one side, there are the “haves.” This population generally has access to the best of digital technology and is largely equipped with the relevant skills to use the equipment. The “have nots” represent the other group with limited or no access of any of the “digital privileges” of the other. This phenomenon has been studied extensively for many years. The primary causative factors have been found to be a combination of socioeconomic and spatial demographics. A 2016 World Bank report (World Bank Group 2016) defined the “digital divide” in terms of a user demographic indicating it is particularly skewed toward poor, rural communities as indicated by Fig. 2.

2 The Challenges of the Digital Divide

The “digital divide” though is a multifaceted concept involving not a single but rather a bouquet of digital technologies. One might today, however, argue that it is the availability of the Internet which serves as the standard metric by which to gauge the presence of the digital divide for a specific demographic group. If a community is

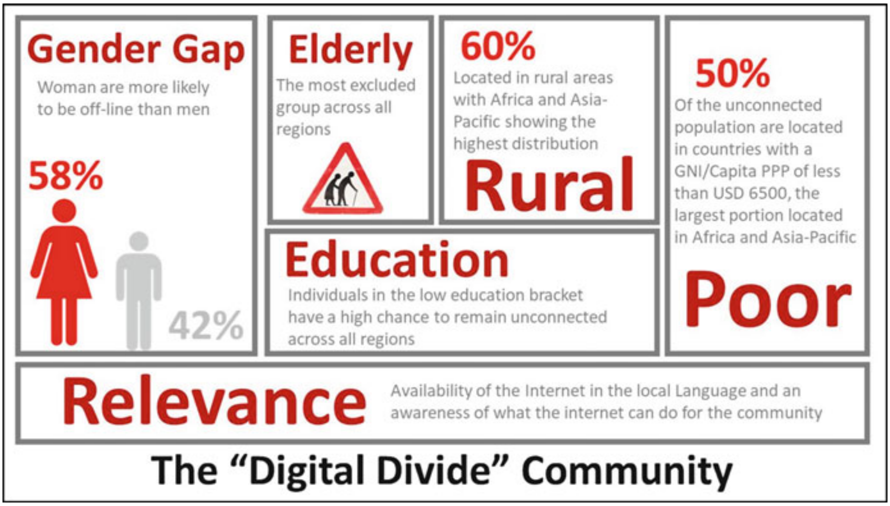

Fig. 2 Demographic profile of the unconnected. (Graphic courtesy of the author)

on the wrong side of the digital divide, it typically means automatic exclusion from the e-commerce economy. According to the last UNCTAD Information Economy report, it had already grown to a 25-trillion USD industry as of year-end 2015 (UNCTAD 2017).

The digital divide at a macro level can eventually impair trade between countries with high levels of digital penetration and those with very low levels of digital integration. As alluded to earlier, the basic availability of infrastructure is the primary exclusion factor for unconnected communities worldwide and thus the primary driver of the "digital divide." Yet, even after the infrastructure problem is resolved, there are still additional barriers to overcome before a user community can productively engage in broadband Internet services. An International Telecommunication Union (ITU) study concluded that in addition to a broadband service being physically available, the following three factors need to be satisfied to determine successful adoption (Biggs 2018b):

- **Cost** – Is the service affordable to the users? An estimated 57% of the global population could not afford Internet access in 2017.
- **Capability** – Do users have the means to access the service, i.e., skill and hardware?
- **Relevance** – Does the user community see a benefit in using the service? Is it applicable from a cultural and language perspective?

Clearly the mitigation of the challenges surrounding infrastructure is key. Yet it is important to note that all relevant factors need to be satisfied for the installation to have a chance of success.

3 The Remote Community Communication Challenge

As illustrated in the previous section, a person living in a rural area has a much higher chance not to be connected to the Internet than one residing in an urban setting. Sub-Saharan Africa where 63% of the population is based in rural areas has the lowest Internet penetration as opposed to the European Union characterized by a very high broadband penetration where only 26% of the population resides in rural areas. In sociology the “Matthew effect” (Rigney 2010), a term coined by Robert K. Merton, refers to a situation where advantage propagates further advantage, and vice versa this can be applied to Internet access. In short, the more you have, the more you can do with it. Rural areas with little to no access thus will, according to the Matthew effect, fall increasingly behind urban areas in activities surrounding “connected” living.

Rural areas have got unique challenges when it comes to the rollout of basic infrastructure which can make these areas more likely not to be included in new technology rollouts. Typically it is the product of a number of causative factors. Yet the strongest factors relate to large distances or difficult terrain that needs to be navigated in order to reach these areas. To investigate the unique challenges faced by rural communities, a study was commissioned by the European Union (EU) in 2008. The study identified four main categories of problems plaguing rural areas (Bertolini et al. 2008):

- **Demography** – rural areas are typically inhabited by a population overrepresented by older people, with a diminishing young populace often leading to an underperforming local economy.
- **Remoteness** – this makes it more difficult to provide and maintain good infrastructure, compounded with an underperforming economy, motivating urban migration consequently acting as inhibitor to an incentive of improving infrastructure.
- **Education** – typically of a lower level among the rural populace, a causative factor in a number of problems experienced by such areas, e.g., lower employment and economic opportunity and increased poverty. Due to a lack of infrastructure, the chance to obtain a better education is diminished.
- **Labor market** – the confluence of the other three factors described limits employment opportunities for residents in rural areas; consequently skilled people leave the area as there is no opportunity, which prevents investment in the area due to a lack of a capable available labor force.

Though the study was done on developed countries within the EU and European Economic Area and therefore is not necessarily applicable directly to developing countries, it does serve as a point of departure to approach challenges affecting rural development in the developing world. Included in one of the many challenges faced by rural areas unfortunately is the ready and cost-effective availability of communication systems.

4 Internet Access Challenges in Remote Areas

For a user to interact with the Internet, a number of primary components must all be available in one place to facilitate the process, namely:

- A communication service to connect the end user to the Internet or the so-called last mile
- Hardware and software to facilitate the connection and allow the user to engage the Internet
- Available electricity to power the Internet-enabling equipment

The requirement to connect to the Internet for a user in a city is in principal the same for an end user in a remote rural setting; however the availability electricity and "last-mile" options typically can be a real constraint.

4.1 The "Last-Mile" Issue

The term "last mile" is a figurative term used in the telecommunications industry used to describe the link between the primary telecoms infrastructure and the end user, e.g., the cable between the telephone and a house or a "Wi-Fi" hotspot. Bridging the "last mile" remains the principal problem preventing the mass rollout of broadband Internet services; the more remote the area, the smaller the probability of a traditional fixed-line connection. In remote areas it is quite often not economically viable to lay cable infrastructure such as fiber optics; quite often it is not even physically possible. Remoteness also impacts the rollout of mobile phone technology where mass rollout is challenged by accessibility maintenance and security issues. Cell phone base stations are increasingly the target of opportunistic theft as thieves target the air-conditioning units, copper wire, and especially the backup batteries; remote isolated towers are especially vulnerable to this kind of theft. An Internet service provider (ISP) typically is a profit-driven commercial enterprise which typically will not willingly deploy to an area where no financial incentive exists or an area where the infrastructure would be difficult to maintain. Satellite technology is particularly well suited to act as the "last-mile" link as it is not bound by physical accessibility, having the ability to connect virtually any area on earth. Yet there is still the challenge of how the consumer achieves connection to the satellite system. This is the key aspect addressed in this chapter.

4.2 Satellite Broadband

Satellite technology by its very nature has to have many layers of redundancy built-in due to the fact that maintenance for the spacecraft is virtually impossible, which practically translates into a highly reliable service. Traditionally satellite broadband delivered by geosynchronous spacecraft has been plagued by cost, capacity, and particularly the problem of latency issues. In recent years technological development across the space industry has benefited the satellite industry. High-throughput GEO satellites can provide a cost-effective broadband service able to compete with terrestrial broadband services in terms of capacity and cost. New standards now include the use of spoofing techniques and larger delay windows to avoid GEO delay not to be mistaken for system congestion. These adjustments and new standard to address GEO satellite latency concerns have increased the ability of these systems to support networked services. Yet latency remains an issue.

Latency is largely determined by the round-trip distance the signal has to travel between source and destination. There can be other factors such as processing times. The transmission round-trip distance will be primarily determined by the orbit the satellite orbits in, which is one aspect that in some cases serves as an exclusion factor for broadband services using geosynchronous earth orbit (GEO). Broadband satellites using GEO orbits have the distinct advantage that it can use a stationary antenna at the user end as opposed to low (LEO) and medium earth orbit (MEO) where tracking is required. However this comes at the price of high latency. The lower orbit constellations can produce very competitive latency performance albeit with the requirement for more sophisticated user antenna tracking arrangement which comes at a cost. Substantial reduction in cost per unit has made satellite broadband increasingly affordable and is expected to continue as additional capacity is added especially in view of a number of small-satellite-based mega-constellations that have been announced and with many now being implemented. Unlocking the true potential of these new mega-constellations which will be operating in the lower orbit segments will depend how well the market can develop the ground equipment necessary to optimally connect to these constellations.

4.3 Smallsats

In the past decade, rapid development in the information and communication technology (ICT) sphere has led to significant increases in the capability and capacity of hardware and the software able to exploit it. These developments have filtered down into all aspects of modern industry including satellite development in the form of small satellites commonly known as “smallsats.” These are highly capable functional units featuring a small footprint and are relatively cheap to produce and less costly to launch. This emerging class of satellites can range from very small “cubesats” (weighing as little as 1 kg) to larger units with a mass typically in the 150–500 kg range. The lesser weight translates into lower launch costs, coupled with the availability of cheaper launch option now becoming available. Between 2008 and 2018, more than 1200 “smallsats” have already been launched, a figure dwarfed by the many thousands of additional units planned for launch by 2028.

The increasing market for spaced-based services to provide communication and remote sensing is expected to continue to drive demand upward for low earth orbit (LEO)-based services leading to increased competition and a decrease in cost for these services and the space and ground systems. Decreased launch costs make shorter technology cycles of space-based assets feasibly relative to terrestrial providers. “Smallsats” are particularly well suited for broadband provision, and as such a number of “smallsats” mega-constellations are now being implemented such as the OneWeb (Dean) network backed in part by Google and the Starlink (Coldewey 2019) system backed by SpaceX; many systems have been announced such as Amazon’s “Kuiper” (Henry 2019). The large number of small-satellite constellations to provide broadband networking services and remote sensing services – now exceeding over 20,000 of such new types of satellites – has raised concerned about a glut of such types of satellite services, large price wars, and serious concerns about orbital debris.

4.4 Electricity

Without the availability of electricity at an end user’s location, the availability of a satellite broadband signal will not mean much as all digital devices need a certain amount of electricity to drive its components. Though the minimum power requirement of the end user hardware is normally quite minimal, it still needs to be available to enable a practical engagement with the Internet (see Table 1).

For urban users the availability of electricity normally is not a problem in most areas of the world where, on average, 96.4% of the urban population has access, as opposed to 73% of the rural population across the globe (SE4ALL 2018). On a regional scale, the difference between urban and rural can be much more pronounced. One such example is sub-Saharan Africa, the region with the fastest growing population in the world. This region which will by 2035 also have the youngest population in the world has a pronounced difference in electricity penetration, where 79% of urban dwellers has access and less than 23% of the rural population has such access (Bello-Schünemann 2017).

5 Broadband Access for Remote Underserved or Unserved Communities

With technological development making satellite broadband an increasingly viable solution for mass rollout, the question is how can it and other emerging technology be utilized to make broadband rollout a practical solution for the unconnected in remote areas. A product that can bridge the “last mile” while also providing the ability to address the other barriers of broadband adoption to effectively present

Table 1 User-end broadband power requirement (Energy Use Calculator 2018)

Broadband “user-end” power requirement					
Access device	“Feature phone”	Notebook	PC	Smartphone	Tablet
Consumption	2–6 W	20–100 W	90–350 W	2–6 W	2–6 W

Table 2 Features, advantages, and benefits of a broadband apparatus for remote communities (BARC)

Broadband access for remote communities (BARC) (Features, advantages, and benefits (FAB) analysis)	
Features	Self-contained broadband Internet system, using satellite communication and renewable energy technology, with the ability to provide additional wireless services such as Wi-Fi connectivity to villages
Advantages	Can be deployed in most remote areas, not dependent on any existing infrastructure, and provide all required supporting services for practical broadband Internet use
Benefits	Allows the community to benefit by being able to use broadband Internet in a practical and costeffective manner

broadband is presented and analyzed here. This is called for this discussion and analysis a broadband apparatus for remote communities (BARC). Such a BARC must have the ability to deliver broadband Internet to any remote community without the need for power or additional communication infrastructure to be already available at the proposed site. Ideally such a product should be designed to be integrated into the daily lives of the user population in such a way that full acceptance of the technology is achieved to the maximum benefit of all stakeholders. Table 2 presents the basic expected features, advantages, and benefits (FAB) of such a product.

The features, advantages, and benefits (FAB) of such a product can further be translated into requirements to define it more clearly as presented below.

A successful product in one way or another is the result of a sound requirement analysis, which can be based on information obtained from various sources and on observed trend data and recommendations and ideally should include some degree of user consultation. This process is generally known as the requirements definition, and arguably the most important phase of the product lifecycle, literally being the first make-or-break point (Daniels 2000). Requirements are typically split into functional and nonfunctional requirements. Functional requirements are based on “feature” or “what” the product must achieve typically described as single requirement. Non-functional requirements are the criteria used to assess the system, i.e., the “how.” Defining “how” the system should deliver the “what” is also referred to as the “quality requirements” and will typically include a set of “acceptance criteria.”

In the case of a product that will serve the remote underserviced market, the basic requirements are determined to a large degree by an acceptance model based on the criteria of availability, accessibility, affordability, and applicability. Such an acceptance model is based on research by various international institutions such as the International Telecommunications Union (ITU), the United Nations (UN), and the World Bank Group among others. Product requirement thus must have as its primary goal the elimination of these four barriers preventing the successful adoption of broadband services in unconnected communities. A product deployed in a remote area where access is not easy nor necessarily guaranteed will also have to offer a very high degree of reliability.

Low-maintenance requirements augmented by a robust remote management and monitoring abilities constitute important considerations. It is also desirable to involve a degree of training to establish a certain community knowledge base to carry out basic maintenance and building community ownership. To ensure additional "buy-in" into the use of the product by the local community, it might be beneficial to add extra features to the product which falls outside of just communications device. Such additional features could be a direct service, i.e., provide light at night in an area where electricity is not available or collect data to serve the community indirectly down-the-line.

The quality requirements can be split into two main groupings, namely, the basic user acceptance requirements and performance requirements. Typical requirements falling under the ambit of performance requirements will relate to product performance, reliability, supportability, and usability. The four generic conformance criteria for community acceptance of broadband serve as the "acceptance criteria." These are very important design considerations as they will determine the product's acceptance rate (Sprague et al. 2014).

These acceptance requirements must importantly include a component to create a "desire" in the target user to "want to" use the product which in turn can be influenced by the design.

6 The Basic Broadband Apparatus for Remote Communities (BARC)

In its basic form, a BARC needs to deliver the means to practically engage broadband Internet to a user in an underserviced remote community anywhere in the world. To achieve this it needs to perform four "foundation" functions, namely, engage two-way communication with a broadband constellation, generate and store electricity, and provide a practical user interface – all delivered in a single unit. This section explores the basic architecture with some notes on enabling technology.

6.1 Architecture

The foundation architecture required to deliver the basic purpose can be viewed as an interrelationship between four integrated functional modules, namely, structure, power, communications, and user interface. In this configuration the product should be able to provide all that is required for an end user to engage a space-based broadband signal. The architecture can be modelled analogously to the concept of a "biological cell," where the environment for all functional components to interact and enable the cell to function as a single unit is created within the boundaries of a "cell wall" – in this model represented by M1 the "Structure Module" (see Fig. 3).

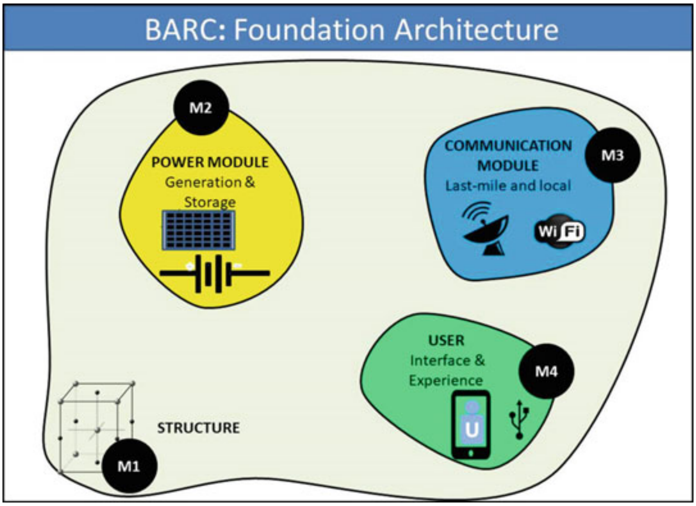

Fig. 3 BARC foundation architecture. (Graphic courtesy of the author)

6.1.1 Structure Module (M1)

This module not only provides the physical structure to anchor all the necessary equipment but also provides the means to integrate and control all the modules into a single workable unit. As the "heart of the system," it is the central point of failure for the system, and the design should be robust enough to minimize risk of failure. Typically it will contain at least the following functionalities:

- Anchor points
- Central control distribution and connections
- Power distribution and connections
- Physical structure to accommodate all required hardware and software
- Reticulation conduits and connectors
- Telemetry

6.1.2 Power Module (M2)

This module is responsible for the generation and storage of electrical power for the BARC system. It will need to utilize a form of renewable energy appropriate to the area of deployment, e.g., photovoltaic panels, which is then stored in batteries. Power generation for any device in a remote area will have to rely on a type of renewable energy which can easily be integrated into a BARC, currently dominated by two types, namely:

- **Photovoltaic (PV) technology** generates electricity through the interaction of a semiconductor material and sunlight. PV is widely used in multiple applications in diverse settings, from powering satellites in space to the pumping of water in the desert and powering of a plethora of personal equipment (NREL 2018). New technology using non-silicon-based materials allow for ever-increasing application allowing PV materials to be directly applied on different shapes and surfaces (Energy.gov). PV technology is by far the most popular technology for rapid rollout of power at underserviced areas and is widely used to power equipment in marine craft such as sail yachts.

- **Wind** power, arguably the oldest form of renewable energy, started out propelling boats in ancient Egypt then gradually evolved into more sophisticated applications with wind-powered water pumps believed to be in use in China as early as 200 BCE (USEIA). Generating electricity by converting the rotational force of wind has therefore been a logical evolution with large windfarms already producing 597 GW by the end of 2018 (WWEA). Small wind generators (SWGs) are less efficient albeit not as complicated as the large commercial systems but can be deployed effectively in remote areas with frequent windy conditions. Compact SWGs have become a popular proven technology and can often be seen on gantries with security cameras and on most oceangoing sail yachts.

Table 3 provides an overview of the key choice considerations for deployment of PV or SWG.

Albeit lesser known than solar and wind and not currently quite a practical consideration yet for a BARC are fuel cells (Kurtz 2016), yet worthy of a mention as potential future power generator for a remote setting. Generating electricity using the electrochemical reaction between oxygen and hydrogen, an extremely energy-efficient process (80–95%) and only producing water as effluent, it presents an attractive prospect. An additional advantage of the technology is that, it being essentially a battery running on “fuel,” it does not require the major storage overhead in the form of batteries normally associated with small-scale PV and SMG. Current virtually all portable versions need recharging of its fuel source which might not be a practical arrangement for remote communities where distance plays a role. Globally a number of commercial initiatives are driving fuel cell development, for example, the platinum mining sector, in search of additional applications for

Table 3 Renewable energy PV and SWT (Fong)

Solar cells – photovoltaic (PV)				
Advantages	Very low eco-impact	Low operational expense	Ease of use	Portability
Disadvantages	Limited power supply	High capital expense	Day only – needs storage system	Efficiency determined by environment
Small wind turbine (SWT)				
Advantages	Cost-effective – depending on location	Can produce power as long as the wind blows	Relatively portable	Small installation footprint
Disadvantages	High operational expense	Mechanical failure	Spare part availability in rural areas	Efficiency determined by environment

its product, which may ultimately lead a practical unit for remote communities (Minerals Council South Africa).

In the future a combination of photovoltaic (PV) cells, small wind generators (SWGs), and fuel cell each complementing the other might be the best option, and in reality it has already been practically demonstrated by the Energy Observer (Stewart) an oceangoing catamaran which uses all three technologies to power its planned 6-year odyssey around the globe.

In the case of any renewable power, the issue of storage always needs to be taken into account to ensure a consistent power supply when the renewable source is not available, i.e., the sun sets or the wind does not blow. Lithium-ion battery technology is currently the preferred choice as the source of backup power for electronic signal equipment, for example, cell phone base stations, where deep-cycle lithium-ion units have been proven as a reliable choice. With low internal resistance (Battery University), high cycle life, low charge time, self-discharge protection, low toxicity, low mass, compactness, and virtually maintenance-free, it is the best current option for a BARC. On the downside it is still relatively expensive although costs have been pushed down driven by the development in mobile electronics and recently increasingly the electric car market. The technology relies on a flammable non-water-based electrolyte, a potential fire hazard (Ribière et al. 2012), which can be mitigated by building a suppressant system capable of dealing with lithium-ion fires into the design especially important in remote locations (Maloney 2013). Redundancy is an important consideration in any battery installation that the design should also accommodate.

6.1.3 Communication Module (M3)

Functionally this module is responsible for all communication services; practically it serves two distinct purposes, namely, taking care of the "last mile" via a suitable antenna and serving as portal to local users via a medium, e.g., Wi-Fi.

Key to this module is the use of satellite ground antennas to communicate to the chosen constellation. The ubiquitous fixed parabolic antennas are universally associated with satellite communications and as with the writing of this chapter still remain the most popular option to provide broadband Internet in remote areas. Fixed parabolic antennas by its nature receive service from GEO satellites and are suitable for broadband applications where latency is not an issue, and therefore currently it is the most widely rollout technology to provide satellite broadband to remote areas. Successfully engaging a broadband constellation operating in lower orbits – where the individual satellites will travel faster and cover a much smaller area than is the case with GEO constellations – a fixed parabolic system will not suffice necessitating the use of a user-end antenna capable of "tracking" the constellation.

A new generation of flat-panel antennas (FPAs) with no moving parts using electronic "steering" with the ability to engage LEO, MEO, and GEO constellations has entered the market already albeit still on the high-end of the market. Incorporating technology such as phased array allows communications tracking by using a RF beam focused at the target constellation using software controlling antenna emissions. Technological advances in a variety of fields have allowed companies to overcome traditional challenges relating to cost and performance to produce antennas feasible for the mass market. Cost is of particular importance when considering penetrating a market dominated by low-income consumers for which an estimate of USD 100 for a complete kit is considered the target “affordability” price point for the “poor” demographic (Werner 2017). It is important to note that tariffs and installation costs can easily double when antennas are actually put in place.

FPAs do have an added design advantage as they offer more freedom to be integrated into a BARC design as they do not have the design constraints that comes with a parabolic antenna.

Since Apple, the first major mainstream manufacturer to adopt the technology into its product lineup, introduced Wi-Fi in its “AirPort” in 1999 (Apple 1999), Wi-Fi has become the “face” of pervasive wireless connectivity, with over nine billion (WorldWiFiDay) devices shipped as of the end of 2017. Providing ease of use, this well proven technology is easy to integrate into virtually any design. Typical considerations are coverage area, distance, capacity, and security. Security is increasingly an important factor in relation to cybercrime and privacy issues. Introduced into the market in 2018, WPA3(Wi-Fi Alliance WPA3™) offers compliance to more strict data security requirements with stronger cryptographic strength while at the same time allows the use of less complex passwords.

6.1.4 User Interface Module (M4)

The purpose of this module is to provide the end user with the utility to translate the available services into a practical reality. In unserviced remote areas, end users will need to have the means to charge the intended access device such as a tablet computer provided to them. The interface must provide an easy-to-use physical interface, providing utility in the form of charge points featuring a variety of industry standard connectors, e.g., USB 3. It might also be used to house biometric authentication devices if so required. At face value it is not as technically complex as the other modules; it is however the most crucial from the perspective of the end user. As design consideration it is the only truly user-facing component with direct physical user engagement, i.e., the “face” of the product. Should it fail to serve the user community, it will render the BARC practically useless to its intended user base; therefore it should be robust enough to survive the rigors of daily use in a challenging environment and should offer a high degree of redundancy all translating into a very low mean time to failure.

6.2 Augmented BARC

Though the basic BARC design will achieve the goal of connecting the “unconnected,” a design that allows to easily add additional features, beneficial to different types of communities, will present a distinct advantage. Different communities might identify different additional needs, and a design that will also allow for new features to be added with relative ease in the future will be highly desirable.

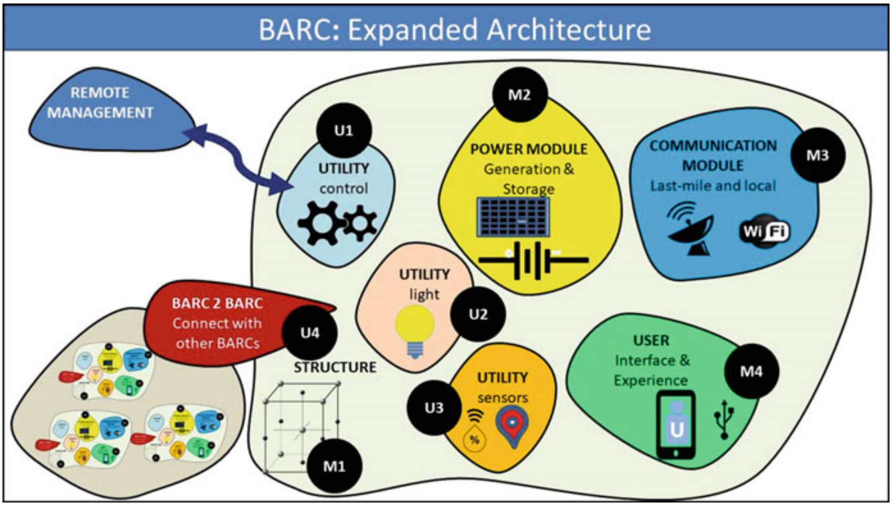

Fig. 4 Expanded BARC architecture model. (Graphic courtesy of the author)

This section presents a number of modules that will not only enhance the utility of the BARC for on-site users but also present the BARC to be of value to other nonlocal stakeholders. Figure 4 presents an expanded model of the BARC; in addition to the four basic modules, an additional four utility modules marked U1–U4 are shown. These are modules accommodated by the structure module (M1) in a similar fashion to the foundation modules (M2–M4) and may use features of these modules as required.

6.2.1 Utility Control Module (U1)

The purpose of this module is twofold: firstly it should provide a unique identity token (UIT) to the BARC, and secondly it must provide the means for remote management. The UIT token can be used among others for remote management and data encryption. Remote monitoring and management of a BARC can be used to proactively identify impending problems, conduct routine maintenance, and apply upgrades among others. Where the BARC is part of a third-party sponsored system, it can also serve as an asset control mechanism.

6.2.2 Light (U2)

The purpose of this module is to provide light and alleviate “light poverty,” a term used to describe communities without the benefit of “decent light” at night. Typically this problem is a function of not having access to electricity; it introduces a number of constraints to the community after dark including but not limited to movement, productivity, and security. Globally an estimated 17% of the population spends up to 1000 times more money on a “unit of light” than their “on-grid” compatriots. The situation impacts the environment as the “light poor” are forced to burn fuel to provide light which is estimated to be equal to the greenhouse gas emissions of

30 million (Mills) cars. LED technology comes in a variety of forms and is easy to integrate into any design and provides high lumens output at a low power consumption. Coupled with low cost and a superior longevity compared with other lighting technologies, LED illumination is ideal as a supplementary utility service of a BARC.

6.2.3 Sensor (U3)

The purpose of this module is to host a number of sensors which can be used for collection of data and meta-data for a variety of reasons. It is said that the Fourth Industrial Revolution is "powered by data," data collected from "new" areas such as the intended deployment of BARC might be of particular value which could be monetized to assist the community. In remote unserviced communities, such collection of data may thus be of benefit to any number of stakeholders. A vast variety of sensors are already available on the market in the form micro-electromechanical systems (MEMS) (MEMSnet) which can be used for reliable data acquisition for virtually any mainstream application. This module can also be used to encrypt the collected data using the BARC UIT (refer U1) which can be deployed as part of an attribute-based encryption scheme (ABE) (Sahai and Waters 2005). The module can also collect meta-data; the communications module (M3) will be used to transfer the encrypted data to its destination.

6.2.4 BARC-2-BARC (U4)

This utility module enables additional BARC units to be added at a location should the need arise to expand the coverage of the system or for redundancy purposes.

7 Form as Consideration

Whereas not the only, "uncertainty" is cited as one of the main reasons people will resist the change typically associated with the introduction of a new product into a chosen demographic. Severe resistance to change can result in the complete failure of a novel product introduced into an environment where the purpose is not clearly understood (Sørensen 2013). Rosabeth Kanter (2012) stated that a target demographic will often "remain mired in misery than to head toward an unknown," when faced with the "excess uncertainty" introduced by a novel product. The product ideally therefore needs to overcome inherent resistance to change, by clearly presenting itself in a beneficial way to the intended demographic, i.e., a product that is perceived useable, useful, and "desirable to use." When planning Disneyland originally the question "How will it provide the customer with a magical experience?" (Thomke and Reinertsen 2012) was used with great success in order to make the eventual product desirable from a user perspective. The more intuitively the design can accomplish this, the greater the chance of success. Product desirability must be achieved within the constraints of what is possible and what is affordable. The ideal product design can be illustrated as a virtual "point" where product desirability, feasibility, and viability intersect while satisfying the basic generic acceptance

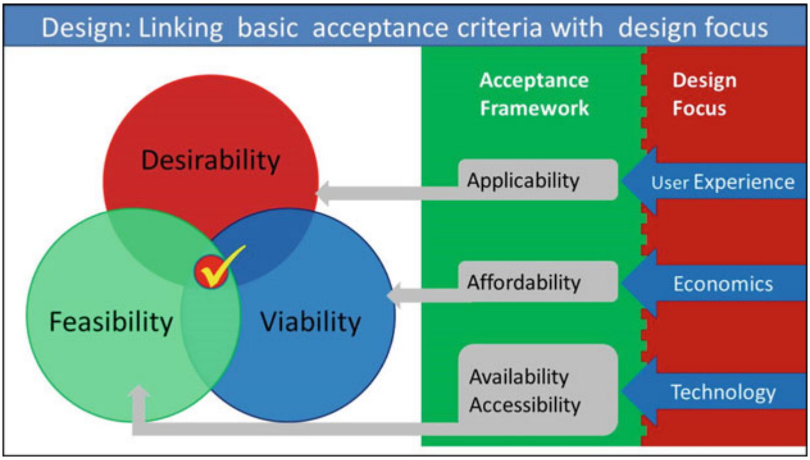

Fig. 5 Conceptual design framework linking basic acceptance criteria with design focus. (Graphic courtesy of the author)

requirements (refer to Fig. 5). This needs to be created within all relevant constraints which could take many forms be it cultural, economic, regulatory, or technological.

Introducing broadband Internet into an unconnected community that does not necessarily perceive a benefit with regards to Internet use, will have to follow a different strategy than engaging one with an existing desire to use broadband Internet. This could be achieved through using the form of the design to offer the user community some obvious other function that the community will find of "immediate value" and as such will accept the presence of a BARC.

A BARC integrated into a functional form such as a structure providing shelter during the day from sun and rain and at night providing illumination to the area might have a better chance of being accepted than an abstract structure dedicated to just providing a broadband signal. Another example could be to integrate the BARC into a water tank, as water plays such an important role in any community, in the developing world especially. According to data from UNICEF (2016), daily more than 200 million hours per day is spent in collecting water mostly by women. Providing a facility to store water locally while providing light at night might be valuable for communities where such a facility does not exist (refer to Fig. 6).

This concept can be explored further as discussed by way of the following three examples exploring three basic themes starting with the idea presented above, a water tank.

The design (Fig. 7) is dominated by a large water tank acting as center piece, with three distinct flat trapezoidal roof frame sections extending outward from the tank. As with the aforementioned design concepts, the roof sections feature PV material on the outside and LED for the ground-facing part. A FPA and sensor pack are mounted on top of the tank; additional sensors are mounted in a utility "ring" mounted lower on the tank also containing the Wi-Fi. A round utility base surrounds the tank, in which the batteries are housed.

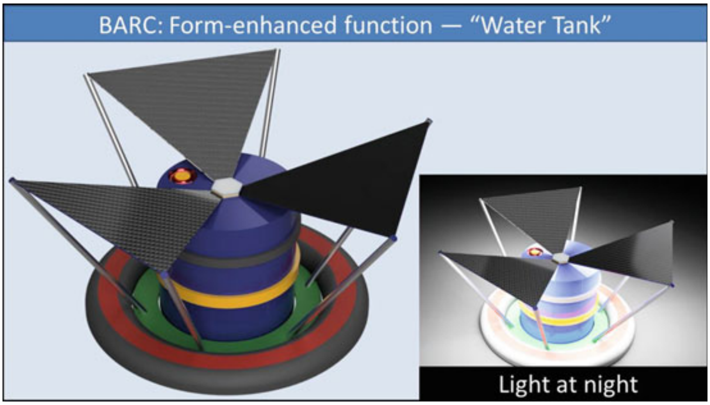

Fig. 7 BARC modules using water tank for enhanced function. (Graphic courtesy of the author). Copyrighted by the author and licensed to the publisher for this publication

Featuring shelter as a central design theme, the second design concept (Fig. 8) aims to provide the end users a shelter to use where they can charge their access devices sheltered from the sun. The roof is clad with material featuring integrated PV collectors; the inside roof ceiling is in turn clad with material featuring integrated ultrathin LED providing light at night. The design is dominated by a conical roof structure with a FPA mounted at the apex, supported by a number of pillars which apart from their obvious structural duty also host the additional BARC functional modules, housing batteries, housing data collection sensors, and providing integrated charge points.

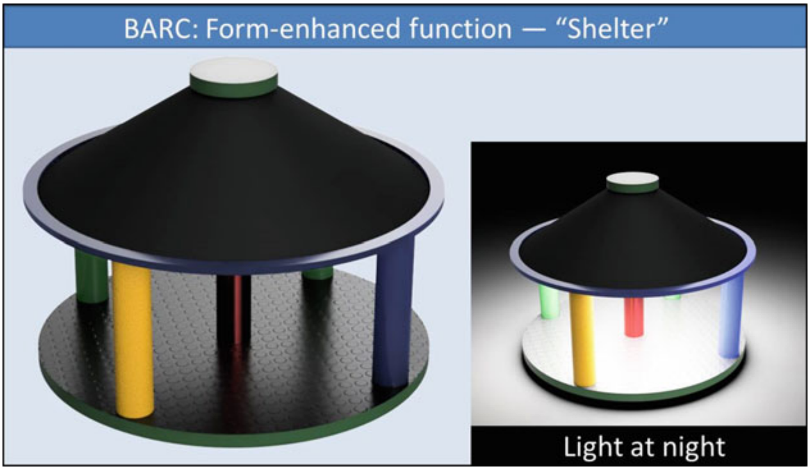

Fig. 8 BARC modules featuring shelter as the enhanced function. (Graphic courtesy of the author). Copyrighted by the author and licensed to the publisher for this publication

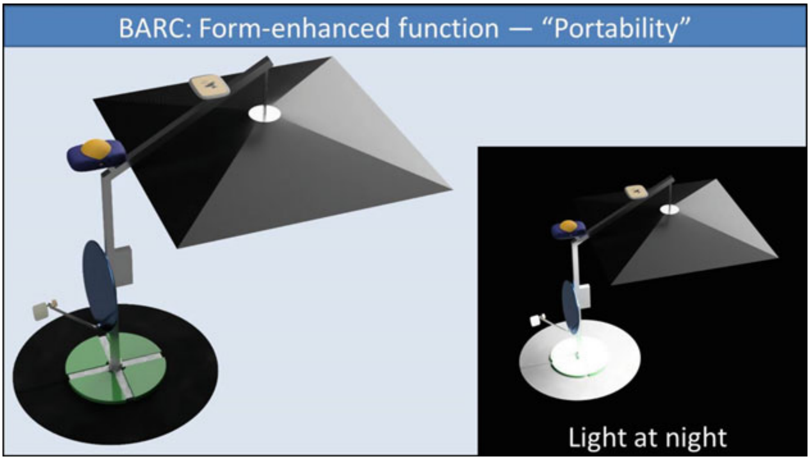

Fig. 9 BARC modules integrated into a collapsible design. (Graphic courtesy of the author). Copyrighted by the author and licensed to the publisher for this publication

The third featured concept (Fig. 9) resembles a cantilever garden umbrella. This concept places emphasis on portability; this could be of particular use to remote communities leading a nomadic existence. Center to the design is a collapsible roof suspended from a cantilever frame anchored to a modular base housing the battery packs. The collapsible roof is made from a material with integrated PV on the top "sun-facing" layer with the inside layer of the "umbrella" featuring flexible LED materials. This design features both a FPA and parabolic satellite antennas. Sensors and Wi-Fi components are housed in a weatherproof enclosure mounted on the top of the frame and the charge points integrated into the frame.

In addition to the immediate acceptance, practical value demonstration of broadband will have to be demonstrated to enhance community acceptance of the product and willingness to explore the potential of the broadband service. The evolution of satellite navigation as a product is a good example; in 1997, very few people saw the value of a handheld GPS receiver providing the user navigation information in the form of numerical coordinates. Yet the same information is still used today; the difference is that it is presented in a practical way. Take a person using a map-based navigation system on a smartphone, the software takes the same information that was presented in 1997 from essentially the same service; the difference is now it comes in a converged form, the user association is not with the coordinates but rather with finding their destination, i.e., the "what" as opposed to the "how."

The design needs to be augmented by a suite of applications relevant to the target community which is "readily available" to be rolled out and installed. Thus there is a need for easy-to-use applications that allow farmers' access to market information in a practical way. This needs to keep into account skill levels and accessibility in native languages. These features will have an immediate impact. The users must be equipped and trained with the relevant skills to practically use these applications. In organizations the ability of the user pool to recognize the value of new external information, assimilate it, and then find ways to apply it to the benefit of the user community is known as the "absorptive capacity" (Tsai 2001). In the long run the true benefit of deployment such as BARC will lie in the ability of the user community to identify new opportunities the broadband ecosystem can bring to their immediate socioeconomic environment which is bound to resonate further up the value chain.

8 Conclusion

The aim of this chapter was to provide a brief overview of practical approaches to provide broadband Internet delivery systems to remote unserviced areas by use of integrated functional modules, i.e., BARCs. The motivation to develop such a product is fairly straightforward; in 2019, more than three billion people globally are still unconnected, a large portion of which is due to the lack of infrastructure. Opportunity is presenting itself through a very large number of small-satellite-based broadband constellations which will present a significant increase in available bandwidth in the next couple of years. The technology to construct such a product is available in the market in the form of flat-panel antennas, renewable energy, and reliable storage systems.

Broadband can only be of benefit to a community if it leads to some improvement in the socioeconomic status quo. Key to this process is getting the community to use the service and importantly to continue using the service; acceptance of the product by the user community is as important as the product itself, and care must be taken to "up-skill" the potential users adequately. True economic benefit can be achieved by broadband implementation into a community. This is possible only when the recipient community has the capacity to fully exploit the capabilities offered by the service, leading to increased use of the system and a widening circle of benefits achieved.

There is a tendency to focus on the satellite technology and even the satellite ground systems, but to provide effective connection to rural and remote areas and the entire system that links the end users and address their needs must be considered. An end-to-end capability that meets local consumer needs is essential to success.

Economic and Market Trends for Ground Systems to Support New and Future Small Satellite Systems

Bernardo Schneiderman and Joseph N. Pelton

Contents

Abstract

The history of space applications and especially satellite communications has been significantly focused on the deployment of spacecraft in geosynchronous orbit, as first proposed by Arthur C. Clarke. This special orbit uniquely allows ground antennas to be constantly pointed to satellites in GEO orbit that appear to hover constantly overhead. This feature allows the ground stations to be simple in design and, once installed, actually require a minimum of maintenance. This has been a particularly attractive feature for applications such as direct broadcast

satellite radio and television services where many hundreds of millions of users are receiving programming from the skies.

The concept of using much lower orbiting satellite clearly could have advantages if there were a low cost and efficient way of tracking such satellites as they passed overhead from horizon to horizon. These advantages include reduced latency or transmission delay, less signal spreading or so-called path loss, and higher-efficiency spot beams that allow more efficient use of spectrum by means of frequency reuse. These new types of satellite systems, in theory, might be able to more closely approximate the effectiveness of cellular telecommunications services.

In short, the choice of GEO systems over MEO or LEO satellite constellations has been driven most powerfully by the cost, technical design complexity, and operational difficulties of ground antenna systems needed for these MEO and LEO satellite systems that require rapid track of spacecraft in these lower orbits as they traverse the skies.

The recent breakthroughs in the design of satellite ground antennas that can be designed to track satellites via electronic means rather than physical tracking processes have been the key to the small satellite constellations. The design of cost-effective flat panel satellite antennas is seen as the answer to ground systems being too expensive because of the need for rapidly moving satellites in LEO orbit. In short these new flat panel systems with electronically steered antenna systems that can be deployed in remote areas and operate reliably will be key to the success of the new smallsat LEO constellations. These new ground systems can be designed to support telecommunications, Internet broadband networking, cellular backhaul, and other services such as IoT messaging, machine to machine (M2M) services, and possibly even broadband Over-the-Top video streaming for news and movie/radio entertainment.

This chapter explores the changes that have come and will evolve in terms of the economics and market trends related to the production and use of ground stations that can electronically track small satellite constellations in LEO and MEO orbits. It examines not only the market for these new type of ground systems but also looks briefly at the many suppliers that are developing the ability to produce these new types of antennas. It also explores some of the emerging strategic partnerships between the operators of these new small satellite constellations and the manufacturers of these flat panel satellite antennas – also known as conformal shaped antennas. It notes that some traditional suppliers of parabolic dishes are adapting to produce these new types of antennas.

Clearly there are many new start-ups that are now also entering this new market. The billions of dollars that are being spent on new small satellite constellations are clearly creating a new market opportunity for a new billion-dollar market for flat panel satellite antennas or what are also called electronically steered antennas with auto signal acquisition. Other conventional antenna suppliers are focused on creating larger units for tracking, telemetry, and control of these large networks, but this will generally not require new technology. Some estimates have placed the market for new flat panel satellite antennas to be as large as $11 billion by 2028. This chapter explores the many factors that might influence the growth of this new market and the companies that are seeking to

respond to this new market demand. It also seeks to provide some preliminary information about the strategic partnership between small satellite constellation operators and the suppliers of electronically steered antennas. Some of the biggest operators of small satellite constellations in LEO and MEO systems, however, might seek to build, deploy, and license their own ground systems.

1 Introduction

The history of most types of satellite applications has often revolved around ways to simplify the ground segment so that more users can access and use the satellite in a lower cost and more widely distributed basis. The initial steps involved creating higher-powered and more sophisticated GEO satellites with high-gain antennas that could operate effectively to smaller and increasingly low-cost parabolic dish antennas on the ground. These antennas were lower in cost, in part, because they did not have to track the GEO satellites that appeared to hover in a fixed location in their special orbit.

These geosynchronous orbiting satellites, because they were so distant from the Earth – almost a tenth of the way out to lunar orbit – were subject to significant transmission delay and also major path loss as the signal from the satellite spread out in an ever widening circled as they traveled between the ground and the satellite.

When thought was given to the idea of creating satellite systems for mobile satellite services, the idea of using low Earth orbit (LEO) satellites in a constellation was given serious consideration. Since the mobile users would be moving, the key advantage of constantly pointing user antennas to a GEO satellite was no longer there. Further, a LEO satellite, since it would be on the order of 30–40 times closer to Earth, would experience much less path loss. This could allow the user antennas to operate with lower gain. This could help make user antennas, or transceivers, smaller and less costly and even allow handheld units for satellite links. Also there would be less latency or transmission delay. The quarter of a second delay for a signal to go to GEO orbit and return had always created some concern when providing a voice or interactive service.

The two commercial satellite systems that were designed for mobile voice services, Iridium and Globalstar, and the one for data messaging, Orbcomm, all chose to operate in LEO orbits for these reasons. They sought to devise new designs for user devices that could be small enough to be handheld and could receive signals

360° across the azimuth from horizon to horizon. This was an enormous technical challenge. There were efforts to create antenna designs that were capable of receiving signal above the horizon and to create deployable antennas in order to achieve higher gain when extended for use. The main technical advance that was critical to these new satellite telephones was the development of application-specific integrated circuits (ASIC) that allowed advanced digital processing of the transmitted signals between the satellite and user transceivers. There were also advancements in the design of the satellite antennas to create narrower beams using phased array antennas. This allowed computer electronics to form the beam shapes electronically.

The initial designs of these phased array antennas were quite expensive to fabricate. Thus the use of electronic beam formation by means of phased array antennas was initially restricted to the satellites and not applied to ground systems. In short, phased array antennas, which are also referred to as flat panel antennas, were not considered economically viable for user antennas on the ground. The experience with the phased array antennas used on the first- and second-generation Iridium satellites and on the second-generation Globalstar satellites provided useful and important developmental advances of this technology that could be in some senses transferred to research related to the ground transceivers.

The latest evolution in thought about the delivery of satellite services has been to seek ways to provide broadband digital services with a minimum of delay (or latency) at high-throughput speeds that are comparable to terrestrial laser systems using fiber optics. This concept was first originated by the so-called Teledesic mega-LEO system that proposed the deployment of some 840 high-throughput LEO satellites plus 80 spares that could blanket Earth with a digital network operating with high-speed services operating in the Ka-band.

This proposed network of the 1990s lacked the technological and advanced production techniques to deploy such breakthrough technology (neither for the satellites or perhaps especially for the ground systems). This innovative Teledesic satellite system that was backed by Cellular service entrepreneur Gregg McCaw and Microsoft founder Bill Gates ultimately declared bankruptcy. This possible future vision of a new type of satellite system was important to the future evolution of satellite system design. This trailblazing design foreshadowed the LEO and MEO systems of the 2020s that envisioned improved satellite services that could cover the world and provide comprehensive access to rural and remote areas. The experience from Iridium, Globalstar, Orbcomm, and Teledesic opened the door to thinking about small satellite constellations in LEO and MEO orbit. The new vision was new types of satellite networks that could deliver broadband, high-throughput and low latency services comparable to fiber-optic networks. The technical challenges were many. The greatest challenge was developing ground systems capable of electronic tracking of broadband satellites in a LEO or MEO constellation.

Today a large number of so-called mega-LEO networks and some in medium Earth orbit (MEO) are in various stages of deployment. The ability to design, engineer, and manufacture the high-performance small satellites for large constellations is now relatively well established, but the ability to make low-cost flat panel antennas with electronic steering is another matter. The costs of these types of user terminals remain too high. There are estimates from the Northern Sky Research 4th Report on Flat Panel Satellite Antennas, 4th edition, that the market for these new type of antennas will grow rapidly in the next decade (Northern Sky Research 2019). The NSR market analysis, however, suggests that the use of these types of antennas will be predominantly targeted in the nearer term for mobility applications (i.e., cellular backhaul and aircraft, ships, trucks, buses, and even self-driving cars) (i.e., 94%). Thus the NSR market analysis for flat panel satellite antennas associated with the new smallsat constellations and ground systems for these networks might represent only 6% of the total market – at least for the nearer term. The latest projection by the Northern Sky Research has anticipated that the global market might reach some 1.5 million units being shipped in that year with revenues totalling $11 billion per year by around 2028 (see Fig. 1) (Northern Sky Research 2019).

Yet these estimates are based on several key assumptions. Thus, critical factors in the market projections are as follows: (i) the rate of breakthrough in design and production, particularly with regard to how quickly there will be reductions in the cost of designing, fabricating, and installing flat panel antennas; (ii) the overall demand for flat panel antennas/electronically steerable antennas to support 4G and 5G cellular backhaul services and other so-called mobility markets; (iii) the success of new smallsat constellations for broadband networking; and (iv) and the extent of the eventual demand for flat panel satellite antennas to support GEO satellite systems and related high-throughput satellite markets as the cost of flat panel satellite antennas drop over time.

Some market estimates, as the Northern Sky Research study noted above, suggest that the demand for flat panel antennas will be almost entirely driven by demand for these units for 4G and 5G cellular, aeronautical, and other mobility services and that satellite-based demand for such aspects as broadband LEO and MEO constellations will perhaps be much smaller in the next 5 years through 2024. Some have said that the demand for flat panel satellite antennas represent the “tail” of the dog, that is, this larger and more significant market that will be installing flat panel antennas on aircraft, ships, trucks, trains, and buses and for military-related mobile services.

Some have said that the largest market may be for self-driving cars that have to be instantly updated via 5G cellular systems and satellite connections to avoid collisions. Even more mundane requirements associated Wi-Fi/Wi-Max systems and IoT or SCADA messaging may drive the overall flat panel antenna market at least in terms of volume of units sold. One of the biggest variables might relate to the volume of the market related to military systems and retrofitting of aircraft and ships, and this assessment is beyond the scope of this article.

At the Paris World Satellite Business Week Conference held in early September 2019, leading satellite experts concurred that flat panel antennas will have a dramatic and profound impact on satellite communications services market. This will likely start with mobility services (including cellular related applications) and Internet of Things (IoT) satellite services and then expand to support all forms of satellite services as performance increases and production costs fall.

Pradman Kaul, CEO and President of Hughes Network Systems, stated the view that broadband satellite services from constellations in low or medium Earth orbits

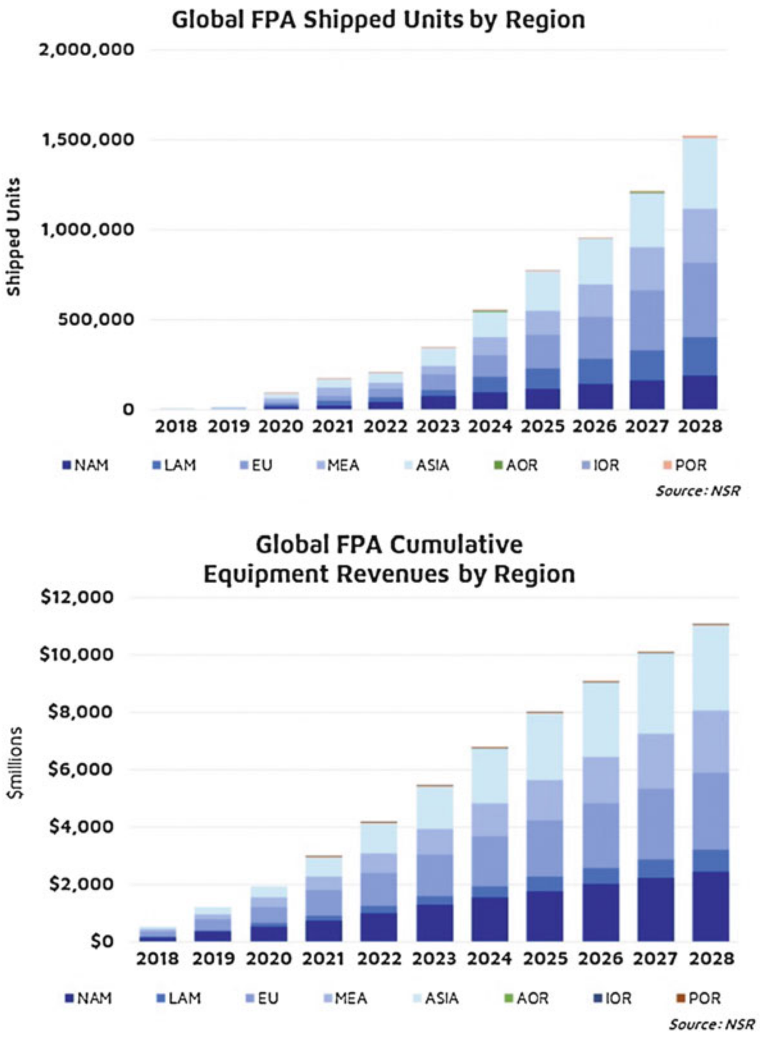

Fig. 1 Northern Sky Research (NSR) projections of market demand for flat panel satellite antennas. (Graphic courtesy of NSR). Code: *NAM* North America, *LAM* Latin America, *EU* Europe, MEA Middle East-Africa Asia, *AOR* Atlantic Ocean region, *IOR* Indian Ocean region, *POR* Pacific Ocean region

required inexpensive flat panel antennas to be successful. He declared this was a “critical” need but we were not there yet. He added, “That is the biggest application today that we can’t address because we don’t have a low-cost, electronic array-based flat-antennas (Werner 2019).”

iDirect CEO Kevin Steen added that demand for satellite connectivity to provide global Internet of Things (IoT) services was another area where low-gain flat panel satellite antennas were a key to the future. He suggested small electronically steerable antennas, i.e., flat panel antennas, will be a "game changer" for increasing the role satellites play in this area. "It changes the economics when you look at the installation (Werner 2019)."

In the maritime market, the picture is more mixed. Some believe that offshore drilling rigs and the largest cruise ships and freighters will keep higher-gain conventional dishes, but smaller vessels with lower-throughput rates will go to flat panel antennas sooner. Aircraft and backhaul for 5G cellular are also seen as prime markets for these electronically steerable antennas.

Opinions differ on some aspects of the flat panel antenna market as to where usage will be quickly adopted. Some believe that cruise ships will continue to rely on large antennas working to high-throughput larger GEO satellites. Others believe that high-throughput but smaller satellites in MEO orbit such as the m-Power network can respond to this market. SpeedCast CEO Pierre-Jean Beylier, who spoke to the issue of cruise ship markets presented the view that this industry needed high throughput and video services and thus required ". . .. . . hundred of megabits and highly efficient antennas. We are not going to get there with flat-panel antennas (Werner 2019)."

The bottom line is that the flat panel antennas and the small satellite constellation market do not perfectly line up. Some believe that highly cost-efficient flat panel satellite antennas will also work to GEO satellites. Further the flat panel antennas for aircraft, ships, and military aircraft and ships will be different in cost and performance. Further the flat panel antennas for messaging, low data rates, Internet of Things, and machine to machine (M2M)-type applications will be different than other broadband and cellular backhaul services. In short there is not a single future flat panel satellite market, but a series of them.

Clearly there are many remaining unknowns for flat panel satellite antennas. It is unclear as to how much market demand will actually develop for the large constellations being deployed for global networking and broadband services.

In particular, it is uncertain as to which of all the now proposed, nearly 20 small satellite constellations for broadband services and another 12 for messaging and (IoT) networks will succeed and which will fail. It is clearly uncertain as to what will be the market demand for the so-called mobility market that is now leading demand. The market demand for military communications and commercial systems appear to be different. Further, the flat panel satellite antennas (FPSAs) that will serve the LEO-based broadband small satellite constellations for commercial aircraft and ships will be different than the antennas used for military mobile services. Finally, it is not clear how quickly the demand for flat panel satellite antennas associated with GEO-based satellite systems will develop. Answers to these market demand characteristics will likely hinge on the most cost-efficient systems. In short, the future of flat panel satellite antennas will be highly price-dependent vis-a-vis traditional dish-based antennas. Technical, operational, and maintenance performance factors will also be highly relevant.

It would seem that there could be substantial demand for flat panel satellite antennas if the cost were to go low enough to support GEO systems. Here the service could be for fixed satellite services (FSS), for mobile satellite services (MSS), and even broadcast satellite services (BSS) if the cost for these antennas fall to competitive levels with conventional dish antennas. The new systems being developed by Isotropic Systems that use optical processing seems to have a good shot at truly cost-efficient systems with the prospect of $300–$600 units, but this will have to be proven, and it is still early days in the development of FPA/ESA systems. There has also been good progress for those developing credit card or deck of playing card systems for IoT messaging. Again it is still early days.

And on top of all these uncertainties, there are questions as to which companies that are planning to deploy LEO or MEO small satellite constellations might manufacture these new type antennas on their own. Further it seems that for a number of reasons related to national security concerns, protective regulations, and particular specification, the development of the FPSA systems will this divide into the two areas of commercial FPSAs and defense related FPSAs as well as broadband versus narrow band services?

Further it seems that, it does appear that there are a number of suppliers for defense systems and particularly for aircraft and ships and their communications that may seek to provide flat panel satellite antennas for defense-related mobility where special specifications are applicable. In this regard, suppliers such as Lockheed Martin, Boeing, General Dynamics, Cobham Plc, and Airbus Defence and Space may serve to be suppliers to military requirements but may not serve as major suppliers for commercial networks. The one exception might be Boeing, if it ultimately decides to deploy a commercial LEO small satellite constellation. The uncertainty noted above are thus good reason to be cautious in accepting any market projection that might be made at this time, although the NSR market profile seems to be the most carefully researched (Flat Panel Satellite Antenna 2019).

It appears that both Amazon and SpaceX are now planning to develop their own FPSAs for their LEO smallsat constellations. The design and fabrication processes for these antennas, in order to get costs down to an acceptable level, is a significant undertaking. SpaceX has filed with the US government a document indicating that they will seek to deploy one million of these flat panel satellite antennas and have their licensing approved. Amazon/Kuiper Satellite Network have indicated plans that they will build their own ground antenna systems as well.

Amazon and SpaceX are perhaps the two largest small satellite constellations that are now planned to be deployed. If both SpaceX and Amazon/Kuiper go the route of vertical integration and end up manufacturing their own antennas, this will clearly affect the potential market size for those that are focused entirely on developing and manufacturing flat panel antennas/electronically steerable antennas.

Today the Northern Sky Research study of flat panel antennas has identified over 20 companies either now providing or actively engaged in their development. The companies that are pursuing this market as producers and/or integrators include the following: ALCAN Systems, Anoki Systems, Ball Aerospace, Boeing, C-Com, GetSat, Gilat Satellite Networks, Kymeta, HiSky, Honeywell, Hughes Network Systems, Isotropic Systems, Omni Wave, Phasor Systems, Satixfy, StarWin, Thinkom, Tianyi Satcom Company, Toshiba, and Viasat (NSR Press Release). In addition it appears that SpaceX and Amazon/Kuiper might be self-suppliers (see the Appendix at the end of this article to learn more about these companies and the status of these development efforts).

Many of these companies are currently focused on the aviation and shipping mobility market for both commercial operators and military systems. As the new smallsat constellations are deployed, the market can be expected to shift.

What must be kept in mind throughout this analysis of the market demand for flat panel satellite antennas (FPSAs) is that currently the biggest market demand is for 4G and 5G cellular and mobility market and not units to support small satellite constellations. This could just be a sideline for the largest suppliers of flat panel antennas.

The rapid success (or not) in the build out of a number of the large LEO constellations such as those of One Web, SpaceX, Amazon (Kuiper Network), Telesat, Carousel, Comstellation, Thales, Boeing, SES/O3b m-Power, and others now planned systems will be key to the ultimate success of the Flat Panel Satellite Antenna market in the next decade.

This chapter explores the various companies seeking to develop and market lower-cost flat panel antennas, analyze their marketing strategy, and ultimately assess what the market potential is for these new types of ground antenna systems.

2 Assessing the Market Potential of the Companies Seeking to Provide Their Own Flat Panel Antennas

Only a few manufacturers of flat panel antennas/electronically steerable antennas (FPAs/ESAs) have come to market, and even those manufacturers are not providing detailed pricing information since costs and pricing are still in a high period of development. Especially when production goes to a very high level, then significant reductions in both cost and pricing can be expected.

Essentially the market in satellite antenna production seems to be separated into the following categories: (i) developers of mega-LEO or new MEO systems that opt to design and manufacture their own FPA/ESA units (at this stage, this seems to be SpaceX and Amazon/Kuiper and possibly several others); (ii) developers that are seeking to develop and supply FPA/ESAs to serve the needs of 4G and 5G backhaul and broadband Internet services; (iii) developers that are seeking to design and manufacture ground systems to support narrow band data messaging services; and (iv) established producers of ground system equipment that will seek to meet demand for satellite ground systems with conventional fixed dish antennas, and mechanically steerable dish antennas, or other conventional antenna systems such as helix antenna or omni antennas. It is assumed in this analysis the conventional dish offerings will tend to phase out and not be other than a very modest part of the market by 2028. This amounts to saying that the options that will be pursued are fairly complex. There are many ways that the lines of the division between satellite developer, satellite operator, ground segment supplier, and investors in these various systems and equipment developers may be divided. After another decade of experience, the roles will likely become much clearer.

An assessment of these suppliers and their current market and technology conditions and projections of market conditions are provided in the section that follows.

3 Smallsat Constellation Developers Seeking Vertical Integration and the Production of Their Own Electrical Steering Antenna

At this stage there seem to be only two companies that have clearly indicated their intention to produce their own FPA/ESAs for their large-scale LEO smallsat constellations. These are Amazon and SpaceX. It is possible that several other companies that are planning large-scale constellations may follow suit. These companies might particularly include those that have worked with phased array technology in the past such as Boeing and Thales Alenia. On the other hand, it is possible that either Amazon or SpaceX might for various reasons reverse direction and seek ground equipment from other suppliers at a future date.

If Amazon and SpaceX plus other providers of large-scale small satellite constellations do proceed to produce their own ground equipment, this will have a clear impact on the market. Just in the case of SpaceX, they have filed plans with the FCC and the iTU to deploy a total of over 12,000 satellites. They have also indicated plans to produce a total of one million FPA/ESA units. In the case of Amazon/Kuiper Network, they have indicated plans to deploy over 3200 satellites and an unspecified number of ground segment units. If indeed other providers of large-scale small satellite constellations for telecommunications and networking services decide to follow suit and produce their own ground systems, this will restrict the market for new suppliers of FPA/ESA equipment.

At this stage, only a few of the small satellite constellation operators have indicated their plans to work strategically with companies specializing in the production of FPA/ESA equipment. These include OneWeb (assuming successful refinancing). SES/O3b m-Power, and Telesat which intends to deploy a smaller constellation. The following provides the latest information about the planning by Amazon/Kuiper Network and SpaceX. It is recommended that one go to the websites of these companies for the latest updates.

Amazon/Kuiper Constellation: Amazon has filed to deploy a LEO constellation of 3236 broadband satellites in Ka-band. Amazon during july 2019 announced that Kuiper System will rely on a user-terminal mix of comprised of flat, electronically steered, phased-array antennas and mechanically steered dish antennas. Amazon has experience with developing complex electronic products for a mass market such as its Alexa device. In order to make its global digital satellite constellation feasible, it needs to be able to have a very large number of antennas on the ground to use this system at low cost. A FPSA product that could be sold via Amazon to access the Kuiper satellite network to buy products and services from Amazon could also be used to get access to entertainment, the Internet, health and educational information, and more. Amazon has experience with advanced electronics, application-specific integrated circuits, and global marketing of its products.

In some ways the Amazon Alexa system has some comparable experience. This is not only technological expertise but also includes experience dealing with tariffs and local taxation and permitting requirements. No specifics are currently available as to actual design or costing of the Amazon/Kuiper networking ground systems.

SpaceX has plans for a Ka-band network of over 4500 satellites operating in the Ka-band, as well as a Q/V band network that would have over 7500 satellites. This huge investment of over $10 billion for these networks is dependent on being able to allow consumers to access these systems at relatively low cost. The filing for up to one million ground antennas that SpaceX has made with the FCC was made with few specifics. The business philosophy that Elon Musk has used in other business ventures such as Tesla electric autos and SpaceX rockets has consistently been based on the principle of vertical integration, or creating as much of a product in-house without depending on suppliers of parts and component – to the maximum extent possible. Thus creating ground systems to operate with the SpaceX large- scale global constellations would be consistent with past practices.

4 New Suppliers of FPA/ESA Equipment

There are only a few suppliers that are currently offering FPA/ESA but a growing number of potential suppliers who have product under development and who are now actively marketing the product they hope to offer within a short period of time. The number which are expected to provide flat panel antennas (FPA) to support the new small satellite constellations is currently around 20, but the prospects of others joining the effort to produce new flat panel satellite antennas appears to be growing steadily. If the market does reach $11 billion per year as of 2028, that number will have undoubtedly increased from those reported on in Table 1.

SES of Luxembourg now owns and operates the O3b MEO constellation. SES is planning to deploy the next generation of MEO-based satellites known as the m-Power constellation. It has announced strategic partnerships in the deployment of the ground systems for their new system. This new m-Power network has promised the capability to provide speeds sufficient to meet the networking and enterprise service needs of large multinational companies. This suggests the m-Power will seek to serve the same market as the LEOSAT network as well as provide new networking capabilities to rural and remote parts of the world in a dual-pronged campaign to serve more than a single market.

The announced partners include ALCAN Systems, Isotropic Systems and Viasat. Reportedly these three companies are being asked by SES under contract to develop “smart” high-throughput terminal solutions. Thus these high-throughput ground antenna systems are different in design, performance, and cost than ground systems designed for individual consumers or remote communities. These high-throughput systems thus would have much greater capability than simpler, lower gain systems

Table 1 Currently active companies involved in FPA/ESA for commercial small satellites

Name of company	Profile and headquarters location	Web site
ALCAN Systems	**ALCAN Systems** of Darmstadt, Germany. It is developing a new class of innovative smart antennas that will use ultrathin flat panel technology, and with very low power usage, and able to adjust its beam electronically without any moving parts	https://www.alcansystems.com
Amazon/ Kuiper Systems	The **Amazon/Kuiper System** is US based and a system application for 3236 satellites in a low Earth orbit constellation, and it is apparently the case that Amazon/Kuiper System is intending to manufacture and install a large number of consumer flat panel antennas around the world for use of this system. No strategic partnerships for antennas have been announced. Location for any FPA production not yet known	https://www.space.com/amazon-plans-3236-satellite-constellation-for-internet.html There is no current corporate site by Amazon Kuiper Systems website, but FCC filing is available
Anoki Wave	**Anoki Wave is** focused primarily on developing antennas for the much larger 5G cellular equipment market. It has developed silicon-based and integrated circuit flat panel antennas for satellite communications in the K-band, Ku-band, and Ka-band	https://www.anokiwave.com/products/index.html
Ball Aerospace	**Ball Aerospace** has five US locations. These include plants and facilities in New Mexico, Colorado, Missouri, Ohio, and Virginia. Ball Aerospace has developed and tested phased array applications for communications, radar, space, and electronic warfare applications**.** This includes S-band and geodesic dome phased array antennas. To keep costs low, Ball Aerospace has sought to leverage commercial off-the-shelf technologies, software, and processes	https://www.ball.com/aerospace/markets-capabilities/markets/defense-intelligence/antenna-systems
Boeing	**Boeing,** headquartered in the United States, has developed its flat panel antennas initially for installation on military jets. It is possible that if they deploy their proposed LEO small satellite constellation that they might seek to produce FPA/ESA for use with this network. Decision to deploy such a system is currently on hold. Boeing has also received a $1.6 million contract to design satellite communications phased array **antennas** for navy submarines	https://boeing.mediaroom.com/1999-11-08-Boeing-Receives-Contract-To-Design-Prototype-Communication-Phased-Array-Antennas-For-Navy-Submarines

(continued)

Table 1 (continued)

Name of company	Profile and headquarters location	Web site
C-Com Satellite System Inc.	**C-Com Satellite Systems Inc**. of Ottawa, Canada has successfully tested its 16 × 16 subarray phased array antenna using 4 × 4 Transmit and receive building block modules. The panels were developed and tested at the Centre for Intelligent Antenna and Radio Systems (CIARS) at the University of Waterloo	http://www.c-comsat.com/news/c-com-announces-successful-test-ka-band-phased-array-mobile-satellite-antenna/
GetSat	**GetSat** of Rehovot, Israel, and GRC of Hereford, UK, have announced a strategic partnership for the production of conformal and flat panel antennas for military aircraft and ground and maritime communications	https://www.getsat.com/news/get-sat-and-u-k-s-grc-create-strategic-cooperation-relationship/
Gilat Satellite Networks	**Gilat Satellite Networks** of Israel has developed the RaySat SR300 phased array as a flat panel antenna. This includes the 300-M system which is a compact, MIL-STD compliant antenna. This is a two-way antenna system that enables real-time broadband satellite communications, primarily for voice and data services. This can include both “on-the-move” or “on-the-pause” services. RaySat SR300 antennas are based on a flat panel array. This covers transmit and receive bands. The antenna features multiple onboard tracking sensors, which enable accurate tracking, short initial acquisition, and instantaneous reacquisition in the case of signal loss	https://www.gilat.com/technology/sr300-m/
HiSky	**HiSky**, based in Tel Aviv, Israel, is in a strategic partnership with Hispasat to provide flat panel antenna to provide low data rate mobile satellite services and Internet of Things (IoT) messaging services. There is an intent to expand this effort to use the Hispasat Arizonas 5 satellite to provide similar type services to Latin America, Portugal, Spain, and northern Africa. This service involves GEO satellites, but the flat panel antenna technology could potentially be applied to LEO smallsat constellations	https://www.hiskysat.com/2019/04/30/hispasat-and-hisky-to-offer-iot-and-mss-in-mexico-through-small-portable-terminals/
Honeywell	**Honeywell** and **Kymeta** (both of the United States) and **Inmarsat** (based in the United Kingdom) have a strategic partnership. Kymeta has a contract to send its flat panel antenna to Honeywell for testing and integration so that it can be used	https://www.satellitetoday.com/telecom/2015/04/15/honeywell-inmarsat-kymeta-to-develop-antenna-for-advanced-ifc-system/

(continued)

Table 1 (continued)

Name of company	Profile and headquarters location	Web site
	with Inmarsat GX systems. This partnership is in support of flat panel antennas to be used in partnership with GEO satellites, but this type of technology could also be adapted to use with LEO broadband small satellite constellations	
Hughes Network Systems	**HNS,** an Echostar Company located in Germantown, Maryland, US, has noted the importance of flat panel antennas but has not released specific information about development plans for flat panel antennas. They currently have a large back order for conventional VSAT antennas to support demand to communicate to GEO high-throughput satellites including their own Jupiter System	http://www.hns.com/
Intellian	**Intellian** is a strategic partner with Kymeta that is integrating Kymeta m-Kymeta antenna into maritime communications systems	https://www.intelliantech.com/News/pressrelease/view/185
Kymeta Systems	**Kymeta** and **OneWeb**, of the United States and the United Kingdom, respectively, announced in 2018 that they were working together to deploy flat panel satellite antennas. Kymeta's flat panel antennas with fast tracking of LEO smallsat constellation are one of the first to market and can be deployed in units that are modular to allow increased gain and throughput. It has the special feature of being partially financed by Microsoft founder Bill Gates	http://www.kymetacorp.com
Omni Access	See Phasor Solutions. **Omni Access** is a strategic partner with Phasor Solutions in the installation of Phasor Solution flat panel satellite antennas on luxury yachts and other maritime vehicles/ships	https://www.omniaccess.com/omniaccess-teams-up-with-phasor-inc-to-showcase-first-maritime-ku-band-digital-flat-panel-antenna/
Phasor Solutions	**Phasor Solutions**, based in Washington, DC area, is designing modular flat panel or conformal shaped units with an emphasis on aeronautical and maritime usage. Phasor has strategically partnered with Omni Access for installation of their FPSAs on yachts and ships	www.phasorsolutions.com
SatixFy	**SatixFy UK Limited**, of the United Kingdom, has introduced what it has described as the world's first ESMA (electronically steered multi-beam array) Ku-band 256 element array antenna as of	http://www.satixfy.com/news/satixfy-launches-worlds-first-silicon-based-electronically-steered-multi-beam-array-antenna/

Table 1 (continued)

Name of company	Profile and headquarters location	Web site
	February 2019. This antenna uses fully digital beam forming technology array which can use all 256 element to create complex antenna patterns. Costing not available	
SpaceX	**SpaceX** Space X has filed with the FCC for licensing approval of the small flat panel antennas that it intends to deploy a million flat panel antennas with it Starlink system. How and where these FPAs will be fabricated is not yet announced. It would seem that it is also intended that it would also design and fabricate the V band FPAs/ ESAs as well	https://techcrunch.com/2019/05/24/spacex-reveals-more-starlink-info-after-launch-of-first-60-satellites/
Star Win	**Star Win Science and Technology Ltd**. which is based in China has been a provider of VSAT and larger dish antennas but is now developing flat panel satellite antennas. The characteristics of these electronically steerable antennas include high efficiency ≥90%; simple structure and low-cost maintenance, fully automatic and high accuracy targeting of satellite and compact and low weight, and portable	http://www.starwincom.com/
Thinkom	**Thinkom** Thinkom which is based in California, US, has a proved phased array conformal antenna system is currently in use on 15 airlines and some 1300 aircraft is one of a few providers with a proven ability to provide service installed on airlines. It has also claimed that its technology could serve to aid in the replacement of antenna farms which are expensive and also requires a great deal of room	www.Thinkom.com
Tianyi Satcom	Shaanxi-Tianyi Satcom of China is a manufacturer of satellite communications antenna. They are developing flat panel satellite antenna technology for Satcom on-the-move and internet access	http://satcom-sys.com/vendors/shaanxi-tianyi-antenna-co.,-ltd.html
Toshiba	**Toshiba** of Japan has developed flat panel antennas for X-band radar services and could extend this technology in the future for small satellite constellation services at a future date	www.toshiba.com

(continued)

Table 1 (continued)

Name of company	Profile and headquarters location	Web site
Viasat	**Viasat**, based in San Diego, California, is designing and building an all-electronic dual-beam flat panel antenna system to meet the requirements of the O3b mPower next-generation MEO satellite fleet. The Viasat antenna is based on proprietary flat panel core technology, a new radio-frequency (RF) integrated circuit and a modular approach that will enable multiple types of user terminals to keep pace with growing broadband connectivity demands	www.viasat.com

that would operate a much lower speed. The exact specifications and performance requirements for these systems are not clear and perhaps have not even been set. Presumably these would be at least in the 100 megabit/sec up to multiple gigabit/sec throughput capabilities. The direct connection to corporate sites via the m-Power MEO sat constellation would presumably be at least three times faster than GEO systems, but still have greater latency than the mega-LEO networks. Presumably scaled-down versions of these ground systems might be created to support rural and remote areas.

The following represents a brief report on the capabilities and design and production capabilities of the strategic partners that are supporting the SES m-Power MEO constellation.

- **ALCAN Systems GmbH** is based in Darmstadt, Germany. In August 2017, it announced that it had raised 7.5 million euros to design, engineer, and manufacture its new type of "smart" antennas to support the latest broadband cellular services as well as broadband connection to new satellite constellations. The three main funders were SPC, SES, and Merck. ALCAN Systems is reportedly now developing a new "smart antenna" that is a flat panel design and would presumably have no moving parts or mechanical components. The beam steering would be controlled by an integrated circuit designed for this purpose. In most cases, this would be an application-specific integrated circuit (ASIC). The design is intended to be mountable on airplanes, ships, buses, trains, and even self-driving cars to support 5G sensors needed to maintain instantaneous control and avoidance of collisions. Thus this type of unit would have an electronic beam steering capability to support satellite and cellular network needs. Most market assessments suggest that the predominant market would be for cellular and mobile applications and satellite systems would be the secondary market. The design would be intended to support GEO, MEO, and LEO satellite networks.

  The ALCAN Systems design would primarily consist of mass-produced liquid crystal panels and integrated circuits that could control the desired beam forming. The concept would be to produce these units for different applications at high volume. Once a high degree of automation is achieved, the liquid crystal panels could be proceeded at a much lower cost and rapid production rate achieved through robotic assembly line manufacturing (ALCAN Systems 2017).

- **Isotropic Systems**, of London, United Kingdom, and Lithicum, Maryland, was founded in 2013. It is developing a low-cost, low-power multi-service antenna capability. This is not a flat panel satellite antenna per se. Rather it is a multi-beam antenna that is scalable in size and service capabilities to reach from the smallest consumer-use capabilities to high-throughput service needs. The patented Isotropic Systems design is seeking to provide instantaneous bandwidth, to create an optical-based, multi-beam electronically steerable terminal that can transmit and receive high-bandwidth signals within the a modular, and thus scalable aperture.

  Isotropic Systems describes its capabilities in the following manner: "Isotropic Systems is developing the world's first multi-service, high-bandwidth, low power, fully integrated range of high throughput terminals designed to support the satellite industry to 'reach beyond' traditional markets (Isotropic Systems 2019).

  Isotropic Systems claims that their antennas can be scaled up from consumer-use antennas to provide multiple types of higher rate services. Thus they indicate that increased performance antennas using the optical-based beam forming can provide electronic connectivity for aeronautical uses, coaches and buses, trains, ships, cellular backhaul, and defense-related com-on-the-move services. The essence of their design is enabled by their optical-based beam former module. This design reduces the circuitry needed for multi-beam formation and reduces costs in an exponential basis. The claim is that this can provide Ku- and Ka-band antennas with multi-beam forming antennas that are 70% to even 95% lower than phased array or flat panel antennas currently on the market (Isotropic Systems 2019).

  In a recent interview, John Finney, the Founder and CEO of Isotropic Systems, has explained the claim of low-cost systems as follows: "We can produce a terminal, certainly in Ku-[band], that is lower than $300. . .. A Ka-band terminal would be sub-$450 (Henry 2019)."

  In addition the Isotropic Systems design is also geared to increase continuity of service and resilience against dropped connectivity during handover of service when switching from one beam to another.

  > The capability of this design includes so-called 'make-before-break'; of a beam hand-over of service from a satellite operating to a single terminal. This capability can also support link aggregation, path diversity, additional on-demand capacity, and greater resiliency of service. (Henry 2019).

  These innovations have served to win Isotropic Systems several awards for design innovation. These accomplishments have led to new levels of investment, including most recently the Boeing company through its Boeing Horizon X investment arm that has made a $14 million investment. Inmarsat has also become a strategic partner and customer for Isotropic Systems antennas where

Fig. 2 A graphic showing an Isotropic Systems antenna and the modular format underneath (Graphic courtesy of Isotropic Systems)

it has indicated a plan to use these innovative antennas to extend its Inmarsat Express services around the world (PR Newswire 2019).

Although the Isotropic Systems product is not a phased array flat panel antenna as normally understood, its surface is indeed flat. What is below the surface is different than what either ALCAN or other flat panel antenna manufacturers are providing (see Fig. 2).

- **Viasat** is designing and building an all-electronic dual-beam flat panel antenna system to meet the requirements of the SES/O3b mPower next-generation MEO satellite fleet. The Viasat antenna is based on proprietary flat panel core technology, a new radio-frequency (RF) integrated circuit and a modular approach that will enable multiple types of user terminals to keep pace with growing broadband connectivity demands.
- **Thinkom** announced early in 2019 that it has already tested their antenna with Telesat LEO satellite.
- **Kymeta** and OneWeb announced in 2018 that they were working together to deploy flat panel satellite antennas. These are one of the first to market and can be deployed in units that are modular to increase gain and throughput (Fig. 3).

5 The Overall Field of Companies Who Are Seeking to Develop Flat Panel Satellite (FPSA) Systems

The previous section discussed the companies that have capabilities in the FPSA field and are working as strategic partners with those deploying broadband smallsat constellations. In this section, there is an attempt to summarize all of the known commercial enterprises seeking to bring this new technology to market. Some of these may have already have working relations with small satellite constellation providers, but these have not yet publicly announced or these relationships have not been discovered in the authors' research to date.

Just as is the case with those designing and manufacturing small satellites, those seeking to launch these growing number of smallsats, the number of organizations

Fig. 3 The Kymeta flat panel satellite antenna is now available on the global market. (Graphic courtesy of Kymeta)

who have sought to enter the new flat panel antenna/electronically steerable antenna field, are volatile and fast changing. If commercial organizations that are seeking to develop this type of new antenna has been overlooked, this has been unintentional. There undoubtedly will be new entries that will continue to appear around the world as this new market continues to evolve.

Those companies that have been profiled in the previous section are not repeated in this section. Those companies that have existing strategic partnerships with small satellite constellations should not be interpreted to mean that their products are superior in technology, reliability, or price. Indeed some of those listed in this section may already have developed relationships that were not obvious or publically announced at the time this chapter was published. Finally, the development of flat panel antennas to support military and defense needs for aircraft, ships, and other military vehicles is largely not covered since much of these market transactions are not publicly available. Further many of these efforts involve non-satellite antennas that involve ground communications for aircraft and not satellite communications. This is clearly a part of the new and growing market, but not explicitly covered here except to note some of the suppliers as noted earlier.

The number of companies that are currently involved in developing FPA/ESA systems is provided below (Table 1). Any omissions from this list are not intentional. Clearly more companies will be joining this field of suppliers in the future.

6 Conclusion

This field of electronically steerable antennas for satellite communications and networking is an exciting new market. This new market for satellite ground equipment is largely an outgrowth that comes from the needs of the so-called mobility market that requires conformal antennas and electronic beam forming.

The flat panel satellite antennas are crucial to the new small satellite constellation industry and the new services that they will develop. These will range from the very small antennas the size of credit cards and cigarette packages for low data rate IoT messaging and machine to machine (M2M) services to the very high broadband services to support enterprise networks for large corporations with offices around the world.

The development will vary from region to region and will spread from mobility markets to fixed satellite services. The huge amount investment that are now pending in new LEO and MEO small satellite network will translate into future investment in flat panel satellite antennas that will first perhaps be on aircraft, on ships, on military vehicles, and then spread to other types of services. The utility of these new systems are to support broadband Internet to rural and remote areas, to support cellular network backhaul, and to enable satellite-based Internet of Things (IoT) data relay and M2M messaging.

The formula that has been used in satellite systems engineering that says that suggests that investments in satellites and ground control systems for the space segment should more or less equal the investment in user terminals that access the satellites. Today there are more than $20 billion in planned investment in small satellite constellations with some $10 billion related to the two SpaceX networks. The $11 billion per year of ground segment investment for users of these networks as projected by NSR for 2018 today seems very aggressive. Yet the wide range of new applications and services that can be unlocked with these new systems, seem to make such projections credible.

The one very serious concern that weighs against these projections are very much related to the issue of space safety, and the very real threat of orbital space debris. The single factor that could have a major negative impact on the growth and level of demand for smallsat LEO constellations, the services they provide, and the demand for user terminals – especially flat panel satellite antennas – would be one or more serious collisions that endanger the continued safe operation of these LEO and MEO constellations populated by as many as 20,000 satellites. Currently NSR has projected that only 7000 of the projected 20,000 smallsats will actually be launched. Even this number of satellites appears to raise substantially the risk of one or more orbital space collisions that could endanger the entire future of this new type of satellite constellation and the electronically steerable antennas that would support these new smallsat networks.

Small Satellites and Innovations in Terminal and Teleport Design, Deployment, and Operation

Martin Jarrold and David Meltzer

Contents

Abstract

Bridging the gap between innovation and implementation is at the very heart of *NewSpace*, and the emergence of the small satellite ecosystem, a new era for the space and satellite industry, heralds great promise for the global economy, for society, and for development. Among other themes, this chapter will explore:

M. Jarrold (✉) · D. Meltzer

e-mail: martin.jarrold@gvf.org; david.meltzer@gvf.org

J. N. Pelton (ed.), *Handbook of Small Satellites*,
https://doi.org/10.1007/978-3-030-36308-6_103

- The current trends in the “smallsats” ecosystem
- The game-changing developments in the antenna/terminal ground segment
- The importance of the mobility markets
- The competing “state-of-the-art” solutions in the flat panel antenna market and associated forecasts and trends to 2028
- Drivers other than just technology
- Teleports transitioning to data center centric models
- The changing interrelationship of the satcoms and Earth observation environments
- The responsibilities of the operators of the emerging mega-constellations to maintain the sustainability of the operational environment of low Earth orbit

1 Introduction

NewSpace is big, but not in the same way as the now decade-long history of the business of launching satellites to Earth orbit. Before *NewSpace*, the "big" in satellite essentially related to the physical size and mass of spacecraft – for commercial communications, for Earth observation and imaging, for weather forecasting, for defining military strategies and tactical objectives, for government intelligence gathering and surveillance, and for numerous other applications – and to the scale of the commercial sector and government sector budgets which funded their design, construction, launch, and in-orbit operations.

NewSpace, the overall context within which the "smallsats" developmental phenomenon is evolving, while it is not, at least yet, replacing or supplanting the established "models" of commercial and government space activity, is a radical departure from those "models." In addition, *NewSpace* entails a tremendously accelerated growth cycle that has been described as the "industrialization of space" and a phenomenon that bridges the gap between innovation and implementation.

The *NewSpace* phenomenon is not only about space segment, however. It is having a multifaceted impact on ground segment infrastructure, with innovation in satellite antennas/terminals and in teleport, design, deployment, and operation.

Affecting the former, the ground segment, to the extent that the long-anticipated paradigm shifts in antenna technology from parabolic – and multi-axis gimbal mounted in the case, for example, of maritime antennas/terminals – to flat panel designs is about to be realized. Affecting the latter, teleports, to the extent that the traditional notion of the teleport – as a substantial physical infrastructure and numbering relatively few – is of declining contemporary applicability and relevance as software comes to dominate and the number of teleports is likely to increase well into the hundreds, worldwide.

2 The GVF Perspective

GVF perspectives, as presented in this chapter, arise out of the ever-widening remit of GVF. Founded in 1997, GVF continues to be headquartered in London and registered in the UK (http://www.satelliteevolutiongroup.com. Last date of access 6th January 2020). One of a very few global nonprofit associations of the satellite industry, GVF, brings together organizations from around the world representing the satellite ecosystem that are engaged in the development and delivery of satellite technologies and services for consumers, commercial, and government organizations worldwide. Its aim is to facilitate expanded access to satellite-based connectivity solutions globally, achieved through regulatory, policy, and spectrum advocacy; training and certification; product quality assurance; and collaboration with user groups and other satellite stakeholders.

Over the decades, satellite connectivity has provided the communications foundation and requirements of many commercial and government vertical markets, but now satellite is increasingly trending to center stage for applications and users right across the economic and social spectrum. Satellite is no longer regarded by the wider sphere of communications solution provisioning as being stage left, no longer regarded as a niche market-only technology, and no longer a solution of last or remote resort. All of this is reflected in the emergence and growth of *NewSpace* and of the "smallsats" revolution – in respect of both space segment and ground segment – as part of it.

So, What Is Different About *NewSpace*? The business of getting to space and applications using space are endeavors undergoing change, moving from domains dominated by governments and by big satellite manufacturing, satellite launcher, and satellite operator companies to a more affordable and entrepreneurially oriented domain populated by many small-scale start-ups and spin-offs from academia.

A plethora of satellite launch companies and launch aggregating service companies now complement the emergence of a myriad of spacecraft manufacturers, building satellites to serve a wide range of applications. This manufacture – featuring shorter development cycles, smaller development teams, off-the-shelf components, miniaturization technologies, mass-production construction techniques, and standardized form factors – is based on a low-cost per unit of functional capability with easier and cheaper launch vehicle integration. In some instances, these techniques are akin to factory production lines. These processes are wholly distinct from the traditional way of building commercial or government satellites, involving a bespoke multi-metric tonne spacecraft design and construction taking several years and absorbing hundreds of millions of dollars.

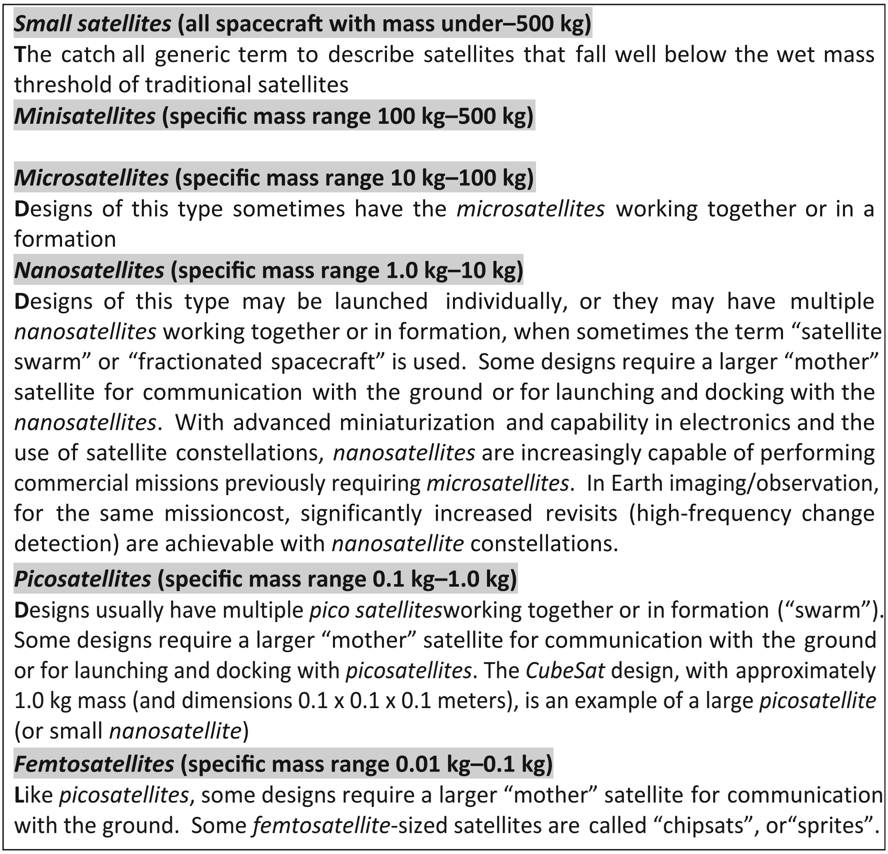
Investors range from well-known business persona such as Jeff Bezos, Elon Musk, and Richard Branson to iconic companies such as the Coca Cola Company and Google. All are driven by the commercial opportunities created by satellites. They are channeling funding into this revolutionary expansion in the commercialization of space, and this is happening in a widening range of countries, not only in the more traditional space nations but in many smaller and developing nations.

3 Small Satellites

While this label is useful as a general catchall term for this new field of commercial space activity, it is more accurately used within a defining grouping or range of spacecraft size classifications. The following tabulation (Fig. 1), *Small satellites: an overview*, reflects the widely recognized terminological conventions:

The full realization of that part of the *NewSpace* revolution that is the technology of small satellites will be across three principal segments:

- ***Communications*** including connectivity for the Internet of Things/Industrial Internet of Things (IoT/IIoT) and machine-to-machine (M2M) applications as well as the emerging broader 5G environment
- ***Earth imaging/observation*** including situational awareness as well as imagery-based intelligence



***Small satellites* (all spacecraft with mass under–500 kg)**

The catch all generic term to describe satellites that fall well below the wet mass threshold of traditional satellites

***Minisatellites* (specific mass range 100 kg–500 kg)**

***Microsatellites* (specific mass range 10 kg–100 kg)**

Designs of this type sometimes have the *microsatellites* working together or in a formation

***Nanosatellites* (specific mass range 1.0 kg–10 kg)**

Designs of this type may be launched individually, or they may have multiple *nanosatellites* working together or in formation, when sometimes the term “satellite swarm” or “fractionated spacecraft” is used. Some designs require a larger “mother” satellite for communication with the ground or for launching and docking with the *nanosatellites*. With advanced miniaturization and capability in electronics and the use of satellite constellations, *nanosatellites* are increasingly capable of performing commercial missions previously requiring *microsatellites*. In Earth imaging/observation, for the same missioncost, significantly increased revisits (high-frequency change detection) are achievable with *nanosatellite* constellations.

***Picosatellites* (specific mass range 0.1 kg–1.0 kg)**

Designs usually have multiple *pico satellites*working together or in formation (“swarm”). Some designs require a larger “mother” satellite for communication with the ground or for launching and docking with *picosatellites*. The *CubeSat* design, with approximately 1.0 kg mass (and dimensions 0.1 x 0.1 x 0.1 meters), is an example of a large *picosatellite* (or small *nanosatellite*)

***Femtosatellites* (specific mass range 0.01 kg–0.1 kg)**

Like *picosatellites*, some designs require a larger “mother” satellite for communication with the ground. Some *femtosatellite*-sized satellites are called “chipsats”, or“sprites”.

Fig. 1 Small satellites: an overview

- ***Scientific/technological***

As scientific and technology demonstration applications lay beyond the remit of GVF, the focus here is, primarily, on communications and, secondarily, on Earth imaging/observation applications.

4 Trends in the Small Satellite Ecosystem

Since 2012, activity in the small satellite industry has grown as entrepreneurs, and nations alike have joined a new space race. Fueling the new space race have two factors. First, the capabilities of satellites are growing due to technological innovations. Second, the costs of “smallsats” are falling due to innovations in spacecraft manufacture, increased data processing capabilities, the ubiquitous presence of GPS enabling location and attitude determination, improvements in ground system costs, and signal processing capabilities. Together, the increased capabilities and falling costs are facilitating market expansion. The global consulting firm, Euroconsult, predicts that approximately seven times more "smallsats" will be launched during the 2018–2027 period compared to the prior 10-year period (i.e., 7,000 vs. less than 1,000) (Euroconsult 2019).

Of note, small communications satellites, whether part of communications mega-constellations or single Earth imaging spacecraft, operate in non-geostationary orbits (NGSO), that is, low Earth orbit (LEO). This orbit enables higher performing *link budgets* (https://www.tutorialspoint.com/satellite_communication/satellite_communication_link_budget.htm. Last date of access 6th January 2020) and reduced transmission latency while having the coverage of higher altitude orbits. Small Earth imaging/observation satellites operate in Sun-synchronous orbit (SSO) – a LEO variant – which reduces revisit times or increases revisit frequencies (high-frequency change detection) for the same Earth surface territory.

5 A Game-Changing Ground Segment

NewSpace is bringing change to the ground segment – the infrastructure of antennas/terminals and teleports which transmit and receive today's IP-based data and which facilitate management of satellite networks.

6 Terminals/Antennas

An increasing range of Earth imaging/observation applications, such as high-resolution and full-color ports/docks surveillance, maritime routing, and sea-lanes security monitoring, are real time from LEO or SSO. This means they have more in common with data communications than with more traditional Earth observation techniques. This also means that to stay in permanent contact with ground segment infrastructures, the antennas – unlike the fixed satellite service (FSS) installations in geostationary satellite links – have to point and then have to move to track a given satellite and then constantly change the satellite to which they are pointing as the successive elements of a constellation traverse the sky.

7 Mobility, Mobility, Mobility

Today's mobile communications paradigm is very familiar. Readers of this chapter, consumers of all sorts of broadband-based applications, accessed via various types of devices over cellular networks and private and public Wi-Fi, expect no limitation on exactly where to get access to the Internet – including on buses and trains (and cars), on ships at sea, and at 12,000 m above the oceans.

The deployment of satcoms-on-the-move (SOTM) solutions across transportation networks is a key fact of *NewSpace*. Satellite-based maritime communications have been around for years in the mobile satellite service (MSS), or L-band, arena. More recently, however, the shipping industry has been transitioning to VSAT-based broadband systems in the fixed satellite service (FSS) of GEO spacecraft with shipboard installations known as Earth stations in motion (ESIMs).

ESIMs enable container vessel captains to maintain their links into company corporate networks and to enable the functioning of a ship's bridge as an office at sea. ESIMs give cruise line passengers a broadband experience, and they provide globe-trotting senior executives and super-entrepreneurs aboard their mega-yachts the kind of connectivity necessary to stay in touch with the global financial markets.

In the commercial airliner environment, ESIMs enable broadband access for passengers who comprise a new type of airline customer, a customer whose choice of airline is influenced by the availability and quality of inflight connectivity. ESIMs are vital for the airline too (aircraft systems monitoring, aircraft fleet management, cabin crew-passenger communications, etc.), for jet engine manufacturers (engine performance monitoring), and for air traffic management infrastructures at the national, continental, and global level.

With the advent of constellations of communications "*smallsats*," ESIMs – on ships and on planes – will need to have moving terminal antennas continually pointed at moving LEO and medium Earth orbit (MEO) satellites tracking from horizon to horizon. This has, of course, long been achieved with reference to the GEO satellite environment. Such traditional tracking antennas – the familiar tri-axis gimbal-mounted parabolic reflector that has long been the very icon of satellite communications – maintain satellite links as the platform on which they are mounted undergoes the pitch, roll, and yaw movements of the sea-going vessel or the aircraft in flight. Of course, there are other considerations that impact the relative performance of gimbal-mounted parabolic antennas as the vehicular platform on which they are mounted moves around the geography of the Earth. Two such considerations are "skew" and "scanning." In this chapter, it is not intended to engage in a detailed technical appraisal of these issues.

The physical footprint and physical positioning of an antenna (and the radome necessary to protect it from harsh weather and other atmospheric conditions) aboard a ship, or another maritime platform such as a jack-up or floating oil rig, are often an installation and operational challenge in terms of available deck space and the avoidance of superstructure obstacles to clear line-of-sight between antenna and satellite. With the arrival of passenger broadband access provision aboard commercial airliners, the footprint (and weight) of antennas and the overall size of fuselage-mounted antenna radome "bubbles" – which is an atmospheric drag and fuel budget-related issue for airlines – are additional concerns.

Satellite antennas have improved in aperture performance (https://en.wikipedia.org/wiki/Antenna_aperture#Aperture_efficiency. Last date of access 6th January 2020), pointing accuracy and form factor by leaps and bounds in recent years. The continuation to even smaller form factors – and reduced weight in the case of airlines – in antenna technology will be a significant step forward for these user market sectors.

While, as noted above, SOTM is not really *NewSpace*, the long and keenly awaited arrival of flat panel antennas (FPAs) is a part of *NewSpace* because these new antenna technologies will help enable the revolution.

8 Antenna Revolution (But They Don’t Move, Do They?)

FPAs are broadly anticipated to make a major contribution to revolutionizing the entire communications sector. With such defining attributes as low aperture, high reliability and pointing accuracy, small form factor, and low weight, they are the imperative solution for the mobility markets and for those facets of the IoT, including, as a subset, the IIoT that includes such developments as connected cars and trucks, the emergence of the “Smart City,” and industrial process and utility monitoring.

However, it is not as simple or straightforward as that, and much like the classification of types of small satellites in the *NewSpace* space segment, it is important to note the technology-type subsets of FPAs of the *NewSpace* ground segment. This will be explored below.

9 FPAs: What Is the “State of the Art”?

A multitude of companies in today’s FPA market all offer their own respective “state-of-the-art” solutions. Currently, more than 20 antenna manufacturers are in various stages of development and deployment of FPA solutions. These companies are attracted by a market potential that (Northern Sky Research 2019a) is predicted to bring cumulative FPA equipment sales to approximately US$11 billion by 2028. This is a market that has many orders of magnitude above the historical positioning of FPAs.

FPAs have for long been a niche alternative to parabolic antennas. FPAs of the fixed phased array type have been in use since the 1950s and have progressed significantly since then – beginning with mechanically steered units and moving to the greater efficiency and reliability of electrically steered technology. But, due to high costs and variable performance, market potential has been limited, until now. Now, just the right combination of factors has created a “Goldilocks Zone,” a coincidence of new demand from evolving and expanding markets, radical technologies, advanced engineering techniques and manufacturing processes, and opportunities for scale which is expected to finally address the issue of unit costs.

The FPA market is benefiting from partnerships up and down the industry value chain, with operators, service providers, and ground equipment manufacturers forming relationships to drive advances in antenna ecosystem development and achieve the right mix between performance and price. These partnerships have resulted from the widespread recognition that the satellite industry is in a state of fundamental transformation, where falling capacity prices are signaling major technology-shift dynamics. The impact of high-throughput satellite (HTS) technologies has required a concomitant response and rebalancing reaction from the ground segment to build on a long-held expectation that all the necessary pieces of the satcoms jigsaw will come together. Perhaps, there will soon be limited distinction between fixed, inclined, MEO, and LEO satellites from the perspective of the antenna/terminal.

There is no single FPA solution that is a best fit for all current, and potential future, markets. The solutions from the many companies referenced above take different technology paths but tend to be one of the two principal FPA technology types – the *mechanically* steered antenna (MSA) and the *electronically* steered antenna (ESA).

MSAs – which currently dominate the FPA market, at 95.5% of all shipped units (Northern Sky Research 2019a) – have enjoyed a first-to-market advantage in the aeronautical vertical. This has been at least partially achieved by leveraging the actual and existing mechanical advantage which satisfies the rigorous antenna performance requirements, regulations, and barriers to entry in this user segment.

A commercially available FPA of the MSA type on today's market offers a Ku-band solution with two beam-forming antennas, transmit and receive. The antennas create beams by mechanically rotating a series of internal disks/plates which amplify and direct signals in a specific way. Although the internal disks/plates are moved mechanically, unlike a gimbal antenna, the entire antenna face is not pointed directly at the satellite, and instead small changes in plate position are used to adjust the elevation and azimuth scan angle. This technology is capable of achieving data rates up to 70 Megabits per second (Mbps) down and 15 Mbps up; however, this is expected to increase to as high as 100 Mbps as new spot-beam satellites become more available.

As noted above, MSAs are currently dominating in the aeronautical sector. Dividing this sector into commercial and government user segments, NSR expects the MSA lead in shipped units – at 76% and 95%, respectively – to continue until 2028, partly due to factors already noted and additionally due to momentum generated by value chain dynamics, partnerships, and norms in respect of installation costs and timing (Northern Sky Research 2019a).

The land mobile sector is similarly divided into government and commercial user segments, with the latter split into the train and bus markets, as well as the connected car market. However, the connected car market is not expected to be realized until much later than the train and bus markets. Again, according to NSR, government segment users are currently caught between the reliability and ruggedness of MSAs and the anticipation of next-generation terminal capabilities. The segment will only slightly favor ESAs by 2028, with 55% of shipped units at that time. In the interim, government requirements on testing and certification will lead to legacy MSA predominance. Favoring ruggedness and reliability is the connected train market which provides the principal commercial land mobile opportunity, followed by the connected bus market. However, given that both markets also want physically low-profile installations, ESAs will eventually come to the fore, by 2028 taking up 82% (Northern Sky Research 2019a).

10 "2028" Vision: A New Era for the Antenna/Terminal

The expectation is that the FPA market will transition, medium term. While, in the view of NSR, FPAs with low-profiles and high-bandwidth efficiency characteristics are those that are generally advancing the technology and bringing business changes in the satellite industry, thus advancing the possibility of new applications, it is the electronically steered FPA technology on which the future of satcoms is principally dependent. Indeed, the NSR forecast puts ESAs as accounting for 97% of FPA shipments in 2028 (Northern Sky Research 2019a).

ESA technology is still developing, and today it remains expensive to engineer, thereby making the current per unit cost of manufacture too high to secure mass market interest and penetration. However, the market for ESA technology is not entirely closed as some companies are selling actual product, albeit on a limited scale. While this should change as more of the LEO constellations start to orbit their first satellites, the likely scenario will not be one of the wholesale replacements of MSA deployments by ESAs but by competition between, and customer choice of, the two technologies.

Unit prices coming down will not change the fact that ESAs are complex high-tech devices. There is, as noted above, not a single ESA technology, and different manufacturers claim their own "state-of-the-art" ESA. However, all ESAs – in order to ensure precise satellite pointing in the most demanding of circumstances where the antenna/ESIM platform is moving and the target satellite is also moving in its LEO or MEO orbit and the target satellite must continually change as one spacecraft hands-off to another – have to be able to make thousands of tiny, individually tuned elements work together as one, unified antenna. This process must operate for long periods of time, covering extreme temperature ranges, with power to actively control high-demand phase shifter components and amplifiers. However, having noted this broad definition, other technological approaches to how satellites are tracked, how the beam is pointed, and how quickly the beam can be moved to another satellite are available!

The most currently competitive rival technology to the gimbal-mounted antenna is the type of FPA known as phased array, of which there are two basic designs – the passive electronically scanned array and the active electronically scanned array. Phased array antennas have numerous radiating elements, tiny, fixed antennas, each with a phase shifter to form a beam, or beams, by shifting the phase of the signal emitted. This creates a constructive/destructive interference which may be used to steer the beam, or beams.

Beam(s) can be pointed instantaneously in any direction, tracking the movement of a satellite in the sky, regardless of the movement of the vehicle mounted ESIM. These antennas usually have a very low profile, no external moving parts, and although exact designs vary, high reliability. This high reliability results from the fact that in the event of an antenna element failure, the remaining elements continue to function and the collective pattern of the whole is modified slightly to overcome the loss.

Passive electronically scanned array (PESA) systems have elements connected to a single transmitter and/or receiver and are the most common type. In active electronically scanned arrays (AESA), each antenna element has an individual transmitter/receiver unit, controlled by a computer. AESAs can radiate multiple beams of radio waves in different directions, at multiple frequencies, at the same time.

Electronic beam-steering performance – similar to phased array technology but without the same power-hungry characteristics – is also possible without expensive phase shifters, amplifiers, etc. The absence of phase shifters means that this technology is, rather paradoxically, deemed to be “passive” even though advanced capabilities mean dynamic creation and correction of phase and amplitude distribution to form the most focused beam possible. In the absence of active RF components, and despite many more elements than a typical phased array antenna, there are no power amplifiers to create excess heat and thus no need for a cooling system. Overall power consumption amounts to only a few watts, a significant contrast to the 1,000+ watts for a typical phased array antenna.

One example of an electronically steered, low-profile, high-throughput phased array antenna takes all the supporting electronics like block upconverters (BUCs) and amplifiers and compresses them into application-specific integrated circuits (ASICs) with the objective of reducing costs through manufacturing efficiency and high volumes. In place of phase shifters, this solution uses a large number of ASICs, each of which is connected to a small patch antenna.

The ASICs allow satellite signals to be separated from background signal noise, and microprocessors in the electronics dynamically control signal phases of all individual elements, combining and steering transmit or receive beams in any direction. No moving parts equate to a compact and reliable system which is also very thin.

Rows of ASICs on the underside of the antenna board are connected to rows of element patch antennas on top. Multiple control/antenna boards can be combined to increase capacity, and importantly, boards may be shaped to conform to curved surfaces, reducing atmospheric drag (important for aircraft) and enabling scanning for and links to satellites low on the horizon.

Another technological approach avoids the use of large numbers of phase shifters and amplifiers or the fitting of separate BUCs and low-noise block downconverters (LNBs) into ASICs for each antenna element. This approach uses a single LNB and BUC, similar to antennas across the satellite industry. The antenna itself is passive, with no mechanical parts and no requirement for rows of actively controlled phase shifters.

The antenna provides for satellite auto-acquisition and tracking, with transmit and receive using a single aperture, offering a wide-angle scanning to the horizon. RF beam steering, beam forming, polarization selection, and angle pointing control are all electronic and software defined. A metamaterial-based approach enables the formation of a holographic beam, with very low-level power requirements, to transmit and receive satellite signals. The elements of the antenna act together like “pixels” to create the holographic beam. Using software to change the pattern, the antenna can be pointed in the correct direction using no moving parts, internal or external. The design lends itself well to mass production, which will drive costs down with increased manufacturing volumes of scale.

11 “Graceful Degradation” and Millimeter Wave

A feature of the drive toward fully passive phased array technology, sometimes described as the “Holy Grail” of the intelligent antenna community, and one alluded to above, is phase-shift independent insertion loss where, even with some antenna elements turned off, the unit still delivers an acceptable radiation pattern without significant performance degradation. Preparation in the phased array technology environment for operational extension into the higher millimeter-wave band is another important development in anticipation of wider rollout of next-generation 5G mobile cellular.

12 Optical Beam Forming

It is arguable that *the* general major issue with the FPA/phased array technology ecosystem is that a lot of circuitry is needed to create a single beam, or satellite link, in any given direction for optimal connectivity. This functionality is power-hungry, expensive, and not radio efficient. There is another alternative technology on its way to market, a cutting-edge field known as optical beam forming.

This approach begins by noting the simplicity and high efficiency of parabolic antennas with their geometric structure focusing energy into a single feed source. In between the antenna parabolic geometry and the feed source, there is only air, creating a simple and highly efficient system but non-scanning. Beam-forming optics take legacy technology together with FPA technology and use the best features of both, in as much as a beam’s energy is directed to a single feed source, going passively through air and avoiding aberrations and losses prior to signal processing.

Engineered for Ku- and Ka-band terminals, the structure features multiple beam-forming sources, each of which can support an individual beam. When not in use, individual sources can be switched off, reducing power requirements – compared with current FPAs and phased array antennas – by as much as 80%. Design flexibility is such that if scanning range is reduced, the electronics can be reduced, configuring to include only the electronics needed to support a given application. The final product is an integrated solution that includes modem, BUC, and LNB components in a single package. The solution avoids the limitations of phase shifters, enabling it to handle GHz of instantaneous bandwidth, ensuring that the terminal is never the bottleneck, and supporting any commercial carrier size currently available.

While it is very clear that maximizing the benefits to be derived from the satcoms future does depend on the coming era of electronically steered FPAs, the antenna, or terminal, is not the only evolving piece of an increasingly complex industry puzzle.

13 New Technology, Not the Only Driver

The actual *adoption and deployment* of the new technology that is the very fabric of the *NewSpace* industry environment is not only driven by the coming into existence of said space and ground segment technologies. There is now taking place an entrepreneurially driven “industrialization of space,” wherein entrepreneurs are launching cheap – US$1 million - satellites to last for just a few years. This reflects change in the industry risk dynamic and change to a mindset which is very different to that of operators of expensive communications satellites which are the product of a lengthy design and manufacturing cycle and which are planned to have an orbital life of 15–17 years. *NewSpace* technologies are now brought into operation in months, not years.

14 5G and IoT/IIoT

The 5G standard specification is not yet finalized by the 3GPP – the 3rd Generation Partnership Project, the standards organization which develops protocols for mobile telephony. However, it is clear that small satellite constellations will have to be a vital contributing element to the success of the emerging IoT and Industrial IoT world and of the global 5G mobile broadband communications future as a whole.

5G will be a quantum leap from the person-to-person communications focus of current and earlier generations of mobile to a device-to-device focus, with devices on the network achieving speeds between 1 and 10 Gigabits per second (Gbps), together with practically unlimited capacity. This quantum leap goes way beyond the realms of the maturing, and still expanding, M2M connectivity environment which has an already long-standing dependency on, and synergy with, satellite communications links.

The 5G networked world of IoT/IIoT, and manifold-related applications, will require that every device is connected wherever it happens to be, and while Wi-Fi, Bluetooth, and today’s terrestrial wireless network connections are able to support many IoT/IIoT applications, these technologies are not ubiquitous and seamless.

IoT/IIoT coverage, to be truly global in scope – in terms of both urban device density and remote device deployment – will require wholesale integration of the terrestrial network with the ubiquity and seamlessness that only satellite networks can provide. These satellite networks will increasingly include small satellite constellations. The world of IoT/IIoT will be built on a connectivity foundation which will comprise a highly integrated functionality of, and between, terrestrial broadband wireless platforms and broadband satellite platforms.

Thus, small satellite constellations will develop as a core element of *NewSpace.* As referenced by the 3GPP, satellite will no longer merely be an “interfacing” technology and service, with a secondary role in the “network,” but an “integrated” technology and service, fully part of an evolving and complex “network of networks.”

Mobile backhaul, and cellular base station networking, has long been an important business driver for satellite and for teleport operators, and IoT/IIoT is already now becoming an additional market driver for these sectors. With this as backdrop, rollout of 5G mobile services has the potential to vastly accelerate growth in this business, given that supporting the “network of networks” will lead to a very significant growth in the mobile backhaul requirement.

In the 5G world, communications with objects in motion, currently a satellite specialty, will increase demand, likely driven in large measure from a massive increase in video to mobile devices. The economics suggest that caching video files at the edge could become a major business for teleports. Additionally, features already being deployed in existing 4G/LTE networks encourage mobile operators to concentrate heavy-duty processing in data centers linked to remote base stations, creating a market for “fronthaul” that is currently provided by fiber but is very likely to need satellite in the 5G future.

This is one reason, among others, why now it can be argued that it makes sense for satellite teleports to be considered as data centers – or, on the flipside – data centers to be considered teleports. More on the other reasons follow below.

15 In Transition: Teleports, Data Centers, and Emerging “X as a Service” Business Models

As these developments become more clearly in evidence, a number of important points should be recognized. Firstly, just as it is understood that 5G is an architecture that will have a massive impact on how the whole world communicates, the satellite industry must recognize that the mobile industry wants to finalize the 5G standard to match its own commercially exclusive interests and in doing so potentially push back on facilitating the necessary enabling environment for the satellite component to be entirely realized. Accordingly, the satellite and teleport industries must apply pressure to ensure a share in the investment that 5G will create over its deployment.

Until very recently it would have been true to say that satellite teleports have not really changed very much in 20 years, usually consisting of 19-in. racks of hardware, and being relatively few in number. However, teleports are now changing with one development being the teleport-data center dichotomy and the other having its focal point outside of *NewSpace* but that is nevertheless adjunct to *NewSpace*, and will contribute to its growth.

In this latter connection, more and more of the satellite industry’s traditional and long-standing end-user customers, often operating in remote and sometimes mobile contexts such as oil and gas, shipping, and more recently mining and farming, are rapidly digitizing their internal commercial and industrial processes. These commercial enterprises want their remote IoT/IIoT, and other sourced data resources, to be accessible from multiple originating locations and transmitted, via big data analytics infrastructure, on to decision-making centers.

For such enterprises, the development and creation of the necessary analytics infrastructure are just the means to the end of dealing with influxes of big data in order to extract core information and key insights for decision-making processes and devising solutions to actual problems. This "means to an end" is CAPEX intensive. Increasingly, an OPEX-oriented enterprise world has been turning to the *Cloud*, having recognized that data analytics offerings on virtual systems – perhaps in the public *Cloud* as opposed to private *Cloud* servers – offer many advantages. These advantages run from lower costs to being able to leverage service offerings that integrate the function of the "virtualized" data center (potentially including artificial intelligence and machine learning) with the function of the teleport.

Ground infrastructure companies which provide hardware and software for teleports increasingly recognize the greater efficiencies that can be achieved by relying on *Cloud* servers to virtualize network functions, as well as the big data analytics.

The development of "Managed Platform as a Service" (MPaaS) solutions – a facet of the "X as a Service" *Cloud* environment within which IaaS (Infrastructure as a Service), PaaS (Platform as a Service), and SaaS (Software as a Service) were the early primary elements – can combine satellite hubs, teleport/data center uplinks, and terrestrial networking contributions, enabling easy deployment of high-throughput connectivity in vertical market user customer locations across the globe. The addition of new GEO HTS generations, expanding MEO constellation capacity, and upgraded and new LEO mega-constellations, many of them comprising small satellites, will bring vast additional bandwidth capability to orbit which will further facilitate the rise of fully managed satcom services.

Given this, and the perspectives cited earlier, the reason for satellite teleports now to be considered as data centers or, on the flipside, data centers now to be considered teleports gains additional traction.

What is the next step for the data center? Some satellites currently in orbit already function analogously to mini-data centers, receiving data from Earth, processing and storing information, and transmitting back to Earth. Small satellite constellations in LEO – as well as the altitude of the orbit itself offering the advantage for some, time-sensitive, applications of reduced latency – provide for greater amounts of in-orbit data processing, storage, and transmission, as well as resiliency in the form of a multiple redundancy of nodes that is akin to the distributed resiliency strategies used by *Cloud* platforms. A LEO system could potentially geospatially distribute and replicate information around the constellation to prevent data outage or loss. Additionally, a secondary group of satellites could provide another data backup.

16 Teleports as Data Centers: Earth Observation Small Satellite Ecosystem

The "industrialization of space" is not only about satcoms. Manifestations of the *NewSpace* race can be more clearly seen, and at a considerably more advanced stage of development, in the Earth observation (EO) arena, within which the most advanced optical observation constellations are nearing completion of their first generational iteration. Other platforms with nonoptical sensors are emerging – i.e., synthetic aperture radar and hyperspectral imaging – but relatively few have so far progressed as far as launch.

Today, enormous volumes of EO data are generated each day. Various flavors of small satellites, launched to Sun-synchronous orbit (SSO), have rapid revisit times/ frequencies (high-frequency change detection) for the same part of Earth's surface, generating many thousands of images, vast quantities of imagery-based geospatial analytics, and information to feed into geospatial information systems (GIS) applications. Combining this with IoT/IIoT sensor-based applications (with hundreds of zettabytes of data generated each year by billions of devices), it is possible to comprehend the magnitude of the big data analytics environment into which the evolving teleport functional dynamic is migrating.

Differences in business models are evident in the EO ecosystem, models defined by a range of variables (including type of application) determining the associated degree of resolution required, the use of visual or other spectrum wavelengths, geographic imaging dimension parameter requirements (e.g., width of swath), frequency, and speed of data downlinks. Added to the modeling equation are such factors as the cost-effectiveness of different platform design iterations, often employing combinations of CubeSat units, together with build lead times that feed into as short as possible time-to-orbit.

EO business models also often feature the development of strategic partnerships which pairs EO with the global communications infrastructure providers in the satellite space segment. This reflects the continued blurring of the boundaries between communications and EO that has been engendered by the "smallsat" phenomenon within *NewSpace* and the fact that EO data – and the actionable intelligence derived from it via predictive analytics and machine learning – needs to be quickly, efficiently, and cost-effectively distributed to customers and stakeholders.

While there are very many examples of current optical-based EO missions, one decade-long program has been amply demonstrating that a low-cost "smallsat" (technically microsatellites, weighing-in at 90 kg) approach can provide solutions that have a medium resolution (i.e., between 6 m and 30 m) requirement is the Disaster Monitoring Constellation (DMC). The optical payload of the constellation's microsatellites – each of which is the product of one of the DMC's international consortium of entities – generates a total of approximately 500 images per day, covering equatorial sites daily and more frequently at higher latitudes.

EO originated big data will only increase in volume as optical imaging sources are increasingly complemented by the launch and operation of other sensor technology payloads, for example, synthetic aperture radar (SAR). SAR has some operational advantages over optical imaging, but it is only comparative recently that SAR missions have, like optical missions, come to be applications-driven rather than being driven by performance characteristics.

Not the least of SAR's operational advantages is its ability to penetrate through cloud cover and to continue to generate imaging data when the Earth's surface is in darkness. Despite this, it is only now that SAR technology is moving from a large budget, institutional mission, environment – one within which priority is given to all imaging parameters (resolution, swath, sensitivity) being fully technologically optimized – and taking the same evolutionary step in satellite design which is not at odds with low cost and is fully applications-driven. That is the very step that has enabled numerous optical EO programs to become affordable to a widening customer user base.

Thus, as various commercial SAR EO missions come to maturity, the microwave region of the spectrum will also come to be driven by an orientation to serving a broad range of actual applications. Such applications include agricultural crop assessment, coastal and maritime (ship detection, oil spill monitoring, maritime safety, defense/security), disaster management and monitoring, flood monitoring, forestry management and monitoring, land use mapping, etc.

17 Store-and-Forward Data Delivery and "Smallsats" Networks

One of the pioneer companies in the field of nanosatellite telecommunications solutions, together with a market-leading provider of radio and satellite communications solutions (Kepler Communications and Cobham SATCOM), have quite recently announced a strategic partnership aimed at facilitating the elimination of barriers to the adoption of high capacity data services over the pioneer's currently orbiting nanosatellites, the first few of an as yet still under construction LEO constellation.

The partnership's offering – defined as a "User Terminal-as-a-Service" (UTaaS) – centers on the use of proven, reliable ground segment, and budgeting for equipment costs (installation, technical support, terminal maintenance) and future capabilities for add-on services as a monthly operational fee (OPEX) rather than a more traditional onetime capital expense (CAPEX), the level of which would otherwise be significantly determined by the still high cost of today's tracking antennas. This business model also includes "airtime," permitting the customer a day-to-day frictionless experience and enabling the customer to maintain focus on their application with the advantage of economic transmission of gigabytes of data, to and from the end user's location. The solution – based on a store-and-forward technology model – is suited for delay-tolerable data such as large multimedia files, high-resolution videos and imagery, and other bandwidth-intensive data within, for example, the maritime and oil and gas sectors.

18 Small Satellites: Maturity? Operator Responsibility!

The “industrialization of space” is an entirely apt metaphor for *NewSpace* in many ways, for many reasons, but three, in particular, stand out:

1. NewSpace, like the industrial revolution of the nineteenth and twentieth centuries, will suffer from the ups and downs and uncertainties of innovation, difficult to predict dynamics which can easily be misinterpreted, obscured, or glossed over in the course of the understandable enthusiasm and excitement surrounding the opportunities created by any (r)evolutionary change.
2. In relation to the importance of not making the same mistakes as in the period of Earth-bound industrialization, which is understood to have come to compromise the *sustainability* of Earth’s current environmental equilibrium through fossil fuel emissions induced climate change, the keyword here is *sustainability.*
3. In ensuring the continued *sustainability* of space operations which, as well as being important for the satellite industry itself, will be the key enabling factor in the application of imaging and detection/measuring technologies that together with various other “frontier technologies” will contribute to the building of a global digital ecosystem to support socioeconomic development objectives.

As noted at the beginning of this chapter, the “smallsats” environment is at the beginning of a tremendously accelerated growth cycle. Euroconsult sees the market as being full of uncertainties as growth gives way to a more stable pace of maintenance and replenishment of satellites in large constellations by 2025 (Euroconsult 2019). This report anticipates the rolling 5-year growth rate for “smallsats” to peak in 2024 at 48%, following which market size should stabilize until second-generation mega-constellations begin to launch. Euroconsult projects that in the period 2019–2028, more than 8,500 satellites will be launched, half of which will be in broadband constellations. The report cautions, however, that market acceptance of the mega-constellations has yet to be validated and that the availability of a new generation of low-cost terminals and efficient distribution networks will be key success factors for them. Despite the justified celebration of the technology gains, in the years to come, it will be the market that will drive the value of propositions and determine whether “smallsats” are now reaching a maturity threshold or if radical and quick changes are now part of the industry as a whole.

The overall growth of the “smallsat” market is a boom time, a massive expansion in the space economy. Barriers to entry have been lowered, new applications are constantly emerging, and established applications are being supported in more effective ways, and substantial new revenue streams are a near-term prospect. The key question must be, “Is all this sustainable?”

NSR estimates that 39% of all “smallsats” launched over the next 10 years will be of <10 kg mass, that is, nanosatellites, and notes the growing trend in picosatellite (<1 kg) launches. This impacts on the sustainability issue (Northern Sky Research 2019b). Over the years the issue of space, or orbital, debris has been acknowledged as a major problem. Current space situational awareness (SSA) capabilities cannot accurately and precisely track objects of size less than 10 cm, which makes some small satellites – as well as small pieces of debris generated by a host of causes over decades of space activity – almost impossible to track. This can only add to the pre-existing problem which encompasses debris that ranges in scale from spent launcher stages down to a rogue nut and bolt and now also includes the consequences of anti-satellite actions by state actors. Even without the Kessler syndrome, orbital collisions are almost inevitable, given the sheer number of satellites comprising multiple mega-constellations. But, of course, it's not only collisions that matter; it's the sheer number of satellites that, given relatively short time from launch to end-of-life, must be disposed. GEOs, after 15 or, perhaps, 17 years, can be parked in a graveyard orbit out of harm's way. In contrast, LEOs should/must be deorbited in Earth's atmosphere where they are expected to meet a fiery end.

Some of the mega-constellation operators have designed their satellites with onboard independent and autonomous decommissioning systems to be used for orbit clearance at satellite end-of-life. This strategy makes obvious business sense and addresses the concerns of governments and many other stakeholders regarding sustainable space operations.

The SSA "industry" is reaching beyond just debris tracking and Earth-bound collision avoidance methods and is initiating efforts to tidy-up Earth's orbital backyard. There are varied approaches to this, such as "active debris removal" (ADR) missions using, for example, a specialized platform equipped with cameras and laser-ranging Lidar to track, characterize, target, and capture orbital debris (e.g., an out of control or drifting satellite), using a harpoon plus a net and a "dragsail" membrane which unfurls to hasten its atmospheric reentry and destruction, along with the captured "space junk." In another ADR approach, a debris removal vehicle, akin to a "tow truck," will use robotic arms to capture a target body and then engage in powered deorbiting maneuvers. In yet other approaches, "smallsats" (though not the very smallest variants) might be refueled or otherwise maintained in orbit by robotic space tugs, although any future availability of refueling technology should not remove from "smallsat" operators the responsibility for ensuring that satellite end-of-life is managed by clear protocols.

In relation to the debris issue, there is an apparent change in the measure of "mission success" in the *NewSpace* world. Mission success used to be an "all-or-nothing" matter, but this is no longer the case. Orbiting tens of satellites in a single launch, yet losing a few of them to technical failure, is still deemed a success. Multiple mega-constellations experiencing a failure rate of just a few percent will result in hundreds of nonoperational satellites occupying otherwise viable orbital positions, increasing operational costs for the remaining satellites in the constellation and potentially increasing collision risks.

19 Conclusion

The fundamental conclusion here must be that the technology innovation that is the small satellite is bringing about a qualitatively and quantitatively different space economy and one that might, at long last, even bridge the world's *digital divide*. Equally, "smallsats" will be able to deliver solutions for the other long sought-after next step – universal, unrestricted, and low-cost broadband connectivity that is mobile. The final aspect of this conclusion relates to an expression of hope in what NewSpace can deliver for the future. Of course, finally bridging the *digital divide* will itself contribute to equalizing the great differences in socioeconomic development around the world, but that is not enough – the world needs a "global digital ecosystem."

In a UN paper of 2019 – a product of the Development and Environment programs, UNDP, and UNEP – Jillian Campbell and David E. Jensen discussed the building of such an ecosystem.

In 2015, the UN adopted 17 Sustainable Development Goals as part of *Agenda 2030* to achieve a better future for all humanity. Radio communications, including satellites, have a key supporting role in achieving the 17 SDGs. This is all the more evident when noting, as does the UNDP, that 68% of the 93 environmental SDG indicators cannot currently be measured due to lack of data. This is the other "digital divide" which must be bridged, enabling us to acquire and deploy data sets to build a digital ecosystem for the entire planet which will allow data flows to be eventually transformed into insights for sustainable decision-making. This will require contributions from the various "frontier technologies" alluded to above – e.g., *Cloud* and edge computing, AI and machine learning, IoT/IIoT, and distributed databases, with the addition of the recent news from Google on quantum computing – but also from small satellite and related communications technologies. The context for this is, again as noted above, the continued blurring of the boundaries between communications and EO that has been engendered by the "smallsat" phenomenon of *NewSpace*.

Abstract

The use of small satellites as a tool for education, training, and recruitment of new talent for engineers and scientists in the field space applications and space science has grown enormously in the past two decades. Perhaps the most significant event in this regard was the defining of the cubesat standard and then the subsequent definition of the pocketqube standard that has followed more recently. Indeed the development of concepts of the femtosat, picosat, and nanosat have allowed the development of ways to undertake student experiments in much more cost-effective ways for student experimenters to undertake projects within the resources of colleges, universities, and even students at the pre-university level. Projects to undertake mini-experiments that can be carried out on-board the International Space Station (ISS) or other spacecraft designed to carry out space experiments have broaden the scope of student space experiments in scores of countries around the world, broadening the scope and extent of space education.

There are now multiple groups, organizations, and foundations, plus most space agencies, providing active support, training sessions, and contract awards to universities to foster and encourage these new initiatives for students and university researchers. These sponsors, among numerous others, include institutions and nonprofits that sponsor STEM educational initiatives and space agencies such as NASA, ESA, Canadian Space Agency, CNES (French Space Agency), and JAXA, the Japanese Space Agency. These organizations, foundations, institutes and space agencies provide new opportunities for cubesat training and actual projects, provide research grants, offer assistance with regard to technological and safety screening, provide relevant research grants and contracts, and assist with regard to launch arrangements – all to facilitate student smallsat tests and experiments.

This article describes the types of space experiments that are now possible with various types of smallsats. It provides background with regard to the most commonly used standards that are employed for these experiments and how to arrange for these smallsat experiments to be launched into space. This covers primarily nanosats (or cubesats) and picosats (such as pocketqubes). There is even some discussion of femtosats, at the very smallest end, and microsats at higher end of such programs. In the case of microsats of up to 100 kg, this most typically would be a developing country with a smallsat project leading an activity but perhaps one or more national university assisting in the satellite definition or assisting in training related to the operation of the microsat. There are today a wide range of universities, colleges, institutes, schools, foundations, organizations, and space agencies all seeking to promote smallsat space experimentation, technology verification, and proof of concept. There are also an increasing number of projects where university projects are actually seeking to verify smallsat systems for practical commercial projects. In the majority of cases, such projects are a means of providing training for young people and to excite their interest into the world of aerospace engineering and space applications.

Finally there is a discussion in this article about two subjects of particular concern. One issue is the reliability issue (or failure rate) concerning academic and student-related small satellite projects. The other is about concerns related to the longer-term sustainability of space and how student experimentation can be conducted so as to minimize the creation of space debris and space objects that remain in orbit.

1 Introduction

The 10 cm cube "cubesat" as a type of satellite designed for student experimentation has now grown significantly in importance. The smallsat as an educational and training tool and as a way to demonstrate new technology is now a key factor in the satellite industry. In short, it has many implications beyond its first intended purposes of simple and inexpensive student education and training. This standard not only opened the door to student experimentation, but it also led to many useful developments as well that have begun to permeate the aerospace industry. The "smallsat" has, for instance, also helped to show how satellites for commercial use could be designed to be better, faster, and more cost-effective. The smallsat revolution has helped to demonstrate how satellites might be much smaller in size while performing the same task. They have helped to show instances where it also might be possible to use many off-the-shelf components to reduce cost. Smallsats, due to their smaller mass, also obviously help to reduce launch costs.

Today there are many commercial systems that are using 3 unit cube satellites within commercial constellations such as Planet Inc. for remote sensing, and Spire for remote sensing, environmental measurement, and automatic identification service (AIS). These and other smallsat ventures started off as student initiatives and developed from designs that evolved from university-based experimental programs. The later evolution of new standards such as pocketqube that is one eighth the size of a cubesat, namely, 5 cm × 5 cm × 5 cm (i.e., picosats) and even femtosats (10 to 100 g) have opened the door to even more cost-effective ways to undertake student experiments and demonstrate new satellite technologies.

The 1 Unit CubeSat "standard" (i.e., a 10 cm × 10 cm × 10 cm cube with a mass of no more than 1.33 kg) was first started in 1999 as a cooperative effort between two US universities, Professor Jordi Puig-Suari of California Polytechnic State University (Cal Poly) and Professor Robert Twiggs of Stanford University's Space Systems Development Laboratory. They sought to create a new approach to satellite design on a scale suited to student experimentation and university and school budgets.

At that time, satellite programs were largely undertaken by civilian space agencies, military space programs, and large aerospace corporations that were typically working for governmental space programs. The original intent of the project was to offer a lower-cost access to space for the university science and engineering programs, so that the cost of designing and building the satellite and getting it launched might be such that a university or school might be able to undertake such a project. The speed of development was also a benefit. Indeed such projects could be conducted while a group of students were in school together. The fact that there have now been hundreds of cubesats launched as student experiments in the last 20 years shows just how successful this concept has proven to be.

Cubesat projects have now been successful not only by students at large universities but also smaller universities and schools at all levels of study even down to secondary and primary levels of education. New standards such as the pocketqube (5 cm cubes and up to 250 g of mass) and even femto-satellites (10 to 100 g) in size keep opening new doors to new and innovative smallsat experiments. Each new innovation has opened the door wider to a broader base of training and educational opportunity for a broader range of students in developing countries as well. New options such as ever smaller smallsats and projects that can be quickly built and launched at lower cost of these options open the door to students to devise and conduct space experiments in a better way.

These small satellite projects also can be a very effective way to train new entrants into the space industry how to design, test, and build satellites and learn key lessons in space safety. Even projects that fail can help expose new information about types of failures that can occur, and other key thing that can go wrong (such as incompatible standards). New designs, new materials, and new manufacturing techniques might lead to new levels of cost efficiencies (Cubesat 101 Basic Concepts). This experience has shown that a great diversity of designs, antennas, solar arrays, remote sensing cameras, and sensors, plus very strong processing power can be encapsulated with a 1 unit cubesat as it is deployed in outer space. Even capabilities that can be packed into a 1-meter cube now equal things that once involved satellites that were six to ten times larger. (See Fig. 1).

This article describes some of the prime instruments, standards, and approaches that can now be employed for student experiments. It explores some of the means of assistance that might be sought as well as some of the issues and concerns that arise

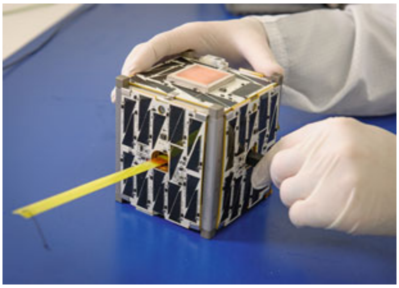

Fig. 1 PhoneSat 2.5, a CubeSat built at NASA's Ames Research Center in 2013. (Graphic Courtesy NASA. https://www.nasa.gov/content/goddard/nasas-science-mission-directorate-cubesat-initiative)

from the student projects. These concerns includes such areas reliability, frequency of failure within a month or two of launch, and rising concerns about orbit space debris and debris removal or avoidance.

2 Cube Satellite Programs

The number of cubesats that have been launched over the last 20 years has grown from a handful per year at first to a growing stream of cubesats. The cubesat assistance programs that NASA and the European Space Agency (ESA) have undertaken to encourage the launch of small satellites have certainly contributed to this increase. NASA has provided an advisory and technical review unit to help in the design of cubesats. This has aided in avoiding possible mistakes in the design of these units and to avoid the use of wiring that does not safely operate in space, as well as other common errors.

Despite the assistance provided, the success rate with cube satellites has not been particularly high. The overall success rate has been about 40% for academic programs and about 77% for commercial cubesat programs.

There are now dozens of professional training courses and seminars at various locations around the world or that are offered on-line. These courses can be taken to assist in the proper design, engineering, and manufacture of cubesats as well as to acquire expertise as to how they should be deployed in space. Such courses and the knowledge that are acquired from these courses are perhaps valuable as the assemblage of the cubesate itself. Such course can certainly be a key part of the overall learning process. There are also tutorials that are available free online such as the courses that are available from NASA known as “Cubesat 101: Basic Concepts” which is designed to impart fundamental knowledge and useful knowledge to those wishing to take on a cubsesat project.

The key elements which will likely be found in most other comparable training programs are outlined below, as they are set forth for the Teaching Science and Technology Inc. Ascend program. In this case, the program is organized into five separate short courses, as described below. Other program will tend to be consolidated into more integrated and somewhat shorter programs. Space Agencies and other institutions in some cases even provide free training programs to cover many of these elements. (See Fig. 2). (Ascend Cubesat Training 2019).

“The Ascend 5 Part Course on Cubesats

- **Solve** technical problems in orbital mechanics and space system design;
- **Describe** the inputs, processes and outputs of a space system verification and validation program including the unique requirements for environmental testing.

(continued)

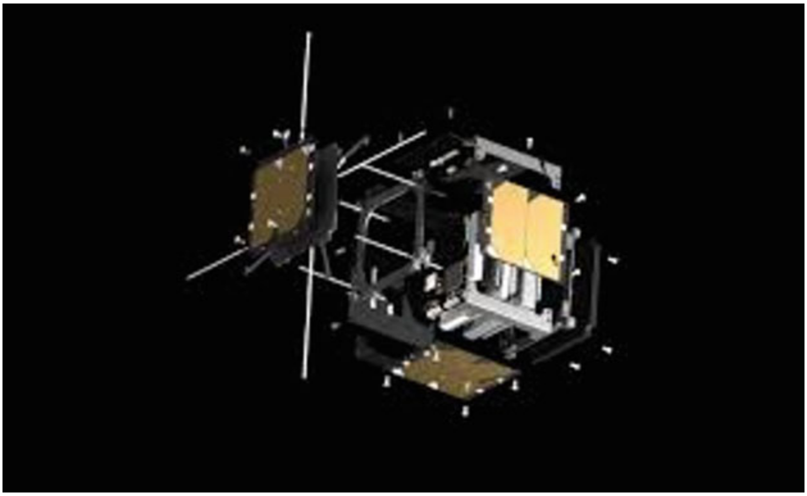

Fig. 2 A Cubesat with its deployable antenna extended. (Graphic courtesy of global commons)

- **Define** the planning, execution and support requirements for real-time space mission operations.
- **Apply** space systems engineering processes and system design principles, along with software tools to develop a conceptual design for a space mission.
- **Synthesize** all tools and techniques learned in the program during end-to-end concurrent mission design workshop. Given a real-world set of mission goals and objectives, along with a set of integrated design tools, design, develop, build, integrate and test a bench-top payload into a non-flight educational satellite system.
- **Take the next crucial step** up the space development ladder to embrace NANOBED and other tools to develop space payloads and undertake serious discussion with hardware vendors and explore launch and deployment option."
- Ascend Cubesat Training course by TSTI https://www.tsti.net/ascend/

Today, the starting point for undertaking nanosatellite projects for universities or even schools with a STEM (Science, Technology, Education, and Math) focus is much easier than a few years ago. There are many organizations that offer training programs and support obtaining or even fully integrated and designed cubesat systems. There are also websites that are available to help find specific components, structural elements, sensors, payload instruments, and so. There are omnibus websites such as "Cubesat.com" that can be very helpful. Such a website provides helpful listings of companies and their capabilities. These listings are broken down into companies that provide cubesat components, testing equipment, buses/chasses, and assistance with launch arrangements (Cubesat.com 2019).

3 Pocketqube

The small compact nature of cubesats offered a viable means for student experiments, but the cost of cubesat launches was still too expensive for many student projects, so an even smaller standard seemed to be a good idea. Thus scientists and engineers at Morehouse State University and the Kentucky Space Grant Consortium in 2009 pooled their resources to come up with the idea of a pocketqube. (See Fig. 3).

This was a 5 cm × 5 cm × 5 cm cube that would allow eight student experiments to be packaged within the volume represented by a cubesat. The name is derived from the idea that the satellite could fit in your pocket. As miniaturization of electronic components, sensors, and other components continue to shrink, the idea of a pocketqube has now come to have growing appeal, and the ability to obtain pocketqube-sized kits and components is continuing to grow as well. The first four pocketqube were launched on November 11, 2013, packaged within the so-called mothership known as Unisat-5 (The Group of Astrodynamics for the Use of Space Systems UNISAT-5 Mission 2019). Three of these were 1P units and the largest of these, known as T-Logicqube, was the size of a 2.5 P satellite. Currently there are over 20 pocketqube projects under development with P satellite projects now coming from around the world.

The idea of an even smaller than a Cubesat standard with a mass of no more than 250 g that can be provided as a kit has thus started to catch on around the world. The idea has continued to be developed and is now a powerful means to save costs and allow the experimenters to focus on the payload and experimental efficiency for student space projects. The latest launch for pocketqube missions was on a Vector-R, a small launcher using Alba Cluster 1 that occurred in 2019, and the number of launch opportunities will continue to grow (Zack et al. 2013).

One of the means that have been used to develop new information as well as support for pocketqube projects has been a series of workshops. In April 2014, NASA hosted the first of the pocketqube workshops. This consisted of a workshop at Ames Research Center in California and a session in Florida at the Kennedy Space

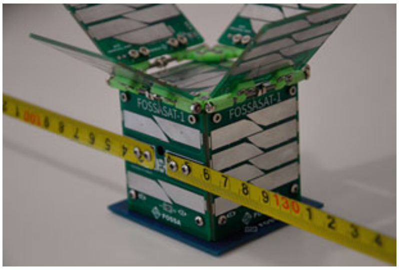

Fig. 3 FossSat-1 A Pocketqube satellite. (Graphic Courtesy of Julian Fernandez)

Center. It was not until March of 2017 that the second workshop was held at the Technical University of Delft that has evolved into an annual event to learn about the latest projects and advances in components design and the latest knowledge about launch arrangements and integration (Poxkwrqube 2019).

The number of pocketqube missions now in development is over 20 in number and will continue to grow each year. Interest in these very small launch systems will be driven forward by the development of practical information about to design, build, and launch a pocketqube continues to grow. Currently the two organizations offering the ability to provide launch integration services for pocketqubes are Alta Orbital and Gauss Srl (Pocketqube 2019).

4 Femto Satellites

The idea of small satellites for student experimentation and training has even gone beyond the limits of cubesats and pocketqube systems down to so-called femto-satellite level. This is q satellite that is in the range of 10–100 g. This diminutive satellite has an upper limit of about 4 ounces. This means that the mission must be truly limited in its scope with current technologies. At this scale, one approach is to have an experiment that is not a free flyer but is designed to carry out a test program, not as a free flyer, but simply as being in a test-bed that can fly on the International Space University (ISU) or on other space platforms deployed by China, or even private space stations such as the Bigelow Genesis or other future private space station systems. In such arrangements, the experiment, or the test results can be returned to Earth, or even more simply the experimental results might be relayed directly to the ground from the space station's telecommunications system. In this instance, an astronaut might be able to activate the experiment and take readings or otherwise assist with the experimental exercise.

Clearly, the very small size of 10–100 g for a Femtosat experimental project imposes exacting limits. Such a diminutive unit will not be able to have a payload large enough to test something such as an electronic sensor or a biological system and still have room for a large enough telecommunications capacity and antenna to relay communications back to Earth. Thus the solution is to be able to relay communications a short distance to a space station data relay system or operate within a "mothership" that can relay a signal to Earth of the test results.

5 International Cubesat and Small Sat Initiatives and University Relationships

Many beginning international satellite projects start out at universities and involve designing and building cubesat or small satellite projects that can be adapted effectively to commercial services. In some cases, the relationship with universities stems from participating in the annual small satellite conference hosted by academic institutions. These particularly include Utah State University in the United States, the annual conference at the Technical University of Delft, or international cubesat meetings such as those started in Peru. The complete records of all the papers presented at the Utah State University Program since its beginning are available online as open source documents. This database alone is a truly invaluable source of information for anyone seeking to embark on a new cubesat academic project.

In other cases, the keys are university-based technical assistance or consulting programs that provide valuable design, technical services, or key training on new satellite systems and ground systems (which are sometimes unfortunately overlooked yet are still vital).

The program that started at the University of Surrey and is now represented by the Surrey Space Technology Ltd. (SSTL) in the United Kingdom represents perhaps the best example in this category. Particularly in the 20-year period from 1995 to 2015, the University of Surrey program in small satellites helped the developing and emerging nations to expand their space programs and projects to get smallsat projects off the ground. Indeed, they provided key support to smallsat programs where local universities were able to play a key role in helping entirely new space initiatives get off the ground.

Indeed dozens of such new international small satellite projects have begun in this matter. Just some of the international cooperative programs between SSTL and small satellite projects in developing countries have included programs involving Thailand, Malaysia, Algeria, Taiwan, Korea, China, Kazakhstan, Turkey, etc. come to fruition. In some cases, Surrey engineers and scientist played a predominant role, but in other cases, the help was just in training or advising university faculty, students, and national expertise create their own capability. The following examples of Surrey Sat projects are summarized below.

6 Thailand: Thai-Paht (TMSat): Launched in1998

Thai-Paht was the first Thai microsatellite. It was a cooperative project with the Mahanikon University, which is located in Bangkok, Thailand. This small satellite was designed for multispectral Earth observation. It also used data storage and advanced onboard processing and communications to download the remote sensing data it acquired. It had a mass of 55 kg. It was launched on July 10, 1998 on a Zenit launcher from the Baikonur launch center. This small satellite project was completed with a team of 12 engineers from the University under a transfer program. Training of these engineers was accomplished in the UK at the SSTL (Surrey Space Technology Ltd 2019).

7 Malaysia: TiungSat-1: Launched in 2000

The TiungSat-1 satellite was Malaysia’s first operational satellite and it contained both operational units and technology demonstration elements. It was built under contract with Malaysia and was launched in 2000. As was typical of these developmental contracts, this arrangement also included a training provision. This allowed a team of Malaysian space engineers to operate the satellite for Earth Observation and space science experiments. It covered training on how to operate the high capacity data storage and store and forward downloading of the information at Malaysian terrestrial sites.

8 Algeria: ALSAT-1: Launched 2002

ALSAT-1 represented Algeria's first national satellite that was a free flyer satellite, although it leased capacity for domestic telecommunications and video services from Intelsat many decades previously. This experimental satellite was designed and constructed in collaboration with the Algerian Centre National des Techniques Spatiales (CNTS).

ALSAT-1 was designed to carry out Earth observation data collection. The ALSAT-2 experimental satellite provided moderate levels of resolution. Its imaging cameras only provided 32-meters resolution, but operated across three spectral bands, namely, green, red, and near Infra-red. This was one of first satellites to be activated to participate in the Disaster Monitoring Constellation.

9 Turkey: BILSAT-1: Launched in 2003

This satellite, known as BILSAT-1, represented the first Turkish Scientific Earth Observation satellite. This satellite contained a number of advanced features. This included, GPS assisted navigation and an experimental package to multiband remote sensing. This was a cooperative program between TUBITAK-BILTEN and the Surrey Space Technology Ltd. Team. It also included onboard propulsion, an advanced Control Moment Gryoscope, and high precision solid-state data recorders and star trackers. Its remote sensing payload included five cameras that operated in the near-infrared, red, green, and blue bands plus one panchromatic (i.e., black and white) camera.

10 Nigeria: NigeriaSat-1: Launched in 2003

This 100 kg experimental minisat was built for the Nigeria Space Research & Development Agency. It was able to provide 32 m multispectral imaging across a 600 km wide coverage path which allowed frequent updating on a global basis. It had a special capability to provide a read-out known as a Normalized Differential Vegetative Index (NDVI). This feature allowed a rapid alert with regard to possible environmental blights. This capability and other images were unexpectedly used to produce the very first Earth observation satellite images of the Hurricane Katrina disaster in New Orleans. This was discontinued in service in 2012 after 8 years of service.

11 China: Beijing-1: Launched in 2005

Beijing-1 was an improved Earth Observation (EO) satellite with one of two cameras having a much higher resolution imaging capability. This spacecraft thus carried two digital imaging payloads. One was the 4 m black and white quite high resolution imaging camera for a small satellite, while the color imaging camera had a 32 m resolution camera that tracked a 600 km wide path. Support was provided for the platform and the sensors for this project.

Beijing-1 was able to provide rapid updates on Chinese issues such as water resources, agricultural yields, urban growth patterns, environment pollution, and disaster monitoring throughout China. This new capability was also used to generate new digital maps of China as a whole and precision maps of cities and urban areas.

12 NigeriaSat-2: Launched 2011

This was the second small satellite that SSTL collaborated with Nigeria on in terms of design, manufacture, and deployment. The NigeriaSat-2 Earth, like NigeriaSat-1 is an Earth observation satellite that is based on the standardized Surrey Space Technology Ltd.'s SSTL-300 platform. The satellite gathers data that is utilized by both the Nigerian National Space Research and Development Agency (NASRDA) and the Disaster Monitoring Constellation. This satellite carries a 2.5 m resolution digital camera for black and white imaging and a 5 m resolution camera for multispectral imaging. This satellite records images that follow imaging swaths that are 24 km in width (See Fig. 4).

13 Kazakhstan: KazEOSat-2: Launched in 2014

Kazakhstan decided to collaborate with Surrey Space Technology limited on its KazEOSat-2 satellite. This spacecraft is designed to deliver medium resolution images with a 6.5 m GSD and a 77 km swath. Under the contract SSTL also provided 6 months hands-on training for 19 customer engineers and Managers. KazEOSAT-2 medium resolution imagery is utilized for mapping, agricultural monitoring, and resource management.

14 Formosat-7 Launched in 2019

In this cooperative program with Taiwan, SSTL has supplied six satellite platforms. As part of the formosat-7/Cosmic-2 program, these satellites are used for meteorological and ionosphere readings and observations and also part of a climate change investigation. This system is intended to replace the current Formosat-7 cosmic 2 constellation. SSTL has supplied 6 spacecraft platforms for the FORMOSAT-7/

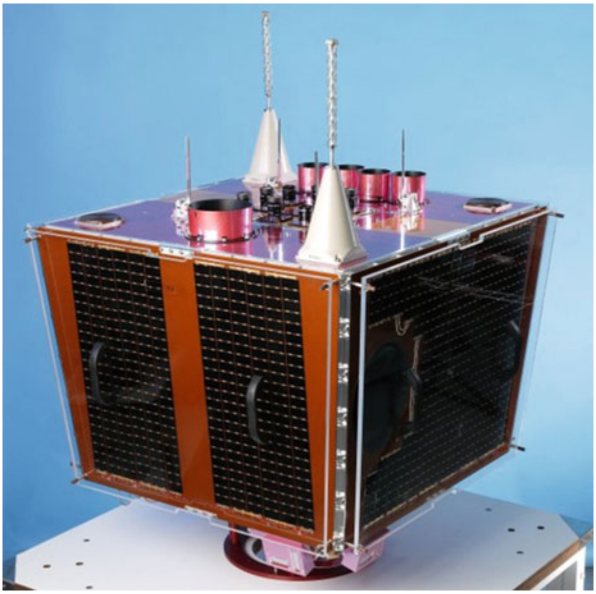

Fig. 4 NigeriaSat-2 Small Satellite for Higher Resolution imaging. (Graphics courtesy of surrey space technology center)

COSMIC-2 Program. This was less of a developmental and shared learning project and more of an equipment supply transaction.

15 NigeriaSat-X: Launched 2011

The NigeriaSat-X Earth observation satellite provides the Nigerian National Space Research and Development Agency (NASRDA) and the Disaster Monitoring Constellation with 22 m imaging capability. The spacecraft delivers 22 m GSD across a 600 km swath width.

NigeriaSat-X was used as a Training Model spacecraft for the team of Nigerian engineers who participated in SSTL's training and development program. Over a period of 18 months, the Nigerian engineers were based at SSTL in the UK and were involved in the design, manufacture, and test phases of the NigeriaSat-X spacecraft in a controlled real project, real engineering environment. After launch, NigeriaSat-X was commissioned in orbit by the Nigerian engineers.

Today there are such opportunities for exchanges between and among universities about advances in the design and building of cubesat project such as at the International Conference on Cubesat Technology. This conference held in Peru in October 2018. At these sessions, there were presentations on cubesat initiatives that were being undertaken by the Universidad Catolica San Pablo, Arequiba, Peru, by INPE of Brazil, and universities and national space initiatives from all over South America, as well as from Japan, Canada, the USA, and Mexico (International Conference on Cubesat Technology 2018).

One example is the Chasqui 1 cube satellite project of Peru. This 1 kg cubesatellite is designed to take visible and infrared images of Earth. It was notable for its unusual launch when it was tossed into space by a Russian cosmonaut during a spacewalk from the International Space Station (ISS) (Kramer 2014).

Peru then quickly moved forward from this modest cubesat project to a high-definition remote sensing satellite known as PeruSat-1. This was procured from the Airbus, and built in their new "Projects Factory" that is designed to produce satellites more quickly and at reduced cost using the latest manufacturing techniques. In this case, Peru purchased not only the spacecraft, which was manufactured in 2 years, but also obtained ground equipment and training in the analysis of the remote sensing data that PeruSat-1 will produce (PeruSat-1 by AirBus 2019). (See Fig. 5).

This rapid transition from the Casqui-1 cubesat project launched by a cosmonaut tossing it into orbit from outside the ISS to the 2016 launch of the minisat PeruSat-1 that has hundreds times more massive was a large leap forward by Peru's space program. This project also involved extensive training and the creation of a sophisticated ground receiving station and development of a processing team to analyze the remote sensing data. These large steps forwards were accomplished through contracted services from Airbus. A part of the reason that this rapid progress was possible was the small satellite revolution that has helped to manufacture small satellites, from cubesats, microsats, and even minisatellites in the 100–1000 kg class much more rapidly and with greatly reduced cost.

Another key source of support is the many organizations that help to sponsor student smallsat projects. Sometimes these are only very small experiments that can be entirely on the International Space Station and sometimes these can be as large as cubesat projects. Some of these programs are sponsored by Arthur C. Clarke Institute for Space Sciences Education (Arthur 2019), IGOSat (2019), and

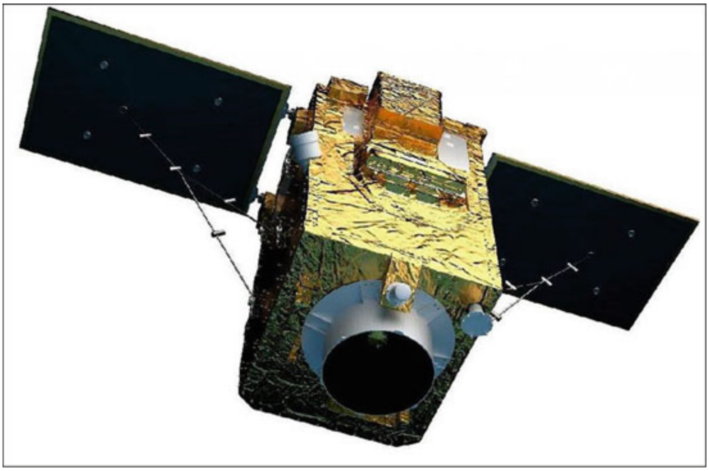

Fig. 5 The PeruSat-1 satellite for high-definition remote sensing. (Graphic courtesy of Airbus)

PolyOrbite (2019). These are only some examples. There are many others that can be located by on-line searches.

16 Concerns Related to Reliability

The reliability of cubesats and other types of small satellites is a particular area of concern. The experience to date has actually been problematic. Up through 2017, the reliability statistics (i.e., successful operation of satellite for at least 2 months) of academic small satellites has only been about 40%, and even with commercial small satellites, the reliability of operation has only been a 77%. Although these success rates are low, it can be argued that these results are still acceptable in terms of the cost efficiency of such projects when compared to larger satellites. Nevertheless, there needs to be a concerted effort to understand why the failure rate is so high and to seek ways to improve the reliability of small satellites and particularly academic and student projects which are quite low. The failure of satellites, however, must be seen not only in an economic sense but in an environmental sense as well. The implications of too many satellites left in orbit and thereby posing a risk of a major collision that proliferates orbit debris is a key concern that increases as more and more small satellites are deployed.

17 Concerns Related to Orbital Debris

The launch of small satellites of all types continues to rise. With it has come the fear of runaway orbital debris. For years it seemed that one could responsibly ignore the possibility of the orbital debris problem and note that natural hazards from small meteors and space dust far outnumbered man-made debris. In the 1970s and 1980s, few thought there was a little possibility that the orbital debris problem could spiral out of control. In particular, the forecast of a Carrington Syndrome, i.e., a runaway avalanche of space debris created by humans, was not taken very seriously. Yet today, there is a real possibility that the buildup of 22,000 trackable space debris objects and 500,000 debris elements in millimeter range could continue to multiply in the next decade. There is real concern that more and more collisions will occur as more satellites are deployed in orbit – for commercial, governmental, military, scientific discovery, technology verification, and academic experimentation. Recent studies carried out by the Aerospace Corporation of the problem of deploying and deorbiting satellites from large constellations without risking collisions underscore these concerns.

Certainly cubesats, picosats, and femtosats built for experimental purposes are not the main problem. Nevertheless they do contribute to the overall buildup of small debris, and they are a very visible and new component of space. The hundreds of small satellite projects undertaken by students for tests, demonstrations, and experimental purposes that are launched into orbits above 300 km take a long time to naturally decay and return to Earth. If student-based satellites had some form of system to aid deorbit such as a passive system that would inflate to create drag or an active thruster system to help reentry into the Earth's atmosphere this would help, but would also be difficult given the size, weight, and cost constraints of small academic space projects. Further, consolidated systems that might fly a number of student systems aboard a mothership and then actively deorbit on a controlled basis this would also help to alleviate the space debris problem.

A new international guideline would be beneficial. This might be in the form of guidance that would specify that student projects, especially those without active space deorbit control systems, should be launched into orbits below 300 km, or perhaps even better be limited to below 250 km. Such an orbital altitude limit would be a clear step forward to help ensure that student small satellite tests, demonstrations, or experimental investigations would not contribute to the overall space debris problem.

This restriction would limit the use of the International Space Station (ISS) to dispense student cubesats for experimental, demonstration, and technology verification, unless there were some special orbital launch system devised that would create an orbit that had an apogee at the ISS and a perigee at perhaps 200 km or even lower.

18 Conclusion

The development of the cubesat standard represented a breakthrough in the ability of students to participate directly in the process of designing, texting, building, integrating, and launching of spacecraft into orbit. This process has had many unexpected benefits. It has turned out to be an excellent training tool for young engineers who wanted to enter the field of aerospace and space manufacturing and design. It has been a useful tool for entrepreneurial students who have funded cubesat experimental projects via Kickstarter and crowd sourced funding mechanisms and then went on to use successful demonstrator small satellite projects to move to venture capital funding and startup of new commercial space businesses. This was the case for the startup of the Planet Labs effort – now simply known as Planet. It was also the case for Spire that used its cubesat experimental test and demonstration project as a means to get financing for its now operational Spire systems that is now backed by a billion dollar contract from ESA for environmental data.

Perhaps the most profound aspect of student developed cubesatellite projects has been its contribution to what is now commonly known as "NewSpace" or "Space 2.0." The various university-based cubesat initiatives have helped to show how more can be done with less. Some of the most successful new commercial satellite constellations, such as the Planet and Spire 3-unit cubesat constellations mentioned above. Both of these commercial ventures grew out of student initiatives and proof-of-concept student projects. Thus, the cubesat initiative that started as a teaching and learning experience has shown more ambitious results. There is solid evidence that student and university-based activities centered around cubesat projects have helped to create successful new satellite ventures that have embraced the new and highly innovative design techniques and concepts at the heart of cubesat projects.

This is actually in some ways history repeating itself. The first small satellite activities dating back three decades ago came from Surrey University in the United Kingdom that designed the first Surrey Sats. Today Surrey Space Technology Limited (SSTL), now owned by Airbus is a key designer and producer of small satellites that range from cubesats up to minisats. The Oscar satellites for amateur radio were built by volunteers from industry and academia. Today, countries seeking design, build and launch their first satellites often start with cubesat projects and turn to organizations such as SSTL, still located on the Campus of the University of Surrey or to Utah State University that host the annual Small Satellite Conference for assistance.

The European Space Agency has characterized student-based cubesat initiatives in the following way: “CubeSats offer students a true hands-on experience in designing, developing, testing, and operating a real spacecraft system and its ground segment. Lately, CubeSats have also started to show an increasing potential for commercial use, and are recognized as one of the current top trends in space activities” (Fly Your Satellite Programme: Cubesats and Education 2019).

Thus there are new ways of design, manufacturing, testing, and deploying commercial application satellites and satellites for governmental military or other programs that have benefitted from new ways of thinking about what a small or smaller satellite might be able to do as well as its size, functionality, and overall design.

Scientific Discovery and Geomagnetic Monitoring in Earth Orbit Using Small Satellite Systems

James Green, David Draper, Helen Grant, and Jonathan Rall

Contents

Abstract

The field of SmallSats and CubeSats is evolving very rapidly, making this short review of how they are used in geomagnetic monitoring only a snapshot in time. The desire for shorter development times, lower launch costs, and the opportunity to provide a teaching, hands-on environment will keep the momentum for this type of platform going well into the future. It is important to note that SmallSats and CubeSats cannot address all important science objectives and are not a low cost substitute for every application, such as needing large apertures, but where they can produce major results is in simple well focused science, requirements of multipoint observations, or in short duration missions that can be executed under low cost constraints. In particular, these missions are generally within the mass constraints of 1.33 kg per CubeSat unit, e.g., a 3U CubeSat could have a mass of up to 4 kg, up to a maximum of 180 kg for a SmallSat. Despite their smaller mass,

volumen, and launch costs they are able to achieve significant scientific results. The quality of experimental space missions is not measured in how large the satellites are but rather the quality of the derived data and their significant contributions to scientific knowledge. This overview will not be a comprehensive list of geomagnetic monitoring missions, also called heliophysics missions, but will discuss a representative set in various development and operational phases.

1 Introduction

In the early days of space exploration, satellites were restricted by the technology and launch vehicle capabilities of the time. The first artificial satellite, Sputnik, launched by the former Soviet Union on 4 October 1957, was 58 cm in diameter and weighed only 83.6 kg (NASA 2019a). Soon after Sputnik, Dr. James Van Allen of the University of Iowa provided a cosmic ray detector as the only science instrument for the first satellite launched by the United States, called Explorer 1. This mission was launched 31 January 1958. The cosmic ray detector was designed to investigate the flux of these high energy particles with altitude but it also measured the particles trapped in Earth's magnetic field, later named the Van Allen belts. Explorer 1 weighed 14 kg and was operational until 23 May 1958 (NASA 2019b).

Explorer 1 ushered in a multidecade era of small satellites that made significant contributions to space sciences. As technology and launch vehicle payload capacity improved, the research community exploited this capability, building ever larger and more capable satellites until they became the norm. Large scientific spacecraft such as the Hubble Space Telescope (HST) and James Webb Space Telescope (JWST) take advantage of this increased capacity to develop large, complex spacecraft with more sophisticated instrumentation. In the case of HST, the life of the mission could be extended by upgrades and maintenance performed by visiting astronauts. This trend continues even today.

NASA science is strategically defined by a set of fundamental science questions and associated missions that are delineated in National Academy of Sciences (NAS) reports that are referred to as "decadal surveys" since they are issued in each science discipline that NASA supports (Earth Science, Heliophysics, Planetary Science, Astrophysics, and Life Science & Microgravity) once per decade. Over time, decadal missions involved an ever increasing difficulty in making critical measurements that continued to lead to larger and larger missions.

In recent years, however, advances in miniaturization and a desire to develop lower cost missions have led to an increase in interest in smaller spacecraft. Initially used as technology demonstration missions or as an avenue to provide students hands on experience in designing and building spacecraft, the small satellite also holds promise as a full-fledged research platform. Simply stated, these new types of smaller missions leveraging new technologies began to show characteristics of disruptive innovations that needed to be further studied (e.g., Shkolnik 2018; Mercer 2019). As a result, NASA and the National Science Foundation asked the NAS to establish an ad hoc committee to examine the potential use of CubeSats to obtain high priority decadal level science. The result was the report, *Achieving Science with CubeSats* (NAS 2016).

In just a few short years, SmallSats and CubeSats have become a mainstream activity for a number of Space Agencies and are showing up in NAS decadal reports. Fig. 1 is an overview of the NASA SmallSat and CubeSat missions that are currently operating, under development, or in formulation. Not shown are the extensive number of missions that are currently under study. The missions in Fig. 1 span the areas of technology development, Earth science, Heliophysics, Planetary Science, and Astrophysics with the future missions shown in bold.

Currently, NASA has multiple activities designed to support the use of small satellites that demonstrate a benefit to NASA's missions. Since access to space is a critical concern, the CubeSat Launch Initiative is designed to connect NASA supported CubeSat developers, as well as educational institutions and nonprofit organizations with launch providers (NASA 2019c). In addition, NASA's Space Technology Mission Directorate (STMD) sponsors the Small Spacecraft Technology Program to identify technologies and use SmallSats as a flight test and demonstration platform (NASA 2019d). NASA also sponsors the Small Spacecraft Systems Virtual Institute (S3VI) that provides information useful to small satellite developers

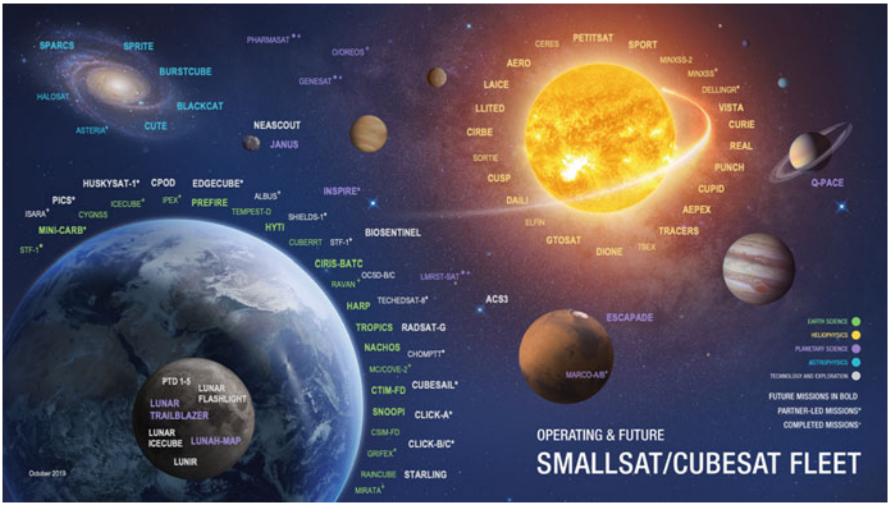

Fig 1 All operating and future SmallSat and CubeSat missions covering Earth and space science as well as technology demonstrations

including design tools and information about upcoming NASA solicitations (NASA 2019e).

2 NASA Smallsats and CubeSats: A Snapshot in Time

Briefly described here, the growing fleet of NASA-sponsored SmallSats and CubeSats intended to study the Sun and Earth's magnetosphere. Although some of these missions are intended primarily to demonstrate technologies for later use, all of them include significant contributions to advancing knowledge in Heliophysics. Table 1 summarizes the missions described here in four subsections: those in preformulation (i.e., pre-Phase A), those selected for flight and in formulation (Phase A), those selected for flight and in design or production (Phases B through D), and those currently operating (Phase E).

2.1 Selected Missions in Preformulation

These are concept studies awarded by NASA to principal investigator (PI) led mission teams. Concept studies are typically for approximately 1 year of work to develop the mission concept in such a way that it would be competitive in an eventual call for flight proposals. Concept study selection does not assure selection for flight. The preformulation concept studies were awarded in the 2018–2019 timeframe.

2.1.1 Aeronomy at Earth: Tools for Heliophysics Exploration and Research (AETHER)

The AETHER concept proposes to characterize how geomagnetic storms affect the ionosphere-thermosphere system using instrumentation aboard the International Space Station. These observations would be complemented by ground-based data on electrons in the same region. AETHER would constrain complex processes of space weather by measuring interactions between charged particles in the ionosphere and the neutral, terrestrial-weather-driven thermosphere. AETHER would launch no later than 2024; the lead institution is the University of New Hampshire in Durham, NH.

2.1.2 COronal Spectrographic Imager in the Extreme ultraviolet (COSIE)

The COSIE concept would mount a solar-observing instrument onto the International Space Station to acquire wide field images of the corona and full Sun spectral images with high sensitivity and rapid cadence. These data would constrain the global field topology and track coronal mass ejections from the disk through the inner heliosphere and contribute to space weather. These constraints would in turn allow determination of the magnetic connectivity between the lower and outer corona where the transition between open and closed magnetic fields occur. In this

Table 1 Summary of NASA-sponsored heliophysics smallsats

Mission name	Host institution(s)	Anticipated launch date	Science objectives
In pre-formulation (pre-Phase A)			
AETHER	University of New Hampshire	NLT 2024	Measurements of how the thermosphere interacts with the ionosphere's charged particles
COSIE	Smithsonian Astrophysical Observatory	tbd	Constrain the global field topology, track coronal mass ejections from the disk through the inner heliosphere
CURIE	University of California Berkeley	tbd	To study radio burst emissions from solar eruptive events in the inner heliosphere
EUVST	Naval Research Lab	NLT 2025	Measure interplay between solar plasma and geomagnetic fields
EZIE	Johns Hopkins University Applied Physics Laboratory	NLT 2024	Measurements of auroral electrojet
MEME-X	NASA GSFC	tbd	Measuring atmosphere mass flux and loss through the upper atmosphere to space
SETH	NASA GSFC	tbd	Energetic neutral atom detections of signatures of major solar eruptions
Solar Cruiser	NASA MSFC	tbd	Simultaneous measurements of magnetic field structure and velocity of CMEs; tech demo for solar sail
In formulation (Phase A)			
AERO	Massachusetts Institute of Technology Haystack	2022	Test a novel "Vector Sensor" radio capable of sampling low radio frequencies from orbit in the Earth's auroral zones
AWE	Utah State University, NASA GSFC	Aug 2022	To investigate how atmospheric gravity waves impact transport of energy and momentum into space
CIRBE	University of Colorado LASP	2021	To study the formation, source, intensity, and dynamic variations of inner Van Allen radiation belt electrons
CuPID	Boston University	2020	Miniaturized X-ray camera to study Earth's magnetic cusps via solar-wind soft X-rays
GLIDE	University of Illinois Urbana-Champaign	Oct 2024	Lyman-alpha measurements and images of geocorona from outside the exosphere
MUSE	Lockheed Martin	2022	Measurements of mechanisms of energy release in the corona and the dynamics of the solar atmosphere
REAL	Dartmouth University	2021	To characterize physical mechanisms that scatter radiation belt electrons into the atmosphere

(continued)

Table 1 (continued)

Mission name	Host institution(s)	Anticipated launch date	Science objectives
SunRISE	University of Michigan	tbd	Synthetic aperture radio telescope to assess how solar energetic particles are accelerated and released into interplanetary space
THOR-US	University of New Hampshire	NET 2025	US contributions to European Space Agency's Turbulence Heating ObserveR M-class candidate mission
TRACERS	University of Iowa	NLT Aug 2022	To study global variability in magnetopause reconnection with targeted set of new and unique in situ measurements
VISTA	Massachusetts Institute of Technology Haystack	2022	To operate with AERO, yielding vector interferometry to study wave emissions in the Earth's auroral zone
In design or production (Phases B-D)			
B: DAILI	Aerospace Corporation	2021	To provide density and compositional data for atmospheric models used in calculating precise orbits and understanding propagation of radio signals
B: GTOSat	NASA GSFC	2021	To detect very high energy particles for understanding acceleration and loss of relativistic electrons in Earth's outer radiation belt
B: LLITED	Aerospace Corporation	2021	To investigate equatorial temperature, wind, and ionization anomalies in the neutral atmosphere or in the region containing charged particles
B: PetitSat	NASA GSFC	2021	To study density irregularities in mid-/low-latitude ionospheric plasma to better understand irregularities in long-distance radio communication
B: PUNCH	Southwest Research Institute	NLT Aug 2022	To study how coronal structures fuel ambient solar wind with mass and energy, and dynamic evolution of transient solar wind structures
C: CuSP	Southwest Research Institute, NASA GSFC	tbd	To serve as a "space weather station" to measure particles and magnetic fields in space
C: SPORT	Instituto Tecnológico de Aeronáutica (Brazil), NASA MSFC	2020	To observe scintillation structures and plasma bubbles in order to predict their behavior and assess ways to mitigate their effects
D: LAICE	University of Illinois Urbana-Champaign	2019	To make in situ measurements of wave perturbations in the ionosphere and remote sensing of the middle atmosphere

Mission name	Host institution(s)	Anticipated launch date	Science objectives
Operational or closed out (Phases E-F)			
ASTERIA (Astro IR&D tech demo)	Massachusetts Institute of Technology, NASA JPL	Nov 2017	Precision photometry to study stellar activity, transiting exoplanets, and other astrophysical phenomena
CeREs	NASA Science Mission Directorate	Dec 2018	Measuring how electrons are energized and how are they lost from the Earth's radiation belts, and how solar flare electrons are energized
Dellingr (Helio IR&D tech demo)	NASA GSFC	Aug 2017	Measure magnetic fluctuations and molecular changes in upper atmosphere to determine baseline conditions and observe space weather impacts
ELFIN	University of California Los Angeles	Sep 2018	Measure the angle and energy distribution of precipitating relativistic electrons within and near the loss cone
E-TBEx	NASA GSFC	Jun 2019	Explore bubbles in the electrically charged layers of Earth's upper atmosphere, which can disrupt key communications and GPS signals
FOXSI-3	NASA GSFC	Sep 2018	Hard X-ray telescope to detect hot plasma and energetic electrons near energy release sites in solar corona
MinXSS-2	Colorado University LASP	Dec 2018	Measurement of soft X-ray flare energetics over the solar cycle
SORTIE	ASTRA LLC, University of New Mexico, COSMIAC	May 2018	SORTIE measures wave perturbations, electric fields, and observations of the irregularities in plasma density which result from instability growth
SWARM	European Space Agency	Nov 2013	Most precise and highest-resolution measurements of Earth's vector magnetic field

GSFC Goddard Space Flight Center, *JPL* Jet Propulsion Laboratory, *MSFC* Marshall Space Flight Center

way, COSIE would provide a "missing link" between the physics of the low corona and that of the heliosphere. COSIE is hosted at the Smithsonian Institution/ Smithsonian Astrophysical Observatory in Cambridge, Massachusetts.

2.1.3 Cubesat Radio Interferometry Experiment (CURIE)

The CURIE concept is a pathfinder for developing future low-frequency (0.1–40 MHz) interferometry observatories. It would fly a pair of CubeSats in low Earth orbit separated by a distance between 1 and 3 km. The CubeSats would be launched in a 6 U configuration and separate on orbit to two 3 U satellites. The primary science objective is to make radio interferomic observations of radio bursts that arise from coronal mass ejections (so-called Type II bursts) and from solar flares (Type III bursts). Secondary objectives achievable with the same dataset include in situ measurements of temperature and electron density in the ionosphere and producing a map of the "radio sky" at frequencies below which ground-based observations are not possible (the ionospheric cutoff). Only space-based measurements can accomplish these goals. CURIE would set the stage for additional CubeSats added to the array to enable better characterization of transient events and even to place them in cis-lunar space to make observations from the lunar farside on the early universe's epoch of re-ionization. CURIE would be operated at the Space Science Laboratory at the University of California in Berkeley, California.

2.1.4 Extreme Ultraviolet High-Throughput Spectroscopic Telescope (EUVST)

The primary goal of the EUVST concept is to make the first simultaneous observations of interactions between magnetic fields and solar plasma to understand how these interactions drive solar activity and eruptions, such as solar flares and coronal mass ejections. These observations would constrain how the two systems affect solar atmospheric dynamics. EUVST is conceived to launch with the Japan Aerospace Exploration Agency's Solar-C mission, planned for 2025. The lead institution for EUVST is the US Naval Research Laboratory in Washington, D.C.

2.1.5 Electrojet Zeeman Imaging Explorer (EZIE)

The EZIE concept would study an electric current known as the auroral electrojet, which traverses Earth's polar atmosphere at ~60–90 miles elevation and can cause disruptive geomagnetic storms. The concept is for three SmallSats to measure magnetic fields and observe electrojet structure and evolution, with a view toward ultimately deriving predictive models for these types of storms. EZIE would launch no later than 2024. The lead institution for EZIE is the Johns Hopkins University Applied Physics Laboratory in Laurel, Maryland.

2.1.6 Mechanisms of Energetic Mass Ejection – eXplorer (MEME-X)

MEME-X would constrain the physical processes that control mass flux to space through Earth's upper atmosphere. MEME-X data will improve (in a potentially far-reaching way) understanding of how planetary atmosphere loss operates both from solar and local influences. The host institution for MEME-X is NASA's Goddard Space Flight Center in Greenbelt, Maryland, and the team includes members from NASA Marshall Spaceflight Center in Huntsville, Alabama.

2.1.7 Science-Enabling Technologies for Heliophysics (SETH)

SETH is primarily a technology demonstration concept for two enabling technologies. The first is less-complex small- and CubeSat optical communications hardware that could yield major increases in data rates, while reducing the burden on NASA's Deep Space Network. This type of advance has obvious applications to enabling future refinements for smallsats (including fleets of satellites operating in tandem) requiring communications at high data rates. The second is technology to detect energetic neutral atoms in the solar wind along with other solar particles and waves. This improvement would be useful for generating early warning of potential threats to astronauts from energetic solar events. SETH, along with the Solar Cruiser concept (see below), is a candidate to fly as a secondary payload on NASA's Interstellar Mapping and Acceleration Probe, currently slated to launch in October 2024. Only one of these two missions will be included as secondary payload after concept studies are complete. The lead institution for SETH is NASA's Goddard Space Flight Center in Greenbelt, Maryland.

2.1.8 Solar Cruiser

The Solar Cruiser concept would also demonstrate two technologies. The first is a "solar sail," a more than 1670-m^2 sail, in the spacecraft's polar orbit around the Sun. If successful, it would enable the use of solar radiation as a propulsion system. The second is a coronagraph that would acquire simultaneous measurements of the structure of the Sun's magnetic field and the velocity of coronal mass ejections, which are potentially harmful to terrestrial electronic infrastructure. As in the case for SETH, it would improve the ability to provide advance warning of potential solar disturbances before their effects arrive at Earth. Solar Cruiser, along with the SETH concept (see above), is a candidate to fly as a secondary payload on NASA's Interstellar Mapping and Acceleration Probe, currently slated to launch in October 2024. Only one of these two missions will be included as secondary payload after concept studies are complete. Solar Cruiser's host institution is NASA's Marshall Space Flight Center in Huntsville, Alabama.

2.2 Selected Missions in Formulation (Phase A)

These missions have been at least provisionally selected for flight and are currently in formulation. Phase A studies are typically for approximately 1 year, and after review a key decision point will determine whether each mission concept advances to later development Phases for design and fabrication.

2.2.1 Auroral Emissions Radio Observer (AERO)

AERO is a one-year 3 U CubeSat mission that will determine if auroral kilometric radio emissions extend into the lower atmosphere. Scheduled for launch in 2022, it will test a novel "Vector Sensor" radio capable of sampling low radio frequencies from a polar orbit in the Earth's auroral zones above the ionospheric peak. The CubeSat will measure the direction of arrival of auroral radio emissions, making it capable of imaging their source regions. It will also have auxiliary sensors including a magnetometer and optical aurora sensor. These activities will address fundamental questions about nonthermal emission mechanisms and the structure of the ionosphere. The host institution for AERO is the Haystack Observatory of the Massachusetts Institute of Technology, with partnerships including MIT's Lincoln Laboratory, Morehead State University, Dartmouth University, and Merrimack College.

2.2.2 Atmospheric Waves Experiment (AWE)

The AWE concept would deploy a high-resolution infrared imager on the International Space Station to make measurements of temperatures using the 87-km altitude OH nightglow emission. These data would then be used to resolve gravity waves on a nearly global scale in terms of momentum and energy fluxes. These data will be modeled at high-resolution to assess the interplay of controlling factors in causing gravity-wave spatial and temporal variability. AWE is hosted at the Utah State University Research Foundation in Logan, Utah.

2.2.3 CubeSat: Inner Radiation Belt Experiment (CIRBE)

CIRBE's primary objective is to constrain the formation and decay of inner belt electrons ($>$100 keV to $>$ 1 MeV) and to determine the intensity and dynamic variations of these electrons. The mission will use a miniaturized version of an instrument that flew on NASA's Van Allen Probes, on a CubeSat in a steeply inclined low-Earth orbit. Even heavily shielded instruments on the Van Allen Probes have suffered degradation from the penetration of highly energetic protons. To make these determinations on inner belt electrons, particularly those with energy close to 1 MeV and higher, low-Earth orbital measurements with more refined energy resolution are needed. The orbital inclination allows the avoidance of trapped highly energetic protons, which are detectable only when the spacecraft goes through the South Atlantic Anomaly region. The host institution for CIRBE is the University of Colorado at Boulder, CO.

2.2.4 Cusp Plasma Imaging Detector (CuPID)

The CuPID Cubesat Observatory is a 6 U design intended to test competing models of solar wind-magnetosphere coupling. CuPID will carry a first-of-its-kind wide field-of-view soft X-ray telescope that will measure soft X-rays emitted during charge-exchange when solar-wind plasma collides with neutral atoms in Earth's atmosphere. The primary observations will be spatial and temporal patterns of X-ray images collected by the telescope. The project is a collaboration between Boston University, Drexel University, NASA Goddard Space Flight Center, Johns Hopkins University, Merrimack College, Adcole Maryland Aerospace, Aerospace Corporation, and the University of Alaska, Fairbanks.

2.2.5 Global Lyman-alpha Imagers of the Dynamic Exosphere (GLIDE)

The GLIDE mission would track, on a global scale, far ultraviolet light emitted from hydrogen as a constraint on the uppermost region of Earth's atmosphere. Only a few such observations have been made from outside the atmosphere previously. Exospheric responses to solar and terrestrial influences can interfere with radio communications in space, and these results should help lessen (or mitigate) these impacts. GLIDE is run out of the University of Illinois, Champaign-Urbana, IL.

2.2.6 Multislit Solar Explorer (MUSE)

MUSE would improve high resolution extreme ultraviolet (EUV) imaging and spectroscopy of the solar corona. It features a multislit EUV spectrograph combined with an imager. MUSE would yield detailed measurements, at far better resolution than those made previously, of the dynamics of the corona and transition region. These dynamics are integral to the heating the solar corona, driving solar wind, and energetic eruptions. The MUSE data will be treated using state of the art numerical modeling. The MUSE team is led by Lockheed Martin's Solar and Astrophysics Laboratory, Palo Alto, CA, with contributions from the Smithsonian Astrophysical Observatory, Michigan State University, the University of California Berkeley, the Norwegian Institute for Theoretical Astrophysics (Oslo), and NASA Goddard and Marshall Spaceflight Centers.

2.2.7 Relativistic Electron Atmospheric Loss (REAL)

REAL aims to improve understanding of the physical mechanisms that scatter radiation belt electrons into the atmosphere by addressing three main science questions. When and where do diffusion, strong diffusion, and nonlinear scattering precipitation loss modes occur? How do these loss modes depend on energy? What are the relative contributions of these loss modes on electron scattering in the radiation belts? The REAL mission will use a 3 U CubeSat in low-Earth orbit to characterize the different loss modes via high time resolution measurements of the electron pitch angle and energy distributions over a wide energy range (keV to MeV). Low-Earth orbit, where the atmospheric loss cone is ~60°, is better suited for these measurements than at the equatorial plane where the loss cone is only a few degrees. The pitch angle-resolved measurements will also enable precipitating, quasi-trapped, and trapped populations of electrons to be distinguished to best quantify the electron loss rate from the radiation belts. REAL is hosted by Dartmouth College in Hanover, NH, with a partnership with Montana State University in Bozeman, Montana.

2.2.8 Sun Radio Interferometer Space Experiment (SunRISE)

SunRISE would provide a constellation of CubeSats operating as a synthetic aperture radio telescope and would be the first of its kind. Flying in a 10 km diameter formation, it would address how solar energetic particles are accelerated and released into interplanetary space. SunRISE will measure coherent Type II and III radio bursts produced during coronal mass ejections and solar flares. These bursts are detectable from space before major arrivals of energetic solar particles, but they cannot be seen from Earth because of absorption by the ionosphere. The host institution for SunRISE is the University of Michigan in Ann Arbor.

2.2.9 US Contributions to the THOR Mission (THOR-US)

The Turbulence Heating ObserveR (THOR) mission is one of four proposed missions currently under consideration by the European Space Agency (ESA). A Partner Mission of Opportunity proposal, THOR-US, has been selected for analysis for three in situ secondary payload instruments. Work will begin on implementation of THOR-US only if THOR is selected.

THOR-US would investigate how kinetic processes heat and accelerate plasma by the dissipation of turbulent fluctuations. The concept study for THOR-US was conducted prior to its selection for NASA's Explorer Program, so the team is prepared for the detailed design phase if ESA selects THOR. The THOR-US team is led by the University of New Hampshire in Durham, New Hampshire.

2.2.10 Tandem Reconnection and Cusp Electrodynamics Reconnaissance Satellites (TRACERS)

TRACERS is expected to be launched as a secondary payload with PUNCH (see section below) and will observe particles and fields in the region of Earth's northern magnetic cusp. This area encompasses Earth's pole, where magnetic field lines curve down toward the surface. As a consequence, particles from the boundary between Earth's magnetic field and interplanetary space are guided down into the atmosphere, particularly during magnetic reconnection events. TRACERS will characterize this process in the cusp with two matching spacecraft, permitting simultaneous reconnection measurements near Earth. The host institution for TRACERS is the University of Iowa in Iowa City, Iowa.

2.2.11 Vector Interferometry Space Technology Using AERO (VISTA)

VISTA is designed to work in tandem with the AERO mission (described above) targeting Earth's radio aurorae. It is a 3 U twin to AERO, launching and deploying with it into a polar orbit. VISTA will demonstrate vector sensor interferometry in space, use that technique to take measurements of the radio aurora, and characterize radio-frequency interference at high frequencies in low-Earth orbit. The missions will demonstrate whether interferometric arrays of vector sensors will maintain sensitivity in the presence of terrestrial interference. If so, low frequency interferometers could be placed in low-Earth orbit, reducing cost and increasing data volume. AERO and VISTA should have 90 day nominal mission lifetimes. Like AERO, VISTA is hosted by the Haystack Observatory of the Massachusetts Institute of Technology, with partnerships including MIT's Lincoln Laboratory, Morehead State University, Dartmouth University, and Merrimack College.

2.3 Selected Missions in Final Design or Construction (Phases B-D)

Missions in these Phases have cleared key decision points and design reviews and have been approved to advance to the next phase eventually leading to flight. Each mission must still pass a critical design review before being finally selected for flight.

2.3.1 Phase B (Preliminary Design, Technology Completion)

Daily Atmospheric Ionospheric Limb Imager (DAILI)

DAILI is a 6 U CubeSat intended to characterize dynamical changes in the composition of Earth's atmosphere in the approximate altitude range of 140–290 km (the so-called thermosphere gap). It will measure, on a daily basis, the absolute O_2 density at mid- and low latitudes (there are few existing measurements in this regime). It will characterize the variability of tides and planetary waves from 140–180 km and determine the extent of neutral O_2 transport during geomagnetically active periods as functions of latitude and altitude. It will also measure electron density profile variations in the F-region above 200 km that arise from tides and planetary waves. These observations will be made via images of Earth's limb acquired over a 6° field of view. DAILI is expected to be launched from the International Space Station using the NanoRacks CubeSat Deployer, resulting in a nominal 51° inclination orbit at 400 km altitude. DAILI is designed to last at least 1 year, but anticipated to last up to three. The mission is run by The Aerospace Corporation, headquartered in El Segundo, California.

Geosynchronous Transfer Orbit to Study Radiation Belt Dynamics (GTOSat)
GTOSat is a 6 U CubeSat envisioned as a pathfinder for new radiation-tolerant technologies of potential use to smallsats operating above low-Earth orbit. GTOSat will be launched into a highly elliptical geosynchronous transfer orbit commonly used in deploying communications satellites to geostationary orbit. It will use a more robust version of the NASA-developed Dellingr spacecraft bus known as Dellingr-X. GTOSat will measure very high energy particles to constrain the acceleration and loss of relativistic electrons in Earth's outer radiation belts. At the same time, it is intended to measure electron spectra and pitch angles of both the seed and the energized electron populations using a high-heritage instrumentation similar to those flown on NASA missions such as Juno, Parker Solar Probe, and the Van Allen Probes. The mission is being developed by NASA's Goddard Space Flight Center in Greenbelt, MD.

Low-Latitude Ionosphere/Thermosphere Enhancements in Density (LLITED)
The goal of the LLITED mission is to characterize two important interactions in the low-latitude dusk-side ionosphere and thermosphere, the Equatorial Ionization Anomaly (EIA) and the Equatorial Temperature and Wind Anomaly (ETWA). It will determine ETWA variability as a function of season, longitude, and latitude and constrain its role in EIA heating. It will characterize whether and how neutral winds interact with the EIA zonal structure and investigate small-scale wave fluctuations in neutral atmosphere quantities for comparison with features of ionospheric density. To do this, it will fly two 1.5 U CubeSats with their payloads, separated by ~30° of latitude, in a low-inclination orbit. The spacecraft are anticipated to be launched from the International Space Station. The mission is run by The Aerospace Corporation, headquartered in El Segundo, CA.

Plasma Enhancements in The Ionosphere-Thermosphere Satellite (PetitSat)
PetitSat is a 6 U CubeSat in development to study ionospheric density irregularities in the mid- and low-latitudes, including depletions, enhancements, and small-scale scintillation. All of these can distort the propagation of radio waves in the ionosphere. PetitSat will provide in situ measurements of plasma density, ion drift in three dimensions, and plasma composition in terms of ion and neutral species. The instrument suite will measure plasma fluctuations and changes in the neutral profile.

PetitSat is to be based on the Dellingr design (see section 3.1.4 below) and anticipated to be deployed from the International Space Station into a 51° inclination orbit at 400 km altitude. The lead institution for the mission is NASA’s Goddard Spaceflight Center in Greenbelt, Maryland.

Polarimeter to Unify the Corona and Heliosphere (PUNCH)

PUNCH will study the Sun’s corona and how it produces the solar wind. Composed of four small satellites, PUNCH will record the solar wind as it leaves the Sun as well as track coronal mass ejections to constrain their evolution and improve the ability to predict such eruptions. Through polarized Thomson-scatter imaging of the transition from corona to heliosphere, PUNCH will advance understanding of how coronal structures drive the ambient solar wind and of the dynamic evolution of transient structures in the solar wind near the source surface. These measurements will complement other NASA missions such as Parker Solar Probe, and the upcoming European Space Agency/NASA Solar Orbiter, due to launch in 2020. PUNCH will be able to image the solar atmospheric structures encountered by these missions by blocking out the Sun’s bright light, enabling examination of the much fainter atmosphere. PUNCH is intended to complement the TRACERS smallsat mission (see below) as well. PUNCH is hosted at the Southwest Research institute in Boulder, Colorado.

2.3.2 Phase C (Final Design and Fabrication)

CubeSat for Solar Particles (CuSP)

CuSP is planned as a 6 U CubeSat secondary payload on the first flight of NASA’s Space Launch System in the early 2020s and is intended as a “space weather station” to measure particles and magnetic fields in interplanetary space. It will occupy a trans-lunar heliocentric orbit at 1 AU with a nominal lifetime of 3 months, although it is anticipated to last for over 2 years. Its science payload consists of a suprathermal ion spectrograph, a vector helium magnetometer, and a miniaturized electron and proton telescope. The mission is hosted by Southwest Research Institute in San Antonio, Texas, with contributions from NASA’s Jet Propulsion Laboratory in Pasadena, California, and Goddard Spaceflight Center in Greenbelt, Maryland.

Scintillation Prediction Observations Research Task (SPORT)

SPORT is a 6 U CubeSat mission to address the conditions leading to the formation of equatorial plasma bubbles. To augment descriptions in the scientific literature, most of which have resulted from observations at a single site in Peru, SPORT will systematically study prebubble conditions at all longitudes. Science objectives include improved predictions of ionospheric disturbances that affect radio propagation of telecommunication signals, which will be accomplished by combining satellite observations from a nearly circular, middle inclination orbit with extensive ground based observations from South America near the magnetic equator. SPORT is an international partnership between NASA, the Brazilian National Institute for

Space Research, and the Technical Aeronautics Institute under the Brazilian Air Force Command Department.

2.3.3 Phase D (System Assembly, Integration, Testing, and Launch)

Lower Atmosphere/Ionosphere Coupling Experiment (LAICE)

LAICE seeks to study atmospheric gravity waves via in situ measurements of perturbations in the ionosphere and remote sensing of the middle atmosphere. These measurements will then be correlated with weather maps of the lower atmosphere, allowing for atmospheric coupling studies over a wide altitude range. The initial concept was funded by the US National Science Foundation, making LAICE the first publicly funded (and university-constructed) 6 U satellite. Its goals include demonstrating a unique magnetic torqueing altitude control system that constrains the satellite in a fixed altitude, acquiring measurements of neutral and ion density properties in the 150–325 km altitude range, and to remotely sense wave parameters between 90 and 100 km as the waves propagate from the lower atmosphere into the ionosphere. The mission is run by the University of Illinois in Urbana-Champaign, in partnership with Virginia Tech in Blacksburg, Virginia.

2.4 Selected Missions in Operation (Phase E)

Missions in Phase E are operating in flight. Missions that have ceased operations or otherwise reached the end of their life cycle are closed out during Phase F and are not described here.

2.4.1 Arcsecond Space Telescope Enabling Research in Astrophysics (ASTERIA)

ASTERIA is primarily a technology demonstration mission to establish fine-pointing capability through arcsec-level line of sight pointing error and highly stable focal plane temperature control. ASTERIA is a 12 kg 6 U CubeSat operating in Low Earth Orbit and has a payload consisting of a lens and baffle assembly, a CMOS imager, and a two-axis piezoelectric positioning stage on which the focal plane is mounted. ASTERIA was launched on 14 Aug 2017 on the SpaceX CRS-12 Dragon flight to the International Space Station on a Falcon-9 launch vehicle and was deployed from the ISS on 21 November 2017. It operates in a near circular orbit with an altitude of ~400 km and an inclination of 51.6°. ASTERIA is a collaboration between the Massachusetts Institute of Technology and NASA's Jet Propulsion Laboratory, with JPL handling the program management and mission operations.

2.4.2 Compact Radiation Belt Explorer (CeREs)

The primary science goal of CeREs is to make rapid, high-resolution energy spectra measurements of electrons over a broad energy range to improve understanding of radiation belt electron energization and loss processes. CeREs is a 3 U CubeSat in a high inclination low-Earth orbit. CeREs will examine how radiation belt electrons are energized and lost, particularly during microbursts. The mission also characterizes high-energy solar wind particles. The spacecraft bus and the payload were developed, tested, and integrated at NASA's Goddard Spaceflight Center, Greenbelt, MD, with contributions from the Southwest Research Institute in San Antonio, TX. The project also involved graduate students from the Catholic University of America in Washington, DC, and the University of Texas, San Antonio. CeREs was one of ten CubeSats on the 19th Educational Launch of NanoSatellites (ELaNa) mission through NASA's CubeSat Launch Initiative.

2.4.3 Dellingr

Dellingr is a 6 U CubeSat that carries three fluxgate magnetometers for space weather measurements and a spectrometer to measure upper atmosphere ion and neutral particles. These in situ measurements of atmospheric composition and density are useful both for understanding atmospheric dynamics and to define the steady state background conditions. Two magnetometers were body-mounted, with the third on the end of a 55 cm boom to allow comparison of data from the two regimes. Dellingr helped establish baseline estimates of magnetic variation and particle fluxes in the exosphere. Its deployment and operations were highly challenging but ultimately successful (NASA 2019f). Dellingr is managed by NASA Goddard Spaceflight Center in Greenbelt, Maryland.

2.4.4 Electron Losses and Fields Investigation (ELFIN)

ELFIN is a dual, 3 U CubeSat system designed to study one of the processes that allows energetic electrons to escape the Van Allen Belts and fall to Earth. ELFIN launched from the Vandenburg Air Force Base in California on 15 September 2018. The primary objective of the mission is to understand mechanisms by which relativistic electrons in the radiation belts are lost via measurements of the full energy distribution and pitch angle resolution of precipitating electrons. A secondary science objective is to identify the source locations in the magnetosphere of ionospheric field aligned currents in relation to dipole region magnetotail boundaries via measurements of multiple 100–500 keV ion and 0.5–5 MeV electron isotropy boundaries. ELFIN includes a 3-axis Fluxgate Magnetometer to detect electromagnetic ion cyclotron waves. ELFIN is a largely student-operated project run out of the University of California in Los Angeles, CA.

2.4.5 Enhanced Tandem Beacon Experiment (E-TBEx)

E-TBEx is designed to investigate bubbles in Earth's ionosphere, whose evolution is unpredictable and difficult to characterize from the ground. It consists of a pair of 3 U CubeSats in near-identical, low-inclination orbits, each carrying tri-frequency radio beacons, that are complemented by ground-based diagnostic sensors in the Central Pacific. E-TBEx seeks to understand how lower-atmosphere forcing acts through plasma-neutral coupling processes to yield local, regional, and global-scale structures and dynamics in Earth's exosphere. It characterizes the development of plasma structure, including equatorial plasma bubbles (EPBs) by sending signals to these receiving stations, some of which pass through the EPBs. In this way, the total density of any ionospheric bubbles in the signal paths can be deduced. E-TBEx was launched in June 2019 aboard a SpaceX Falcon Heavy launch vehicle, and the mission is run out of NASA's Goddard Spaceflight Center in Greenbelt, Maryland.

2.4.6 Focusing Optics X-ray Solar Imager (FOXSI-3)

FOXSI-3 is the third experiment in a series intended to refine hard x-ray telescopes for imaging of the Sun. To focus X-rays, FOXSI uses 7 iridium-coated optics modules, each containing nested X-ray mirrors. Photons are imaged using energy sensitive detectors made of Si and CdTe. The team includes contributions from NASA Marshall Spaceflight Center, the University of Minnesota, the Japanese Aerospace Exploration Agency, and the lead institution is NASA Goddard Spaceflight Center.

2.4.7 Miniature X-Ray Solar Spectrometer 2 (MinXSS-2)

The MinXSS 2 mission flies a duplicate of the MinXSS 1 CubeSat that launched in 2015 and operated for two years, and is intended to investigate study solar flares, active regions, the quiescent Sun, and their impact on Earth's upper atmosphere. It launched on 3 December 2018 from a SpaceX Falcon-9 and is in a polar and sun-synchronous orbit at approximately 575 km altitude, with a mission life anticipated to have a duration of approximately 4 years. MinXSS 2 observes the Sun's soft X-ray energy distribution, improving upon the first mission with upgraded versions of the X-ray spectrometer and attitude control systems, and took advantage of advances in low-mass silicon drift detectors between the first and second missions. The mission utilizes a Sun Position Sensor and X-ray Photometer to provide independent, fine-pointing knowledge of the solar position and broadband X-ray comparisons for use in science processing. The mission is run out of the University of Colorado in Boulder, Colorado.

2.4.8 Scintillation Observations and Response of the Ionosphere to Electrodynamics (SORTIE)

The overall goal of the SORTIE mission is to understand wave-like plasma perturbations in the ionosphere, which can result from a variety of causes. It was launched on 21 May 2018 aboard an Antares/Cygnus rocket and consists of a 6 U CubeSat configuration to measure electric fields from which the growth rate of instabilities near plasma bubbles can be determined. SORTIE also provides initial observations of plasma density irregularities that result from the growth of these instabilities. The mission is led by ASTRA LLC (Atmospheric and Space Technology Research Associates) of Boulder, Colorado, the Air Force Research Laboratory of Kirtland Air Force Base, NM, the University of New Mexico in Albuquerque, New Mexico, the University of Texas at Dallas, COSMIAC (Configurable Space Microsystems Innovations & Applications Center) of Albuquerque, Minnesota, and Boston College of Boston, Massachusetts. The UNM team were the integrators of the CubeSat, and COSMIAC built the satellite and collects the data from it.

2.4.9 SWARM

SWARM is an ESA mission comprising three, near-polar orbiting satellites, two of which fly side-by-side in identical circular orbits (290 mi, inclination 87.4°), and a third in a higher circular orbit (330 mi, inclination 88°). The objective of the mission is to make the most precise measurements of the Earth's magnetic field ever taken resulting in a survey of the overall geomagnetic field and how it evolves over time. SWARM makes high-precision, high-resolution measurements of the vector magnetic field, that is, both the strength and direction of the field. The instrument suite on each spacecraft consists of fluxgate vector magnetometer to make the field measurements, a scalar magnetometer to calibrate the vector magnetometer, an electric field instrument to measure ion density, drift velocity, and electric field, an accelerometer to eliminate atmospheric drag, and a laser retro-reflector for precise, ground-based laser range measurements. The majority of the science objectives relate to inferring dynamic processes in Earth's interior but the mission also measures currents flowing in the magnetosphere and ionosphere, and quantification of magnetic forcing in the upper atmosphere. The mission was launched in 2013 and is still operating.

3 Conclusion

The "process by which a product or service takes root initially in simple applications at the bottom of a market and then relentlessly moves up market, eventually displacing established competitors" was the definition used by Clayton Christensen as a disruptive innovation (Christensen 2019). SmallSats and CubeSats, aided by major advances in miniaturization and launch vehicles with multispacecraft deployers, are becoming more mainstream. Despite their small mass, volume, and launch costs they are able to achieve significant scientific results. Successful experimental space missions are not measured in how large the satellites are but rather the quality of the data returned nad their impact to advancing scientific knowledge. CubeSats were introduced in ~2000 but obtained a significant boost in 2008 when US government funding began primarily for technology development and instrument maturation in addition to training objectives (NAS 2016). Since that time the funding has continued to increase until these types of missions are becoming, once again, critical ways to obtaining decadal level science. Today, SmallSats and CubeSats are the disruptive innovation that many hoped they would be.

Abstract

This chapter examines the current state and scientific potential of CubeSats through a series of representative examples drawn from several fields. The aim is not to provide an exhaustive catalogue of smallsat science missions, but rather to give a flavor of the rich diversity of scientific applications of smallsats.

The rapid growth of CubeSat-based projects developed by the scientific community has been enabled by low entry cost barriers, access to frequent, affordable launch opportunities, open standard interfaces for subsystems, the ready availability of commercial off-the-shelf components for the non-scientific, mission-specific spacecraft subsystems, and a growing user community that openly shares its experiences and knowledge. This makes smallsats ideal platforms for a short-cycle "fly-learn-refly" approach to carrying out scientific missions. The chapter ends with some remarks on the importance of utilizing these new possibilities offered by nanosats in a responsible manner.

Constellation · CubeSat · Educational Launch of Nanosatellites (ELaNa) · Explorer 1 and 3 · Fly-learn-refly · Launch licensing · NASA · Radio frequency allocations · Responsible behavior in space · Smallsat · Space Grant Consortium · Sputnik 1

1 Introduction

The use of small satellites for scientific investigation is nothing new. Sputnik 1, launched by the Soviet Union on 4 October 1957, had a mass of 83 kg and was equipped with temperature and pressure sensors that transmitted their readings from space. This first satellite was what would be termed in today's lexicon a small satellite, or "smallsat." The motion of the satellite provided information about the density of the Earth's upper atmosphere, while its radio signals were used to map out the electron distribution in the ionosphere. The satellite itself was also a meteor detector. Since the spacecraft was pressurized with a nitrogen atmosphere, any breaches or punctures would be noticed by its onboard barometer and transmitted back to Earth (although no such events were recorded during the 3-week mission of Sputnik 1).

Soon after, the United States launched its first satellite, Explorer 1, on January 31, 1958 (Fig. 1). This satellite had a mass of 14 kg and contained several scientific payloads. These included a cosmic ray detector, five thermal sensors (one internal, three external, and one on the nose cone), an acoustic sensor, and a wire-grid sensor to detect micrometeoric impacts (Fig. 2). Data from Explorer 1 and the nearly identical Explorer 3 (launched on March 26, 1958) were used by James Van Allen and his colleagues at the University of Iowa to detect the existence of charged

Fig. 1 A life-size replica of the Explorer 1 satellite, held aloft by Dr. William H. Pickering, former director of JPL, which built and operated the satellite, Dr. James A. Van Allen, of the State University of Iowa, who designed and built the instrument on Explorer 1 that discovered the radiation belts, and Dr. Wernher von Braun, leader of the Army's Redstone Arsenal team, which built the first stage Redstone rocket that launched Explorer 1. (Image courtesy of NASA)

particle radiation trapped by Earth's magnetic field – now known as the inner Van Allen radiation belt.

While Sputnik 1's 83 kg mass would place it in the category of a microsatellite in modern parlance, the 14 kg mass of Explorer 1 approximates the mass of a 6 U CubeSat, so for the purposes of the missions to be discussed in this chapter, a maximum spacecraft size of 6 U for the missions will be considered. The size of Explorer 1 is a good benchmark to illustrate just how much space technology has advanced in the past 60 years, and how much more capability we can pack into a given volume of spacecraft nowadays than was possible in 1958.

In November 2011, Montana State University launched a 1 U CubeSat to repeat the Explorer 1 observations on the 50th anniversary of the discovery of the Van Allen belts. The satellite, named Explorer 1 PRIME-2 (E1P-2), was launched from Vandenberg Airforce Base in California on 28 October 2011 as part of the ELaNa-III mission (Fig. 3). ELaNa refers to a NASA initiative titled Educational Launch of Nanosatellites that aims to attract and retain students in the science, technology, engineering, and mathematics disciplines through providing opportunities for these students to build, launch, and operate their own satellites. Each ELaNa launch typically places anywhere from three to a dozen or more nanosats in space at a

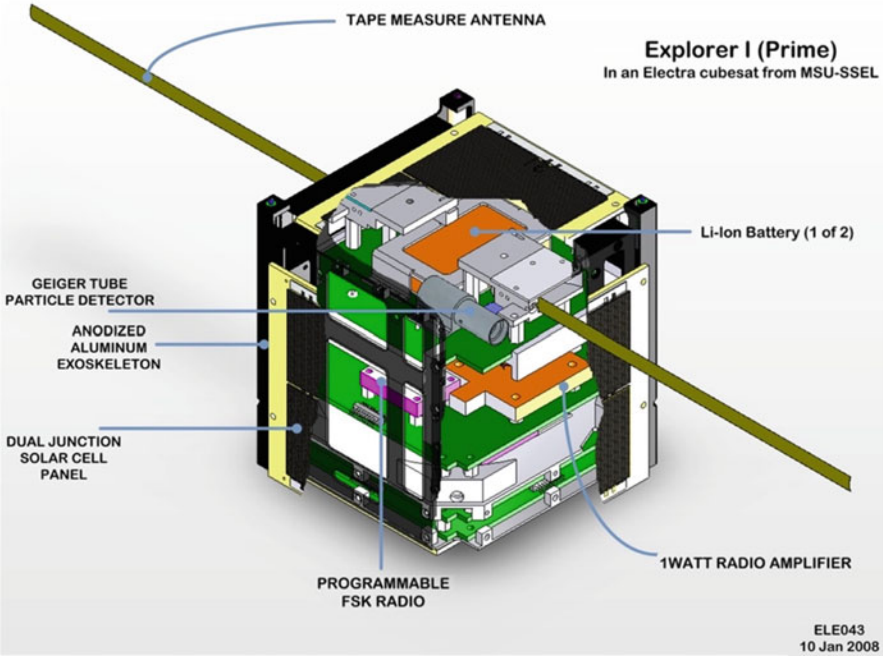

Fig. 3 Cutaway view of the Explorer 1 PRIME-2/HRBE spacecraft, a 1 U CubeSat built by students at the University of Montana to commemorate the discovery of the Van Allen radiation belts in 1958. The spacecraft contained a Geiger counter donated by Dr Van Allen. (Image courtesy of NASA)

time. As of this writing, 28 ELaNa launches have been conducted, and several more are planned.

The Explorer 1 PRIME-2 (E1P-2) satellite was placed in a sun-synchronous, near-circular polar orbit at an altitude of 824 km and an inclination of 98.7°. E1P-2 carried a miniature Geiger tube donated by Dr. Van Allen to measure the intensity and variability of ionospheric electrons from low Earth orbit. A passive magnetic attitude control system was used to align the Geiger tube perpendicular to the local magnetic field.

Shortly after launch, the E1P-2 mission was renamed the Hiscock Radiation Belt Explorer (HRBE), in honor of Dr. William A. Hiscock, the founder and former director of the Montana Space Grant Consortium. By mid-February 2012, the CubeSat had completed over 1500 orbits in LEO and had collected data for 111 days (Fig. 4), surpassing the entire 111-day mission of its history-making predecessor, Explorer 1. This is a demonstration of how CubeSats have become robust platforms for science in space.

When Explorer 1 was launched, it was the sole payload riding atop its Redstone rocket. E1P-2/HRBE was one of six secondary payloads launched together with NASA's NPOESS Preparatory Project spacecraft on a Delta-2 launch vehicle. This illustrates how much the capacity per launch to loft more payloads into space has increased in the past 60 years.

In the next few sections of this chapter, the scientific applications of smallsats of size 12 U and under are illustrated in a variety of scientific applications. CubeSats are particularly useful when one needs a distributed network of sensors to obtain either simultaneous measurements or an uninterrupted time series of measurements. Examples of smallsats used in individual missions and in networks of distributed sensors, where they come into a class of their own, will be discussed.

2 QB50: A CubeSat Constellation to Study the Earth's Thermosphere

The thermosphere is a layer of the Earth's atmosphere, so named because temperature increases with altitude in this region. It extends from about 90 km to about 500–1000 km above the Earth and is the layer in which the aurorae (Northern Lights and Southern Lights) mostly occur. At the base of the thermosphere, the air density is too low to sustain aerodynamic flight, but the residual atmospheric drag is also too high to sustain long-duration orbital flight. This boundary is referred to as the Kármán line, named after Theodore von Kármán (1881–1963), who sought to define the air/space boundary as that layer of the atmosphere that delineates the transition from aeronautics to astronautics. Sounding rockets can be launched to provide vertical profiles of atmospheric conditions in the thermosphere, but provide at most a few minutes of data at one location and at one time. Because of this characteristic, it is not surprising that this layer of the atmosphere has not been widely explored with in situ sensors. The QB50 mission was designed to provide the first multipoint measurements of the density, composition and conductivity of the thermosphere using a distributed constellation of sensors on board CubeSats. The small size and low mass of CubeSats make them ideal for a low-cost distributed sensor network that can provide new scientific data over wide regions of the thermosphere for a short period of time.

The QB50 project was conceived by the Von Karman Institute (VKI) in Belgium and supported financially by the European Commission under the FP7 framework at the level of just under €8 million. The idea of the QB50 project was to use a constellation of CubeSats launched into relatively short-lived orbits to study the middle and lower thermosphere, and also to perform re-entry research. It goes without saying that an improved knowledge of the density of the thermosphere and its properties will greatly improve reentry models and help to mitigate the risks posed by space objects reentering the atmosphere. The constellation would be allowed to fall under drag from an initial deployment altitude of around 420 km down to 200 km in 1 year, observing the chemistry and other properties of the thermosphere as it did so. Additional objectives of QB50 were European industrial development, student training, and workforce development.

2.1 The QB50 Satellites and Their Scientific Instruments

Most of the QB50 satellites were 2 U CubeSats equipped with a QB50 sensor. In addition, many of them also carried additional payloads developed by their respective university or organization. The satellites typically used body-mounted solar cells, had a navigation means such as GPS, had attitude control capability, and communicated in the UHF and VHF radio amateur frequency range.

The QB50 consortium agreed on three different types of sensors, which were provided to the participating institutions for incorporation in their CubeSats:

- Ion and Neutral Mass Spectrometers (INMS), supplied by the Mullard Space Science Laboratory (MSSL), to probe the major chemical species such as O, O_2, NO, and N_2 and possibly others.
- Flux Ion Probe Experiment (FIPEX) sensors, supplied by the Technical University of Dresden (TUD), to measure atomic and molecular oxygen by means of two separate solid electrolyte sensors.
- multi-Needle Langmuir Probe (mNLP) sensors, supplied by the University of Oslo (UiO), to probe electron density and other electron characteristics of the thermosphere.

Each participating institution was asked to incorporate one of these sensors and a thermistor/thermocouple in their CubeSat. They were free to utilize the remaining volume, mass, and power budget to incorporate whatever additional payloads they could fit within the volume/mass/power envelope of their spacecraft.

2.2 Development of the Constellation

VKI was selected as the project leader and coordinated the work of 33 partner institutions from 24 countries on 5 continents. The process of designing and building the QB50 CubeSats lasted 6 years. One of the main benefits of the QB50 project was the experience gained by the many teams who participated in this project under the leadership of VKI. Although initially planned, as the name QB50 suggests, to have 50 or more CubeSats, in the end 36 were actually launched, which is still a very impressive accomplishment.

It is instructive to describe how this widely distributed consortium of partners with different levels of technical capabilities and spaceflight experience in 24 countries managed itself to design, build, launch, and operate the constellation. As several of the VKI partners had limited experience in the design and construction of satellites, VKI and the QB50 consortium provided technical guidance for CubeSat development through the definition of technical requirements, support for meeting technical requirements (such as sensor alignment), advice (such as standards), and support for participating in milestone reviews (such as templates for the technical documents that had to be submitted for these reviews). Formal acceptance of each QB50 spacecraft was agreed by the QB50 consortium at the Flight Readiness Review, following which ISIS handled the final integration of each satellite with its science instrument, transportation of the integrated CubeSats to the launch site and their installation in a launch deployer.

VKI also supported the participating teams by obtaining all necessary legal permits for launch. The satellites were registered by VKI with the government of

Belgium. VKI also supported the QB50 partners with radio frequency allocations by carrying out frequency coordination with AMSAT and IARU, the Belgian Institute for Postal sevices and Telecommunications (BIPT) and the ITU. This approach allowed the QB50 partner teams to focus on their own national regulatory requirements for carrying out a space activity and related issues, such as export/import regulations. Despite being registered in Belgium, each satellite remained the property of the organization that developed it and it was under the control of that institution from its own ground station.

2.3 Deployment

Two precursor satellites were launched on a Kosmotras Dnepr rocket 19 June 2014 from Yasni, Orenburg Oblast, Russia, into a 630 km circular, 98° inclination orbit. The orbit of the precursor satellites was chosen to be at a higher altitude than the operational satellites to allow for longer mission operation time for troubleshooting, gaining operational experience and operations training for the partners.

The first 28 CubeSats of the full constellation were deployed from the International Space Station during the period 16–26 May 2017 into a 415 km, 51.6° ISS inclination orbit. The deployment was managed by Nanoracks (Fig. 5). Another 8 QB50 satellites were launched on 23 June 2017 on an Indian PSLV rocket into a

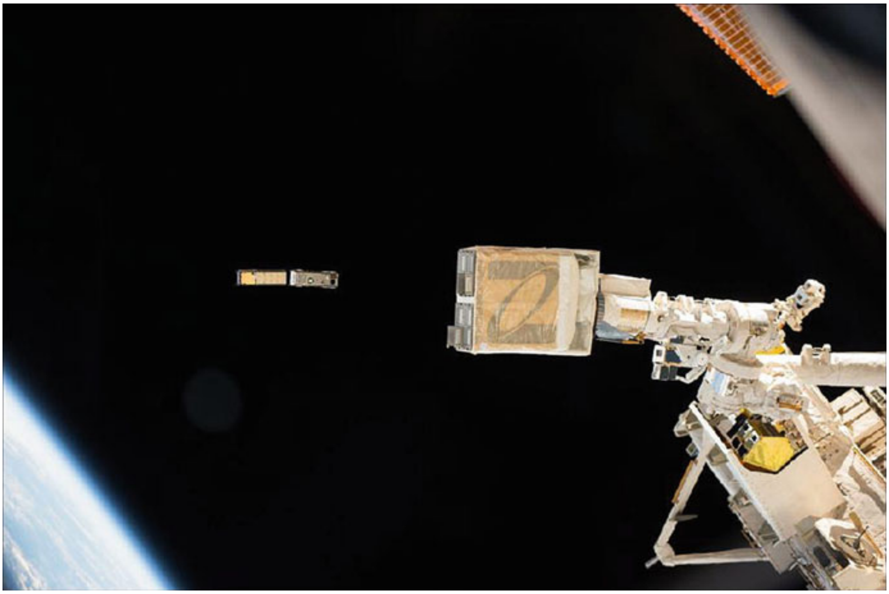

Fig. 5 This image shows deployment of nanosatellites from the ISS by NanoRacks on 16/17 May 2017. The two satellites pictured here are not QB50 satellites, which were released on the same day. (Image courtesy of NASA)

500 km, 97.1° polar orbit. However, 10 of those 36 satellites were dead on arrival in orbit or failed soon after, so in the end there was a 72% success rate, which is higher than the historical success rate for CubeSats. The final, as-launched constellation (Table 1) comprised 10 Ion and Neutral Mass Spectrometers (INMS), 14 Flux Probe Experiments (FIPEX), and 10 multi-Needle Langmuir Probes (mNLP). Two of the satellites had drag augmentation payloads only.

2.4 Operations

The science data downloaded from the satellites comprised the data obtained by the QB50 Science Unit along with its respective orbital information, such as position and time of acquisition. The ground segment for QB50 was distributed among all the partners around the world and allowed a high coverage of communication. Typically, the partners had access to a radio amateur ground station with UHF and VHF capabilities; some also had access to S-band communications. Satellite control software developed by the École Polytechnique Fédérale de Lausanne (EPFL) was made available to other partners, which relieved them of the burden of developing or procuring such software. It also facilitated data submission to the central server located at VKI, which functioned as the heart of the QB50 ground segment, allowing central collection of all the data obtained by the CubeSats, and interfacing to all ground stations at the QB50 participating institutions.

2.5 Results

The official report of the QB50 project (Von Karman Institute 2017) contains an interesting account of how the project was managed and the lessons learnt by the various academic and industry participants. From a purely scientific perspective, the QB50 project did not meet its scientific goals. The mission did not yield any major new insights on the physical processes in the thermosphere. Nevertheless, it was a boldly conceived project, and many lessons were learnt.

Apart from the scientific data generated by the QB50 constellation, there were numerous other benefits. QB50 involved more than 50 professors and 300 students from 24 countries, all of whom now share a common experience of having designed, built, integrated, tested, launched, and operated a satellite, and who have practical experience in international space cooperation. The project also provided development opportunities for the NewSpace industry, not only in developed countries but also in developing countries. For example, the South African company CubeSpace provided the attitude determination and control systems for 15 of the satellites in the constellation.

Hence, bearing in mind that this was the first time anyone had tried to place a nanosat-based scientific network in space, one may conclude that the QB50 project was a worthwhile experience that paved the way for placing similar, more robust distributed scientific networks of sensors in space in the future.

3 Bright(-Star) Target Explorer (BRITE) – A Nanosat Constellation for Astronomy

Astronomical objects display changes in their observable properties (such as brightness, polarization, spectrum) that serve as important clues to their physical nature. These changes occur on timescales ranging from milliseconds to millennia. In the twentieth century, with the advent of electronic sensors, astronomers started discovering and studying rapid light fluctuations in several types of stars. Our Sun, for example, oscillates with a 5-min period and studies of these oscillations have yielded a great deal of information about the interior structure and dynamics of the Sun, and even shed light on a long-standing mystery of fundamental particle physics, known as the solar neutrino problem. The study of solar surface oscillations to yield information about the interior of the Sun is termed *helioseismology*, and is an extension of the application of the basic techniques of *seismology*, the study of Earthquakes and the propagation of elastic waves through the Earth's interior to study its interior structure. In the last few decades of the twentieth century, astronomers discovered rapid oscillations in other stars, and the field of *asteroseismology* was born.

With time, astronomers have become able to study ever-smaller amplitude changes in the light emitted by stars, ranging from several parts in a thousand to several parts in a million. In order to study these extremely low-amplitude temporal variations, astronomers need to accumulate time series of observations – often very long ones to achieve the necessary signal-to-noise ratios. Ground-based astronomers work under several limitations, such as inclement weather, the day/night cycle and limited target accessibility imposed by fixed viewing locations. These limitations introduce gaps in the time series data that can mask the very subtle signals from the stars.

Astronomers have devised several ways to minimize the gaps in their time series data. One common method is for astronomers around the world to collaborate in observing the same star, so that as the star sets at one observatory, it is rising at the next. Of course, such multisite observations are still subject to the vagaries of the weather and optical distortions introduced by the atmosphere. The advent of the Space Age provided an opportunity for astronomers to loft their telescopes up above the distortions of the atmosphere and no longer be subject to interruptions in their observations caused by cloudy nights.

Space telescopes in low Earth orbit, like the Hubble Space Telescope, are only able to observe a target for part of the orbit when the target is not obscured by the Earth. With multiple telescopes in orbit, it is possible to achieve continuous coverage as one telescope takes over from another that is about to lose sight of a given target. Of course, space telescopes like the Hubble Space Telescope and its even larger successor, the James Webb Telescope, are extremely expensive to build and operate, which is why there isn't a fleet of such telescopes in space. This is where small satellites can fill a scientifically valuable niche.

The BRITE constellation comprises five nanosatellites operated by a consortium of universities in Austria, Canada, and Poland. BRITE stands for Bright(-star) Target Explorer and its purpose is to conduct time-series observations of the brightest stars in the sky. Since each BRITE satellite is a nanosatellite of size $20 \times 20 \times 20$ cm^3, the telescope aperture is necessarily small (only 30 mm in diameter), which means that it can only be used to study very bright stars (see Figs. 6 and 7). In this sense, it complements beautifully the excellent asteroseismic data produced by the Kepler mission (Molnár et al. 2016), which has a much larger telescope with a diameter of 1.4 m. In its search for planetary transits, which is Kepler's main mission, Kepler has discovered and observed many thousands of variable stars, but these tend to be quite faint and may not be suitable targets for other more precise follow-up observations.

3.1 Constellation Design and Development

The BRITE satellites were designed by the Institute for Aerospace Studies at the University of Toronto under the Canadian Advanced Nanospace eXperiment (CANX)

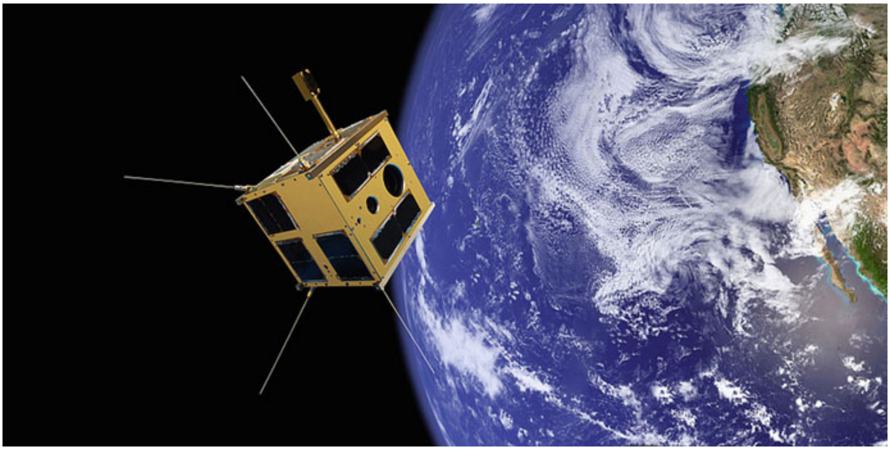

Fig. 6 Artist's conception of the BRITE-Austria satellite in space. (Image courtesy of the BRITE consortium)

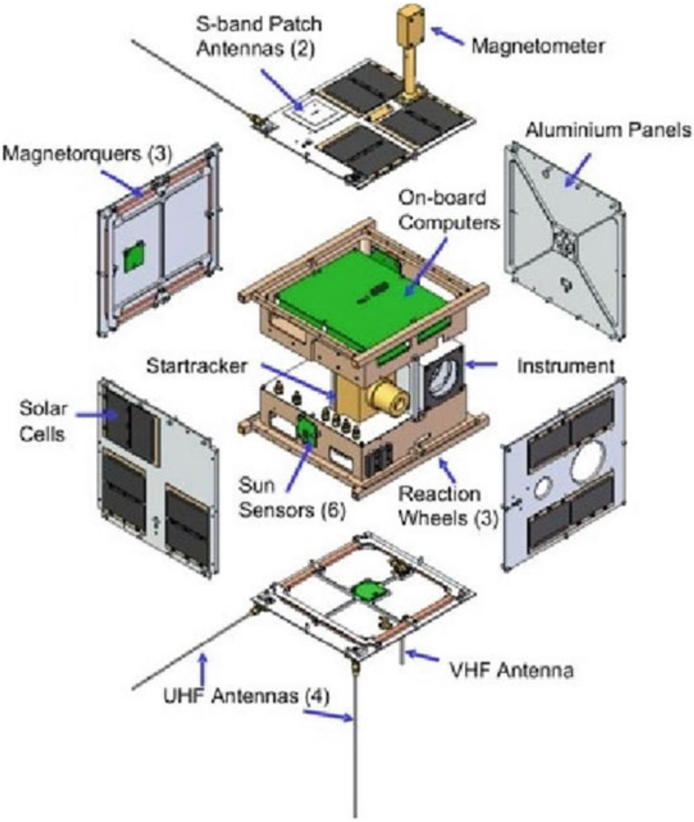

Fig. 7 Exploded view of the BRITE-Austria satellite. (Image courtesy of the BRITE consortium)

Program. Each satellite is a cube-shaped spacecraft with sides of 20 cm and a mass of 7 kg. Thin antennas and a magnetometer boom extend from the bus (see Figs. 6 and 7).

Since accurate pointing is a critical capability for targeted astronomy observations, each BRITE satellite has three orthogonal reaction wheels and three orthogonal vacuum-core magnetorquers for three-axis pointing and momentum dumping. This system provides pointing stability with rms of approximately 1–1.5 arcmin (corresponding to 2–3 pixels on the CCD).

Each satellite has three computers: a main onboard computer; an attitude determination and control system computer; and an instrument control computer. These three computers have the same design, built around an ARM7 processor operating at 40 MHz.

The satellites have six body-mounted solar cells on each face, except for the face with the telescope and star tracker apertures, which has only four cells. These solar cells give a maximum instantaneous power generation capacity of about 10 W, with a worst-case minimum power generation of 5.4 W.

The command uplink to the satellite is handled onboard by a UHF receiver. An S-band transmitter provides the primary downlink for data and telemetry. It uses two 5.5 cm × 5.5 cm patch antennas installed on opposite sides of the spacecraft to provide a nearly omnidirectional radiation pattern.

The science instrument on the BRITE satellites consists of a small refracting (i.e., lens-based) telescope and an uncooled CCD detector. The telescope objective has an aperture of 30 mm and effective focal length of 70 mm. The BRITE CCD detector is a 35.3 mm × 25.7 mm chip with 11 million 9 μm × 9 μm square 14-bit pixels. The CCD is not actively cooled, but there is a heater to provide thermal stabilization, if needed. The BRITE constellation collects data in two optical passbands (red and blue). As the optics on each satellite were optimized for either the red or blue filters, this means that each satellite observes in only one passband. Therefore, each of the BRITE partner countries (Austria, Canada, and Poland) contributed two BRITE satellites, one optimized for the blue wavelengths and the other optimized for the red wavelengths. Thus, two BRITE satellites must observe a given astronomical target simultaneously in order to acquire blue and red passband data. Table 2 shows the basic information for the BRITE satellites.

The two Austrian satellites were developed in a collaboration of the Space Flight Lab (SFL) at the University of Toronto Institute of Aerospace Studies (UTIAS), the

Table 2 Basic parameters of the satellites in the BRITE constellation

Institute of Communication Networks and Satellite Communications (IKS) at the Technical University of Graz (TUG), and the Institute for Astronomy of the University of Vienna. The Polish BRITE satellites were developed by the Space Research Centre of the Polish Academy of Sciences and the Nicolaus Copernicus Astronomical Centre of the Polish Academy of Sciences. The two Canadian BRITE satellites were developed by the Space Flight Lab (SFL) at the University of Toronto Institute of Aerospace Studies (UTIAS) under contract to the Canadian Space Agency.

3.2 Launching the Constellation

The BRITE satellites were launched as secondary payloads on a number of different launches. The two Austrian BRITE satellites were launched on 25 February 2013 from Sriharikota on an Indian Space Research Organization (ISRO) PSLV launcher. The first Polish BRITE satellite, BRITE-Lem, was launched on 21 November 2013, from Yasni, Russia, on a DNEPR launcher. The second Polish satellite, BRITE-Heweliusz, was launched from China on 19 August 2014 on a Chinese CZ-4B launcher. The two Canadian satellites, BRITE-Toronto and BRITE-Montreal, were launched together on a Russian Dnepr launcher on 19 June 2014, from Yasni in Russia. Unfortunately, BRITE-Montreal did not separate properly from the upper stage of the rocket and failed. Hence the final constellation has only five operational satellites (Table 2).

3.3 Operations

The BRITE satellites complete 14 orbits per day, yielding 6–7 passes per ground station. The operation and control of each individual BRITE satellite is the responsibility of each institution that receives funding from their respective national funding agency for their participation in the BRITE consortium. The BRITE constellation has ground stations in Graz (BRITE-Austria and UniBRITE), Warsaw (BRITE-Lem and BRITE-Heweliusz), and Toronto (BRITE-Toronto), which control and download the data from their national BRITE satellites, and they can also act as backups for each other.

Each BRITE satellite collects photometric data of stars in a $24^\circ \times 19^\circ$ field of view. The wide FOV ensures that there will almost always be several suitable on-chip comparison stars for differential photometry of the target stars. Since the start of operations in February 2013, BRITE has taken over 3.5 million measurements of some 500 stars. These observations have yielded new insights into the structure and evolution of stars.

The BRITE consortium is managed by the BRITE Executive Science Team (BEST), which oversees the evaluation of target proposals, generation of observing schedules, data analysis and archiving, and other aspects related to the overall management and control of the project. The BRITE constellation data archive is located at the Copernicus Astronomical Center in Warsaw. Although the BRITE constellation is currently funded and operated by Austria, Canada, and Poland, participation in the scientific activities of the consortium has been open the broader international scientific community from the outset to encourage the best scientific return from the project. In early 2020, the consortium announced that all data would henceforth be made publicly available immediately after acquisition, without any proprietary period through the BRITE data archive.

3.4 Scientific Results

Since the start of operations in February 2013, the BRITE satellites have acquired over 3.5 million high-precision photometric measurements of some 500 stars in two colors (red and blue) to study micropulsation, wind phenomena, and other forms of stellar variability. These BRITE observations are contributing to our understanding of stellar structure and evolution of the brightest and most massive stars in the galaxy and their interaction with their local environment. These massive BRITE target stars are important places for producing the chemical elements in our universe and recycling them in winds and supernovae.

The BRITE science community comprises over 60 scientists from Austria, Canada, and Poland, as well as other countries. The consortium has published over 70 conference papers and peer-reviewed papers. Preliminary science results have been summarized by Handler et al. (2017). The constellation is expected to continue to operate and provide scientifically valuable data beyond 2020, demonstrating that small, inexpensive nanosats can successfully carry out multiyear astronomy missions in space.

3.5 Lessons Learned

As the first operational nanosatellite-based space astronomy constellation, BRITE has encountered and overcome a number of challenges, such as unexpected radiation damage of its CCD detectors, radio interference issues impeding the communication between the satellites and the European-based ground stations, and systematic errors in the BRITE light curves. All of these challenges have been overcome, demonstrating that small, inexpensive spacecraft can serve as useful platforms for small telescopes in space to complement the scientific capabilities of the much larger telescopes in orbit.

4 Firefly: A CubeSat Mission for Atmospheric Lightning Research

Firefly is a 3 U CubeSat mission that was developed by Goddard Spaceflight Center and Sienna College under sponsorship of the U.S. National Science Foundation to study VLF, optical and gamma ray emission from lightning flashes in the Earth's atmosphere. The overall aim of the mission was to study the relationship between lightning and Terrestrial Gamma-ray Flashes (TGFs), which are sudden energetic bursts in the upper atmosphere. The TGF phenomenon was first reported in the open civilian scientific literature from data acquired by NASA's Compton Gamma Ray Observatory mission in 1994, but the origin of the flashes was unknown at the time. A subsequent study by Stanford University in 1996 linked a TGF to an individual lightning strike occurring within a few milliseconds of the TGF, suggesting a causal link between lightning flashes and TGFs.

It is thought that TGFs are produced by beams of very energetic electrons, which are accelerated in the intense electric fields generated by large thunderstorm systems. The objective of Firefly was to explore the link between lightning and TGFs and to determine which types of lightning produce these electron beams and the associated TGFs. To confirm the connection of TGFs with lighting, the Firefly mission was designed to observe lightning strikes simultaneously in the optical, radio and gamma-ray wavelengths (Fig. 8). This was the first time that such simultaneous multiwavelength measurements of lightning storms were collected from space.

4.1 Firefly Design

The Firefly was a 3 U nanosatellite, designed to be deployed by a P-POD deployer. The spacecraft was attitude controlled to point within 20° of nadir using a 3-meter-long gravity gradient boom that also served as a monopole antenna element for the

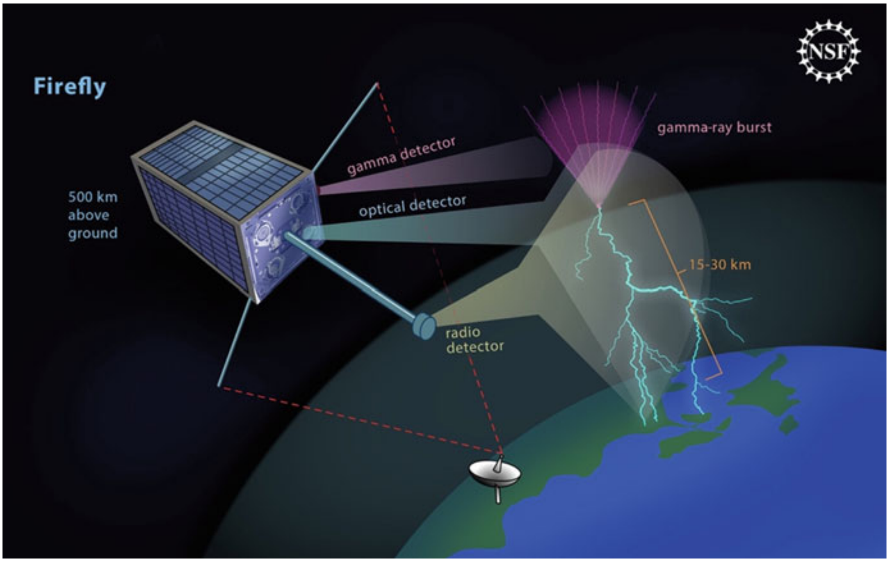

Fig. 8 Schematic representation of Firefly's observation and data relay functions. (Image courtesy of Zina Deretsky, National Science Foundation)

VLF radio receiver system. The optical photometers and gamma ray detector were on the nadir-facing end of the spacecraft. The communication antennas were also on the nadir side of the spacecraft. The zenith facing end of the spacecraft contained most of the spacecraft bus components, such as the flight computer, radio, electrical power system, batteries, GPS receiver, GPS antenna, magnetometer, as well as the power switching and detector interface circuitry. The sides of the spacecraft had either 6 or 7 body mounted solar cells, depending on the side. Figure 9 shows a schematic view of how the various subsystems in the spacecraft were arranged.

4.2 Launch and Operations of Firefly

The Firefly nanosatellite was launched from Wallops Island on 19 November 2013 on an Orbital Sciences Corporation Minotaur-1 rocket as a secondary payload on the ORS-3 (Operationally Responsive Space-3) mission of the U.S. Department of Defense.

First contact with the satellite was achieved on 6 January 2014. The data showed that the spacecraft was healthy and transmitting a strong signal. Not surprisingly, the data volumes on the spacecraft had been filled, as expected, given that the spacecraft had been acquiring data from its onboard sensors since shortly after launch on 19 November 2013.

The Firefly satellite captured over 60 high time resolution measurements of lightning and gamma ray activity, contributing to our improved understanding of lightning physics and the link between electron acceleration in lightning strikes and Terrestrial Gamma Ray Flashes.

With no propulsive capability of its own, Firefly was unable to maintain its altitude and its orbit decayed. Firefly reentered the atmosphere on 1 November 2017. At the time of reentry, the satellite was still operational. In addition to its scientific contributions, the Firefly project also had several educational outcomes. Some 30 undergraduate students were involved in the project, either at universities or as interns at NASA's Goddard Space Flight Center.

5 CubeSats in the Life Sciences: Thinking Inside the Box

Satellites have been used as research platforms by the space life sciences community from the earliest days of the Space Age. The first microbiological experiments were carried out in 1960 using *E. coli* onboard the Soviet Korabel-Sputnik-2 satellite (sometimes referred to as Sputnik 5) and *Clostridium sporogenes* onboard the United States' Discoverer 17 satellite (the life science experiments provided the scientific cover for the real mission of this satellite, which was reconnaissance). Subsequent experiments on microorganisms in space were performed using the uncrewed Russian Foton capsules and the European Retrievable Carrier (EURECA), or crewed spacecraft, such as the space shuttles, and space stations, such as Skylab, Mir, and the International Space Station, which allowed possibilities for the return of samples for further post-flight study on Earth. These early experiments have been described by Dickson (1991) and Zea et al. (2014).

In all such cases, the life science experiments were secondary to the main purpose of the mission, meaning that the experiments had to be designed around the main mission. The advent of CubeSats has allowed the spacecraft to be designed around an experiment's scientific objectives, and not the other way around. The leader in using CubeSats for microbiological research is NASA's Ames Research Center, which has built and flown several life science missions in the CubeSat form factor, demonstrating that CubeSats are viable, cost-effective platforms for certain kinds of life science research in space.

5.1 GeneSat-1

The first CubeSat-based life science experiment to fly in space was GeneSat-1, a 3 U CubeSat with a mass of 6.8 kg, which was launched on 16 December 2006. GeneSat-1's scientific objective was to characterize bacterial growth and metabolics using *E. coli* as the model organism. This required creating a controlled environment onboard the satellite to allow bacteria to grow in space. In terms of payload requirements, this meant a microfluidic payload comprising a well plate that had to be operated in microgravity, with temperature regulated to within 0.5 °C of the set point temperature of 34 °C. The payload contained a growth medium and illumination source to excite fluorescence in the microorganisms in 100 μl wells in the well plate. There were also optical sensors required to measure gene expression in the test subjects. Observations of the ratio of fluorescence to scattering in the microorganisms allowed scientists to quantify gene expression in those organisms. In addition to the life science payload, there was also a secondary STEM mission which used a radio beacon operating in the amateur band. GeneSat-1 was designed, built, and operated as a technology demonstrator to prove that it is possible to conduct biological research on a small satellite. In this regard, the mission was to pave the way for other CubeSat-based life science missions that followed.

5.2 PharamaSat

PharmaSat was the first nanosatellite to host a competitively peer-reviewed bioscience experiment. The scientific goal of the mission was to study the effects of microgravity on growth and metabolism of the yeast *S. cerevisiae*. The experiment also investigated the efficacy of antifungal agents under microgravity conditions. The scientific payload comprised a well plate to accommodate the specimens. It needed the capability to provide nutrients for growth and to introduce antifungal agents into the wells in the well plate. This required a miniaturized microfluidics system with pumps and valves. It also needed sensors to measure the optical density in the wells to determine culture growth and it needed to transmit the payload conditions and observations back to Earth.

The 3 U PharmaSat had a mass of 5.1 kg and made use of the 1 U bus developed for GeneSat-1. The attitude determination and control system (ADCS) was based on magnetotorquer rods that aligned the antenna to point to Earth and damped wobble. The data was transmitted in S-band at a rate of 960 bps. The science payload was contained within a pressurized and heated 1.2 l volume. Two 2 W heaters maintained the temperature of the fluidics card within 0.3 °C of 27 °C.

PharmaSat was launched as a secondary payload on a Minotaur 1 rocket 19 May 2009 from Wallops Flight Facility and placed in a 410 km, 40° inclination circular orbit. The satellite reentered on 4 August 2010; it was still operational at that time. The PharmaSat mission revealed that yeast grew more slowly in microgravity conditions than controls on Earth, but also suggested that yeast could continue to have limited metabolic activity at higher antifungal concentrations in space than on Earth. This finding could have could have significant implications for the treatment of fungal infections in microgravity conditions. The scientific findings of the mission were published by Ricco et al. (2020).

5.3 *E. coli* AntiMicrobial Satellite (EcAMSat)

With several space agencies contemplating a return to the Moon and onward exploration of Mars, maintaining the health of astronauts during long-duration space missions will be paramount. Crews will be exposed to a number of pathogens, and it is important to understand whether these pathogens behave differently in microgravity conditions in space than they do on Earth. Previous space experiments have reported increased virulence and antibiotic resistance of microorganisms under such conditions. This, combined with a depressed immune response observed in astronauts, suggests that there may be an increased risk of opportunistic bacterial infections in space.

The EcAMSat mission is a 6 U mission that was launched in 2015 to study the effects of microgravity on the antibiotic resistance of *E. coli*, a bacterial pathogen that is common in humans and animals. EcAMSat was developed jointly by NASA's

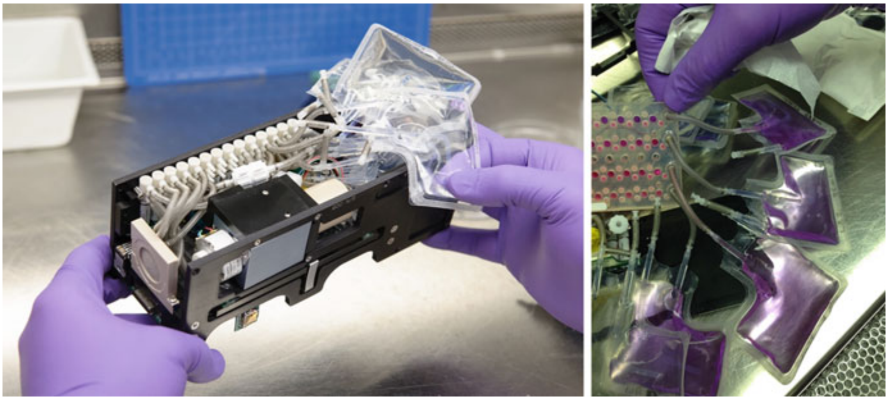

Fig. 10 The experimental module in EcAMSat (left). Bags containing nutrients are connected to a microfluidics card (right), where samples of *E. coli* are cultured in 48 small wells. The card is sandwiched between two heaters to maintain the temperature in the wells to within one degree of 37 °C. (Images courtesy of NASA/Ames Research Center)

Ames Research Center and the Stanford University School of Medicine. The satellite was launched on the ELaNa-13 mission on 11 November 2017 on board the Cygnus CRS-8 uncrewed resupply craft to the ISS, where it was deployed via the JEM airlock on 20 November 2017.

EcAMSat's payload (Fig. 10) contained a 48-microwell fluidic card that allowed study of bacterial cultures at constant temperature. A fluid-delivery system provided a growth medium and predefined concentrations of the antibiotic gentamicin, a common treatment for urinary tract infections (which have been reported in astronauts). Measurements of optical absorbance by the cell suspensions were made at three wavelengths for each microwell. These measurements provided an indication of cell growth in each well (Matin et al. 2017).

The experiment began with elevating the temperature of the well plate to 37 °C. Once the temperature was stabilized, one-sixth strength Luria broth (a nutritionally rich growth medium) was added to all the microwells to initiate the experiments. The cells remained in the concentration of Luria broth for 48 h. Their growth was monitored by measuring the optical transmission through the wells. The cells were then challenged for at least 46 h with three different doses of gentamicin (Gm); zero Gm served as a control. The redox-based indicator alamar Blue was then added and its reduction was followed to measure the effect of the antibiotic on cell metabolic activity. Optical measurements were recorded every 15 min at red, green, and blue wavelengths for each well over the course of the 156.5-h experiment. The experiments showed that the two strains of *E. coli* investigated both exhibited slower metabolism in microgravity, consistent with results from earlier smallsat missions. The results also showed that microgravity did *not* enhance uropathogenic *E. coli* resistance to gentamicin; in fact, both strains were more susceptible to gentamicin in microgravity. Full results have been reported by Padgen et al. (2020).

6 Mars Cube One (MarCO)

CubeSats have also been proposed for a variety of lunar, deep space, and planetary exploration missions, though only two have actually flown as of this writing. Mars Cube One (MarCO) is the first CubeSat form-factor spacecraft to operate successfully beyond Earth orbit in a deep space mission; actually, it was a *pair* of spacecraft.

The mission concept was to use a pair of CubeSats to support the atmospheric entry, descent and landing phases of NASA's InSight Mars lander. Both spacecraft were 6 U CubeSats, each with a mass of 13.5 kg, and the mission was to test new miniaturized communications and navigation technologies developed at JPL. These were the first CubeSats to operate beyond Earth orbit, and aside from their communications relay function, they also tested the endurance of CubeSats in deep space.

The two CubeSats, dubbed MarCO-A and MarCO-B, were launched on 5 May 2018, together with the InSight Mars lander. Shortly after launch, the two MarCO spacecraft were separated to fly on their own trajectory to Mars in order to demonstrate the CubeSats' endurance and navigation capabilities in deep space. During the cruise phase, the two MarCO spacecraft were kept about 10,000 km away from InSight. This distance was reduced as the three spacecraft approached Mars. The closest flyby distance to Mars was 3,500 km on 26 November 2018.

During their Mars flyby, the two MarCO spacecraft provided a real-time communications link to Earth for InSight during its entry, descent, and landing (EDL) phase. This relay was vital, because the EDL of InSight occurred on the side of Mars that was out of line of sight from the Earth at that time. The EDL information from InSight was transmitted in the UHF band at 8 kbit/s to the CubeSats, which then relayed the data in X-band to Earth at 8 kbit/s. The MarCO spacecraft used a deployable solar panel for power, but because of the limitations in solar panel efficiency, the power for the X-band frequency was only about 5 watts.

For the CubeSats to relay the information to Earth, they needed a high-gain (i.e., highly directional) antenna that would be reliable, meet the low mass specifications, have low complexity, and be affordable to build. Three possible types were assessed: a standard microstrip patch antenna, a reflectarray, and a mesh reflector. With the small, flat, antenna size required for the CubeSats, MarCO's design engineers chose a reflectarray antenna made up of three folded panels connected to the body of the CubeSat. Figure 11 shows the general layout of the two MarCO spacecraft.

In addition to its communications payload, each MarCO spacecraft carried a miniature wide-angle camera that was used to verify deployments. Figure 12 shows an image taken by one of the MarCO spacecraft during its Mars flyby on 26 November 2018.

The MarCO spacecraft had a propulsion system with eight cold gas thrusters for providing desaturations for reaction wheel momentum buildup and thrusting to change the spacecraft trajectory. Prior to the Mars encounter the propulsion system made five small corrections to ensure the two small spacecraft were on the correct trajectory to support the Insight Lander during its EDL phase.

The MarCO spacecraft retransmitted the InSight lander's telemetry during the landing, which demonstrated the new relay system and technology for future use in

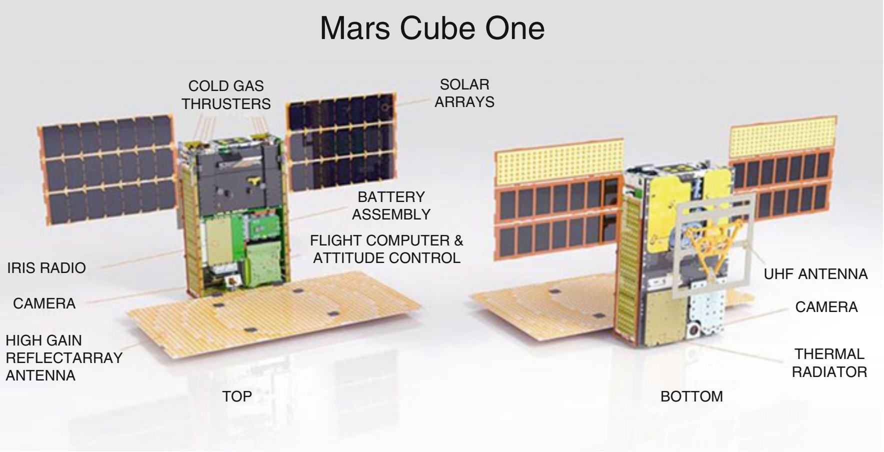

Fig. 11 The MarsCubeOne (MarCO) spacecraft are a pair of 6 U nanosatellites, each with a mass of 13.5 kg. (Image courtesy of NASA JPL)

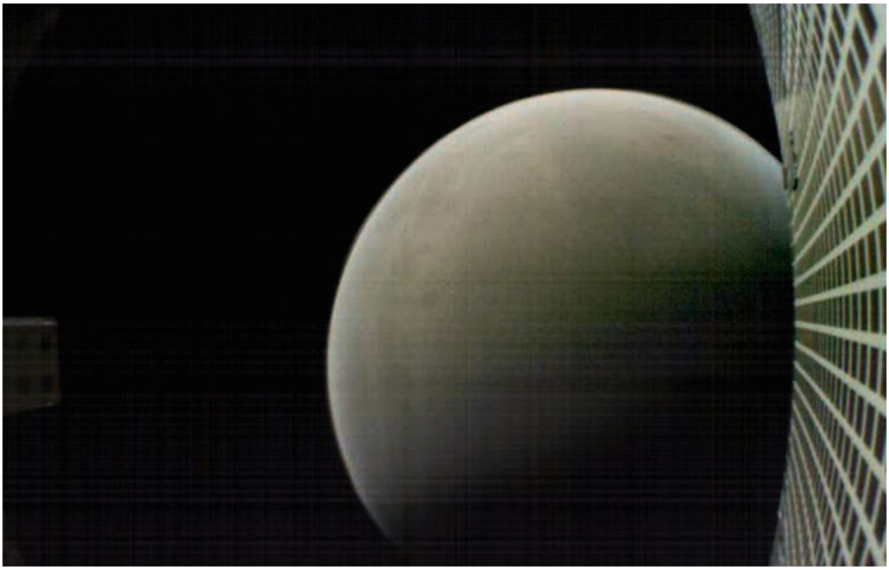

Fig. 12 Image of Mars taken by MarCO-B during its flyby of the planet on 26 November 2018. The spacecraft was at a distance of 6,000 km from the Red Planet when this image was taken at about 12:10 p.m. PST while MarCO-B was flying away from the planet, after InSight had touched down on the planet's surface. (Image courtesy of NASA/JPL)

missions to other Solar System bodies. This provided an alternative to orbiters for relaying information and achieved a smallsat technology development milestone. Having completed their primary mission, the MarCO spacecraft continued in their elliptical orbits around the Sun. The last transmission received from the CubeSats was on 5 January 2019.

The success the MarCO CubeSats achieved in relaying telemetry from NASA's InSight Mars lander demonstrates that such small spacecraft can play important roles in future deep space missions. Indeed, a number of CubeSat missions are planned for cis-lunar space and beyond. The Artemis 1 mission to the Moon, currently scheduled to launch some time in 2021, will carry a dozen or more CubeSats as secondary payloads. Each CubeSat is being developed by a different team, with different scientific goals. Among these will be CubeSats with the Moon and near-Earth asteroids as their destinations. CubeSats, with their inherent power, data, and propulsion limitations, will not replace the larger, more capable spacecraft for deep space exploration, but they have a place in supporting space exploration, such as providing complementary vantage points for simultaneous observations. As such, they can be a cost-effective way of enhancing the scientific return of deep space and planetary exploration missions.

7 Conclusion

In this chapter, it has been shown how smallsats can be useful platforms for scientific research. Although they can be used individually, smallsats come into a class of their own when used in numbers to address problems that require distributed simultaneous observations. The smallsat missions discussed in this chapter have all flown in space and show that smallsats can be effective platforms to perform useful scientific observations and experiments in space. As with any new technology, the early adopters of these smallsat platforms for science are encountering unanticipated technical problems and challenges, but the scientists confronting these challenges today are paving the way for others that will follow in the not too distant future with more capable smallsat missions for scientific research in space.

Traditionally, participation in space exploration has been the preserve of national space agencies, large aerospace corporations, and a few prestigious universities. Smallsats are lowering the technological and financial entry barriers to participation in space exploration, allowing many more universities and nongovernmental entities to participate in exploration endeavors. While a greater and more diverse number of space actors engaging in space exploration is good for science in general, their activities must be carried out in a responsible manner to avoid creating space debris, causing interference with the space activities of other space actors, posing risks to spaceflight safety, or causing biological contamination of the surfaces of other celestial bodies.

There have already been two well-documented instances of deliberate, irresponsible behavior by new space actors that have raised numerous questions about how to promote and ensure responsible behavior and chain of custody, jurisdiction, and control of objects launched into outer space (Henry 2018; Johnson et al. 2019a, b, c).

Regulators will have to balance the interests of the new space actors in space exploration with their obligations under applicable domestic regulations and international law. The regulatory processes for short duration missions as addressed elsewhere in this Handbook provides useful guidelines for scientific missions of this type.

Scientists who make use of the new capabilities offered by nanosatellites to carry out scientific research in space would be well advised to acquaint themselves with the international and domestic regulatory frameworks for conducting space activities and the norms of behavior to promote the sustainable exploration and use of outer space, which are contained in international standards, best practices, and guidelines. The *Handbook for New Actors in Space*, published by Secure World Foundation (2017), provides a very accessible introduction to these issues for a general audience.

Small Satellites and Hosted Payloads for Technology Verification

Joseph N. Pelton

Contents

Abstract

The early days of satellite applications often began with the development of a half or even full-scale engineering models for the purpose of technology verification. These engineering models were fabricated and tested with many key components designed, tested, and subjected to full-scale design reviews before production satellites were developed. In some cases various renditions of prototype models or full-scale subsystems were even flown in orbit to prove the reliability or functionality of such new components of the new generation of satellites. This technology verification was, of course, quite expensive. In the case of geosynchronous satellites, where there were only limited orders for perhaps four to six operational satellites, the result was that some 40% of the cost was invested in R&D and nonrecurrent development and technology verification costs.

Today, in the case of development and manufacturing for large-scale small satellite constellations, the approach can be quite different. The approach

J. N. Pelton (ed.), *Handbook of Small Satellites*,
https://doi.org/10.1007/978-3-030-36308-6_37

to technology verification and manufacturing of reliable small satellites for large-scale constellations can be much different in several ways. This is particularly true in the case of constellations involving significant production runs in the range of hundreds to even many thousands of satellites.

One Web, a year prior to their bankruptcy proceedings, launched six of this first run of “pre-operational” satellites to test their performance technically as well as operationally. In such cases these early test operations not only prove and verify the payload and spacecraft bus capabilities but also allow tests of the ability to avoid interference to geosynchronous satellite networks.

Another newer option is to use the hosted payload systems to carry out performance testing of components or the launch of several CubeSat test satellites as a cluster of technology verification flights. This can be more cost-effective than a separate experimental satellite flight.

The use of small satellites and hosted payloads allows a totally different approach, and more cost-effective approach to research, development, technology verification, and in-orbit test of very small components such as application-specific integrated circuits and electronic switching systems or routers. These new options can allow in-orbit verification tests at much more modest cost.

In short, small satellites as well as hosted payloads offer a range of new possibilities. These various options allow for low-cost test of new technology, verification of components, and use of hosted payloads or small satellites to prove, in-orbit, key new technology. There are now programs specifically designed to use hosted payload systems to carry out verification of new systems or in-orbit lifetime testing. New launch offerings including deployment of CubeSats and almost up to 1 m^3 satellites from the International Space Station have contributed to the cost-efficiencies of such test flights.

This chapter thus outlines the many ways that small satellites and hosted payloads can offer important improvements for the design of satellites to achieve improved performance, longer life, and lower costs. These new options improve the ability to provide for quality testing and verification in the design and manufacture of not only for the entire small satellite and its design but also allow assessment of the performance of components in hosted payload packages and even allow for improvements in the design and reliability of larger-scale MEO and GEO satellites. Small satellite testing can thus aid large satellite design, manufacture, reliability, and performance for all types of satellites – large and small.

1 Introduction

The uses of small satellites are diverse and continue to grow as the utility and cost-efficiency of this type of spacecraft continue to expand. There are useful ways to use small satellites and small packages on large satellites to demonstrate the validity of new technology and systems as well as to carry out effective experiments and lower cost. The past historical experience of the satellite industry is highly relevant. The first needs of the global market for international telecommunications dictated very rapid growth and the expanded use of GEO systems and lower cost ground systems, but as the commercial demand began to peak and the need for mobile services emerged, new patterns of use and spacecraft design emerged. Thus this chapter begins by reviewing this history.

2 Historical Background

The evolution of commercial satellite technology moved quite rapidly in its earliest years. One example of this rapid increase in spacecraft performance can be shown in the improved throughput capability of Intelsat satellites in terms of telephone circuit capacity and television capacity between 1965 and 1986. This expansion of throughput capability by a factor of some 250 times in only two decades is shown in the following table (see Table 1) (Pelton et al. 2004).

In this rapid growth environment, worldwide demand soared as the cost of international telecommunications services plummeted. The demand was met with larger and more sophisticated satellites that were higher in power and included higher gain antennas and extensive reuse of radiofrequency spectrum. This increase in satellite size, technology, and performance allowed the cost of user terminals to drop rapidly. Indeed, this so-called technology inversion allowed ground stations

Table 1 The rapid increase of Intelsat satellite service capacity between 1965 and 1986

Satellite type	Year first deployed	Throughput capacity	Key new technologies
Intelsat 1 and 2	1965 and 1967	240 voice circuits	GEO-squinted beam antenna
Intelsat 3	1968	1200 voice circuits plus 2 TV channels	Spin-stabilized platform, conical higher-performance antenna
Intelsat 4 **Intelsat 4A**	1972 1976	4000 voice circuits plus 2 TV channels/6000 voice circuits plus 2 TV channels	Improved spin-stabilized platform, more transponders, higher gain antenna
Intelsat V	1981	12,000 voice circuits plus 2 TV channels	Three-axis body-stabilized platform, much higher gain antennas, spot beams
Intelsat VI	1986	60,000 voice circuits Plus 2 TV channels	Higher gain antennas, TDMA digital technology, improved spot beams

to decrease from 30 m dishes weighing over 20 t (and staffed with a crew of some 60–70 people) down to VSAT terminals 1 m in size and with no full-time staff required. The abrupt increase to more and more sophisticated satellite technology involved risks as to possible satellite failures due to unproven systems. The Intelsat III “despun” antenna, for instance, froze. This new type of antenna assembly rotated at about 60 rpm as the spinning satellite body spun in the opposite direction at 60 rpm. This arrangement allowed constant pointing of a higher gain antenna to the Earth below with increased accuracy. Rapid reengineering of the antenna bearings had to be undertaken, and the tolerance and lubricant for these satellites “despun mechanism” were changed. This rapid recovery was a success, but in this period of incredible growth, there was no timetable to allow in-orbit tests of the bearing structure (Pelton and Snow 1977).

When the Intelsat V satellite was being first designed, there were two conflicting designs. One anticipated a modest doubling in capacity through higher gain antennas and spot beam designs. The other was for a much more dramatic increase in technology with satellite spot beam and use of more complex switching technology known as the Harrington V – after the Vice President of Technology at Comsat at the time. This more ambitious approach was predicated on the creation of an experimental test satellite that would prove the viability of all the new technologies envisioned in such a new satellite design. The memory of the stuck “despun” Intelsat III remained with the Comsat engineers and Intelsat management committee. Ultimately it was decided that the Harrington V with an experimental test satellite and a series of new technologies represented too high of a risk. The lower-risk design for the Intelsat V was chosen. This approach did not require in-orbit experiments and technology verification. This decision was seen as the right commercial decision. At the time small satellite technology, small satellite constellations, and even small satellite experiments were not even considered an option. GEO satellites in Clarke orbit for telecommunications and radio and TV broadcasting were the predominant commercial satellite applications model. They were predominant because they could work in tandem with very low-cost dishes that could be constantly pointed to satellites without tracking. As the number of satellite dishes that could work to GEO satellites expanded into millions, this approach to commercial satellite services became a solidly entrenched paradigm. No viable design for low-cost tracking ground stations capable of working to LEO satellite networks existed.

The first significant change in how to design, test, verify, and manufacture application satellites for a global commercial market came with the small satellite constellations designed for low Earth orbit services that came in the 1990s. These low Earth orbit (LEO) systems included Iridium, Globalstar, and ICO, all of which were designed to provide new mobile satellite communications services to handheld units. In addition there were also the Orbcomm smallsat network for storing and forwarding data relay or machine-to-machine (M2M) communications. In the case of these services, the ground systems had to be able to track the LEO satellites or provide some form of an omni-antenna for system users that could receive the signal at all angles as it moved across the sky.

The key to these new services was the design of user antennas or transceivers to be used on the ground. What was important to the design of satellite hand phones that could talk to orbiting small satellites in LEO constellations were application-specific integrated circuit (ASIC) chips. These computer chips were vital to the improved performance of these new user devices in terms of performance and reduced costs. This new ground antenna technology enabled the performance of the various small satellite constellations that were deployed in LEO orbits beginning in the late 1990s. The design of such networks with 50–70 satellites in a constellation changed many aspects of how to design, verify performance, manufacture, and test the satellites for these new types of satellite systems.

It should be noted that this was not entirely new in that the US Department of Defense did deploy an Initial Defense Satellite Communications System (IDSCS) in 1965, but this was abandoned in favor of GEO systems after the success of the Intelsat system was also demonstrated in 1965. Also the Amateur Radio League did deploy its OSCAR satellites in LEO orbit, but these and other examples were the exception to the main thrust of commercial satellite applications.

In many ways the Iridium system was the technological leader in this effort to deploy LEO constellation for commercial satellite services. Its design was different in many ways. Instead of spot beams formed by a large reflector, the Iridium system used phased array antennas to form 37 beams (i.e., 12 beams formed with 3 different phase array systems plus a further beam directly downward). The Iridium network also included inter-satellite links (ISLs) that were key to the sparing philosophy for the system. This approach also reduced the cost of ground based network for tracking, telemetry, and command (TT&C).

Instead of launching experimental small satellites to test and verify performance of satellites for the Iridium system, it was decided to manufacture 100 satellites for the 66 satellite constellation with the idea that the earliest satellites for the constellation would test the performance and reliability of the network's design. The plan was that if flaws were detected with earlier satellite deployed, that adjustment could be made to satellites in the later production runs as needed. The 34 satellites beyond the 66 satellites needed for populating the full constellation could be built at modest incremental cost.

It was anticipated that some design upgrades could be made, modifications might be possible to extend lifetime, and most importantly the longer production run could provide for sparing if earlier satellites should fail. This philosophy was generally successful in that the network was first conceived of having a 7-year lifetime from 1997–1998 to 2004–2005, but the initial constellation lifetime extended to 2017–2018 or an amazing 20 years.

The thought was that any satellites not required could always not be launched to save on the total system cost.

Later LEO constellation satellite systems that were designed and deployed starting over a decade later such as the 3-unit CubeSats known as "Doves," as deployed by Planet Labs, in many ways perfected this approach. The first of the "Doves" were seen as prototypes and launched in small numbers, often as piggyback launches one or two at a time. When the design and performance were considered improved, then the shift was made to launching a large number at a time. This culminated in the launch of 88 “Doves” that were placed into orbit on an Indian Polar Satellite Launch Vehicle on February 14, 2017 (Graham 2017).

The price of the launch of experimental or technology verification missions is sufficiently costly that the number of such launches is limited. Nevertheless the history of the last 7 years and projections for the future as proved by Northern Sky Research shows that there have been a fairly constant number of such launches. Further projections for the future suggest that this level will likely continue for the future as more and more satellites are launched for Earth observation, communications, scientific, and other purposes. The dark blue (Technology Development) as indicated in Fig. 1 shows this forecast for the future.

The high cost of experimental satellite launches to test performance and verify new technology has limited this approach for the commercial satellite industry. The approach that has proven quite feasible and has come into more and more frequency use has been to put experimental packages and developmental performance or lifetime testing subsystems on board large missions as hosted payloads. Intelsat carried a router experiment known as IRIS (Internet Routing in Space) on one of its satellites as an experiment for the US Department of Defense that flew in 2009. Inmarsat developed the Alphasat hosted payloads set of experiments that was launched in 2013. The Hosted Payload Alliance has grown and matured since its formation a decade ago. One of prime functions of hosted payload missions has proved to be the test of new technology, regardless of whether these packages have been to test technology for small satellites or perhaps for larger satellites in MEO or GEO.

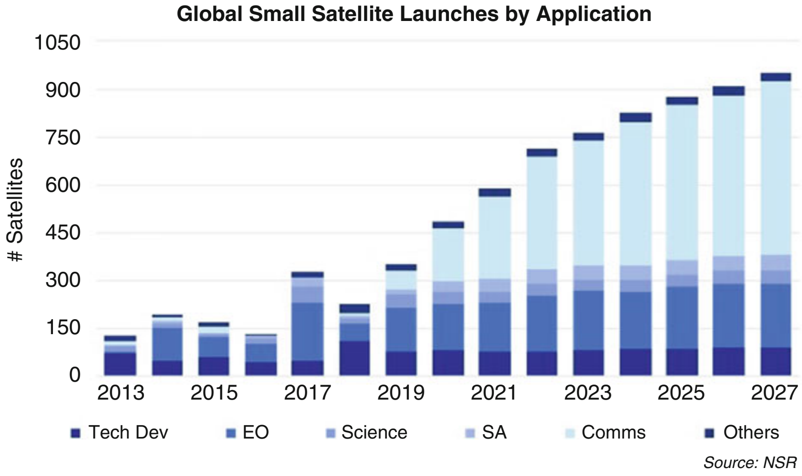

Fig. 1 Northern Sky Research projections of small satellite launches by function. (Source: Courtesy of Northern Sky Research)

3 IRIS Router on Intelsat

One of the early uses of a hosted payload onboard a satellite was to test a key new technology in an experiment known as the Internet Routing in Space (IRIS) as developed by Cisco and then flown as a package attached to the Intelsat 14 satellite. The purpose was to test the viability of onboard routers in order to prove the viability of "smart capability" on a satellite and in particular to assess the value of onboard frequency allocation. This thus became a low-cost way to provide a test of onboard signal regeneration and routing of signals to respond to changing demand. This test was the first instance of the US Department of Defense's Joint Capabilities Technology Demonstration (JCTD) providing a grant to commercial organizations to develop new technology and have it demonstrated in orbit on a commercial satellite (Cisco 2009).

Don Brown, then Vice President of Intelsat General for Hosted Payload, was quoted saying: "IRIS is another example of how hosted payloads allow rapid demonstrations and introductions of powerful new space technologies. This project took less than 3 years from start to launch, showing that the government can evaluate a pivotal new technology in space within a very short period." (ibid.) (see Fig. 2).

There were a number of other hosted payload experiments that preceded and followed on to the IRIS experiment. These included (i) the X-band communications package that flew on the Anik G1 satellite; (ii) the Wide Area Augmentation Service (WAAS) package designed to augment the accuracy of GNSS services provided by GPS Navstar satellites that flew on the Galaxy 15 satellite; and (iii) the UHF package that is flying on the Intelsat 22 satellite. These various hosted payload flights are all examples of technology verification flights (Pelton and Madry 2018).

4 ESA's Alphasat Project (Also Known as Inmarsat 4A-F4 or Inmarsat XL)

Alphasat was launched into geosynchronous orbit at 25° East on July 25, 2013. This launch occurred from the European Spaceport in Kourou, on an Ariane V ECA which is the latest configuration of this heavy-lift launcher. The prime mission for this very large and complex satellite with a mass of 6649 kg (14,659 lb) was to provide mobile communications satellite services for the European, Middle Eastern, and African regions of the world and to supplement the capabilities of the other series of four Inmarsat satellites. This was one of the largest satellites ever launched into GEO and is at the opposite extreme of what might be called a small satellite.

Yet the Alphasat part of the mission, as funded by the European Space Agency, was designed to offer a number of opportunities for hosted payloads to undertake technology verification for new smaller satellite space programs to be tested during the 2013–2016 period designated for these ESA-fund experiments.

This Alphasat experimental undertaking proved to be quite successful for the initial 3-year in-orbit demonstration period. This program jointly administered by ESA and Inmarsat and carried out under a public-private partnership agreement was extended for an additional 3 years that began on January 1, 1917 and ended on December 31, 2019 (https://artes.esa.int/news/alphasat-hosted-payload-extension).

The four extended verification tests that were conducted on the ESA-funded Alphasat programs were as follows (Alphasat I):

- **DP1**: This hosted payload package was developed to test a further evolution of an advanced design for an advanced LCT (Laser Communication Terminal). This test of laser inter-satellite links (ISLs) and laser communications terminal (LCT) design constitutes a continuing development of already existing flight hardware that ESA has funded and tested. Thus this latest LCT experiment is an extension of the developments associated with the TerraSAR-X, NFIRE, and TanDEM-X tests. All of these tests were designed to create a reliable and high-performance data link via laser communications to connect satellites in GEO and low Earth orbit. The objective of these high-data rate transmissions was to test optical links operating at 1064 nanometers with data speeds of up to 1.8 gigabit per second. This test is also used for comparative purposes of inter-satellite link operating in the extremely high frequency via Ka-band ISL developed by Tesat-Spacecom (Germany). The payload was funded by DLR, the German Space Agency.
- **TDP5**: This experimental package tested the transmission reliability of two experimental Q/V-band communications transponders. In particular it examines the sustainability of service during heavy rain rate conditions and the precipitation attenuation mitigation techniques. This type of testing will continue to be the key for many of the new small satellite constellations for communications and networking that are intended to operate in these extremely high-frequency bands such as the Starlink constellation and others planning to operate in the Q/V-band. This technology verification and demonstration package was developed by TAS-I and space engineering of Italy.

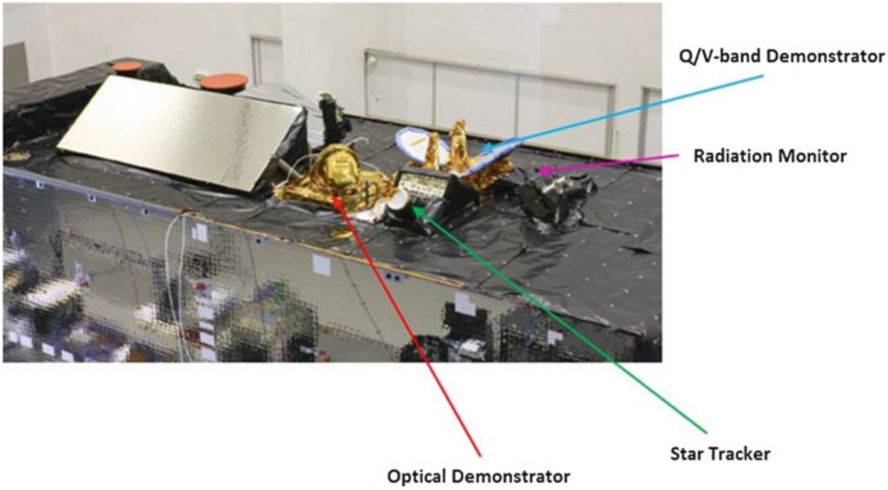

Fig. 3 The massive Alphasat/Inmarsat XL spacecraft under construction with location of the four hosted payloads identified. (Graphic Courtesy of the European Space Agency)

- **TDP6**: The hosted payload project was designed to demonstrate the performance of an advanced Star Tracker with and new type of active pixel detector. This experimental package was developed and built by Jenoptik of Germany.
- **TDP8**: This hosted payload project undertook to demonstrate the performance of an environment effects facility. The purpose of this project was to monitor the GEO radiation environment and its effects on electronic components and sensors. The results of these extended experiments can be useful in the future to the design of both commercial and scientific satellites. This hosted payload experiment was developed by Effacec of Portugal.

These various experiments in the form of hosted payloads are examples of how hosted payloads can provide cost effective technology verification programs. Such an approach allows a form of small satellite mission without the need for separate launches and separate operational control of in-orbit satellites and also allows shared access to common source of energy and a stable three-axis platform. The graphic below shows the four experimental packages for technology verification on the massive Inmarsat XL platform (see Fig. 3).

5 Cost Associated with Hosted Payload Missions

Although the costs associated with a hosted payload can be considered to be lower than a dedicated mission which entails a dedicated arrangement for launch services and other costs associated with launch insurance and operating costs, there are still substantial costs involved. The results of a study carried out by NASA engineers of

Langley Research Center sought to assess the costs and benefits of such a hosted payload approach to experimental packages came up with the assessment of five different projects. The conclusion from their study assessment as to total implementation costs except for operational costs varied from $6.6 million at the low end and up to $15 million for a projected 50 Kg payload. The projects that were evaluated included (i) two L-band experiments launched in 2005 on Telesat and Intelsat satellites; (ii) a VHF communications package on an Orbcomm satellite to validate the ability to provide automatic identification services in 2008; (iii) the IRIS router on the Intelsat 14 in 2009; (iv) an infrared sensor on an AGS satellite in GEO; and (v) a UHF package that flew on an Intelsat satellite in 2012 (Andraschko et al. 2019) (see Table 2).

What is significant with regard to the data collected in this comparative study of hosted payloads undertaken to demonstrate and verify technology with regard to new types of satellite services and key technical systems is the similarity of the costs per kilogram for these various experimental packages. The cost per mass of these technology verification missions did not vary significantly across these five packages. Thus even though there were different governmental agencies conducting the experiments, different suppliers of the payloads, different spacecraft system operators, and different providers of the launch services. The results on the cost of hosted payload were summarized by the NASA analysts in this way:

> The model indicates that the payload hosting costs increase by about $0.175M per kilogram. The result is that the model estimates a cost of $15M to host a notional 50 kg payload. (ibid.)

The advantages that hosted payloads provide, however, would seem to decrease as the cost of launching payloads decrease as new and more cost-efficient launchers optimized for small satellites come online. New providers such as Vector, Rocket Labs, and LauncherOne by Virgin Orbit and nearly a dozen new start-up companies are delivering or promising launch capabilities in $150,000 per kilogram down to around $60,000 per kilogram. Those promising the lowest costs have yet to deliver on their cost projections nor a track record of reliable launch operations.

6 Smallsat Launchers and Technology Verification and Experimental Projects

Certainly another key to the viability of experimental small satellites and test and verification missions comes with reliable smallsat launchers. Many of those seeking to deploy large-scale constellations with a network of small satellites begin by the launch of experimental spacecraft to test the design of these systems. One of the first of these was the TinTin experimental satellites launched for initial test of the SpaceX system and spacecraft design. The test satellites demonstrated that lower orbits might be effectively used and transmission efficiency might be greater than first anticipated by network designers (Wall 2018) (see Fig. 4).

Table 2 Comparative chart of five hosted payload programs with governmental and commercial industry participation

Comparative assessment of different technology verification missions							
Payload	Payload type	Customer	Owner/ operator	Spacecraft Provider Boeing	Payload provider	Launch vehicle	Launch date
WAAS to augment GPS	L-band communications	US Federal Aviation Admin.	Telesat and Intelsat	EAS Astrium and &Orbital Sciences	Lockheed Martin	Proton (Telesat) ArianeV (Intelsat)	Sept. 2005 Oct. 2005
Automatic Identification Service (AIS)	VHF Communications	US Coast Guard	Orbcomm	Polyot	Orbital Sciences	Cosmos	June 2008
Internet Router in Space-IRIS	IP Router	Dept. of Defense	Intelsat 14	Space Systems/Loral	Cisco	Atlas V	Nov. 2009
CHIRP	Infrared sensor	US Air Force	AGS	Orbital Sciences	SAIC	Ariane	3rd quarter 2011
ADF UHF	UHF communications	ADF	Intelsat 22	Boeing	Boeing	Proton	June 2012

This chart depicts the date provided in the NASA Langley Research Study referenced below

Fig. 4 The TinTin prototype satellite for technology verification for the Starlink constellation. (Graphic Courtesy of SpaceX)

Reliable and low-cost small launchers provide another option for small satellite development, proof of concept flights, and even operational deployment. There are many new smallsat launcher companies promising the possibility of reliable operations, flexible on-demand scheduling, and low-cost launches.

Rocket Labs, for instance, successfully launched three experimental satellites for the US Air Force in May 5, 2019, from its New Zealand launch facility. This launch, plus another in late March 2019, was contracted by the US Department of Defense. The recent record of launch by the Electron vehicle by Rocket Labs provides a confirmation of both consistency of reliable launch operations and low cost for insertion into LEO orbit for small satellites.

The total payload for the May 2019 mission was 180 kilograms. Both of the CubeSat missions were to prove the feasibility of the technology. The Falcon Orbital Debris Experiment (Falcon ODE) was designed to help researchers evaluate the effectiveness of ground-based systems for tracking space junk and possibly diverting space debris from the ground to avert collisions. The other CubeSat known as the Space Plug-and-Play Architecture Research CubeSat-1 (SPARC-1) was designed to test in low Earth orbit the performance and accuracy of super small avionics gear and other electronic components (Wall 2019).

There are currently about 40 smallsat launch companies, beyond those already mentioned, that are seeking to bring their new low-cost launch capabilities to the fore. Many of these start-ups are presented in Part 13.3 of this handbook. These start-ups include such firms as ABL Space Systems, Aphelion Orbitals, Bagaveev Corporation, bspace, Celestia Aerospace, Cloud IX, CONAE, CubeCab, CTA of Brazil, Gilmour Space Technologies, Horizon Space Technologies, iSpace, Israel Aerospace Industries, Landspace, Launcher Inc., LEO Aerospace, Link Space Aerospace Technology, Naro Space Center (together with GKNPT Khrunichev), NADA, One Space Technology (Zero One Space), Orbex, Orbital Access, PLD Space, Reaction Engines Ltd., Relativity, Rocket Crafters Inc., Rocket Star, Skyrora Space Technologies, Space Ops, Spaceflight Industries, Space Launch Services, SpinLaunch, Stofield Aerospace, UP Aerospace, and Valt Enterprises.

Clearly not all of these new firms will succeed. There has been speculation in the press as to which of these firms will be able to raise the capital, develop the technology, establish a record of launch success, and acquire the customer-based sufficient to establish themselves as a player in the market. The closely related question is whether this stabilized market will produce a more or less stabilized price for launch services in the range between $50,000 and $100,000 per kilogram. Only some of these 40 firms can succeed. The outcomes that will be clear by the mid-2020s will impact small satellite launch costs and the feasibility and frequency of in-orbit tests of new technology (Foust 2019).

7 Conclusion

The evolution of the space industry and the increasing sophistication in the design, engineering, manufacturing, qualification testing, deployment, operation, and deorbiting of spacecraft at the end of life can be demonstrated in many ways. Perhaps the most important question for system designers is what is the best way to design a small satellite constellation so that it uses the best technology in the most cost effective way and also operates reliably for its full lifetime.

There is now a wealth of knowledge and new expertise in how this might be accomplished. The various ideas and methods about how this might be combined together in an overall design and implementation plan can now draw upon a great deal of knowledge built up on basis of how both large and small satellites are designed, tested, manufactured, and deployed. The number of questions that need to be asked and answered is today quite interesting and indeed almost intriguing. Some of these questions include:

(a) How many satellites are optimum to design and build not only to populate a small satellite constellation but also to provide for prototype technical and operational testing, in-orbit spares, and on-the-ground spares?
(b) Should there be a test of key technologies for reliability verification or sustainability of service (such as in the case of high rates of precipitation attenuation in the case of extremely high-frequency spectrum such as in the q/v or even w bands)?
(c) If there is a need for such technology verification, how might this be best conducted? Should this be through orbital tests, and if so should this be via hosted payload tests that can be flown on a larger satellite mission or via a consolidated series of experiments combined in a single launch or some other process?
(d) Should the early prototype satellites in a large-scale LEO smallsat constellation be considered as verification missions for the satellite design, performance, and operational methods and ground antenna systems.

(e) If the early prototype launches are test systems, what flexibility is there to modify the design for later production runs? Are test parameters related to orbital characteristics, digital processors, software-defined services, phased array antenna design, sensor functionality and/or resolution, interference mitigation techniques, power system design, or other design characteristics?

(f) If design parameters are changed and required that later production models of smallsats to have greater mass or volume, are launch arrangements sufficient to accommodate such changes?

(g) Should in-orbit tests and design modifications be limited to software upgrades or are changes to the physical design of the spacecraft considered viable?

(h) Are there particular volumes of satellite production runs that achieve particularly significant levels of scale economies? Are there methodologies to determine where such economies of scale are possible?

(i) Which particular components or subsystems or operational procedures are most in need of quality or lifetime testing, in-orbit test, or technology verification?

(j) What are the particular concerns related to sparing, replacement of a failed satellite, end-of-life deorbit, or elimination of RF interference, and can these be addressed via in-orbit testings?

(k) Can the experience of small satellite system operators be effectively used to address any of the above questions, and can reliance on this experience replace the needs for in-orbit testing and technology verification?

(l) Can the use of artificial intelligence (AI) spacecraft system management systems assist in creating improved "fail-safe" management systems that can assist with avoiding orbital collisions or near conjunctions, or allow more efficient operations associated with end-of-life spacecraft removal, or replacement of failed satellites? If so how can such systems be tested and introduced into satellite constellation management?

(m) Should a small satellite command and control system be encrypted against possible hacker attacks and should tests be undertaken to access the potential vulnerability of a network's TT&C system be vulnerable to attack (Foust 2018)?

These are only some of the questions that need to be addressed with regard to the design and implementation of a new small satellite constellation. In many cases the key question is whether some sort of in-orbit testing is needed to assist in answering many of these questions. The most difficult and challenging question is whether the cost and time delay associated with such possible tests are considered sufficiently beneficial to the successful operation of a small satellite constellation and whether computer simulations or other methods can eliminate the need for in-orbit tests.

French Space Programs for CubeSats and Small Scientific Research Probes to Deep Space

Pierre Bousquet

Contents

Abstract

French involvement in affordable deep space missions has been illustrated over the last few years by the accomplishments of the Philae lander in 2014 and by the mission of the MASCOT lander, developed with DLR, which was delivered on October 3, 2018, by JAXA's Hayabusa2 probe on asteroid Ryugu. The value of CNES dedicated engineering skills, such as mission analysis for the descent to small bodies, and of French laboratories' know-how in the development of high-performance miniaturized instruments has been demonstrated on both missions. It will be put into practice again through CNES' contribution to JAXA's MMX mission to Phobos in 2024, and more mission concepts are also being defined in partnership with major space agencies. In addition, CNES is also in

charge of deep space instrument operations, notably at the moment for two NASA's Mars missions, the Curiosity rover and the InSight lander. This general background will be elaborated in this article, together with French early microsatellite achievements through the Myriade family and with recent CubeSat development that culminated on December 18, 2019, with the simultaneous launch of the ANGELS 12 U Argos NEO demonstrator and of the EyeSat 3 U student astronomy spacecraft.

The second part of the presentation will elaborate on mission architectures for the most promising concepts that CNES has studied or been associated to where CubeSat class probes offer an advantage in terms of affordability, efficiency, and capacity to take risks. In some cases, typically between Venus and Mars, the small probes can operate as stand-alone missions of their own within the inner solar system. Alternatively, they can also augment larger missions to the most remote and challenging destinations in the solar system.

While microsatellites are affordable, and increasingly more capable, they should not be considered as a replacement for more traditional missions that require multiple coordinated measurements to accomplish their science investigation goal. Additionally, larger spacecraft remain far more powerful and can go to more remote locations and survive longer-duration missions and challenging deep space environments. Under many circumstances, however, large spacecraft can benefit greatly from the risk capacity provided by small probes that can be added on and from the multipoint capacity that they can provide.

1 Introduction

By necessity, the size of several historical missions to deep space was very restricted. In 1959, the 278 kg Soviet Luna 3 was the first ever spacecraft to photograph the far side of the Moon. Earlier in the same year, the first probe of the United States to escape from the Earth's gravity, Pioneer 4, at 6.1 kg, would be called a nanosatellite with today's terminology. At the end of the 1960s, the Pioneer 6–9 probes successfully investigated the solar wind and cosmic rays with a fleet of 62 kg spacecraft in heliocentric orbit. Telemetry contact was still achieved with Pioneer 6 in 2000, 35 years after its launch. In the 1970s, the Pioneer 10 and 11 probes, 260 kg each, were the first probes to pass the asteroid belt and to send back close-up images of Jupiter and Saturn. All these early examples have demonstrated that small probes can contribute greatly to deep space exploration. However, with the increase of launcher performance and the availability of high-performance – resource-demanding – instruments, the general trend of planetary missions until recent times has relied more and more on sophisticated spacecraft, in general of metric ton weight or above.

The success of the little Sojourner rover of the Mars Pathfinder mission in 1997 can be considered as a turning point toward using miniaturized robots for modern deep space endeavors. It corresponds to a period when miniaturization of technologies has started to progress tremendously and when computation capacities have become available for little onboard resources. More recently, the last decade has seen the emergence of CubeSats based on 1 kg–1 liter standardized units, notably from new space actors such as universities. The availability of cheap ultraminiaturized technologies brought by the very dynamic progress of CubeSats opens the way to innovative solutions for planetary missions, notwithstanding their specific – highly demanding – requirements. This has been illustrated over the last year through the various deployments of several auxiliary landers and of a free-flying camera within the frame of JAXA's Hayabusa2 mission around asteroid Ryugu (Yano 2019) and through the tremendous coverage and data relay of the Mars entry of the InSight lander by JPL's pair of MarCO CubeSats (Klesh 2019).

In collaboration with the very dynamic French research institutes in planetology, as a major actor in solar system exploration, CNES participates to all the missions of the European Space Agency in this field and has the privilege to cooperate with the main space agencies who send probes to deep space (NASA, Roscosmos, JAXA, and CNSA). CNES' contributions are mostly instrumental, but it also takes responsibility of operations, notably at the moment for two Mars assets, the Curiosity rover and the InSight lander. In line with operations, CNES provides regularly its expertise in space mechanics, in particular in the area of small bodies. CNES was among the pioneers in small deep space probes through the development of the MASCOT lander in cooperation with DLR, which was delivered to the surface of asteroid Ryugu by JAXA's Hayabusa2 probe on October 3, 2018. CNES considers that miniaturized technologies open new perspectives and valuable mission schemes for solar system exploration and is determined to diversify French contributions and optimize the scientific benefit of future missions. After identifying critical technologies, this article will elaborate some promising mission concepts where CubeSat-sized devices offer an advantage in terms of affordability, efficiency, and capacity to take risks. The spacecraft that will be discussed encompass orbiters and non-orbiting probes, lander, rovers, and the large variety of autonomous robots that can contribute to the exploration of distant objects.

2 Background

2.1 Small Satellites at CNES Before CubeSat Days (Landiech and Rodrigues 2010)

The development of the Myriade microsatellite line of product was initiated by CNES at the end of the 1990s, in partnership with Thales Alenia Space and Airbus Defence and Space. Since 2004, 18 microsatellites built around CNES' Myriade spacecraft bus have been placed into Earth orbit. Their mass range was from 100 to 200 kg. They aimed at low-cost, fast-track development while preserving high performance for a wide range of scientific, military, technological, and commercial purposes. Most of these satellites were launched to LEO, but two were also delivered to GTO.

The track record of the Myriade family is excellent. All 18 satellites launched so far have exceeded their specified lifetime. In addition, through this deployment, CNES also worked closely with Arianespace toward launcher interface solutions for auxiliary passengers which have been implemented on Ariane 5, Soyuz, and Vega and will be the basis of future offers on Ariane 6. CNES also gained customer experience of launching as a secondary payload. Within the frame of Myriade, CNES also provided partners and customers with a ground segment for in-orbit satellite command and control and developed high-efficiency operational schemes. One of the last members of the Myriade family, the TARANIS scientific satellite, will be launched in 2020 on Soyuz from the Guiana Space Centre (Bastien-Thiry and Privat 2019).

2.2 Ongoing CubeSat Developments

CNES is actively involved in this segment, reflected in projects such as the ANGELS demonstrator, with a view to structuring a nanosatellite ecosystem, and JANUS, which supports the development of CubeSats by students.

ANGELS (Argos Neo on a Generic Economical and Light Satellite) is the first nanosatellite designed and developed by French industry with support from CNES. Thus 25 kg – 12 U – CubeSat carries Argos Neo, an instrument ten times smaller and consuming three times less power than the generation of Argos data collection instruments previously in orbit. CNES and French firm HEMERIA have co-funded and developed ANGELS with a resolutely New Space approach to governance, design, development, and testing, systematically employing miniaturized commercial off-the-shelf (COTS) components. This approach comes with a certain degree of risk, but enables big reductions in costs and lead times. ANGELS (Fig. 1) has been delivered to its LEO orbit on a Soyuz launcher on December 18, 2019, from the Guiana Space Centre. HEMERIA is now ready to offer a whole range of nanosatellites in the 10-to-50-kg category for scientific and operational missions such as data collection and location from transmitters, maritime surveillance, radio-frequency spectrum surveillance, and Earth observation.

The JANUS program, initiated by CNES in 2012, aims to engage students in universities and engineering schools and get them interested in space by helping them to develop their own very instrumented CubeSats tipping the scales at 1 to 10 kilograms. EyeSat has been developed by CNES for the Janus program. This 3 U CubeSat equipped with a small space telescope called IRIS is designed to study the zodiacal light and the Milky Way. The mission has a threefold objective of acquiring science data, demonstrating new satellite technologies, and readying students for careers in space engineering. EyeSat has been launched on December 18, 2019, together with ANGELS. It has demonstrated soon after reaching its orbit a pointing

knowledge and stability of less than 0.1°. Its first picture of the sky, Andromeda (M31), is shown in Fig. 2.

2.3 Small Probes to Deep Space Realized or Underdevelopment

After the huge success of the Rosetta mission and the Philae landing on comet Churyumov-Gerasimenko, the small lander MASCOT (Mobile Asteroid surface SCOuT) has been developed by the German Aerospace Center (DLR) in cooperation with CNES. Its main objective was to perform in situ investigations of the surface of asteroid Ryugu and to support the sampling site selection for its mother spacecraft, JAXA's Hayabusa2 sample return spacecraft. After a 4-year cruise and more than 1 year around asteroid Ryugu, it was delivered by Hayabusa2 on October 3, 2018. It went through a free fall of ~ 6 minutes (Fig. 3) and a bouncing phase of ~ 11 minutes

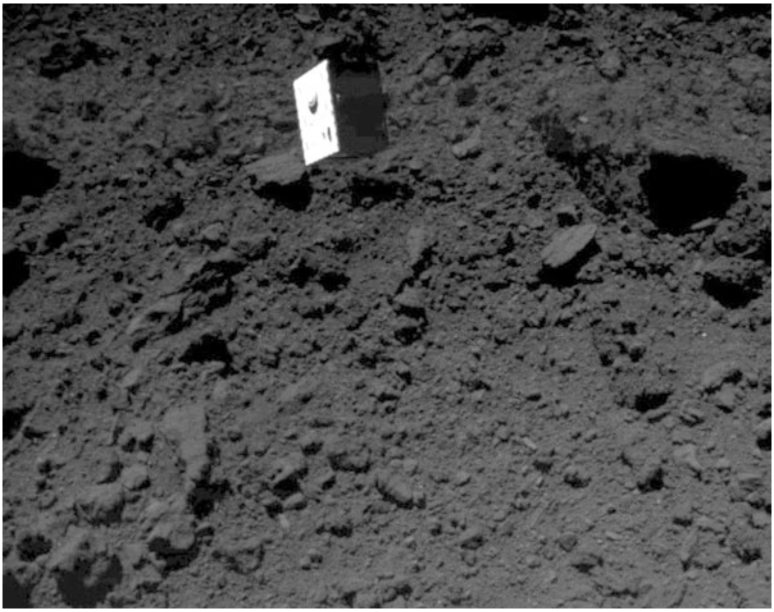

Fig. 3 An image taken during descent by the camera MASCam © JAXA, University of Tokyo

before it finally came to rest at its first settlement point where it entered into its on-surface operational mode. The lander was able to perform science measurements with its payload suite at three locations on Ryugu. After about 17 hours of operations, exceeding its target lifetime, the MASCOT mission terminated with the last communication contact (Tra-Mi et al. n.d.).

DLR was responsible for developing the MASCOT lander and ground segment and was in charge of planning and conducting lander joint operations from MUSC. CNES supplied antennae and power system, provided a support to operations, and was in charge of the flight dynamics aspects of the mission (Moussi et al. 2018). Asteroid surface science is obtained by four experiments: MicrOmega, a near-IR hyperspectral microscope provided by IAS; MASCAM, a wide-angle Si CMOS camera with multicolor LED illumination unit; MARA, a multichannel thermal infrared radiometer; and MASMAG, a magnetometer provided by the Technical University of Braunschweig. The MASCOT lander includes an internal mobility mechanism, a GNC sensor package, and an onboard autonomy software that enable MASCOT to self-right itself and to perform relocation leaps on the asteroid surface. A redundant onboard computer (OBC) provides autonomous control, command and data handling, and preprocessing power. Power is supplied by primary battery via a redundant power sub-system (PCDU). Even though it was not built on the basis of standard CubeSat units, with a 9.8 kg mass (including its 3 kg payload) and a volume of 0.28 × 0.29 × 0.21 m^3, MASCOT fits within the format of CubeSat (Fig. 4). In fact, since its development started in 2010, it can be considered, together with

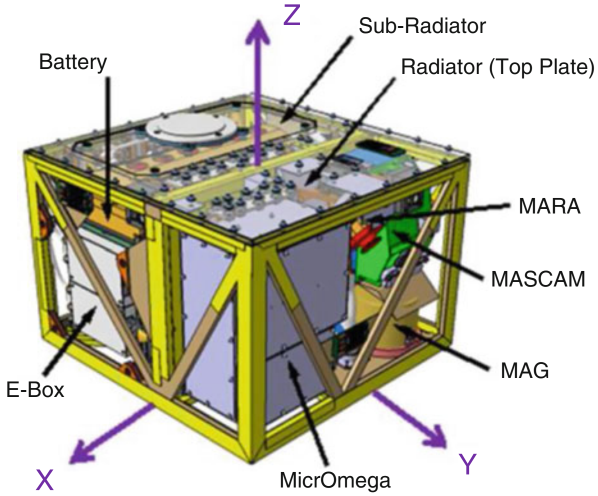

Fig. 4 Schematic of MASCOT lander – credit DLR

JAXA's small MINERVA rovers (that were also part of Hayabusa2) and JPL's Mars relay spacecraft MarCO, as one of the precursors of small deep space probes.

With the same partners as for MASCOT, CNES has started with DLR in late 2019 the phase B of the development of a small-wheeled rover that will be delivered in 2026 to the surface of Mars' moon Phobos by JAXA's sample return mission MMX (Tardivel and Lange 2019). This low-cost and lightweight rover – 25 kg in a 40 × 37 × 23 cm volume – again corresponds to the format of large CubeSats and will use extensively avionics developed for CubeSats. Jettisoned to the surface of Phobos from a low altitude, the rover will autonomously upright and deploy itself from a stowed position. Then, over the course of 3 months, it will carry out its technical and scientific objectives. First, it acts as a scout, experiencing Phobos soil before MMX, de-risking its landing and sampling operations. Second, it is a full-fledged science explorer, with payloads designed to complement or reinforce MMX scientific investigations. Figures 5 and 6 provide an overview of the rover's subsystems and of their provider (CNES or DLR).

2.4 Instrumentation and Onboard Technologies

In collaboration with French planetology, exobiology, and heliophysics/magnetophysics laboratories, CNES has provided an extensive range of scientific instruments for deep space missions over the last years. For future CubeSat applications, a non-exhaustive list of the most relevant families of instrument that are already miniaturized or will be through future R&D efforts can be elaborated:

- Optical camera, in particular the CASPEX color CMOS Camera that will be on board SuperCam on Mars 2020 and on the MMX rover and is proposed on the TeamIndus Moon rover (Virmontois et al. 2019).

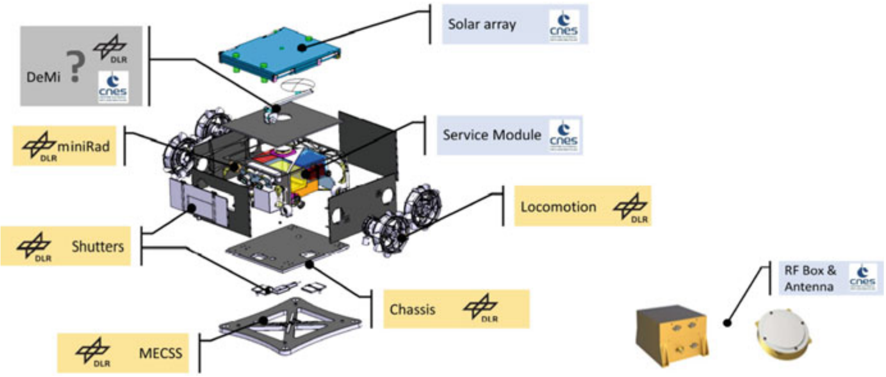

Fig. 5 MMX rover inventory and sharing of sub-systems – top level – credit CNES

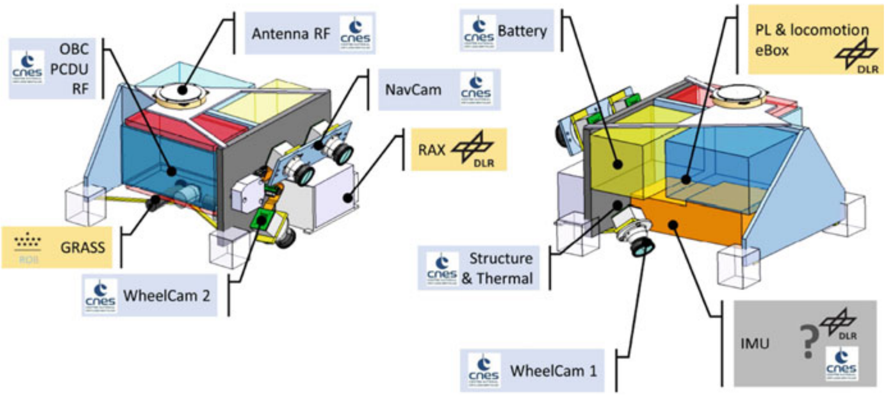

Fig. 6 MMX rover inventory and sharing of sub-systems – service module – credit CNES

- LIBS and Raman spectrometers, where CNES has accumulated an extensive know-how for the Curiosity, Mars 2020, and ExoMars rovers and is considering the development of miniaturized versions (Wiens et al. 2016).
- Hyperspectral infrared microscope (already flown on MASCOT and ready for flight on ExoMars' rover) and spectrometers (will be on board MMX spacecraft) (Royer et al. 2019).
- Chromatography columns for high-resolution mass spectrometers (flown on Curiosity and ready for flight on ExoMars' rover (Buch et al. 2015)), which are currently being miniaturized with MEMS technology.
- High-resolution mass spectrometer based on Orbitrap © technology (Briois et al. 2016).
- Seismometers, with extremely high accuracy solutions such as the SEIS instrument used on Mars for the InSight mission, or coarser sensors such as miniature geophones that can be used for active seismology on small bodies (Murdoch et al. 2017).

- For magnetic measurements, in addition to a wide range of AC and DC sensors, the magnetic cleanliness issue will be solved through measuring the disturbances produced by the CubeSat and setting the sensors at the end of a boom currently developed in CNES' R&D program.
- Langmuir probes, ion and electron spectrometers, and mutual impedance probes are also available: French laboratories will actually provide the electron spectrometer and the plasma sensor of the Comet Interceptor mission (Jones 2019). The development of a miniaturized version of the mutual impedance probe has recently started at R&D level.

In addition, through its extensive experience in Earth observation missions, CNES has developed a very broad image processing expertise which can be highly beneficial to exploration with small probes. These missions need to be autonomous and are generally restricted in terms of telemetry rate: autonomous target choice, onboard image processing and selection, and high-performance compression will be crucial assets that CNES is currently working on.

For spacecraft technologies, CNES' plan is to build upon the solutions developed for ANGELS and for the Janus program, with specific adaptations required by the deep space conditions and mission configuration. In the short-medium term, CubeSats can provide efficient stand-alone solutions for deep space missions between Venus and Mars (including the Moon and near-Earth objects), and the range of critical technologies (qualification to radiations, low-thrust propulsion, communications) shall be extended accordingly. For more distant targets, CubeSats will generally be used under a daughtership/mothership scheme; CNES focuses in this respect on the relative navigation issue and on high-performance inter-satellite link equipment that will be compatible with radio science.

2.5 Flight Dynamics and Operations

As can be seen in the next section, mission concepts using small probes are regularly proposed for the exploration of small bodies or small moons such as for the MMX rover (Virmontois et al. 2019). Orbiting around and landing on these bodies is very challenging, due to the low-gravity environment, the irregular shapes, and the modelling uncertainties of the forces in the close vicinity of the target body. CNES' Flight Dynamics department has acquired a tremendous experience in this area through its responsibility in the preparation and execution of Philae's landing on Churyumov-Gerasimenko and of MASCOT's landing on asteroid Ryugu. It will now be in charge of the landing of the MMX rover on Phobos and support JAXA in the flight mechanic analyses of the MMX mothership for its quasi-orbiting operations around Phobos and its sample collection sequences at the surface (Lorda et al. 2019). French support to the flight dynamic studies of the CubeSats that will orbit the Didymoon asteroid under the frame of the HERA planetary defense mission (Carnelli et al. 2019) is also under consideration. CNES is determined to keep consolidating its position as a major partner in flight dynamics support for future deep space and exploration missions by proposing its expertise, notably for small body applications.

As far as operations are concerned, CNES has an extensive record in operating Earth orbit satellites of all categories, in contributing to ISS operations, and since 2012 in operating instruments at the surface of Mars within the frame of the Curiosity and InSight projects in cooperation with NASA, and it has contributed to Philae and MASCOT operations (Barde and Jocteur 2017). The next logical step should be to operate small deep space probes in the recently created French Operations Centre for Science and Exploration (FOCSE), and CNES is determined to do so in the next decade.

3 Mission Concepts

Examples of mission architectures, studied by CNES independently or in collaboration with potential partner, are associated below to a spectrum of microsatellite and nanosatellite mission “classes” that range from enhancing to enabling and present a definitive advantage in terms of affordability. It can be observed that in some cases, the small probes can operate as stand-alone missions of their own within the inner solar system. Alternatively, they can also augment larger missions to the most remote and challenging destinations in the solar system.

3.1 Technological Demonstration

Two types of demonstrations that could be performed by small spacecraft and be extremely beneficial for future major Mars exploration missions will be emphasized here.

The Mars Sample Return (MSR) Mission currently planned toward the end of this decade requires the detection, localization, and capture of a free-flying orbital sample container: following the ascent of the Mars Ascent Vehicle from the Martian surface, an orbital sample will be released in Mars orbit. At a long relative distance, the MSR Earth Return Orbiter will perform search and detection, approach to rendezvous with and capture the orbiting sample. The search and detection phase, in particular, is very challenging and requires the use of a long-range optical detection by a narrow-angle camera. The early realization of this critical phase by a CubeSat in low Earth orbit would be very valuable to prepare, and ESA has emitted an invitation to tender for such a project at the end of 2019 (Cubesat n.d.).

Aerocapture could valuably be demonstrated at Earth or ideally at Mars by a probe in the range of 100–200 kg, either as an add-on to a larger mission or stand-alone (Sudars and Regnier n.d.). In the frame of the technology development for human Mars exploration, the aerocapture of a vehicle in Mars’ environment needs to be demonstrated. The aerocapture technology is considered as critical to insert heavy vehicles in Mars’ orbit.

The demonstration objectives are:

- To execute an aerocapture in a fully relevant environment and to test specific guidance navigation control techniques and algorithms in a realistic environment
- To contribute to the precise data acquisition of the Martian atmosphere
- To get a better understanding of the parietal heat flux during the Martian atmospheric entry, particularly at the back of the vehicle

3.2 Small Body Reconnaissance and Characterization

The relative accessibility of some near-Earth objects makes them reachable by stand-alone CubeSats, particularly for flybys. CNES has participated in 2019 to a study performed by the University of Strathclyde that showed that pairs of 12 U nano-satellites using low-thrust propulsions could travel together on multi-target flyby trajectories and be designed to be flexible to suit many different target sets (Walker et al. 2019). The primary scientific goal of each spacecraft is to improve the knowledge of visited near-Earth objects in terms of their orbital elements and physical features and properties, in the context of planetary defense. The payload is based on a visible camera and a miniaturized Lidar for ranging. Trajectories aim to maximize the number of visited objects per launch (balanced with favoring larger asteroids).

Along the same line, the Observatory of Paris investigates a concept called BIRDY based on interplanetary CubeSats visiting small solar system bodies and probing their interior (Hestroffer et al. 2019). The aim is to derive the size and shape through imaging, and the mass and bulk density of the small body (asteroid, comet, satellite) through radio-science experiment, making use of a mother craft-daughter craft (or between pairs of stand-alone CubeSats) inter-satellite link. Such CubeSat will rely on low-velocity and close-distance flybys dedicated to the radio-science experiment.

The Comet Interceptor mission (Jones 2019) recently selected for ESA's new Cosmic Vision Class F program is another great example that highlights the great potential of microsats for small body characterization. As mentioned in the instrumentation paragraph above, CNES will provide two instruments to this exciting mission which is based on a mothership with two auxiliary spacecraft and will be launched to the L2 Sun-Earth Lagrange point in 2028. Launch will be shared with the Ariel mission dedicated to exoplanet characterization. From L2, it will wait for the discovery of a comet entering the inner solar system for the first time or even possibly of an interstellar object originating at another star. It will then perform a propulsive ΔV to achieve a flyby of its pristine target. The purpose of the two smaller spacecraft is to venture closer to the target, carrying complementary instrument payloads, to build up a 3D picture of the comet. Figure 7 illustrates this flyby configuration.

This approach will also enable a combination of a low risk and guaranteed baseline science return from the more distant mothership with higher-risk but high-gain sampling of the inner coma by the releasable probes, which do not necessarily need to survive the full encounter for mission success. This mission

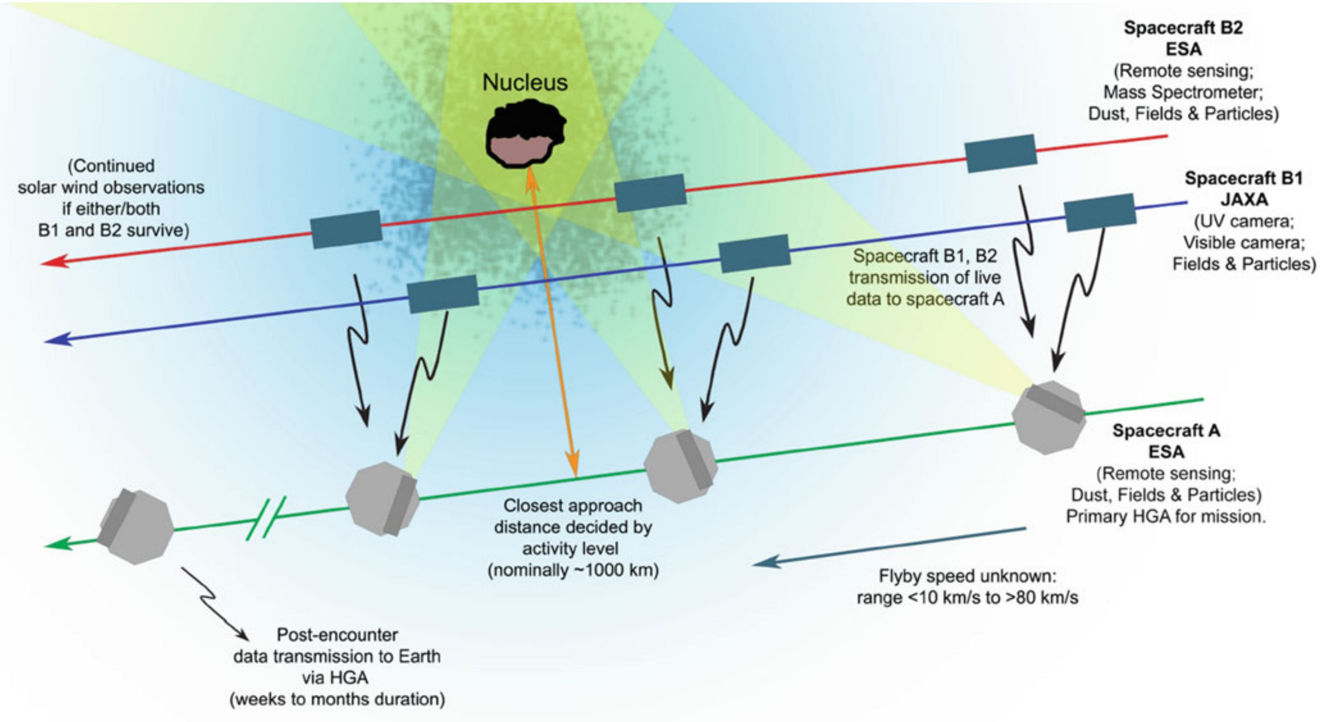

Fig. 7 Flyby configuration of Comet Interceptor – credit UCL Mullard Space Science Laboratory, UK

exhibits two typical features of auxiliary probes for exploration: they can take higher risks than their mothership, and they make multipoint measurements affordable.

The HERA mission (Carnelli et al. 2019) also recently decided by ESA within its planetary defense program is another great example of a mission to a small body that combines CubeSats with a mothership. In this case the set of spacecraft will orbit around the secondary body, Didymoon, of the Didymos binary system. One of the CubeSats, called Juventas, will measure the gravity field as well as the internal structure of the smaller asteroid. In close orbit around Didymoon, Juventas will line up with Hera mothership to perform inter-satellite radio-science experiments and carry out a low-frequency radar survey of the asteroid interior, with an instrumental concept inherited from the concert radar from Rosetta and Philae developed by the French laboratory IPAG. CNES will be in charge of flight dynamics for both CubeSats.

3.3 Multipoint Measurements at Mars or Venus

In the early 2000s, CNES carried the pre-development of a network of four geophysics Mars stations up to phase B. The major goal of this mission, called Netlander (Marsal et al. 2002), was to perform simultaneous seismic and environmental measurements in order to study the internal structure of Mars, its subsurface, and its atmosphere. Each station was deployed by an individual capsule which had a 65 kg mass at entry. It is now generally acknowledged that after the InSight mission which is performing very accurate seismic measurements with a single station on Mars, a network similar in principle to Netlander should be envisioned for a second-generation geological campaign.

Orbital networks are also envisioned around Mars or Venus to characterize the interaction between their upper atmosphere and the solar wind and their magnetosphere. Such a mission is given a lot of attention in the Mars road map elaborated in 2016 by a selection of French scientists (Montmessin et al. 2016). Under the scientific leadership of the LATMOS laboratory, CNES has run a phase 0 study of a mission NETSSEM that would combine a mothership with three CubeSats to investigate Mars' magnetosphere (Leblanc et al. 2019). This generic concept would also apply to Venus (Fig. 8).

3.4 High Risk Enhancement of a Large Mission

Thanks to their low mass and low cost, nanosatellites or microsatellites may fit within the resource margins of large missions to augment their science return. They could allow mixing low- and high-risk investigations, for example, by matching a robust mothership that acquires the primary science and smaller deployables that investigate other aspects of the target, increasing investigation time during a fast flyby, or being deployed during cruise for a different purpose. Galileo and Rosetta have both approached opportunistically several asteroids during their long cruise toward their final target. For future missions of this type, under the same

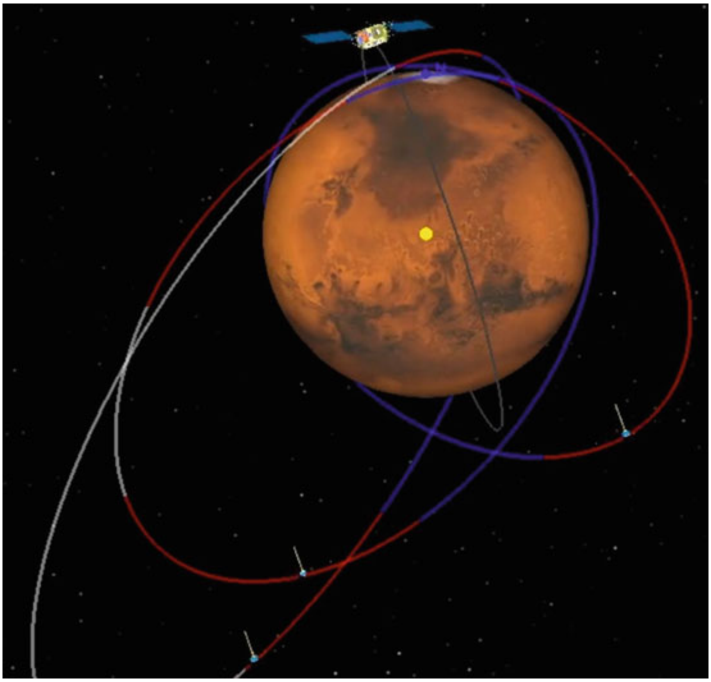

Fig. 8 NETSSEM mission architecture – credit CNES

circumstances, having disposable short-leaved CubeSats on board that could be literally thrown toward the object that the main spacecraft is flying by would add a lot of scientific value by procuring close-up images and measurements (Bousquet et al. n.d.).

Another spectacular possibility of complementary measurements has been associated to the incoming missions to the Europa Jupiter moon. Several short-leaved CubeSat designs, from 3 U to 12 U, have been proposed in France (Gaudin et al. 2017) and in the USA to characterize in situ the plume released by Europe (Fig. 9).

4 Conclusion

Small planetary probes have become a reality, as illustrated by JPL's recent MarCO mission and by JAXA's Hayabusa2 mission where CNES had the privilege to contribute to the MASCOT lander. The amazing current growth of CubeSat launches to Earth orbit and the huge number of conceptual studies based on small spacecraft undertaken over the last couple of years let anticipate that small sat applications to deep space are poised to expand. CNES definitely wants to participate to that trend building up on its CubeSat capacities, on its high

Fig. 9 Europa plume characterization mission architecture – credit IRAP

expertise in flight dynamics, and on its long history of instrument development and operation for planetary science. CNES is very familiar with international cooperation for deep space exploration, and the emergence of dedicated small probe programs in the US (SIMPLEX) and at ESA (Cosmic Vision class F) should boost up opportunities.

CNES can propose a wide range of miniaturized – high-performance – instruments, and the technology is already at reach for daughter spacecraft types of mission architecture. Areas of technological developments that will incrementally enlarge the scope and enhance the scientific output of independent stand-alone small sats, between Venus and Mars as a first step, have been identified.

Microsatellites and nanosatellites can provide a number of unique functions that are both enabling and enhancing to planetary science missions. As shown in the previous section of this article, a broad spectrum of mission architecture based on small probes can contribute to fulfil ambitious scientific objectives, or in some cases provide the only meaningful solution. Yet, while microsatellites are affordable (even though they will undoubtedly be more expensive for deep space than for the more common low Earth orbit applications), and increasingly more capable, they are not a replacement for more traditional missions that require multiple coordinated measurements to accomplish their science investigation goal. Additionally, larger spacecraft remain far more powerful and can go to more remote locations and survive longer-duration missions and challenging deep space environments. Under many circumstances, however, large spacecraft can benefit greatly from the risk capacity provided by small probes that can be added on and from the multipoint capacity that they can provide. In this respect, the combination of small probes with mother crafts will ultimately make it possible to reach further into the solar system and explore new destinations in depth.

Small Satellites and Commercial Satellite Applications

Mobile Satellite Communications and Small Satellites

Amit Maitra and Joseph N. Pelton

Contents

Abstract

The mobile satellite service is in many ways one of the most suited to being provided by a network or constellation of small satellites in low Earth orbit. This type of service requires by far the greatest link margin in order to maintain service

continuity because of obstacles that can block a clear line of sight between the satellite and the user's transceiver. Also the processing time and need for storage and buffering of the MSS digital signals associated with maintaining a mobile satellite signal because of possible interruptions, such as tunnels, forests and trees, billboards, and buildings and skyscrapers, mean that delay associated with a GEO satellite compounds the problem of resiliency of service. A LEO system, because of its lower latency and less path loss due to being some 30 to 40 times closer to the ground, has an advantage over a MEO and especially a GEO system.

For a variety of reasons, the first small satellite constellations for voice, data, and machine-to-machine (M2M) services that included Iridium, Globalstar, ICO, and ORBCOMM all had to be reorganized out of bankruptcy. Yet now all of these systems are going enterprises and other new systems are being deployed. Some of these are for new L-band-based data relay and M2M services. These systems are providing such new applications as automatic identification services (AIS) and Internet of Things (IoT) data relay, and others are being deployed to support 5G-based data relay and other advanced applications related to driverless cars.

This chapter describes the design of small satellite networks to support mobile services and augmentation of broadband cellular networks as well as global voice and data services. It explains the challenges that exist to deploy and operate these types of satellite systems as well as the regulatory, standards, and spectrum allocation issues associated with the development, deployment, and future growth of these networks in the future.

1 Introduction

The development of satellite communications came in a series of stages. First came the development of commercial fixed-satellite services (FSS) that began with the deployment of networks by Intelsat, Eutelsat, and a series of domestic satellite systems that started with the Canadian Telesat Anik system. This was followed by a series of competitive systems for international services. The initial satellite services for voice, data, and television relay were followed by the development of direct-to-the-home television services that used high-powered FSS satellites. This then transitioned to true broadcast satellite services (BSS) that provided direct-to-consumer radio and television services. But all of these satellite systems of the 1960s, 1970s, and 1980s were largely deployed in the geosynchronous orbit. This is because these satellites appeared to remain stationary in their orbit above the equator. This allowed ground stations to point constantly to the same location above the equatorial orbital arc. The main exception was the Russian Molniya communications satellite that deployed three satellites in highly elliptical 12 h orbits. This highly Northern-biased configuration allowed effective coverage of all of Russia. At least one of the three satellites was clearly accessible for at least 8 h in each of the three orbits. These satellites, however, had to have a tracking capability for all of the user Earth stations on the ground below since they did move across the sky. Since they were moving in a slow arc as they approach their orbit's apogee, this did not require fast tracking.

The last of the major commercial telecommunications satellite services to develop as a significant source of revenues was that of the mobile satellite services (MSS). This satellite service developed later for both technical and market-based reasons.

The rapid evolution of geosynchronous satellite services for fixed-satellite services (FSS) and broadcast satellite services (BSS) was quite logical because these satellites could work to low-cost dish antennas that did not have to track the "apparently stationary" satellite overhead. The FSS and BSS market expanded rapidly because of the large demand for these services and the ease of expanding service by adding new ground-based antennas that were always located in a fixed location and always with a stable pointing orientation.

The idea of communications to mobile systems was a different matter. The ground antennas required by users – whether located on an aircraft, a ship, a vehicle on the ground, or even people on the move – automatically implied the need to accommodate movement. Even so, the first mobile satellite systems were still deployed in GEO, and the ground, ship, or even aircraft had to either have active tracking or alternatively have antennas that could receive signals in all directions above the horizon. The huge path loss associated with the GEO satellites and the low gain associated with user transceivers on the ground, on ships, or on aircraft suggested that perhaps low Earth orbit satellites that were 30 to 40 times closer to ground could perhaps present a better option. Arthur C. Clarke, who first conceived of using geosynchronous satellites for global communications, and published the first articles on this subject in 1945, even wrote about LEO satellites and their possible future use as well.

Since the signal from the antennas of a spacecraft in GEO spreads out in a circle, the effective difference in the satellite signal's effective power is not represented by its distance away but rather by the square of the differences in altitude. Thus a LEO satellite that was 30 times closer than a GEO satellite would have a $(30)^2$ effective power advantage or to seem 900 times more powerful. And if 40 times closer, there would be an effective power advantage of 1600 times. But there was also a price to pay by operating satellites at much lower altitudes. One needs a constellation of 50–60 satellites to effectively cover entire Earth. Three satellites in GEO can cover virtually all the Earth except the polar region. About 12–18 satellites can cover the world with medium Earth orbit (MEO) satellites, but a LEO satellite can only see a limited area so much more have to be launched to get universal coverage. In fact satellites are much like a very, very high microwave tower. Since it is not possible to build towers many thousands of kilometers high, the GEO satellite was a cunning substitute.

The case of mobile satellite was different. This is because the ground stations would also be moving in any event. Thus, the idea of smaller satellites in a low Earth orbit (LEO) constellation might be considered a useful option in designing a mobile satellite system. The much lower path loss could be used to advantage in such a mobile satellite system. Instead of having to build larger, more powerful satellites with larger and larger space antennas, then smaller satellites much closer to Earth might provide more effective mobile satellite services and also would greatly reduce the problem of transmission delay that was considered a problem for voice services in particular. More power, less delay, and smaller satellites to launch were all advantages that led designers of the LEO mobile communication satellites to look seriously at these designs.

The challenge was to find a way to design small user antennas that could either track the fast-moving small satellites overhead or find a way to design ground units that could capture signals from satellites at virtually all angles overhead – but with very low gain.

The other reason that mobile satellite services also developed more slowly is that the market was essentially smaller. The Inmarsat system was created in the 1980s to provide essential international mobile satellite services to ships at sea. It expanded to provide services to aircraft as well. The various satellites at the outset were all GEO systems. These include the Marisat system developed by the Comsat Corporation, the maritime package that flew on some of the Intelsat V GEO satellites, and the Marecs satellites developed by the European Satellite Agency. All these systems were combined into the initial Inmarsat system.

This was largely seen as a relatively small market, and only those willing to pay a rate as high as $10 a minute for a telephone call were foreseen as customers plus ship navigators and captains seeking to achieve the best safest sea routes or to avoid large storms. All of these first maritime satellite systems envisioned very large and very powerful GEO satellites to provide these services, and the key was to develop ground transceivers with digital processing sufficient to get a voice signal and not be too large.

The bottom line was that commercial mobile satellite services using small satellites in constellations thus only began to be developed in the 1990s in parallel with the development of terrestrial cell phone development. Prior to the 1990s, people expected to receive their telephone calls in their homes or office. Unless they were cab drivers or police or military personnel, very few people could afford a car radio telephone. But the cell phone revolution began to change expectation.

People did not expect to reach the Internet via cell phones either since there was no Internet. A large-scale consumer market for mobile communications did not really develop until the age of broadband terrestrial wireless services until the 1990s as the terrestrial cellphone build-out began in earnest.

2 The History of Small Satellite Constellations for Mobile Services

In short, the concept of private ventures that might deploy mobile satellite services (MSS) at the domestic or global level did not begin to emerge until the demand for cellular service really began to catch on. The various mobile satellite services (MSS) that envisioned using low Earth orbit small constellations began in earnest in the early 1990s. At the time link budgets for terrestrial cell phone service was minimal, and the build-out was largely in only big cities and urban areas. It was hard to call inside of homes and cars. In the 5 years that followed, the build-out was fast and furious, and the power of cell towers kept going up and up to provide better and more resilient service.

When the various systems such as Iridium and Globalstar began to offer LEO-based satellite cellphone service in 1997 and 1998, they found the terrestrial cell phone market had changed greatly. The power levels had gone up, and the number of cell towers had multiplied many times over, and the size of cell phones had shrunk greatly. The satellite service had difficulties of high rates; dropped calls; problems of connecting from inside of buildings, homes, or cars; and satphones that receive the unwelcome nickname of “bricks.” The market of millions of subscribers that consultants had predicted simply did not materialize (Pelton 2001).

The systems like Iridium and Globalstar for mobile satphone service deployed in the late part of the 1990s ended up almost immediate bankruptcies. ICO that had likewise planned to deploy a mobile satphone system also folded as did the ORBCOMM store-and-forward data relay network. Yet another system named Teledesic was planned to provide fixed-satellite services (FSS) in the Ka-band. This new and unorthodox system became known as a “megaLEO” satellite system. It was to include a constellation of 840 smallsats plus 80 spares or 920 satellites. This innovative project that was backed by Microsoft founder Bill Gates and cell phone entrepreneur Greg McCaw was also cancelled at that time as essentially being too expensive to build and deploy without having an established revenue stream and large-scale base of customers.

The market for Iridium and Globalstar had largely shrunk to areas where cellular service was simply not available. The high price of these early LEO-based mobile satellite services was a key issue indeed. There had been at least a two orders of magnitude overestimation as of the global demand for the satellite service by telecommunication market analysts. This was in part because the prices consumers ultimately had to pay were much higher than market researchers had projected. The providers of these networks found out too late that they had to split their revenues with national governments in order to obtain what are called “landing rights.” Such agreements were needed in order to operate in countries around the world.

This series of misunderstandings, miscalculations, and technical difficulties with the services drove up the cost of the new MSS offerings and lowered the revenues needed to pay off the multi-billion dollar debts incurred to build these new systems. The cumulative effect of these various factors ended up in across the board bankruptcies and in a very short period of service. The ICO network that was a spinoff of the Inmarsat system was not deployed, but it too also filed for bankruptcy.

The restructured and reorganized entities that bought out the satellite assets from the bankrupt companies were able to re-enter the mobile satellite business. They were able to recover from these large financial failures and multi-billion dollar losses. These first-generation satellites in some instances lasted as operating systems for over 20 years despite earlier estimates of 5–7 years.

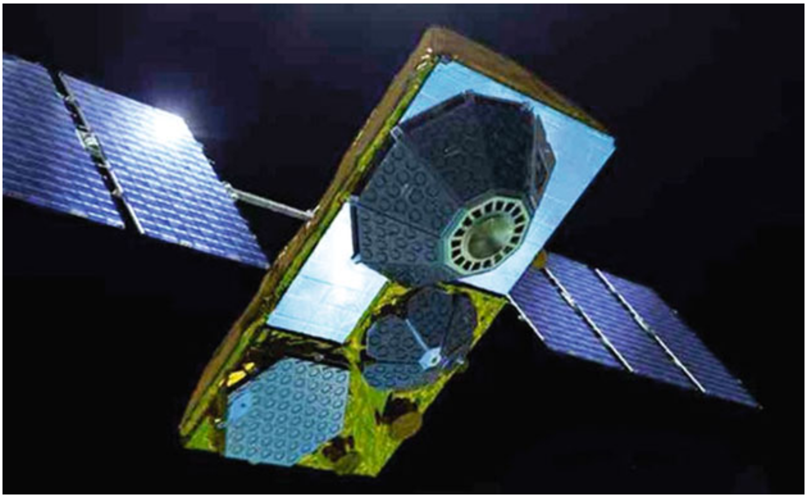

Fig. 1 The Globalstar second generation of satellite with phased array antenna. (Graphic courtesy of Globalstar)

Today, these new iterations of Iridium, Globalstar, and ORBCOMM have deployed new generations of satellites and have recovered from the financially disruptive start of their operations (see Fig. 1 the new generation of Globalstar satellites).

The experience gained has been important. These LEO-based mobile communications satellites operators have improved their offerings in many ways. There are new, smaller, and better user transceivers for consumers. There have been some renegotiation of the landing license requirements and other regulatory challenges met (i.e., such as coordinating frequencies with radio telescope operators around the world). They have learned to make better market forecast and grow their customer base steadily in the past two decades. The new owners and operators were able to learn from past experiences and benefit from much improved technology in space and particularly on the ground.

The second-generation satellites were more powerful and more capable, offered new services, were able to extend and improve landing license agreements, and were able to forecast demand based on real traffic levels and past patterns of growth. The user transceivers and ground equipment are much improved.

3 New Iridium and Globalstar Mobile Satellite Service (MSS) Constellations

The key to success of the small satellites for mobile services has been not only to learn from the past experience but to develop their ability to respond to the needs of the user community with much better-tailored service offerings. The additional power and phased array antenna design on the latest version of the Iridium and

Globalstar satellites that achieve more efficient frequency reuse allow these LEO mobile satellite service satellites to provide broaderband services.

These services compete with the GEO satellite services provided by Inmarsat and Thuraya. The range of users include those involved in sailing, outdoor sports such as cross-country skiing and mountain climbing, those involved in trucking and transport services and mining, those working on offshore oilrigs, prospectors, law enforcement officers, and especially those engaged in military operations or providing emergency aid services in remote areas (Satellite Service).

Both the Globalstar and Iridium satellite systems offer a newer feature. This is a Wi-Fi hotspot that accesses the satellite more efficiently and allows multiple users to access the satellite. Currently for Globalstar there are 8 users and for Iridium there are 5 users.

In the case of Globalstar, this is called a “Sat-Fi system.” This is, in effect, a Wi-Fi hotspot system that allows a regular smartphone to access the satellite without the purchase of a satellite phone. This new mobile satellite voice service and new Sat-Fi hotspot equipment is available for under $1000 and is deployable anywhere it is locally authorized and can be recharged. This allows compatible smartphone to access the Sat-Fi box for voice and data services. This is currently available at subscription rates that are as low as 50 cents to 65 cents per minute in the United States with a minimum usage per month of 150 to 200 min. Another desirable feature is that ordinary country code dialing is possible without using the specific country code number assigned to mobile satellite systems. Its direct connection service rates on a mobile satellite phone are significantly higher (Globalstar SatFi Service).

Iridium Next service has also added new consumer options that are quite parallel to those of Globalstar for both its hotspot type service and its direct to the satellite service via satphone connections. The Iridium service with a mobile hotspot unit is known as “Iridium Go” and is generally comparable to Globalstar Wi-Fi-based service offerings except for allowing five interconnecting smartphones at once rather than up to eight (Iridium Go).

Voice service operations for both of the voice-based satellites directly via satphone currently tend to be more in the range of $1.25 to $2.00 per minute with a requirement of an annual contract to start with and an enrollment fee and early determination fee. Incoming short messaging service (SMS) and voice calls, however, are generally free of charge subject to certain restrictions. Calls to other satellite systems have a high premium charge (2019 Top Iridium Monthly and Yearly Plans).

The key to the success of these smallsat mobile satellite services can be attributed to the following factors as shown below.

4 Success Factors for Small Satellite MSS Networks Providing Voice and Data Services

- Buildup of governmental, corporate, and organization anchor clients over time
- Increased performance of the satellites, user handsets, and Wi-Fi hotspots in terms of capacity, resilience, beam-to-beam handoff, and link budgets to sustain service
- Advances in digital processing, encoding, ASIC chips, and phased array antennas

- Lower latency of LEO constellation versus competitive GEO satellite systems
- New features such as Wi-Fi-satellite hotspots and improved/more compact phones
- Improved agreements with governments for landing licenses
- Shaping the marketing of services to the special needs and requirements to a wide range of potential users so the value of LEO MSS services is better understood

Despite the success of the Iridium and Globalstar networks, there is a constant challenge for these networks to be successful in light of competitive challenges and the new service offerings that can be offered by new entrants into the field of mobile services. There has been competition with satellite systems providing machine-to-machine (M2M) or business-to-business (B2B) messaging services that has come from ORBCOMM, Spire, and others that are also providing automatic identification services for lower-end messaging and other types of lower-cost services such as IoT connectivity. The GEO-based MSS system that are providing voice-based services and broadband data have also challenged the LEO-based MSS smallsat constellations.

In the case of Globalstar and ORBCOMM, they have made a mutual service exchange agreement to meet consumer demand for messaging and identification services. The growing demand for automatic identification services (AIS) for the shipping and transportation industry and other new IoT and 5G-related M2M services have given rise to a greatly expanded number of small satellite networks to provide messaging services of all types. These new requirements and the various new systems that are now being deployed or planned for these types of data and messaging services are discussed in the new section.

5 Small Satellite Constellations for Messaging Services

The ORBCOMM satellite network was deployed at the same time as the original Iridium and Globalstar MSS systems for voice communications. Although ORBCOMM was a much smaller and lower-cost-type satellite that involved much lower capital investment, its mission was to provide store-and-forward data relay, and it also experienced a rapid financial crisis and bankruptcy at essentially the same time. The near simultaneous bankruptcies of Iridium, Globalstar, and ORBCOMM – as well as the fixed-satellite services Teledesic – created major concerns in the financial markets about small satellite constellations in LEO. It required over a decade before investors were willing to consider backing these types of satellite systems again. Technological advances in the satellites, new user antennas on the ground, improved launch vehicles that cost much less, and the confidence that came from the financial and market success of the reorganized Iridium, Globalstar, and ORBCOMM satellites all helped. Thus it was possible to find the support needed for the financing of the second generation of the Iridium, Globalstar, and ORBCOMM systems and also allow new systems to provide data relay and messaging services to emerge in the last few years.

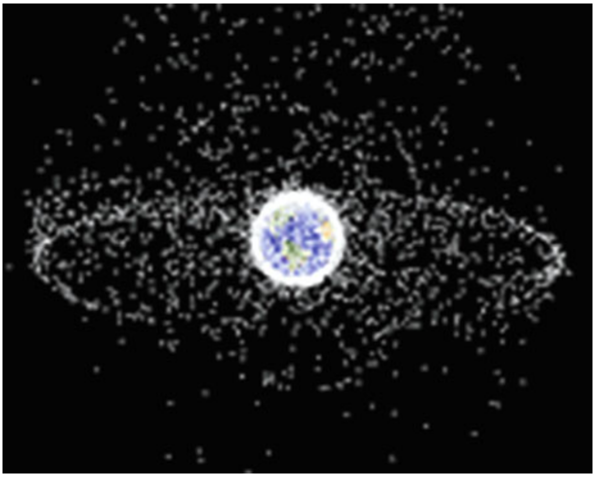

Fig. 2 The mounting orbit debris conditions in GEO and LEO. (Graphic courtesy of NASA)

The current surge in interest to deployment of satellites in LEO networks has now reached a current total of some 20,000 satellites to be deployed in the LEO orbital region between 300km and 1600 km altitudes if they were somehow actually all deployed in coming years. There is a particularly high concentration of new small satellites now proposed for the region between 700 km and 1200 km, with a critical concentration with a peak around 900 km. It is within this altitude band where most mobile satellite constellations are operating or proposed. This raises yet another concern as to the problem of orbital space debris and the threat of orbital collisions that could pose a risk to all types of LEO space operations and the longer-term sustainability of all types of space activities.

The graphic in Fig. 2 shows NASA precise simulation of existing space debris in Earth orbit with the outer ring representing the GEO and the dense inner ring surrounding Earth, shown as a virtually complete white ring, depicting the density of LEO orbital debris as it exists today. Indeed about 45% of the mass represented by orbital debris is crammed into the limited area represented by low Earth orbit (LEO), and with all of the proposed additional launches, it will become much worse.

6 Messaging Services and New Satellite Applications for LEO Smallsat Constellation AIS

The first store-and-forward satellites were the OSCAR 1 AMSAT satellite as built by volunteers and the University of Surrey (UOS) satellites. These early small satellites were constructed by making effective use of miniaturized electronic components and sensors and off-the-shelf parts. These early projects increasingly were able to show that a small satellite could deliver some impressive performance – for both data messaging and remote sensing. The UOS-2 that was launched in 1984 demonstrated that smallsats were not only real but cost-effective and capable of performing such tasks as reasonably fast and effective data relay (Surrey Launched Missions) (see Fig. 3).

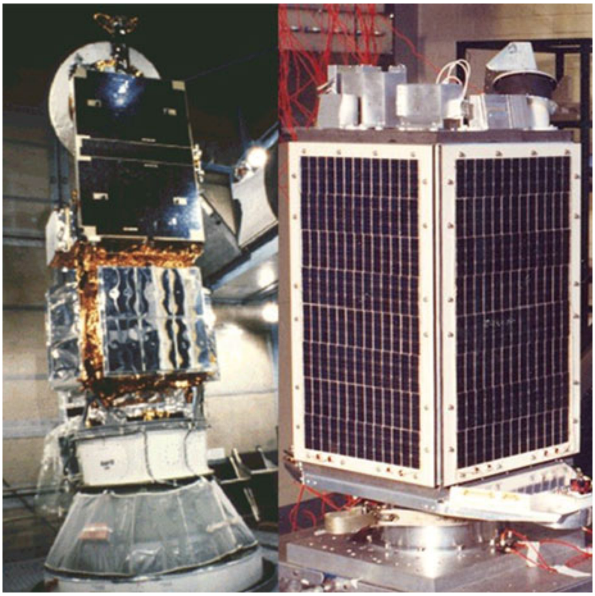

Fig. 3 The UOS-2 store-and-forward 3-unit cube satellite launched in 1984. (Graphic courtesy of the SSTL)

This type of early demonstration of what was possible with small satellites as small as a 3-unit cube satellite in terms of data processing and reasonably high-speed store-and-forward data relay sets the stage for what was to come in the 1990s with the ORBCOMM constellation.

The first commercial small satellite network was the ORBCOMM constellation that Orbital Sciences was bold enough to launch and operate. This was a quite small and compact small satellite that when arranged in a launch configuration could allow over a dozen ORBCOMM satellites to be launched at a time. ORBCOMM manufactured these small satellites and launched them as well. As cost-effective as the manufacture and launch of these small satellites were, there was a difficulty in developing a totally new commercial market that was sufficiently robust to cover the capital and operating costs associated with this startup network. The innovative gravity gradient stabilization design and novel launcher system were not sufficient to save the system from bankruptcy (see Fig. 4).

Yet well over a decade later, the reorganized, restructured, and refinanced ORBCOMM network was able to launch a new constellation of ORBCOMM 2 satellites that had sufficient power, antenna gain, and improved user antennas to support the second generation's sustained operations economically. The new satellite had twice the mass and much higher performance in every regard, but most importantly it had an established and sustained level of customer usage from a wide range of industries, organizations, and governmental customers. This satellite also had a higher-power L-band package that was designed to provide automatic identification services (AIS) to identify ships at sea to help avoid collisions and improve naval operations and safety (Networks: Satellite AIS). This service can also be used for long-distance trucks, buses, and even shipping containers (see Fig. 5).

The market that at one time did not exist when ORBCOMM was created is today quickly evolving as the world of digital communications services has continued to

Fig. 4 The first generation of ORBCOMM. (Graphic courtesy of ORBCOMM)

Fig. 5 The OG2 ORBCOMM satellite with an L-band package for messaging services. (Graphic courtesy of ORBCOMM)

expand in the age of the Internet of Things (IoT) and 5G applications to monitor many mobile functions that vary from sensors on driverless cars to operation of drones. The number of small satellites that are providing functions that include automatic identification services (AIS) to remote data pickup from ocean buoys to store-and-forward or machine-to-machine communications to IoT devices continues to expand. Today, ORBCOMM, an L-band package on Globalstar, Spire, exactEarth, and the international backed ARGOS scientific message relay networks are providing remote data relay services and messaging and also typically supporting AIS applications, but the prospect of providing remote communications to billions of IoT units is attracting a wide range of new smallsat constellations to provide data services.

There is the French-backed Kineis 20 nanosat constellation planned for 2021 that is to replace the long serving ARGOS network. This network currently is using packages on governmentally operated satellites from ISRO, NOAA, and EUMETSAT (ARGOS System). Alexandre Tisserant, Kineis Project Leader, has described this new system as having a laser-like focus on the emerging global satellite-connective IoT market as follows: “Kineis is a satellite operator that will provide unique, universal connectivity fully dedicated to the IoT industry. Any object fitted with a Kineis modem can be located and transmit data wherever it is, whatever the conditions. Kineis connectivity is simple to integrate into third-party devices, consumes very little power and is reliable. All this will be available at a very competitive price, making it accessible to as many people as possible, so Kineis will very soon be locating and collecting data from several million connected objects, in real or near-real time” (Mohney 2018). Of course most of the IoT devices equipped with a modem will be stationary but many will also be mobile. And Kineis is only one of many new systems entering the M2M market with the view to serving the explosively expanding IoT market. Other entries are the Eutelsat-backed ELO (which stands for Eutelsat LEO Objects) and the Else constellation, with perhaps more still to come (Satellite-Based Automatic Identification Market 2025). At this stage, it is hard to forecast how large this market will be and how many of these nanosat-based constellations will succeed.

In summary, the mobile voice and broadband satellite market is today thus divided into GEO-mobile satellite services (i.e., Inmarsat, Thuraya, and Ligado that operates in the United States) and LEO-based constellations Iridium and Globalstar.

The L-band-based smallsat constellations that utilize much smaller and typically nanosats include ORBCOMM, Spire, exactEarth, ARGOS (to be replaced by Kineis), ELO, and Else. New manufacturing techniques and new technology in space and particularly in ground systems have also been key. Finally, demand for new services such as AIS, IoT data relay, and 5G-related demand can all contribute to growth for messaging satellites.

It is important not only to consider the various satellite systems that are providing mobile satellite services and their service characteristics but also to consider in more details of some of the technology that has aided the growth of the larger more capable small satellite constellations, namely, Iridium and Globalstar, as well as the nanosats and microsats that are designed for providing messaging, machine-to-machine (M2M), as well as the newer AIS-, 5G-, and IoT-related services.

7 New Technical Features

A number of technical innovations have aided in the design, engineering, and manufacture of the various types of smallsats used for mobile satellite service (MSS). The following innovations have been key in this regard.

7.1 Additive Manufacturing and Advanced Manufacturing and Testing Techniques

The design, engineering, and testing of the Iridium and Globalstar satellites for their first generations served to transform many aspects of satellite production, especially for smallsats in high-volume production. The production of these satellites used a variety of accelerated production and testing innovations to produce these smallsats at the end of their manufacturing process in under a week rather than in a matter of years as had been the case with large satellites produced in units of just a handful or two at a time. The key was to create and test a satellite's design and manufacturing process so that it could be produced quickly with high quality and reliability. The Iridium and Globalstar first-generation satellites proved to be highly reliable, and these networks lived well past their projected meantime to failure and in most cases two to three times longer than originally projected.

And there were also significant innovations in the design and manufacture of satellite phones. These breakthroughs utilized new design and manufacturing improvements in the production of transceivers with application-specific integrated circuits (ASICs) so that the quality, speed of production, and resilience of these devices produced better and better products. These improvements in user satphone transceivers, of course, were applied to improved consumer products to use with both LEO smallsats and large and powerful GEO sats. Most recently, there has been considerable innovation in the design of ground antennas to relay data and messaging from IoT devices to connect with LEO small satellites. The most recent of these IoT relay antennas are essentially as small as credit cards. Most of these IoT data relay antennas are at fixed locations, but some of these are on mobile platforms or vehicles.

The next step forward in satellite design, engineering, and manufacture has come with additive manufacturing or so-called 3-D printing. Today, a number of key components for satellite manufacture as well as for rockets, including even rocket motors, utilize additive manufacturing production. This not only aids the speed of production as well as the quality and also reduces the costs.

Finally, the miniaturization of computer chips, sensors, and other components has also been added by robotic production that allows these very small units to be produced in a faster, cheaper, and often better way.

7.2 Phased Array Antenna and Intersatellite Links

Another area where mobile satellite systems have led the way in terms of innovation has been in the area of phased array antennas. The phased array antennas on the Iridium satellite were the first time that these types of antennas had been used on commercial satellites, and they allowed efficient beam forming for a maximum amount of frequency reuse to be achieved. These systems performed well and had a very extended lifetime.

The use of intersatellite links was another technical development that came with commercial mobile satellite systems with small satellites operating in low Earth orbit. This innovation allowed for much more efficient operations but required as few as only two command centers for tracking, telemetry, and command which allowed savings in capital investment but over the years substantial savings in operating expenses as well. These were important technical innovations that came with smallsat constellations that operated in low Earth orbit.

7.3 Hosted Payloads and L-Band Packages

The other type of innovation that blossomed with the deployment of mobile satellite constellations involves hosted payloads. Hosted payloads have flown on large satellite for decades, but this has largely been in the form of technology demonstrations. The Intelsat V network flew three maritime packages, and there have been cases of dual-use satellites such as the Marisat satellites that had one payload for US navy communications and another for commercial maritime services. The Iridium Next™ satellites are carrying over 60 Aireon™ hosted payloads to create the world's largest network that operates from a carrier satellite system. Thus the latest Iridium system is also hosting the global network in the form of a package that will be carrying out automatic dependent surveillance-broadcast (ADS-B) services. These innovative services will be the first test of global ADS-B services to allow precision air navigation (Kaul 2019). It can be anticipated that if this large-scale global network functions well the use of ADS-B technology will continue to expand and provide navigation services in all areas of the world not covered by ground-based radar systems.

7.4 Compact Stacking for Launch

Yet another innovation that came with the ORBCOMM system was to design the satellites to be especially compact so that the satellites could be super efficiently stacked to that a number of satellite units could be accommodated in a launch vehicle and placed in orbit in a single launch. The flat phased array antennas that are used in the latest version of the Iridium and Globalstar satellites continue the practice of efficient storage for launch and multiple satellites being accommodated in a single launch operation.

7.5 New Launcher Options

Another key innovation that supports the growth of mobile satellite services is cost-efficient launch options to get the various voice, broadband, and messaging mobile satellite systems into LEO at low cost. The advent of new highly cost-efficient launchers in their latest editions such as the Falcon, New Glenn, Vulcan, Vector, Rocket Labs, Indian Polar Satellite Launch Vehicle, and other new options makes these new mobile satellite networks more affordable. New dispensers and new ways to deploy small satellites such as SpaceX direct insertion from a spinning upper stage represent other launch economies.

8 Conclusions

The small satellites in low Earth orbit (LEO) constellations that were first designed to support new mobile satellite services (MSS) have been a consistent and quite innovative source of many key new ways to design, engineer, manufacture, launch, and operate smallsat networks. The start of this activity came from amateur projects such as the volunteers that built the OSCAR 1 amateur radio store-and-forward small satellites. The Surrey Space Centre and Surrey Space Technology Ltd. began making store-and-forward satellites that could provide messaging and machine-to-machine relay in the 1980s. It was not until the 1990s that there were commercial ventures that designed, built, launched, and operated small satellite constellations in low Earth orbit to provide voice and data relay services. Unfortunately, all of these efforts that included Iridium, Globalstar, ICO, and ORBCOMM all experience a lack of initial sufficient traffic and market and technical issues that led to their bankruptcy.

The revived version of the Iridium, Globalstar, and ORBCOMM satellite networks have all developed a viable traffic base and are now deploying innovative and higher-performance second-generation satellite systems. This has included ever more efficient and higher-performance user transceivers that include the latest in application-specific integrated circuits (ASIC). These systems today (i.e., Iridium Next, Globalstar OG 2, and the current ORBCOMM network) compete with mobile satellite service networks deployed in GEO that include Inmarsat, Thuraya, and Ligado in the United States.

In addition to the voice and broaderband networks, there are new messaging small satellite systems that operate in LEO as constellations and compete with the ORBCOMM network. These systems that most typically are deploying 3-unit cubesats in their constellations include Spire, exactEarth, Eutelsat's ELO, Kineis which is designed to replace the ARGOS space segment (which is a collection of governmentally oriented environmental satellites), and Else. The key to these new smallsat constellations seems to be new types of electronic monitoring and messaging services such as automatic identification services (AIS), IoT messaging services, and 5G-related messaging. The IoT messaging services, in particular, are expected to fuel growth in this area.

Small Satellite Constellations Versus Geosynchronous Satellites for Fixed Satellite Services and Network Services

Joseph N. Pelton

Contents

Abstract

For 50 years GEO satellite systems have dominated the field of satellite communications, and low-cost satellite dishes optimized to work to satellites in the Clarke orbit have dramatically spread across the world. So-called VSATs (very small aperture terminals) have grown by the millions around the globe to provide direct broadcast satellite TV and radio services to homes, offices, condos, and apartments. This type of satellite service has particularly serve to provide connectivity to rural and remote areas of the world. These GEO systems have also support global data networking known as enterprise networks for many large companies. Of all the application satellites providing commercial services to the world well, over 90% of the total revenues come from GEO satellites.

But the world of commercial satellite services seems to be in flux. The birth of "NewSpace" technologies has allowed the faster and more cost-efficient manufacture and reliability testing of small satellites. The new lower-cost launchers have also allowed large constellations of these small satellites to be deployed in lower orbit with greater effectiveness. Finally new types of Earth stations have been developed that can electronically track fast-moving satellites. The new

J. N. Pelton (ed.), *Handbook of Small Satellites*,
https://doi.org/10.1007/978-3-030-36308-6_39

capabilities when combined have allowed the new constellations to function with greater effectiveness. These "NewSpace" systems have now completed the trifecta of new capabilities (i.e., lower cost and more capable small sats, lower-cost launch services, and new electronic-tracking ground systems). All are needed for these new systems to work.

There is concern about just how many of these new small satellite constellations in lower orbit can be cost-effectively and viably deployed in a short period of time. Is there sufficient market to sustain the current plans to launch dozens of these new systems that comprise a total of over 20,000 small satellites? Thus this rapid change to go from about 2000 operational satellites as of 2019 to perhaps over 20,000 satellites as of 2024 represents a series of concerns. Thus there are concerns about space situational awareness (SSA) and tracking, about space traffic management (STM), about market viability, and about the long-term sustainability of space and the near-Earth orbit. This article focuses mainly on the global commercial space market and how quickly it will change and who the winners and losers might be as the world of commercial satellite services undergoes a major transition.

Certainly the so-called NewSpace capabilities have come together quickly – especially in the past 5 years. The aerospace world has been confronted by innovation that has burst forth from Silicon Valley and the World of Google, computer systems, and networking systems. We have seen new ways of thinking, new business models, and new ways of raising capital. We have certainly seen much more rapid evolution of design and a willingness to innovate and provide space services and systems in total new ways. This has started to impact the conventional way of doing business that has ruled the world of aerospace for the past 60–70 years that was largely born of research processes and ways to undertake aerospace innovation born out of World War II.

The new entrepreneurially fueled aerospace initiatives have challenged the models of innovation that have come from the traditional aerospace world and R&D concepts born of the so-called military-industrial complex. New initiatives such as SpaceX, Blue Origin, Planet, O3b, OneWeb, and new enterprise that are designing and building small satellites and ground antenna systems are accordingly opening up new opportunities in the satellite world. Some have questioned whether GEO satellites can survive this new challenge as many new operators have emerged seeking to deploy these lower orbit systems that are well suited for IP-based networking and could help deploy new 5G broadband networks and extended Internet-related services in the least served regions of the world. Others have suggested that the real contest might be those deploying new high-throughput satellites that are ten to a hundred times more capable and cost-effective than those using much more conventional satellite system design that are not cost-competitive.

Another complicating part of this analysis is that a number of the established satellite communications service providers such as SES and Telesat plus others now seem posed to move to provide both GEO satellite and new small satellite constellations in the future. Many of the traditional providers of launch services

such as Arianespace and United Launch Alliance have also embraced significant change in how they design and build new launch vehicles. Many well-established companies that have been around for a long time are adjusting to the new technology and finding new ways to compete in the changing market conditions. This article seeks to look at the markets that GEO, MEO, and LEO satellites might serve in the future and to examine whether both types of services and satellite technology might continue to serve different market demands and find new synergies in the years ahead. Further, some consideration will be given to how changes in the launch services industries and those that are designing and building ground antenna systems will affect the future of satellite communication markets in the coming years. The one thing that is clear is that rapid changes to the world of commercial satellite services will come at an ever faster pace. This means more innovation, lower costs and prices for satellite services, and a fairly chaotic market for at least a decade as rapid progress and technological innovation lead to both lower costs and more market failures.

1 Introduction

The world of satellite communications has been largely dependent on geosynchronous satellite systems for nearly 50 years. The GEO satellite revolution began with the Syncom 2 and Syncom 3 technical demonstration satellites built by Hughes Communications in 1963. This was quickly followed by the Early Bird satellite which was deployed in 1965 by Intelsat. After this success a string of GEO satellites were launched, and the communications satellite industry increasingly relied on geosynchronous satellites. The GEO satellite designs became more and more capable in terms of having more power and with higher gain antennas that could work to smaller and smaller ground antennas. Spot beams that could be constantly pointed to precise locations on Earth and other technology such as polarization discrimination made more spectrum available to use. Digital encoding has allowed higher throughput.

All of these technological advances allowed ground antennas to become lower in cost and more and more widely distributed. In short technology inversion occurred. The satellites were larger and more powerful and more costly, but the ground antennas became smaller, simpler, and less costly. Accordingly the number of user antennas increased in numbers exponentially and became more closely connected to end users. This has now resulted in the ability of users in homes and apartment buildings and condos to access hundreds of television and radio channels from direct broadcast satellites using dish antennas under one meter in size. They can also receive data and download software from high-power satellites using digital standards such as Digital Video Broadcast-Return Channel Service (DVB-RCS) and Data Over Cable Service Interface Specification (DOCSIS).

The growth and development of the Internet and Enterprise data networks have presented a challenge to GEO satellite transmissions. The latency or transmission delay associated with the signal travelling to and from GEO satellites along a pathway of well over 70,000 km creates over a quarter of a second delay.

There are problems with the delay being perceived as system congestion. There are also other transmission difficulties such as headers being stripped off of transmission packet headers. Today there are a number of standards that have sought to work around IP network difficulties and allow more efficient IP transmission over satellites. These include: (i) increasing the window for detecting network delay; (ii) various spoofing techniques to be used at each end of a satellite transmission; (iii) changes to IP Security (IP SEC) processes to better adapt to satellite transmission; and (iv) improved use of virtual private networking in the satellite usage domain (see Fig. 1).

Advocates of low latency transmission systems such as fiber-optic or coaxial cable networks, broadband wireless terrestrial networks, and high-altitude platform systems (HAPS) and now LEO and MEO satellite systems have sometimes suggested that GEO-based systems are no longer up to the task of supporting the needs of a broadband IP world. This idea of using smaller satellites in lower orbit

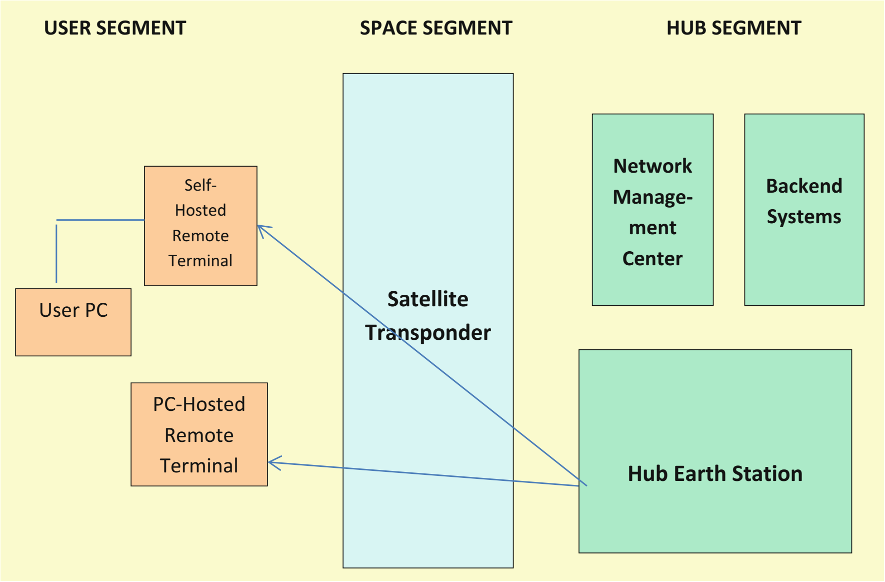

Fig. 1 Diagram showing the application of IP over satellite (IPoS) standards, including IIA Standard 1008, IPoS, TSI Standard TS 102354, and TSS-B

with less transmission delay or latency has in the last 5 years created a groundswell of interest in the deployment of non-geosynchronous satellite networks. The bankruptcies of the Iridium, Globalstar, ICO, Orbcomm, and Teledesic satellite systems of the late 1990s have seemingly been forgotten. While the success of the O3b medium Earth orbit satellite in partnership with SES that now controls this system has rebuilt confidence in such non-GEO systems.

The designers of the new systems feel confident that they can design, build, launch, and operate these new systems that can operate at speeds comparable to that of fiber-optic networks. They feel that they can largely eliminate the latency problems associated with GEO satellite systems. Further they feel the efficiencies of manufacturing satellites using the latest additive manufacturing techniques, accelerated testing and quality assurance techniques, and reduced launching costs associated with reusable launcher systems, and other launcher services innovation have opened up a whole new approach to the cost-efficient delivery of satellite services. What has sometimes seemed to have been overlooked is the need to deploy massive amounts of new low-cost user terminals with terrestrial connectivity that can meet demand for new systems and to complications of deploying these systems globally along with associated licensing and regulatory approvals.

The idea of deploying new satellite systems that are designed to provide new broadband services to the areas of the world where access to the Internet and broadband networking is generally lacking has been the key focus of many of these new initiatives. Clearly there is potential here. Yet there are key challenges to be faced. Deploying of these systems in a timely manner and resolving all of the licensing and tariffing issues clearly and quickly may prove a larger problem than some of the new satellite systems currently envision (Pelton 2017). The earlier bankruptcies of earlier NGSO systems such as Iridium were based on a combination of technical performance, competitive challenges, regulatory constraints related to landing licensing, and revenue-sharing demands and tariffing issues (Pelton 2002).

Greg Wyler was the primary force behind the development and deployment of the medium Earth orbit (MEO) satellite constellation known as O3b. He first examined the idea of deploying terrestrial cable or fiber networks in African countries and then abandoned such efforts as completely uneconomic. Instead he became the entrepreneur leader of an effort to bring new means of connectivity to the Internet in the underserved equatorial regions of the world. He named the O3b satellite system to stand for the “other three billion” people in the world with limited access to data communications. He saw the O3b effort as a means of testing where a lower latency satellite system could better respond to the networking needs of an underserved region of the world. He created a partnership with Luxembourg-based SES and other investors that included Google, HSBC, Liberty Global, Allen & Company, North Bridge Venture Partners, Soroof International, Development Bank of Southern Africa, Sofina, and Satya Capital that financed the new MEO system. In 2016, however, SES exercised its options, increased its ownership share to 50.5%, and then bought out its co-investors (Ownership of the O3b satellite network).

The feasibility of operating lower orbit satellite to provide communications systems had been demonstrated many times in the past. The Initial Defense Satellite

Communication System (IDSCS) had even shown this to be possible as early as 1965, and the Iridium, Globalstar, and Orbcomm systems had shown the technical feasibility of low Earth orbit (LEO) satellite systems again in the late 1990s. The question was whether the O3b satellite system could prove or disprove was market viability. In short, could a non-geosynchronous system, equipped with ground antennas capable of operating with fast-moving satellites, attract enough paying customers to operate in the black? Indeed, the various commercial non-geostationary satellite systems that had gone before, which included Iridium, Globalstar, ICO, Teledesic, and Orbcomm, had also undergone bankruptcy. The first stages of the system were deployed starting in 2013, and by midyear 2016, SES concluded that this service was succeeding in the global marketplace and that the low latency links were attractive from a service perspective.

The backers of O3b that included SES, Google, Liberty Global, Northbridge, and a number of investment banks were largely not testing whether such a system would work, but whether it could gain enough market traction to succeed. In the case of Greg Wyler, the success of O3b propelled him to take not the next step forward but rather a headlong plunge into what he saw as the future of global satellite telecommunications and networking services geared to the world of the Internet and the three billion people who remained largely interconnected to broadband IP data streaming. He with two partners and a small team of people began a project known as WorldVu that evolved into a satellite system known today as OneWeb. The vision was no less that to change the shape and technological vision of what satellite communications meant, especially in the most rural and remote parts of the world that were largely cut off from affordable access to global communications and digital communications.

The idea was to move beyond testing MEO networks with a smaller group of satellites in MEO and to deploy a very large network of small and low-cost satellites in LEO orbit to bring truly broadband services at low cost to the underserved portion of the world and do so at low cost. The vision was in many ways quite similar to that of the designers of the so-called Teledesic satellite network as conceived in the late 1990s.

The question is whether the new LEO systems will succeed in the marketplace by creating new market demand from a pent-up need for services in rural and remote areas of the world where Internet access is limited? Or will new satellite services such as cellular back-haul, Internet of Things (IoTs) messaging, or broader band Internet-based entertainment create totally new market demand? Only time will tell. The problem is that the only market demand that is proven is almost universally carried on GEO satellites. This service is noted in Table 1. Much of this traffic today is on GEO satellites where longer-term contracts are in place to obtain favorable rates. The last few years has seen a loss of subscribers for pay TV satellite distribution in the USA, Japan, and Europe as some users have shifted to so-called over-the-top (OTT) streaming services, but so far this has been a few percentage points and not yet an erosion, and this has been from satellite subscription to terrestrial steaming services. The question thus remains not only whether we are going to see a major shift in market demand for different types of satellite communications networks but also a shift in consumer behavior to move from satellite-based subscription to streaming services. This issue is considered in the next section.

2 The Satellite Communication Service Businesses: How Will It Change?

The business world of satellite communication services is today still heavily focused on GEO orbit satellite networks. This is quite logical in that it is GEO satellites and the satellite service providers who still represent the predominant source of revenue dollars despite some modest revenue declines that have occurred largely in the pay television satellite markets and revenues gain in the launch services, satellite manufacturing, and ground equipment manufacturing sectors.

Well over 90% of those revenues come from GEO satellite networks. Table 1 shows that the satellite services industry and especially pay television service providers are responsible for the lion share of revenues for the global satellite industry (Satellite Industry Association 2019). Table 2 puts the revenues for satellite service providers in better context by showing how significantly satellite service revenues relate to the totals for the overall global space industry. This becomes even clearer when one notes that the ground segment supplier revenues are essentially for GNSS space navigation equipment (i.e., largely application-specific integrated circuit (ASIC) chips in smart phones) or ground equipment for consumers to access communication satellites (Satellite Industry Association 2019).

Although overall satellite service revenues are down in the past 2 years as satellite subscribers for pay TV and radio have shifted to cable television-based over-the-top (OTT) streaming services, this is still the predominant revenue stream. As this trend is expected to continue, it is thought that this will be more than made up by expansion of broadband services in support of 5G service expansion plus other services related to the Internet of Thing (IoT), etc.

The first step to analyzing satellite markets is to realize satellite communication markets are now divided into segments that include broadcast satellite services (BSS), mobile satellite services (BSS), and fixed satellite services (FSS). These broad service categories, and particularly FSS, are now divided into subparts such as broadband, Internet of Things, 5G connectivity, and Automatic Identification System (AIS).

The predominance of broadcast services for direct-to-home and pay television and radio subscription is largely driven by the fact that it is a paid retail service and

Table 1 The commercial satellite service revenues for 2018 broken down by service category

The breakdown of satellite service revenues on a global basis (2018)	
Broadcast (pay television) satellite services	$94.3 billion
Broadcast (pay radio) satellite services	$5.8 billion
Broadband	$2.4 billion
Fixed satellite services	$17.9 billion
Mobile	$4.1 billion
Remote sensing	$2.1 billion
Total satellite services	$126.5 billion

Data derived from the SIA “State of the Satellite Industry” Report, 2019

Table 2 Breakout of revenues for 2018 of key sectors in the global space industry

The key revenue components of the worldwide space industry	
Satellite manufacturing	$19.5 billion
Ground segment equipment	$126.2 billion
Launch services	$6.2 billion
Governmental space and commercial human space flight	$ 82.6 billion
Commercial satellite services	$126.5 billion
Total satellite industry worldwide	$ 360 billion

not a wholesale service as are most of the other satellite services. In the value chain of sales, pay subscription satellite services is able to command both a larger revenue stream and a higher net profitability.

The softening demand for broadcast satellite services and pay satellite services is changing quickly due to the new options that are becoming available by broadband Internet. The global availability of streaming entertainment services, known as over-the-top (OTT) services, is now being offered by NetFlix, Amazon Prime, Hulu, YouTube TV, and others. As these service offerings expand, it is going to have a shrinking effect on revenues for satellite pay TV service providers such as DirecTV, Dish/EchoStar, etc. Indeed Dish and Conviva have formed a partnership some 5 years ago to upgrade its Dish Anywhere and Dish World Digital streaming services (Conviva Swings TVE Deal With EchoStar). AT&T that now owns DirecTV, at an acquisition cost of over $48 billion, is moving toward an all OTT-type service. It is no longer installing direct broadcast dishes but instead mailing consumers a thin “Osprey” box to obtain its OTT digital streaming service via the Internet. John Stevens, an AT&T executive, said recently: “End-users will ‘hook the box into a broadband line’ from AT&T or another service provider in lieu of having a satellite dish installed by AT&T technicians.” Analysts have said that this next iteration of DirecTV, i.e., Osprey, aims to eventually replace direct broadcast satellite service-delivered video content (Engebretson 2019). If these shifts from DBS satellite services to OTT are indicative of the trend line, then satellite revenues are likely to see a major shift. Today DBS satellites do provide other services such as DVB-RCS and DOCSIS types of enterprise services for corporate customers and enterprise data networks, but these are only a modest amount of the overall revenue stream.

Today dozens of digitally streamed OTT service providers are now beginning to blanket the world. The nearly global coverage of these streaming services is indeed softening the subscriber base of the paid satellite television subscribers. The shifts away from DBS service will occur first in the USA, Europe, and Japan. In some parts of the world, it is still easier to access broadcast satellite television through Internet service, but clearly change is happening everywhere. Below is the global coverage map for NetFlix streaming service, and other services such as Amazon Prime are nearly as extensive (Asssayag) (see Fig. 2).

Clearly the rate of that change will be crucial, and it will be different from the regional difference around the world. The crucial question is whether the large-scale digital satellite networks that are now being deployed to serve digital networking and

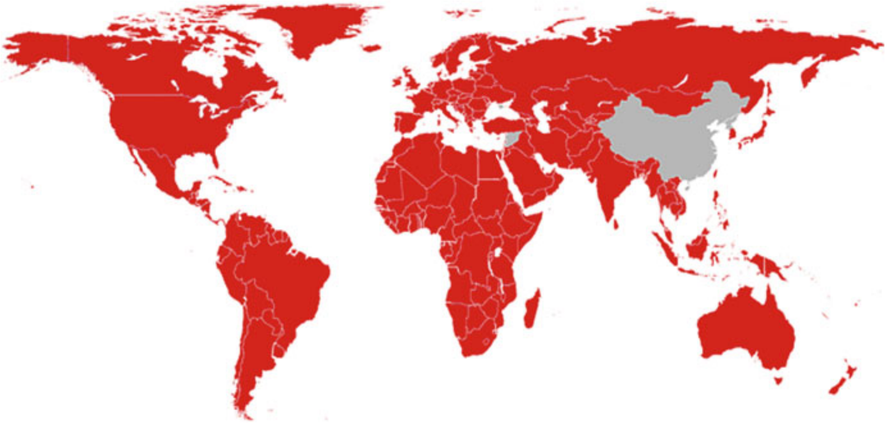

Fig. 2 Worldwide map showing nearly universal coverage of NetFlix and in OTT service. (Graphic courtesy of NetFlix)

broadband Internet and 5G cellular services going to be strategically time to meet new demand that fiber-optic networks cannot respond to effectively?

The current financial status of the top five satellite communication service companies that are providing fixed satellite services (FSS) and some direct-to-the-home satellite services is shown in Table 3. This does not include the revenues for providers of direct broadcast satellite services which represent even higher levels of revenues which are shown in Table 4.

For both types of satellite service companies, the one clear conclusion is that today, the top revenue production for the satellite industry comes from and is dominated by operators of geosynchronous satellites (List of communication satellite companies). The one exception is SES that is now the operator of 44 GEO satellites plus the 20 satellite MEO constellation known as O3b. Also Viasat, which operates Viasat 1 and 2, has indicated that it too plans to move to the provision of digital services on a new MEO satellite network. Intelsat's plan to merge with OneWeb was not consummated and is no longer pending.

Today, it is only in the mobile satellite services (MSS) area that LEO constellations play a major part of the global satellite service infrastructure. Iridium NEXT and the second generation of Globalstar do heavily rely on LEO constellations. Their experience provides useful background and information with regard to the operation, frequency of switching from one beam to another in low orbit, deployment, end-of-life disposal of satellites, and economics of such networks. The next 10 years will provide much more useful information about the safe operation of much larger LEO constellations. The next 10 years will provide much more useful information about the technical, operational, market viability, regulatory processes, and service makeup of small satellite constellations. There are many organizations such as Northern Sky Research, Bryce Research, Euroconsult, and other others that are seeking to understand how fast the global satellite services market will change. This in turn will

Table 3 Global revenue streams for the top five fixed satellite service (FSS) providers. (Prepared by the author)

The top five global satellite service providers of fixed and direct-to-the-home services (based on revenues in millions of dollars)		
Company	Revenues (euros/US dollars (2018))	Products
SES (Luxembourg)	2010 milion euros about $2400 million	44 GEO satellites and O3b MEO system Video and data networking services
Intelsat (Luxembourg)	$2161 million (Intelsat Announces 4th Quarter and Annual Earnings for 2018)	36 GEO satellites. Talks of merger with OneWeb failed
Eutelsat (France) (Henry 2019)	1300 million euros about $1600 million	37 GEO satellites
Viasat	$1600 million	Viasat 1 and 2 High-throughput GEO satellites and proposal for a 20 satellite MEO constellation
Telesat (Canada)(Telesat Reports Results for the Quarter 2019)	$903 million	14 GEO satellites and beginning to deploy LEO system

The total revenues for these FSS service providers were taken from publicly released annual financial statements for 2017 or 2018. These are considered to be only approximation of current revenue streams. Please consult corporate web sites for more current numbers

Table 4 Revenues for the providers of DBS services. (Prepared by the author)

Key providers of broadcast satellite services globally		
Name of company	Estimated total revenues	Satellite network
Sky Vision (owned by Comcast with subsidiaries operating in the UK, Ireland, Germany, Austria, Italy, Switzerland, and Spain) (Skyvission)	13 billion pounds (about 17 billion dollars)	In addition to network of Sky satellites offering pay TV, there are also offerings of broadband digital services and significant entertainment and media productions
DISH(DISH Network Reports Fourth Quarter 2019)	$13.6 billion (2018)	16 GEO satellite between 61 and 148 degrees west
Direct TV and various subsidiary companies (DirecTV)	On the order of $12 billion/yr (it is a part of the AT&T Entertainment Group, and precise figures are not available)	13 GEO satellites between 95 and 115 degree west
JSAT and sky perfect satellite network	200 billion yen (about $2billion dollars)	3 GEO satellites

The total revenues for these DBS service providers were taken from publicly released annual financial statements for 2017 or 2018. These are considered to be only approximation of current revenue streams. Please consult corporate web sites for more current numbers impact the world of satellite manufacturing, the launch services, the space insurance markets, and more.

The danger of many market forecasts is that they often look to the future by looking through a rearview mirror. All the past revenues, all of the millions of subscribers to pay TV satellite systems, all of the DBS satellites in orbit, and all of the millions of parabolic dish antennas deployed around the world now working via GEO satellites would suggest that this is a solid business. Small satellite constellations are not well suited to reception of video, movie, and news. But if the world changes so that people have access to 5G cellular service and broadband Internet, the advantages of DBS satellites can be severely undercut. The moves by AT&T/DirecTV and Dish/Internet to OTT-distributed media services and the shrinking revenues and number of subscribers to DISH and DirecTV are signals that satellite service providers need to look at new business models. Intelsat is already working with Softbank Japan to see a merger with OneWeb. SES has successfully deployed O3b and has plans for a new MEO system that can deliver laser system-type throughput and new levels of cost efficiency. Viasat that operates Viasat 1 and 2 that represents the highest throughput GEO system in the world currently in operation has announced plans to move to a MEO system as well.

The strategic business and market indicators seem to suggest that the world data networks and media distribution networks are all moving in the direction of digital streaming and broadband distribution networks that are geared to low latency. The Internet, IP-based networking, and broadband networking geared to support 5G, Internet of Things connectivity, and media distribution will contain a satellite component for some years to come. This conclusion is inescapable when one considers the vast regions of the world where fiber-optic cable cannot provide connectivity to users. There are large areas of the Earth such as the oceans, lakes, deserts, jungle and mountain regions, the arctic areas, and more where satellites can offer broadband digital networking connectivity. Even in areas where DBS areas may be replaced by OTT services using terrestrial telecommunications capabilities, the transition will take time.

The point of this analysis is that the huge installed base of parabolic DBS dishes for home entertainment and news could become meaningless resources to be recycled if the DBS satellites are no longer beaming down programming. There are concerns among industry officials and analysts that there is now enormous momentum that entertainment and news services are shifting their distribution to OTT streaming systems. These systems can provide movies and news at a fraction of the now available DBS networks. Of course this is only the case in regions of the world where reliable, affordable, and technically viable Internet connections are available.

One of the groups studying the changes to the world of satellite communications is the BusinessandMarkets.com group. They have developed the following key questions that they will address in conducting a systematic study of how the world of satellite communication services will change in the coming decade and the top market, strategic, and technical forces that will shape this change – particularly in terms of small satellite constellations and its impact on the established world of geosynchronous satellite networks. These are key strategic questions, and the answers once developed will provide useful insight. Of all these key questions as noted below, the prime one not stated, seems to be how large a role will communication satellites play in providing news and entertainment to the world and via which types of satellites in a world that has large shifted over to 5G cellular service, digital streaming, and most devices enabled with IoT connectivity?

- "How has the satellite communication market performed (segmented by region and services) in the last 5 years?
- What was the regional and services market shares of the top satellite operators in the last 5 years?
- Who were the top-performing satellite operators in terms of revenue generation and revenue growth in the last 5 years (segmented by region and services)?
- What are the key industry trends that may drive/restrain the satellite communication market growth?
- What are the key value propositions by the new market entrants?
- How are incumbent players responding to the market challenges and competitions?
- How is the satellite communication market (segmented by region and services) forecasted to grow from 2018 to 2025?

3 Conclusion

The number one market consideration with regard to the future of satellite networks seems to be related to the satellite distribution of global entertainment and news. The question is whether existing satellite broadcasting systems and direct-to-the home television systems that are today essentially dependent on GEO satellites in Clarke orbit will give way to new digital streaming networks and OTT systems? It is not clear as to how quickly a transition to OTT will occur and how this will be different in different parts of the world. Today GEO satellite networks in locations such as India, China, Indonesia, Brazil, Nigeria, and many underserved portions of the world use satellite for television, radio, and telecommunications systems. This is even more important for rural and remote areas that lack terrestrial telecommunications networks or even reliable access to power.

Of course, the issue of whether satellite networks are used to provide television, radio, and connectivity to the world has implications that are, in fact, much wider. To the extent that remote access shifts from satellite networks to terrestrial systems and 5G data streaming for news and entertainment, it will also shift for virtually all other applications. In this new data streaming, world small satellite constellations with low latency will be better adapted to providing this service than GEO networks that are so dominant today.

GEO satellite connections, of course, are now used to provide connectivity for news and entertainment, but they can also be utilized to provide a wide range of other essential services that are key to life, especially in rural and remote areas. Thus satellite connectivity can provide key conduits of information for safety and disaster warning alerts. It can provide a mechanism to provide tele-education and tele-health services, especially to rural and remote areas where these services might be quite limited if not totally absent. The key question is as follows: In a new world of OTT for news and entertainment and data streaming, how does this impact the world of satellite networking and services? Does this new world – the world of 5G broadband wireless connectivity and IoT device connectivity – foretell a major shift in satellite network design and deployment? Does it suggest that GEO-based satellite networks are phased out in favor of small satellite constellations with low latency and very high transmission speeds that are comparable to optical-fiber laser transmission speeds? If this transition occurs, how quickly will it occur?

Satellite broadcasting revenues using GEO systems only decreased 1.7% in 2018, but transitions to OTT systems by DirecTV and Dish/EchoStar to OTT systems suggest a more rapid change in coming years (Satellite Industry Association 2019).

This is of course about much more than entertainment and news services via satellite networks. It is a leading indicator for other such services and for other vital applications such as tele-education, tele-health, safety alerts, governmental services, and even tele-business and tele-work connection. Critical regions to monitor will be India and China where GEO satellite provides vital services such as tele-banking and other services including television and radio connectivity. There are other technical factors such as the design, cost, and availability of new electronic tracking ground antennas that are key to the speed of the rollout and use of LEO and MEO satellites for data streaming services. This too will be a key factor as to how quickly markets, services, and satellite networks change to the new data streaming world.

Messaging, Internet of Things, and Positioning Determination Services via Small Satellite Constellations

Joseph N. Pelton

Contents

Abstract

The focus of the satellite application market for many years has been on broadband services and especially on video services provided by large high-powered satellites located in geosynchronous earth orbit (GEO). This type of service, known in the parlance of the International Telecommunication Union (ITU) as broadcast satellite service (BSS), has been the top source of revenues. Companies providing direct broadcast satellite services have, in fact, produced over 70% of satellite service income. Today there is a burgeoning new market associated with digitally networked services that small satellite constellations might be able to provide with particular skill. Some of these services require only thin data streams

and can be provided by quite small and cost-effective satellite networks. Others may demand much higher data rates and thus may be serviced by significantly higher data rates.

The focus of this particular chapter is on messaging, machine-to-machine (M2M), automatic identification services (AIS), and new forms of satellite-based Internet of Things (IoT) services. These are the new types of services that much small satellite constellations with lower bit rates can provide. These new systems such as Orbcomm, Kepler, Spire, Else, Kineis, ELO, and others can be deployed at much lower cost than the bigger mini-satellite systems seeking to provide broadband services. They can also operate to much lower-cost omnidirectional ground terminals.

It is possible that mini-satellite constellations with much higher-throughput rates optimized for 5G services and video via over the top data streaming services will create very large new multibillion dollar markets. These types of services, however, will be provided by larger types of small satellites configured to operate in higher data rate constellations. These services will be reserved for either GEO high-throughput satellites or mini-satellite constellations. This gigabit per second market, if served by small satellites, will be reserved for those megaconstellations being implemented by OneWeb, SpaceX's Starlink, LeoSat, Boeing, Thales, and others.

This chapter concentrates on the interactive satellite messaging services that deal in megabits per month rather than process information in gigabits/second.

Automatic identification services (AIS) · Data relay services · Else constellation · Eutelsat LEO for Objects (ELO) · Geolocation · International Telecommunication Union (ITU) · Internet of Things (IoTs) · Kepler · Kineis · Messaging · Machine-to-machine (M2M) · Orbcomm · Position determination · Spire · VHF data exchange services (VDES)

1 Introduction

The Surrey Space Centre, now known as Surrey Space Technology Limited (SSTL), played a key role in the early development of small satellites with advanced digital processing and storage capability that could provide messaging and store and forward services. These "Surrey sats" could provide messaging relays to support remote locations such as medical clinics, oil platforms, and remote mining sites and collect data from ocean buoys and score of other locations. These low-cost satellites that operated at low data rates did not require sophisticated or expensive ground terminals.

The idea that small and efficient satellites might be able to assist with messaging and location tracking continued with the GeoStar network that operated in geosynchronous orbit and then with the Orbcomm small satellite constellation that was deployed at the same time as the first systems for mobile satellite communications. The Orbcomm system, first developed by the Orbital Sciences Corporation, allowed trucking companies, shipping lines, rental car companies, bus companies, and others to stay in touch via messaging services. Additional capabilities that were added to provide GNSS capabilities via the GPS network augmented the messaging services with navigational and geolocation services as well.

In the world of cubesat and nanosat technology, there are today a number of systems that are deploying or developing new capability to deploy quite small satellites to use messaging or machine-to-machine (M2M) services for a much wider range of data relay services at modest data rates. These new networks are not seeking to compete with broadband high-throughput systems such as SpaceX, OneWeb, and many other companies that are now deploying. The emphases of these data relay satellite systems are messaging, machine-to-machine communications, geolocation, automatic identification services, and Internet of Things data relay. Some of the systems that are now providing these services or are planned for such services in the near term are discussed in this chapter. The presentations explain the various types of services offered, technical and service challenges and competitive options, and finally regulatory or standards issues that pose issues with regard to the provision of such services.

2 Orbcomm

The Orbcomm initial system was deployed in the 1990s. At that time this type of small commercial messaging satellite constellation represented a completely new start-up enterprise seeking to develop a new market. The Orbital Sciences Corporation provided the launch services, designed and manufactured the satellites, and was responsible for the marketing of the new global messaging services. Although it had a very innovative satellite design, low launch costs, and other positive attributes, it was an entirely new type and thus a high-risk undertaking. It had the difficulty of starting a new global messaging service from scratch where the intended customer base around the world had little appreciation of the value that could be derived from the new services provided. Further Orbcomm had little experience in marketing its service to customers who might most benefit from these services. The end result was that it went bankrupt. All of the somewhat parallel mobile satellite communication ventures, namely, Iridium, Globalstar, and ICO, also failed financially and so went bankrupt.

Orbcomm was reorganized under new management, and this messaging service gradually became financially viable. Currently a second generation of packet-switched (M2M) messaging satellites, as manufactured by Thales Alenia, has now been deployed at a cost of $240 million. This second-generation spacecraft is described by Orbcomm as offering up to six times the data throughput capacity and up to twice the transmission rate of the earlier satellites. This second generation of satellites was initially deployed as a network of 18 satellites. The second generation of Orbcomm satellites also has an L-band package that allows satellite-

Fig. 1 One of the second-generation Orbcomm satellites as pictured in orbit. (Graphic courtesy of Orbcomm)

based automatic identification services. System failures with the second generation of Orbcomm satellites (OG2), however, have reduced this second-generation network size significantly. The current network combines both first- and second-generation satellites, but 80% of the traffic is now on the second-generation satellites. There is also a cooperative agreement with Inmarsat to provide mutual support for services. A third generation of satellites is now under active study (Henry 2017a) (see Fig. 1).

Although the basic service is described as machine-to-machine (M2M) messaging, the range of services described under this general "umbrella" is now quite large, sophisticated, and geared to various industries. Over time many types of industries in areas such as transportation, product shipment, mining and resource extraction, etc. have learned the value of the various satellite services now on offer by Orbcomm and other messaging satellite service providers. The Orbcomm satellite services have also become more refined and diversified to respond to various types of market needs. The Orbcomm offerings now break down into three categories of (i) Web Applications, (ii) Radio Frequency Identification/Real-Time Location Services (RFID/RTLS), and (iii) IoT Solutions for Remote Monitoring and Control.

Under **Web Applications** Orbcomm offers services that include:

Road Transport. (i) Fleet management for trucks, trailers, and refrigerator units; (ii) CargoWatch (for trailers and chassis); and (iii) ReeferTrak (to provide compliance with regulatory requirements as well as optimized temperature levels for fuel savings).

Intermodal Transport This typically involves shipping, air, rail, and truck operations. This provides sub-options such as (i) Reefer Connect, (ii) Vessel Connect, (iii) Cargo Watch Security, and (iv) Fleet Edge (this last offering is designed to support various types of equipment telematics-related services and data interactions).

The second broad category of messaging service that Orbcomm now provides is **RF Identification (RFID)/Real-Time Location Services (RTLS)**.

This type of service is broken down into:

(i) **RFID Software** (for both manufacturing and inventory control)
(ii) **AssetWatch** (to provide for asset safety and security and inventory control)

The third area that is also now growing the most rapidly as a market is **IoT Solutions for Remote Monitoring and Control**.

In this satellite messaging arena, Orbcomm offers an entire toolkit of services as well as hardware options. These offerings range from a turnkey type of comprehensive service that provides software and hardware. There are also other types of satellite messaging services as well as more discrete satellite services or hardware options.

These offerings in the IoT Solutions area include:

DeviceCloud: This allows interactive communications with connected devices in a customer's system. This proprietary system, as provided by Orbcomm, creates a single interface to manage multiple networks and devices.

Application Enablement Platform known as iApp: iApp is an application enablement platform that Orbcomm claims can reduce the time, cost, and complexity of deploying high-performance RFID as well as sensor-enabled IoT applications. This can allow RFID and IoT applications to be communicated with interactively and on a global scale with only modest delays. With the second-generation OG2 satellite messaging connections, times have continued to improve with delays being measured in seconds or at most a few minutes.

Orbcomm Provided IoT Hardware: It is possible to obtain via Orbcomm a range of tracking and monitoring capabilities. The types of hardware that can be purchased or leased include programmable terminals and sensors and compatible satellite modems that allow a variety of telematics solutions. These various hardware offerings are designed with suitable software to operate under different international standards.

It is possible to sign up for a complete end-to-end IoT deployment that includes both the service and the hardware. These comprehensive end-to-end offerings include a suite of cloud-based software as a service (SaaS) capabilities. It is possible to operate these from a platform as a service (PaaS) basis. The purpose of these Orbcomm offerings is to allow near real-time reporting on the status of assets. Thus Orbcomm and other newer entries into the satellite messaging service industry can provide global tracking and managing of assets for many different types of industries with goods and materials widely distributed around the world (ORBCOMM 2019). These other satellite messaging services will be described below. Many of these new systems that are concentrating on IoT service or automatic identification service are presented below.

Orbcomm has the advantage of many years of experience. Over that time Orbcomm has become less and less an operator of small satellite constellation. Instead it has become a provider of services – and specialized telematics and data networking or geolocation hardware – to those involved in transportation and other industries such as mining, manufacturing, and other industries that are concerned with efficient management of assets – especially organizations that have resources widely deployed all over the globe and where supply chain efficiencies have become quite important.

This detailed reporting on Orbcomm services as provided above in many ways might be seen as a model for the types of satellite messaging services that can be expected to be offered by other small satellite systems now being deployed. The Orbcomm satellite experience in terms of developing tools and interactive capabilities well suited to client industries is a useful paradigm for a number of new companies now seeking to provide M2M messaging services via small satellite constellations to support safety and security, inventory control, interactive IoT services, automatic identification services, and position determination and geolocation updates.

3 Satellite-Based Automatic Identification Services (S-AIS)

The established small satellite constellation, Orbcomm, is now equipped via an L-band package to provide satellite-based automatic identification services (S-AIS). Nevertheless, Orbcomm is not unique or predominant in this satellite service area. It has strong competition from several other satellite service providers including from entities operating with new nanosat constellations which have shown innovation in this area such as more extensive coverage, very rapid domain identification capabilities as well as cost reductions for the service.

exactEarth, in particular, has deployed a near real-time network that now operates from a second-generation hosted payload capability installed on the Iridium Next constellation for this purpose. exactEarth has joined with the Harris Corporation to create the payloads and with Iridium to deploy its AIS payloads on the Iridium Next 66 host platforms that are employed to provide this global service.

Currently there are 58 operational exactEarth payloads plus 7 spares that are flying as hosted payloads on the Iridium Next system to form the exactEarth RT constellation. This second generation of the exactEarth constellation is capable of rapid domain identification for ships and ocean-going vessels (exactEarth's Revolutionary Global Real-Time Maritime Tracking and Information System now Fully-Deployed n.d.).

Automatic identification system (AIS) is a global standard for ship-related messaging services operating in the VHF band and 161 and 162 MHz. This service is designed to avoid collisions and aid search and rescue (SAR) operations and maritime domain awareness through near-instantaneous ship and other vessel tracking. AIS was ruled to be a mandatory safety and security service for all ships and vessels for A and B types of service under the International Maritime Organization's (IMO) International Convention for the Safety of Life at Sea (SOLAS). This Convention was adopted and entered into force in 1974. Satellite-based automatic identification service (S-AIS) allows for global coverage in remote areas, such as isolated oceanic and arctic regions. It complements terrestrial AIS and coastal radar coverage. This service is particularly important to enhance AIS connectivity in arctic and more isolated ocean areas where satellite access is largely the only available option (see Fig. 2).

The problem for the future is that the VHF band is only able to support very limited bandwidth services because of the now very intense use of spectrum between 30 and 300 MHz on a global basis. The very narrow bands available for the automatic identification service is on Channel A 161.975 MHz (87B) and Channel B 162.025 MHz (88B). Thus the offerings such as the VHF data exchange service cannot be expanded. The only option is more efficient coding that allows more bits/Hz to be transmitted.

The exactEarth constellation claims the following capabilities with regard to S-AIS domain identification for ocean-going vessels: (i) global average satellite revisit coverage of under 1 min; (ii) customer data latency under 1 min; (iii) reliable detection of both Class A and Class B AIS messages; (iv) tracking of large populations of small vessels with suitably equipped with AIS transceivers (this is known for the exactEarth-Harris service as exactTrax™); and (v) support for the future evolution of AIS to provide VHF data exchange service (VDES) and other initiatives in the maritime VHF band (exactEarth: Real Time Global Ship tracking n.d.) (as noted above the limited frequency spectrum available in L-band limits any great expansion of VDES).

In addition to exactEarth, the Spire small satellite constellation has developed a capability to provide global S-AIS services. In the case of Spire, it provides not only

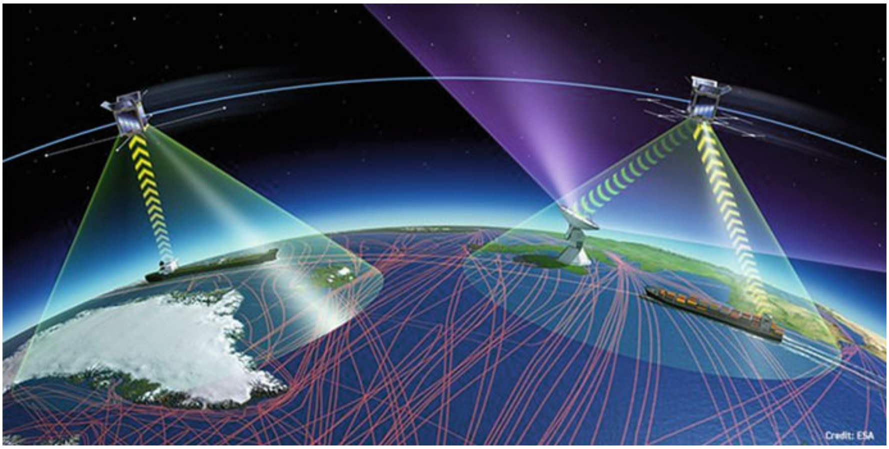

Fig. 2 Graphic showing satellite reception of S-AIS signals from ships on the high seas. (Graphic courtesy of the European Space Agency)

domain identification for ships and vessels but also data analytics that projects with good accuracy where a ship will be at the time of the next location update. There are also several other start-ups that are seeking to provide S-AIS services via new cubesat-type constellations.

There are detailed market studies that have projected that global shipping and demand for S-AIS services will continue to grow. One of these market analyses is the insight report known as the "Satellite-Based Automatic Identification Systems Market 2025 – Global Analysis and Forecasts by Type (Class A Transponder and Class B Transponder) and Applications (Ship, Defense, Aerospace, and Intelligence and Security)."

The question is whether this market is sufficiently large and diverse enough to sustain a growing number of small satellite constellations. Most systems such as Orbcomm, Spire, and several others have seen the S-AIS market as a source of incremental revenue, but exactEarth has seemed to focus on this service as a primary source of revenue (Satellite-Based Automatic Identification Market 2025 n.d.).

The market demand and size for S-AIS have been seen to be in flux. This market is currently still small and largely depends on governments contracting to obtain the S-AIS data in order to track shipping and vessel activity and provide for at sea safety and security. In many cases governments depend on coastal radar for tracking shipping movements within 100 miles (160 km) of their shores. Thus some governments see S-AIS as an optional service. Shipping lines are still seeking to prove that their savings in fuel, shortened port stays, and safety and security are sufficient to pay for such services.

The Canadian government contract services is a case in point. It awarded an initial contract to exactEarth S-AIS service provider in 2014 in the amount of $19 million (Canadian) or ($14.5 million US), but after fierce competition between Orbcomm and its Canadian subsidiary Skywave Mobile Communications for the renewal of this contract, it was determined that the Canadian requirements for data were to be severely cut back. The reduction of some $7 million in revenues (or $600,000 per month) represented about 25% of exactEarth revenues at the time. This major loss of revenues resulted in a major reduction in the stock price of exactEarth that is offered on the Toronto Stock Exchange. As more constellations join Orbcomm, Spire, and exactEarth to compete for AIS-type service (i.e., the Else nanosat constellation, the new Eutelsat LEO for Objects (ELO) constellation, the French Kineis constellation, and others), the profitability of quite so many messaging, IoT, and truly small satellite constellations may come into increasing question (de Selding 2016).

4 Other Systems for Messaging, IoT, AIS, and Lower-Data Rate Services

The idea behind many of the true small satellite constellations now being planned is that they can be deployed for a modest cost. Some estimates have been as low as $50 million and most at a cost of around a quarter of a million. Low cost alone is not sufficient. The key question is whether a low-cost small satellite system operating at low data rates can find sufficient market and revenue streams to sustain their operation. Some of these systems have started with test satellites funded by kickstarter programs on the Internet, and others have been funded by satellite companies operating geosynchronous satellite systems but envision that LEO constellations might be key to providing data services requiring low-latency transmission times. Each of the following small satellite constellations provides useful insight into these new systems and the thought process behind their planning and implementation.

5 Spire

Currently Spire Global Inc. characterizes its business operations in a much different way than when it first started**.** Today it indicates that its role is focused on data analytics related to tracking of global data sets derived from the tracking of maritime, aviation, and weather patterns. Its main focus shifted from data messaging and provision of AIS type services when it received major contracts in the weather data analysis areas. The breakthrough award came from the European Galileo project to conduct longer-term weather data analytics. This contract over time is potentially worth $2.7 billion (Sheetz 2018). This Galileo Award was preceded by 3 months by a much smaller award from NASA for a weather data and observations analysis contract. This NASA contract was, however, likely a critical antecedent to the European award (Mohney 2018)

Spire Maritime was launched as a new business unit at the end of 2018 and officially announced in February 2019. The purpose of this is to focus on use of L-band systems to collect automatic identification service information on a global basis using its Lemur 2 constellation of a 100 deployed nanosats to identify the names and ownership of all ships at sea and their routes on a near-instantaneous basis. Further they will seek to generate predictive data as well in order to provide historical data on vessel usage or cargo shipping patterns. The purpose of Spire Maritime analytics will be to help enforcement against illegal fishing, smuggling, drug running, polluting activities, etc. as well as to assist with more efficient routing of ships and vessels and provide for accurate tracking of cargo and improved safety and security on the high seas.

The idea is to seek to “reinvent the maritime world” through the use of data analytics. The leadership of Spire Maritime has state its goal to be “to create new technologies for the maritime industry under the guide of seasoned leaders. Spire Maritime will utilize technologies like machine learning to deliver real-time data and insights that raise the bar in the maritime world” (Spire Announces a New Business Unit for Maritime Data and Analytics n.d.).

It also uses its 100 satellite constellations of Lemur 2 satellites, the third largest constellations in the world in terms of operational satellites, to operate hosted payloads for automatic dependent surveillance broadcast (ADS-B) for airline tracking and safe navigation and security. (Note: the Iridium Next 66 satellite constellation now is the host platform for 58 ADS-B operational units plus 7 spares).

Spire thus lists its services to include (i) Spire Sense Cloud (satellite and terrestrial AIS); (ii) Spire AirSafe (satellite ADS-B); (iii) Spire Stratos (GPS-RO and GPS-R); and (iv) Orbital Services The main focus is the environmental and weather data

Fig. 3 Lemur 2 nanosat with payloads for AIS, ADS-B, and weather data. (Graphic courtesy of SPIRE Global Inc.)

analytics or Spire Stratos, although with its 100 satellite constellation deployed in orbit, it is a serious provider of all these services (Spire Global n.d.).

Spire was the first to launch its multiunit cubesats from the NanoRacks launch dispenser from the International Space Station (ISS), and it has also used a wide range of other launchers to get its large fleet to orbit. Since the Lemur satellite constellation only has a lifetime of 2–3 years, it is in need of rather constantly manufacturing new satellites at its joint facility with Clyde Space in Scotland, as well as to provide for deorbiting of defunct spacecraft (see Fig. 3).

6 Kepler

The Kepler constellation is a much more straightforward story in that this start-up had a clear commercial focus on creating a global small satellite constellation for messaging and highly efficient M2M services. Its prime market focus is seen as Internet of Things connectivity for very small and compact transceivers the size of credit cards. Its mission statement emphasizes that the system that they are designing, building, launching, and operating is “satellite communications simplified.” Kepler Communications website states that their ambition is designed to “integrate our satellite connectivity solutions into your global operations and communicate like never before.....to provide connections from small sensors to large ocean going vessels so that ‘One Standard IoT’ can be made available everywhere” (Kepler n.d.).

The emphasis of the Kepler offering is on a simple cellular link via a compact transceiver to provide connectivity for Internet of Things (IoTs) units. This is, in fact, a credit card-sized transceiver that runs on an AA-sized battery for years. This type of IoT-designed Kepler link is geared to provide service at up to 1 megabit capacity per ground transceiver per month for data collection and control messaging. In many ways this capability is similar to that provided by tradition supervisory control and data acquisition (SCADA) systems that operate with pipelines, elevators, or

Fig. 4 Kepler nanosat constellation that specialized in satellite links to credit card-sized transceivers so as to provide connectivity to Internet of Things (IoT)-enabled units. (Graphic courtesy of Kepler Communications)

utility operations. The Kepler constellation is uniquely designed for global connectivity including satellite service and coverage even in the polar regions (Kepler Services n.d.) (see Fig. 4).

In addition, Kepler with its S-AIS capability is also able to offer fleet and route tracking, alerts to any route variations, asset monitoring, and other services that are similar to those offered by Orbcomm, exactEarth, and other small satellite constellation discussed in this article.

7 The Else Nanosat Constellation

This project is a joint venture of Astrocast of Switzerland and Yahsat/Thuraya of Emirates. Around the world operators of geosynchronous-based satellite networks such as Intelsat, SES, Thuraya, Eutelsat, and Telesat are exploring how they might diversify into LEO-based constellations and capture data networking services that require low latency or minimal delay in their transmitted services. The Else nanosat system is to be operated by Yahsat. Yahsat now operates GEO satellite systems. This includes the Thuraya system which is a large GEO based system for mobile satellite communications services. The Else constellation represents the way that Yahsat is examining a way to enter the LEO constellationa market by means of a lower-data rate nanosat constellation. (Henry 2017b).

Astrocast that has designed and manufactured nanosats previously is manufacturing the Else small satellites. Thuraya, now owned by Yahsat, is providing the capital financing and also sharing its expertise in marketing satellite services in the Middle East, Africa, and elsewhere.

Fig. 5 Else cubesat constellation by Astrocast in partnership with Yahsat/Thuraya

The idea is to use limited L-band capacity to provide M2M messages via the Astrocast 64 satellite constellation. This constellation will consist of eight satellites located in eight planes. The terminal design for messaging from the ground will be even smaller than the Kepler system. Its currently proposed size is about the size of a stamp, and its L-band antenna will be about the same size. It can be battery operated or connected to a local power source. Its current objective is to be able to relay messages to its customers operations center within a 10–15 min time period (Henry 2017c) (see Fig. 5).

8 Eutelsat for LEO Objects (ELO)

Eutelsat has purchased from Tyvak International a number of nanosats for the purpose of providing a low-data rate Internet of Things (IoT) service. This represents yet another instance of a large GEO operator seeking to find ways to enter the LEO constellation market but not necessarily making a large capital investment to do so.

This project will be drawing on the technology currently used by Sigfox to operate a land-based low-power wide area network (LPWAN) messaging system. Sigfox and other similar operators use their WAN-based systems to provide asset tracking, environmental monitoring, and tracking of utility meters such as for water, electricity, natural gas meters, and other systems controlled by supervisory control and data acquisition (SCADA) networks. The range of coverage for these low-powered WAN networks with connectivity to nearby gateway or nodes is typically in the range of 10 km and at the outside is usually 20 km. This range is insufficient to provide coverage in areas such as the desert, jungles, mountainous terrains, and oceans. This is where a global constellation becomes quite useful. Although GEO systems are adept at many services, this type of data collection

Fig. 6 Eutelsat LEO Objects (ELO) nanosat designed for the IoT market. (Graphic courtesy of Eutelsat)

from very small terminals connected to Internet of Things-enabled devices and SCADA-like systems is difficult. This type of service at L-band is well suited to LEO constellations. In short the LEO constellation two test satellites will test this type of service before the full constellation is deployed (see Fig. 6).

Yohann Leroy, Eutelsat's deputy CEO and chief technology officer, has explained the reasoning behind the ELO constellation initiative as follows:

> "There are fundamental differences from a technical standpoint between the broadband market and the IoT market, which is a narrowband market. . .....The only way to transmit megabits per second with satellites that move through the sky is to have a tracking – and necessarily expensive – antenna on the ground. [For IoT], when you only need to transmit a few kilobits per second and not megabits per second, omnidirectional – and much cheaper – antennae are sufficient" (Henry 2019). This logic also means that the terminals and their antenna and their power sources can also be quite small.

9 Kineis

There is another important French nanosat constellation that is in active planning. This system is to augment and then replace the seven-satellite Argos system that has been in operation since 1978. It will use L-band systems for messaging, M2M, and IoT connectivity. The new system is to be known as Kineis. This is to be a 25-satellite constellation that will draw on the experience gained by the Argos satellite system that has been providing messaging services to a world community of environmentalists and other users for several decades. This project is backed by CLS, CNES, Thales Alenia, Nexeya, and others in France. There are currently two preliminary satellites in orbit to provide experimental tests with ground equipment and refine the design of the satellites and ground terminals. While Argos was a project of the French government and CNES, Kineis is seen more of a commercial venture (Kineis constellation n.d.).

10 Other Messaging Satellite Systems

The above discussion and summary discussion of planned small satellite messaging systems that also includes the second generation of Orbcomm still do not represent a completely exhaustive list of all the various types of small satellite constellations that have been announced as possible new initiatives in the field of AIS and messaging services. There are some that have indicated plans for a sort of satellite communications service that would be sold on a public subscription basis and other types for safety, development, and scientific services. The above listing is representative of the systems that seem likely to be deployed. The listing of constellations in Part 13.1 is provided as a more complete listing of various systems that might be deployed within the next 5 years.

11 Cost of System Versus Size of Markets

Most of the systems that are now envisioned or are in actual deployment at this time are quite cost-effective. Many of these systems can be deployed for a cost that is equivalent to the cost of the launch of a single high-powered and high-throughput geosynchronous satellite system that might be deployed by Intelsat, Eutelsat, Telesat, SES, or Viasat, but there is still doubt as to whether the market for such AIS and messaging services is sufficient to cover the total cost of operations of so many new LEO constellations planned for operation in the L-band with such limited data throughput capability. The messaging smallsat constellations, even with advanced new coding systems, are limited in their throughput. Planned expansion of VHF data exchange services (VDES) will be limited by L-band allocations for this service to ships.

For decades, the Argos system has been subsidized in its global messaging service by CNES. Now at least six LEO constellations, i.e., Orbcomm, Spire, Kepler, Else, ELO, and Kineis, are planning to provide these various types of messaging services. Clearly the new IoT market with perhaps many billions of interactive units seeking to be interconnected creates new market opportunities. Nevertheless some of the market analysis has now undertaken a question that the planned investment costs for these various systems that will likely top a billion dollar (US) can all be recouped.

12 Conclusions

The world of “NewSpace” and particularly the ongoing effort to create new types of small satellite services seem to continue apace. There is clear appeal to create new small satellite constellations, especially low-cost nanosat systems that can typically be deployed for under $300 million dollars. This is a business that start-up companies, especially if helped by larger satellite companies, can contemplate entering.

New space investment strategies that can be started with kick-starters and crowdsourcing and then financed by angel investors with rounds of funding have allowed companies such as Planet and Spire to soar into prominence. These two start-ups currently operate two of the largest satellite networks in the world.

The success of some of the smallsat constellations and new launch vehicle firms like SpaceX, Blue Origin, and Rocket Labs can create false expectations in some of the small satellite initiatives now seeking to create new LEO constellations to serve new markets that have yet to be entirely proven. The arena of data analytics is perhaps the new space market with the greatest potential for new vibrant space applications, but it is also the area where the greatest commercial risks might also lie. The large number of these new systems, existing and proposed, represent a risk that is now heightened by the economic downturn associated with the Covid-19 virus.

Remote Sensing Applications and Innovations via Small Satellite Constellations

Su-Yin Tan

Contents

Abstract

Small satellites are opening up new remote sensing applications and changing the economics of space. Small spacecraft missions are more affordable, have shorter development times, and are more flexible than traditional satellite markets. There has been a rapid evolution and diversification of technologies, and new business cases are being tested within the small satellite industry. The application of small satellites and constellations to Earth observation has arguably made the greatest impact, transforming our understanding of Earth, our ability to monitor the environment, and our capacity to address targeted scientific questions in a rapid and more affordable manner. Although many spacecraft utilize "off-the-shelf" components and instruments to perform remote sensing observations, there are

technical challenges for synthetic aperture radar (SAR) and hyperspectral imaging on small satellites, as well as limited launch opportunities, growing space debris, Earth observation policies, and communication frequency allocations among other constraints. This chapter provides an overview of satellite developments and constellations for remote sensing or Earth observation applications. The aim is to review current small satellite systems and innovations and to discuss developments in small satellite applications related to remote sensing with a special focus on small satellite constellations.

1 Introduction

Small satellites are a growing phenomenon and opening up a new class of remote sensing applications. These new tools have revolutionized the economics and technical approach for Earth observation. The growth of the small satellite industry is driven by its low costs for development, launch, and operation, which enable more access by universities, startup companies, emerging countries, and government space agencies. This also enables outer space to be more affordable to a larger group of people and for a variety of applications.

The growth of small satellites has created unprecedented opportunities for innovation in the broader satellite market and related businesses. Indeed, there has been rapid evolution and diversification of technology and business by the startup and growth of small satellite companies. This results in an interesting dynamic with traditional satellite markets, which rely on large spacecraft and complex designs.

More space-based remote sensing observations have also transformed our understanding of Earth, its environment, the solar system, and the universe at large. Small satellites enable experimenters and operational users to address targeted scientific questions as well as operational activities such as weather forecasting, smart farming, resource monitoring, and many other practical services in a rapid and more affordable manner. Many small spacecraft utilize “off-the-shelf” components and instruments for less expensive ways to perform remote sensing observations. This is not always possible. There are technical challenges for synthetic aperture radar (SAR) and hyperspectral imaging on small satellites, which may offer more high-resolution observation capabilities for supporting future space applications. These may require more specialized sensors.

This chapter provides an overview of small satellite developments since the launch of Sputnik 1 and historic and current developments for remote sensing or Earth observation applications. This review has three objectives: (a) to provide a historical overview of the development of the small satellite industry, (b) to review current small satellite systems and innovations, and (c) to discuss developments in small satellite systems for applications related to remote sensing or Earth observation with a special focus on small satellite constellations. Since the small satellite industry is rapidly evolving, this review may not be exhaustive in nature but mainly focuses on examples of small satellite systems in relation to remote sensing and their current and future applications.

2 A Historic Perspective

In the beginning, all satellites were small. These satellites were “small” because launch capacity was limited and there was initially no need to make satellites of great size. Sputnik 1 was launched in the Fall of 1957 and had a mass of 83 kg. The first US satellite was Explorer 1 launched on January 31, 1958. This was followed by Vanguard 1 that was launched on March 17, 1958. Both of these satellites would be considered small by today’s standards, and indeed Vanguard 1 had a mass of only 1.6 kg. Spacecraft for Earth observation did not come until later, but at the start, they too were smaller but, over time as they were designed to achieve higher resolution, became larger and larger until they became quite large such as Envisat, which had a mass of over 8,000 kg and was launched in 2002 by the European Space Agency (ESA). This satellite and the dangers of launching gigantic satellites will be discussed later in this chapter.

Any trend in satellite development – and especially in satellite applications – has been to design them to be larger and larger. This has certainly been the case for telecommunications and meteorological and remote sensing satellites that are also widely known as Earth observation satellites. Each spacecraft and all of their subsystems including their thermal control, solar power and battery systems, propulsion, attitude determination and control, TT and C, communications as well as payloads for telecommunications and Earth observation grew larger and more sophisticated. The drive was for greater and greater economies of scale and higher performance. There was also the thought that a more thoroughly tested satellite could minimize risk and provide greater reliability. On the other hand, this also brought disadvantages. These included higher launch costs, higher design and development costs, long-term manufacturing schedules, and increasing testing costs. This trend also required large technical teams and sophisticated manufacturing facilities; these also added to the cost and made the systems more and more intricate in design.

Spacecraft design for meteorological satellites, remote sensing, and telecommunications for the last half century has been in many ways quite parallel. This has sometimes been called technology inversion. The satellites had become larger, more complex, and more capable in space, while the ground systems had become simpler. The earliest satellites were small as a result of both limited launch systems and limited mission requirements. Application satellites became larger and larger since the 1970s and 1980s. The launchers became perhaps 100 times more capable, and the satellite infrastructure strengthened in capabilities. In the case of Earth observation, there were also military requirements that drove the need for sophisticated satellites with space reconnaissance capabilities. In the early 1990s and at the end of the Cold War, some of these dynamics began to change. Small satellite systems with surprising new capabilities began to emerge. Some of the larger and more complex projects of NASA and ESA and other space agencies experienced fewer launches. Some of the projects that involved space applications became much more extended in length.

The overall NASA approach to developing remote sensing was known as the Earth Observing System (EOS). This program was initiated in the early 1980s. It comprised of a series of satellite missions in Earth orbit to carry out long-term global observations of the land surface. It was quite ambitious in that it was designed to observe the biosphere, the oceans, and the atmosphere. The satellite component of the program extended over several decades and included satellites that included Terra (which was once known as AM-1) (1999), Aqua (2002), and Aura (2004). This program was also publicized as part of the "Mission to Planet Earth."

The National Polar-Orbiting Operational Environmental Satellite System (NPOESS) also was conceived as a joint program funded by both NASA and the US Department of Defense. It was to produce meteorological data that was useful for atmospheric research but could also support the requirements of the Defense Department for up-to-date weather information as well. In short, this system was to be the next-generation satellite system. This lower polar orbiting system could monitor Earth's very wide range of conditions that included the upper atmosphere, and near-space conditions, the oceans of the world, and land and agricultural conditions and also provide current weather information. In a joint US Department of Defense (DoD)/NOAA/NASA tri-agency endeavor, the intention was to combine the civil and military operational polar-orbiting meteorological satellite programs for both the DoD's DMSP and the NOAA Polar-Orbiting Operational Environmental Satellite (POES) series. However, the NPOESS program was terminated by the US government in 2010 due to severe cost overruns and program delays. In the aftermath of the White House's decision to cancel NPOESS, a new civilian satellite program, the JPSS (Joint Polar satellite System) was created, which would be managed by NASA/GSFC, while the spacecraft would be owned and operated by NOAA. The DoD's portion of the NPOESS program was called DWSS (Defense Weather Satellite System), which was subsequently cancelled in 2012.

Initially designated as JPSS-1 prior to launch, the first satellite in the JPSS program is now known as NOAA-20, which was constructed by Ball Aerospace & Technologies Corp. and launched on November 18, 2017. It joined the Suomi National Polar-Orbiting Partnership (Suomi NPP) satellite in the same orbit. The project incorporated five instruments, providing meteorologists information on atmospheric temperature and moisture, clouds, sea surface temperature, ocean color, sea ice cover, volcanic ash, and fire detection, thus enhancing weather forecasting, including hurricane tracking.

A well-known example of a large and complex European Space Agency (ESA) project is Envisat ("Environmental Satellite"). This very large, complex, and expensive undertaking represents what was the world's most complex and mammoth Earth observation satellite by a civil space agency. The planning for Envisat started in the early 1980s and took essentially two decades from conception to launch. It was not until March 2002 that it was finally launched. This huge satellite had ten different instruments for remote sensing and cost some 2.3 billion Euros to build and place in orbit. The objective of this satellite was to monitor the Earth's resources, study the world's atmosphere, and also explore the dynamics and composition of the globe's crust and even its interior composition. Unfortunately, the control of this very expensive satellite was suddenly lost on April 8, 2012. After several concerted attempts to re-establish communications and control, the mission ended as of May 9, 2012. This huge satellite now constitutes the largest cross-section for a low Earth orbit collision as the spacecraft with a mass of over 8,000 km represents a danger and is currently the top candidate to be removed from orbit. In many ways, Envisat represents a strong case for small satellites that undertake Earth observation using smaller spacecraft rather than using a massive satellite with a very large number of sensing capabilities on a giant satellite (Kramer and Cracknell 2008).

Combining remote sensing activities on a large satellite lessened the opportunity for technical advances and lessened flight opportunities. If control of such a spacecraft was lost, then all the experiments could be lost all at once. This also lessened opportunities for scientists and technical experiments to gain experiments with smaller and less costly missions that could be undertaken at lower cost and on a more compressed time scale (Sweeting 1991). Furthermore, austere funding climates have encouraged interest in cheaper and more frequent missions, which is forcing established space agencies to rethink their approach to spacecraft procurement and mission design.

Change takes time, but significant growth in the small satellite industry and a trend towards small satellites was in the making for over a decade with advancements accelerating during the last several years. Changes have been not just in spacecraft mass but in more than just a single design parameter, ranging from different approaches in planning and development to operations and financing. Changes have also included simpler vehicles, a higher risk tolerance, easier acceptance of new technology, and a significant reduction in costs. Such divergent paths can be considered to be a form of "disruptive innovation" for the satellite industry, redefining the trajectory of the satellite market and focusing on simpler, more convenient, and less costly products. This has also generated lower barriers to entry to the remote sensing satellite market and opportunities for new innovation in what used to be the traditional satellite path in the industry (Rivers 2015).

3 The Small Satellite Industry

Small satellites were often overlooked by space agencies and the established space industry. However, small satellites had been used by the international amateur radio satellite community and universities due to financial and technical constraints. The Radio Amateur Satellite Corporation (AMSAT) was an educational organization formed in the District of Columbia during 1969 to foster space research and communication for amateur radio satellites. AMSAT likely coined the term “micro-satellite,” since their communication spacecraft was below 10 kg – orders of magnitude smaller than established spacecraft missions at that time. The international amateur radio satellite community and universities are regarded as the true pioneers of small satellite technology (Kramer and Cracknell 2008).

Surrey Satellite Technology Ltd. (SSTL) was formed in 1985. This entity was a spin-off company from the University of Surrey (UK). Its mission was to transfer the technology that it had developed from its research and use it to create a new commercial company. This effort began with the development of what were essentially amateur radio satellites. These first satellites were known as UoSATs that reflected their origin as University of Surrey Satellites. These early small satellite were known as OSCAR satellites. The name OSCAR stood for Orbiting Satellite Carrying Amateur Radio. The first of this series was known as UoSAT-1. This satellite was notably constructed using commercial-off-the-shelf (COTS) components. It was launched on October 6, 1981 as a secondary payload to NASA’s Solar Mesosphere Explorer (SME) mission. This satellite had a mass of 72 kg and was about the size of a mini refrigerator. This UoSAT-1 was less costly and was much smaller and faster to build than traditional satellites of this time. It was also included in reprogrammable computer and in a charge-coupled device (CCD) that formed an array that was capable of imaging the Earth from space.

UoSAT-2 was launched on March 1, 1984. This small satellite was a secondary payload that flew as an adjunct to the Landsat 5 launch. UoSAT-1 and UoSAT-2 microsatellites thus both also carried key experimental packages for telecommunications and for technology demonstrations. These satellites were not only small and demonstrated new technology but also successful technology for 8 years in the case of UoSat-1 and 5 years for UoSat-2 (Kramer and Cracknell 2008). UoSat-3 was the third in the series. It was launched on January 22, 1990. It used a new modular bus design, which has become key to small satellite designs that have followed. This type of modular construction allows for more rapid construction and flexibility to respond to different types of payloads and a variety of missions.

Martin Sweeting of SSTL, who has been knighted for his innovative aerospace and small satellite designs, first proposed a classification system that is largely accepted as the basis for small satellite design. This classification system is based on mass (as shown in Table 1). What constitutes a small satellite is a very relative concept. A space agency’s small satellite may be considered to be a very large spacecraft to a university or a student experimenter. There are other criteria on which a satellite classification system could be based. These include size, type of orbit, function, cost, and performance. Classification of satellites by mass has been widely

Table 1 The first satellite classification developed by Sweeting (1991)

Nanosatellite	<10 kg
Microsatellite	10–100 kg
Minisatellite	100–500 kg
Small satellite	500–1,000 kg
Large satellite	>1,000 kg

Table 2 A satellite classification according to mass modified from Table 1 (Xue et al. 2008)

Femtosatellites	<100 g
Picosatellites	0.1–1 kg
Nanosatellites	1–10 kg
Microsatellites	10–100 kg
Minisatellites	100–500 kg
Medium satellites	500–1,000 kg
Large satellites	>1,000 kg

used due to its direct bearing on the launch cost of a spacecraft, which is a significant challenge of any mission.

Subsequently, the classification of satellites by mass was further modified as shown in Table 2. It should be noted that the size of satellites known as minisatellites is sometimes considered to range up to 1,000 kg. These changes also include adding smaller mass classes (e.g., pico- and femto-) to Sweetings' original classification. Barnhart et al. (2007) also noted particular trends in emerging small satellite technologies, including advances in electronic miniaturization and associated performance capability, such as micro-engineering pioneered by Helvajian and Janson (2008). These innovations are largely based on microelectromechanical systems (MEMS) sensors and micro-fabrication. In parallel with the introduction of micro-engineered aerospace systems, the concept of multifunctional structures and architectures has also backed the idea of low-cost mass production of satellites. This proposes that satellites be built and rapidly deployed using streamlined manufacturing processes and modular technologies.

The lack of sufficiently small or inexpensive launch vehicles for putting small satellites to orbit is another key factor that is considered by some to constitute a significant barrier to small satellites. One solution has been that of launching small satellites as secondary payloads. The Indian Polar Satellite Launch Vehicle has famously launched over a hundred CubeSats as part of a "piggyback" launch operator. The SpaceX reusable launch operations have now indicated that it will reserve space for small satellite launches and at a very low rate and a regularly scheduled base. Blue Origin is apparently seeking to offer, in the future, a similar type of capability.

In the past, the costs of such piggyback launches have often been quite high. In some cases, the costs have been greater than the specific cost ($/kg) of the launch vehicle itself (Crisp et al. 2015). This, however, no longer seems to be the case. Other constraints of piggyback launches include a lack of flexibility and control over the launch schedule and destination orbit of the vehicle.

In addition to the ability to fly on larger launchers as a “piggyback” launch or to be dispensed from the International Space Station, several new small launchers are starting to address the need for dedicated microsatellite and nanosatellite launch capabilities.

Some examples include the Virgin Galactic LauncherOne, the XCOR Aerospace Lynx Mk.III suborbital vehicle, and the DARPA ALASA program that are working towards launching a 45 kg payload to orbit for less than $1 million. Nevertheless, the present lack of sufficiently small launch vehicles still makes the launch of nanosatellite and picosatellites a challenge unless launched in large numbers. The Planet Labs Flock constellation of 3 U CubeSats was achieved by a resupply launch to the ISS. There is still much dependency on the deployment of small satellites as secondary payloads.

The emergence and rapid growth of the small satellite market has created significant opportunity for new technologies, business practices, and markets for the space industry. There is a continuing trend of reductions in mission complexity and associated costs often associated with management, meeting safety regulations, etc. (Barnhart et al. 2007). Although the actual cost per kilogram payload on a micro- or nanosatellite can be equal to or exceed costs of traditional larger satellites, the quick turnaround and fast response times are also important advantages to consider. Notably, small satellites are also important avenues of exploring and testing new devices and ideas for spacecraft missions without spending a significant amount of funds (Xue et al. 2008).

4 Small Satellite Systems and Innovations

Small satellites represent a “disruptive innovation” for the satellite industry that has opened up many new opportunities. A disruptive innovation has been defined as changes that “disrupt and redefine that trajectory by introducing products and services that are not as good as currently available products. But disruptive technologies offer other benefits-typically, they are simpler, more convenient, and less expensive products that appeal to new or less-demanding customers” (Christensen et al. 2015).

Small satellite ventures experience much lower barriers to entry to the satellite market. Satellite ventures based on cube satellites have a higher tolerance for failure. Not only are satellite and launch costs much lowered, but there is significantly shorter planning, manufacturing, testing, and deployment times. This enables the small satellites not only to serve as a test bed for new ideas but increasingly as operational systems such as the Spire system that is based on three-unit CubeSats.

For many years space-based remote sensing programs have traditionally used large platforms. This has involved high costs in terms of mass, size, testing, launch arrangements, and overall complexity. Further, it has often been the case that those serving as the spacecraft manufacturers as well as the operators of remote sensing satellite networks are not closely in sync with the needs of the remote sensing user community. How existing small satellite technology could be more effectively designed for the purposes of remote sensing applications is discussed in a number of useful sources (Cvetkovic and Robertson 1993).

In the remainder of this section, major design problems and constraints influencing small low-cost remote sensing satellites are discussed and organized based on a subsystem approach. Key design areas include the improvement of battery technology and the development of a deployable solar array, attitude control assemblies, onboard data processing/storage, and ground data acquisition (Xue et al. 2008).

One of the key concerns with regard to the use of small satellites for remote sensing is its reliability requirements. Many see the potential lack of reliability that is associated with a small satellite network as possibly conflicting directly with their low-cost mission design, limited reliability testing, and overall development approach. One of the key challenges in this regard is the command and data handling (C&DH) subsystem. Most designers of remote sensing satellites believe that these and other critical subsystems require more mass and power resources to produce reliable and capable systems.

These critics believe that remote sensing satellites, which also do not meet a certain mass and power budget, cannot fully meet reliability requirements. There is also a concern with processing power – and in some cases, preprocessing power – that must be sufficient for supporting increased software functions required for remote sensing systems.

These requirements include not only basic data processing but also such capabilities as compression, failure detection, and rapid response to functional failures. Further concerns are overall flight safety and redundancy with regard to the execution of critical single point of failure processes (Homan and Young 2008).

In the case of more sophisticated payloads, there is a perceived need for higher data rates and larger data storage requirements and adaptability to some component failures. This can translate into the need for greater input and output (I/O) capabilities. Such expanded capability may provide additional safety, switching flexibility, etc. These issues are often addressed by the addition of greater levels of monitoring hardware and more redundancy. These perceived needs can be difficult to meet without adding to the mass and power budgets available for most small satellites, although 12-unit CubeSats and larger are becoming more adept. The response by some operators such as Spire has been to add more satellites to their network, rather than increase the size and redundancy of their spacecraft.

The Guidance, Navigation, and Control (GN&C): This subsystem represents a critical operational capability. The GN&C includes both the components used for position determination and the components used by the Attitude Determination and Control System (ADCS).

The performance specification for small spacecraft GN&C performance can vary. Perhaps the most common capability specification is 1.5 m accuracy for onboard orbital position accuracy. This is typically achieved using Global Positioning System (GPS) capabilities. Also a pointing accuracy of better than 0.1° is typically achieved by using a combination of reaction wheels, gyros that employ MEMS technology, and a star tracker. These combined capabilities are designed to change a spacecraft's attitude to achieve the needed level of performance. A magnetorquer that might be used for a student experiment, for instance, would not be sufficient for precision remote sensing (Burton et al. 2016).

Many attitude control and determination algorithms and equipment might be suitable for use in small satellites for such activities as an experiment or technology demonstration. Most of the technology for key components used for precision pointing for many Earth orbiting missions is now mature (NASA Ames 2018). Although 3-axis stabilized and GPS-equipped spacecraft are sufficient for the precise operation of 100 kg spacecraft (about the size of a small refrigerator) for a number of years, it has only been in recent years that precise pointing systems for smaller satellites in the 10–100 kg category have become available. There is a continuing trend towards the miniaturization of existing Guidance, Navigation, and Control (GN&C) technologies for use in small spacecraft. This has allowed small satellite design for even hyperspectral sensing systems.

Telecommunication Relay System: Another key subsystem is that for communications that can both transmit data and telemetry to the ground and receive commands. It is essential that small satellites for Earth observation be able to relay information to ground systems and vice versa. The design of these telecommunications subsystems is driven by the challenges of minimal size and yet maximum power. Any miniaturization of the antennas used on small spacecraft reduces antenna gain. The lower the gain, the lower the amount of information that can be transmitted.

CubeSats typically use (lower gain) whip or patch antennas that also require lower power. This limits the data that can be transmitted (NASA Ames 2018). The decrease in antenna gain can be offset by operating in a lower orbit to limit path loss or by increasing power. Power, however, is a significant challenge in small satellite systems. Power requires either solar arrays or batteries, and both require mass and volume.

The higher data rates desired for an operational spacecraft that is engaged in remote sensing are considerable. There is a need for power and higher gain antennas to relay higher data rates that systems are engaged in activities such as hyperspectral sensing. There is a need in this case for large increase in the power dedicated to the communications subsystem. One solution is to use a constellation of three small satellites in place of one larger satellite (Homan and Young 2008). Another trend that aids in improving RF-based communication systems is the development of software-defined radio (SDR). Laser-based communication (lasercom) has been used in larger spacecraft (e.g., LADEE). Optical communications for small satellites have been successfully demonstrated and transmitting data, such as the Optical Communications and Sensor Demonstration (OCSD) mission, launched in 2017 (NASA Ames 2018). Laser communication systems could potentially increase performance in future small spacecraft.

Electrical Power Subsystem: The electrical power subsystem (EPS) is another critical aspect of a small satellite for Earth observation that encompasses electrical power generation, storage, and distribution. The electrical power is not only a major subsystem which can take up to 25–33% of the mass of the spacecraft, but it is also often the basis of satellite failure. The only plus here is that it tends to be scalable. More solar or photovoltaic (PV) cells and larger batteries can be added to adjust to larger power needs. The diodes, power converters, shunts, and grounding systems are also all fairly scalable. Some of the challenges with regard to design and reliability are the solar array drive mechanisms, temperature control, and battery lifetime (Homan and Young 2008). The ongoing challenge is fitting the electrical power system and all of its components within size constraints. It is difficult to achieve a high power-to-mass ratio when designing a small satellite system – especially for certain Earth observation systems such as radar satellites and hyperspectral satellites (NASA Ames 2018).

Thermal Design: Miniaturized thermal management systems are another major challenge. Such systems are required to ensure thermal control requirements do not overheat or freeze components in a small satellite. Sufficient power, mass, and volume are required for heaters, temperature sensors, etc. (Homan and Young 2008).

Structural Design: The choices to meet the design of a small satellite structure and materials are really limited. The choices for the primary structure design in small satellites frequently come down to either commercial-off-the-shelf (COTS) structures or custom machining or specially printed components that are made to order. If it is possible to use COTS components, this can simplify the development of a small spacecraft. The threshold question is: Can the mission needs and payload requirements be met reliably and fully within the COTS structure offered? It is essential that structural components are as volume-efficient as possible but also serve the necessities of thermal management and radiation shielding (NASA Ames 2018).

Propulsion System: A variety of propulsion systems for small satellites are available. Nevertheless miniaturization of these systems for small satellites remains particularly challenging (NASA Ames 2018).

This subsystem is desirable for many functions that may or may not be required for a particular mission. These functions include attitude control, orbit boost or orbital adjustment, precise station keeping, and end-of-life disposal. Cold gas or pulsed plasma systems for small delta-V maneuvers are possible via a number of systems that are commercially available. Higher levels of propulsion – or higher delta-V applications – require newer systems that are still in the development stages (NASA Ames 2018).

The latest versions of chemical and electric propulsion systems have also significantly matured during recent years. Improved propulsion systems for smaller CubeSat buses, called electric propulsion devices, are being miniaturized and adjusted to small buses. These only provide low-thrust options.

There have also been technological advances in new alternative green propellants that involve less dangerous and noxious gases than the hypergolic fuels that have been used in chemical systems for many years. There are also propellant-less systems. There have been tests such as of LightSail, which employs solar sail capabilities for small satellites (NASA Ames 2018). Most small satellites have operated in low Earth orbit (LEO). There are increasing plans to use small satellites for MEO, GEO, or even deep space missions. Propulsion systems for such missions will require new and increased power propulsion systems.

Flight Software: The software needed to support a mission is a direct function of the complexity of the spacecraft and the purpose of a particular mission (Homan and Young 2008). These requirements may change to accomplish a particular "high mission utility." In some cases, there is a direct trade-off between the hardware design and the software design. In such cases, this can and does influence spacecraft design. The most obvious way would be in the design of the mission's main processor as well as the size of its memory storage capabilities. These decisions on software and hardware design can lead to an increase – or decrease – in the mass and power of the spacecraft. This could, in turn, affect the overall cost of the mission. Telecommunication satellites are often referred to as software-defined processor in space. This is almost equally true of Earth observation satellites – if perhaps not more so.

The current challenge is that customers that rely on remote sensing data are increasingly depending on these space systems for high reliability in the data they use for farming, mining, fishing, urban planning, control of pollution, or even law enforcement. There is clearly now conflicting demands. On one hand there is a desire for reliable, space-qualified hardware and software to produce actionable data. Yet there is also an offsetting desire to receive this data at lower cost. This is likely to be achieved via spacecraft that is smaller in size and mass, with a shorter development time.

Despite current trend innovations coming from the small satellite industry, it is unlikely that small satellites will be able to replace the larger space with higher levels of resolution and other requirements related to meteorological requirements, climate change monitoring, and military and defense requirements.

This suggests that small satellites will not replace larger and more conventional remote sensing satellites, but rather there will likely be a form of coexistence. It is possible that there will be a sharing of the market that might ultimately prove beneficial to both. One of the unresolved questions is where remote sensing using aircraft and high-altitude platform systems (HAPS) will be a part of the mix. These are issues to be resolved in the aerospace industry in the coming decade as a whole (Rivers 2015). It is also likely that these markets will directly compete at times but, in other cases, they will find a symbiotic relationship.

5 Emergence of Small Satellite Constellations

Small satellite constellations that are deployed in large numbers can offer widespread and rapid updates of complete global coverage when deployed in low Earth orbit (LEO). In was in the 1990s that there were various proposals for small satellite constellations. These initial proposals were made to exploit advances in digital communications technologies. The first of these systems was to support mobile communications (i.e., Globalstar and Iridium), data networking (i.e., Orbcomm), and in one case, broadband communications (i.e., Teledesic) (Sweeting 2018). It was thought that stabilized geostationary Earth orbit (GEO) satellites could not provide such services, even though systems such as Inmarsat and Thuraya did develop viable mobile satellite networks from GEO after the LEO-type systems were deployed.

There were consistent initial financial failures and bankruptcy associated with the Iridium, Globalstar, Orbcomm, and Teledesic systems. The proposed ICO system in MEO orbit was never deployed even though it also experienced bankruptcy. But now almost three decades later, small satellite technology has matured, and new types of markets for satellite data and networking have been developed. Thus there recently has been renewed interest in new constellation projects for low and medium Earth orbits for supporting worldwide communications, broadband data networking, and Internet of Things (IoTs) services – especially in remote areas. Not only were the second generation of Globalstar and Iridium-NEXT satellites launched in 2017, but another player has since emerged, which is the O3b constellation owned by the satellite operator SES. The first O3b satellites were launched on June 25, 2013 with initial services offered in March 2014. The last four of the 20 satellites in the O3b Medium Earth Orbit (MEO) telecommunications constellation were successfully launched by Arianespace from the Guiana Space Centre in French Guiana on April 4, 2019. The constellation was deployed in a circular orbit along the equator at an altitude of 8,000 km in MEO, offering greater capacity, enhanced coverage, and improved efficiency and reliability. This system has become financially viable, and now a second generation has been launched. This has created a rush of interest. Some 20 different systems of LEO small satellite constellations are now planned to provide either broadband or narrowband networking or an automatic identification system (AIS).

Thales Alenia Space, among others, has established a particular expertise to develop and manufacture LEO and MEO telecommunication satellites at low cost. It has also been working on a number of startups, such as a joint venture LeoStella LCC to build BlackSky and a constellation of 60 optical high-resolution satellites that offer high revisit times. France's Nexeya is also planning to develop Kinesis, which will be a constellation of 20 nanosatellites dedicated to the Internet of Things. Also up to three Chinese commercial companies are deploying LEO systems for optical imaging using Chinese technology.

The use of satellite constellations for communications is expected to continue to grow, since constellations satisfy a unique combination of needs in terms of achieving global coverage and low latency and minimal path loss associated with space to Earth transmission. Such systems, as they are deployed in the 2020s, are expected to complement existing geostationary satellite communications system rather than to replace the established networks. The question is how many of these new systems can be successfully deployed commercially. Already the LeoSat system has gone bankrupt, and other failures seem to be likely. Even with the rising demand for global data networking and need for greater communications coverage, it seems unlikely that the dozens of new systems can all succeed.

6 Remote Sensing Applications of Small Satellites

Modern small satellites have matured during the early 2000s to combine technology, use of commercial-off-the-shelf components, reduced cost for satellites and launches, and overall utility.

There have been many innovations that allow Earth observation satellites to use small satellite technology very efficiently. This has been coupled with many technological improvements in sensors, high-speed data downlinks, precise pointing and attitude control, and onboard data storage handling capacity, among other innovations. Small satellite Earth observation missions are now able to exploit two-dimensional CCD area arrays that provide new economies. Small satellites are also able to use multispectral push-broom imagers. These are just two of the major innovations which are now possible to increase the performance of small satellites for remote sensing. The miniaturization of sensors, electronics, and digital processors has all allowed for greater performance and improvement in the cost and reduced size of Earth observation satellites.

Some small satellite Earth observation missions that are now possible due to these types of innovations are explicitly shown in the Bispectral and Infrared Remote Detection (BIRD) satellite that was developed by DLR the German Space Agency. This spacecraft, developed in Germany, was launched by the Indian Space Research Organization (ISRO) as early as 2001. This was a microsatellite technology mission with remarkable capabilities for its time. This spacecraft hosted a two-channel infrared sensor system as well as a Wide-Angle Optoelectronic Stereo Scanner (WAOSS). The spacecraft had a new and remarkable fire detection capability. It managed to operate successfully for 2 years before experiencing a gyro malfunction.

SMART-1 was a Swedish-designed European Space Agency (ESA). This satellite orbited around the Moon to map the lunar surface, and it was launched on September 27, 2003 from Kourou, French Guiana. This microsatellite was comparatively lightweight in comparison with other probes. SMART-1 ended its mission after about 2 years and performed extremely well even though it was quite low in cost for a lunar exploration spacecraft. SMART-1 was part of ESA's strategy to build very inexpensive and small spacecraft. This spacecraft represented a total cost of only 110 million Euros (or about US$170 million).

RapidEye represents another milestone in the remote sensing industry. This company was established in 1998 with the idea of carrying out imaging using microsatellites as a commercial operation. This company's plan was to use a constellation of five microsatellites for global coverage. The German-based geospatial information provider was able to deploy and operate a constellation of five satellites built by Surrey Satellite Technology Ltd. (SSTL) of the UK. Despite the small size of its satellites, it was able to produce imagery with 5 m resolution. All satellites were placed in LEO with a common altitude. SSTL was subcontracted by MacDonald Dettwiler (MDA). Each satellite measured less than 1 cubic meter and had a mass of only 150 kg – each with identical sensors. The five satellites as a constellation were capable of providing five-band color imagery daily over a broad area of the Earth. RapidEye's satellites had several unique capabilities. One of these was the fact that these satellites were sensitive to detecting changes in chlorophyll content through their ability to sense the “Red Edge band.” This ability to detect the Red Edge band was used to monitor vegetation health. It could also help to allow analysts to separate various types of vegetative species. It also provided a new type of tool for measuring nitrogen and protein content in all forms of biomass (Sweeting 2018). RapidEye unfortunately filed for bankruptcy in 2011. It has now been acquired by Planet as of 2015. Today the so-called Planet “flock” satellites provide rapid updates of the global imaging database with lesser resolution, while RapidEye satellites provide higher-resolution imaging where greater precision of imaging is required.

It is evident that there are many applications for small satellites today and these keep growing. The uses of remote sensing spread across such areas as scientific research, atmospheric and pollution monitoring, ship tracking, airplane navigation and detection, and Earth observation. Although these applications continue to expand, it seems unlikely that small satellites will entirely displace existing methods of data collection. A combination of sensing in the future that combines aircraft, drones, high-altitude platforms, LEO small satellites, and GEO satellites may be seen. This combination of capabilities will thus form a more comprehensive and supplementary form of data collection. The uses continue to multiply. Geospatial information is now needed to support agriculture, forestry, security and law enforcement, emergency services, fire detection, environmental protection and climate change monitoring, energy- and infrastructure-related services, and much more.

6.1 Disaster Management

Effective disaster management activities are said to follow a cycle of four phases. These include preparedness, mitigation, response, and recovery (Santilli et al. 2018). Satellite data for supporting disaster management often translates into the urgent need for high to very high spatial resolution requirements. There is not only a need for satellite data on a rapid demand basis but for analysts that can properly interpret the data with a high degree of accuracy (Tobias et al. 2000). Moreover, disasters often extend beyond borders and affect ground infrastructures, affecting the accessibility and surveillance of an area. This type of data can most frequently be provided via constellations of satellites in low Earth orbit, which are able to meet disaster management requirements and are becoming more affordable and accessible. Although using satellites for disaster management is not new, the explicit statement of disaster management requirements as a mission objective in the design of remote sensing systems is a significant new development.

Albayrak (2005) suggests that dimensions of disaster management that restrict the utilization of small satellites or dictate the requirements of a satellite constellation system include:

- The type of disaster (Is it a natural, terrorist, or some other form of manmade event?)

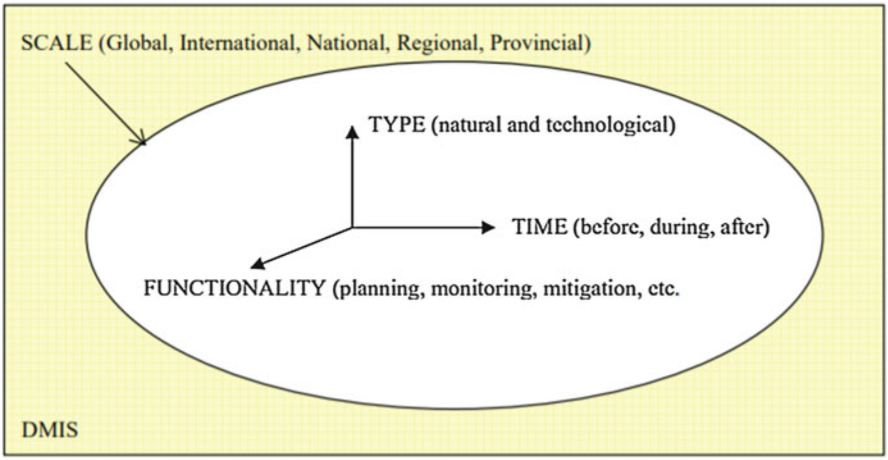

Fig. 1 The application of small satellites at four dimensions of disaster management. (Courtesy of the Disaster Management Information System)

- Time (Is the mitigation or response being directed before, during, and after a disaster?)
- Functionality (What is the nature of function such as preparedness, mitigation, response, and/or recovery?)
- Scale (Where is the disaster occurring and how widespread are the impacted areas, such as local, regional, national, international, global?)

Figure 1 illustrates the utilization areas of small satellites for a Disaster Management Information System (DMIS) based on these four dimensions. The two figures below suggest that small satellites can be utilized for all types of disasters, for every time period, and for every functionality. Better results are attainable by small satellites for larger-scale disasters, such as international and global. There are nevertheless important applications that can be achieved even for very localized disaster events (see Fig. 1).

Remote sensing products are currently used daily in all phases of risk management. This is done despite their limitations as to precision or rapidity of updates. For example, the European Remote Sensing (ERS) satellites have been used since 1991 to develop numerous products for applications. These uses might include detection and monitoring of oil slicks, identification of algae blooms, detailed imaging of landslides, and monitoring of flooding risks (see Fig. 2).

Rather precise fire hazard indices have been developed using data provided from the Advanced Very High Resolution Radiometer (AVHRR). These indices have been developed based on a combination of vegetation and meteorological data. There is now a growing demand for observations with high temporal resolution or quick updates of the impacted sites. These response times usually vary between 30 min and 1 h up to 7 days. There are also different types of demand for the precision of the imaging. These can typically vary between medium to high spatial

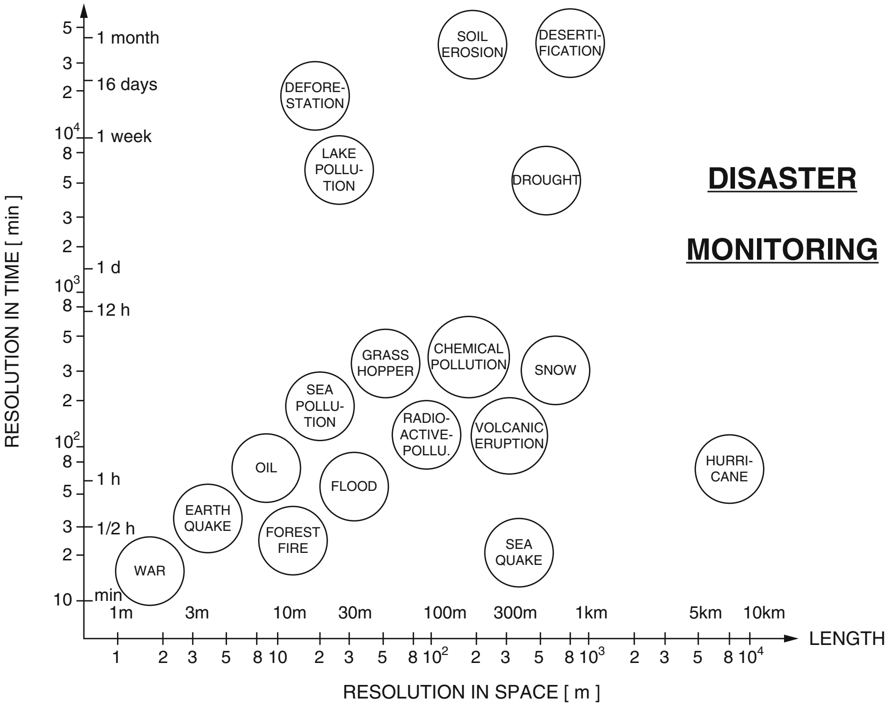

Fig. 2 Types of disasters and their temporal and spatial resolution requirements. (Adapted from Iglseder et al. 1995)

resolution and between 10 m and 1 km for most disaster monitoring events. A spatial resolution of 10–30 m is often desired for most disaster monitoring requirements. The swiftest repetition times can especially be accommodated by a large constellation of small satellites.

The particular type of disaster will, of course, dictate the technical requirements for a sensor design (Iglseder et al. 1995). The ability of satellite constellations to provide updates also depends on the number of orbits, the quantity of satellites in each orbit plane, and their elevation and altitude. Mean time gaps between contacts for five small satellite constellations which is based on a sun synchronous orbit are provided in Table 3. A constellation with four orbital planes and eight satellites at each orbit is probably sufficient to provide temporal resolution for monitoring most kinds of disasters, although a larger constellation such as that provided by Planet or Spire is probably even more desirable (Iglseder et al. 1995).

The number of satellites in a constellation is a significant cost driver for the overall mission. The relationship between the type of constellation, elevation, and resolution is time, as illustrated in Fig. 3. For example, for securing a revisit time of about 30 min, a constellation of at least 32 satellites would likely be necessary (Iglseder et al. 1995). Such constellations can potentially be developed by multiple

Table 3 Mean time gaps between contacts for small satellite constellations using sun synchronous orbits. (Adapted from Iglseder et al. 1995)

	Orbit planes/satellites p. Pl.				
Elevation	4/1	4/3	4/8	6/2	8/4

20°	73.5′	24.0′	5.9′	25.4′	6.2′
30°	101.9′	31.3′	11.9′	35.0′	10.2′
40°	143.3′	45.1′	18.0′	51.0′	17.3′
50°	165.7′	62.2′	22.9′	60.8′	23.0′
60°	253.3′	253.3′	34.4′	103.2′	39.2′
75°	339.3′	339.3′	92.8′	121.7′	142.4′

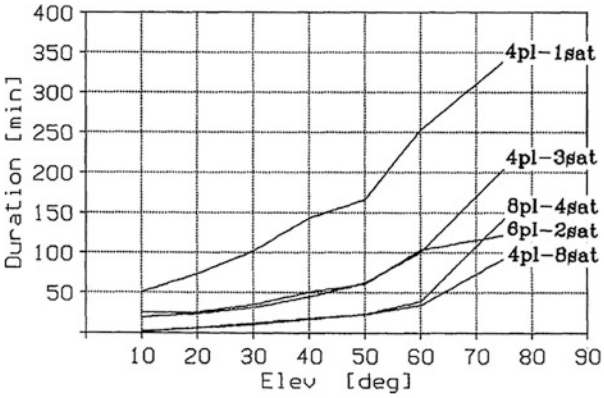

Fig. 3 Time gaps between contacts versus elevation. (Adapted from Iglseder et al. 1995)

country players as has been the case in the past. The Disaster Monitoring Constellation (DMC) described below is one specific case in point.

TopSat is an example of a British Earth observation (EO) satellite with disaster monitoring applications. This particular satellite operates in LEO. It was launched in October 2005 from Russia and built in the UK by Surrey Satellite Technology Ltd. (SSTL) with supporting participation from QinetiQ and the Rutherford Appleton Laboratory. This project was funded under the British National Space Centre Mosaic program.

TopSat was designed to be three-axis stabilized. Its specifications include panchromatic imaging with a 2.8 m resolution and 5.6 m multispectral imaging capability. Despite these relatively high resolutions, it was still quite a bit smaller and less costly than imaging satellites with similar high-resolution capabilities.

The high resolution was possible as a result of using a precise three-axis fiber-optic gyro. This allowed the sensor to be pointed to observe its particular target for a longer period of time. This was in some sense like an analog camera taking a picture with a longer exposure time from space. TopSat has also been used to demonstrate the feasibility of providing higher-resolution images on demand to portable ground stations. This demonstration by TopSat showed the capabilities and associated affordability of using small satellite constellations for traditional remote sensing missions. The result being significant cost savings.

The Disaster Monitoring Constellation (DMC) is another example of a small satellite constellation developed for Earth observation and disaster monitoring. The satellites for this constellation were all constructed by SSTL even though the five satellites were paid for by five different countries. The design of the DMC was envisioned as being able to provide emergency Earth imaging for disaster relief under the International Charter for Space and Major Disasters. These remote sensing satellites are owned individually by the participating countries which are Algeria, Nigeria, Turkey, the UK, and China. Nevertheless these five satellites are operated together as a single system. The DMC can thus provide rapid response Earth observation data to support national response to disaster needs and international disaster relief on demand. The DMC, since it was designed for this purpose, is able to cover far larger spatial areas than government remote sensing satellites such as Landsat. It is also important that higher-resolution imagery can be provided far more rapidly and with far more frequent revisit times as a result of having multiple satellites in orbit. The five satellites of the DMC constitute a constellation that can observe any location on Earth at least once per day, although cloud cover does not guarantee that images will always be usable.

During the period 2003 to 2008, seven DMC satellites were launched. It was significant that all of these small satellites were built to a common standard to enable commonality of image resolution so that images could be easily interchanged (Sweeting 2018). The DMC has monitored the effects and aftermath of the Indian Ocean Tsunami (December 2004), Hurricane Katrina (August 2005), and many other disasters. The next phase of the DMC system is called DMC-3. This is a three-satellite system that SSTL is building for the Chinese company known as the Twenty First Century Aerospace Technology Company (21AT). This will particularly be utilized to respond to Chinese disasters, but the constellation will also assist with global disasters (Disaster Monitoring Constellation-3 2020).

6.2 Fire Detection

Forest fire detection requires simultaneous imaging in various spectral channels and frequent revisit times for monitoring purposes. Fire managers have to make difficult decisions about resource allocation for fire suppression based on information such as the number of fires, their location, potential damage to property and human life, and harm to natural resources. There is a need to provide fast, reliable information on fire locations, especially when they are very small (<0.2 acres), as well as to integrate information on lightning strike locations and ground observations of fires. With traditional spaceborne systems, there have been challenges with very large data volumes that require substantial transmission and interpretation efforts, as well as difficulties in time coverage for efficient use of data during fire events. Fire classification based on temperature alone is not possible due to sensor saturation and existing spacecraft instruments, and sensors are not specifically designed to measure fire parameters. Small satellite constellations offer significant advantages from more frequent revisit times to tailored or dedicated payload design and signal processing for fire detection.

Most immediate and life-or-death decisions when fighting forest fires, such as sending smoke jumpers or calling an evacuation order, are made by firefighters and chiefs in ground command centers. The current system for fire detection would be greatly enhanced by the ability to detect small and nascent fires across regional or synoptic scales. Satellite and airborne data provide situational awareness and are important for planning fire management strategies. For example, NASA and the National Oceanic and Atmospheric Administration (NOAA) often utilize satellite constellations and a small fleet of aircraft operated by the US Forest Service (USFS) to help detect and map the spatial extent, spread, and environmental damage of forest fires (NASA 2019). As technology has advanced, the value of remote sensing data for forest fire detection has also been enhanced to better inform decisions for active wildfire suppression and capturing burned areas.

One of the first instances of using remote sensing for forest fire detection was in 1980 when two scientists, Michael Matson and Jeff Dozier, were working at NOAA's National Environmental Satellite, Data, and Information Service detected bright spots on the Persian Gulf on imagery from the Advanced Very High Resolution Radiometer (AVHRR) instrument on the NOAA-6 satellite (3.8 μm and 11 μm sensors) (NASA 2019). The observed bright spots were actually steel mills and campfire-sized gas flares caused by the burning of methane in oil wells. Dozier subsequently developed a mathematical technique to distinguish small fires from surrounding heat sources, which formed the foundation for subsequent satellite fire detection algorithms (Matson and Dozier 1981).

Initial developments with AVHRR helped to inform the design of NASA's Moderate Resolution Imaging Spectroradiometer (MODIS), which was the first instrument that included spectral bands explicitly designed for fire detection. MODIS was launched in 1999 on the Terra satellite, and a second MODIS instrument was launched on Aqua in 2002 (NASA 2019). MODIS subsequently informed the design of the Visible Infrared Imaging Radiometer suite (VIIRS) on the Joint Polar Satellite System's NOAA/NASA Suomi-NPP and NOAA-20 satellites. Collectively, these technological advancements represented major advancements in fire detection technology for traditional large spacecraft.

The instruments onboard polar-orbiting satellites, such as Terra, Aqua, Suomi-HPP, and NOAA-20, are able to monitor and observe wildfires at known locations several times daily, whereas geostationary satellites, such as NOAA's GOES-16 and GOES-17 (launched in November 2016 and March 2018, respectively), provide continuous observations and updates at the same location, although at a coarser resolution. The optical and thermal bands on MODIS have continued to provide daytime visible imagery and nighttime data on active fires, contributing significantly to mapping fires and burn scars. However, the poor temporal resolution of MODIS sensors limits its ability for early warning and detection.

VIIRS has also improved fire detection capabilities by providing higher spatial resolution data (375 m), enabling smaller and lower-temperature fires to be detected. Through its Day-Night Band, VIIRS also provides nighttime fire detection capabilities, measuring low-intensity visible light emitted by smaller and lower-intensity fires. GOES satellites have also been used for early detection and precise geolocation of fires in remote areas, such as early detection of the Adobe Fire in California on July 2, 2018. Fire and characterization algorithms are continually improved for earlier fire detection and reduction of false positives.

The Multi-angle Imaging Spectroradiometer (MISR) instrument on Terra uses nine fixed cameras that can measure the motion and height of a fire's smoke plume. It is able to capture the amount of smoke particles from a fire, which provides further information about a plume's composition. Moreover, instruments from Forest Service aircraft can complement remote sensing data from spaceborne systems. For example, the US National Infrared Operations Program (NIROPS) integrates data from multiple systems and sources to visualize wildfire information in web mapping services, such as Google Earth. A NIROPS aircraft can detect a hot spot from an altitude of 10,000 ft that is 6 inches in size. As a result, infrared aircraft instruments are often able to fill some of the gaps in satellite data. Since 2003, NASA and the Forest Service have formed a tactical fire remote sensing committee, which discusses how to harness new and existing remote sensing technologies for detecting and managing wildfires (NASA 2019). NIROPS has addressed the operational need for acquiring, preprocessing, and near real-time delivery of high-resolution data, which enable the generation of fire mapping products that support situational awareness and informed decision-making by incident command teams.

As previously mentioned, the Bispectral InfraRed Detection (BIRD) Experimental Small Satellite of the German DLR was launched on October 22, 2001. This satellite operated until 2004 as an optimized fire detection satellite in a 568 km altitude orbit. BIRD was a small satellite weighing no more than 94 kg and was only a 60 cm cube in size. It was the first satellite to demonstrate that forest fires and their extent and the temperature of the flames can be identified early from space. BIRD was also the first satellite designed specifically to detect and examine fires. This led DLR, the German Space Agency, to develop a new generation of infrared sensors specifically designed for remote fire sensing and deployment on small satellites. Its main sensor payload consisted of a two-channel infrared Hot Spot Recognition Sensor system (HSRS) and a Wide-Angle Optoelectronic Stereo Scanner (WOASS-B). This led to new possibilities of the observation of hot events, such as forest fires and volcanic eruptions, from space, whereas other satellites are not specifically designed for the observation of hot events. With the infrared sensor technology installed on BIRD, new fire detection methods developed by DLR played a key role in FUEGO (Spanish for fire), which was a fire detection satellite project sponsored by the European Union.

More recently, the University of California (UC) Berkeley has collaborated on a proposed satellite system: the Fire Urgency Estimator in Geosynchronous Orbit (also called FUEGO). FUEGO is a proposed method for early detection and evaluation of

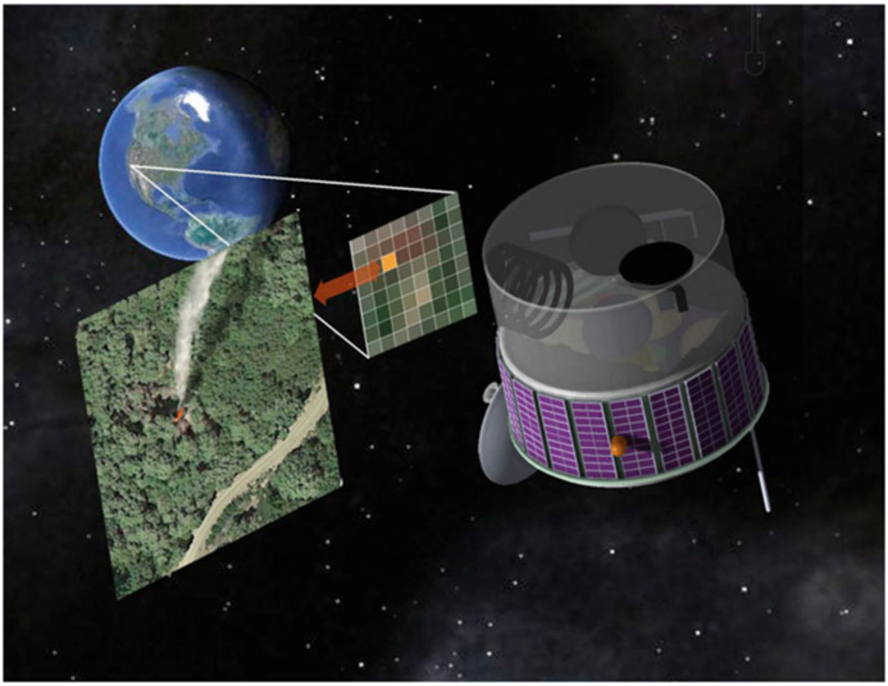

Fig. 4 An artist's concept of the Fire Urgency Estimator in Geosynchronous Orbit (FUEGO) operating during a fire alert. (Art by R.E. Lafever, Space Sciences Laboratory)

wildfires using a system of drones and satellites in geosynchronous orbit equipped with infrared sensors (Fig. 4). It is a space-based system designed to provide firefighters with a tool for early fire detection and monitoring of forest fires, as well as an efficient risk and damage assessment tool. Incorporating a small telescope with a 0.5 m diameter mirror and a 4 × 4 k mercury cadmium telluride IR detector registering 10 million photons per second, FUEGO can potentially detect a 10 m^2 fire within minutes of ignition. The growth rate of the fire can be measured, as well as observed in other spectral bands and compared to historical data.

The proposed FUEGO system also combines several new technologies. These include multispectral sensing using newly available large format HgCdTe sensors. It will also be able to provide rapid mathematical classification of trends and onboard software and computational hardware that can yield a wealth of information. This is intended to allow "calibrated decisions, time-sensitive autonomous, multispectral adjustment of detection thresholds, and precise spacecraft pointing and replicability for robust image acquisition" (Pennypacker et al. 2013). Figure 5 shows a comparison of FUEGO performance with existing and planned satellites, such as BIRD, GOES, ISIR, MODIS, etc. It is clear that timeliness, early detection, and responsiveness are critical to the future designing of truly effective wildfire detection systems.

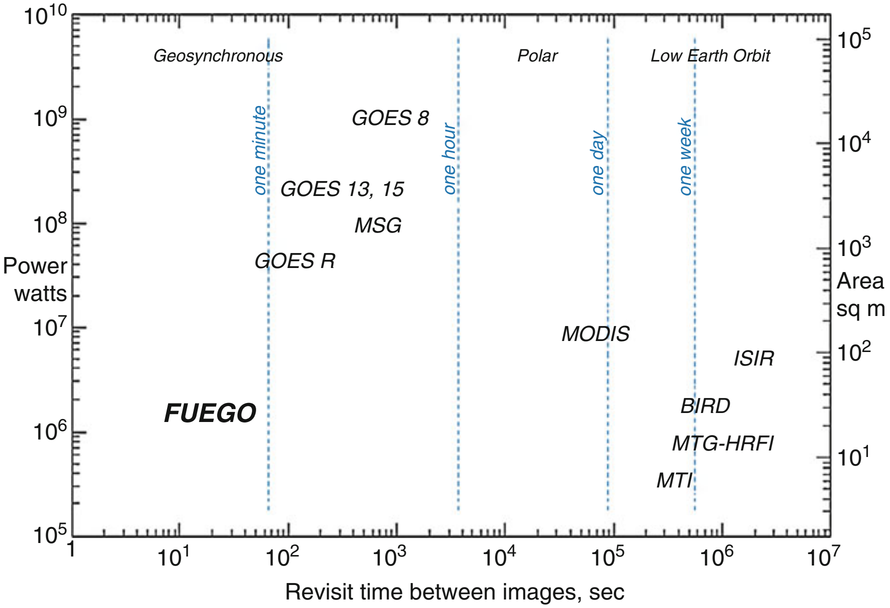

Fig. 5 Comparison of FUEGO performance with existing and planned satellites (Pennypacker et al. 2013)

6.3 Environmental Monitoring

Earth observation has undergone a dramatic revolution and now plays a major role in observing and understanding global environmental change and how it will impact humanity's future. Monitoring and predicting the human health consequences of environmental change are especially challenging, and there are substantial efforts to use satellite imagery to monitor environmental parameters and land cover change that influence the spatial and temporal patterns and spread of vector-borne diseases, such as malaria, dengue, and the Zika virus. A disease early warning system would enable high-risk areas to be identified and for directing control measures. For malaria, key environmental factors include vegetation type and condition, elevation, water bodies, land use, and human settlements. Satellite images can be used to estimate which areas have favorable weather, soil, and moisture conditions to support mosquito activity, as well as identify where human settlements are located and how accessible they are via transportation networks. Recent medical cases can be mapped to show where specific diseases have been treated. This has led doctors to identify settlements that require spraying and other control measures. Shortcomings of existing satellite systems, such as Landsat and SPOT, include timeliness and readiness of data access. These traditional systems often have insufficient spatial and temporal resolution for capturing trends and changes in sufficiently rapid fashion.

Remote sensing provides an adequate means for filling knowledge gaps related to heat and water budgets. These needs are critical for modeling meteorological, agricultural, hydrological, and environmental changes. The Infra-Red miniSatellite Unit for Terrestrial Environment (IRSUTE) was a scientific small satellite mission that provided thermal imagery for determining and analyzing soil/vegetation/atmosphere processes (Becker et al. 1996).

This system was designed to provide high spatial resolution across- and along-track viewing capabilities. It also allowed for four thermal infrared bands, a 1-day revisit time, and an orbital altitude of 540 km. The instrument is useful for meteorological, hydrological, and agricultural studies, especially for environmental monitoring, such as frost mapping, forest fires, volcano activity, and thermal pollution. The small satellite design of IRSUTE was largely driven by the need to meet specific characteristics and limiting factors, such as measurement physics (including atmospheric effects), high spatial resolution for accurate estimates of regional surface fluxes, and frequent revisit time to capture the natural variability of surface fluxes (Seguin et al. 1999).

Yang and Yang (2002) conducted a feasibility study of using a small satellite constellation to perform Interferometric Synthetic Aperture Radar (InSAR) global 3D imaging. This comprised of three identical small satellites, including two flying along parallel orbits with slightly different ascending nodes and observing the same area. The purpose of this effort was to develop interferometry in real time without any time delay (Xue et al. 2008). The third satellite thus flew along another orbit and observed the same area within a short revisit time to provide virtual real-time correlation. Together, the three satellites performed differential interferometry. This enabled surface changes and deformations to be observed accurately.

It is evident that satellite Earth observation systems provide consistent and accessible information about the state of the natural environment. Much of government-owned environmental satellite data is provided freely to users. NASA is currently providing data from its approximately 20 Earth observation satellites online. The European Space Agency operates the Copernicus Programme that provides environmental data from satellites freely to users. Other government agencies in countries such as Japan, India, Brazil, China, and South Korea operate Earth observation satellites and provide at least some of the data for free. Emerging for-profit companies mainly operate satellites with cameras that produce imagery in the visible part of the spectrum (Wood and Stober 2018). Commercial satellite Earth observation companies generally charge an access fee for either original data or access to value-added services or data analytics based on their data. The market for commercial satellite Earth observation is still evolving, and new business models are continually being proposed and examined.

The evolution of small satellite Earth observation companies, such as RapidEye, Skybox, BlackBridge, and Planet (Labs), is an example of the significant growth that has taken place and volatility of the remote sensing small satellite market (Sweeting 2018). As previously mentioned, RapidEye (Germany) was the first commercial Earth observation constellation of small satellites. However due to financial difficulties, it was eventually acquired by BlackBridge (Canada) in 2011 after filing for bankruptcy. It was finally then acquired by Planet in 2015.

Skybox Imaging is another startup company that was formed in California in 2009 and eventually also acquired by Planet. Skybox Imaging launched its first 83 kg Earth observation microsatellite, SkySat-1, on November 21, 2013, which provided 0.9 m resolution panchromatic imagery. It was the first company to release HD video from space, capturing up to 90 s video clips at 30 frames/s at a spatial resolution of 1.1 m at nadir. It was envisioned that the high-definition satellite video would help understand the world better by analyzing the movement of goods and people and observing objects that affect the global economy, such as road vehicles and shipping containers. The first two prototype satellites (SkySat-1 and SkySat-2) were produced in-house and did not have a propulsion system. The other 13 satellites (SkySat-C series) were slightly larger and heavier (about 120 kg) and manufactured by Space Systems/Loral (SSL) with satellite thrusters built by ECAPS and optical payloads developed by L3 Technologies. Google acquired Skybox Imaging for about $500 million in 2016, and it was subsequently renamed as Terra Bella with the intention of supplying Google's imagery repository for keeping Google Maps up-to-date. However, in early 2017, Google sold Terra Bella and its Skybox constellation to Planet Labs and made a multiyear agreement to purchase imaging data produced by these satellites. Planet has since launched 6 more now renamed SkySat satellites with 15 SkySat satellites launched in total, which complement Planet's Dove 3 unit CubeSats. The constellation's goal is to provide high-resolution satellite imagery of any place on Earth multiple times a day.

Planet Labs (now Planet) is an American private Earth imaging company founded in San Francisco in 2011 as a startup by former NASA employees. Their goal is to image the entire planet daily to monitor changes and to identify trends. The company designs and manufactures Triple-CubeSat miniature satellites called Doves, which are mainly secondary payloads on other launch missions. Each Dove satellite continuously scans the Earth's surface, forming the largest satellite constellation in the world and providing complete global coverage at 3–5 m optical resolution via a technique called line scan. Planet designed and manufactured 5 kg CubeSats with a "3 U" form factor (10 × 10 × 30 cm) with foldout solar arrays and antennas and a 3-year design lifetime. Dove satellites were first launched in 2013 and were shortly followed by the first "flocks" of multiple small satellites to form a constellation. With the acquisition of BlackBridge in July 2015, Planet launched 87 Dove and 5 RapidEye satellites. Planet also launched an additional 88 Dove satellites in 2017 on the Indian Polar Satellite Launch Vehicle. This represents the largest fleet of small satellites ever orbited on a single launch. This successful launch brought their total number of Dove satellites launched into orbit to over 150 as of early 2020. The images gathered by Doves are transferred to Planet's cloud infrastructure and into the company's data processing and distribution pipeline, which has some open data access imagery available. By September 2018, the company has launched nearly 300 satellites in total of which about 150 are active.

ICEYE Oy is a Polish and Finnish startup company and microsatellite manufacturer based in Finland and founded in 2014. In 2015, the company demonstrated that synthetic aperture radar (SAR) could be used on small satellites to monitor hazardous ice features, such as pack ice. Its proposed constellation of microsatellites provides SAR imagery for a variety of applications, ranging from urban infrastructure planning and monitoring marine shipping ports to various environmental applications. Its first satellite (ICEYE-X1, also known as ICEYE POC1) was launched on a PSLV-XL rocket on a PSLV-C40 mission from the Sriharikota Launching Range. It was the first satellite under 100 kg to carry a SAR instrument, and it was also the first Finnish commercial satellite. Up-to-date, 5 satellites have been launched, which is part of the ICEYE vision to develop a satellite constellation of 18 microsatellites equipped with SAR in collaboration with ESA.

SSTL adopted an innovative business model in 2015, which was adapted from the geostationary communication market, where many service providers lease transponder bandwidth and time from satellite owners on a pay-as-you-go basis. This allowed for a maximum of flexibility in response to demand for the service provider while minimizing capital outlay (Sweeting 2018). This model was adapted to the Earth observation market by launching three 450 kg minisatellites, while leasing guaranteed imaging payload capacity to separate international Earth observation service operators, while retaining ownership and orbital operations. The advantage of this model was enabling service providers to focus on their imaging services for customers, rather than satellite operations and housekeeping. Three optical Earth observation minisatellites were launched in 2015 providing 1 m panchromatic and 4 m multispectral imagery daily global coverage, which was leased by a single customer.

A fourth satellite developed by SSTL was the NovaSAR-1, which is a small synthetic aperture radar (SAR) mission designed to be a low-cost S-band SAR mission on a minisatellite. It was launched on September 16, 2018 on the PSLV-C42 vehicle of ISRO from Sriharikota. As a joint technology initiative of SSTL, UK, and Airbus DS, funded by the UK Government, the overall objective of NovaSAR-1 was to make SAR observation missions more affordable to a customer base and to open up new applications in the microwave region of the spectrum. There is a range of applications including urban planning, agricultural monitoring, land classification, natural resource management, and disaster monitoring.

7 Challenges of Small Satellite Constellations for Remote Sensing

As previously mentioned, several challenging factors constrain the development of small satellite constellations for Earth observation. A major constraint will continue to be the availability of low-cost and timely launchers, which will continue to limit the growth of the small satellite market. The mushrooming of nanosatellites and microsatellites has spurred the growth of small launcher developers. This includes some from space agencies, such as Vega/ESA, Kuaizhou/China, and Epsilon/Japan. There are also a host of startup companies that include Rocket Lab and Orbital Express. In some ways the launcher companies that are pioneering reusable launch vehicles such as Space X and Blue Origin may ultimately bring the greatest new economies to launch operation for small satellites.

There are about 50 new small launch vehicles in various stages of development, and several of them have gone bankrupt already, but perhaps many of them will succeed and bring new vigor to the launch industry (Sweeting 2018). Several of these intend to utilize "green" propellants. There is some debate about the resulting $/kg for small satellites on small launchers versus large launchers. It appears that medium launchers capable of 1,200–1,500 kg to sun synchronous orbit may be optimal, such as Dnepr and PSLV, where payloads with similar schedule and orbit requirements can be grouped together (Sweeting 2018).

SpaceX has developed the Falcon 1 launcher for small satellites in 2008, which successfully delivered the Malaysian RazakSAT satellite to an equatorial orbit in 2009. Future potential may also exist in air-launch proposals (e.g., Virgin Galactic) associated with the market for space tourism, although this business case may be difficult to manage and predict. A new trend is the emergence of launch brokers (e.g., Spaceflight and TriSept), which accumulate customers for specific rideshare missions (Sweeting 2018). Therefore, launch cost is still a primary driver of the mission cost and associated commercial business cases for small satellites. In order to observe significant cost reductions, radical innovations in future satellite design and manufacturing approaches will bring about new business models.

Other concerns that constrain the growth of small satellite businesses include space debris, Earth observation policies, and communications frequency allocations. The abundance of small satellites launched since 2005 has resulted in significant pressure and demand on frequency spectrum allocations, especially since many amateur satellite services have used VHF and UHF allocations (Sweeting 2018). Available bandwidth continues to be highly restricted, although many university-grade microsatellites are relatively short-lived and allow the frequency to be reused. Significant spectrum demands and competition exist, especially for larger "mega-constellation" small satellite missions.

Small satellites are in themselves not necessarily a major space debris issue, as long as they do not fragment and have a natural end-of-life deorbit, such as through a deorbiting mechanism (e.g., a drag sail or robotic capture). In fact, it is often said that one factor in the original conceptualization of the 10 × 10 × 10 cm CubeSat design was the minimum size that was detectable and trackable by the US Air Force in LEO. Small satellites can pose as additional space debris, if they do not have the propulsion capability to maneuver out of the way of orbital debris and do not comply with deorbit guidelines. Large numbers of satellites can also arise out of constellations, which suggests that the creation of an analogous space traffic control system may be required in the future (Sweeting 2018), especially if space debris continues to increase. Several small satellite missions are being proposed for active debris removal, such as the European Union's (EU) low-cost in-orbit microsatellite demonstrator mission called "RemoveDEBRIS."

There are also significant issues with Earth observation policies and regulatory mechanisms, especially with privately owned commercial small satellite constellations that provide high temporal and spatial resolution of 0.5 m or better. More precise data that is constantly being updated is changing the world.

This level of high resolution raises personal privacy concerns. Currently, countries control data collection and delivery and can potentially interrupt services for political motivations or national security reasons. We are also entering an era of big data availability from a combination of in situ sensors, airborne platforms, and remote sensing satellites, which already cause issues with data quality, handling, and integration. Moreover, the maintenance of metadata standards across all of these platforms needs to be addressed, if reliable information about these sources is to be made readily available.

Constellations present unique problems of satellite coordination and integration or interoperability with other satellite constellations. Examples of constellations for navigation and geodesy include GPS, Galileo, and GLONASS, while examples for remote sensing include the Disaster Monitoring Constellation (DMS), RapidEye, COSMO-SkyMed (Constellation of small Satellites for the Mediterranean basin Observation), and the Huanjing constellation (the Small Satellite Constellation for Environment Protection and Disaster Monitoring). The primary benefits of constellations are enhanced sensors, continuity of data, timely observations, global coverage, and extraordinary pace of development and manufacturing. As a result, small satellite constellations can generate a huge amount of data on a daily basis, and there is significant processing demand from the remote sensing user community.

Integration of remote sensing data within Geographic Information Systems (GIS) enables improved access to geographic information for enhanced analysis and decision-making. GIS may also play a role in the dissemination of data or purchasing of imagery from private satellite companies. Advances in computer-based planning models, satellite imaging, and machine learning are able to optimize available data for infrastructure planning, lowering costs, and ultimately making better decisions.

The biggest change of all is in the area of data analytics and the more intensive use of data derived from small satellite remote sensing data. There is now what might be called a "deep learning revolution." This is coupled with the availability of faster and cheaper computing, as well as advantages in artificial neural network models; it is expected that artificial intelligence will transform big data into useful information in the future – and at a faster and faster rate. The data that comes from the skies will be fed into value-added economic systems at a faster and faster pace. Satellite remote sensing will be coupled with advances in artificial intelligence and data mining techniques. It may become easier for analysts to extract features from satellite imagery semiautomatically and to turn data into meaningful information.

8 Conclusion

Small satellites have been exercising a disruptive force in the satellite industry, in both an economic and technological sense. As a result of rapid innovation and technical disruptions, the small satellite market is changing rapidly. There are now lower barriers to entry with respect to capital and infrastructure. The main paradigm seems to be a modular-based manufacturing model. This small satellite revolution is also fueled by frequent and greater launch opportunities at lower costs. Another part of this revolution seems to be a higher tolerance for failure. This in turn enables a shorter timeline to market compared to the traditional satellite market. However, small satellites will likely not replace large satellite missions in the near future but will become often complementary in nature. This is due to different goals, market opportunities, and competing advantages/disadvantages. The primary benefits of small satellites include the speed and lower capital costs of adopting new technologies, as well as rapid product and development cycles. This, in turn, allows low relative costs and the ability to exploit a more agile management and business model (Sweeting 2018).

Modern innovations with small satellites in LEO are especially changing the remote sensing business. These include new applications such as the linking of big data warehouses and artificial intelligence data mining, machine learning, and data analytics. These systems and commercial satellite operators are not only engaging in remote sensing by satellites, but also focusing on analyzing the data that they collect to create new understanding of the practical implications of this data. In short, these new small satellite companies are selling the "data analytics" derived from the EO data rather than the collected data. It is in this way that the greatest value can be derived and the key objective is to rise higher up the economic value chain.

The greatest constraint to the growth of the small satellite market was once feared to be the cost and availability of launch to orbit. Innovations in the launcher industry such as reusable launchers and other innovations in production techniques and even materials are serving to change the level of concerns of this nature (Sweeting 2018).

Small satellite constellations – primarily for telecommunications, networking, and remote sensing – result in the mass production of small satellites that have contributed to a more crowded space environment, especially in LEO, and a greater demand for launch capabilities and big data processing. There is ongoing research into the in-orbit manufacturing of satellites and new launch technologies to support the assembly of large systems and so-called mega-constellations.

It is expected that small satellites – both for networking and EO activities and related data analytics – will continue to change the economics of space. Their low cost, rapid development times, and relative simplicity remain appealing. There are concerns related to orbital debris and saturation of low Earth orbits, especially in the range of 700–1,100 km where the threat of orbital collision appears to be rising sharply.

Small satellite constellations will have to rapidly expand their services to customers. This will lead to new ways to meet demands for reliable and responsive sources of imagery. This will rapidly lead to new approaches for monitoring the Earth's surface and new ways to process the data for various applications. Such services have matured considerably based on experience gained through large traditional satellite systems over the last 50 years. The satellite industry has produced many new applications, such as smart farming, pollution controls, law enforcement, disaster management, and wildfire management, and scores more of new ways to use satellites to learn more about today's world. Such data streams have significant potential to be applied by different and nontraditional end users, customer bases, and research communities. The question also remains whether the economic value of data analytics will justify the large capital investment that is being made in large-scale constellations for Earth observation.

There is an exciting future ahead for small spacecraft missions, especially for the development of future cooperative distributed space systems, such as constellations and formations, to provide more capabilities and observation capacity in the field of remote sensing. New constellations will need to make use of new technological advancements in electronics, materials, and sensors to create satellites that are physically smaller, technically simpler, and more affordable to acquire, launch, and operate. This is an exciting time for small satellite design and testing new business plans in the "NewSpace" era, which will translate into innovation and greater benefits for government, industry, academia, and the global population. The small satellite revolution has been described in many ways. One insight is as follows: "Silicon Valley has discovered and revolutionized the space industry and it will never be the same."

Contents

Abstract

Small satellites are among the fastest-growing and evolving new markets today. Technological innovations include the ranges of satellite masses (*picosat*, nanosat, microsat, and minisats), sizes (including volume ranges from thumbnail to commuter bus), functions (Earth observation, communication, resupply, etc.), and project structure (e.g., individual satellites vs. large-scale constellations). This chapter asserts that a significant fraction of market analysis is initially conducted using variance methods, despite the lack of supporting theory and clear research questions. Despite challenges of high labor intensity and complexity of data interpretation, process research methods can underpin the development of relevant theory first, before variance research methods are executed. Furthermore, the data collected using process methods, if done thoughtfully and deliberatively, can support multiple research questions, and different data sets can be

1 Introduction

Three major sources of new market creation include technological innovations, shifts in societal norms and values, and changes in laws and regulations (Aldrich and Ruef 2006). Small satellites are among the fastest-growing and evolving new markets today. Technological innovations include the ranges of satellites masses (picosat, nanosat, microsat, and minisats), sizes (including volume ranges from thumbnail to commuter bus), functions (Earth observation, communication, resupply, etc.), and project structure (e.g., individual satellites vs. large-scale constellations). Shifts in societal norms include the perception that space activities can be conducted by individuals and small groups and are no longer limited to sovereign nations or governmental agencies. Legal and regulatory changes have made these emerging markets possible, by lowering barriers of operational uncertainty and enabling the flow of private capital into these activities. Changes in all three of these areas need to be accounted for and modeled to understand the trends in small satellite markets.

This chapter discusses these perspectives to query, model, and analyze market dynamics and trends and industry emergence and evolution, more generally characterized as processes of organizational change and development. It begins with an introduction to the characteristics of research questions as applied to small satellite markets. Next, the approaches of market modeling are discussed, including systems of technologies, neoclassic economics, and social functions. This is followed by a brief discussion of analysis strategies, including the origins and mitigation of phenomenological uncertainties and the presentation of variance and process research methods. Each method employs certain instruments and methods and has certain advantages and disadvantages, is appropriate for different stages of the overall research process, and can ultimately complement each other. Finally, a discussion of data collection instruments is given.

Content for this chapter was collected primarily from existing literature, as noted in the Acknowledgments section. Additional concepts, explanatory text, and ideas were inserted as appropriate, to present complementary information and to target the discussion to topics of small satellite market emergence and growth.

2 Research Questions

Understanding of market phenomena is of great interest to both academics and practitioners. Industry and governmental practitioners (including business executives, government administrators, political leaders, and lawmakers, whether as individuals or as part of a collective body) communicate relevant policy challenges in ways that are easy to understand, typically in the form of brief, concise, declarative statements, or straightforward questions. Buried within these statements and questions are complex challenges that need to be expressed as well-formed research questions, before potential solutions can be found. Extracting those questions is an important job of the research community, and the nature of those questions will determine appropriate data collection approaches and theory development methods to be used. For the small satellite market, these questions include topics industry emergence, evolution, and change. Industry practitioners in technical fields naturally approach questions about market capability, capacity, and growth from a technological perspective. Government policy-makers commonly turn to neoclassical economic experts to analyze market emergence questions (Etzioni 1988). Recently, social science academics in organization theory (OT) have joined the discussion with a different perspective and approach, to answer these questions with increased methodical rigor and a broader contextual understanding. Generally speaking, social scientists (including economic and OT researchers) analyze rapidly emerging and evolving markets in two principal ways, using variance and process research methods (Mohr 1982).

For example, challenges to CubeSat industry emergence "include the reality and the perception of CubeSats generating orbital debris, spectrum challenges, and difficulties related to obtaining affordable access to space" (National Academy of Sciences Engineering and Medicine 2016, p. 71). Taking the orbital debris challenge as a particular example, "because CubeSats typically are not maneuverable, they are seen as orbital debris threats, especially in near-Earth orbits, with low Earth orbit being a special challenge because of the presence of the International Space Station. CubeSats comprise less than a percent of all resident objects in space and are expected to remain a small fraction, even as their number in space grows" (National Academy of Sciences Engineering and Medicine 2016, p. 75). The following questions are intended to demonstrate how these highly relevant statements need to be translated into many more complex and interesting research questions:

- How much of a real threat are CubeSats to the International Space Station (ISS)?
- Can anything be done to change the perception of CubeSats as a threat to other orbital objects?
- As CubeSat numbers increase, how will the real threat they pose change?
- What policies can be implemented to minimize the threat posed by CubeSats?

This chapter discusses the characteristics of these research questions and the approaches, strategies, and instruments that can be applied toward a solution. The first section discusses the types of theory and market models currently in use for analysis of market emergence, including modeling markets as technology systems, neoclassic economic systems, and societal systems. Next, the sources of uncertainty for each system are discussed, and two appropriate strategies for mitigating those uncertainties are described. Each strategy generally corresponds to a category of research methods, either variance or process (Mohr 1982). Finally, the common data collection instruments for each method are discussed briefly, giving the advantages and disadvantages of each and explaining how variance and process research methods, when appropriately employed, are complementary to each other.

3 Modeling Markets

3.1 Two Types of Theory

Theory can achieve two different goals. The first is to design, control, or predict the outcome of a given phenomenon, and the second is to describe or explain a phenomenon. The sample questions above demonstrate both types of theory development. The first and third questions convey research to design or control the outcome of an assumed process. The first question requires the researcher to quantify the value of risk to the ISS associated with the current state of CubeSats in orbit (i.e., by predicting the function of risk caused by the interaction of CubeSats and the ISS). The third question asks for a prediction of the change in risk as a function of CubeSat numbers. Both of these are predictive questions and will be generally better served through the development and application of variance models. The second and fourth questions are different, however. The second question asks for a description of threat mechanisms posed by CubeSats to other orbital objects, and the fourth question delves into alternative risk mechanisms that may exist as the number of CubeSats increases. These are questions that require the creation of process theory and models, to describe or explain the steps of a process, mechanism, or phenomenon.

In short, predictive questions, generally associated with variance research methods, tend to be “outcome driven,” starting with the dependent variables (DV), or outcomes (e.g., the threat level caused by CubeSats), and working backward to the independent variables (IV), or inputs, of the research topic. Predictive questions invoke analytic perspectives that can be described as overly reliant on analytic structure (“paradigmatic”), or hyper-rational (“logico-scientific”). As will be discussed below, predictive questions are commonly approached using the predictive strategy of uncertainty mitigation. In contrast to predictive questions, descriptive questions are event-driven, asking how the research topic develops or changes as a function of time, building forward from inputs to outputs. Descriptive questions generally best employ process research methods and the adaptive strategy of uncertainty mitigation, resulting in a narrative perspective.

3.2 Technological and Economic Systems

Research to describe and analyze emerging and newly evolving markets, such as small satellites and large constellations, can be conducted in many ways. Scientific and technical researchers and analysts tend to focus on their areas of expertise and interest, providing a microscopic perspective of technological issues and solutions, and attempt to link those results to a "market" by translating those details into estimates of price or cost. Despite the accuracy of their modeling efforts, the technical approach as applied to a sociological phenomenon has obvious disadvantages, having minimal connections to economic theory and ignoring entirely the real-world socioeconomic factors and interactions. Alternatively, neoclassical economists constrain markets through simplifying assumptions, resulting in a focus on aggregate indicators of financial resources and factors of industrial production. Self-imposed constraints in neoclassic economics include disregard for social connections (Fourcade 2007), methodological individualism (identifying collectivities as an aggregation of individuals) (Etzioni 1988), rational behavior (Malerba et al. 2016), and market differences based solely on production control and prices (Parsons and Smelser 1956), to name a few. Methodologically, economics has been primarily focused on predictive theory (Friedman 1953), with little interest in descriptive research. The underlying constraints limit the ability of neoclassic economics to sufficiently characterize the emerging and evolving markets phenomena of dynamic, industry-level interactions. Advances in evolutionary economics (Malerba et al. 2016; Nelson and Winter 1982) recognize the neoclassic limitations but are themselves also limited in different ways:

> We believe that there is a broadly shared view in this community that much of the modeling that has been done by economists over the past half century has not provided much insight into how the economy really works. Modeling efforts often aim at elucidating causal mechanisms, and may succeed at least in sharpening intuitions about particular mechanisms. Most of the models, however, have been too stylized to give us an understanding that is relevant to the complicated economic reality we need to know about, where multiple mechanisms are typically in play. To acquire such an understanding, it is necessary to face up to the intrinsic difficulty of the task, rather than assuming it away. We argue that in the future the models we build should be oriented more closely by what we know about particular segments of that complex reality, so as to provide more believable insight into those aspects that we are struggling to understand. This, of course, is the basic commitment of history-friendly modeling. But there is wider recognition today of the need to engage with the complexity of economic reality, even at the price of seeing it in 'a much messier, less pretty view (Krugman 2009).' (Malerba et al. 2016, p. 246)

3.3 Social Systems

Academics in economic sociology (Parsons and Smelser 1956; Smelser and Swedberg 2005) and OT (Baum 2005) engage with "the complexity of economic reality" by expanding the perspective of markets (beyond technologies, or financial and production factors) to include additional functions of a social system not previously modeled. Emerging markets are characterized to include numerous industry actors, both national and international, representing many sectors of society, including organizations that are private, nonprofit (nongovernmental), and governmental and networks that focus on issues, social movements, knowledge-based subjects, or belief-based topics (Fligstein 2005). These actors work in responsible or opportunistic ways, individually and cooperatively, to achieve long-term industry survivability. For new markets, actors build and accumulate critical resources to enable industry emergence (Etzioni 1963). These resources, referred to as industry infrastructure elements (Van de Ven and Garud 1989), contribute to critical market functions of institutional arrangements, resource endowments, and proprietary functions, respectively, corresponding to Parsons' functions of goal setting, integration, and adaptation (1960). Whereas this resource accumulation framework provides more realism (i.e., is "much messier" and "less pretty") to the representation of markets, especially in comparison to technology or neoclassic economic models, it under-represents the fourth critical social system function of culture. More recently, Geels (2002, 2005, 2006, 2010, 2018) expanded a multilevel perspective model of sociotechnical transitions, originally developed by Rip, Kemp, and Schot (Van Driel and Schot 2005), that includes all four social system categories, closing the gap of previous theory.

4 Analysis Strategies

4.1 Mitigating Uncertainty

For any of these market models, whether based on technologies, neoclassic economics, or OT, the overall uncertainty level of results is high. The study of organizational systems, such as markets, is different from studies in other types of sciences. Physical sciences, such as physics, can be highly deterministic, yielding results with low uncertainty. For example, the value for the acceleration due to gravity will remain constant in well-formed experiments, regardless of the number of trial runs, or who is conducting the research, because the phenomena being studied is unique, unchanging, and separate from the empirical examination process. Uncertainties begin to increase for studies in the natural sciences, yielding results that are more probabilistic when compared to the physical sciences. The phenomena may be unique, but there exists variation among the experimental specimens. Consider the anecdotal life sciences example often told about unlucky laboratory frogs. When a lethal dose of a drug is calculated for and injected into some number of frogs, a certain fraction of them die, while others show mild symptoms before getting better, and the rest show no reaction to the injection, whatsoever. In both the cases, however, no matter the degree of variation observed by the physicists or life scientists in their experiments, the phenomena they study do not themselves change.

Uncertainty levels increase still more in studies of social systems, due to the overall complexity of the problem and the free will of individuals. "People are not billiard balls, but have complex intentions operating in a complex web of others' intentions and actions" (Miles and Huberman 1994). Whereas some uncertainties of some sciences can be minimized through the collection of more data, models based in social systems are highly nonlinear with respect to the actions of individuals, and the ability to adequately predict individual actions (which is different than probabilistic outcomes of a social group) is low. Furthermore, social systems are performative (Fourcade 2007), meaning that as research is conducted and revealed, the laws (i.e., theories) act upon, and change, the social system they describe. In this way, social sciences may unwittingly be technologies instead of pure sciences, resulting in increased system interactions and complexity.

Two possible strategies for dealing with uncertainties, referred to as the predictive or adaptive approaches (Packard and Clark 2019), represent idealized extremes available to the researcher. Uncertainties result from "insufficiently known phenomena and . . . human acts of choice" (Von Mises 1949, p. 105), the former representing a lack of knowledge, and the latter being inherently unpredictable. The goal of the predictive strategy is to acquire more specific and higher-quality data, to more completely explain and understand the phenomenon being researched. An implicit assumption of the predictive strategy is that a theory-based model was developed prior to the data collection effort. Improved understanding of a given phenomenon is the goal, hidden in the shadows of uncertainty, and improved data collection is the light that can lead to the unique solution. On the other hand, the adaptive, or flexible, nonpredictive strategy assumes that the phenomenon can be understood through "effective navigation" of uncertainty via "rapid informational processing and response" (Packard and Clark 2019). Instead of focusing on specific data, the adaptive strategy collects data of general context. When based on common definitions of mid-level concepts (e.g., the innovation process), these events can be used collectively, in abductive theory development, by different researchers pursuing separate research questions based on the common, mid-level concepts, or by the same researcher, trying to solve different research questions. Alternatively, because of the broad scope of the data collected, multiple research questions can be served by the same data pool. This type of approach is implied by the process research method and is ideal for theory development, thereby implicitly appropriately positioning it before the predictive strategy. The predictive strategy implies the use of variance research methods.

Regardless of the type of research question, both variance and process methods make basic assumptions of the underlying mechanisms being investigated. On the one hand, variance methods are built on necessary and sufficient causality as a basis of explanation and uniformity across different contexts. Variance methods incorporate IV and DV that do not change in meaning over time and are related through immediate application of efficient cause. (This is a reference to Aristotle's description of four causes of why change occurs, or "aitia." (1) Efficient cause is described as being caused by an agent which is separate from the item being changed. (2) Material cause results from the material properties of the item being changed. (3) Formal cause is the pattern that guides a change to an item. (4) Final cause is the reason for the change to the item.) In efficient cause, the time ordering of IV has no effect on the DV.

On the other hand, process methods are based in probabilistic rearrangement of discrete states and events, where antecedents are necessary, but not sufficient, for the consequents. Process methods incorporate final cause as a reason for why change occurs, and time ordering of IV is critical to the resulting DV (Mohr 1982). In any case, neither approach is superior or inferior to the other.

Both research methods are appropriate at different stages of research. Process methods complement variance methods by supporting the early stages of theory development and the development of models. After that stage, variance methods are appropriate for the testing of hypotheses, so models can be verified and then appropriately applied to answer the design or prediction problem (Van de Ven 2007).

Whether using variance or process research methods, any theory of industry emergence and evolution should satisfy four basic criteria: it should include all relevant influential forces, provide satisfactory explanations of how organizational changes are generated and resolved, collect data directly from the process being investigated, and use analytic methods to discover and evaluate underlying process complexity. The reason variance research methods are characterized as "too stylized" is because these four criteria are not addressed sufficiently. For example, Mohr (1982) characterizes variance methods as taking a limited perspective of process, assuming "continuous change driven by deterministic causation," which is obviously not the case when considering industry emergence timeframes of decades, where multiple actors from different segments of society interact in discontinuous ways, with no guaranteed outcome for overall industry survival. A method of process research, on the other hand, "encompasses continuous and discontinuous causation, critical incidents, contextual effects, and effects of formative patterns." Variance research methods characterize change by an analytical expression, collecting IV and DV, or proxies thereof. Process research collects data of relevant events from the change process itself, thereby exposing the underlying phenomenology of industry emergence and evolution. Variance research methods can ultimately be used to complement the process approach in theory development but cannot substitute for or meaningfully precede it.

4.2 Variance and Process Methods

Research using variance and process methods adopts different definitions of process and employs different data collection instruments to support the work.

Common variance study instruments include cross-sectional and longitudinal panel surveys. These variance instruments typically conceive of process as a causal sequence of inputs (IV) and outputs (DV), or as a sequence of organizational actions, described by examining antecedents and consequents of the change process under investigation. The large sample size of the cross-sectional survey is an obvious strength. Shortcomings of this instrument include the use of summary or proxy indicators that provide little insight into the process being investigated, the reliance on the memory of survey respondents to recall historic events that will be subject to subjective biases or unintended mistakes, and the weak support for inferences of possible process causality. Longitudinal panel surveys provide stronger support of process causality than the cross-sectional approach, since longitudinal data can identify time dependence of a sequence of events. Also, unforeseen processes may be discovered within the data that would not have been possible with a single-shot, cross-sectional survey. A major limitation of the longitudinal survey, however, is the requirement to predict which variables (both IV and DV) are important enough to the process for measurement. Although the longitudinal survey improves on the cross-sectional survey, neither instrument can match the insights available with process research methods to understand the complexities of industry emergence and evolution processes.

Process research data collection differs from that of variance research methods, conceptualizing process as a sequence of events, with minimal regard for input-output variables or antecedents-consequents. As compared to variance methods, the data collected is greater in number, broader in scope, and more complex to efficiently and effectively process. These seeming disadvantages provide equally extreme advantages, supporting the inference of phenomenon causality, permitting the investigation of intermediate (mediating and moderating) process steps, and generating a rich and detailed narrative history of the process under investigation. Since the sample size in process research is the number of observed events, the sample size can be substantial although the number of cases being investigated is low. Furthermore, sufficient information may permit the estimation of the magnitude of influence a given event, or set of events, may provide at a given point in the process. The abundance of data allows for the investigation into additional research questions that may arise unexpectedly (a common occurrence in policy-making circles).

Ultimately, among the stages of research activities that iterate between problem formulation, theory building, research design, and problem-solving (Van de Ven 2007), the event-based identification of a phenomenon (using process methods) naturally precedes model development and validation (using variance methods). Process cannot be constructed from variance method concepts (such as causal sequence or organizational actions, defined by IV and DV constrained by implicit methodological assumptions), because of insufficient information collected. It is possible, however, and more logical, to reduce process and the event sequence data to a series of variables, or generalized narrative, satisfying the variance method definitions of process.

5 Conclusion

Industry and government leaders seek questions to answers in order to make decisions about the economy at the industry level and above. Typically, these questions are the bases for relevant research questions. Generally speaking, questions that seek to design, control, or predict a phenomenological process are based on preexisting theoretical understandings and use a predictive strategy to mitigating the uncertainty of the results. The variance approach of research is used to solve these types of problems. On the other hand, questions that seek to describe or explain a phenomenon call for process methods of data collection and theory creation. In this way, researchers are adopting an adaptive approach to uncertainty mitigation, not entirely sure of the path or end result of their research activities. These results can be more labor-intensive to collect, and complex to interpret, but process research methods provide three major advantages over variance research methods. First, the approach is flexible, allowing for the investigation of multiple research questions with a foundational set of data, enabling insights of new processes from the initial data set to be uncovered and subsequently investigated, and permitting the comparative evaluation of multiple competing theories that may not share common foundations of input-output variables, or antecedents and consequents. In turn, multiple theories can be combined into hybrid explanations of a complex process. Similarly, multiple process method data sets could feasibly be used to investigate a single process theory, provided a minimum level of commonality of the data collected at a pre-specified level of analysis. This was done in the Minnesota Innovation Research Program (Van de Ven and Poole 1990, 2000). A second advantage of process method research is that it complements variance methods, providing insights into the process phenomenology that is not possible with variance research. A third advantage of process research is that it acknowledges the complexity of the organizational change processes (including industry emergence and evolution), in contrast to traditional variance studies that are "under-socialized" (Granovetter 1985).

Governmental and academic research thus not only focused on understanding how big a particular market, such as small satellites, will grow or change over time. Rather, it is often focused on what impact a change will have on systems of social services, education, political, and ethical and how a particular industry impacts, and is impacted by, the overall social system. In the case of small satellites, issues such as orbital space debris, global interconnectivity of the Internet, and the impact on remote area education are important aspects of the industry analyses. In this way, market research is tied to the broader aspect of societal change and interaction.
