adjacent molecule, with consequent H-bond formation and stabilization of the twin chains (formation energy of $\approx 0.2\,\mathrm{eV/molecule}$). Chiral recognition within the twin chain structure can be rationalized: the crooked shape of the molecule promotes optimal sideward bonding of the carboxylic acid group only when it smoothly matches the bending of its antiparallel counterpart, which corresponds to the condition of identical chirality. It is more intriguing to observe that the twin chains form nanogratings extending over micrometer-size domains. On Ag(111) the periodicity of such nanogratings could be tuned by varying the PVBA coverage. All twin chains in each domain have the same chirality, so that the homochiral pattern extends over mesoscopic length. The authors exclude that the self-replication of supramolecular chirality is a phenomenon mediated

by the surface. They demonstrate indeed that the effect takes place in the course of the gratings' evolution and that it is driven by the formation of metastable molecular structures (observed at low temperature) interconnecting the molecular chains.

29.3.2 Self-Assembled Monolayers of Thiols

Another interesting class of molecules is the one represented by thiols, i.e., organosulfur compounds that contain a SH group. In fact, sulfur has a strong affinity to transition metal surfaces [29.25] and therefore, usually, the S–H bond breaks, the thiolate unit anchors onto the metal surface through the S atom and the dissociated H atom recombines with the one originating from another molecule and desorbs in the form of H_2. In fact, SAMs are assemblies formed onto the surface of a solid by the adsorption of organic molecular constituents having a chemical functionality, the headgroup, with a specific affinity for the substrate and organizing spontaneously into structures with crystalline (or semicrystalline) order through noncovalent, electrostatic or van der Waals interactions. Adsorption is also possible on the surface of liquids, as in the case of mercury [29.89, 90], but that case will be not treated here. In this section, we will limit our description to the main results obtained, in particular, for alkanethiols, while further information on SAMs and gold–sulfur interaction can be found in recent reviews [29.80–83, 91].

After the first observation that polar organic compounds diluted in nonpolar solvents adsorbed on solid surfaces forming well-oriented monolayers [29.92], pioneering work on the deposition of organic compounds exploiting the S–Au interaction was started by *Nuzzo* and *Allara* in 1983 [29.93, 94]. They investigated disulfides that spontaneously produced an ordered organic film by the simple immersion of the substrate in a solution of the compound: this technique is an alternative to the more complex procedure necessary for the growth of Langmuir–Blodgett films [29.95] and can be usefully employed for the growth of SAMs of alkanethiols [29.96].

The most studied among the different thiols-substrate systems are SAMs of alkanethiols (R–SH) on Au(111). Since gold is inert toward corrosion and oxidation, the growth can be performed also with the substrate kept in ambient conditions. Usually the thiolate moiety (R–S–) is thought to anchor on Au surfaces through a S–Au covalent bond of ≈ 2.1 eV [29.82], which is strong enough to displace adventitious organic species that always adsorb onto the surface in ambient conditions.

The molecular structure of some alkanethiols is shown in Fig. 29.8. The so-called normal alkanethiols (Fig. 29.8a, sometimes indicated as C_nSH or simply C_n, with n the number of carbon atoms in the alkyl chain) consist in an alkyl chain (R) terminated on one side, with a thiol (–SH) headgroup and on the other side, with a methyl group (the so-called endgroup or tailgroup). It is possible to synthesize compounds with different endgroups, such as those shown in Fig. 29.8b,d) and many others (e.g., $-CF_3$, $-NH_2$, $-CN$, $-SO_3H$, etc.), thus obtaining functionalized alkanethiols to be employed in SAM formation [29.97–102].

In Fig. 29.8e a dialkyl-disulfide is also shown. Symmetric disulfides with structure R–S–S–R produce SAMs identical to the ones obtained by alkanethiols having the same alkyl chain [29.104], but their solubility is generally lower than for thiols and the adsorption kinetic can be different.

Two main phases can be foreseen for SAMs of alkanethiols: the lying-down phase and the standing-up phase. In the limit of very low coverage, isolated molecules interact only with the substrate: the thiol molecule anchors its headgroup to the surface and the

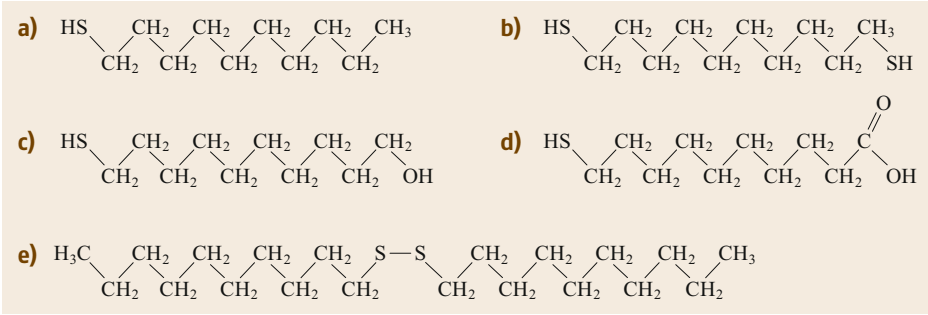

Fig. 29.8a–e A few examples of compounds used to form self-assembled monolayers. The compounds are plotted with a number of carbon atoms $n = 10$. **(a)** Normal alkanethiols (*n*-alkanethiols), endgroup is a methyl group: $HS-(CH_2)_{n-1}-CH_3$; **(b)** α,ω-alkanedithiols, endgroup is a thiol group: $HS-(CH_2)_n-SH$; **(c)** ω-mercaptoalkanol, endgroup is an alcohol group: $HS-(CH_2)_n-OH$; **(d)** ω-mercaptoalkane carboxylic acid, endgroup is a carboxylic acid group: $HS-(CH_2)_{n-1}-COOH$; **(e)** 1,1′-dialkyl-disulfide, two identical *n*-alkanethiolates are connected by a disulfide S–S bond: $CH_3-(CH_2)_{n-1}-S-S-(CH_2)_{n-1}-CH_3$. (Reprinted from [29.103], with permission from Elsevier)

interaction of the rest of the molecule with the surface determines adsorption in a flat-lying configuration. As shown by *Poirier* [29.105], the isolated molecules are highly mobile on the surface. On increasing the coverage the molecules start to interact with each other and the lying-down phase acquires a periodic order, the so-called striped phases (STM image in Fig. 29.9b). At intermediate coverage other lying-down phases are observed (Fig. 29.9c–e and following Fig. 29.16, where also a model for these assemblies is presented). Above a critical molecular density, the intermolecular interaction gets stronger and can compete with the interaction with the substrate. Therefore the standing-up phase grows and covers almost all the surface, except for a few vacancy islands, which are clearly visible as dark features (Fig. 29.9f). In this phase the molecules stand with their axis at about 30° from the normal and arrange in a $(\sqrt{3}\times\sqrt{3})$R30° superstructure with hexagonal lattice rotated by 30° with respect to the lattice of the Au(111) substrate. In fact, the nearest neighbor distance for Au atoms ($a = 2.88$ Å) is too short to accommodate the alkyl chains, while they can occupy next-nearest sites at a distance of $\sqrt{3}a = 4.99$ Å. Assuming as the standard model that S binds at threefold hollow site at this $\sqrt{3}a$ distance, the hexagonal lattice for the SAM is shown in Fig. 29.10a. Such configuration does not maximize the lateral van der Waals interactions between the alkyl chains within the SAMs. In order to minimize the free energy of the layer, the molecules adopt a tilted conformation reducing their distance, as shown in Fig. 29.10b.

Therefore, at high coverage, the substrate surface is covered with the alkanethiol SAM in the standing-up phase, i.e., the sulfur headgroup anchors the molecules to the gold substrate and the exposed surface presents the endgroups of the compound. As a consequence, as mentioned before, the organic film can change the physico-chemical properties of the gold substrate through its functionalization. This explains why this type of organic material is so attractive, not only for studying self-assembling but also in such diverse fields of applications such as sensing [29.108], molecular electronics [29.109], molecular switching [29.110], control of protein adsorption [29.111, 112], and surface patterning [29.113–115]. In fact, they are an example of the modular concept of organic chemistry: as shown schematically in Fig. 29.10b, they present the same sulfur–gold anchor, a spacer represented by the alkyl chain that decouples the metal surface from the endgroup and the environment and a functional endgroup with tunable properties.

An alkanethiol SAM can be grown on gold by following two different procedures [29.103], i.e., deposition from the gas phase or from the liquid phase:

a) In gas phase deposition, also known as physical vapor deposition (PVD), the gold sample is exposed to the vapor of the compound in vacuum. This is a very clean method for producing a self-assembled monolayer, since contamination from the environment can be minimized and the substrate can be prepared with the usual procedure of ion sputtering and annealing cycles and checked by typical surface science techniques. In gas phase deposition, the molecular flux depends on the vapor pressure of the evaporant. Therefore, this growth method is efficient for the production of low-coverage SAMs in the lying-down phase and is useful to study the early stages of the dynamics of the assembly at submonolayer coverage, e.g., the striped phases. On the contrary, the standing-up phase can form only if the vapor pressure of the compound is high enough and it can be more difficult to be achieved

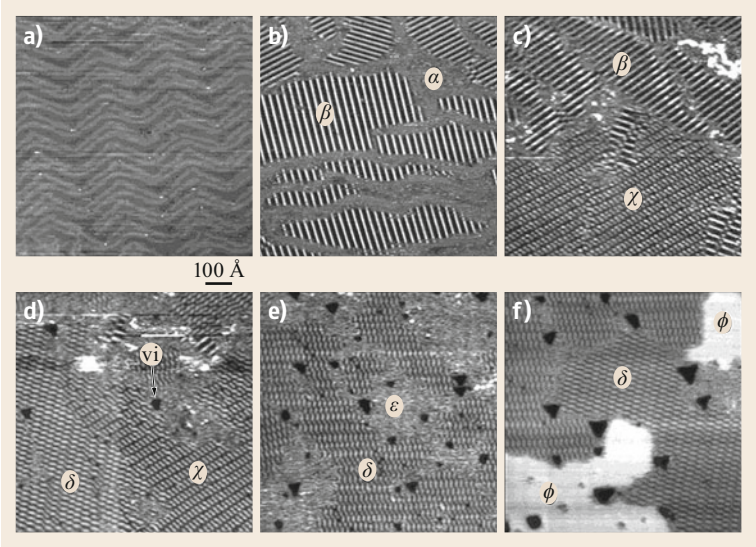

Fig. 29.9a–f STM images of the isothermal growth at 22 °C of decanethiol in ultrahigh vacuum. **(a)** Herringbone reconstruction of the clean Au(111). **(b)** Exposing the surface to a small dose of decanethiol, the formation of different domains of the striped β-phase in coexistence with a highly mobile α-phase, i.e., a two-dimensional gas, was observed. Au reconstruction was lifted in the regions covered with the β-phase. The growth proceeds with an increase of the β-regions. **(c)** When the surface is saturated by β, a new χ-phase was observed to nucleate in coexistence with β. **(d)** With a further increase in the surface coverage, another new δ-phase is formed that coexists with χ. Moreover, dark features are also observed: these pits are Au vacancy islands (vi). **(e)** At even higher surface coverage, a new disordered ε-phase was observed in coexistence with δ. **(f)** At higher surface coverage, ε-phase is replaced by the standing-up ϕ-phase, which coexists with δ. At saturation, the surface is covered with the ϕ-phase. (Reprinted with permission from [29.106]. Copyright (2001) American Chemical Society)

especially with long chain molecules (for $n > 11$) and solid compounds (for $n > 17$). We also mention that for solid compounds, alternative deposition techniques such as the supersonic organic molecular beam deposition (SuOMBD) [29.116] can be employed. SuOMBD exploits the heating and sublimation of the compound in a flow of a carrier gas and the supersonic expansion of the seeded mixture

through a nozzle. The molecular flux is still very low, which allows to investigate molecular adsorption in the limit of zero-coverage [29.117]. On the other hand, since the compound is transported to the speed of the carrier gas, it can reach hyperthermal energies, available to the molecule to overcome adsorption or diffusion barriers if present.

b) In liquid deposition the gold sample is immersed in a solution of the compound to be deposited. The solution is a complex environment and the dynamic aspects of this form of deposition are difficult to characterize with the same type of details as for the case of gas-phase studies. However, the evolution of the structural phases formed during the self-assembly is similar to that for assembly from the gas phase [29.118–120]. Figure 29.11 schematizes the adsorption process in presence of solvent molecules. The kinetics of film growth can be influenced by the presence of the solvent, modifying the adsorption picture we have described previously [29.107]. In fact, physisorbed solvent molecules can be present on the gold surface after the immersion of the substrate and those molecules must be displaced to allow the thiol to adsorb. In particular, for long chains, adsorption of a lying-down thiol molecule requires to displace a number of solvent molecules greater than the one needed to adsorb in a standing-up conformation. Therefore, standing-up thiolate domains can form directly when depositing from solution and could also be favored over the formation of a striped phase. Moreover, solvent molecules can also favor the transition from the lying-down to the standing-up conformation due to additional interactions (alkyl chain-solvent and solvent–substrate interactions). In liquid deposition, it is also possible to control the chemisorption of the alkanethiol electrochemically [29.121] but this topic will be not treated here.

As explained above, a standing-up phase is easily obtained with liquid deposition. This is the most common protocol for preparing SAMs on gold since it does not require a complex vacuum system but only a suitable solvent for the compound. A freshly prepared (or flame annealed) supported gold film is immersed into a dilute (1−10 mM, rarely also micromolar) ethanolic solution of thiols for several hours at room temperature. The adsorption starts with a fast process: in fact, after a few seconds or few minutes, an adsorbate with a high coverage is obtained. On the other hand, the film contains defects and, in order to minimize them, incubation times of some hours (or sometimes some days) are necessary: the reorganization process to maximize the density of molecules is slow, in particular for long alkyl

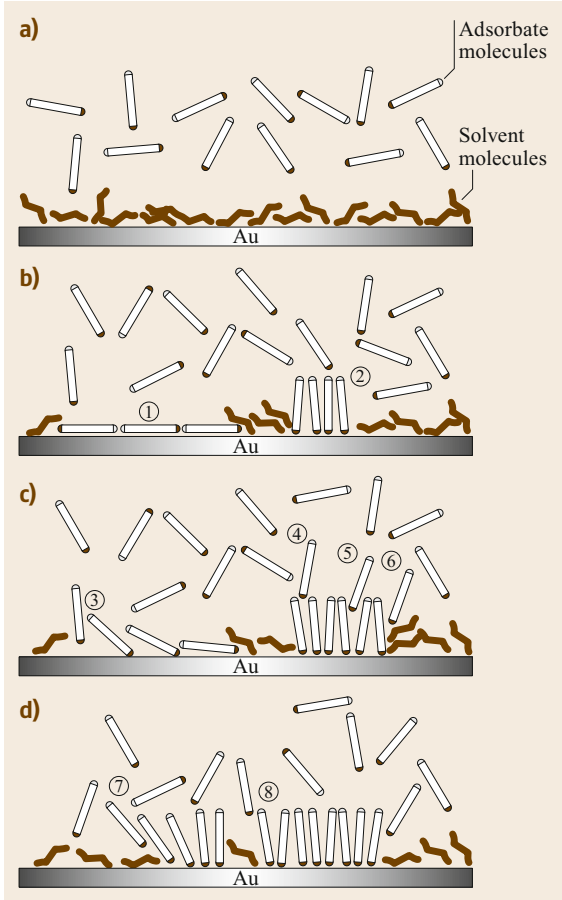

Fig. 29.11a–d Illustration of the adsorption processes in solution. The first steps correspond to a fast growth regime. **(a)** The adsorbate molecules in solution approach the gold substrate, which is coated with a layer of physisorbed solvent molecules (Note: the solvent molecules surrounding the adsorbate molecules have been omitted for clarity.) **(b)** The adsorbate molecules displace the solvent molecules to form either lying-down domains (1) or upright domains (2). **(c)** Additional adsorbate molecules incorporate into the lying-down domains and initiate a transition to an upright domain (3). Alternatively, adsorbate molecules can impinge on the surface (4), within the boundaries (5) or at the boundaries (6) of upright domains and incorporate into them. **(d)** The upright domains formed from either the lying-down phase (7) or direct adsorption (8) continue to grow until maximum coverage is attained. chains. Besides the immersion time, the parameters that can affect the SAM structure and formation rate are the type of solvent, the temperature, the concentration and structure of the adsorbate (such as its chain length), the adsorbate purity and the cleanliness of the sub-

strate. Alkanethiol SAMs obtained from liquid phase deposition using alternative solvents to ethanol (such as toluene, tetrahydrofuran, dimethylformamide, acetonitrile, cyclooctane) do not differ significantly from those formed from ethanolic solutions [29.96]. Ethanol has the advantage of being cheap, available with high purity, of low toxicity and to solvate a variety of alkanethiols with varying degrees of polar character and chain length.

Temperatures of the solution above RT improve the kinetics of the layer formation and reduce the number of defects in the SAM, producing larger domains [29.122]. Post-treatment of the deposited film up to 85 °C did not show any loss of molecules, while some changes were observed starting from 100 °C, that evolved into a severe deterioration of the monolayer topography at 115 °C [29.123].

Immersion time and concentration parameters are inversely related, longer times being required for lower concentrations. On the other hand, the minimum concentration to deposit a SAM must be $> 1\,\mu M$, as demonstrated by experiments on SAMs obtained by immersion for a week in solutions with concentrations $\approx 1\,\mu M$. It was indeed shown that the physical properties of the SAM are not the same as those formed starting from more concentrated solutions [29.96], probably because impurities are deposited along with thiols and this fact hinders the use of extremely dilute solutions except for the investigation of the initial stages of the adsorption in liquid [29.118–120].

As mentioned before, SAMs contain defects. Impurities can be introduced in the film during the deposition process, which is especially true when the compound is provided from immersion in solution. Considering the substrates, the evaporated gold films present many grains with boundaries that limit the crystallinity of the SAM. Also, when single crystals are employed, steps are always present. Even on large grains, the $(\sqrt{3} \times \sqrt{3})$ registry of the thiol molecules with the substrate can determine orientational and translational domain boundaries with the presence of missing rows. Including also the molecular tilt, the organic film is in general formed by domains with different alignments. On the other hand, the typical $(23 \times \sqrt{3})$ reconstruction of Au(111) (the so-called herringbone reconstruction [29.124–126], as shown in Fig. 29.9), is lifted after SAM formation, leaving in turn monatomic-height vacancies [29.127–129]. The origin of these pit-like defects, shown in Figs. 29.9 and 29.12 for deposition from the gas and from the liquid phase, respectively, can be understood by considering the different atomic density of the reconstructed and unreconstructed Au(111) surface. Indeed, the atom density in the $(23 \times \sqrt{3})$ reconstruction is 4.3% higher than in the unreconstructed gold surface; the change in the atom density induced by adsorption causes a relaxation of the surface, with the formation of single-atom vacancies that subsequently nucleate into large vacancy islands [29.128, 130]. The topography of the organic film faithfully replicates the underneath topography of these defects. Finally, intrinsic defects of the film are related to the chain of alkanethiolate. In fact, all the chains should be in the all-*trans* configuration but some molecules can present gauche defects, as shown in Fig. 29.13.

Let's consider in more detail the different phases obtained by vapor deposition. Figure 29.14 reports the low-energy atom diffraction (LEAD) patterns measured versus time (i.e., at different doses) during exposure of Au(111) at 278 K to decanethiol [29.131]. The evolution of the SAM structure is evident; from the ordered striped phase, the layer passes through an intermediate phase which does not show any diffraction pattern (a film without a long-range ordering) and finally it reaches the standing-up configuration, with a new diffraction pattern. The main peak is associated with the $(\sqrt{3} \times \sqrt{3})$R30° periodicity but, at the highest dose, a superlattice peak corresponding to the so-called c(4×2) structures appears.

Schreiber et al. [29.132] studied the uptake curve, ranging over four orders of magnitude, of decanethiol on Au(111) at RT (Fig. 29.15). Diffraction data are reported together with the evolution of the XPS signal, which provides an estimation of mass coverage. After the fast completion of the striped phase (measured by

LEAD after an exposure of a few tens of langmuir), the amount of sulfur remains almost constant up to an exposure of about 1000 L, above which the standing-up phase (and in particular the c(4 × 2) one) starts to form, as evinced by LEAD and grazing incident x-ray diffraction.

For the striped phase, LEED measurements by *Dubois* et al. [29.133] and LEAD studies by *Camillone* et al. [29.134, 135] showed that the lying-down molecules form a rectangular $(p \times \sqrt{3})$ unit cell, where p is the number of Au spacings of 2.88 Å. Of course, the value of p is chain length-dependent and close to twice the one found in the corresponding bulk phases of the molecule; for decanethiol, p was ≈ 11, corresponding to a spacing of ≈ 32 Å. On the other hand, different lying-down phases could be grown [29.136]. For instance, with a small displacement of every second row of stripes in the perpendicular direction, the primitive rectangular cell transforms to a centered one very similar in terms of area per molecule [29.137, 138].

STM investigations provided further information on lying-down phases also on small domains that are not resolved in diffraction [29.105, 139–141]. Figure 29.16a–d shows a sequence of STM images of a Au(111) surface at 293 K [29.139] with a low thiolate coverage. Different lying-down phases coexist on the surface [29.105], namely the ordered structures β, χ^* (it is a variant of the χ-phase of Fig. 29.9), and δ, and the disordered ε-phase. At very low coverage a phase of isolated molecules with high mobility, called α-phase [29.105], is present (not shown in Figs. 29.16, 29.9 and [29.105]). The four images are

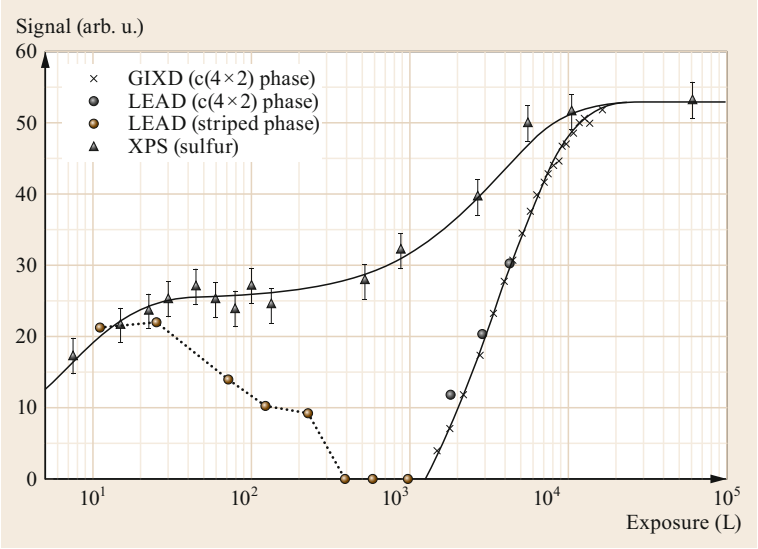

Fig. 29.15 Decanethiol deposition on Au(111) single crystal at 300 K by vapor-phase deposition in ultrahigh vacuum. Different measured signals versus thiols exposure are shown. XPS: signal from sulfur 1s. LEAD and grazing incident x-ray diffraction data correspond to the particular phase formed at the given coverage. (Reprinted from [29.103], with permission from Elsevier)

acquired with a time lapse of 420 s and it is evident that the boundaries between two phases are changing in time. The β-phase is a striped phase in which the decanethiolate molecules are lying flat on the Au(111) surface and are arranged in an alternating head-to-head and tail-to-tail registry (Fig. 29.16g) with a corrugation of 0.5 nm along the row direction and a periodicity of 3.3 nm across the stripes. The δ-phase is similar, but the tails of the molecules are lying partly on top of each other. Therefore the stripe width is only 7.5 times the nearest-neighbor gold distance (2.2 nm), with a periodicity $(5\sqrt{3}\times\sqrt{3})$R30°. The χ^*-phase is a mixture of small β- and δ-domains and shows a dynamical behavior with a switching between the stripe components. The disordered ε-phase does not show any structure but the height profiles are consistent with decanethiolate molecules lying flat on the Au(111) substrate. In the images of Fig. 29.16a–d, the δ-phase covers completely the lower terrace (top part of the image) and remains stable with time. The β and χ^*-domains occupy the upper terrace (bottom part) and partially convert into each other with time. Vacancy islands with a single layer depth also show some dynamics since they change size and, in most cases, a well-ordered β-phase is observed inside them.

At higher coverage, a standing-up phase is formed. For long chains ($n > 9$) the structure has a $(\sqrt{3}\times\sqrt{3})$R30° registry, as expected from the packing of molecules on Au(111). The alkyl chains are tilted by an angle θ and twisted by an angle ψ, according to the notation reported in Fig. 29.10c. Depending on the endgroup, these angles are in the range 28°–40° and 50°–55°, respectively, as determined by IR spectroscopy [29.142]. A study performed with x-ray diffraction on n-alkanethiols with $10 \le n \le 30$ [29.143] showed two different regimes: $32° < \theta < 34°$ for $10 \le n < 15$ and $30° < \theta < 31°$ for $15 < n \le 30$. The tilt direction from the next-nearest neighbor was $\approx 15°$ for the former regime and between 4° and 9° for the latter.

Finally, for a full coverage SAM, the formation of an overlayer was discovered by LEAD [29.144] and confirmed by x-ray diffraction [29.145, 146] and STM [29.147, 148] (Fig. 29.17). It is usually referred to as c(4 × 2) using an unconventional notation; in fact the unit cell size is referred to as the $(\sqrt{3}\times\sqrt{3})$R30° overlayer of molecules. With respect to the Au(111) lattice, the structure is more appropriately denoted as $(3\times 2\sqrt{3})$.

The evidence for two inequivalent molecules in the c(4 × 2) structure means a break of the hexagonal symmetry. A possible explanation is the difference in twist angle between the inequivalent molecules. However, x-ray data [29.149] suggested that the difference should be also related to the different adsorption site of the headgroup. In fact, a study performed with x-ray standing waves (XSW) [29.150] showed that there are two distinct lateral and vertical positions for sulfur. This was in contrast with the single site predicted by the standard model and based on the observation that elemental sulfur adsorbs on transition metal surfaces at highly coordinated sites, such as the threefold hollow site on fcc(111) surfaces (e.g., S/Ni(111) [29.151]). The XSW investigation [29.150] also showed that the results for striped phases are indistinguishable from standing-up ones.

STM studies could determine the sulfur position but, if the alkanethiolates in the SAMs are too long, the Au–S interface is buried underneath the hydrocar-

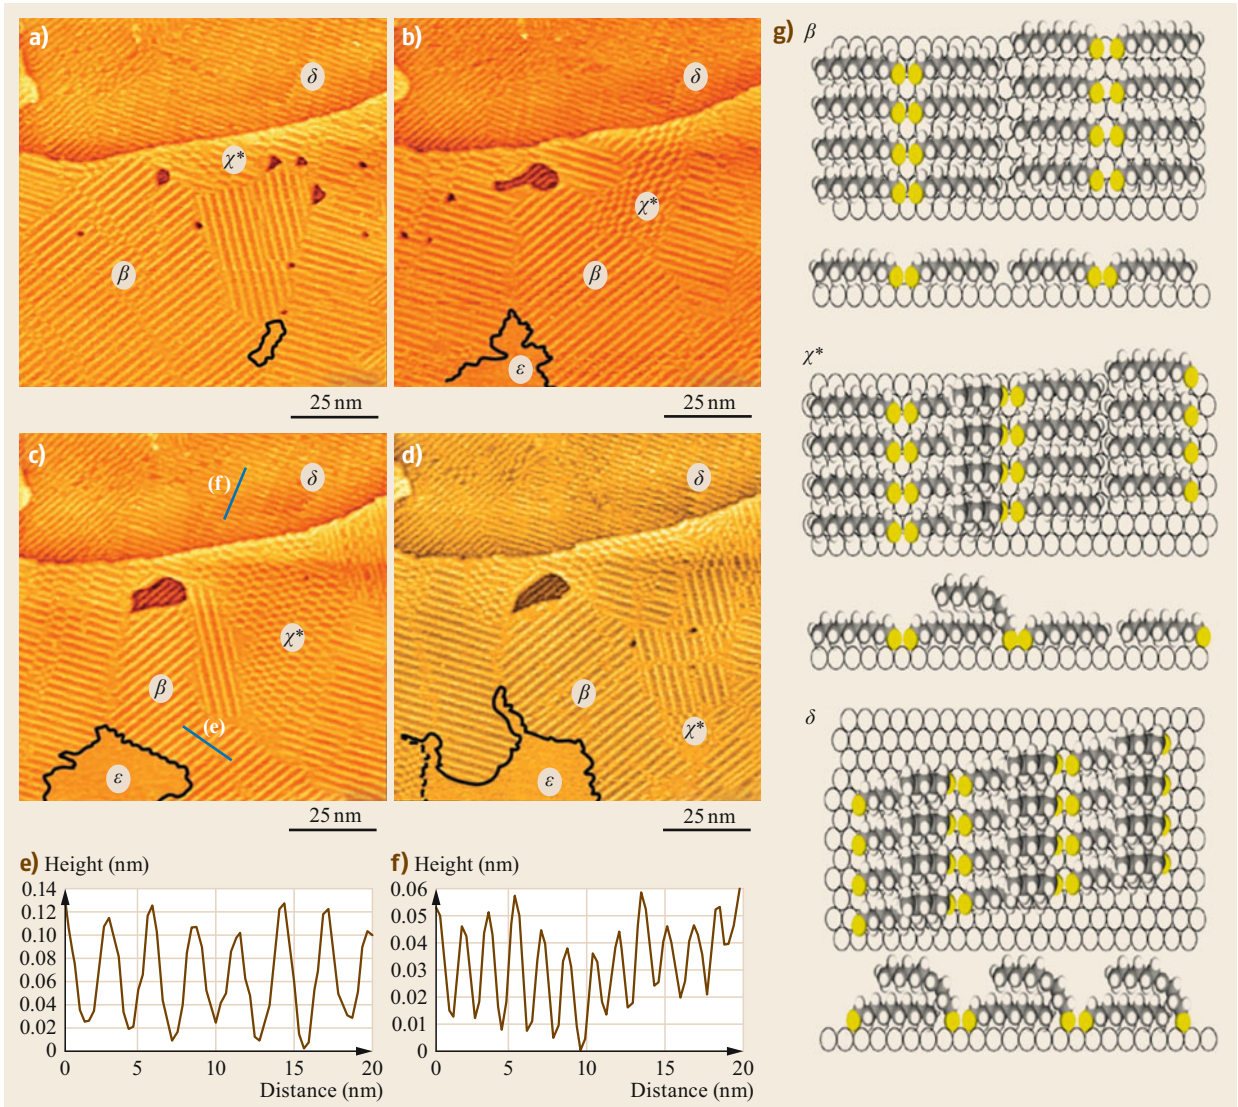

Fig. 29.16 (a–d) Sequence of STM images of a decanethiolate SAM on Au(111) at 293 K ($V = 1.2$ V, $I = 190$ pA). Regions β, δ, and χ^* are ordered phases while ε is a disordered phase. The *solid line* marks a domain boundary between the β-phase and the disordered ε-phase, while the *dashed line* marks a χ^*-ε-domain boundary. Consecutive images were measured with a time lapse of 420 s. Line profiles **(e,f)** were taken across the β and δ-phases in **(c)**, respectively. The stripe widths are **(e)** 3.3 nm and **(f)** 2.2 nm. **(g)** Schematic representation of top and side views of β-, χ^*-, and δ-phases. bon chains. Therefore, short chain alkanethiols SAMs attracted a lot of interest both for the possibility of a direct imaging of headgroups and because they can be simulated more easily.

For methylthiolate SAMs, the shortest and apparently simpler *n*-alkanethiol, *Dishner* et al. [29.152] reported a coexistence between $(2\sqrt{3} \times 3)$ and $(2\sqrt{3} \times \sqrt{3})$R30° structures. The latter was confirmed by *Danisman* et al. [29.153], while a new (3×4) structure was observed [29.154–156]. At low temperature, the (3×4) was coexistent with the previously mentioned hexagonal phases but He atom diffraction and LEED data did not support the $(2\sqrt{3} \times 3)$ [29.156]. Moreover, the (3×4) diffraction pattern disappeared

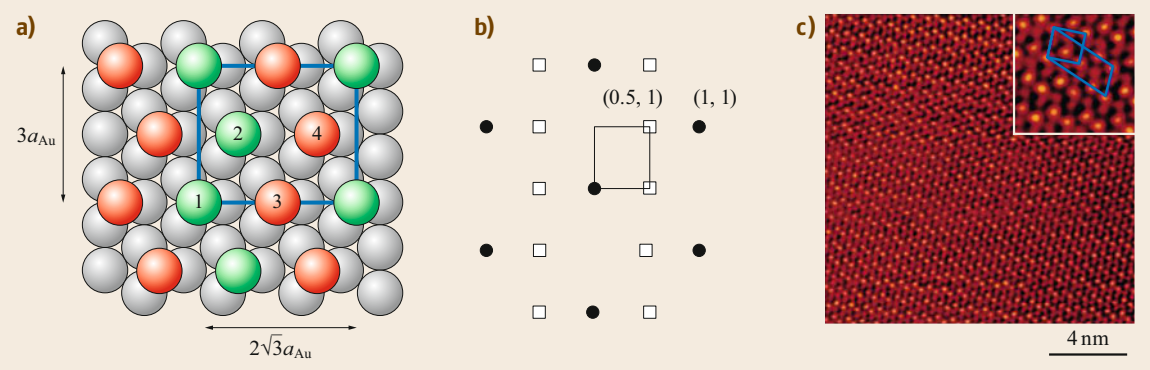

Fig. 29.17a–c A c(4×2) superlattice (or rectangular $(3\times 2\sqrt{3})$ overlayer, if expressed with respect to the lattice spacing of the Au substrate) of decanethiol on Au(111). Two-dimensional schematic view of the structure in real space **(a)** and in reciprocal space **(b)** and corresponding STM image **(c)**. Diffraction peaks: *full circles* correspond to the hexagonal $(\sqrt{3}\times\sqrt{3})$R30° periodicity, *open squares* are related to the superlattice. The systematic absence of superlattice peaks with integer indices, such as (1, 0), (1, 2), etc., indicates the presence of symmetry equivalent molecules in the unit cell of the overlayer. In particular, the pair of molecules labeled 1 and 2 and the distinct pair labeled 3 and 4. (Reprinted with permission from [29.148]. Copyright (2003) American Chemical Society)

at (315±10) K, leaving only the hexagonal overlayer and this transition was reversible. More recent studies have suggested that the $(\sqrt{3}\times\sqrt{3})$R30° periodicity might not be the real character for RS–Au bonding [29.157]. In fact, experimental observations supported by calculations [29.129, 158, 159] showed that the sulfur headgroup is not directly adsorbed to Au(111) and that the gold adatoms play a role in forming the SAM. The creation of gold adatoms is consistent with the observation of vacancy islands on thiol-covered surfaces; adatoms were observed to coexist with striped phases [29.127]; adatoms can also assist the dissociation [29.160] and stabilize the structure [29.161], and could explain the relatively high mobility in SAMs. Another indirect suggestion that adatoms are involved in the alkanethiols SAMs is the study of surface morphology after the removal of an octanethiolate SAM. Large triangular Au islands were observed to form where the SAM was present [29.162]. For example, after water dissociation under the STM tip, the resulting hydrogen determines the breaking of the Au–S bond of an octanethiol SAM and the release of gold adatoms [29.163]. Going back to the methylthiolate-gold system, the distance between the two methyl groups in the CH_3S–Au–SCH_3 complexes is too large, so that the complex does not directly fit into a $(\sqrt{3}\times\sqrt{3})$R30° lattice [29.164]. On the other hand, in the structural model by *Mazzarello* et al. [29.158] a dynamic equilibrium between adatom-methylthiolate complexes and bridge-bonded thiolate species adjacent to vacancy creates a disordered monolayer in which the average structure satisfies the $(\sqrt{3}\times\sqrt{3})$ symmetry. Alternatively, *Voznyy* et al. found a $(3\times 4\sqrt{3})$R30° structure for methylthiolate [29.159] and, using the previous idea of the disordered phase by assuming a $(3\times 4\sqrt{3})$ with reduced long-range order at 75% of saturation coverage, they were able to show that the corresponding diffraction pattern showed a $(\sqrt{3}\times\sqrt{3})$ periodicity although, locally, the unit cell is different. Voznyy et al. also discussed the possibility to transform *trans*-complexes into their *cis*-isomers of the $(3\times 4\sqrt{3})$ structure to describe the c(4×2) of long chain SAMs.

Figure 29.18 shows STM images, measured on a low-coverage methylthiolate film on Au(111) by *Voznyy* et al. [29.159]. The analysis of the images shows adatom complexes in which sulfur atoms bind covalently both to the Au adatom of the complex and to surface gold atoms, besides preserving the radical methyl tail. Those complexes are chiral due to the presence of different substituents around the sulfur atoms which, by using the stereochemical nomenclature, can be both *S*-type or *R*-type. The complex is a *trans*-isomer if both sulfur atoms are of the same type, *R* or *S* (Fig. 29.18f for the *R*-type case); otherwise it is a *cis*-isomer, as in Fig. 29.18g. For the two isomers, the authors calculated a difference in adsorption energy < 0.1 eV but with a barrier of 0.50 eV to transform an isomer into the other. Moreover, the authors observed the formation of stripes in which the complexes are in the same *trans*-configuration, but on increasing coverage, they did not observe a 2-D-ordering; this fact is probably related to a weak or even repulsive interstripe interaction. Instead, this 2-D ordering was observed for propylthiolate ($n = 3$), for which there is an increase of van der Waals interactions between tails. It is also interesting

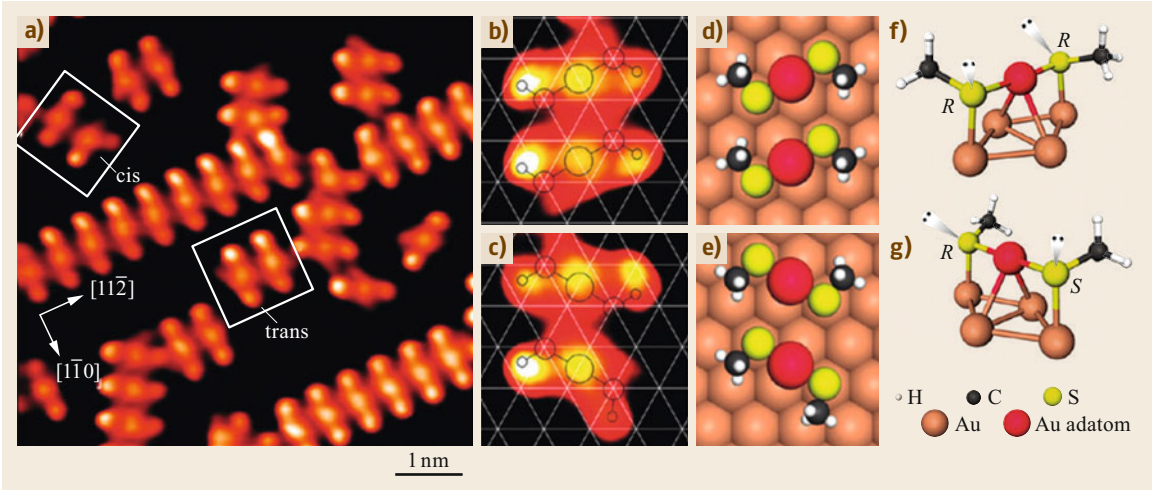

Fig. 29.18a–g Methylthiolate at low coverage on Au(111). **(a)** STM image. *White squares* indicate the different complexes reported in the enlarged images of panels **(b)** and **(c)**. Panel **(b)** refers to adjacent *trans*-$(CH_3)_2Au$ complexes; panel **(c)** shows adjacent *cis*- and *trans*-adatom complexes. The superimposed triangulation represents the Au lattice. The corresponding schematic models are shown in panels **(d)** and **(e)**, respectively. Panels **(f)** and **(g)** show the DFT optimized structures for *trans*- and *cis*-configurations. that in this last case the authors found a chiral recognition between the 1-D stripes, since adjacent stripes present alternating *R*,*R* and *S*,*S* symmetries [29.159].

A (3×4) structure was also observed for ethanethiolate ($n = 2$) [29.165, 166] and propylthiolate ($n = 3$) SAMs [29.166], while not observed for butylthiolate ($n = 4$) [29.167]. Therefore, the experiments show that, at $n = 4$, steric hindrance and van der Waals interactions between chains start to compete with the headgroup–Au interaction to produce the hexagonal structure of long chain SAMs.

The gold adatoms seem to be a general feature for the adsorption of thiolates on Au(111). On the one hand, the structure of short chain thiolates seems based on dithiolate complexes; on the other hand, XSW experiments on hexylthiolate ($n = 6$) and octylthiolate ($n = 8$) SAMs demonstrated that such species also bind to gold adatoms but form *R*,*S*-Au_{ad} complexes with a single thiolate [29.168]. More generally, considering thiols with a structure different from a simple alkyl chain, STM studies on low-coverage benzenethiol on Au(111) revealed the role of gold adatoms; in fact phenylthiolate was observed to self-assemble into surface-bonded complexes with gold adatoms [29.169]. Instead, mercaptobenzoic acid, the thiolate which was observed to form gold adatom complexes on gold clusters [29.170], adsorbs on Au(111) without the formation of vacancy islands; the observed gold islands present a low coverage and are not consistent with Au-adatom models [29.171].

29.3.3 Amino Acids

Finally, a large category of molecules which naturally undergo self-assembly are small molecules of biological interest. Indeed, the first investigations on the H-bond-mediated assembly on surfaces were stimulated by the observation of selective base pairing of nucleic acids. DNA nucleotides were therefore among the first biological molecules to be studies on surfaces in a controlled way, i.e., with the approach typical of surface science and with the aim of understanding the phenomena at the molecular level [29.19, 20]. However, most surface science studies on the anchoring and self-assembly of biological molecules have been performed on amino acids and short peptides [29.17, 18]. The reasons are manifold. First, amino acids are the basic constituents of peptides and proteins, while oligopeptides represent the simplest organized structure formed by amino acids. Thus, the structure of these molecules is simple enough to use these systems as models for the chemisorption of biofunctional molecules. On the other hand, they are *complex* enough to provide useful information on the fundamental mechanisms governing the hybrid organic–inorganic interface. Finally, all the twenty natural amino acids, except glycine, are chiral. Since it is now established that the surface reactivity can be modified by exploiting the intrinsic chirality of amino acids and peptides [29.174, 175], their action as a chiral modifier is crucial for chiral separation or enantio-selective heterogeneous catalysis.

Most of the studies on self-assembly of amino acids at metal surfaces has been performed on Cu and other noble metals, though a few works on transition metals as Pt, Pd and Ni have been reported [29.176–180]. The results underline the role of the substrate, which is determined mainly by its reactivity, but also the existence of some common features. The general trend is that amino acids adsorb on Cu, Au and Ag surfaces at RT in the monolayer regime, self-assembling in ordered structure of various geometry, depending on experimental conditions (Fig. 29.19). Multilayers form rarely at 300 K [29.181], while they are observed at lower T.

Almost all the twenty natural amino acids have been deposited on Cu surfaces. The comparison among results on the different systems allows to draw a global picture in which both similarities and differences related to the surface geometry and/or to the molecular structure are evinced. This same comparison is much less straightforward on other metal surfaces, which have been investigated less systematically.

Amino acid adsorption can occur either in the neutral, in the anionic or in the zwitterionic form. The occurrence of zwitterionic adsorption is immediately evinced by XPS analysis of the layer since the presence of a charged $-NH_3^+$ functionality causes an upshift on the N 1s photoemission line (from a binding energy $E_b(\mathrm{N\,1s}) < 400\,\mathrm{eV}$ to $E_b(\mathrm{N\,1s}) \approx 401\,\mathrm{eV}$). On the other hand, adsorption in the anionic/zwitterionic form is evinced also by the presence of well-defined bands in the reflection adsorption infra red spectrum of each amino acid species. As an example, for Ala/Cu(110) direct evidence of an anionic species at low coverage is given by the presence of the symmetric stretch vibration of the carboxylate functionality, $\nu_s(\mathrm{COO}^-)$, at $1411\,\mathrm{cm}^{-1}$ (Fig. 29.20; [29.39]).

Molecules in direct contact with the Cu surface adsorb, in general, in the anionic form, while zwitterionic adsorption is characteristic of the multilayer. A common adsorption configuration can be identified for the different amino acids: the simplest species bind to the Cu surface in a μ_2 or μ_3 configuration, depending on coverage and annealing temperature. As shown in Fig. 29.20 for the case of alanine, they correspond, respectively, to the situation in which two or three bind-

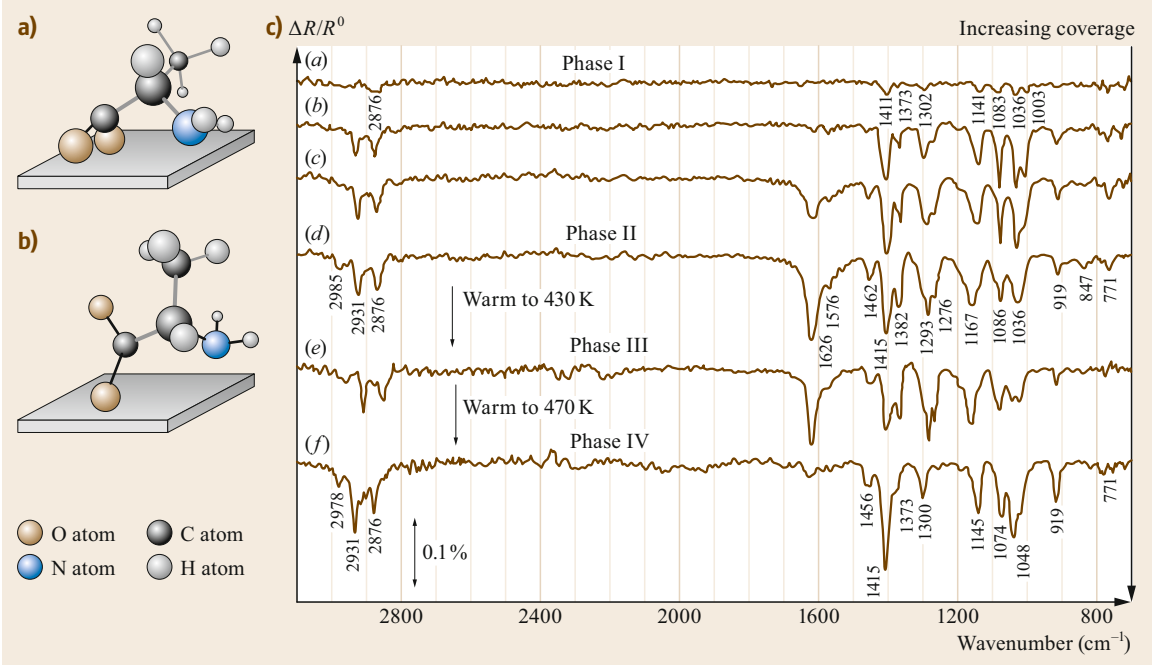

Fig. 29.20a–c Representation of the μ_3 and μ_2 bonding schemes discussed in the text, for the case of *S*-alaninate on Cu(110). **(a)** In the μ_3 configuration the two carboxylate oxygens are equidistant from the surface. This is evinced in RAIRS data (spectra (*a*) and (*b*) in **(c)**) by the intensity of the symmetric carboxylate stretch vibration, $\nu_s(\mathrm{COO}) = 1411\,\mathrm{cm}^{-1}$, and by the absence of the corresponding asymmetric stretch, $\nu_{as}(\mathrm{COO})$, expected around $1625\,\mathrm{cm}^{-1}$. Further analysis of the RAIR spectrum suggests that the OCO plane of the carboxylate group must be tilted towards the surface plane and that the plane of the NH_2 group lies almost parallel to the surface. **(b)** In the μ_2 configuration (spectra (*c*)–(*e*) in **(c)**), on the contrary, one O atom points away from the surface, as revealed by the strong intensity of the $\nu_{as}(\mathrm{COO})$ mode at $1626\,\mathrm{cm}^{-1}$, and the methyl group is held almost vertical along the surface normal. **(c)** The identification of phase I to IV is coherent with the STM analysis discussed in Fig. 29.21. (Reprinted from [29.39], with permission from Elsevier)

ing points are present. In μ_2 configuration, usually the molecule binds through the N atom and one O atom of the carboxylate/carboxylic group, with the second O atom protruding into the vacuum. In the more stable μ_3 configuration, the N atom and both carboxylate O atoms are bound to the surface. For the smallest amino acids, like glycine and alanine, the side chain protrudes towards the vacuum. On the contrary, if the side chain is more complex and contains additional, possibly reactive functional groups, it may bend towards the surface and anchor to it in a fourth point (μ_4 conformation). This behavior has been observed, e.g., for lysine on Cu(110) [29.182] and for serine on Cu(531) [29.183].

An immediate consequence of the very similar adsorption conformation of the different amino acid species is that these molecules self-assemble on the surface forming similar long-range adsorption patterns, as demonstrated by LEED and STM data. Three distinct phases may form on Cu surfaces with increasing molecular density:

i) The 2-D gas, at low coverage. This phase is driven by repulsive interaction among the molecules, which are very mobile on the surface so that they cannot be imaged by STM
ii) The intermediate phase, in which *standing* molecules align in short rows and are stabilized by intermolecular H-bonds
iii) The solid phase, consisting of extended, ordered superstructures.

The (3×2) superstructure is the most stable pattern observed on Cu(110) for simple molecules as *Gly* and *Ala* [29.39, 184, 185] (Fig. 29.21d), but also for more complex ones as *Lys* [29.186]. At saturation coverage, the other amino acids usually organize in less-dense superstructures, due to the need of accommodating larger molecules. In all cases, hydrogen bonding is essential for the stabilization of the layer.

The case of alanine on Cu(110) is paradigmatic of how the self-assembly behavior of amino acids can

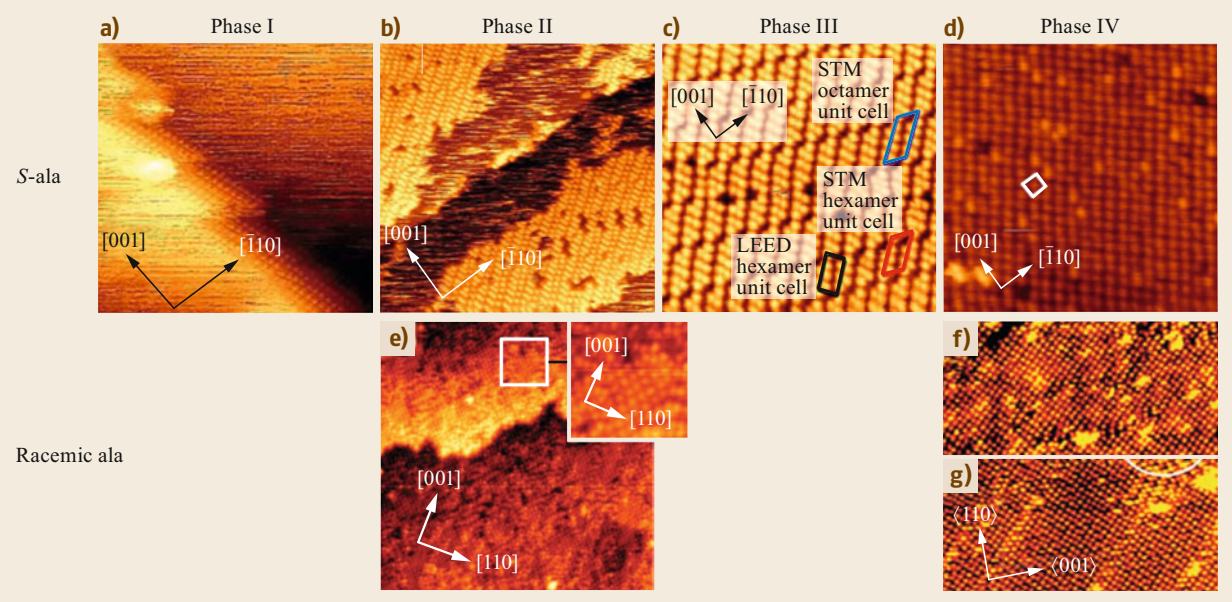

Fig. 29.21a–g STM images showing the various geometries of alaninate on Cu(110) obtained under different experimental conditions. *Top row*: *S*-alanine/Cu(110). **(a)** Phase I, showing alaninate molecules at step edges and streaky areas on terraces (image size $29.2 \times 24.6\,\mathrm{nm}^2$, $V = 1.02\,\mathrm{V}$, $I = 1.08\,\mathrm{nA}$). **(b)** Phase II, showing the details of chiral chains covering large terraces (image size $25.4 \times 24.6\,\mathrm{nm}^2$, $V = 2.08\,\mathrm{V}$, $I = 1.97\,\mathrm{nA}$). **(c)** Phase III. The image shows size-selected clusters of 6 or 8 molecules (image size $12.7 \times 12.3\,\mathrm{nm}^2$, $V = 2.08\,\mathrm{V}$, $I = 1.97\,\mathrm{nA}$). Hexamer clusters occupy a unit mesh of $17.5\,\text{Å} \times 9\,\text{Å}$ and octamer clusters a unit mesh of $21.5\,\text{Å} \times 9\,\text{Å}$. The corresponding unit cells as determined by STM and the hexamer unit cell determined by LEED are marked. The hexamer unit cell in matrix notation is (5,3,3,1) according to STM and (2,2,5,3) according to LEED. **(d)** Phase IV. The STM image shows the achiral (3×2) reconstruction (image size $12.7 \times 12.3\,\mathrm{nm}^2$, $V = 2.83\,\mathrm{V}$, $I = 1.14\,\mathrm{nA}$; annealing temperature 453 K). The unit cell (marked in the figure) contains two molecules and measures $7.2\,\text{Å} \times 7.6\,\text{Å}$. *Bottom row*: racemic alanine/Cu(110). **(e)** Phase II showing patches of achirally ordered molecules (image size $40 \times 40\,\mathrm{nm}^2$, $V = 0.36\,\mathrm{V}$, $I = 0.15\,\mathrm{nA}$). The *inset* is an enlargement of the area marked by the *square* and shows the details of the local order of racemic phase II. **(f)** Racemic phase IVa associated with the distorted (3×2) LEED pattern (image size $22.4 \times 11.2\,\mathrm{nm}^2$, $V = 1.05\,\mathrm{V}$, $I = 0.17\,\mathrm{nA}$). **(g)** Racemic phase IVb associated with the true (3×2) LEED pattern (image size $22.4 \times 11.2\,\mathrm{nm}^2$, $V = 1.49\,\mathrm{V}$, $I = 0.59\,\mathrm{nA}$). (Reprinted from [29.34], with permission from Elsevier)

depend on experimental conditions and how chirality plays a role in this process. For this reason, we are going to treat it in some details in the following. According to RAIRS data, in the multilayer regime, stable below room temperature, the molecules are predominantly in a zwitterionic state, as expected for solid alanine [29.187]. Conversely, adsorption in the 300–470 K temperature range always yields to the formation of an alaninate species, as witnessed by the sequence of RAIRS spectra of Fig. 29.20.

This picture, relatively simple from the spectroscopic point of view, gets much more complicated when the morphology of the alanine layers is taken into account. STM analysis reveals, indeed, a polymorphic behavior of the L-Ala/Cu(110) system [29.35, 39], with the identification of four different surface structural phases depending on alanine coverage and surface temperature (Fig. 29.21). At low coverage and RT, a disordered phase occurs, in which the alaninate molecules are found concentrated in small areas close to the steps (phase I in Fig. 29.21a). Due to the high mobility of individual alaninate units, no STM images could be recorded for the molecular species at terraces, even if RAIRS data show a significant growth of the molecules in the μ_3 configuration (spectra (*a*) and (*b*) in Fig. 29.20c). Increasing the coverage, molecules at terraces get to interact with each other and self-assemble into chains some tens of nanometers long and aligned in the $\langle\bar{1}12\rangle$ direction (phase II in Fig. 29.21b). The chain structure is not homogeneous, since single chains (formed by individual alaninate units) and double chains (consisting of paired molecules) turn into each other every few molecular units along the chain length. We note that $\langle\bar{1}12\rangle$ is not a symmetry direction of the Cu(110) surface; therefore, the system is starting to organize in a chiral fashion. Spectroscopic anal-

ysis indicates the coexistence of alaninate molecules both in μ_3 and in μ_2 conformation (spectrum (*d*) in Fig. 29.20c). The creation of the μ_2 species at higher coverage is attributed to kinetic factors since only the μ_3 species is formed at all Θ. Interestingly, the authors suggest that the μ_2 species triggers chain formation at the terraces, and thus that the presence of alaninate units in this configuration is essential for supramolecular chiral organization.

Upon annealing of phase II, the RAIRS spectra remain unaltered (trace (*e*) in Fig. 29.20c), indicating that molecules in both the μ_3 and μ_2 configuration are still present. Instead, the alaninate chains evolve into a highly ordered chiral overlayer (phase III in Fig. 29.21c) formed by clusters of 6 or 8 units lined up in pairs in the ⟨110⟩ direction and with an overall growth direction broadly parallel to the nonsymmetric $\langle\bar{1}12\rangle$. In phase III, 2-D chirality is expressed at the macroscopic length scale, since size-defined chiral clusters self-assemble into a defined chiral array with chiral channels and spaces of bare metal left between them. The identical experiment performed with *R*-alanine produces the mirror image domain [29.188]. To determine the long-range order of the overlayer, several models of individual hexamers are proposed [29.35, 39], involving a different proportion of molecules in μ_3 and in μ_2 conformation on an unreconstructed or a reconstructed Cu(110) surface.

The chiral chains of phase II are precursors to the size-selected clusters of phase III. Both the chains of variable width observed at RT and the the peculiar organization in small, size-selected clusters at the higher temperature are the result of a competition between intermolecular forces and molecule–substrate interaction. Above a critical cluster size, the stress induced by maintaining optimum adsorption sites for the alaninate molecules and by maximizing the intermolecular interactions leads to a fracture in the assembly of the chains, opening two possible scenarios. In the former case, molecules can be forced away from their optimal adsorption site by intermolecular interactions; alternatively, the strength of the chemisorption bond forces surface reconstruction in order to optimize adsorption geometry. The former mechanism may well dominate at room temperature (phase II), where the barrier to significant reconstruction cannot be overcome. On the other hand, the higher temperature required to create phase III suggests that metal reconstruction may accompany the formation of regular size-selected clusters. The competition between molecule–molecule and molecule–metal interactions is a phenomenon to be generally taken into account on self-assembly processes. The behavior observed in the case of Ala/Cu(110) indicates a predominance of molecule–metal interactions. On the contrary, on less-reactive substrates such as Ag, intermolecular forces prevail and the formation of extended amino acid layers is observed [29.36, 189].

Further heating of the Ala/Cu(110) system in phase III to 470 K causes substantial changes in the RAIR spectra (trace (*f*) in Fig. 29.20c), indicating full conversion of μ_2 alaninate units into the μ_3 geometry. According to LEED and STM data, a new achiral (identical for both *S*- and *R*-alaninate) organization of the molecules appears on the surface (phase IV in Fig. 29.21d), characterized by a (3×2) superstructure with two molecules per unit cell ($\Theta = 1/3$) and by a pseudoglide plane in the ⟨001⟩ direction. This overlayer is stable up to 520 K. DFT analysis [29.190] found that, in the lowest energy configuration, each unit cell of the (3×2) enantiopure overlayer contains two molecules with opposite footprint chirality. The result is coherent with photoelectron diffraction measurements [29.191], which indicate the existence of two molecules with slightly different local adsorption sites within the (3×2) unit cell.

The formation of chiral/achiral overlayers starting from L-ala and depending on experimental condition indicates that chirality is a factor to be strictly monitored and considered when dealing with the self-assembly of amino acid species. Therefore, it is interesting to understand what happens when a racemic mixture is deposited on the surface. Separation of enantiomers within racemic crystals has been known for some time, while chiral recognition at surfaces has been investigated more recently but is nowadays a well-established phenomenon [29.17]. Despite that, there is not a straightforward behavior for surface chiral segregation—the formation of enantio-pure domains of opposite chirality—and each amino acid/metal system needs to be tracked separately. In general, if heterochiral interactions prevail, a racemic layer forms. This is the case for adsorption of racemic alanine on Cu(110) [29.188], for which formation of achiral domains is observed and the suppression of some of the phases present for the enantio-pure species occurs. In particular, while the disordered phase I is observed also for racemic alanine, phase II is significantly different. STM images show achiral patches with poor long-range order (Fig. 29.21e) and the LEED pattern, consisting of split and faint spots, confirms this picture. Also the thermal evolution of the racemic system follows an alternative path with respect to the one observed for the enantio-pure layer. Racemic phase II converts directly into the achirally organized phase IV at $T = 358$ K. The (3×2) overlayer of the racemic alanine mixture differs from the one described for pure *S*-alaninate since: (a) a smaller energy barrier is required for the racemic mixture, because both the energetically preferred foot-

prints of *S*- and *R*-alaninate can be accommodated at the surface. (b) The (3×2) structure presents initially a glide plane (see phase IVa in Fig. 29.21f), as in the case of *S*-alaninate, but the coverage can be further increased to create a *true* (3×2) LEED pattern with no glide plane (see phase IVb in Fig. 29.21g).

On the contrary, if homochiral interactions dominate, chiral segregation of enantiomers is favored. An example in this respect is provided by racemic Cys deposited on Au(110) [29.192]. The molecules organize in domains of dimers identical to those observed in previous experiments performed using pure enantiomers, while no new structures associated to the pairing of molecules of opposite chirality are found. Therefore, dimers are either of the LL form (rotated clockwise) or of the DD form (rotated anticlockwise), suggesting that the dimerization of the cysteine molecules is highly enantioselective, with each molecule binding exclusively to partners of the same chirality.

Chiral recognition is the preliminary step to chiral separation of D- and L-enantiomers, which is a key issue for chemical and pharmaceutical industries. This process can be enhanced by the use of suitable chiral surfaces and, in this respect, the case of serine adsorption at high Miller index Cu surfaces is emblematic. Distinct enantio-resolution ability was observed on Cu(110), where the L- and D-enantiomers aggregate in well-ordered islands, and on the stepped Cu(643) and Cu(3 1 17) surfaces [29.193, 194]. However, since the two enantiomers have very similar adsorption energies, chiral separation is not straightforward. On Cu(531), on the contrary, the difference in adsorption energies between D- and L-serine is significant and this is the reason why many theoretical and experimental efforts focused on exploring the adsorption configurations and enantioselective ability of serine on this surface [29.183, 195, 196]. Very recently, *Wang* et al. calculated the adsorption geometries and energetics of D- and L-serine at the (531) face of Cu, Ag, Au, and Pd [29.197]. Cu(531) is the most efficient in chiral separation due to the conformational strain imposed both on the molecule and on the substrate upon adsorption of D-serine. In addition, enantio-selectivity is predicted to be enhanced up to 36% by decorating the (110) and the (311) microfacets of Cu(531) with Ni atoms.

Focusing the attention back to the self-assembly process and to the forces involved, we recall that, in the above-mentioned case of Ala/Cu(110), the molecule–substrate interaction is the driving force of the self-assembly mechanism. On the contrary, if a less-reactive metal is employed, intermolecular interactions may prevail and interesting phenomena can be observed. This is indeed the case of glutamic acid on Ag. Though adsorption of this amino acid has been investigated on all low Miller index surfaces [29.36, 84, 189, 198], the L-Glu/Ag(100) system has been unravelled in great detail [29.28, 36, 84].

As shown in Fig. 29.22, L-Glu self-assemble on Ag(100) forming single-layer islands, the geometry and extension of which changes by varying the surface temperature between 250 and 350 K. A row-like structure is observed at $T = 250$ K (Fig. 29.22a), a comb-like structure at $T = 300$ K (Fig. 29.22b), while a flower-like (Fig. 29.22c) and a square-like (Fig. 29.22d) structure coexist at $T = 350$ K. XPS analysis indicates that, in all cases, the Glu units are in the nonzwitterionic form. The co-presence of comb-like and flower-like domains at the transition temperature $T = 325$ K, combined with the thermal evolution measured by XPS, suggests the existence of several local minima in the energy diagram of the Glu/Ag(100) system.

The two assemblies observed at 350 K were reproduced by DFT-D calculations [29.28, 84] and simulated STM images in very good agreement with the experimental ones confirm the validity of the proposed models (Fig. 29.23). At variance with the majority of cases reported in literature, the *square* structure consists of neutral molecules physisorbed on the surface through weak vdW forces, while H-bonds between carboxyl groups and the formation of a OCOH–OCOH–OCOH–OCOH cycle at the vertex of the squares are the main driving force for the self-assembly (Fig. 29.23b).

The flower structure (Fig. 29.23a,c,e) is formed by 50% of deprotonated Glu units in upstanding conformation and arranged in the bright tetrameric units. The other molecules are in the neutral form and lie flat on the surface. This configuration is characterized by glutamate anions strongly bound to the surface and by the physisorbed surrounding Glu molecules, which conserve some degree of freedom in the layer. As evident from the table in Fig. 29.23, the *flower* and the *square* assemblies have similar dispersion energy and H-bond interaction energy but, as a consequence of the different chemical states of the Glu molecules, the binding energy to the substrate is significantly different. This is therefore a good example of how the balance among the different forces acting on the molecules may affect their final configuration. In addition, the thermodynamical isostability of the two assemblies at 350 K is explained by considering entropic factors which have a strong stabilizing impact on the poorly adsorbed *square* structure [29.199]. The transition from one structure to the other is expected to be kinetically possible thanks to the low reactivity of the Ag(100) surface.

Finally, it is worth considering self-assembly of amino acids at metal surfaces also in view of their perspective role as base catalysts for enantioselective

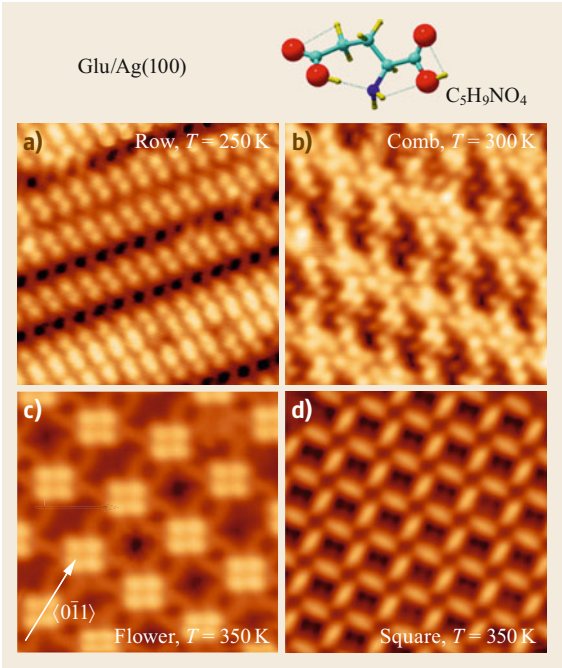

Fig. 29.22a–d Overview of the self-assembled structures observed upon L-Glu deposition on Ag(100) at different T (image size 80 Å × 80 Å). **(a)** *Row* structure: The amino acids lie flat on the surface and form long, one-molecule-wide rows oriented ≈ 40° off the $\langle 0\bar{1}1\rangle$ direction. In each row, adjacent molecules are separated by (6.5 ± 0.2) Å and their molecular axis is at an angle of ≈ 65° with respect to $\langle 0\bar{1}1\rangle$. The estimated local coverage is $\Theta_{Glu} \approx 0.09$ ML. **(b)** *Comb* structure: The surface is covered by large monolayer islands consisting of elongated features oriented along the $\langle 0\bar{1}1\rangle$ directions (periodicity ≈ 26 Å). Each feature is formed by a linear backbone (two lines of molecules separated by (5.6 ± 0.2) Å) and by additional Glu units inserted as *teeth* at ≈ 45° (periodicity (14.0 ± 0.2) Å, $\Theta_{Glu} \approx$ 0.09 ML). **(c)** *Flower* structure: Clusters of four molecules (the *flowers*) are linked by *sticks* showing a lower contrast. Adjacent maxima within each tetramer are separated by 5.8 and 5.4 Å, respectively. Tetramers form a square pattern with the main axes aligned within 5° with the $\langle 0\bar{1}1\rangle$ directions (periodicity ≈ 21 Å). The sticks are also oriented in the high symmetry direction of the substrate. The Glu local coverage is $\Theta_{Glu} = 0.14$ ML but, considering that only a fraction of the surface is covered by Glu islands, the overall coverage is likely to be significantly smaller. **(d)** *Square* structure: Glu molecules are physisorbed and lie flat on the surface, 4.6 Å above the surface plane. They arrange in a square geometry oriented ≈ 20° off $\langle 1\bar{1}0\rangle$. The axis of the Glu units is oriented ≈ 10° off the $\langle 1\bar{1}0\rangle$ direction, so that a chiral pattern forms in self-assembled islands. The average dimensions of the single squares are $a = (13.2 \pm 0.8)$ Å and $b = (12.2 \pm 0.7)$ Å for the sides and $c = (19.7 \pm 0.8)$ Å for the diagonal, from which a local coverage $\Theta_{Glu} \approx 0.10$ ML is deduced. reactions, the importance of which is growing and growing due to the demand of pharmaceutical and chemical industries for large quantities of optically pure chemicals. Though several studies on enantioselective systems have been performed on Cu, which is also the most investigated substrate in this respect [29.17], it is in this field that amino acid adsorption at transition metals becomes of interest. Enantioselectivity is transferred to the metal substrate by adsorption of a chiral species (modifiers) but, so far, only a few categories of enantioselective heterogeneous catalytic processes have been investigated at the fundamental level. Among them, we mention the enantioselective hydrogenation of α-keto esters over Pt-based systems and the asymmetric hydrogenation of β-keto esters over Ni-based catalysts [29.174, 175]. On Ni-based materials the most studied chiral modifiers are (*R*,*R*)-tartaric acid [29.200, 201] and (*S*)-glutamic acid [29.202]. The latter species shows a peculiar behavior as a modifier, since the chirality of the final product in the hydrogenation of β-keto esters depends on T_{ev} (Fig. 29.24). Glu adsorption below 350 K results in a preference for the *R*-enantiomer, while Glu adsorption above 350 K favors the *S* species [29.174]. (*S*)-Glu adsorption at Ni(111) and at Ni/Au bimetallic systems was thoroughly investigated by the group of *Baddeley* [29.202–204], who also studied the chemical activity of the chirally modified (*S*)-Glu/Ni catalyst with respect to the simplest β-keto ester, i.e., methylacetoacetate (MAA) [29.180, 205]. By combining STM images with RAIRS results, they could demonstrate that (*S*)-Glu initially adsorbs on Ni(111) at 300 K in the zwitterionic form and prevalently at steps. With increasing coverage (Fig. 29.25a) the terraces are populated by molecules in the form of anionic monoglutamate. Small areas in which the molecules present an ordered $(\sqrt{7} \times \sqrt{7})$R19.1° geometry (local coverage 0.14 ML) or a $(3\sqrt{3} \times 3\sqrt{3})$R30° geometry (local coverage 0.11 ML) appear. Such structures are stabilized by hydrogen bonding. The extent of ordering is limited, since the authors estimate the ordered domains to cover 10–20% of the surface and to have a typical diameter of ≈ 10 nm, but it increases by annealing the surface to 350 K (Fig. 29.25b). On the contrary, further heating to 400 K (Fig. 29.25c) changes the nature of the adlayer: it consists now of 1-D structures, probably stabilized by H-bonding interactions between neighboring molecules and extending along the close-packed Ni directions.

Energy	Flower assembly (eV/molecule)		Square assembly (eV/molecule)	
E_{total}	−2.83		−1.29	
E_{disp}	−0.82	29%	−0.38	29%
E_{H_bond}	−0.75	26%	−0.89	69%
E_{bind}	−1.26	45%	−0.02	2%

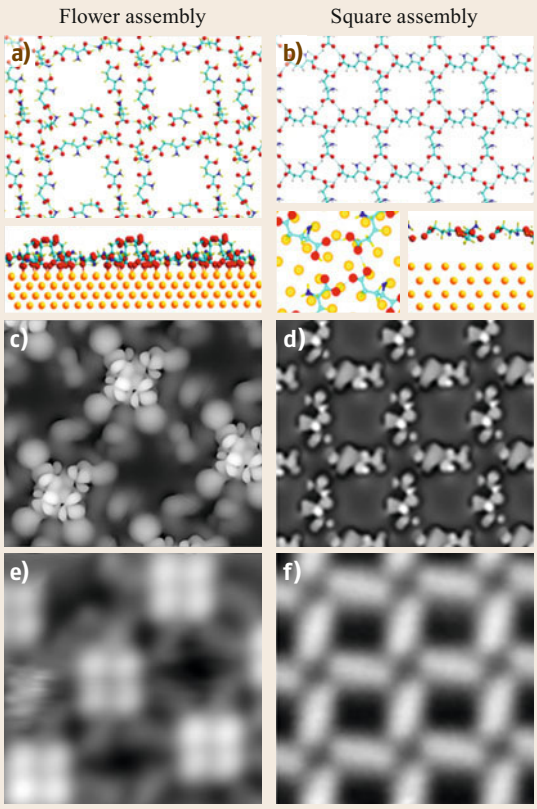

Fig. 29.23a–f The Table summarizes the adsorption, binding and cohesion energies of the *flower* and *square* assemblies formed by Glu/Ag(100) at $T = 350$ K (energies in eV per GLU molecule). **(a,b)** Optimized geometry of the assemblies. The molecular density of the calculated structure is 1.95×10^{18} Glu molecule/m^2 (mixture of neutral and radical species) for the *flower* assembly **(a)** and 1.39×10^{18} Glu molecule/m^2 for the *square* assembly **(b)**. **(c,d)** Simulated STM image deduced from the configuration in **(a,b)** for $V = 1.0$ V. The good agreement with the corresponding experimental image, reported in **(e,f)**, is evident. (Reprinted with permission from [29.28, 84, 199]. Copyright (2013, 2010, 2014) American Chemical Society)

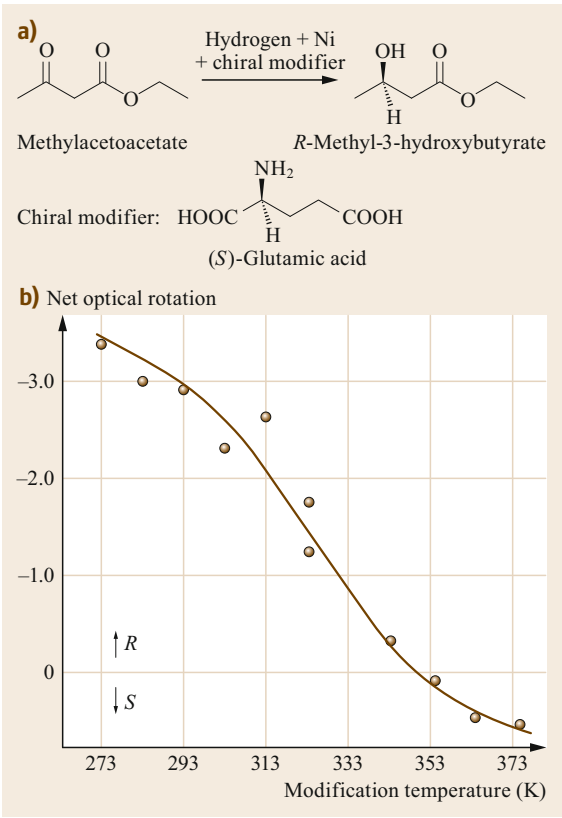

Fig. 29.24 (a) Reaction scheme for the enantioselective hydrogenation of β-keto esters over Ni catalysts in presence of (*S*)-glutamic acid. **(b)** Net optical rotation of the methyl-3-hydroxybutyrate product formed over (*S*)-Glu modified Ni catalysts as a function of modification temperature. (Reprinted from [29.202], with permission from Elsevier)

Deposition of the amino acid at $T = 350$ K produces a surface ordering similar to the one obtained upon annealing the 300 K layer but, in addition, it causes a restructuring of the step edges, which assume a *saw-tooth* appearance. Chiral faceting of the step edges upon adsorption of a chiral molecule is a phenomenon already documented for several systems, e.g., for Lys/Cu(001) [29.44] and Glu/Ag(110) [29.189], and it can be relevant in explaining the different enantioselective properties of the catalyst at 300 and at 350 K. In fact, MAA adsorption at 300 K occurs mainly in the diketo tautomeric form (with a direct interaction between the NH_3^+ group of zwitterionic Glu and the ketone group of the MAA molecules) if the (*S*)-Glu chiral modifier is pre-deposited at 300 K. Conversely, it occurs in the enol form if Glu deposition is performed at 350 K [29.205]. In liquid solution, the nature of the final product is also influenced by pH. The more protonated the Glu modifier is, more diketones tend to form. The optimum enantioselective catalytic performance occurs

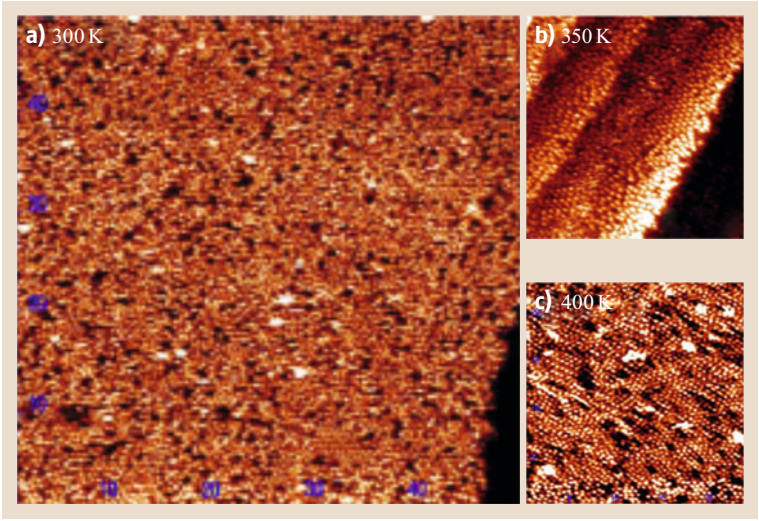

Fig. 29.25 **(a)** STM images of a high-coverage (*S*)-Glu/Ni(111) layer produced at 300 K (image size $49.7 \times 49.7\,\mathrm{nm}^2$; $I = 0.34\,\mathrm{nA}$; $V = 0.55\,\mathrm{V}$). **(b)** STM image obtained after annealing the sample in **(a)** to 350 K (image size $21.4 \times 21.4\,\mathrm{nm}^2$, $I = 0.32\,\mathrm{nA}$; $V = 0.36\,\mathrm{V}$). **(c)** Same as **(b)** after annealing the layer to 400 K (image size $23.5 \times 23.5\,\mathrm{nm}^2$; $I = 0.30\,\mathrm{nA}$; $V = 0.54\,\mathrm{V}$). (Reprinted from [29.202], with permission from Elsevier)

following modification at pH 5, at which the keto/enol ratio continues to drop with increasing modification temperature. Since (*S*)-Glu adsorbs in the zwitterionic form at 300 K and low coverage and in the anionic form with step restructuring at 350 K, the switch in the preferred enantiomeric product with modification temperature may be related to the ability of Glu to behave either as an amino acid or as a chiral diacid (as tartaric acid).

29.4 Conclusions

In this chapter we have presented a necessarily incomplete overview of the self-assembly process occurring at surfaces at the nanoscale. The few examples reported here should provide an overview of the different self-assembly mechanisms and of the different kinds of molecules involved in this process. We also believe that they should convey to the reader the idea of the wide range of possibilities opened by self-assembly to control the structure and properties of the organic–inorganic interface by choosing the most suitable molecular species.

Letizia Savio is a researcher at the Istituto dei Materiali per l'Elettronica ed il Magnetismo of CNR, Italy. She received her PhD in Physics at the Universita degli Studi di Genova in 2002. Her research interests are centered on the investigation of molecule–surface interactions at the nanoscopic level, with particular focus on the hybrid organic–inorganic interfaces and on self-assembly phenomena at metal surfaces and 2-D layers.

30. Energetics of Adsorption: Single Crystal Calorimetry

Luca Vattuone, David A. King

Adsorption energy is a fundamental thermodynamic quantity in the description of gas–surface interactions. In general, it depends not only on the ad-species and on the chemical nature of the substrate but also on the surface coverage and the density and nature of the surface defects. It can also be significantly affected by the presence of coadsorbates and by temperature when the latter determines a different arrangement of species on the substrate or even the formation of different moieties at the surface. On the one hand, the measure of the heat of adsorption by the isosteric method can be used only in selected cases, where adsorption occurs reversibly and a reliable control of the coverage over a large enough range of temperatures is experimentally accessible. On the other hand, temperature-programmed desorption, which until now has been the most widely used technique, is not applicable when adsorption occurs irreversibly, and care is needed to properly analyze the experimental data, especially when the heat of adsorption is strongly coverage dependent. Single-crystal calorimetry (SCAC) provides a means of overcoming most such limitations. Since it is impossible to cover all the results obtained by this technique in a single review, a rich bibliography is provided and only selected results (in the opinion of the authors) are summarized here. The first section addresses the results obtained by the infrared calorimeter of the Cambridge group, which mostly deals with the coverage dependence of the heat of adsorption of different gases on single-crystal (both low and high Miller index) surfaces. The second section deals with the results obtained by the pyroelectric calorimeter by the Washington group, which cover both the adsorption of large organic molecules and of non-gaseous species. The impressive results obtained to date have drawn other research groups into the field, and new designs have appeared that enable, for example, the study of the adsorption of gas molecules at the surface of nanoparticles and at oxide surfaces. The last section of this chapter is devoted to such results.

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-46906-1_30

The heat of adsorption of molecules at surfaces is a key thermodynamic parameter for the understanding of adsorption and reaction at surfaces and, consequently, also for heterogeneous catalysis. It is also a key parameter in providing a test for the first principles quantum theory calculations now widely used to study processes at surfaces.

30.1 Methods for Calorimetry

The isosteric method, which measures the pressure required to keep a constant coverage of the adsorbate at the surface as a function of temperature, can be effectively used only when it is possible to check the equilibrium coverage in a reliable way over a large enough range of temperatures. It cannot, thus, be employed when irreversible adsorption occurs, and it can be affected by the changes in the arrangements of adsorbates at the surface while the temperature and the pressure are being modified [30.1]. Thermal desorption spectroscopy (TDS or TPD) is more routinely used, since it is compatible with conventional UHV experimental setups; it cannot, however, be used when desorption does not occur. Moreover, the extraction of thermodynamic data from TPD curves is affected significantly by the method employed for the analysis. The basic idea of calorimetry is to measure the temperature change occurring at the surface when adsorption occurs. While measurements for non monocrystalline surfaces have been conducted over a long period of time [30.2], measurements for single-crystal surfaces became systematically available only in the 1990s. After a few previous attempts by *Kyser* and *Masel* [30.3], the first single-crystal calorimeter was developed by the group of *King* in Cambridge [30.4, 5], and a systematic investigation of adsorption of different gases at single-crystal surfaces was undertaken. These results have already been reviewed in detail [30.1]. Here, we shall present only some of them: the effect of promoters on the heat of adsorption, the measurement of the energy difference between surface phases, the heat of reaction, lateral interactions among adsorbates, and the role of defects in adsorption. The main limitation of the first Cambridge calorimeter, which essentially monitored the change in the infrared emission caused by the temperature increase upon adsorption, was the restriction to room temperature adsorption and to nonactivated systems. A different calorimeter, based on pyroelectric detection, was then developed by the same group; this calorimeter allowed the measurement of heats of adsorption at different temperatures [30.6]. This design was extensively improved by the group of *Campbell* [30.7, 8] at Washington University in Seattle, who extended the method to the measurement of the heat of adsorption of metals and of nanoparticles at surfaces. Some of their latest achievements will also be reviewed in this chapter. Recently, similar experimental setups have been developed also by other research groups [30.9, 10] improving the sensitivity and extending the set of systems for which the heat of adsorption can be measured.

30.2 Definition of the Heat of Adsorption

Adsorption at surfaces is an exothermic process, and the differential molar enthalpy change is, thus, negative. According to the usual convention we define the differential molar adsorption heat q as its opposite. The isosteric adsorption heat q_{st} is defined according to the Clausius–Clapeyron equation

$$q_{\mathrm{st}}(\theta) = -R\left[\frac{\partial \ln P}{\partial(1/T)}\right]_{\theta} , \qquad (30.1)$$

where P is the pressure, T the absolute temperature, R the gas constant, and θ the fractional surface coverage. In practice it is necessary to measure the change in the gas pressure needed to keep the fractional surface coverage constant while changing the temperature. This approach suffers from two drawbacks: firstly it can be applied only when adsorption takes place reversibly, and secondly, a reliable indicator of the actual surface coverage is needed; θ can be checked in different ways, i.e., monitoring the work function, the diffraction pattern, or some specific spectroscopic signal (vibrational or electronic) related to the adsorbate, but care is needed since these indicators may be affected in some cases also by change in the temperature, especially because a relatively wide range of temperatures is required for an accurate measurement. Moreover, when the temperature is increased, the pressure required to maintain a constant coverage may increase beyond the capabilities of traditional UHV techniques, thus further limiting the practical feasibility of this approach. An example is reported in Fig. 30.1, which shows the pioneering work of *Tracy* and *Palmberg* [30.11]. They first measured the

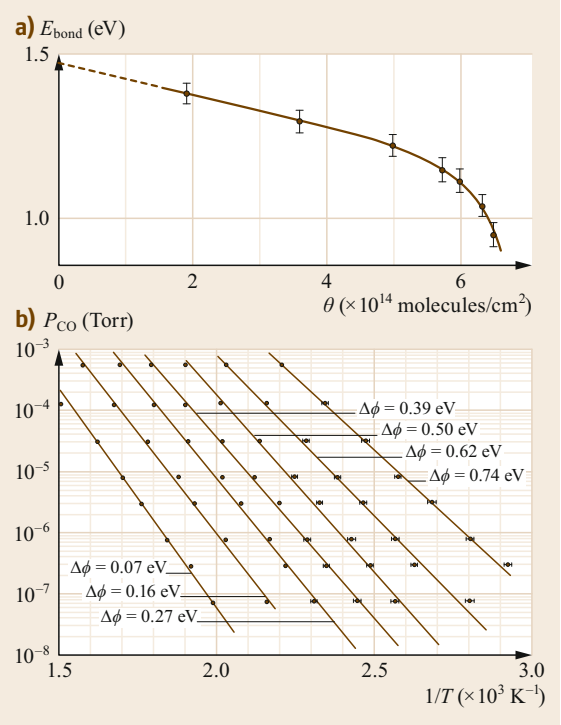

Fig. 30.1 **(a)** Heat of adsorption as a function of coverage for CO on Pd(100). **(b)** Pressure as a function of the inverse temperature required to keep a constant CO coverage on Pd(100). Coverage is monitored by the work function of the surface. *Curves* corresponding to different work functions and, thus, to different coverages are reported (Adapted from [30.11], with permission from Elsevier) ◄

change in the work function $\Delta\Phi$ of Pd(100) as a function of temperature for different CO pressures. From these curves of pressure versus inverse temperature were obtained (Fig. 30.1b). The coverage of CO on Pd(100) is monitored by monitoring the work function. The coverage for each $\Delta\Phi$ was obtained as follows. In a series of experiments CO was adsorbed at room temperature until the work function changed by $\Delta\Phi$.

The sample was then rapidly flashed to 500 °C; the integral of the pressure rise is proportional to the amount of CO that has desorbed. The absolute calibration of the coverage was possible using the c(4 × 2)-45° low-energy electron diffraction (LEED) pattern which corresponds to a coverage of 0.5 ML. Using the Clapeyron equation, the heat of adsorption as a function of θ is obtained.

30.3 Experimental Setups

As outlined above, the basic principle behind the development of a single-crystal calorimeter (SCAC in the following) is the measurement of the change in the temperature of a sample upon adsorption of a measured dose of adsorbate. In order to obtain a quantitative result for the heat of adsorption it is necessary to measure accurately and reliably the heat released to the sample upon adsorption and the amount of adsorbing gas. The result was attained by using sample of very low thermal capacity (i.e., single crystals with a radius of some mm, and a thickness of some micrometers) and by dosing the desired gas by use of a supersonic molecular beam (SMB). The flux of the SMB is measured prior to each experiment by a spinning rotor gauge. The surface of the sample is then exposed at normal incidence using a pulsed SMB and the sticking probability and the increase in the temperature are measured simultaneously. The coverage is obtained by integrating the amount of gas adsorbed at each pulse. The different SCAC setups can be classified on the basis of the method used to measure the heat released and the temperature change.

The calorimeter initially developed by the group of King (Fig. 30.2a) measures the change in the infrared intensity emitted by the back of the sample upon adsorption of gas. The intensity is measured by a suitable IR detector and is calibrated by comparing the signal measured upon adsorption with the one recorded when the clean surface is exposed to a laser of known power impinging at normal incidence and correcting for the reflectivity of the sample at the laser wavelength. The reflectivity is measured in a separate experiment by optical methods. The change in radiated power from the back of the crystal is proportional to the third power of the temperature times the change in T due to adsorption. The sensitivity, thus, drops as T^3 and for this reason the infrared detection technique is inadequate for low-temperature measurements.

In order to overcome this limitation another detector was developed that employs the pyrolectric effect; the increase in the temperature produced by adsorption is measured by monitoring the pyroelectric signal in place of the IR emission. In the first design [30.6], the detector element was a $LiTaO_3$ wafer 0.3 mm thick onto which AuCr electrodes had been deposited. The single crystal (which had a thickness of $\approx 2\,\mu$m) was bonded to the wafer by cold welding onto an intermediate layer of polycrystalline Ni, which, in turn, was

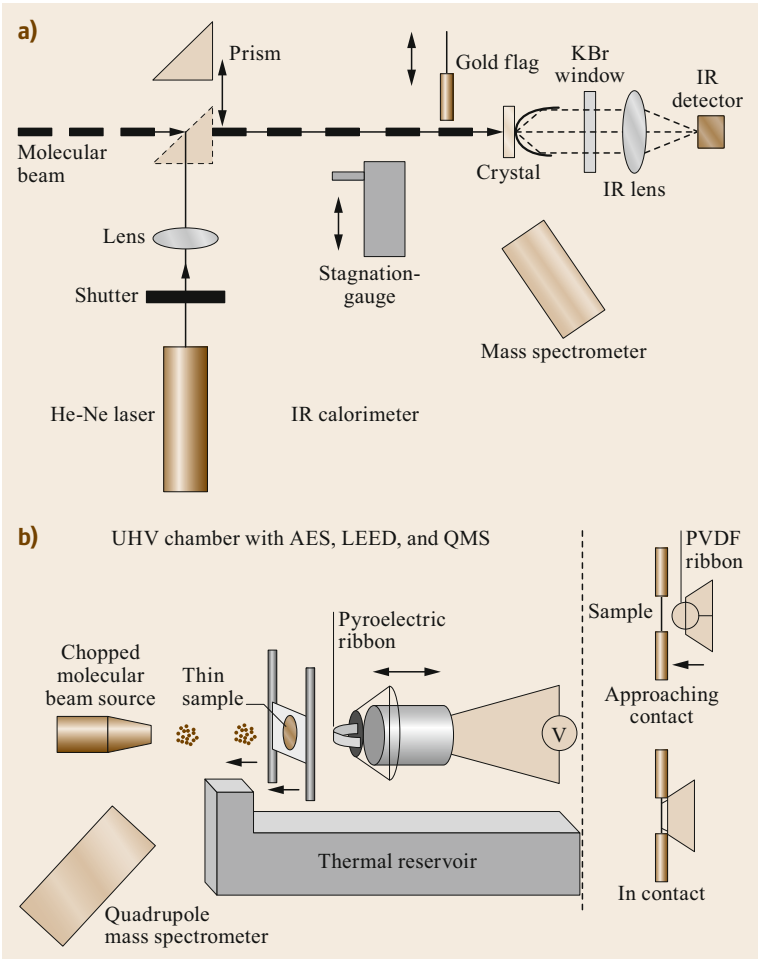

Fig. 30.2 **(a)** The Cambridge calorimeter (Adapted from [30.5], with permission from Elsevier). **(b)** The pyroelectric calorimeter in Washington (Adapted from [30.7], with the permission of AIP Publishing)

evaporated onto one AuCr electrode. The voltage signal generated between the two electrodes was passed through a specially designed high-impedance amplifier and then acquired digitally. In subsequent designs (Fig. 30.2b) [30.7, 8], a pyroelectric ribbon is moved carefully until it touches the backside of the sample and the pyroelectric signal is recorded. A similar method is used in the latest experimental setups [30.9, 10].

30.4 Overview of Experimental Results by the Cambridge Group

A very large amount of data has been obtained by the Cambridge group starting from the 1990s. We shall briefly overview the most significant results in the opinion of the authors. We shall consider the following topics here:

a) The dissociative adsorption of oxygen from the regime of chemisorption to the onset of oxidation on low Miller index Ni surfaces
b) The effect of surface temperature and potassium precoverage on Ni oxidation
c) The experimental determination of the energy difference between surface phases
d) The effect of lateral interactions between adsorbates on the heat of adsorption and their role in surface chemistry
e) The heat of adsorption in presence of defects
f) Heat of adsorption of hydrocarbons and determination of the metal–C bond energy
g) The heat of reaction for CO oxidation
h) The determination of prefactors for desorption.

30.4.1 Dissociative Adsorption

Dissociative oxygen adsorption and substrate oxidation are among the most common phenomena occurring when reactive surfaces are exposed to O_2. Figure 30.3a shows the sticking probability s measured at normal incidence and at room temperature (RT) by the King and Wells method using a pulsed supersonic molecular beam of O_2 impinging onto a clean Ni(100) surface. By integrating s over the exposure time and multiplying it by the beam flux it is possible to obtain the total amount of oxygen that has adsorbed (apparent oxygen adatom coverage). In Fig. 30.3a, s is plotted versus such apparent coverage. Three regimes are present:

i) Initially s is large (≈ 0.55) and decreases rapidly with increasing exposure to the beam.
ii) After reaching a minimum s increases again and remains relatively large (> 0.1) until an apparent coverage of ≈ 5 ML of oxygen adatoms is reached.
iii) Thereafter, s remains constant, indicating that a stable regime has been attained in which the amount of oxygen adsorbing during the length of the pulse is desorbed in the time between two subsequent pulses.

The contributions of these three regimes have been deconvoluted and are shown by the continuous lines in the figure. Figure 30.3b shows the net sticking probability (obtained by subtracting the reversible contribution to s) as a function of the net adatom coverage (obtained by subtracting the amount of oxygen that desorbs between subsequent pulses). The first regime corresponds to the rapid building up of an adsorbed oxygen layer, while the second one indicates the formation of an oxide layer at the surface. Ni oxidation is believed to start at nucleation points and to go on by island growth. Oxygen incorporation occurs only at the edges of the islands; after an initial increase s reaches a maximum and decreases as long as islands get larger until the oxide growth stops at ≈ 3.5 ML. Formation of a thicker oxide then becomes extremely slow or suppressed under the experimental conditions of this experiment.

Figure 30.3c shows the heat of adsorption as a function of coverage for Ni(100), as well as for the other low Miller index surfaces (Ni(110) and Ni(111)) at RT. The heat of adsorption is relatively large for all surfaces but exhibits different behaviors. On Ni(100) a rapid decrease with increasing coverage is present. This decrease is due to repulsive lateral interactions between second-nearest neighbors. The interaction between third-nearest neighbors must be, on the contrary, weakly attractive, since an ordered $p(2\times 2)$ structure forms. For Ni(110), the initial heat (475 kJ/mol) is lower than for Ni(100), and the drop with θ is less steep because of the formation of Ni–O chains, which shield the O atoms, thus decreasing the magnitude of repulsive interactions between them. Also, for Ni(111),

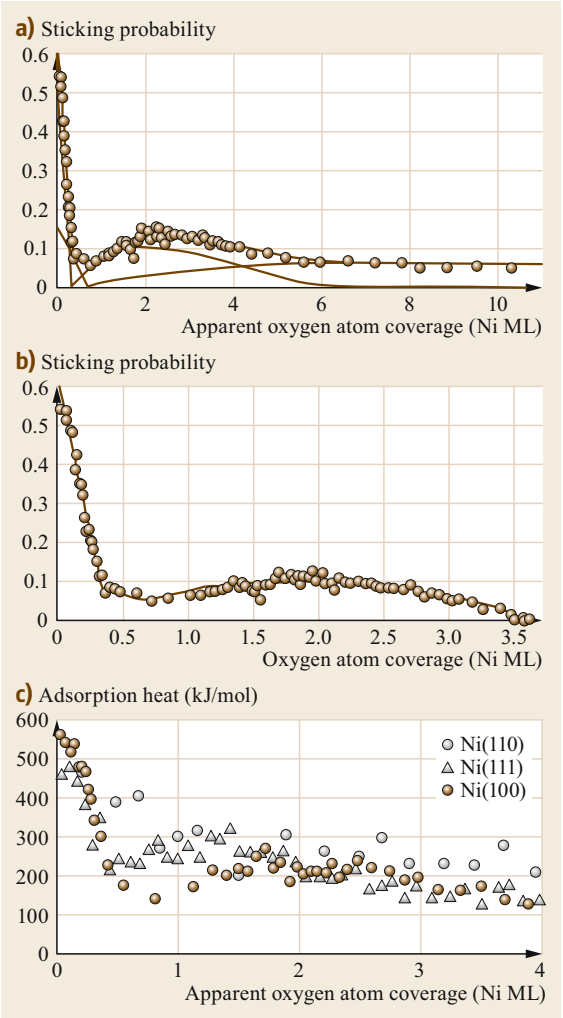

Fig. 30.3 **(a)** Sticking probability versus apparent O adatom coverage on Ni(100) at RT, showing the chemisorption, oxidation, and reversible regimes. The *smooth line* running through the experimental data is the sum of the other lines used to fit the data, including two *straight lines* as an empirical fit to the chemisorption sticking probability, a peaked curve corresponding to oxidation by island growth, and a curve corresponding to reversible molecular oxygen adsorption. **(b)** Net sticking probability (obtained from the one in **(a)** by subtracting the reversible contribution) as a function of absolute coverage. **(c)** Oxygen differential adsorption heat on different Ni single-crystal surfaces at 300 K (Reprinted from [30.12], with the permission of AIP Publishing)

q is initially (440 kJ/mol) lower than for Ni(100), since adsorption occurs at threefold hollow sites; q initially increases due to the rearrangements of the adatoms at the surface to minimize the repulsive interactions. Such a reordering is made possible by the presence of an effective precursor-mediated adsorption path (evident from $s(\theta)$, which is, however, not reported here). Repulsive interactions set in thereafter, causing a decrease of q. The three low Miller index surfaces studied here behave similarly in the oxidation regime with heat of adsorption of the order of 200 kJ/mol. Finally, when oxide growth stops, and reversible adsorption of oxygen starts to occur on the oxide film, the heat of adsorption decreases to ≈ 87 kJ/mol.

30.4.2 Surface Temperature and Potassium Precoverage on Ni Oxidation

The heat of adsorption of O_2 on Ni(100) was also measured as a function of the surface temperature using a pyroelectric detector [30.12]. The results are shown in Fig. 30.4. It is apparent that: i) for $\theta \leq 0.25$ ML, q is constant (and possibly slightly increasing with θ) at 410 K, while it is initially lower and decreases with increasing coverage for lower temperatures. ii) Above 0.25 ML, q decreases rapidly at 410 K than at lower T. A simple Monte Carlo simulation using a lattice-gas model provides a consistent explanation for all these observations [30.12]. The interaction between first neighbors is prohibitively high, since the saturation coverage does not exceed 0.5 ML in the chemisorption regime. The interaction between second-nearest neighbors must be strongly repulsive (by 30 kJ/mol) in order to account for the sudden drop observed at 410 K above 0.25 ML when the sites of the c(2 × 2) structure starts to be occupied. The third-nearest neighbors' interaction must be weakly attractive (by 1.5 kJ/mol) to explain the tendency to form the p(2 × 2) structure and in this way to account for the slight increase in q between 0 and 0.25 ML at 410 K. Since 0.25 ML is the coverage expected for an ordered p(2 × 2) overlayer, these findings indicate that at 410 K, the mobility of the O adatoms is high enough to allow the system to minimize the repulsive interactions by avoiding the occupation of second-nearest neighbor sites and possibly even to maximize the heat of adsorption, exploiting the fact that third-nearest neighbor interaction is weakly attractive. At RT, on the contrary, the mobility is not high enough to allow for the formation of a fully-ordered overlayer; repulsive interactions show up already < 0.25 ML, because of the occupation of second-nearest neighbor sites. This effect becomes even more evident at 90 K, where the limit of immobile adsorbate is reached and a nearly monotonic decrease in q is observed. The effect

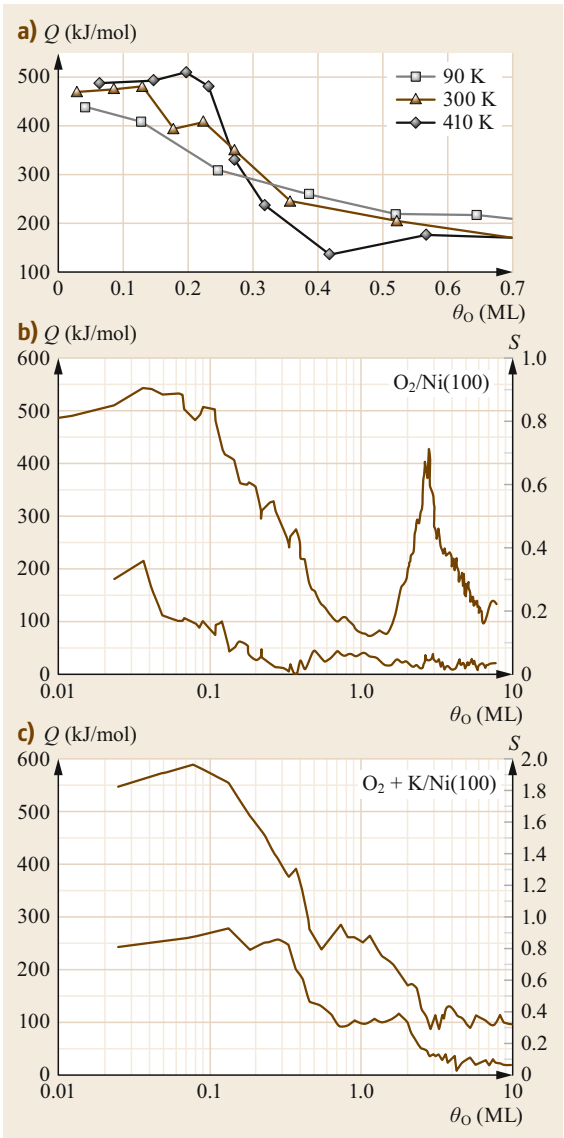

Fig. 30.4 **(a)** Differential heat of adsorption of O_2 on Ni(100) versus apparent O adatom coverage on Ni(100) at different temperatures in the low-coverage regime (Adapted from [30.12], with the permission of AIP Publishing). **(b)** Sticking probability (*lower graph*) and differential heat (*upper graph*) for O_2 on Ni(100) at RT without K. **(c)** Sticking probability (*lower graph*) and differential heat (*upper graph*) for O_2 on Ni(100) at RT for a K precoverage of 0.3 ML (Reprinted from [30.13], with permission from Elsevier)

of K preadsorption [30.15] on q and s for oxygen adsorption on Ni(100) is apparent from Fig. 30.4b,c. For $\theta_K = 0.3$ ML, the initial sticking coefficient is 0.85, i.e., more than two times larger than for the bare Ni(100)

surface, and remains constant up to $\theta_O = 0.33$. The heat of adsorption is initially higher (by 40 kJ/mol) than for the bare surface and decreases similarly with increasing coverage. In the range of coverage corresponding to the formation of the oxide, the presence of K completely modifies the behavior of the system; s remains nearly constant up to an oxygen coverage of 2 ML, while q is constant until 1.3 ML of oxygen and decreases towards the reversible adsorption regime afterwards. The presence of K thus affects the kinetics much more effectively than the thermodynamics of oxygen adsorption at Ni(100). The increased charge density in the surface region due to K adsorption increases the probability of dissociation of O_2 in the molecular precursor. For a K precoverage > 0.15 ML, the molecular state is stabilized and the rate of oxidation of the substrate is increased. The measurements of the effect of the K precoverage on the heat of adsorption of O_2 on Ni(111) and Ni(100) are discussed in larger detail in [30.1].

30.4.3 Energy Difference Between Surface Phases

We now show that it is possible to use microcalorimetry also to measure the energy difference between surface phases, information previously obtained only by theoretical methods [30.16]. It is known that the bare Pt(100) surface can exist at RT in two different phases: a metastable (1 × 1) and a hex phase. Upon annealing to 500 K the (1 × 1) phase turns into the hex one. It is, however, possible to adsorb molecules such as CO (or NO) at RT starting from both phases and ending with a (1 × 1) phase. The differential heat of adsorption of CO was then measured at RT starting from both

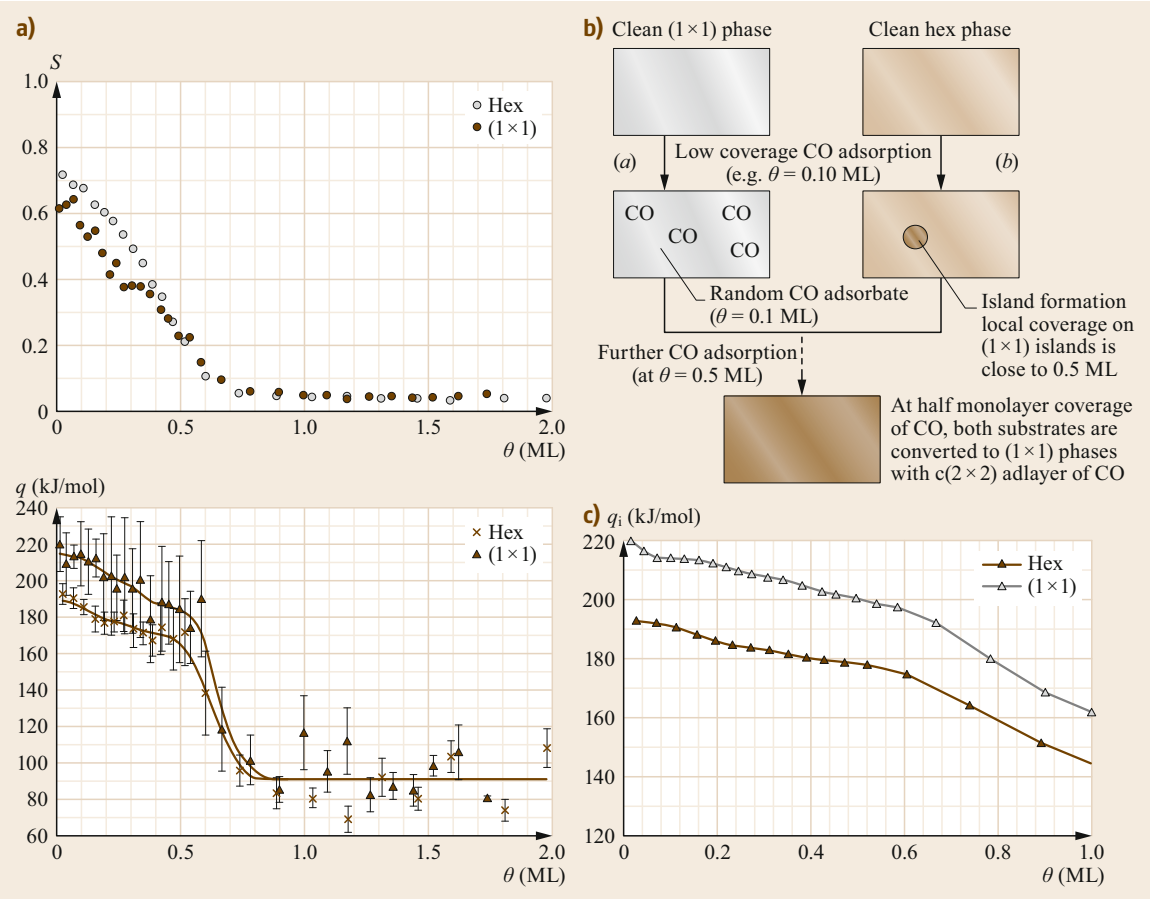

Fig. 30.5 **(a)** Sticking probability S (*top*) and differential heat of adsorption q (*bottom*) for CO adsorption on Pt(100)-hex and Pt(100)-(1 × 1) at RT. **(b)** The two initial states of clean Pt(100), the two different CO adsorption pathways (*a* and *b*), and the identical final state, Pt(100)-(1 × 1)–c(2 × 2)-CO. The difference in the integral adsorption heat q_i **(c)** along paths *a* and *b* is the energy difference between the initial states (12 kJ/mol). ([30.1], © ACS 1998; adapted from [30.14], with the permission of AIP Publishing)

phases. Since the final state is the same, i.e., a c(2 × 2) CO-covered (1 × 1) phase with a coverage of 0.5 ML, by comparing the integral heat of adsorption it was possible to obtain experimentally the energy difference between the hex and the (1 × 1) phase [30.16]. The integral heat of adsorption is defined as

$$q_{\mathrm{int}}(\theta) = \frac{\int q_{\mathrm{diff}} \mathrm{d}\theta}{\int \mathrm{d}\theta} \,. \tag{30.2}$$

The difference between the integral heats q_{int} at a coverage of 0.5 ML multiplied by the coverage is, thus, equal to the difference in energy between the bare hex and (1 × 1) phases, which comes out to be 12 kJ/mol.

30.4.4 The Role of Lateral Interactions in Surface Chemistry

The heat of adsorption of molecules is often strongly coverage dependent. Such dependence can arise for different reasons: direct and indirect interactions between adsorbed molecules, coexistence of molecular and dissociative adsorption, etc. Lateral interactions may arise from three contributions: dipole–dipole interaction, Pauli repulsion, and substrate-mediated interactions.

Dipole–dipole interactions are long-range forces but they are too small to explain the experimentally observed decrease in q. Pauli repulsion is definitely stronger, but since it arises from the overlap of electron wavefunctions it can play a role only between first neighbors. Thus, we can conclude that the major contribution to lateral interactions is provided by substrate-mediated interactions. They can be either repulsive or attractive, and their magnitude can be estimated by the change in the heat of adsorption with increasing coverage. One example is provided in Fig. 30.6 for CO adsorption on Pt(111). For $\theta =$ 0.33 ML, a $(\sqrt{3} \times \sqrt{3})$R30° overlayer of CO molecules forms (Fig. 30.6). In this structure, each CO admolecule is surrounded by six next-nearest neighbors. If we assume that adsorbate–adsorbate interactions can be described as sum of forces between couples of molecules (or atoms), i.e., if pairwise addictivity holds, then the repulsive interaction ω_2 can be easily estimated

$$\omega_2 = \frac{q(0) - q(0.33)}{6} = 3.8\,\mathrm{kJ/mol}\,. \tag{30.3}$$

Lateral interactions play a key role in surface chemistry. A paradigmatic example is provided in Fig. 30.7. The differential heat of adsorption of NO on the bare Ni(100) is initially quite high and decreases rapidly with increasing NO coverage, due to lateral interactions. The relatively high initial value indicates that dissociative adsorption takes place. The same figure shows also the differential heat for NO on the same surface precovered with different amounts of O adatoms; the initial heat decreases rapidly with increasing O precoverage. The data can be modeled by considering the sites occupied by the adatoms generated by the dissociation of

NO into N and O adatoms or by the oxygen adatoms generated by the dissociation of O_2 [30.18]. The integral heat is shown in Fig. 30.7b. The model (MC) assumes an initial heat of adsorption equal to the experimentally measured initial value and fits the decrease in the heat of adsorption by assuming the same repulsive interaction between N–O, N–N, and O–O adatoms in second-nearest neighboring sites. Occupation of first-neighbor sites does not occur, as indicated by the value of the saturation coverage in the chemisorption regime, which is < 0.5 ML. The model properly describes the data up to a certain coverage of adatoms (≈ 0.12 ML for the bare surface and ≈ 0.09 ML for a surface precovered with O adatoms) and thereafter drops more rapidly than experimentally observed. Above such coverage, the experimentally measured differential heat exhibits a plateau, which is assigned to nondissociative chemisorption. We can, thus, draw the following picture. As long as lateral interactions are not too strong, the heat of adsorption is higher for dissociative than for molecular adsorption, and O and N adatoms form. Dissociation eventually ends (and molecular chemisorption starts) at the coverage for which the heat of dissociative adsorption falls below the heat of molecular chemisorption.

The schematic in Fig. 30.7c clarifies what happens in the different geometrical arrangements of the O and N adatoms present on the surface. If a NO molecule lands at the X site, the adatoms resulting from its dissociation can try to occupy second and third-neighbor sites. If the preadsorbed adatoms occupy the sites shown in the left part of the scheme, dissociative adsorption cannot occur because occupation of first-neighbor sites is forbidden. If, on the contrary, the sites around the X site are free, dissociation can occur by occupying the Y sites. Occupation of the Z sites is not expected to occur, it being thermodynamically less favored. These results indicate that the array of empty sites that are required for dissociative adsorption to occur is quite demanding if the repulsive interactions are large, as in the present case. The model is able to describe consistently both the coverage dependence of q and of the sticking probability (not shown, [30.19]). We expect this scenario to occur for several different systems; a similar argument has, in fact, been invoked to explain the onset of molecular adsorption for NO on Ni(211) [30.20, 21].

30.4.5 Heat of Adsorption at Defects

It is well established that high Miller index surfaces can be model systems for the investigation of adsorption at well-defined defects; such surfaces indeed exhibit a high amount of majority defects arranged in a regular way [30.22]. Several stepped surfaces have been studied by microcalorimetry (i.e., adsorption of CO on Fe(211) [30.23], of NO on Ni(211) [30.20], O_2 and NO on stepped Pt surfaces [30.24], and O_2 on Ni(211) [30.21]). Here, we will summarize here the results obtained for two different cases: oxygen adsorp-

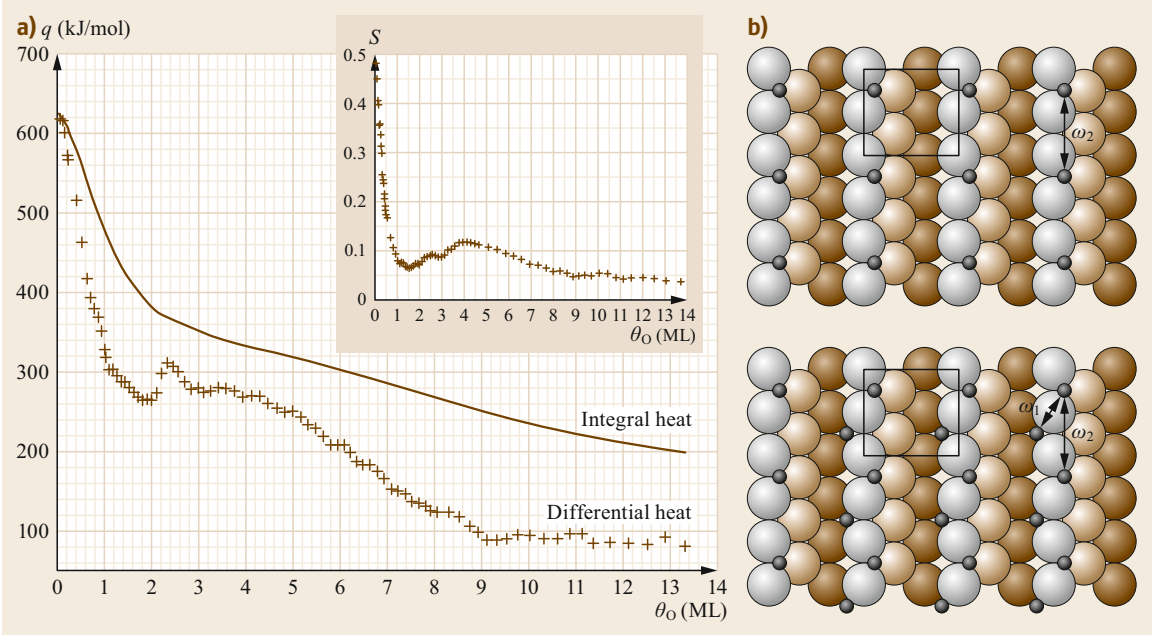

Fig. 30.8 **(a)** Differential and integral heat of adsorption for O_2 on Ni(211) as a function of the O adatom coverage. The *inset* shows the coverage dependence of the sticking probability. **(b)** Model of the (211) surface with the sites occupied at 0.5 ML (*top*) and at 1 ML (*bottom*) oxygen coverage. The contributions to pairwise lateral repulsive interactions between adatoms at different distances are shown schematically (see text) (Adapted from [30.21], © 2004 American Chemical Society)

tion on stepped Ni(211) [30.21] and NO dissociation on stepped Pt surfaces [30.24]. In Fig. 30.8, the differential heat of adsorption and the sticking probability of O_2 on Ni(211) are reported as a function of the apparent adatom coverage. The initial differential heat of adsorption q (620 kJ/mol) is significantly higher than for low Miller index surfaces (Fig. 30.3) because of the presence of low-coordinated adsorption sites at the steps; q then decreases rapidly with coverage due to strong lateral repulsions between adatoms until a coverage of 1.8 ML of oxygen adatoms is reached. The drop in q from 620 to 460 kJ/mol between 0 and 0.5 ML is due to repulsions between adatoms at a distance of about 4.98 Å (corresponding to $\omega_2 = 40$ kJ/mol in Fig. 30.8). At 1 ML, q has dropped to 300 kJ/mol due to an additional repulsive interaction between adatoms at a distance of 3.45 Å. The addition of further adatoms at the steps would cause further and stronger repulsive interactions between adatoms; at this coverage, the steps are, thus, saturated and adsorption at terrace sites must set in until a coverage of 1.8 ML is reached. At this coverage, q suddenly increases, reaching a maximum value of 310 kJ/mol at 2.3 ML and remains constant at about 270 kJ/mol up to 4 ML. The coverage dependence of the differential heat of adsorption is closely related to the sticking probability shown in the inset of Fig. 30.8. As for low Miller index surfaces, oxidation starts at nucleation points on the surface and proceeds via formation of islands of oxide. The number of sites at the boundaries of the islands increases until the islands starts to merge; at this point, the length of the island boundaries progressively diminishes, and the sticking probability approaches zero. Above this point, q decreases slowly to attain the steady-state value of 90 kJ/mol around 9 ML. In Fig. 30.9, the differential heat and the sticking probability for NO adsorption on Pt(111), Pt(211) and Pt(411) are compared. The fcc(211) surface consists of two-atom wide (111) terraces separated by a single-atom step of (100) orientation. The fcc(411) surface is more complex; it consists of two terraces of (100) character, one being two atoms wide and the other one atom wide, separated by a single-atom step of (111) orientation. The sticking probability behaves similarly on these surfaces; it decreases quite slowly with coverage, indicating that a precursor mechanism is active and is not affected significantly by the presence of an ordered array of steps or by the size of the terraces. The initial differential heat of adsorption is, on the contrary, significantly affected by the presence of the steps: q is higher on the (411) surface (217 kJ/mol), intermediate on Pt(211) (192 kJ/mol), and lower on Pt(111)

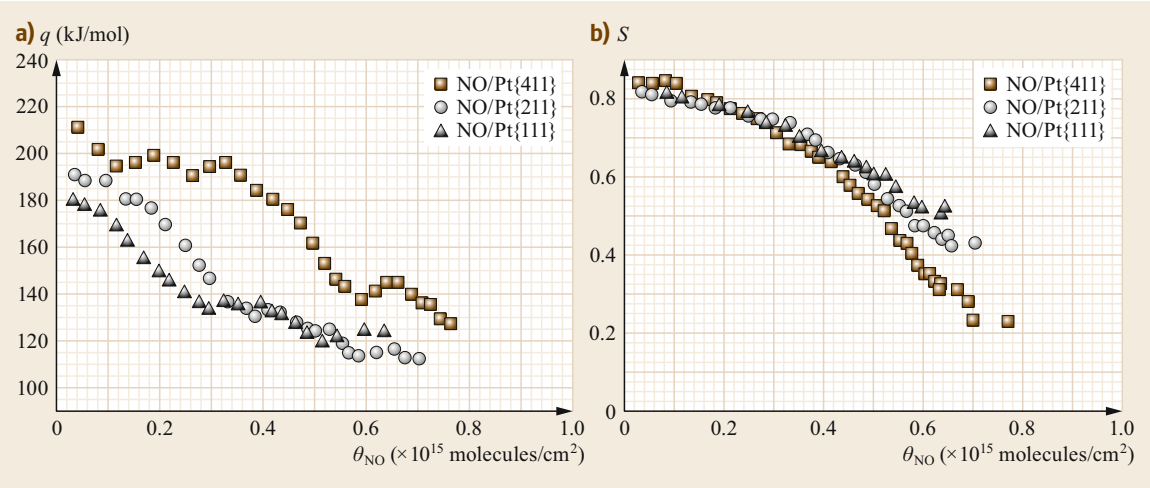

Fig. 30.9a,b Differential heat **(a)** and sticking probability **(b)** for NO adsorption on low and high Miller index Pt surfaces (Adapted from [30.24], with permission from Elsevier)

(182 kJ/mol). This result is consistent with the following trend: NO adsorbs molecularly on Pt(111), while it dissociates at steps on Pt(211) and Pt(411). The amount of dissociated NO is found to be greater for the latter surface because of the larger size of the (100) facets on Pt(411). For Pt(211), q indeed indicates dissociative adsorption up to 0.26 molecules/cm^2, while a similar argument suggests dissociative adsorption to occur up to 0.31 molecules/cm^2 for Pt(411). At higher coverage, when the steps are saturated, molecular adsorption sets in, thus explaining the similar heat of adsorption observed for Pt(111) and Pt(211). For Pt(411), q remains relatively high up to a larger coverage; probably incoming NO molecules will not be as close to the adsorbed N and O adatoms and lateral interactions are, thus, weaker, and a lower drop in q is observed [30.24].

30.4.6 Heat of Adsorption of Hydrocarbons

The measurement of the heat of adsorption of hydrocarbons is particularly relevant, since it also provides a way to determine the metal–C bond energy. This value cannot be obtained by thermal desorption experiments because adsorption of hydrocarbons at reactive metal surfaces in most cases occurs irreversibly, producing many different surface species, with different degrees of dehydrogenation and with different rehybridizations of the C–C bond inside the molecule. An essay of such complexity is provided in Fig. 30.10, which shows the heat of adsorption of a simple hydrocarbon like ethene (C_2H_4) on different Pt surfaces. The different initial value of q and its different coverage dependences can only be understood by considering that different radicals form. On Pt(100)-hex [30.25] quad-σ acetylene forms on the bare surface, followed by ethylidyne between 0.06 and 0.18 ML. At higher coverage di-σ ethylene forms. Finally, reversible adsorption of π-bonded ethylene occurs. These assignments explain the decrease in q and the plateau present at the different coverages. On Pt(100)-(1×1), the situation is similar, except for the fact that ethylidyne does not form because of the absence of threefold sites on this surface; quad-σ acetylene forms on the bare surface, followed by di-σ-bonded ethylene, and then by reversibly adsorbed π-bonded ethylene. For Pt(110), the situation is quite different; it has been suggested that ethylylidine (C–CH_2–) forms on the bare-surface bonding in the troughs of the (1×2) missing-row reconstruction. The next species is ethylidyne (C–CH_3), which probably adsorbs on the (111) microfacets of the Pt(110) surface; above 0.5 ML, di-σ ethylene and then reversibly adsorbed π-bonded ethylene are observed [30.26]. On Pt(111) [30.27] an unusual, nonmonotonic, dependence of q on coverage is obtained. In the present case, several reactions can occur

Ia) $C_2H_4(g) + 2^* \rightarrow CHCH_3(a)$
Ib) $CHCH_3(a) + 2^* \rightarrow CCH_3(a) + H(a)$
II) $C_2H_4(g) + 3^* + H(a) \rightarrow CCH_3(a) + H_2(g)$

At low coverage, no loss of hydrogen by recombination takes place, and reactions Ia) and Ib) occur. At 0.17 ML, reaction II) starts to occur, and a minimum in q is observed, since hydrogen desorption is endothermic. After consuming all the preadsorbed H, eventually formation of ethylidyne (reaction Ib) occurs. As the ethylidyne islands grow, fewer and fewer threefold sites are available and only bridge sites are vacant. They then favor the for-

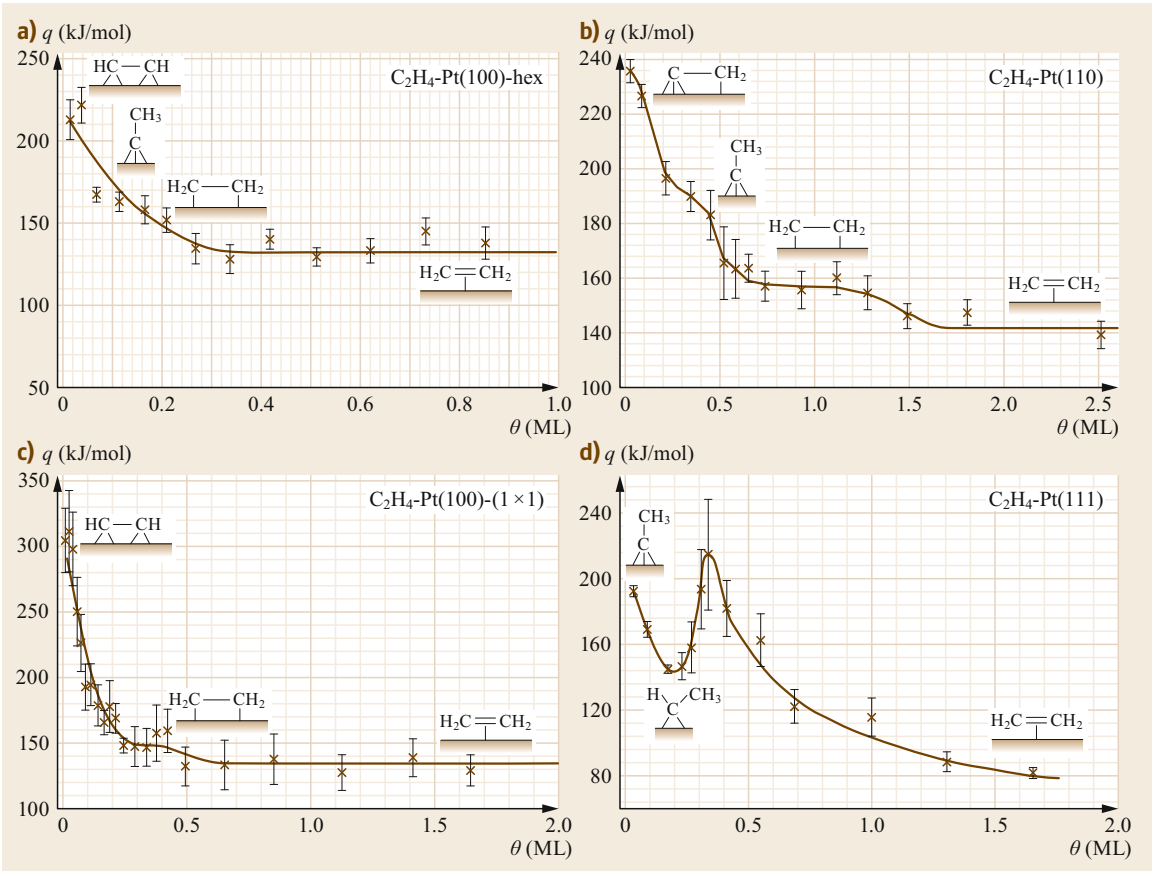

Fig. 30.10a–d Differential heat of adsorption for C_2H_4 adsorption on (**a**) Pt(100)-hex, (**b**) Pt(100), (**c**) Pt(110)-(1 × 1), and (**d**) Pt(111) at RT ((**a**,**c**) Adapted from [30.25], with permission from Elsevier; (**b**,**d**) adapted from [30.26], © 1995 by the American Physical Society)

mation of $CHCH_3$ and direct formation of ethylidyne stops. Since no H_2 is lost by desorption, the measured heat of adsorption increases, giving rise to a maximum at ≈ 0.35 ML. Thereafter, q decreases again, declining towards reversible π-bonded ethylene adsorption. Similar experiments were performed also for Pd(100) and Ni(100). On Pd(100), adsorption of ethylene occurs reversibly at RT, and the measurement of q is difficult. The data for Ni(100) are shown in Fig. 30.11. As for Pt surfaces, the interpretation of the results relies entirely on the identification of the species present on the surface. According to the literature (see the original papers and [30.1] for details), CH and CCH initially forms on this surface. The initial heat is associated with the formation of methylidyne (CH) followed by acetylide (CCH). The heat of adsorption was measured at RT also for acetylene on Ni(100) and Pd(100). The results are shown in Fig. 30.11. On Ni(100), the formation of CH and then of CCH can account for the observed results. The lower value observed for Pd(100) is explained by the fact that on the latter surface, dehydrogenation does not occur and that di-σ acetylene is present at low coverage after exposure at RT. The calorimetric data have, thus, been used to estimate the metal–carbon bond energy for Pt, Ni, and Pd. The results are summarized in Table 30.1. It is apparent that the metal–C bond energy is strongly dependent on the nature of the substrate, being 20% higher for Pt than

Table 30.1 Averaged metal–C bond energies as obtained from SCAC. (Data from [30.1])

Surface	Metal–C bond energy (kJ/mol)
Pt(110)	242
Pt(111)	244
Pt(100)	240
Pd(100)	171
Ni(100)	205

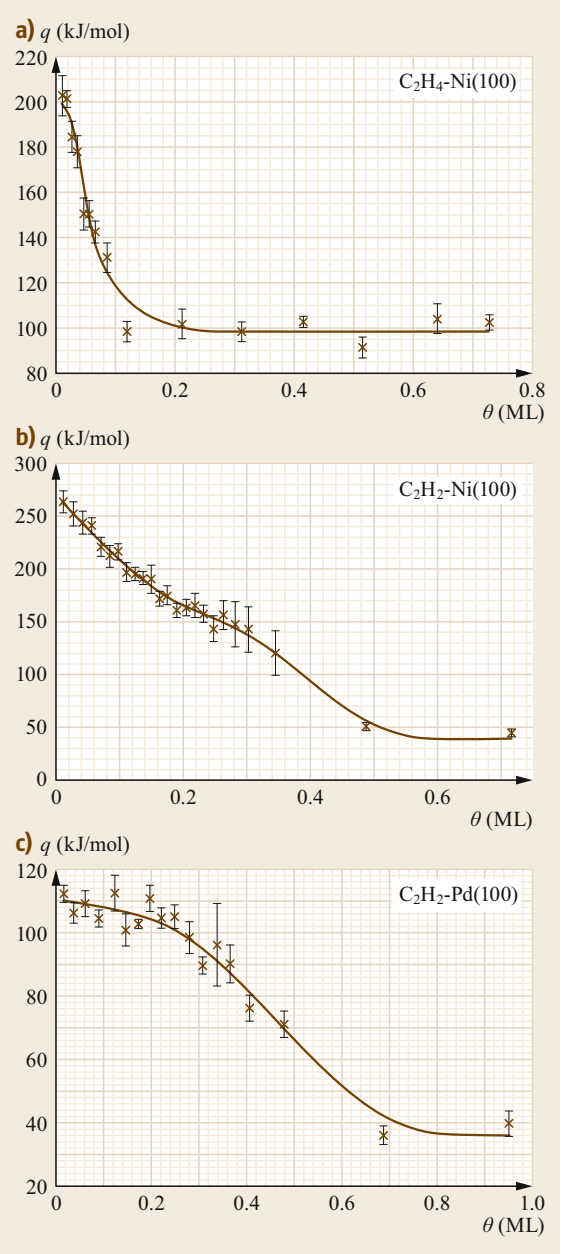

Fig. 30.11a–c Differential heat of adsorption for C_2H_4 adsorption on Ni(100) **(a)** and for C_2H_2 adsorption on Ni(100) **(b)** and Pd(100) **(c)** (Adapted from [30.28], with permission from Elsevier)

for Ni and 30% higher than for Pd. It is, however, nearly independent of the surface structure, at least for Pt surfaces. The database should be extended further in order to gain deeper insight into such general trends [30.29].

30.4.7 Heat of Reaction: CO Oxidation

The heat of adsorption of CO on an oxygen precovered surfaces have been measured calorimetrically for Pt(110) [30.30] and Pt(111) [30.17]. The results of the experiments are shown in Fig. 30.12. The initial heat measured when CO is adsorbed onto an O-precovered surface is 177 kJ/mol for Pt(110) and 157 kJ/mol for Pt(111). The heat of reaction ΔH_r can be easily estimated by considering the reaction

$$\mathrm{CO(g) + O(Pt) \rightarrow CO_2(g)} \qquad (30.4)$$

and it reads

$$\begin{aligned}\Delta H_r &= \Delta H_f(\mathrm{CO_2}) - \Delta H_f(\mathrm{CO(g)}) - \Delta H_f(\mathrm{O(Pt)}) \\ &= (-171 \pm 16)\,\mathrm{kJ/mol}\,.\end{aligned} \qquad (30.5)$$

If the CO_2 molecules would leave the surface without any excess energy, we would expect a differential heat of adsorption for CO on an oxygen-covered surface of 171 kJ/mol. The difference between the calculated heat of reaction and the measured differential heat is (-6 ± 17) kJ/mol and is, thus, compatible with a vanishing excess energy. On the contrary, when O_2 is dosed on a CO-precovered Pt(110) surface, the measured differential heat is 190 kJ/mol. Indeed, the following relations hold

$$\mathrm{O_2(g) + 2\,CO(Pt) \rightarrow 2\,CO_2(g)} \qquad (30.6)$$

and this reads

$$\begin{aligned}\Delta H_r &= 1\Delta H_f(\mathrm{CO_2}) - 2\Delta H_f(\mathrm{CO(Pt)}) - \Delta H_f(\mathrm{O_2})(\mathrm{g}) \\ &= (-287 \pm 24)\,\mathrm{kJ/mol}\,.\end{aligned} \qquad (30.7)$$

An adsorption heat of 287 kJ/mol would be measured if the reaction products would leave the surface without excess energy. The measured value of the differential heat is, however, significantly lower than expected! These results indicate that the desorbing CO_2 molecules have an average kinetic energy of (49 ± 21) kJ/mol [30.1]. Adsorption of CO on O-precovered Pt(111) leads to similar results [30.17].

30.4.8 Frequency Factor for Desorption

In all SCAC experiments, a steady state is reached characterized by a constant sticking probability and a constant differential heat of adsorption. In order to

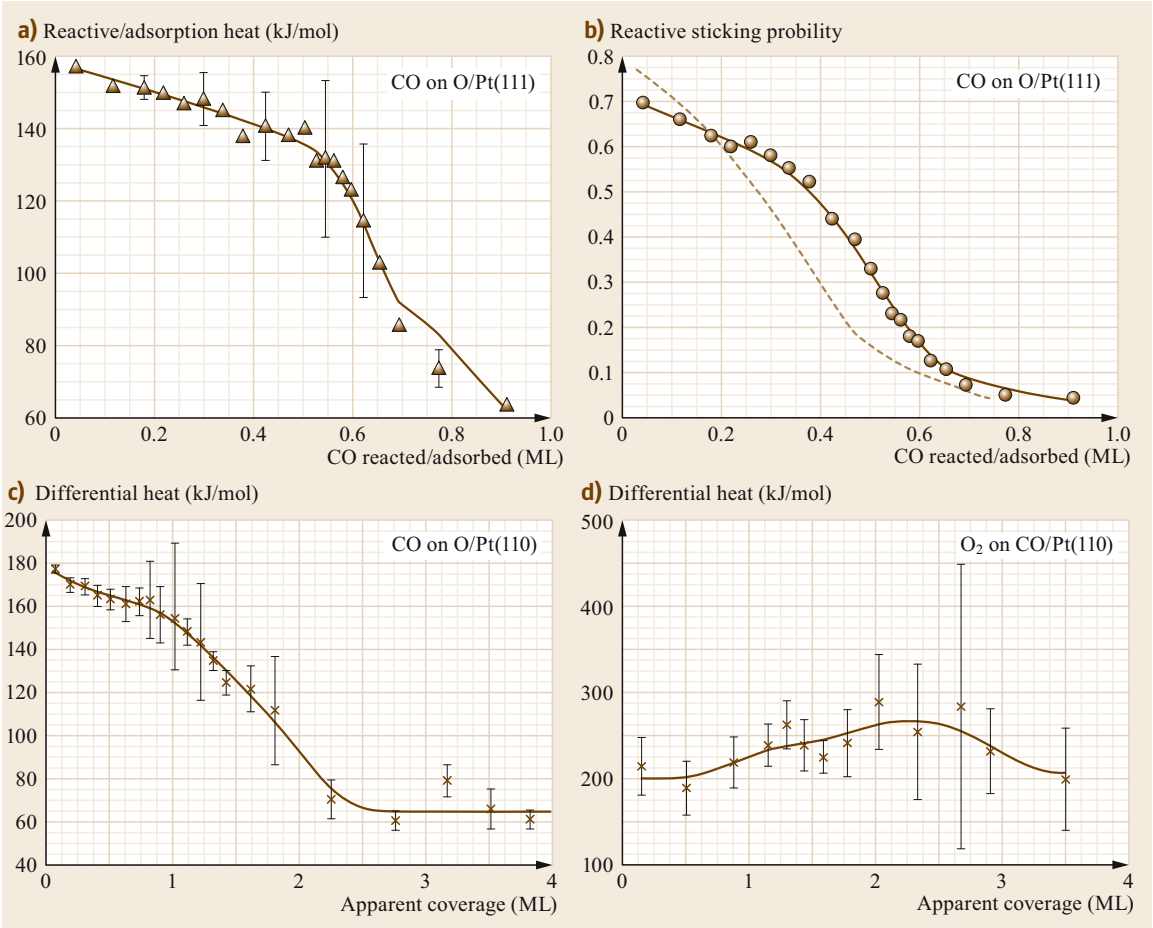

Fig. 30.12a–d Differential heat of adsorption (a) and sticking probability (b) for CO adsorption on Pt(111) precovered with a saturation coverage of oxygen. ([30.17], © AIP 1997). Differential heat of adsorption for: CO adsorption on O-saturated Pt(110) (c) and for O_2 adsorption on CO-saturated Pt(110) (d) (Adapted from [30.1], © 1998 American Chemical Society)

understand the meaning of this fact we must remember that in a SCAC experiment, a pulsed molecular beam is used. Typically, pulses last for 50 ms and are separated by 2.5 s. When a steady state is reached, the molecules adsorbed during each pulse desorb in the time between subsequent pulses. The number of molecules adsorbing during each pulse is, thus, just the number of molecules present in each pulse multiplied by the sticking probability. It is usual to express the rate of desorption using the following expression

$$\frac{\mathrm{d}\theta}{\mathrm{d}t} = \nu_{\mathrm{des}}(\theta)^n \mathrm{e}^{-q/(RT)} \,, \tag{30.8}$$

where n is the desorption order and ν_{des} the desorption frequency factor (also called prefactor for desorption). Since the number of molecules desorbing in the time between pulses is equal to the number of molecules adsorbing during the pulses in the steady-state region, it should be possible to determine ν_{des}. Since under steady-state conditions the Gibbs free energy change for adsorption vanishes, it is possible to determine also the entropy change due to adsorption directly from the calorimetric data

$$\Delta G = \Delta H - T\Delta S = 0 \,, \tag{30.9}$$

and then

$$\Delta S = \frac{\Delta H}{T} = -\frac{q}{T} \,. \tag{30.10}$$

The standard entropy for a gas can be calculated using the law of perfect gases as

$$S = S^0 - R \ln\left(\frac{p}{p^0}\right), \tag{30.11}$$

where S^0 is the standard entropy of the gas (i.e., 198 J/(K mol) for CO at 1 atm and 298 K), p the gas pressure, and p^0 the standard pressure. By using the experimentally obtained ΔH, it is possible to extract the differential entropy of the adsorbed phase S_a

$$S_a = S^0 - R \ln\left(\frac{p}{p^0}\right) - \frac{q}{T}. \tag{30.12}$$

The results of this analysis for CO adsorption at RT on different single-crystal Ni surfaces are summarized in Table 30.2. The extraction of prefactors from calorimetric data, however, requires some care. The same analysis for CO Pt(110) [30.31] leads to a prefactor for desorption of $2.5 \times 10^{(9\pm1.2)}$ Hz. This is a value that is remarkably lower than usually assumed ($\approx 10^{14}$ Hz)! The reason for this discrepancy is that the desorption rate is not exactly given by (30.8). This simple and widely-used expression is somewhat oversimplified, since it neglects several processes that may take place; for example, a mobile precursor may be involved also in desorption, thus providing a path back to the chemisorbed state. If these processes are considered, the desorption rate is reduced by a factor F, which can be written as [30.33]

Table 30.2 Differential heat q_{ss}, S_a and frequency factor for desorption as obtained from steady-state conditions for CO adsorption on different Ni surfaces (data taken from [30.32])

System	q_{ss} (kJ/mol)	S_a	ν_{des} (Hz)
CO/Ni(111)	95	71	3×10^{14}
CO/Ni(100)	99	58	1×10^{15}
CO/Ni(110)	101	50	3×10^{15}

$$F = f_d + f_m\left[1 - \left(1 + \frac{f_d}{f_a}\right)^{-1}\left(1 + K\frac{\theta}{1-\theta}\right)^{-1}\right], \tag{30.13}$$

where f_d, f_m, and f_a are the probabilities of desorption, migration to a neighbor site, and chemisorption for a molecule in the precursor state; K is the Kisliuk constant. The smaller K is, the more mobile the precursor, while $K = 1$ represents an immobile precursor. Since F cannot be directly obtained by the experimental data, care must be taken in extracting the frequency factor directly from steady-state values using (30.8).

30.5 Overview of Experimental Results by the Washington Group

The main limitations of the Cambridge IR calorimeter arise from the need to operate it at room temperature and to use pulsed supersonic molecular beams of gases. In particular, the IR setup did not allow the study of activated adsorption systems, adsorption of gases with low vapor pressure around room temperature, and adsorption of nongaseous species (such a metals). Most of these limitations were overcome by the use of pyroelectric detectors, which enabled an extension of the range of temperatures at which the measurements can be performed, and by the development of modified sources enabling also the use of effusive beams of low vapor pressure molecules [30.7, 8] and adatoms [30.34–37].

A large set of systems have been investigated in such ways obtaining calorimetric data regarding in particular:

a) Heat of adsorption of both simple [30.38–41] and more complex organic compounds [30.42–50] and subsequent determination of bond energies and heat of formation of chemically important radicals
b) Heat of adsorption of adatoms at both metal [30.51, 52], oxides [30.53–60], semiconductors [30.61], and insulating surfaces [30.62].

Dedicated reviews have appeared [30.37, 63–67] and just a few selected examples will be highlighted here.

30.5.1 Heat of Adsorption of "Large" Molecules at Surfaces

The supersonic molecular beam source successfully used for gases by the Cambridge group cannot be used to dose molecules having a vapor pressure < 100 Torr at room temperature. Under these conditions, an effusive beam with a source operating < 400 K can be used for molecules with a vapor pressure between 0.01 and 100 Torr at room temperature [30.7, 8]. The source is schematically shown in Fig. 30.13. Thanks to this improvement it was possible to measure the heat of adsorption and the sticking probability of species like benzene and other larger organic molecules with mo-

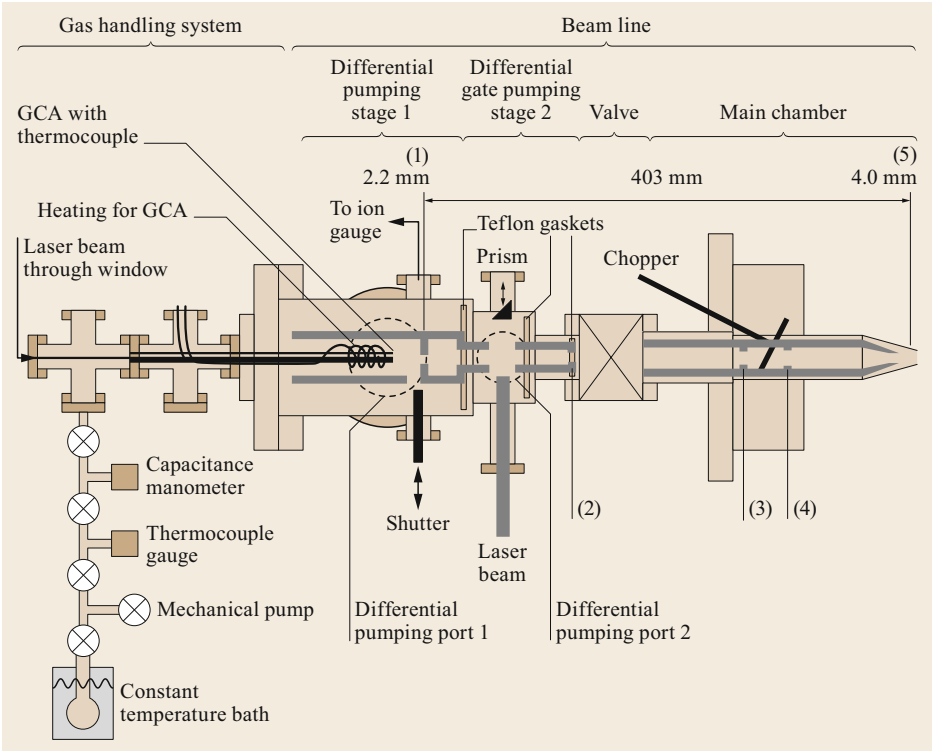

Fig. 30.13 Schematic of the effusive molecular beam and its separate elements: gas handling system and beam line, with five orifices indicated by numbers: (1)–(5). The beam line consists of two differential pumping stages separated from the main chamber by a gate valve. The purpose of the gas handling system is to deliver the low vapor pressure molecules in the constant temperature bath, kept at 280 K, to the glass capillary array (GCA). The temperature of the GCA is monitored by a thermocouple and is resistively heated to maintain a temperature of 300 K. The line between the constant temperature bath and the GCA is maintained at 290 K, using heating tape, to prevent condensation of the low vapor pressure molecules along the way. The beam line consists of five orifices, only two of which are beam defining: (1) and (5). The inner diameter (ID) of (1) and (5) are 2.2 and 4.0 mm, respectively, and the distance between them is 403 mm. Orifices (2), (3), and (4), which are not beam defining, but only slightly larger, have IDs of 2.8, 3.8, and 4.0 mm, respectively. Also indicated are ports for the laser and prism for calibration with the laser beam, the shutter, used to stop the molecular beam, and the chopper, used to chop both the laser and molecular beams (Adapted from [30.7], with the permission of AIP Publishing)

lar mass exceeding 70 g/mol. The measurement of the heat of adsorption of such "large" organic molecules sometimes presents some additional complexity, which is schematically shown in Fig. 30.14 for the case of cyclohexene adsorption on Pt(111).

The lower trace in Fig. 30.14a shows the QMS signal when the molecular beam hits the inert gold flag. The duration of the pulse is 50 ms. The above trace shows the QMS trace when the molecular beam hits the Pt(111) surface. It is apparent that the cyclohexene signal does not end when the molecular beam is interrupted but continues thereafter. This result indicates that, under the conditions of that experiment (263 K and coverage > 0.15 ML) transient desorption occurs off the surface.

The corresponding calorimetric signal exhibits a more complex behavior. Firstly, there is a delay between the instant at which adsorption and release of heat starts and the onset of the calorimetric signal, because of the limited thermal contact between the Pt(111) sample and the pyroelectric polymer. The heat deposited by the molecules is measured by the slope of the calorimetry pulse during the initial steep rise, typically 40–140 ms after the pulse hits the sample. Since the calorimetry signal after the initial steep rise is not used for calculating the amount of heat deposited, any desorption occurring after that point in time (140 ms) is neglected in the evaluation of q. However, desorption occurring during the first 140 ms will affect the measured heat. In order to account for this

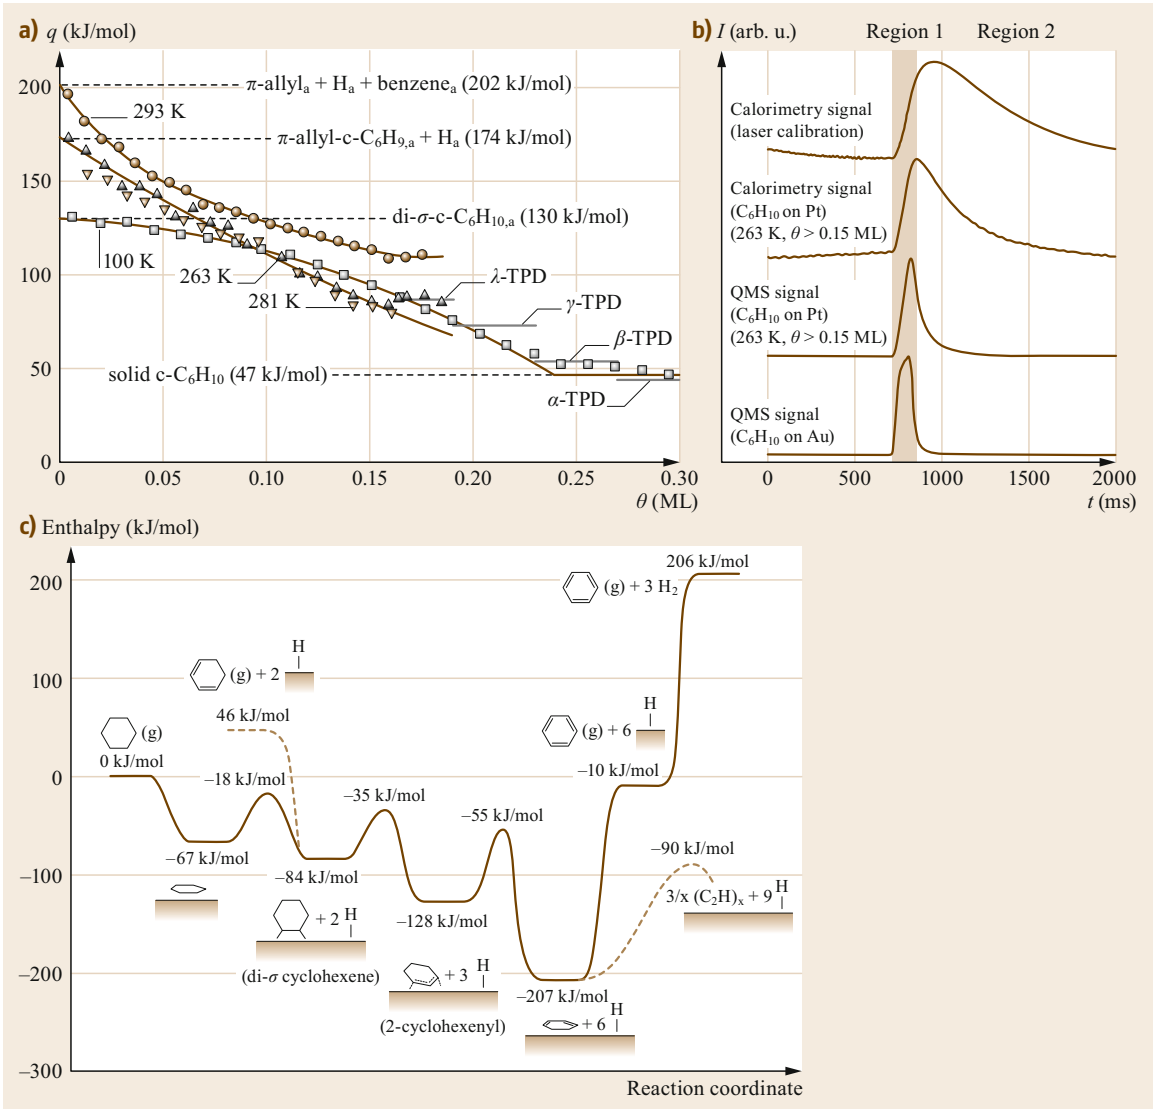

Fig. 30.14 **(a)** Differential heat of adsorption for cyclohexene adsorption on Pt(111). **(b)** Comparison of the pyroelectric and QMS signal versus time (see text). **(c)** Energetic of cyclohexane dehydrogenation on Pt(111), as obtained by calorimetric data. Only the heats of adsorption of H_2 and cyclohexane were obtained by analysis of TPD data (see the original papers for details) ([30.63], © Roy. Soc. Chem. 2008; adapted from [30.44], © 2008 American Chemical Society)

effect, a correction was introduced [30.44]. A short-time sticking probability was defined as the fraction of the impinging molecules, which is considered to determine the heat of adsorption. This fraction is higher than the fraction of molecules, which has not desorbed before the next cyclohexene pulse starts to hit the surface (the so-called "long-term sticking probability") and which is used to determine the surface coverage. This somewhat rough correction, which is essentially a linear interpolation scheme neglecting desorption after the pulse has reached its maximum intensity, is sufficient when transient desorption is limited. Its validity is questionable when transient desorption is relevant, e.g., for cyclohexene adsorption Pt(111) at 263 K and > 0.15 ML; q for cyclohexene on Pt(111) was measured as a function of coverage for temperatures in the range from 100 to 300 K. The results are shown in Fig. 30.14. At 100 K, cyclohexene adsorbs as di-σ-bonded cyclohexene with an initial adsorption heat of 130 kJ/mol. From this calorimetric result and using the standard enthalpy of formation of gas phase cyclohexene (−5 kJ/mol), the standard enthalpy of for-

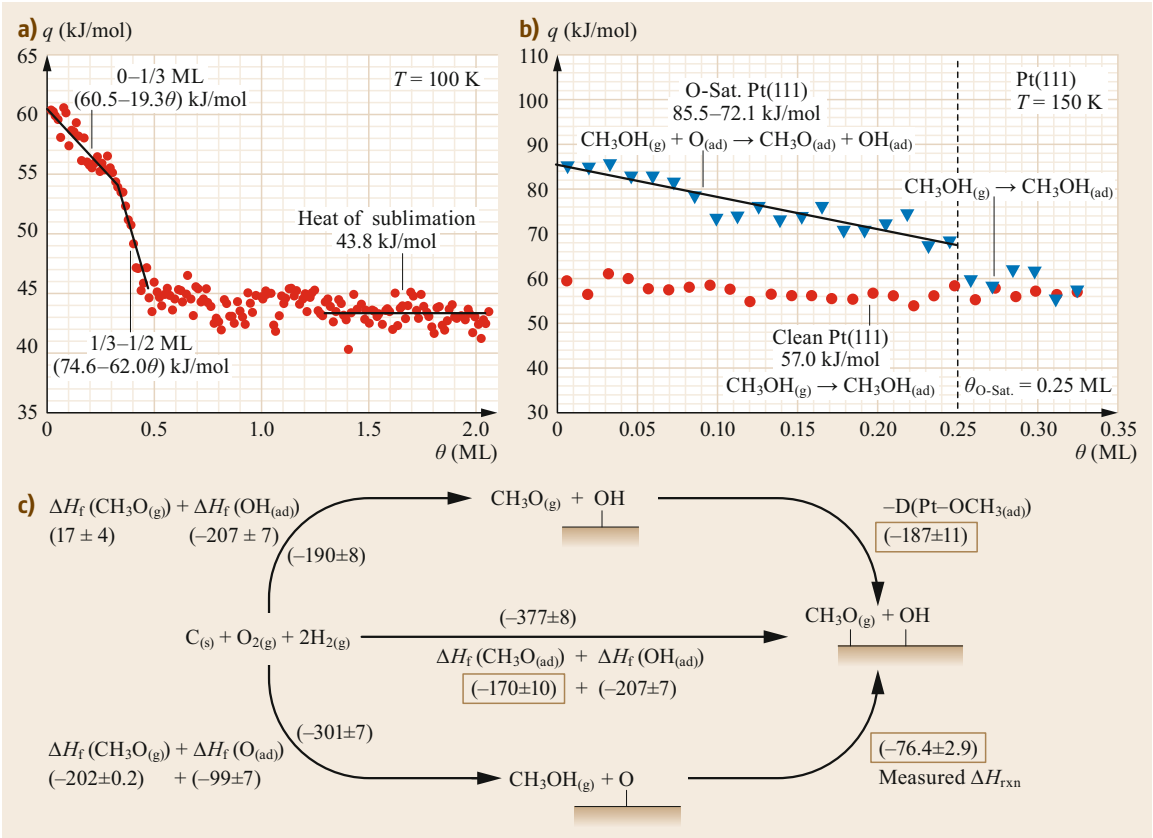

Fig. 30.15 **(a)** Differential heat of adsorption of methanol on clean Pt(111) at 100 K versus total methanol coverage. **(b)** Differential heat of adsorption of methanol versus total methanol coverage on (*circles*) clean and (*triangles*) oxygen-saturated Pt(111) at 150 K. **(c)** Thermodynamic cycle at 150 K used in calculating the bond enthalpy and standard heat of formation of adsorbed methoxy. The values are expressed in kJ/mol (Adapted from [30.45], © 2012 American Chemical Society)

mation of adsorbed di-σ-bonded cyclohexene was obtained (−135 kJ/mol). A similar argument was used to analyze the experimental data recorded at 281 K; at this temperature, cyclohexene dehydrogenates upon adsorption, forming adsorbed 2-cyclohexenyl (π-allyl-c-C_6H_9) plus a hydrogen adatom. The initial heat of adsorption is 174 kJ/mol, so adding the heat of formation of gas cyclohexene and one-half the heat of adsorption of H_2 on Pt(111) (72 kJ/mol), the heat of formation of adsorbed π-allyl-c-C_6H_9 was estimated (−143 kJ/mol). Finally, from the measured heat of adsorption of benzene on Pt(111) at 300 K (197 kJ/mol) and using the enthalpy of formation of gaseous benzene (83 kJ/mol), the standard enthalpy of formation of adsorbed benzene was found (−114 kJ/mol). By combining all these calorimetric data a partial energy landscape of the dehydrogenation of cyclohexane to benzene on Pt(111) was obtained. The reader is referred to the original papers for the details of this complex diagram, which nicely illustrates the extent of information attainable from calorimetry [30.42, 44, 63]. Inspection of the diagram provides deeper understanding of cyclohexane and cyclohexene dehydrogenation as well as of benzene hydrogenation in presence of a Pt catalyst. In particular, since the barrier for cyclohexene desorption is higher than the barrier for its further dehydrogenation it is difficult to stop the dehydrogenation of cyclohexane to cyclohexene. Similarly, the barrier for benzene desorption is too high at low coverage, thus explaining why no benzene is obtained from dehydrogenation of cyclohexane and cyclohexene. It is, however, possible to obtain benzene by increasing the coverage of co-adsorbed species; this way, the barrier to overcome for further dehydrogenation increases and desorption of benzene becomes competitive with its dissociation.

Under the high-pressure conditions at which real catalysts operate, the desorption of dehydrogenated products is, thus, kinetically competitive with complete

The multilayer heat of adsorption is indicated by a *red line* through the 100 K data in the *lower right corner*. **(c)** Thermodynamic cycle used to determine the enthalpy of formation of adsorbed monodentate formate on Pt(111) and its HCOOPt(111) bond enthalpy from the integral fast S1 heat of adsorption at 150 K and 3/8 ML, shown as the *bottom right-hand step*. The values are expressed in kJ/mol (Adapted from [30.49], © 2014 American Chemical Society)

dehydrogenation. Note that the latter should also be avoided to completely coke the catalyst itself.

Campbell and co-workers undertook a systematic investigation of the heat of adsorption of several species on Pt(111) surfaces: methanol on an oxygen precovered surface to obtain methoxy [30.45] (Fig. 30.15), formic acid on oxygen-saturated Pt(111) to obtain formate [30.49] (Fig. 30.16) and water on oxygen precovered Pt(111) [30.38]. The results are summarized in Table 30.3, reporting the adiabatic PtOR bond dissociation enthalpies for three oxygen-bound molecular fragments to the Pt(111) surface: deuterated hydroxyl (OD) [30.38], monodentate formate (O(O)CH) [30.49], and methoxy (OCH_3) [30.45], where R is the part of the fragment bonded with oxygen. Quite interestingly, these ROPt(111) bond enthalpies vary linearly with the ROH bond enthalpies in the corresponding gas-phase molecules (water, methanol, and formic acid), and the

Table 30.3 Adiabatic RO–Pt(111) and gas phase R–OH bond strengths. The values are expressed in kJ/mol (data taken from [30.41])

Adsorbed species	ΔH_f^0	Gas phase R–OH bond strength	Measured bond enthalpy for RO–Pt(111)
–OD	-210 ± 7	500	248 ± 7
–O(O)CH	-353 ± 10	469 ± 13	224 ± 13
$-OCH_3$	-170 ± 12	437	187 ± 11

slope is compatible with 1.00. This result resembles the known trend for organometallic complexes and is explained by the local character of chemical bonding, even on extended metal surfaces. It is, thus, possible to predict bond enthalpies for many other molecular fragments at metal surfaces and derive the energetics of relevant catalytic reactions [30.41].

30.5.2 Heat of Adsorption of Metal Adatoms at Surfaces

The measurement of the heat of adsorption of metal adatoms at surfaces [30.68] became feasible thanks to substantial upgrades of the Cambridge calorimeter. Such modifications involved both the source and the detector of the released heat. The heat of adsorption q for Ag on Si(100)-(2 × 1) is shown in Fig. 30.17. Chopped pulses of a silver atom beam from a hot effusive source are directed at the surface of a thin Si(100) sample, releasing energy into the crystal upon adsorption. This causes a small transient temperature rise, detected by a thin pyroelectric polymer ribbon pressed into contact with the backside of the crystal during the measurement. The signal provided by the pyroelectric detector is calibrated by comparison with the signal produced by light pulses of known energy provided by a He-Ne laser. The sticking probability is obtained by measuring the amount of metal in a pulse that is reflected off the sample with a line-of-sight quadrupole mass spectrometer. The incident flux is measured with a quartz crystal microbalance. For adsorption on the bare surface, $q = 347$ kJ/mol. It decreases rapidly until at 0.55 ML it drops below the bulk heat of sublimation of Ag (285 k/mol). At 1 ML, q rises again reaching a value compatible with the bulk heat of sublimation at 2.5 ML. The sticking probability is surprisingly monotonic; indeed, it increases with coverage despite the complicated behavior of q.

The data can be rationalized as follows. The initial value of q is higher than the value expected for isolated

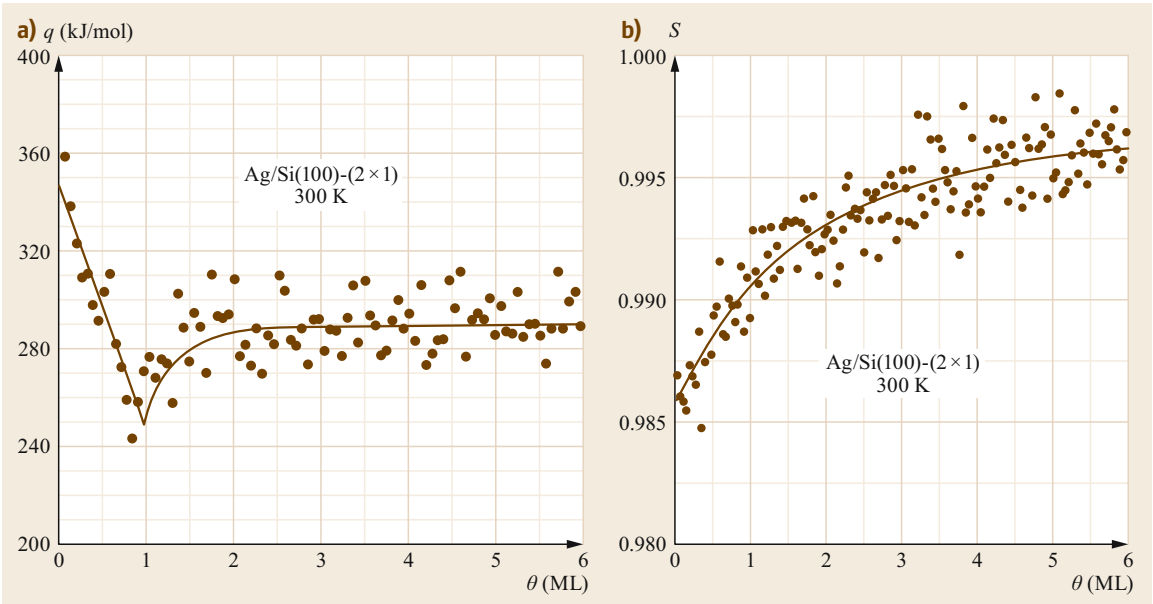

Fig. 30.17 **(a)** Heat of adsorption of Ag atoms on Si(100)-(1 × 2) versus adatom coverage. The *solid curve* is formed by a linear fit to the data over the first ML and a double exponential fit to the data at coverages > 1.0 ML. **(b)** Sticking probability of Ag atoms on the same substrate (Adapted from [30.61], © 2001 by the American Physical Society)

adatoms due to the formation of chains of adatoms. Such elongated Ag islands, seen by STM at 300 K up to a coverage of 1 ML, would normally imply attractive Ag–Ag interactions. The observation of a globally decreasing q with coverage implies that they are, on the contrary, repulsive. The formation of Ag–Si bonds induces significant strain in the neighboring surface sites, thus explaining the overall repulsive interaction between islands. If the growth were controlled by thermodynamics alone, 3-D growth should start ≈ 0.55 ML i.e., when q becomes lower than the heat of sublimation. Due to kinetic constraints, this happens, however, only ≈ 1 ML; indeed, at such a coverage, q rises quickly towards the bulk sublimation value. Once large 3-D particles have formed on top of the wetting layer, they provide more stable sites for Ag than in the wetting layer. This example shows that the information provided by calorimetry can be successfully used to explain the different regimes in the growth of metallic films on different substrates.

The same kind of measurements are able to also highlight size effects in the growth of nanoparticles. The calorimeter measures sticking probability and heat of adsorption versus coverage. In order to obtain information on the effect of particle size it is necessary to correlate the coverage with the size of the nanoparticles. Quantitative analysis of spectral intensities in Auger electron spectroscopy and ion scattering spectroscopy for the different elements as a function of Ag coverage was employed to characterize the growth morphology of the Ag films on magnesia and ceria surfaces. The data were well fitted by assuming that the Ag grows as three-dimensional (3-D) Ag particles with an hemispherical shape and a fixed, coverage independent, number N of Ag particles for unit of area. The data are not sensitive to the exact shape of the nanoparticles but are very sensitive to their aspect ratio. The analysis of Auger data showed that, > 0.03 ML, N is independent of coverage. Dividing the Ag coverage (atoms/cm^2) by N (particles/cm^2), the average number of Ag atoms per particle is obtained at any given Ag coverage. Measurement of q for Ag adsorption on different substrates was performed and compared as a function of particle size and of the number of atoms in the nanoparticle. The results are summarized in Fig. 30.18. It is apparent that the initial value of q, i.e., the value proper to very small particles, is strongly dependent on the nature of the substrate; for nanoparticles containing < 1000 atoms, Ag atoms are 30–70 kJ/mol more stable when they are deposited on ceria than on MgO surfaces.

This result nicely explains the pivotal role of the support in the sintering of nanoparticles. As long as a metal atom is less stable in a nanoparticle of a certain size than in the bulk, it will prefer to move and to form larger particles. The point is that this driving force for sintering drops below 10 kJ/mol for Ag nanoparticles of 400 atoms (3 nm) on ceria and for nanoparticles of 3000 atoms (6 nm) on MgO(100). For nanoparticles consisting of ≈ 5000 atoms, the energy of the added atoms reaches the value of the bulk metal also on MgO. Data for Pb exhibits a similar behavior [30.56].

Very recently, a similar study was performed also for Cu deposited on ceria. By comparing the heat of

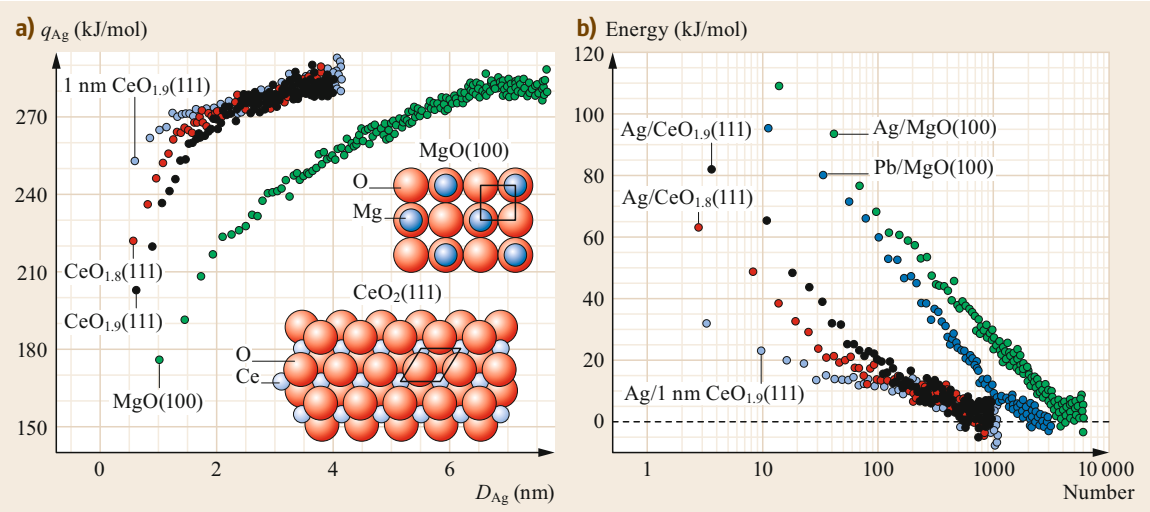

Fig. 30.18 **(a)** Measured heat of Ag atom adsorption q_{Ag} versus the Ag particle diameter D_{Ag} to which it adds, for Ag adsorption onto four different surfaces. **(b)** Measured energy of a Ag atom, relative to its energy in bulk Ag(solid), versus the number of metal atoms already in the particle, for Ag particles on different surfaces (From [30.58]. Fig. 30.19 **(a)** Cu atom heat of adsorption at 300 K (*diamonds*) and 100 K (*squares*) on $CeO_{1.95}(111)$ as a function of Cu coverage. **(b)** Chemical potential of Cu atoms in Cu nanoparticles on $CeO_{1.95}(111)$ relative to that in bulk Cu (solid) versus the effective diameter of the Cu particle down to the single atom limit (Adapted from [30.67], © 2015 American Chemical Society)

adsorption at 300 and at 100 K, it was possible to obtain the chemical potential as a function of particle size [30.67]. Ion scattering spectroscopy (ISS) was employed to determine the number of nanoparticles for unit of area; the normalized ISS signals directly provide the fraction of the ceria surface, which is masked by Cu particles, and the fraction of the total maximum Cu signal (due to complete coverage by Cu) that is observed at any given Cu coverage. The heat of adsorption for Cu nanoparticles with a diameter from 0.45 to 0.8 nm is lower at 100 K than at room temperature by some 30–50 kJ/mol on the same $CeO_{1.95}(111)$ surface; this difference was attributed to cluster nucleation on terrace sites at 100 K and at step-edge sites at 300 K. Hence, at 100 K, the number of nanoparticles for unit of area (5.3×10^{13} particles/cm^2) is about seven times higher than at 300 K (7.8×10^{12} particles/cm^2). Since the entropic contribution to the free energy changes very little with particle size compared with the enthalpic one, the chemical potential of a metal atom in a particle of diameter D, $\mu(D)$, is higher than that in the bulk metal, $\mu(\infty)$, by an amount equal to the heat of sublimation of bulk Cu minus the differential heat of Cu adsorption at diameter D. It is, thus, possible to obtain $\mu(D)$ from the calorimetrically measured q as a function of particle size. The results are shown in Fig. 30.19. The chemical potential decreases with increasing particle size. The Cu chemical potential is 110 kJ/mol higher for isolated Cu adatoms on stoichiometric terrace sites than for Cu in nanoparticles exceeding 2.5 nm diameter, where it reaches the bulk Cu(solid) limit. In Cu dimers, the Cu chemical potential is notably 57 kJ/mol lower at step edges than on stoichiometric terrace sites.

We finally mention the possibility to use metal adatoms to characterize the defectivity of oxide surfaces [30.57]. Figure 30.20 shows the heat of adsorption for Ca and Li on pristine and ion-bombarded MgO. While ion sputtering causes a strong increase in the initial adsorption energy for Li on MgO(100) at 300 K, the initial adsorption energy for Ca is independent of the extent of sputtering. In order to explain this intriguing result, density functional theory (DFT) calculations were also performed. DFT revealed that while Ca adatoms thermally diffuse to look for the remaining defect sites, Li adatoms remain blocked when they reach a terrace site nearby an occupied step or kink site. The measured dependence was simulated with a kinetic model taking the binding energies and the adatom migration barriers provided by DFT as inputs. The lines is the figure show the result of this model, which evidently captures the essential physics ruling the behavior of this system.

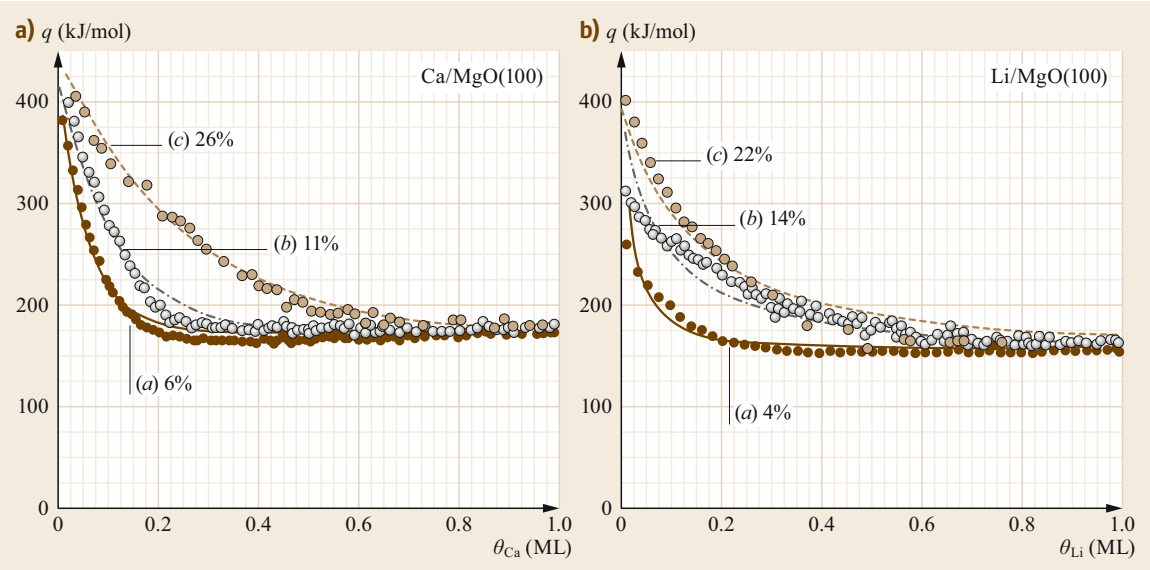

Fig. 30.20a,b Heat of adsorption of Ca (**a**) and Li (**b**) versus coverage at 300 K for adsorption on (*a*) pristine MgO(100) and (*b*) and (*c*) MgO(100) irradiated with increasing Ar^+ ion doses (from 10^{14} to 10^{16} ions/cm^2) to create more defects. 30.6 Results of Other Research Groups

The impressive achievements of single-crystal calorimetry obtained in Cambridge and in Washington stimulated further developments of the technique [30.9, 10]. In recent years, some papers have appeared focussing on the heat of adsorption of gases at nanoparticles of different size [30.69], on water adsorption at oxide surfaces [30.70], on the adsorption of chiral molecules [30.71], and on the effect of surface temperature on the coverage dependence of the heat of adsorption [30.72]. Such results are briefly reviewed in the final part of this chapter.

30.6.1 Heat of Adsorption of CO on Pd Nanoparticles

Although results obtained on single-crystal surfaces have provided valuable insight into the behavior of more complex systems, researchers are presently trying to investigate directly adsorption and reactions on nanoparticles supported on oxide substrates. Such efforts have also increased the range of operation of microcalorimetry. Figure 30.21 shows the dependence of the heat of adsorption of CO and of O_2 on Pd nanoparticles of different size deposited on a thin Fe_3O_4 film grown on Pt(111). By depositing different amounts of Pd on the film, nanoparticles of different sizes were obtained. The particle size was determined by STM the smallest nanoparticles correspond to ≈ 120 atoms/particle, while largest ones consist of ≈ 4900 atoms/particle. The data are compared with the results obtained for a Pd(111) single crystal. The dependence of the initial adsorption energy for oxygen on the particle size exhibits a clear trend. It strongly rises from about 205 to 250–275 kJ/mol when moving from Pd(111) to large Pd nanoclusters where it passes through a maximum and decreases thereafter, reaching a value of 205 kJ/mol on the smallest Pd nanoparticles. The initial rise is accounted for by the fact that on Pd(111) oxygen adatoms adsorb at threefold-hollow sites, while on large Pd nanoclusters, oxygen first occupies undercoordinated sites at the edges of the particle, which usually have a higher heat of adsorption. For smaller nanoparticles, the first sites to be occupied are still undercoordinated sites at the edges. The decrease of q is, thus, due to a pure size effect; in smaller nanoparticles, the lattice spacing is lower, the d bands are downshifted [30.74], and this causes a significant decrease in the heat of adsorption [30.75]. The decrease of the particle size causes, moreover, a lower van der Waals contribution to the heat of adsorption, thus resulting in an overall decreasing value. The data for the initial heat of adsorption of CO on the same nanopar-

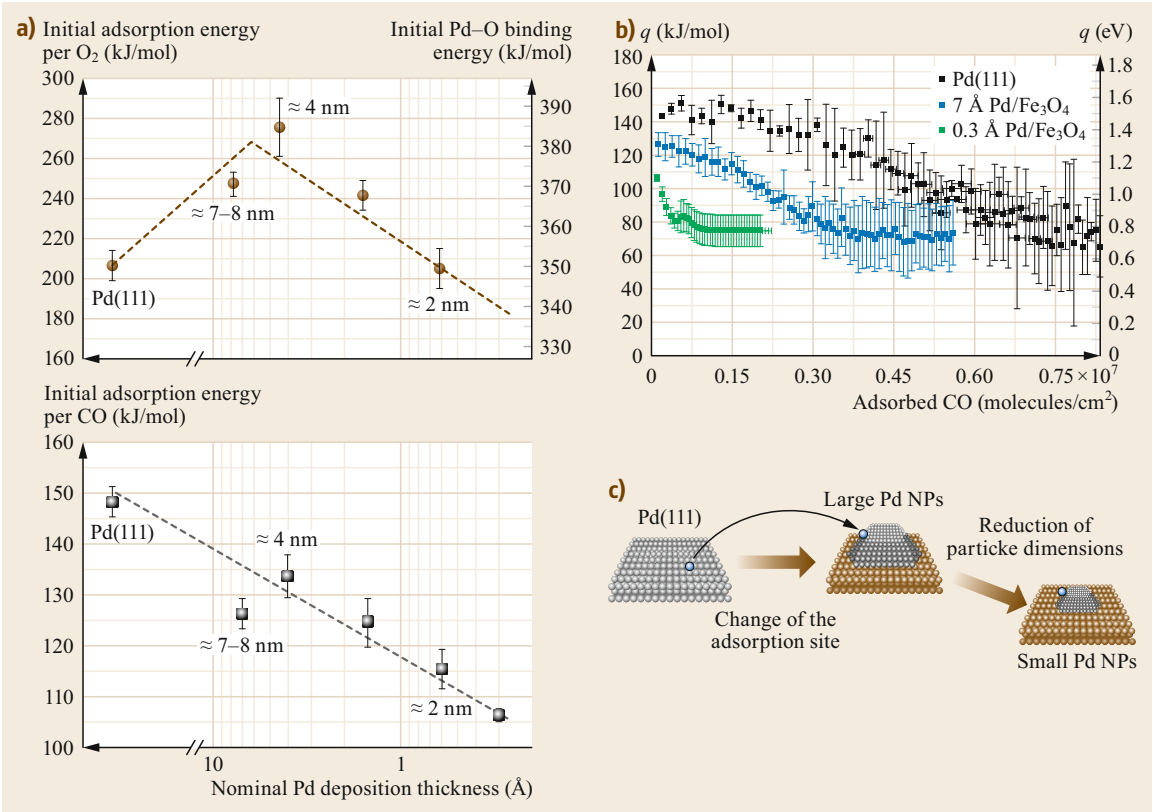

Fig. 30.21 **(a)** Initial adsorption energy for (*upper panel*) O_2 and (*lower panel*) CO molecules plotted as a function of the nominal Pd coverage on the $Fe_3O_4/Pt(111)$ samples with the nominal deposition thickness of 0.3 (only for CO), 0.6, 1.5, 4, and 7 Å and on the Pd(111) single-crystal surface. Next to the data points, the average diameters of the Pd particles are given. Error bars show the standard error of the mean. The *dashed lines* are given to guide the eye. **(b)** Adsorption heat of CO on Pd(111) and on a $Pd/Fe_3O_4/Pt(111)$ model catalyst plotted as a function of CO surface coverage. Each curve is an average of four to six experimental runs measured on freshly prepared samples. **(c)** A model describing two microscopic trends affecting the binding energy: the local configuration of the adsorption site, and the particle size. NPs = nanoparticles (Adapted from [30.73], © 2010 by the American Physical Society; [30.69], © Wiley VCH 2013)

ticles exhibits, on the contrary, a monotonic decrease with particle size. Since the heat of adsorption of CO on Pd(111) does not change so much from terrace to corner sites, the behavior of the heat of adsorption is dominated by size effects over the whole range considered in these studies.

30.6.2 Heat of Adsorption of Propylene Oxide

In Fig. 30.22, the heat of adsorption of the *R* and *S* enantiomers of propylene oxide on bare and NEA-covered Pt(111) surfaces are reported. 1-(1-Naphthyl)ethylamine (NEA) is a model chiral modifier; it has an aromatic group for binding to a metal surface and an amino group close to the chiral centre capable of hydrogen bonding. Adsorption of *S*- and *R*-propylene oxide (PO) on the bare Pt(111) surface shows an initial heat of adsorption of 50 decreasing to 42−43 kJ/mol at a coverage of $\approx 1.5\times10^{14}$ molecules/cm^2 corresponding to 1 PO molecule every 10 P atoms. Above this coverage, *q* either goes through a small local maximum (*S*-PO) or, rather, remains constant (*R*-PO) up to the coverage of 4.1×10^{14} molecules/cm^2. Saturation is then reached at a coverage of 5.5×10^{14} molecules/cm^2. When PO adsorbs on the pristine Pt(111) surface, its binding energy rapidly reaches a constant level; this plateau is most likely due to the formation of PO islands. After some PO nuclei consisting of a few PO molecules are formed on the surface, further PO molecules diffuse to the boundary of these nuclei and adsorb with a constant binding energy. It is only after the PO surface coverage increases to such an extent that neighboring PO islands start to coalesce that the binding

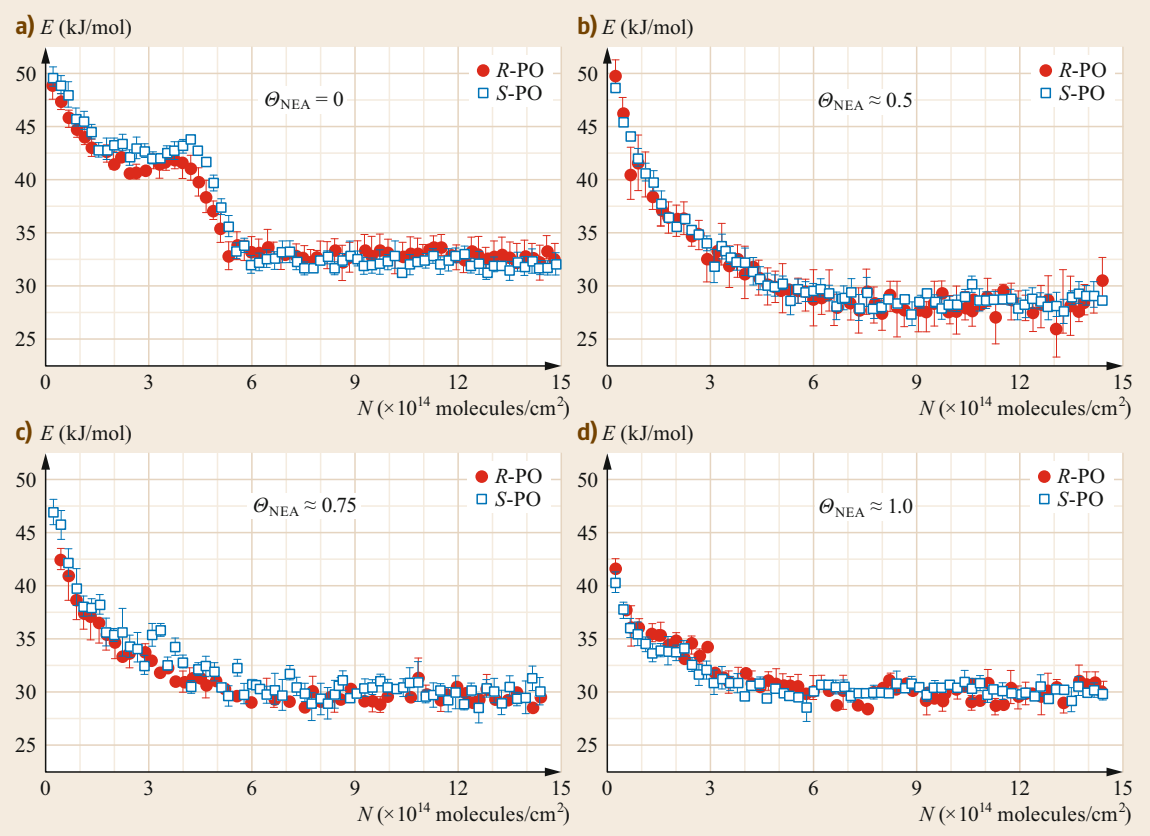

Fig. 30.22a–d Adsorption energy of *S*-PO and *R*-PO as a function of the number of adsorbed molecules on **(a)** bare Pt(111), as well as *R*-NEA-covered Pt(111) with the *R*-NEA relative coverage of **(b)** 0.5; **(c)** 0.75; **(d)** 1. The data points are averages of 35 independent measurements; the error bars show the error of the mean value. ([30.71], published by the PCCP Owner Societies licensed under a Creative Commons Attribution 3.0 Unported Licence 2015)

energy of the last incoming PO molecules decreases and approaches the value characteristic for PO adsorption in the second layer. The coverage dependence of q changes completely if NEA is present on the surface; as evident from Fig. 30.22b–d a monotonically decreasing heat of adsorption is measured in this case. When the surface is covered with 50% of NEA, i.e., when half of the surface still exposes Pt atoms, the plateau in q has completely disappeared. Most likely, there is a preferred adsorption of PO in the vicinity of NEA, preventing PO island formation on the still available metal sites. All these results suggest a preferential interaction between PO and the adsorbed modifier possibly resulting in the formation of a complex between these molecules.

30.6.3 Heat of Adsorption of Water at Metal and Oxide Surfaces

We conclude our review by presenting in Fig. 30.23 the microcalorimetric results for H_2O adsorption on Pt(111) and on two thin iron-oxide films. On Pt(111) and on FeO/Pt(111), the heat of adsorption is initially 47 kJ/mol and remains nearly constant until ice is formed. On Fe_3O_4(111)/Pt(111), q is initially much higher (87 kJ/mol) and decreases thereafter, monotonically leveling at a coverage of 1.2×10^{15} molecules/cm^2. The high value of q is indicative of water dissociation. Measurements performed at different temperatures are shown in Fig. 30.23b. The initial adsorption energy at higher temperatures reaches 101 kJ/mol and decreases, leveling off at a lower coverage without forming multilayer ice. An increase of the initial binding energy from 87 kJ/mol at 120 K to 101 kJ/mol at temperatures > 180 K is most likely related to a kinetic hindrance of water dissociation at 120 K. Since the initial adsorption energy remains constant for all temperatures > 180 K, this value can be considered as the true thermodynamic value that is not affected by the slow kinetics of water dissociation. The leveling of q corresponds, as is usual in calorimet-

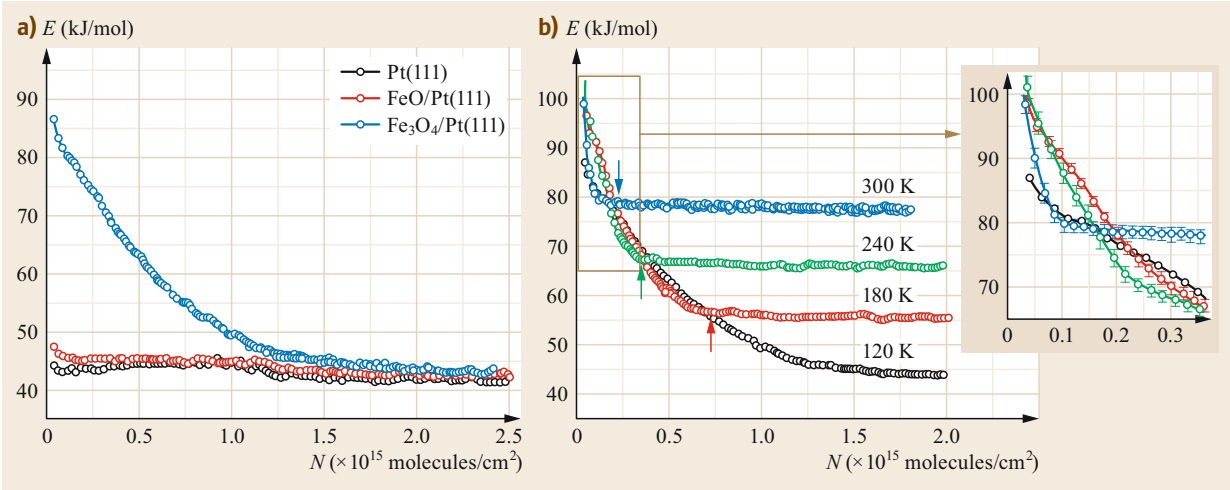

Fig. 30.23 **(a)** Differential adsorption energy measured at 120 K plotted as a function of the number of adsorbed H_2O molecules for Pt(111), FeO(111)/Pt(111), and Fe_3O_4 (111)/Pt(111). **(b)** Differential adsorption energy of H_2O on Fe_3O_4(111)/Pt(111) as a function of the number of adsorbed H_2O molecules measured at different temperatures. ([30.70], © Wiley VCH 2015)

ric experiments using pulsed beams, to a steady-state equilibrium between molecules adsorbing during the water pulse and molecules desorbing in the time between subsequent pulses. The initial heat of adsorption at high temperature is higher than that obtained by thermal desorption methods (65 kJ/mol) [30.76]. These calorimetric data shed light on a possible failure of the generally-accepted simple model of water dissociation leading to two individual OH groups. IRAS measurements using isotopically labeled water molecules and DFT calculations suggested, on the contrary, a more complex mechanism: a dimer form consisting of one H_2O molecule dissociated into two OH groups and another nondissociated H_2O molecule [30.70].

30.7 Conclusions

Although SCAC is only about 20 years old, it has already developed into a mature and powerful technique. The complexity of the experimental setups and the need for accurate calibrations are still probably limiting its further utilization despite the huge amount of information that could be provided.

In our opinion, we foresee and welcome two possible future directions of development:

a) A systematic use of the existing SCAC setups with an extension of the sets of investigated systems, thus enriching the amount of data and the development of a more extended database covering more and more systems of catalytic interest. In this effort, the calorimetric information provided by SCAC will, however, need more and more precise identification of the moieties forming upon adsorption, which can be provided mainly by spectroscopic techniques, as has already happened for the analysis of calorimetric data obtained for simple organic molecules.

b) Further developments of the technique will be necessary to allow the investigation of currently inaccessible adsorption systems, in particular of activated adsorption systems. This direction will most likely require the use of supersonic beams to overcome adsorption barriers and to attain high-enough adsorption probabilities and, thus, an acceptable signal-to-noise ratio in the calorimetric signal.

Sir David is Exec Chair, Centre for Climate Repair at Cambridge, and Partner at SYSTEMIQ. He was UK Climate Envoy, 2013–2017, UK Government Chief Scientific Adviser, 2000–2007, and Professor of Physical Chemistry at the universities of Liverpool (1974–1988) and Cambridge (1988–2000). He has published over 500 papers on surface science and catalysis. He has received many international awards and honors.

31. Kinetics of Adsorption, Desorption and Reactions at Surfaces

H. Jürgen Kreuzer

We review the kinetic theories of adsorption, desorption, surface diffusion, and surface reactions, emphasizing the physics and chemistry underlying these processes. In particular, the need for local equilibrium in setting up macroscopic rate equations is discussed in detail, in particular for lattice–gas models. Several examples, such as hydrogen adsorption on rhodium surfaces and desorption from a coadsorbate, are presented. To go beyond the macroscopic level, one needs further details of the kinetics, such as the time evolution of correlators (in addition to the coverages), which are furnished by kinetic lattice–gas models, which also cover surface diffusion. An important point demonstrated in this chapter is the need for a consistent explanation of all data on a particular adsorbate system, including not only desorption spectra but also coverage and temperature-dependence of sticking coefficients and, last but not least, all thermodynamic data, such as adsorption isobars and heats of adsorption.

In Sect. 31.2, we present the theory for adsorbates that remain in quasi-equilibrium throughout the desorption process, in which case a few macroscopic variables, namely the partial coverages θ_r and their rate equations, are needed. We introduce the lattice–gas model and discuss results ranging from noninteracting adsorbates to systems with multiple interactions treated essentially exactly with the transfer-matrix method in Sect. 31.2.1. In Sect. 31.3, we discuss two examples to show the utility of theoretical approaches: adsorption and desorption of hydrogen on Rh(311) and coupled desorption and site conversion of coadsorbates: (NO+O)/Ru(001). In Sect. 31.4, we then proceed to the mesoscopic level by outlining recent advances in the theory of the kinetic lattice–gas model, such as nondissociative adsorption, and precursor-mediated adsorption and desorption. Finally, we make some concluding remarks in Sect. 31.5.

Surface processes such as adsorption, desorption, surface diffusion, and surface reactions can be described at the macroscopic level by writing kinetic equations for macroscopic variables, in particular rate equations for the (local) coverage or for partial coverages. This can be done rigorously by using the framework of nonequilibrium thermodynamics, which itself is based on the concept of local equilibrium [31.1]. The latter is established over length scales that are large compared to a mean free path and slow on the scale of the collision time. If this cannot be guaranteed, then a set of macroscopic variables is not sufficient, and an approach based on nonequilibrium statistical mechanics involving time-dependent distribution functions must be invoked.

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-46906-1_31

31.1 Surface Reaction

The kinetic lattice–gas model, based on a Markovian master equation, is an example of such a theory. The greater details that can be described in such a theory involve time-dependent correlation functions. Going beyond phenomenological approaches, one must start from a microscopic Hamiltonian of the coupled gas–solid system and derive a rigorous master equation for which transition probabilities are calculated from first principles. So far, this program has only been completed for phonon-mediated physisorption kinetics, as is reviewed in a monograph by *Kreuzer* and *Gortel* [31.2].

A theory of surface processes must provide a consistent description and explanation of the experimental data available on a particular adsorbate system. For adsorption, it is the coverage and temperature-dependence of the sticking coefficient. For desorption, it is the desorption rate of the various desorbing species, again as a function of coverage and temperature. This may be either the isothermal desorption rate or the rate of temperature-programmed desorption (TPD). In the latter experimental setup, the adsorbate is prepared for different initial coverages at low temperature, and the substrate is then heated to give a (preferably linear) rise in temperature, during which the desorption products are detected. With time-resolved EELS and IR spectroscopies, some species remaining at the surface can also be monitored with which the partial coverages of the theory must agree. In addition, LEED can be used to record, via the scattering intensities, the time evolution of local correlations in the adsorbate, which thus must also be provided by the theory. Lastly, because any kinetic theory yields the equilibrium properties of the adsorbate via its time-independent solution, these must be consistent with the measured equilibrium properties of the system, such as adsorption isotherms and isobars, the heat of adsorption and the differential entropy, and correlation functions, all as a function of coverage and temperature. Only when a large set of kinetic data and all equilibrium data are explained satisfactorily within the same theory, can one claim to have a realistic model of the system.

31.2 Desorption with Fast Surface Diffusion

If surface diffusion is fast on the time scale of desorption, the adsorbate is maintained in equilibrium throughout the desorption process, i.e., all correlation functions attain their equilibrium values at the remaining coverage $\theta(t)$ at temperature $T(t)$. Thus, the adsorbate can be uniquely characterized by its chemical potential, $\mu(\theta(t), T(t))$. Take as an example desorption of an adsorbate that shows coexistence of a dense and a dilute two-dimensional phase in a certain range of coverage and temperature, then during desorption the distribution between the two phases will be in equilibrium at the remaining coverage $\theta(t)$ and the attained temperature $T(t)$, i.e., a description of the desorption process is possible with only a few macroscopic variables.

To derive an explicit expression of the rate of desorption, we restrict ourselves for the moment to nondissociative adsorption. Other systems will be dealt with later. We look at a situation where the gas phase pressure of a molecular species, P, is different from its value, $\overline{P}$, the equilibrium pressure needed to have a coverage θ at temperature T. There is then an excess flux to re-establish equilibrium between gas phase and adsorbate, so that we can write [31.3–6]

$$\frac{\mathrm{d}\theta}{\mathrm{d}t} = S(\theta, T)(P - \overline{P})\frac{a_\mathrm{s}\lambda_\mathrm{th}}{h}\,, \tag{31.1}$$

where

$$\lambda_\mathrm{th} = \frac{h}{(2\pi m k_\mathrm{B} T)^{1/2}} \tag{31.2}$$

is the thermal wavelength, a_s is the area of one adsorption cell, and h is Planck's constant. Next, we express the equilibrium pressure in terms of the gas-phase chemical potential, μ_g,

$$\overline{P} = \frac{k_\mathrm{B}T}{\lambda_\mathrm{th}^3} Z_\mathrm{int} \mathrm{e}^{\mu_\mathrm{g}/(k_\mathrm{B}T)}\,. \tag{31.3}$$

Here, Z_int is the intramolecular partition function accounting for rotations and vibrations. However, in equilibrium, the chemical potential in the gas phase is equal to that in the adsorbate, μ_a, so that we can write the desorption rate in (31.1) as

$$R_\mathrm{d} = S(\theta, T)\frac{a_\mathrm{s}^2}{\lambda_\mathrm{th}}\frac{k_\mathrm{B}T}{h} Z_\mathrm{int} \mathrm{e}^{\mu_\mathrm{a}/(k_\mathrm{B}T)}\,. \tag{31.4}$$

This is the principal result for the rate of desorption from an adsorbate that remains in quasi-equilibrium throughout desorption. Noteworthy is the clear separation into a dynamic factor, the sticking coefficient $S(\theta, T)$ and a thermodynamic factor involving single-particle partition functions and the chemical potential

of the adsorbate. The sticking coefficient is a measure of the efficiency of energy transfer in adsorption. Since energy supply from the substrate is required for desorption, the sticking coefficient, albeit usually at a higher temperature, must appear in the desorption rate as well by the detailed balance argument. The sticking coefficient cannot be obtained from thermodynamic arguments but must be calculated from a microscopic or mesoscopic theory, or be postulated in a phenomenological approach, based on experimental evidence for a particular system.

For dissociative adsorption [31.7], i.e., for systems in which the gas phase is predominantly molecules that dissociate into fragments A and B on the surface (not necessarily atoms), the desorption rate is given by

$$R_{\mathrm{d}}(\mathrm{A}+\mathrm{B}\rightarrow\mathrm{AB}) = S_{\mathrm{dis}}(\theta_{\mathrm{A}},\theta_{\mathrm{B}},T)\frac{a_{\mathrm{s}}^2}{\lambda_{\mathrm{th}}} \times \frac{k_{\mathrm{B}}T}{h} Z_{\mathrm{int}}^{(\mathrm{A})} Z_{\mathrm{int}}^{(\mathrm{B})} \mathrm{e}^{(\mu_{\mathrm{A}}+\mu_{\mathrm{B}})/(k_{\mathrm{B}}T)} , \tag{31.5}$$

where $S_{\mathrm{dis}}(\theta_{\mathrm{A}},\theta_{\mathrm{B}},T)$ is the dissociative sticking coefficient at the indicated partial coverages and at the desorption temperature.

This approach is adaptable to more complicated systems, such as multilayer growth and reactive processes, provided that the individual species remain in local equilibrium, allowing, of course, for dissociation and reaction disequilibria.

31.2.1 Lattice-Gas Models

Most microscopic theories of adsorption and desorption are based on the lattice–gas model. One assumes that the surface of a solid can be divided into two-dimensional cells, labeled i, for which one introduces microscopic variables $n_i = 1$ or 0, depending on whether or not cell i is occupied by an adsorbed gas particle. (The connection with magnetic systems is made by a transformation to spin variables $\sigma_i = 2n_i - 1$.) In its simplest form, a lattice–gas model is restricted to the submonolayer (ML) regime and to gas–solid systems, in which the surface structure and the adsorption sites do not change as a function of coverage. To introduce the dynamics of the system, one writes a model Hamiltonian, which, for the simplest system of a one-component adsorbate with one adsorption site per unit cell, is

$$H = E_{\mathrm{s}}\sum_i n_i + V_{1n}\sum_{\langle ij\rangle} n_i n_j + V_{2n}\sum_{\langle ij'\rangle} n_i n_{j'} + \ldots \tag{31.6}$$

Here, E_{s} is a single-particle energy, and V_{1n} and V_{2n} are the two-particle interactions between nearest neighbors $\langle ij\rangle$ and next-nearest neighbors $\langle ij'\rangle$, respectively. Interactions between farther neighbors and many-particle interactions can be easily added. As long as the (average) number of particles in the adsorbate does not change, which is the case for systems in equilibrium, or for diffusion studies, the first term in (31.6) is constant and can be dropped from further consideration. However, if we want to study adsorption–desorption kinetics, the number of particles in the adsorbate changes as a function of time, and a proper identification of E_{s} is mandatory. Arguing that the lattice–gas Hamiltonian should give the same Helmholtz free energy as a microscopic Hamiltonian (for noninteracting particles), one can show that the proper identification is given by

$$E_{\mathrm{s}} = -V_0 - k_{\mathrm{B}}T\ln(q_3 q_{\mathrm{int}}) , \tag{31.7}$$

where V_0 is the (positive) binding energy of an isolated particle on the surface. Moreover,

$$q_3 = q_z q_{xy} \tag{31.8}$$

is the vibrational partition function of an adsorbed particle with (in the harmonic approximation)

$$q_z = \frac{\mathrm{e}^{h\nu_z/(2k_{\mathrm{B}}T)}}{\mathrm{e}^{h\nu_z/(k_{\mathrm{B}}T)}-1} \tag{31.9}$$

its component for the motion perpendicular to the surface. Likewise, q_{xy} is the partition function for the motion parallel to the surface. We have also made adjustment for the fact that the internal partition function for rotations and vibrations of an adsorbed molecule might be changed from its free gas-phase value Z_{int} to q_{int}, if some of the internal degrees of freedom become frozen out or frustrated.

31.2.2 Chemical Potential

Equations (31.1), (31.4), and (31.5) show that to determine the equilibrium properties of an adsorbate and also the adsorption–desorption and dissociation kinetics under quasi-equilibrium conditions, we need to calculate the chemical potential as a function of coverage and temperature. The simplest case is a single-component adsorbate. The case of dissociative equilibrium with both atoms and molecules present on the surface has been reported elsewhere [31.7].

For a noninteracting molecular adsorbate, the chemical potential is given by

$$\mu_{\mathrm{a}}(\theta,T) = -V_0 + k_{\mathrm{B}}T\left[\ln\left(\frac{\theta}{1-\theta}\right) - \ln(q_3 q_{\mathrm{int}})\right] . \tag{31.10}$$

Inserted into (31.3) this gives the Langmuir isotherm

$$\overline{P} = \frac{k_B T}{\lambda_{th}^3} Z_{int} e^{\mu_a/(k_B T)} = \frac{k_B T}{\lambda_{th}^3} \frac{Z_{int}}{q_3 q_{int}} e^{-V_0/(k_B T)} \frac{\theta}{1-\theta} , \tag{31.11}$$

from which we get the isosteric heat of adsorption

$$\begin{aligned} Q_{iso}(\theta, T) &= k_B T \left. \frac{\partial \ln \overline{P}}{\partial T} \right|_\theta \\ &= V_0 + \frac{5}{2} k_B T - k_B T^2 \frac{\partial}{\partial T} \ln \left(\frac{q_3 q_{int}}{Z_{int}} \right) \end{aligned} \tag{31.12}$$

and the differential entropy

$$\Delta s(\theta, T) = \overline{s} - s_G = -k_B \ln \left(\frac{\overline{P}}{P_0} \right) - Q_{iso}(\theta, T) , \tag{31.13}$$

where

$$\overline{s} = \left. \frac{\partial S}{\partial n} \right|_{T,P,A} \tag{31.14}$$

is the differential entropy of the adsorbate and s_G that of the gas phase; P_0 is the pressure of the reference state.

Similarly, we obtain the rate of desorption

$$R_d = S(\theta, T) \frac{\theta}{1-\theta} \frac{a_s}{\lambda_{th}^2} \frac{k_B T}{h} \frac{Z_{int}}{q_3 q_{int}} e^{-V_0/(k_B T)} . \tag{31.15}$$

Note that if sticking is controlled by site exclusion only, i.e., if $S(\theta, T) = S_0(T)(1-\theta)$, this rate is that of a first-order reaction at low coverage. This simple picture breaks down when either the sticking coefficient depends differently on the coverage, as it does, for instance, for precursor-mediated adsorption, or when lateral interactions become important. It then does not make much physical sense to talk about the order of the desorption process.

To gain some qualitative insight into the effect of lateral interactions, it is useful to employ simple analytical approximations in the calculation of the chemical potential of which the quasichemical approximation is the best suited. We split the chemical potential into a noninteracting part (31.10) and a term due to lateral interactions, $\mu_a = \mu_a^{(ni)} + \mu_a^{(lat)}$, and obtain for the latter, for c nearest-neighbor interactions only,

$$\mu_a^{(lat)}(\theta, T) = c V_{1n} + \frac{1}{2} c k_B T \ln \left(\frac{\alpha - 1 + 2\theta}{\alpha + 1 - 2\theta} \frac{1-\theta}{\theta} \right) , \tag{31.16}$$

where

$$\alpha^2 = 1 - 4\theta(1-\theta) \left[1 - e^{-V_{1n}/(k_B T)} \right] . \tag{31.17}$$

This adds to the isosteric heat, which now reads

$$Q_{iso}(\theta, T) = Q_{iso}(0, T) + \frac{1}{2} c V_{1n} \left(\frac{1 - \alpha - 2\theta}{\alpha} \right) . \tag{31.18}$$

For a large repulsive interaction, $V_{1n}/(k_B T) \gg 1$, Q_{iso} exhibits two distinct and essentially constant values for $\theta \lessgtr 1/2$, because for $\theta < 1/2$, adsorbed particles are essentially isolated from each other by the mutual repulsion on nearest-neighbor sites, whereas, for $\theta > 1/2$, those particles that have c neighbors have their binding energy reduced by cV_{1n}. The consequence of this energetics on desorption is that in temperature-programmed desorption, one observes one desorption peak for initial coverages $\theta_0 < 1/2$, essentially that of a noninteracting adsorbate, and, for initial coverages $\theta > 1/2$, an additional peak at lower temperature for desorption out of a local environment of c neighbors.

Such analytic approximations based on clusters of particles quickly become mathematically intractable with variation in cluster size, geometry, and range of interactions [31.8, 9].

31.2.3 Transfer-Matrix Method

With the availability of computers, the transfer-matrix method [31.10] emerged as an alternative and powerful technique for the study of the cooperative phenomena of adsorbates resulting from interactions [31.11, 12]. Quantities are calculated exactly on a semi-infinite lattice. Coupled with finite-size scaling towards the infinite lattice, the technique has proved popular for the determination of phase diagrams and critical-point properties of adsorbates ([31.13–19] and magnetic spin systems [31.20–22], and further references therein). Application to other aspects of adsorbates, e.g., the calculation of desorption rates and heats of adsorption, has been more recent [31.23–26]. Sufficient accuracy can usually be obtained for the latter without scaling and essentially exact results are possible. In the following, we summarize the elementary but important aspects of the method to emphasize the ease of application. Further details can be found in the above references.

To introduce the transfer-matrix method, we repeat some well-known facts for a 1-D (one-dimensional) lattice gas of N_s sites with nearest-neighbor interactions, V_{1n} [31.27]. Its grand canonical partition function is

given by

$$\Xi(T,N_\mathrm{s},\mu)=\sum_{\boldsymbol{n}}\mathrm{e}^{-[H(\boldsymbol{n})-\mu N(\boldsymbol{n})]/(k_\mathrm{B}T)}\,, \tag{31.19}$$

$$N(\boldsymbol{n})=\sum_{i=1}^{N_\mathrm{s}} n_i\,, \tag{31.20}$$

where $\boldsymbol{n}=(n_1,n_2,\ldots,n_{N_\mathrm{s}},n_{N_\mathrm{s}+1}=n_1)$ specifies one of the 2^{N_s} microstates of the (two-state) adsorbate, with cyclic boundary conditions imposed. Substituting the Hamiltonian (31.6), we can rewrite Ξ as a sum over products

$$\begin{aligned}\Xi&=\sum_{\boldsymbol{n}}\prod_{i=1}^{N_\mathrm{s}}T(n_i,n_{i+1})\,,\\&=\sum_{\boldsymbol{n}}T(n_1,n_2)T(n_2,n_3)\ldots T(n_{N_\mathrm{s}},n_1)\,,\end{aligned} \tag{31.21}$$

$$T(n_i,n_{i+1})=\exp\left[\frac{\varepsilon}{2}(n_i+n_{i+1})-\upsilon n_i n_{i+1}\right], \tag{31.22}$$

with

$$\varepsilon=\frac{\mu-E_\mathrm{s}}{k_\mathrm{B}T}\quad\text{and}\quad\upsilon=\frac{V_{1n}}{k_\mathrm{B}T}\,.$$

If the factors $T(n_i,n_{i+1})$ are regarded as the elements of a 2×2 matrix in the basis $\{|0\rangle,|1\rangle\}$ for each site i ($z=\exp(\varepsilon)$; $y=\exp(-\upsilon)$)

$$\mathbf{T}=\begin{pmatrix}T(0,0)&T(0,1)\\T(1,0)&T(1,1)\end{pmatrix}=\begin{pmatrix}1&z^{1/2}\\z^{1/2}&zy\end{pmatrix}\,, \tag{31.23}$$

then the summation over states in (31.21) is equivalent to matrix multiplication, e.g.,

$$\sum_{n_2=0,1}T(n_1,n_2)T(n_2,n_3)=T^2(n_1,n_3)\,, \tag{31.24}$$

where $T^2(n_1,n_3)$ is an element of the matrix $\mathbf{T}^2$. Summing over all intermediate states gives

$$\begin{aligned}\Xi&=\sum_{n_1=0,1}T^{N_\mathrm{s}}(n_1,n_1)=\mathrm{tr}[\mathbf{T}^{N_\mathrm{s}}]\\&=\lambda_1^{N_\mathrm{s}}+\lambda_2^{N_\mathrm{s}}\,,\end{aligned} \tag{31.25}$$

where $\lambda_{1,2}$ are the eigenvalues of the transfer-matrix $\mathbf{T}$. With $\lambda_2<\lambda_1$ the second term becomes insignificant for *large* N_s, so that all thermodynamic information about the system is contained in the largest eigenvalue of the transfer matrix.

One obtains the coverage as

$$\begin{aligned}\theta(T,\mu)&=\frac{\langle N\rangle}{N_\mathrm{s}}=\frac{1}{N_\mathrm{s}}\left.\frac{\partial\ln\Xi}{\partial(\beta\mu)}\right|_{T,N_\mathrm{s}}\\&=\left.\frac{\partial\ln(\lambda_1)}{\partial(\beta\mu)}\right|_{T,N_\mathrm{s}}\,,\end{aligned} \tag{31.26}$$

with

$$\beta=\frac{1}{k_\mathrm{B}T}\,.$$

To avoid numerical differentiation (which is inherently unstable) one uses the fact that an eigenvalue can be expressed as $\lambda_1=\boldsymbol{v}_1^\mathrm{L}\mathbf{T}\boldsymbol{v}_1^\mathrm{R}$, where $\boldsymbol{v}_1^{\mathrm{L,R}}$ are the corresponding normalized left and right eigenvectors. Differentiation of the eigenvalue with respect to any parameter is then equivalent to the differentiation of the transfer matrix, and one finds

$$\begin{aligned}\theta(T,\mu)&=\frac{z}{\lambda_1}\boldsymbol{v}^\mathrm{L}\left.\frac{\partial\mathbf{T}}{\partial z}\right|_{T,N_\mathrm{s}}\boldsymbol{v}^\mathrm{R}\\&=\sum_{k=1,2}p_k v_{1k}^2\,,\end{aligned} \tag{31.27}$$

where $\boldsymbol{v}_1^\mathrm{L}=(\boldsymbol{v}_1^\mathrm{R})^\mathrm{T}=\boldsymbol{v}_1=(v_{11},v_{12})$ in the basis in which the first and second components are the empty ($p_1=0$) and occupied ($p_2=1$) sites, respectively. Thus, the problem of finding the coverage as a function of temperature and chemical potential is reduced to the determination of the (largest) eigenvalue and corresponding eigenvector of a matrix of Boltzmann factors. Other information can be readily extracted in the same way, for instance, the (average) nearest-neighbor correlation function is given by

$$\begin{aligned}\langle n_i n_{i+1}\rangle&=\frac{1}{N_\mathrm{s}\Xi}\sum_{\boldsymbol{n}}\sum_{i=1}^{N_\mathrm{s}}n_i n_{i+1}\mathrm{e}^{-[H(\boldsymbol{n})-\mu N(\boldsymbol{n})]/(k_\mathrm{B}T)}\\&=-\frac{1}{N_\mathrm{s}}\left.\frac{\partial\ln\Xi}{\partial(\beta V_{1n})}\right|_{T,N_\mathrm{s}}=\frac{y}{\lambda_1}\boldsymbol{v}^\mathrm{L}\left.\frac{\partial\mathbf{T}}{\partial y}\right|_{T,N_\mathrm{s}}\boldsymbol{v}^\mathrm{R}\,.\end{aligned} \tag{31.28}$$

The transfer-matrix method extends rather straightforwardly to more than one dimension, systems with multiple interactions, more than one adsorption site per unit cell, and more than one species by enlarging the basis in which the transfer matrix is defined. Explicit details are given elsewhere [31.28]. The construction of the transfer matrices and associated numerical procedures is essentially the same for these systems, and such calculations are done routinely [31.29]. If

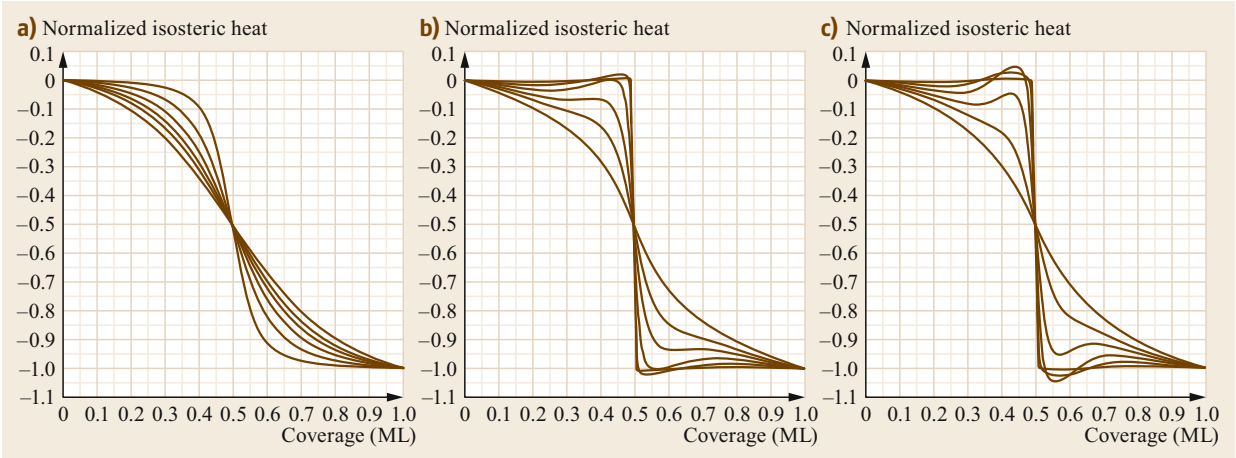

Fig. 31.1a–c Normalized isosteric heat, $(Q_{\mathrm{iso}}(\theta,T)-Q_{\mathrm{iso}}(0,T))/4V_{1n}$, as a function of coverage for first-neighbor repulsion on a square lattice, for temperatures (*top to bottom* at 0.2 ML) $k_{\mathrm{B}}T/V_{1n}=0.25$, 0.35, 0.45, 0.55, 0.65, and 0.85. **(a)** Quasichemical approximation, see (31.16); **(b)** transfer-matrix result for $M=4$; and **(c)** for $M=8$

there are two or more nonreacting (but interacting) species on the surface, then the partial coverages depend on the chemical potentials specified for each species.

As an example of the quality of the quasichemical approximation versus the transfer-matrix method, in Fig. 31.1 we show the isosteric heat for repulsive first-neighbor interactions on a square lattice [31.25].

31.3 Examples

Our first example of the utility of the theoretical approach to thermal desorption kinetics is a study of the thermodynamics and adsorption and desorption kinetics of hydrogen on Rh(311) obtained from an anisotropic lattice–gas model [31.30].

31.3.1 Adsorption and Desorption of Hydrogen on Rh(311)

Understanding this complex system will also allow us to make predictions (without any further information) for hydrogen adsorption on the Rh(110) and Rh(111) surfaces. For the Rh(311) surface, we need to consider three and fourfold coordinated adsorption sites, first-neighbor attraction along the closed-packed $[01\bar{1}]$-direction, and first and second-neighbor and trio repulsions in the $[1\bar{1}\bar{2}]$-direction to account for $(1\times n)$ structures at coverages $\theta=1/4$, $1/3$, $1/2$ and $2/3$, as shown in Fig. 31.2 [31.30].

In Fig. 31.3, we give the experimental and the best-fit theoretical TPD curves, which show very good agreement [31.30].

LEED intensities were also measured during desorption (Fig. 31.4) [31.30]. Because they are proportional to the square of density–density correlations, and the latter can be calculated from the transfer matrix, simultaneously with the chemical potential, one can further elucidate the structures and show their influence on TPD. The two-site correlators of interest are

$$C_k=\langle n_{rc}n_{r,c+k}\rangle\,, \tag{31.29}$$

which for $k=1,2,3$ give the probabilities of finding first, second and third-neighbor sites occupied in the $[1\bar{1}\bar{2}]$-direction. For a completely disordered adsorbate, these correlators have the value θ^2. At sufficiently low temperature, they attain the values $(C_1,C_2,C_3)=(0,0,1/3)$, $(0,1/2,0)$ and $(1/3,1/3,2/3)$ at $\theta=1/3$, $1/2$, and $2/3$ for the 1×3-H, 1×2-H and 1×3-2H structures of Fig. 31.2, respectively.

The LEED intensities are calculated from

$$I(\boldsymbol{k},T)=I_0\sum_{i,j=1}^{M}\langle n_in_j\rangle \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot(\boldsymbol{r}_i-\boldsymbol{r}_j)} \tag{31.30}$$

in terms of two-particle correlators. Because of the attraction in the $[01\bar{1}]$-direction, the correlators do not crucially depend on the interparticle spacings in this direction. Ordering is, therefore, mainly reflected in the variation of the correlators in the $[1\bar{1}\bar{2}]$-direction and,

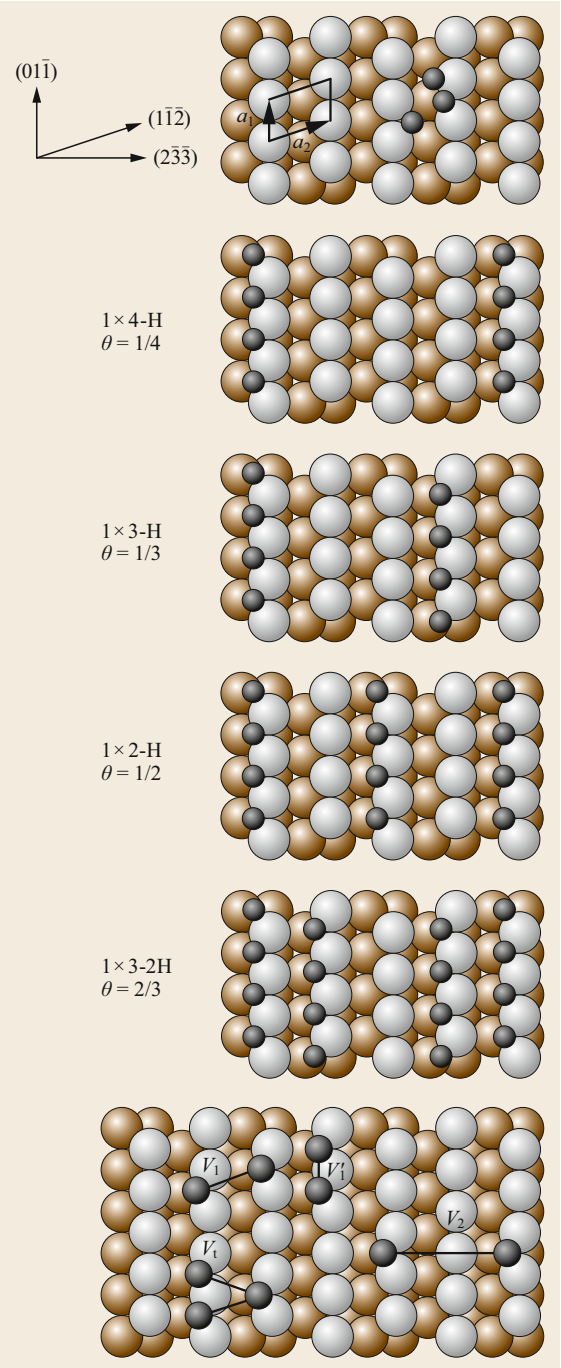

Fig. 31.2 Ordered structures of hydrogen on Rh(311) and model interactions

consequently, we can simplify the calculation and use the two-site correlators calculated in the finite direction of the transfer matrix. The experimental LEED intensities for third-order and half-order spots are reproduced by theory without any further adjustments in the lattice–gas Hamiltonian used to fit the TPD spectra (Fig. 31.4) [31.30].

Because the Rh(311) surface can be thought of as consisting of portions of (111) and (110) surfaces, the lattice–gas model for the (311) surface contains all the necessary parameters for these surfaces as well. Thus, without any further fitting, one can immediately calculate the TPD spectra for these surfaces as well. It turns out to be an excellent fit to the corresponding experimental data [31.30]. This again demonstrates the power of a theoretical approach that is geared to explain *all* available data, thermodynamic and kinetic, on a system; in this case, hydrogen adsorption on three different Rh surfaces.

31.3.2 Coupled Desorption and Site Conversion of Coadsorbates: (NO+O)/Ru(001)

The (NO+O)/Ru(001) system constitutes a good example of complex desorption-site conversion with the advantage that the geometrical structures, the coverages, as well as detailed spectroscopic information on all participating species are available experimentally. A combined set of desorption data and vibrational spectra with in situ determination of partial coverages in desorption that show site conversion for both increasing and decreasing temperatures. This system is understood in detail by modeling the (NO+O) coadsorbate layer on Ru(001) as a lattice gas that accounts for the adsorbate structure and site conversion, and explains the TPD spectra [31.31]. The unusual features of the TPD spectra result in part from the dramatic coverage dependence of the sticking coefficient induced by site exclusion.

It has been found that ≈ 0.5 ML of NO (relative to Ru surface atoms) can be postadsorbed within the (2×1)-O/Ru(001) layer at $\theta_O = 0.5$ ML. For this combined (NO+O) coverage of 1 ML both O and NO reside in hcp-hollow sites, arranged in alternating close-packed O and NO rows (Fig. 31.5) [31.31].

The detailed geometry has been determined by LEED-IV [31.32]. Heating of the layer (at $1\,\mathrm{K\,s^{-1}}$) leads to NO desorption at 250–350 K in a broad peak until 0.25 ML NO is left on the surface (Fig. 31.6); no oxygen leaves the surface in this range. LEED-IV analysis of the remaining layer shows that now the oxygen atoms sit in equal numbers of hcp and fcc sites in a honeycomb arrangement, and the NO molecules sit in on-top sites at the centers of the O hexagons (Fig. 31.5). It appears probable that the conversion of oxygen-site occupancy occurs simultaneously with desorption of half the initial NO coverage. Only upon further heating

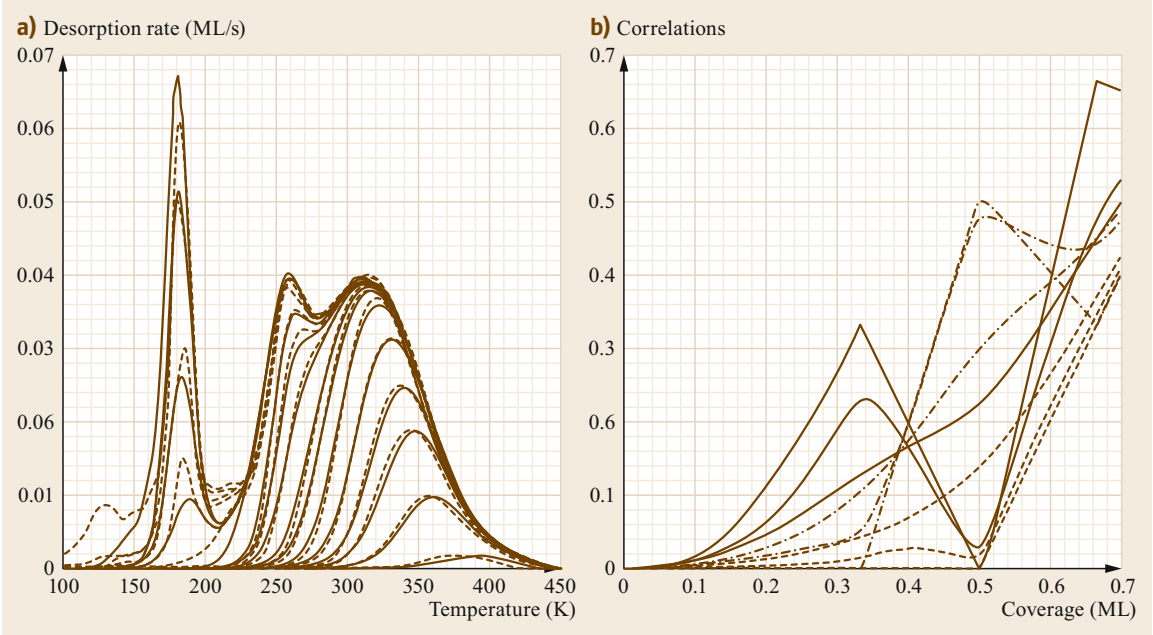

Fig. 31.3 **(a)** Model TPD spectra (*solid lines*) and experimental data (*dashed lines*) for H on Rh(311) for initial coverages in the range 0.01−0.68 ML. Heating rate 10 K/s. Surface-energy parameters: $V_0 = 2.647\,\text{eV}$, $V'_{1n} = -0.029\,\text{eV}$, $V_{1n} = 0.035\,\text{eV}$, $V_{2n} = 0.022\,\text{eV}$, $V_{\text{trio}} = 0.011\,\text{eV}$; vibrational frequencies $2\times10^{13}\,\text{s}^{-1}$, $1.3\times10^{13}\,\text{s}^{-1}$, $5\times10^{10}\,\text{s}^{-1}$; site area $a_s = 12A^2$; dissociation energy $D_0 = 4.478\,\text{eV}$; $T_{\text{vib}} = 6332\,\text{K}$, $T_{\text{rot}} = 87.6\,\text{K}$. **(b)** Isothermal correlators as a function of coverage for temperatures 350, 220, and 100 K (with sharpest features at lowest temperature): C_1 (*dotted line*), C_2 (*long-short dashed line*), and C_3 (*solid line*)

to 420 K is more NO released in a very narrow temperature interval. The oxygen atoms, none of which desorb, return to their original (2×1)-O arrangement at hcp sites. These coupled phenomena constitute a good example of complex desorption with site conversion, with the advantage that the geometrical structures, the coverages, as well as detailed spectroscopic information on all participating species are well known. In particular, vibrational spectra for in-situ determination of partial coverages have been measured not only in desorption and conversion for increasing temperatures, but also for the reverse process. We have studied this system in detail with a suitable theoretical model for desorption, the results of which are compared with the experimental data.

The (NO+O) coadsorbate layer on Ru(001) was modeled as a lattice gas that will account for the adsorbate structure and explain the TPD spectra. To reduce the complexity of the system to manageable proportions the quarter monolayer of O in a was fixed in a (2×2) structure at the hcp sites of a hexagonal lattice. The remaining quarter monolayer of O can sit either on hcp sites to form a (2×1)-O superlattice or on neighboring fcc sites with a weaker binding energy. The NO sits either on the empty rows of hcp sites between the rows of the (2×1)-O structure or on neighboring on-top sites. Lateral interactions of the coadsorbates are mainly those of mutual site exclusion, but long-range repulsive (dipole–dipole) interactions must also be accounted for.

As for the kinetics it was kept as simple as possible but sufficient to account for the main features of desorption and site conversion. Rather than resorting to a complex kinetic lattice–gas model (for which more experimental data would be needed to fix all the parameters) a simple model was used that ignores the details of lateral interactions but includes them summarily in a mean field theory accounting, most importantly, for long-range dipolar forces. An important fact to understand is the coverage dependence of the sticking coefficient, calculated in the framework of a kinetic lattice–gas model, drops dramatically by several orders of magnitude beyond a quarter monolayer of NO. This delays desorption (the desorption rate contains the sticking coefficient!) of the last quarter of NO until it finally blows off explosively in a very narrow temperature range (Fig. 31.6) [31.31].

More work in the NO plus O adsorbate can be found in a follow-up paper [31.33]. Additional applications of the transfer-matrix method to adsorption and desorption kinetics deal with other molecules on low index metal

surfaces [31.34–40], multilayers [31.41–43], multisite stepped surfaces [31.44], and co-adsorbates [31.31, 45–53].

A similar approach has been used to study dissociative adsorption and associative desorption [31.54, 55].

31.4 Kinetic Lattice-Gas Models

If it cannot be guaranteed that the adsorbate remains in local equilibrium during its time evolution, then a set of macroscopic variables is not sufficient, and an approach based on nonequilibrium statistical mechanics involving time-dependent distribution functions must be invoked. The kinetic lattice–gas model is an example of such a theory [31.56]. It is derived from a Markovian master equation, but is not totally microscopic in that it is based on a phenomenological Hamiltonian. We demonstrate this approach with two examples: (i) an adsorbate with nondissociative adsorption, and (ii) precursor-mediated adsorption and desorption. Our basic assumption is that the kinetic phenomena of adsorption, desorption, and surface diffusion can be described as Markov processes, with the occupation numbers in the Hamiltonian (31.6) as stochastic variables.

31.4.1 Nondissociative Adsorption

We introduce a function $P(\boldsymbol{n}, t)$, which gives the probability that the state $\boldsymbol{n} = (n_1, n_2, \ldots, n_{N_s})$ is realized at time t, where N_s is now the total number of adsorption sites on the surface. It satisfies a master equation

$$\frac{\mathrm{d}P(\boldsymbol{n}, t)}{\mathrm{d}t} = \sum_{\boldsymbol{n}'} [W(\boldsymbol{n}, \boldsymbol{n}')P(\boldsymbol{n}', t) - W(\boldsymbol{n}', \boldsymbol{n})P(\boldsymbol{n}, t)] \,, \tag{31.31}$$

where $W(\boldsymbol{n}', \boldsymbol{n})$ are the transition probabilities per unit time that the system changes from a state $\boldsymbol{n}$ to $\boldsymbol{n}'$. They are not completely arbitrary but must satisfy detailed balance

$$W(\boldsymbol{n}', \boldsymbol{n}) \mathrm{e}^{-\beta\left[H(\boldsymbol{n}) - \mu \sum_{i(\boldsymbol{n})} n_i\right]} = W(\boldsymbol{n}, \boldsymbol{n}') \mathrm{e}^{-\beta\left[H(\boldsymbol{n}') - \mu \sum_{i(\boldsymbol{n}')} n_i'\right]} \,. \tag{31.32}$$

To specify these transition probabilities we make the further assumption that the residence time of a particle in a given adsorption site is much longer than the time of an individual transition to or from that state, either in exchange with the gas phase in adsorption and desorption, or for hopping across the surface in diffusion. In such situations there will be only one individual transition at any instant of time, and the transition probabilities can be summed, one at a time, over all possible processes (adsorption, desorption, diffusion) and over all adsorption sites on the surface. To implement this, we first write

$$W(\boldsymbol{n}', \boldsymbol{n}) = W_{\text{ad-des}}(\boldsymbol{n}', \boldsymbol{n}) + W_{\text{diff}}(\boldsymbol{n}', \boldsymbol{n}) \tag{31.33}$$

as a sum of adsorption–desorption and diffusion terms. For the former, we then write the most general power series in the occupation numbers [31.57]

$$\begin{aligned} &W_{\text{ad-des}}(\boldsymbol{n}', \boldsymbol{n}) \\ &= w_0 \sum_l \left[(1-n_l) \left(1 + A_1 \sum_{l'} n_{l'} + A_2 \sum_{l'l''} n_{l'} n_{l''} + \ldots \right) \right. \\ &\quad \left. + D_0 n_l \left(1 + D_1 \sum_{l'} n_{l'} + D_2 \sum_{l'l''} n_{l'} n_{l''} + \ldots \right) \right] \\ &\quad \times \delta\left(n'_l, 1-n_l\right) \prod_{l' \neq l} \delta(n'_l, n_l) \, . \end{aligned} \tag{31.34}$$

Here the sums over l', l'' run over the neighbors of l. The highest term is a product of $(c+1)$ factors with c the coordination number of the lattice.

Detailed balance imposes a set of restrictions on the coefficients A_n, D_n; e.g., if there is only one adparticle present, say in site i, so that $n_i = 1$ and all other $n_j = 0, j \neq i$, then (31.43) gives

$$w_0 D_0 \mathrm{e}^{-E_\mathrm{s}/(k_\mathrm{B}T)} = w_0 \, , \tag{31.35}$$

so that

$$D_0 = \mathrm{e}^{\beta(E_\mathrm{s}-\mu)} \, . \tag{31.36}$$

Note that w_0 cannot be fixed by detailed balance, the reason being that it contains the information about the energy exchange with the solid, which is not contained in the static lattice–gas Hamiltonian. However, by comparison with the phenomenological rate equation (31.1), we can identify it as

$$w_0 = S_0 \frac{P \lambda_{\text{th}} a_\mathrm{s}}{h} \, . \tag{31.37}$$

To obtain the other coefficients we next specify that two particles are adsorbed on neighboring sites, $n_i = n_{i+a} = 1$, with all other sites empty and obtain

$$1 + A_1 = (1 + D_1)\mathrm{e}^{-\beta V_{1n}} \, . \tag{31.38}$$

From situations where three and four neighboring sites are occupied we obtain, respectively,

$$1 + 2A_1 + A_2 = (1 + 2D_1 + D_2)\mathrm{e}^{-2\beta V_{1n}} \, , \tag{31.39}$$

$$1 + 3A_1 + 3A_2 + A_3 = (1 + 3D_1 + 3D_2 + D_3)\mathrm{e}^{-3\beta V_{1n}} \, , \tag{31.40}$$

and so on, for a total of c constraints (and nearest-neighbor interactions only). If longer-ranged interactions are included, this introduces further coefficients and half as many further constraints.

The fact that detailed balance provides only half the number of constraints to fix the unknown coefficients in the transition probabilities is not really surprising considering that, if it would fix them all, then the static (lattice–gas) Hamiltonian would dictate the kind of kinetics possible in the system. Again, this cannot be because this Hamiltonian does not include the energy-exchange dynamics between adsorbate and substrate. As a result, any functional relation between the A and D coefficients in (31.34) must be postulated ad hoc (or calculated from a microscopic Hamiltonian that accounts for coupling of the adsorbate to the lattice or electronic degrees of freedom of the substrate). Several scenarios have been discussed in the literature [31.57].

The simplest choice is to set all $A_i = 0$ in (31.34). Physically, this means that an adsorbing particle will not experience any interactions with its prospective neighbors and sticking is solely controlled by the availability of sites. Thus, the sticking coefficient becomes (for $A_i = 0$)

$$S(\theta, T) = S_0(T)(1-\theta) \, . \tag{31.41}$$

The sticking coefficient at zero coverage, $S_0(T)$, contains the dynamic information about the energy transfer from the adsorbing particle to the solid, which gives rise to its temperature dependence, for instance, an exponential Boltzmann factor for activated adsorption.

The desorption kinetics are thus specified by

$$D_\mathrm{r} = \left(\mathrm{e}^{\beta V_{1n}} - 1\right)^r \tag{31.42}$$

for $r = 1$–c. Because $(\mathrm{e}^\alpha - 1)n = \mathrm{e}^{n\alpha} - 1$ for $n = 0, 1$, we can rewrite (31.34) as

$$\begin{aligned} &W_{\text{ad-des}}(\boldsymbol{n}', \boldsymbol{n}) \\ &= w_0 \sum_l \left[(1-n_l) + D_0 n_l \exp\left(\beta V_{1n} \sum_j n_l n_j \right) \right] \\ &\quad \times \delta\left(n'_l, 1-n_l\right) \prod_{l' \neq l} \delta\left(n'_l, n_l\right) , \end{aligned} \tag{31.43}$$

implying that the local environment enters the desorption rate via a Boltzmann factor. This kind of kinetics has been termed Langmuir kinetics; it contains simple desorption kinetics and trivial adsorption due to site exclusion only. This interconnection between adsorption and desorption is dictated by the principle of detailed balance: if an adsorption system with nondissociative adsorption does not show the linear decrease of sticking as a function of coverage, then its desorption kinetics is most likely also not controlled by (31.51); if direct sticking and desorption are still maintained, then Langmuir kinetics must be abandoned. (Precursors, i.e., nondirect adsorption and desorption, can also alter the kinetics, and this will be discussed below.)

Insisting on the Langmuir kinetics is overly restrictive because in most systems sticking is not controlled by site exclusion only. Because the energy transfer in the adsorption process takes place within angstroms of the surface, the adsorbing particle actually experiences the interaction with particles already adsorbed on neighboring sites in more or less the same way as desorbing particles do, i.e., a lateral repulsion (attraction) will aid (hinder) desorption (desorption). Thus, making the effect of lateral interactions symmetric for adsorption and desorption, one would set $A_\mathrm{r} = -D_\mathrm{r}$; we have called this the interaction kinetics. More generally, one can assume a linear relationship (although this is only dictated by arguments of simplicity) and find

$$A_\mathrm{r} = \gamma_\mathrm{C} D_\mathrm{r} \tag{31.44}$$

$$D_\mathrm{r} = \frac{\mathrm{e}^{r\beta V_{1n}} - 1}{1 - \gamma_\mathrm{C}\mathrm{e}^{r\beta V_{1n}}} - \binom{r}{1} D_1 - \binom{r}{2} D_2 - \ldots - \binom{r}{r-1} D_{r-1} \,. \tag{31.45}$$

This completes the adsorption–desorption kinetics.

Turning next to diffusion we consider hopping from a site l to its neighbors $l+a$ and write

$$\begin{aligned} W_\mathrm{diff}(\boldsymbol{n}', \boldsymbol{n}) &= w_\mathrm{diff} \sum_{l,a} \Bigg[n_l (1 - n_{l+a}) \Bigg(1 + B_1 \sum_{l'} n_{l'} + B_2 \sum_{l'l''} n_{l'} n_{l''} + \ldots \Bigg) \\ &\quad \times \Bigg(1 + \widetilde{B}_1 \sum_{l'} n_{l'} + \widetilde{B}_2 \sum_{l'l''} n_{l'} n_{l''} + \ldots \Bigg) \Bigg] \\ &\quad \times \delta\left(n'_l, 1 - n_l\right) \delta\left(n'_{l+a}, 1 - n_{l+a}\right) \prod_{l' \neq l, i+a} \delta\left(n'_l, n_l\right) . \end{aligned} \tag{31.46}$$

The individual hopping rate (per unit time) is given by w_diff, which most likely contains a Boltzmann factor to account for an activation barrier to diffusion. The sums over l' and l'' run over the neighbors of l (with the exception of $l+a$) and $l+a$ (with the exception of l), respectively. The terms with the coefficients B_i account for the fact that hopping will be enhanced (hindered) if the particle in its initial state experiences a repulsive (attractive) interaction with some neighbors. Likewise, via the terms with $\widetilde{B}_i$, hopping will be reduced (enhanced), if the particle tries to jump into a site that is surrounded by occupied sites, with which the particle will interact repulsively (attractively). Detailed balance, again, imposes conditions on these coefficients similar to those in (31.53) and (31.54) for adsorption and desorption.

To study the time evolution of the adsorbate we define the coverage

$$\theta(t) = \langle \bullet \rangle = N_\mathrm{s}^{-1} \sum_i \sum_{\boldsymbol{n}} n_i P(\boldsymbol{n}, t) \tag{31.47}$$

and obtain its equation of motion by multiplying the master equation (31.43) with n_i and summing over all sites and states. This will introduce on its right-hand side n-site correlation functions that will be site independent, if it can be assured that the adsorbate remains homogeneous throughout its time evolution. For a square lattice, as an example, we find

$$\begin{aligned} \frac{\mathrm{d}\theta}{\mathrm{d}t} = S(\theta, T) \frac{P\lambda_\mathrm{th} a_\mathrm{s}}{h} - r_\mathrm{des} \Bigg[& \langle \bullet \rangle + 4 D_1 \langle \bullet\bullet \rangle \\ & + D_2 \left(4 \left\langle \begin{matrix} \bullet & \\ \bullet & \bullet \end{matrix} \right\rangle + 2 \langle \bullet \quad \bullet \quad \bullet \rangle \right) \\ & + 4 D_3 \left\langle \begin{matrix} & \bullet & \\ \bullet & \bullet & \bullet \end{matrix} \right\rangle + D_4 \left\langle \begin{matrix} \bullet & & \\ \bullet & \bullet & \\ \bullet & & \bullet \end{matrix} \right\rangle \Bigg] , \end{aligned} \tag{31.48}$$

where we introduced a symbolic notation

$$\begin{aligned} \langle \circ \rangle &= 1 - \langle \bullet \rangle \,, \\ \langle \circ\bullet \rangle &= N_\mathrm{s}^{-1} \sum_{\boldsymbol{n}} (1 - n_i) n_{i+a} P(\boldsymbol{n}, t) \,, \\ \left\langle \begin{matrix} \bullet & \\ \bullet & \bullet \end{matrix} \right\rangle &= N_\mathrm{s}^{-1} \sum_{\boldsymbol{n}} (1 - n_i) n_{i+a} n_{i+a'} P(\boldsymbol{n}, t) \,. \end{aligned} \tag{31.49}$$

The sticking coefficient in (31.57) is given explicitly by

$$\begin{aligned} S(\theta, T) = S_0(T) \Bigg[& \langle \circ \rangle + 4 A_1 \langle \circ\bullet \rangle \\ & + A_2 \left(4 \left\langle \begin{matrix} \bullet & \\ \circ & \bullet \end{matrix} \right\rangle + 2 \langle \bullet \quad \circ \quad \bullet \rangle \right) \end{aligned}$$

$$+4A_3\left\langle \begin{smallmatrix} \bullet & \bullet \\ \circ & \bullet \end{smallmatrix} \right\rangle + A_4\left\langle \begin{smallmatrix} \bullet & \bullet \\ \circ & \bullet \end{smallmatrix} \right\rangle \Bigg] . \quad (31.50)$$

In addition to the temperature dependence of $S_0(T)$, we have the correlation functions, which also determine its coverage dependence.

The correlators (31.59) are subject to similar equations of motion involving yet higher correlators, the whole hierarchy being equivalent to the original master equation. For instance, for the two-particle correlator, we have

$$\begin{aligned}
\frac{\mathrm{d}\langle\bullet\bullet\rangle}{\mathrm{d}t} = 2S_0(T)\frac{P\lambda_{\mathrm{th}}a_{\mathrm{s}}}{h}\Bigg[& (1+A_1)\langle\circ\bullet\rangle \\
& +(A_1+A_2)\left(\langle\bullet\circ\bullet\rangle + 2\left\langle \begin{smallmatrix} \bullet & \bullet \\ \circ & \bullet \end{smallmatrix} \right\rangle\right) \\
& +3(A_2+A_3)\left\langle \begin{smallmatrix} \bullet & \bullet \\ \circ & \bullet \end{smallmatrix} \right\rangle \\
& +(A_3+A_4)\left\langle \begin{smallmatrix} \bullet & \bullet \\ \bullet & \circ \end{smallmatrix} \right\rangle\Bigg] \\
-2r_{\mathrm{des}}\Bigg[& (1+D_1)\langle\bullet\bullet\rangle \\
& +(D_1+D_2)\left(\langle\bullet\bullet\bullet\rangle + 2\left\langle \begin{smallmatrix} \bullet & \bullet \\ \bullet & \bullet \end{smallmatrix} \right\rangle\right) \\
& +3(D_2+D_3)\left\langle \begin{smallmatrix} \bullet & \bullet \\ \bullet & \bullet \end{smallmatrix} \right\rangle \\
& +(D_3+D_4)\left\langle \begin{smallmatrix} \bullet & \bullet \\ \bullet & \bullet \end{smallmatrix} \right\rangle\Bigg] .
\end{aligned} \quad (31.51)$$

To describe an arbitrary nonequilibrium evolution of the adsorbate we need the whole hierarchy or at least a suitably truncated subset. We can close the hierarchy at the level of two-site correlators by a factorization of higher correlators with one site overlap [31.58, 59]

$$\left\langle \begin{smallmatrix} \bullet & \bullet & \bullet \end{smallmatrix} \right\rangle = \left\langle \begin{smallmatrix} \bullet & \bullet \\ \bullet & \bullet \end{smallmatrix} \right\rangle = \frac{\langle\bullet\bullet\rangle^2}{\langle\bullet\rangle} , \quad (31.52)$$

$$\left\langle \begin{smallmatrix} \bullet & \bullet \\ \bullet & \bullet \end{smallmatrix} \right\rangle = \frac{\langle\bullet\bullet\rangle^3}{\langle\bullet\rangle^2} , \quad (31.53)$$

$$\left\langle \begin{smallmatrix} \bullet & \bullet \\ \bullet & \circ \end{smallmatrix} \right\rangle = \frac{\langle\bullet\circ\rangle^3}{\langle\circ\rangle^2} . \quad (31.54)$$

This is the simplest closure and corresponds, for the equilibrium solution, to the quasichemical approximation (31.16). If higher accuracy is required, one must keep larger correlators and factor with larger overlap. As an example with two-site overlap, one writes

$$\left\langle \begin{smallmatrix} \bullet & \bullet \\ \bullet & \bullet \end{smallmatrix} \right\rangle = \left\langle \begin{smallmatrix} \bullet & \bullet \end{smallmatrix} \right\rangle^2 \frac{1}{\langle\bullet\bullet\rangle} , \quad (31.55)$$

which results in three coupled nonlinear equations of motion for $\langle\bullet\rangle$, $\langle\bullet\bullet\rangle$, and $\left\langle \begin{smallmatrix} \bullet & \bullet \\ \bullet & \bullet \end{smallmatrix} \right\rangle$.

In one dimension the truncation of the equations of motion has been worked out in detail [31.59]. This has allowed an accurate examination of the role of diffusion in desorption and implications for the Arrhenius analysis in nonequilibrium situations. The largest deviations from the desorption kinetics of a mobile adsorbate obviously occur for an immobile adsorbate where surface diffusion is negligible throughout the temperature range of desorption.

Next, we explore the implications of assuming that surface diffusion is much faster than desorption, so that, during desorption, the structure of the adsorbate rearranges itself appropriately for equilibrium at the instantaneous coverage and temperature. As a result, all correlators also assume their equilibrium values and are, thus, only functions of (instantaneous) coverage and temperature. In such a system the adsorbate is thus in local or quasi-equilibrium on the surface, although during desorption there is no overall equilibrium with the three-dimensional gas phase above the adsorbate. Because for a system in quasi-equilibrium the correlators are known (equilibrium) functions of coverage and temperature, we need only one macroscopic equation to describe the time evolution. This equation has a remarkable structure. First, we note that the equilibrium solution, $\mathrm{d}\theta/\mathrm{d}t = 0$, in (31.57) gives for the chemical potential

$$\mathrm{e}^{\beta\mu} = \frac{\overline{P}}{k_{\mathrm{B}}TZ_{\mathrm{int}}}\lambda_{\mathrm{th}}^3 = \frac{\mathrm{e}^{-\beta V_0}}{q_3 q_{\mathrm{int}}}\frac{\langle\bullet\rangle + 4D_1\langle\bullet\bullet\rangle_0 + \ldots}{\langle\circ\rangle + 4A_1\langle\circ\bullet\rangle_0 + \ldots} , \quad (31.56)$$

where all correlators attain their equilibrium values, indicated by the subscript zero, and should be calculated from the (canonical or grand canonical) partition function, or equivalently from the right-hand sides of their (coupled) equations of motion.

With the help of (31.65) we can now rewrite the equation of motion for the coverage (31.57) for a system maintained in quasi-equilibrium by fast surface diffusion as

$$\frac{\mathrm{d}\theta}{\mathrm{d}t} = S(\theta,T)\frac{a_{\mathrm{s}}\lambda_{\mathrm{th}}}{h}P - S(\theta,T)\frac{a_{\mathrm{s}}}{\lambda_{\mathrm{th}}^2}\frac{k_{\mathrm{B}}TZ_{\mathrm{int}}}{h}\mathrm{e}^{\beta\mu(\theta,T)} , \quad (31.57)$$

where the sticking coefficient is given, as a function of coverage and temperature by (31.59). This is precisely the phenomenological rate equation presented in (31.1) with, however, the sticking coefficient specified explicitly, and is valid for any system. To reiterate: the desorption rate in (31.66) now consists of two factors: (i), the equilibrium fugacity of the adsorbate, $e^{\beta\mu}$, controlling the adsorbate energetics and structure, and (ii), the sticking coefficient controlling the gas-substrate energy transfer in adsorption and desorption. Such factorizations, or similar ones, must always be possible for processes that proceed through a sequence of local equilibrium states because they are completely described by equations of motion for the relevant thermodynamic variables, and the factorization ensures that the equilibrium state is independent of the kinetics. An application of this approach has been presented for oxygen adsorption and desorption from silver [31.40].

31.4.2 Adsorption and Desorption via Precursors

To further demonstrate the power of the kinetic lattice–gas approach we briefly review the work on precursor-mediated adsorption and desorption [31.60, 61]. We consider an adsorbate in which, in addition to the most strongly-bound chemisorbed (or physisorbed) adsorbed state, the adparticles can also be found in intrinsic or extrinsic precursor states. One introduces three sets of occupation numbers, $n_i = 0$ or 1, $m_i = 0$ or 1, and $l_i = 0$ or 1, depending on whether the final adsorbed (chemisorbed) state, the intrinsic precursor state (above an empty adsorbed state) or the extrinsic precursor state (above an occupied adsorbed state) are empty or occupied. The static properties of this lattice gas are controlled by a Hamiltonian

$$\begin{aligned} H = {} & E_{\mathrm{s}}^{(\mathrm{c})} \sum_i n_i + E_{\mathrm{s}}^{(\mathrm{i})} \sum_i m_i + E_{\mathrm{s}}^{(\mathrm{e})} \sum_i l_i \\ & + V_{1n}^{(\mathrm{c})} \sum_{i,a} n_i n_{i+a} + V_{1n}^{(\mathrm{i})} \sum_{i,a} m_i n_{i+a} \\ & + V_{1n}^{(\mathrm{e})} \sum_{i,a} n_i l_i n_{i+a} + \ldots \end{aligned} \tag{31.58}$$

The single-particle free energies are given by

$$E_{\mathrm{s}}^{(\mathrm{r})} = -V_R - k_{\mathrm{B}} T \ln\left(q_3^{(\mathrm{r})} q_{\mathrm{int}}^{(\mathrm{r})}\right), \tag{31.59}$$

(r = c, i, e) in terms of their respective binding energies and partition functions. Furthermore, $V_{1n}^{(\mathrm{c})}$ is the lateral interaction between two particles in the adsorbed state in nearest-neighbor sites, and $V_{1n}^{(\mathrm{i})}$ and $V_{1n}^{(\mathrm{e})}$ are the interactions between a particle in the intrinsic or extrinsic precursor state in cell i and a particle in the adsorbed state in a neighboring site. Longer-ranged interactions can easily be added as done elsewhere [31.61]. To describe the time evolution of the adsorbate we use a kinetic lattice–gas model recently developed to study the effect of lateral interactions on sticking. For the coverages of the three states, we obtain the kinetic equations

$$\begin{aligned} \frac{\mathrm{d}\langle n\rangle}{\mathrm{d}t} = {} & S_{\mathrm{C}}^0(T)(1-\langle n\rangle)\widetilde{S}_{\mathrm{C}} \frac{a_{\mathrm{s}}\lambda_{\mathrm{th}}}{h} P - r_{\mathrm{C}}\widetilde{f}_{\mathrm{C}}\langle n\rangle \\ & + w_{\mathrm{CI}}\left[\widetilde{f}_{\mathrm{CI}}\langle m\rangle - \left(\frac{a_{\mathrm{C}}}{a_{\mathrm{I}}}\right)\widetilde{f}_{\mathrm{IC}}\langle n\rangle\right] \\ & + z w_{\mathrm{CE}}\left[\widetilde{f}'_{\mathrm{CE}}(1-\langle n\rangle)\langle l\rangle - \left(\frac{a_{\mathrm{C}}}{a_{\mathrm{E}}}\right)\widetilde{f}'_{\mathrm{CE}}\langle n\rangle^2\right], \end{aligned} \tag{31.60}$$

$$\begin{aligned} \frac{\mathrm{d}\langle m\rangle}{\mathrm{d}t} = {} & S_{\mathrm{I}}^0(T)\widetilde{S}_{\mathrm{I}}(1-\langle n\rangle)\frac{a_{\mathrm{s}}\lambda_{\mathrm{th}}}{h} P - r_{\mathrm{I}}\widetilde{f}_{\mathrm{I}}\langle m\rangle \\ & - w_{\mathrm{CI}}\left[\widetilde{f}_{\mathrm{CI}}\langle m\rangle - \left(\frac{a_{\mathrm{C}}}{a_{\mathrm{I}}}\right)\widetilde{f}_{\mathrm{IC}}\langle n\rangle\right] + w_{\mathrm{II}} + w_{\mathrm{IE}}, \end{aligned} \tag{31.61}$$

$$\begin{aligned} \frac{\mathrm{d}\langle l\rangle}{\mathrm{d}t} = {} & S_{\mathrm{E}}^0(T)\theta\widetilde{S}_{\mathrm{E}}\frac{a_{\mathrm{s}}\lambda_{\mathrm{th}}}{h} P - r_{\mathrm{E}}\widetilde{f}_{\mathrm{E}}\langle l\rangle + w_{\mathrm{EE}} - w_{\mathrm{IE}} \\ & - z w_{\mathrm{CE}}\left[\widetilde{f}'_{\mathrm{CE}}(1-\langle n\rangle)\langle l\rangle - \left(\frac{a_{\mathrm{C}}}{a_{\mathrm{E}}}\right)\widetilde{f}'^2_{\mathrm{EC}}\langle n\rangle^2\right]. \end{aligned} \tag{31.62}$$

The constants r_{C} and w_{IC} etc. are specified in terms of microscopic parameters and the functions $\widetilde{f}_{\mathrm{C}}$, $\widetilde{f}_{\mathrm{I}}$, $\widetilde{f}_{\mathrm{IC}}$, etc., account for the various lateral interactions between the particles in the adsorbed and precursor states. We have factored out an explicit dependence on the coverages so that in the absence of any lateral interactions, these functions are all equal to 1.

To obtain the equilibrium conditions for the adsorbate we use (31.2) with $P = \overline{P}$ and obtain for the chemical potential of the adsorbate as a function of coverage and temperature

$$e^{\mu_{\mathrm{C}}/(k_{\mathrm{B}}T)} = \frac{h\lambda_{\mathrm{th}}^2}{k_{\mathrm{B}}TZ_{\mathrm{int}}a_{\mathrm{s}}} \frac{a_{\mathrm{C}}\widetilde{f}_{\mathrm{C}}}{\widetilde{S}_{\mathrm{C}}} \frac{\langle n\rangle}{1-\theta}, \tag{31.63}$$

$$e^{\mu_{\mathrm{I}}/(k_{\mathrm{B}}T)} = \frac{h\lambda_{\mathrm{th}}^2}{k_{\mathrm{B}}TZ_{\mathrm{int}}a_{\mathrm{s}}} \frac{r_{\mathrm{I}}\widetilde{f}_{\mathrm{I}}}{S_{\mathrm{I}}^0(T)(1-\theta)\widetilde{S}_{\mathrm{I}}}\langle m\rangle, \tag{31.64}$$

$$e^{\mu_{\mathrm{E}}/(k_{\mathrm{B}}T)} = \frac{h\lambda_{\mathrm{th}}^2}{k_{\mathrm{B}}TZ_{\mathrm{int}}a_{\mathrm{s}}} \frac{r_{\mathrm{E}}\widetilde{f}_{\mathrm{E}}}{S_{\mathrm{E}}^0(T)\theta\widetilde{S}_{\mathrm{E}}}\langle l\rangle, \tag{31.65}$$

$$\widetilde{f}_{\mathrm{CI}}\langle m\rangle = \left(\frac{a_{\mathrm{C}}}{a_{\mathrm{I}}}\right)\widetilde{f}_{\mathrm{IC}}\langle n\rangle, \tag{31.66}$$

$$\widetilde{f}_{\mathrm{CE}}\langle l\rangle = \left(\frac{a_{\mathrm{C}}}{a_{\mathrm{E}}}\right)\widetilde{f}_{\mathrm{EC}}\langle n\rangle \,, \tag{31.67}$$

where $\mu_{\mathrm{C}} = \mu_{\mathrm{I}} = \mu_{\mathrm{E}}$.

To obtain the equilibrium sticking coefficient we assume that at an ambient pressure P_0, the adsorbate is in equilibrium at a temperature T with partial coverages n_0, m_0, and l_0. We then increase the pressure slightly to $P = P_0 + \Delta P$ and linearize the rate equations in the increase in the precursor coverages $\Delta m = \langle m\rangle - m_0$ and $\Delta l = \langle l\rangle - l_0$. If adsorption into and desorption from the precursors is much faster than transitions from the precursors into the adsorbed state, we can ignore terms proportional to $\Delta n = \langle n\rangle - \theta$ on the right-hand side of (31.69)–(31.71) and also assume that the precursors will be in a steady state. It has been shown that the sticking coefficient is then given by [31.61]

$$\begin{aligned} &S(\theta,T) \\ &= S_{\mathrm{C}}(\theta,T) + S_{\mathrm{I}}(\theta,T)\frac{w_{\mathrm{CI}}\widetilde{f}_{\mathrm{CI}}X_1 + z w_{\mathrm{CE}}\widetilde{f'}_{\mathrm{CE}}Y_1(1-\theta)}{X_1X_2 - Y_1Y_2} \\ &\quad + S_{\mathrm{E}}(\theta,T)\frac{w_{\mathrm{CI}}\widetilde{f}_{\mathrm{CI}}Y_2 + z w_{\mathrm{CE}}\widetilde{f'}_{\mathrm{CE}}X_2(1-\theta)}{X_1X_2 - Y_1Y_2} \,. \end{aligned} \tag{31.68}$$

If we suppress the exchange of particles between the intrinsic and extrinsic precursors, $w_{\mathrm{IE}} = 0$, we obtain

$$\begin{aligned} S(\theta,T) &= S_{\mathrm{C}}(\theta,T) + S_{\mathrm{I}}(\theta,T)\frac{w_{\mathrm{CI}}\widetilde{f}_{\mathrm{CI}}}{r_{\mathrm{I}}\widetilde{f}_{\mathrm{I}} + w_{\mathrm{CI}}\widetilde{f}_{\mathrm{CI}}} \\ &\quad + S_{\mathrm{E}}(\theta,T)\frac{z w_{\mathrm{CE}}\widetilde{f'}_{\mathrm{CE}}(1-\theta)}{r_{\mathrm{E}}\widetilde{f}_{\mathrm{E}} + z w_{\mathrm{CE}}\widetilde{f'}_{\mathrm{CE}}(1-\theta)} \,, \end{aligned} \tag{31.69}$$

$$= S_{\mathrm{C}}(\theta,T) + S_{\mathrm{intr}}(\theta,T) + S_{\mathrm{extr}}(\theta,T) \,. \tag{31.70}$$

Only under this condition are the three adsorption channels independent of each other. This is the standard scenario always used in interpreting data. However, this is only one scenario because if, on the other hand, the exchange between the two precursors is the fastest process on the surface, we obtain

$$\begin{aligned} S(\theta,T) &= S_{\mathrm{C}}(\theta,T) + [S_{\mathrm{I}}(\theta,T) + S_{\mathrm{E}}(\theta,T)] \\ &\quad \times \frac{\left(w_{\mathrm{CI}}\widetilde{f}_{\mathrm{CI}}a_{\mathrm{E}} + z w_{\mathrm{CE}}\widetilde{f'}_{\mathrm{CE}}a_{\mathrm{I}}\theta\right)(1-\theta)}{\left\{\left(r_{\mathrm{I}}\widetilde{f}_{\mathrm{I}} + w_{\mathrm{CI}}\widetilde{f}_{\mathrm{CI}}\right)a_{\mathrm{I}}\theta + a_{\mathrm{E}}(1-\theta)\right\} \\ &\quad \times \left[r_{\mathrm{E}}\widetilde{f}_{\mathrm{E}} + z w_{\mathrm{CE}}\widetilde{f'}_{\mathrm{CE}}(1-\theta)\right]\Big\}} \,, \end{aligned} \tag{31.71}$$

and the two precursor channels of adsorption are maximally coupled, and straightforward interpretation is at a loss. One can study the desorption kinetics in the presence of precursors along similar lines.

31.5 Concluding Remarks

In this review article, we have tried to show that an analytical approach to the thermodynamics and the kinetics of adsorbates is not restricted to simple systems but can deal with rather complicated situations in a systematic approach such as multisite and multicomponent systems with or without precursor-mediated adsorption and surface reconstruction, including multilayers/subsurface species. This approach automatically ensures that such fundamental principles as detailed balance are implemented properly.

For the equilibrium properties and for the kinetics under quasi-equilibrium conditions for the adsorbate, the transfer-matrix technique is a convenient and accurate method to obtain not only the chemical potentials, as a function of coverage and temperature, but all other thermodynamic information, e.g., multiparticle correlators. We emphasize the economy of the computational effort required for the application of the technique. In particular, because it is based on an analytic method it does not suffer from the limitations of time and accuracy inherent in statistical methods such as Monte Carlo simulations. The task of variation of Hamiltonian parameters in the process of fitting a set of experimental data (thermodynamic and kinetic) is both fast and systematic. To date, the most accurate modeling of desorption and thermodynamic data has been obtained by this method.

For adsorbates out of local equilibrium, an analytic approach to the kinetic lattice–gas model is a powerful theoretical tool by which, in addition to numerical results, explicit formulae can be obtained to elucidate the underlying physics. This allows one to extract simplified pictures of and approximations to complicated processes, as shown above with precursor-mediated adsorption as an example. This task of theory is increasingly overlooked with the trend to use cheaper computer power for numerical simulations. Unfortunately, many of the simulations of adsorbate kinetics are based on unnecessarily oversimplified assumptions (for example, constant sticking coefficients, constant pref-

actors etc.), which rarely are spelled out because the physics has been introduced in terms of a set of computational instructions rather than formulating the theory rigorously, e.g., based on a master equation.

Ultimately, the coverage and temperature dependence of the kinetic and equilibrium properties of an adsorbate are the result of interactions of the adsorbed species with the substrate and with each other. In the ideal scenario, one would start the theoretical development with quantum-mechanical calculations of the potential energy surfaces for the coupled adsorbate-substrate system. If the system can be approximately described by a lattice–gas model, one then has all the necessary information to specify the interaction parameters in the corresponding lattice–gas Hamiltonian. All equilibrium and kinetic properties then follow from a good theory. This scenario has been initiated for oxygen on Ru(001) using density functional theory for the energy calculations [31.53]. This approach—density functional calculations, lattice–gas modeling, and kinetic theory—provides the necessary link between the fundamental interactions of the adsorbate and the macroscopic theories of equilibrium and kinetics. It is parameter free and, thus, should lead to a deeper understanding of surface physics and chemistry. The application of density-functional theory in a multidimensional approach to catalysis has been discussed in a recent review [31.62].

32. State Resolved Sticking Probability in Gas–Surface Interaction

Luca Vattuone, Michio Okada

This chapter provides selected examples of experimental investigations addressing the role of rotational and vibrational energy in adsorption at surfaces. Such information can generally be obtained in different ways characterized by different degrees of state selectivity. The first part of the chapter deals with the effect of rotational energy, while the second considers the effect of vibrational energy. The former investigations compared the behavior of rotationally hot and cold molecular beams by measuring the sticking probability on well-defined surfaces under controlled, ultrahigh-vacuum conditions. When detection of the rotational state of gas-phase molecules became feasible, a large amount of information was obtained indirectly: researchers first determined experimentally the rotational state of desorbing (or scattered) molecules and then used microreversibility (otherwise called detailed balance) arguments to extract information on the effect of the rotational states on the sticking probability. In recent years, methods to prepare molecules in partially and, in some cases, even fully defined rotational quantum states were developed. The central part of the section highlights recent results obtained using electrostatic and finally magnetic hexapoles. The first section of the chapter ends by reviewing results obtained by exploiting the velocity dependence of the degree of alignment of molecules seeded with inert carriers in a supersonic molecular beam. A brief selection of results obtained with laser methods concludes this section. Laser methods are on the contrary indispensable for the preparation of vibrationally excited molecules, which is the topic of the second section of the chapter. The relative roles of kinetic and vibrational energy are discussed, and the concepts of entrance and late barrier in the potential energy surface are introduced. Pioneering experiments showing greater specificity in surface reactions are briefly reviewed.

The reactivity of a surface towards a gas species can be measured by the adsorption (or sticking) probability S, defined as

$$S = \frac{\mathrm{d}\Theta}{\mathrm{d}\chi} = \frac{\mathrm{d}\Theta}{\Phi \mathrm{d}t}\,, \tag{32.1}$$

where Θ is the coverage, χ is the exposure, and Φ is the flux; $\Theta(\chi)$ is defined as the ratio between the number of molecules adsorbed (impinging) on unit area n_s and the surface density of atoms on the substrate n_0. These are substrate-dependent dimensionless quantities usually expressed in monolayers (ML). Alternatively, the exposure can be expressed in another, substrate-independent quantity, the Langmuir (L). One Langmuir corresponds to an exposure of 10^{-6} Torr lasting for 1 s; For example, exposing a surface to a gas pressure of 10^{-7} Torr for 10 s corresponds to 1 L. The Langmuir is more often used in backfilling experiments, i.e., when the uptake of the gas is performed by exposing the surface to a predefined pressure p for a certain time. To convert from L to ML and back, it is necessary to use

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-46906-1_32

elementary kinetic theory. For an ideal gas, the number of molecules crossing a unit area in unit time is given by

$$\frac{dN}{dAdt} = \frac{N}{4V}\langle v\rangle = p\sqrt{\frac{1}{2\pi kTm}}\,, \tag{32.2}$$

where m is the mass of the gas, k is Boltzmann's constant, and T is the temperature of the gas. The sticking probability S of a gas species at a surface is a function of several variables which describe the status of the molecule (kinetic energy (E) and vibrational (ν), rotational (J), and electronic quantum state), of the surface (temperature (T), coverage (Θ) of different adsorbates, density of defects, etc.), and of the direction of impingement of the molecule (polar (θ) and azimuthal (ϕ) angles of incidence).

$$S = S(E, \nu, J, \ldots; T, \Theta, \ldots; \theta, \phi)\,. \tag{32.3}$$

In general, S can be estimated by considering the change in the coverage produced by a certain exposure. If the exposure is performed by backfilling the experimental chamber, the so-estimated S is averaged over the angles of incidence θ and ϕ, over the Maxwellian energy distribution of molecules at the temperature T of the gas, and over all the internal degrees of freedom of the molecules.

The use of supersonic molecular beams has enabled the direct measurement of the dependence of S on the polar (θ) and azimuthal (ϕ) angles of incidence, on energy E, and at least partly, on internal variables [32.1]. The direction of impingement of molecules onto the surface (i.e., θ, ϕ) can indeed be controlled by rotating the sample with respect to the direction of the molecular beam. The kinetic energy E of the molecules of the gas of interest can be tuned within a relatively large range by seeding them into a carrier gas (usually He or another inert gas) or changing the temperature of the molecular beam source T_N; E is given by

$$E = \frac{m}{<m>} < \frac{\gamma}{\gamma - 1} > kT_N\,, \tag{32.4}$$

where m is the mass of a molecule of the gas and $<m>$ is the average mass of the molecules in the beam (which depends on the masses and concentration of the molecule and of the carrier gas), while γ is the ratio between the specific heats at constant pressure and constant volume.

Changing T_N affects not only the kinetic energy but also the internal state of the molecules in the source, before the occurrence of the supersonic expansion. Despite the fact that, even at room temperature (RT), a high fraction of rotationally excited molecules are present inside the molecular beam source, at the end of the supersonic expansion, the molecules are in general rotationally cold. This is due to the rotational relaxation that occurs during the supersonic expansion.

However, at the end of the supersonic expansion, the molecules retain at least partial memory of their initial state: a significant increase in T_N thus indeed determines also a change of the rotational temperature of the molecules in the beam; for example, the rotational temperature of a pure ethene beam is of the order of 10 K for $T_N = 300$ K but increases to ≈ 100 K for $T_N = 900$ K [32.2].

In contrast, the collisions between the molecules during the supersonic expansion do not allow for significant vibrational relaxation, so that the population of vibrationally excited states at the end of the expansion depends essentially on the temperature T_N of the source. However, even when operating the nozzle at high T_N, only a small fraction of vibrationally excited molecules can be obtained. The reason is quite simple: the typical energy of intramolecular vibrational quanta is on the order of at least 0.1 eV (i.e., for wagging modes) and can reach values close to or > 0.4 eV (for CH and OH stretching modes), so the probability of thermal excitation of vibrational modes is quite low. Moreover, all the vibrational modes can be excited, so the use of a supersonic molecular beam alone does not achieve state selectivity.

Nonthermal methods are thus mandatory to achieve a significant fraction of vibrationally hot molecules or for the preparation of molecules in controlled vibrational states. The molecules in the beam can be used to perform uptake experiments and obtain information about the dependence of the sticking probability on at least some of the dynamical variables. S is often determined using the so-called retarded reflector method (or method of *King* and *Wells* [32.3], KW in the following).

In this method, the partial pressure of the molecules of interest is monitored using a quadrupole mass spectrometer as a function of time. As sketched in Fig. 32.1, when the molecular beam is allowed into the chamber hosting the sample, an increase in the pressure is recorded. However, an inert flag (flag 2) close to the sample prevents the beam from striking the surface of the sample. At a later time, the inert flag is removed so that the beam can hit the sample. A decrease of the partial pressure proportional to the sticking probability is then obtained. When the coverage no longer increases, a steady state is reached and the partial pressure remains constant.

This method allows accurate measurements of S with a sensitivity on the order of 1%. Calibration of the coverage is also possible provided that the intensity of

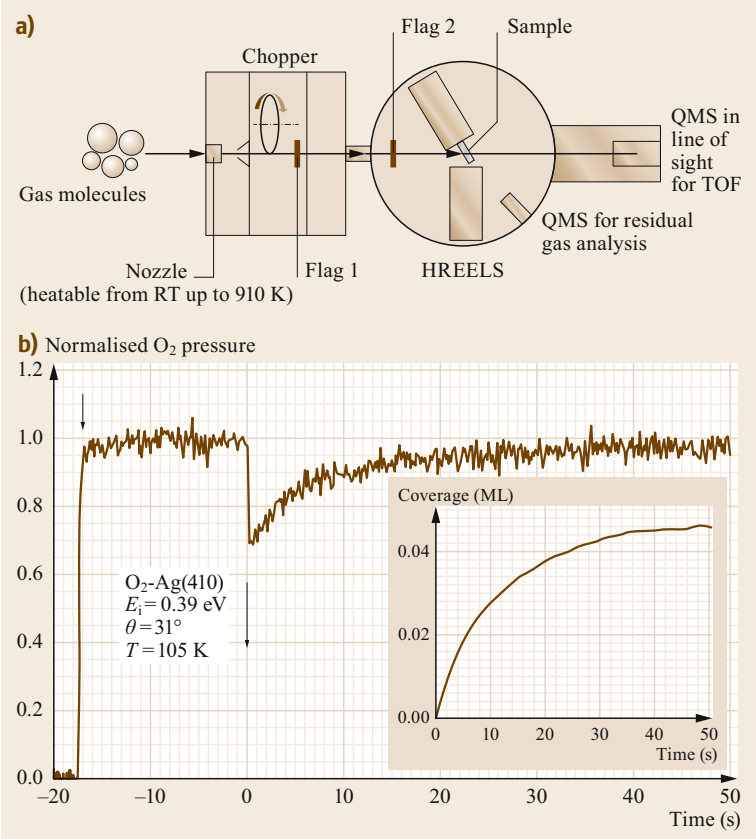

Fig. 32.1a,b Schematic of direct reflector method. **(a)** The setup used in Genoa to measure the sticking probability: it couples a supersonic molecular beam with an ultrahigh-vacuum chamber hosting the sample, a quadrupole mass spectrometer for residual gas analysis, and another one for time-of-flight measurements. The vibrational spectrometer (HREELS, high-resolution electron energy-loss spectroscopy) allows verification of the chemical state of adsorbed species. **(b)** A typical KW trace. When flag 1 is turned down, the molecular beam enters the UHV chamber and the partial pressure (of O_2 in this case) rises to a steady-state value determined by the incoming flux and the pumping speed of the chamber. As long as flag 2 remains up, the beam does not hit the surface. When flag 2 is also turned down, the beam strikes the sample, a fraction S of the molecules sticks to the surface, and the partial pressure drops. When saturation coverage is reached (or when the adsorption probability becomes lower than the experimental sensitivity), the partial pressure recovers its initial value. The inset shows the coverage as a function of time (Reprinted from [32.4], with permission from Elsevier. From [32.5] © IOP Publishing. Reproduced with permission. All rights reserved)

the beam can be determined independently. The coverage can thus be obtained by integrating S over time

$$\Theta(t) = \Phi \int_0^t S(\tau)\mathrm{d}\tau \,. \tag{32.5}$$

This method has been used extensively over the years to measure S for a wide set of systems. This chapter is organized into two different sections, covering the role of rotational and vibrational degrees of freedom, respectively.

32.1 Effect of Rotational Energy on S

The fundamental importance of the role of rotational energy has stimulated extensive theoretical and experimental investigations, and the field is still developing. We thus focus here on some of the most recent results, providing thus only a partial overview of this field; the more specialized reader is referred to dedicated review papers [32.6–23].

To avoid possible misunderstandings, we briefly recall the definition of molecular polarization for a distribution of rotating molecules.

The most straightforward way to do this is to consider the polarization of the angular momentum vector of the molecules, which defines their axis of rotation. While the total angular momentum of a closed-shell molecule arises purely from its rotational motion, in an open-shell molecule there may also be a contribution from electronic angular momentum. Defining the spatial polarization in terms of the total angular momentum vector also provides a way to treat polarization in atoms, in which the only contribution to the total angular momentum is electronic, in the form of spin and electronic orbital angular momentum [32.22].

In this respect, we must distinguish between alignment and orientation. For an aligned distribution, all vectors are aligned along a single axis (or sometimes in a plane) but without a preferred direction: equal numbers of arrows pointing in the up and down directions are then present. For an oriented distribution, on the other hand, the vectors have both a preferred axis and a preferred direction.

From a more formal point of view, let us consider the quantum-mechanical angular momentum vector $\boldsymbol{J}$ and its projection onto the axis defined by the velocity of the molecules M_J.

A beam of molecules which are aligned (but not oriented) have an isotropic distribution of M_J with equal population of positive and negative values of M_J, while a beam of oriented molecules have an anisotropic distribution of M_J.

Experimental investigations on the role of rotational degrees of freedom in molecule–surface interactions can employ both indirect and direct methods. In the former case, the rotational state of the molecules impinging on the surface is not controlled and information about the dependence of the sticking probability on the rotational state is obtained indirectly by analyzing the rotational state of scattered/desorbing molecules (mostly using laser methods) and applying detailed balance arguments. Such methods are addressed in the next subsection.

In direct methods, on the contrary, the rotational state of the incoming molecules is at least partially controlled and the sticking probability is measured directly using the King and Wells method. In pioneering *direct* studies, information was obtained by comparing the behavior of rotationally cold and hot beams obtained by increasing the temperature of the molecular beam source. Later, methods to prepare molecules in at least partially selected states appeared; electrostatic hexapole methods are presented first, followed by very recent results obtained using the magnetic hexapole technique. We then review the main results obtained by using collisional alignment and, finally, experiments performed by preparing the molecules in defined rotational states using laser methods.

32.1.1 Indirect Results Obtained by Use of Detailed Balance

The interaction of H_2 and D_2 with surfaces has been studied extensively both theoretically and experimentally. *Rettner* et al. [32.24] determined the state-resolved flux $I(E,\theta,T,\nu,J)$ for H_2 molecules desorbing off Cu(111) for different rotational states J and for molecules in the fundamental vibrational state $\nu = 1$. The flux of molecules leaving the surface was probed by laser ionization detection, and time-of-flight distributions were obtained by recording the flight times of the photoions to a multichannel plate detector. H_2 molecules were detected quantum-state specifically by laser ionization via a two-photon resonance to the H_2 E,F$^1\Sigma_g^+$ state. Detailed balance, when applied to adsorption/desorption processes, states that, for a system at equilibrium, the rate of adsorption is equal to the rate of desorption for any subset of molecules of the equilibrium flux striking the surface. It has been shown that the principle of detailed balance can be applied to relate adsorption/reflection measurements to desorption measurements made on systems at equilibrium and quasiequilibrium, e.g., under the conditions established in a molecular beam experiment [32.25].

$I(E,\theta,T,\nu,J)$ is related, in the limit of small coverage, to the state-resolved initial sticking probability, $S_0(E,\theta,T,\nu,J)$, via the relationship

$$\begin{aligned} &I(E,\theta,T.\nu,J)\sin\theta\mathrm{d}\theta\mathrm{d}\phi\mathrm{d}E \\ &\propto S_0(E;\theta,T,\nu,J)N(\nu,J,T)E\mathrm{e}^{-\frac{E}{kT}} \\ &\quad\times\cos\theta\sin\theta\mathrm{d}\theta\mathrm{d}\phi\mathrm{d}E\,, \end{aligned} \tag{32.6}$$

where T is the surface temperature, $N(\nu,J,T)$ is the Boltzmann population of state (ν,J), and $E\mathrm{e}^{-E/(kT)}\mathrm{d}E$ is the probability to have translational energy E in the interval between E and $(E+\mathrm{d}E)$.

The sticking probability is described as a function of the normal energy $E_n = E_i\cos^2\theta$ of the incoming molecules with the empiric function (sometimes called the S-function) usually employed to describe activated adsorption

$$S_0(E_i,\theta,\nu,J) = \frac{A(\nu,J)}{2}\left[1+\mathrm{erf}\left(\frac{E_n - E_0(\nu,j)}{W(\nu,j)}\right)\right]. \tag{32.7}$$

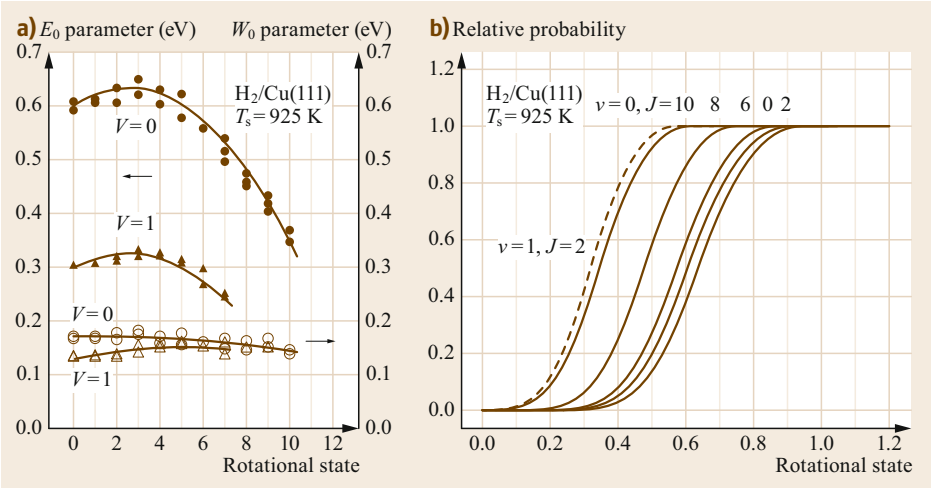

Fig. 32.2 **(a)** Dependence of the parameters E_0 and W on rotational quantum number for H_2 with $\nu = 0$ and $\nu = 1$ desorbed from Cu(111) at 925 K. The *lines* are quadratic fits to the points. **(b)** Quantum-state-specific adsorption probability functions for the same system. *Curves* are shown for $J = 0$, 2, 6, 8, and 10 for H_2 in the fundamental $\nu = 0$ state (*continuous lines*) and for $\nu = 1$ (*dashed line*) (Reprinted from [32.24], with the permission of AIP Publishing)

Here, $E_0(\nu, j)$ estimates the adsorption barrier, defined as the translational energy required for the adsorption probability of molecules in state (ν, j) to reach half its maximum value, $W(\nu, j)$ is a parameter that measures the steepness of the function (intuitively, the energy width of the adsorption barrier), and $A(\nu, J)$ is the saturation value of S_0 at high translational energy, again for molecules in state (ν, j).

The results of this experiment are summarized in Fig. 32.2. The adsorption barrier E_0 is significantly lower for $\nu = 1$ than for $\nu = 0$, indicating that vibrationally excited molecules require less kinetic energy to stick.

The dependence of E_0 on J is more complex: for H_2 in the fundamental vibrational state $\nu = 0$, E_0 rises with increasing J for J lower than 4 but falls steeply as J increases from 4 to 10. Quite similar results were obtained for D_2/Cu(111) [32.25]. These results indicate that the amount of translational energy needed to surmount the adsorption barrier increases with increasing J at low J but decreases with increasing J at high J. At low J, the molecules are very sensitive to the anisotropy of the potential energy surface, so that for $J \leq 4$ steric orientational effects dominate: the amount of time the reactants can remain in the preferred configuration during the reactive collision decreases with increasing J, thus inhibiting the occurrence of dissociative adsorption. For $J \geq 5$, on the contrary, the energy effect dominates: the increasingly effective conversion of rotational into translational energy during the reactive collision increases the sticking probability by effectively increasing the collision energy.

By using the same experimental setup, it was also possible to obtain information on the alignment of D_2 molecules desorbing off Cu(111). By rotating the polarization of the probe light so that it was either parallel or perpendicular to the surface normal vector z and by recording the intensities of the detected signal for these two polarizations as a function of arrival time at the detector, the degree of alignment of the desorbing molecules as a function of velocity was determined [32.26]. This result is shown in Fig. 32.3.

This figure shows that the probability for the formation of molecules with axis perpendicular and parallel to the surface are different and that this difference is large for large arrival times (corresponding to slow molecules) but approaches zero for short arrival times (fast molecules). The right panel shows a polar plot of the classical probability distribution of the angle θ between the angular momentum vector and the surface normal vector. Note that $\theta = 0, \pi$ corresponds to helicoptering motion, while $\theta = \pi/2$ corresponds to cartwheeling motion.

Thanks to detailed balance, such information about the preferred alignment in desorption provides information about the dependence of S_0 on alignment. At the lowest kinetic energy, only those molecules oriented close to the minimum-energy configuration in the transition state can dissociate. As the kinetic energy of the incident D_2 is increased, molecules with a wider range of alignments are able to dissociate, and the steric preference decreases, in agreement with these measurements. The observed *helicoptering* alignment of the recombinative desorption products observed here indicates that

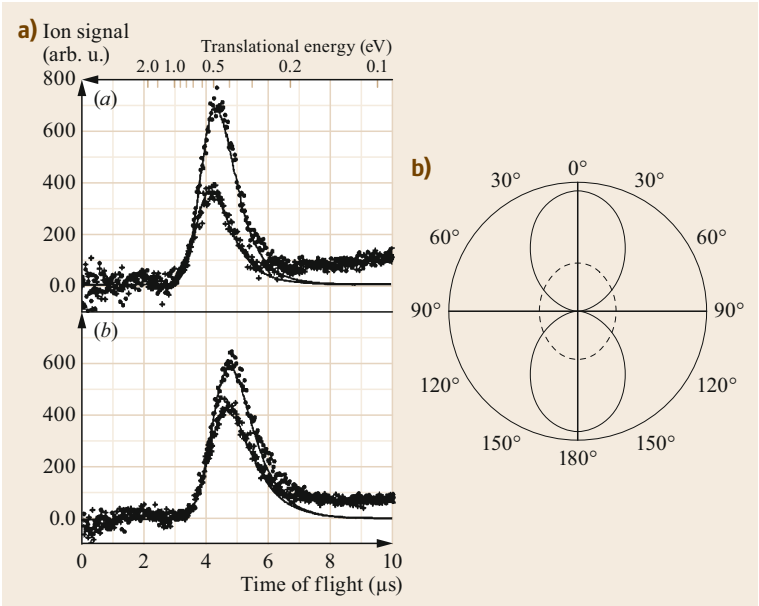

Fig. 32.3 **(a)** Alignment-sensitive time-of-flight spectra of specific quantum states of $D_2(v, J)$ formed by recombinative desorption from Cu(111) for (*a*) $D_2(v = 0, J = 11)$ and (*b*) $D_2(v = 1, J = 6)$. Measurements with the polarization of the probe laser perpendicular (•) and parallel (+) to the surface normal are shown. **(b)** Polar plot of $P(\theta)$, the classical probability distribution of the angle between the D_2 angular momentum unit vector $\boldsymbol{J}$ and the surface normal unit vector $\boldsymbol{z}$. The *dotted* and *solid curves* correspond to the minimum and maximum alignment observed at high and low kinetic energy, respectively (From [32.26]. Reprinted with permission from AAAS)

incident D_2 dissociatively adsorbs with the highest probability when it collides with its bond parallel to the surface. The dependence of the alignment on energy indicates that this steric preference is strong at low translational energies (0.3 eV) but decreases rapidly with increasing translational energy to nearly zero at 0.8 eV.

A similar *indirect* approach has also been employed to investigate larger molecules such as the interaction of N_2 with W(110) [32.27] and N_2 with Ag(111) [32.28, 29].

32.1.2 Effect of the Average *J* on the Sticking Probability

The first direct investigations of the effect of J on the adsorption probability were carried out by comparing its initial value S_0 for rotationally cold and hot molecules. Molecules at the end of the supersonic expansion are typically rotationally cold, especially when they are seeded in inert carriers and when the nozzle is operated at room temperature or below. Rotationally hotter molecules, i.e., molecules with a higher average J, can be obtained by operating the nozzle source at a sufficiently high temperature T_N. When using hydrogen, due to the large separation between subsequent rotational levels, it is possible to change T_N and distinguish between the sticking probability of molecules with close J values. On the contrary, when using larger molecules, for which the separation of rotational levels is much lower, only a semiquantitative result distinguishing between *low* and *high* J values is possible by such methods.

Comparing the existing literature, we conclude that there is not a general trend in the effect of rotational energy on the adsorption probability. As shown above for H_2/Cu(111), the rotational energy has a nonmonotonic effect on the adsorption barrier and thus on the resulting sticking probability; however, even for systems without any adsorption barrier, different behaviors have been reported.

As shown in Fig. 32.4, there exist systems (i.e., O_2/Ni(111), N_2/W(100), CO/FeSi(100) [32.30]) for which the sticking probability depends only on the translational energy but is independent of the amount of available rotation energy.

O_2/Ni(111) is a complex adsorption system. At low kinetic energy, the sticking probability is strongly temperature dependent and increases with *decreasing* kinetic energy at low temperature, indicating the existence of a precursor-mediated adsorption path. At high kinetic energy, S is nearly independent of temperature and increases with *increasing* kinetic energy, indicating the existence of a second, activated adsorption path. The sticking probability depends, however, only on the kinetic energy: it does not matter, for this system, whether its value has been attained by just increasing the nozzle temperature (and with it the average rotational quantum number) or, alternatively, by changing the seeding ratio (and thus without any significant change in the average rotational quantum number). In conclusion, the rotational energy does not seem to affect S_0 for O_2 on Ni(111) within experimental sensitivity.

A similar situation occurs for adsorption of N_2 on W(100): S decreases with increasing kinetic energy as

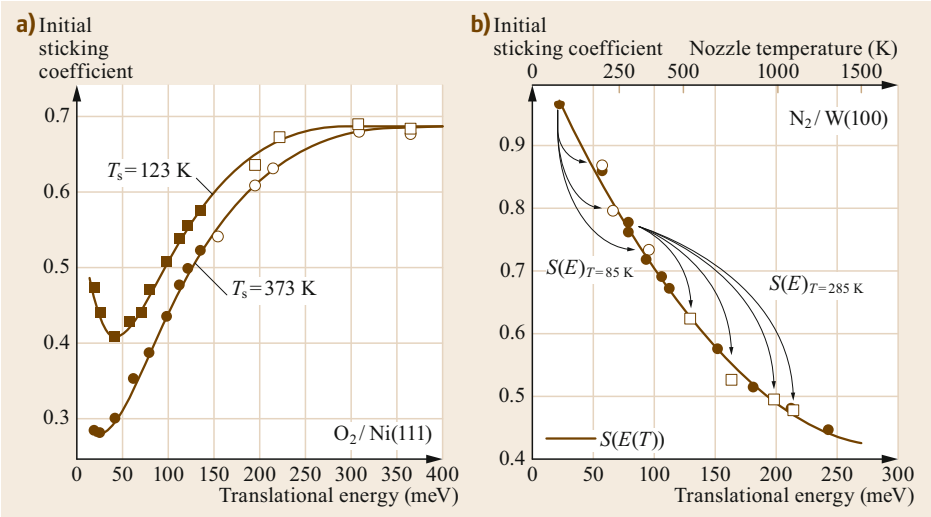

Fig. 32.4 **(a)** Sticking probability for O_2/Ni(111). **(b)** Sticking probability for N_2/W(100). *Filled symbols* correspond to different translational energies obtained by changing the nozzle temperature so that higher kinetic energy corresponds also to higher rotational states. *Open symbols* correspond to different translational energies obtained by different seeding mixtures at the same nozzle temperature. (Reprinted from [32.30], with permission from Elsevier)

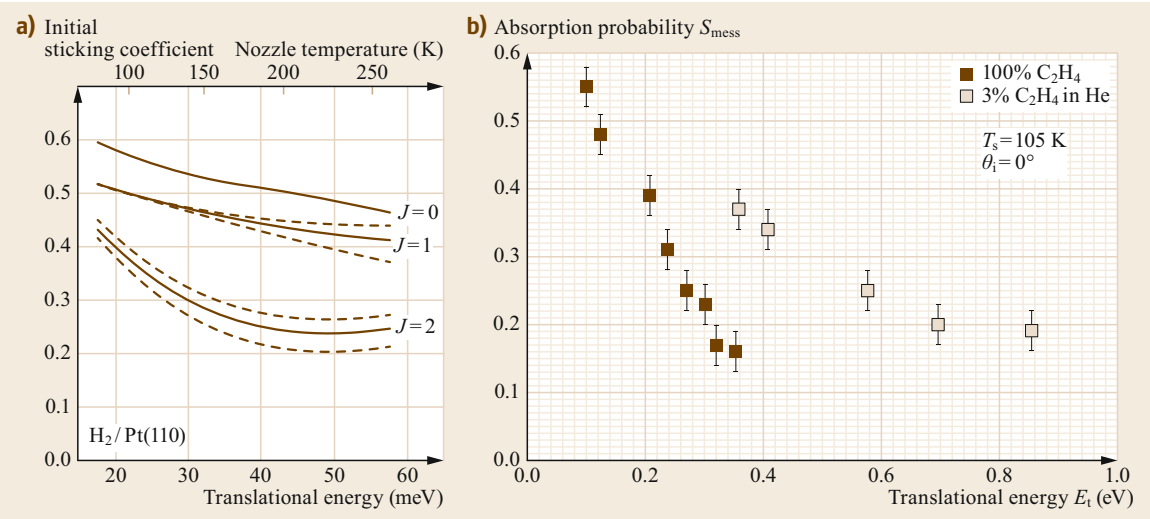

Fig. 32.5 **(a)** Sticking probability for H_2/Pt(110). **(b)** Sticking probability for C_2H_4/Ag(100) (**(a)** Reprinted from [32.31], with permission from Elsevier; **(b)** reprinted with permission from [32.2]. Copyright (1999) by the American Physical Society)

expected for a nonactivated adsorption system. As for O_2/Ni(111), the data points obtained at different nozzle temperatures (for which a different average J is expected) and the data obtained with different mixtures but at the same nozzle temperatures (for which the same or at least close J values are expected) fall on the same curve, thus again indicating a negligible effect of the rotational excitation on the adsorption probability [32.30].

However, there are also systems (i.e., H_2/Pt(110) [32.31], C_2H_4/Ag(100) [32.2]) for which the rotational energy has an adverse effect on adsorption and effectively suppresses the sticking probability.

As shown in Fig. 32.5, the sticking probability for H_2/Pt(110) decreases slowly with increasing kinetic energy and, more interestingly here, with increasing J. A similar result was obtained for a completely different system, viz. C_2H_4/Ag(100). The low adsorption energy indicates that most of the molecules are physisorbed. It is clear that, at the same kinetic energy (≈ 0.4 eV), S_0 is lower for rotationally hot molecules ($< J > \approx 8 \pm 4$,

obtained using a beam of C_2H_4 at $T_N = 900\,K$) than for rotationally cold molecules ($< J > \approx 1 \pm 1$, obtained by seeding ethene in He and keeping the nozzle at RT). In such cases, the presence of rotational energy effectively suppresses the sticking probability, favoring the backscattering of the molecule into the gas phase.

A similar result has been obtained for H_2 and D_2 on Pd(111) [32.32]. We can speculate that the key parameter is the efficiency of conversion of the existing rotational energy into translational energy. When this mechanism is effective, i.e., in the presence of a significantly corrugated interaction potential, the presence of rotational energy may favor adsorption in activated systems but disfavor it in nonactivated ones. When the conversion of rotational into translational energy is not effective, a sticking probability independent of the average rotational quantum number is found, independently of whether an adsorption barrier exists or not.

Such independence of S_0 from J can also occur as a consequence of strong steering: in the latter case, the molecule is attracted towards the adsorbed state, thus losing memory of its initial rotational state. Finally, we want to mention the intriguing results reported for the physisorption of hydrogen at very low temperature, where the adsorption probability is expected to be highest at low kinetic energy. Under such conditions, however, the rotational energy can be comparable to the kinetic energy, due to the larger separation between rotational levels for H_2 (and D_2), thus giving rise to a more complex phenomenology.

Due to the symmetry with respect to permutation of its nuclei, the rotational quantum number (J) of H_2 cannot be fixed independently of the total nuclear spin I. Because of this, molecules with even J must have $I = 0$ (i.e., so-called *para*-H_2), while when J is odd, $I = 1$ (so-called *ortho*-H_2). Such isomers appear in normal H_2 gas (n-H_2) in the proportion 1 : 3.

The reasons for the existence of a preferred orientation in such a weakly physisorbed system are still debated [32.33]. It is interesting to underline that molecular hydrogen physisorbed on smooth metal surfaces such as Ag(111) and Cu(100) behaves as a nearly free rotator [32.34].

Figure 32.6a shows measurements revealing the dependence of the initial sticking probability for n-H_2 and p-H_2. Resonances are clearly present in S_0 [32.35] for *para*-H_2, characterized by four times more molecules in even J states with respect to n-H_2. According to Andersson et al., three different kinds of resonances can occur: (i) rotation-mediated selective adsorption (RMSA) resonances, (ii) corrugation-mediated selective adsorption (CMSA) resonances, and (iii) combined resonances involving both rotation and corrugation, i.e., corrugation- and rotation-mediated selective adsorption (CRMSA).

RMSA involves rotational excitation but no diffraction ($g_{||} = 0$) and is indicated by

$$\begin{pmatrix} j \to j' \\ n \end{pmatrix} ,$$

where n is the bound state level involved; CMSA involves a specific lattice vector ($g_{||} \neq 0$) and is indicated by

$$\begin{pmatrix} hk \\ n \end{pmatrix} .$$

CRMSA involves both rotational excitation and diffraction and is specified by

$$\begin{pmatrix} hk, j \to j' \\ n \end{pmatrix} .$$

For the system shown in the figure, the resonances are of two kinds: RMSA, $j \to j'$, $0 \to 2$ (44.1 meV) and CRMSA, $j \to j'$, $0 \to 2$, and g(10). The peak at 24 meV appears to be dominated by CRMSA.

In Fig. 32.6b, the resonance-enhanced multiphoton ionization (REMPI)-temperature-programmed desorption (TPD) spectra for the two isomers are shown. It is apparent that the desorption temperatures are not the same, with *para*-H_2 starting to desorb first. The TPD spectra show the first-order desorption with $E_d = (28 \pm 2)$ meV for *ortho*-H_2 ($J = 1$) and (26 ± 2) meV for *para*-H_2 ($J = 0$). The difference in the desorption features can be ascribed to the anisotropic physisorption potential, where the perpendicular orientation is preferred over the parallel orientation.

This difference in adsorption energy is not peculiar to the H_2/Ag(111) system. Indeed, different desorption temperatures have also been observed for D_2/ice [32.36], where again molecules in the state $J = 1$ are more strongly bound. Note that, for D_2, the more strongly bound species, i.e., the one with rotational state $J = 1$, corresponds to *para*-D_2.

The inversion with respect to H_2 is due to the fact that the nuclei of this molecule consist of protons (with semiinteger spin) while D_2 consists of deuterons (with spin 1); the total wavefunction of H_2 must thus be antisymmetric with respect to permutation of the nuclei, while the wavefunction of D_2 must be symmetric under the same operation [32.37].

32.1.3 State-Selected Molecular Beam by Electrostatic Hexapole

The Stark effect was studied in the 1950s [32.6] for various kinds of molecules, and its application to obtain focusing and orientation started about 50 years ago [32.7–

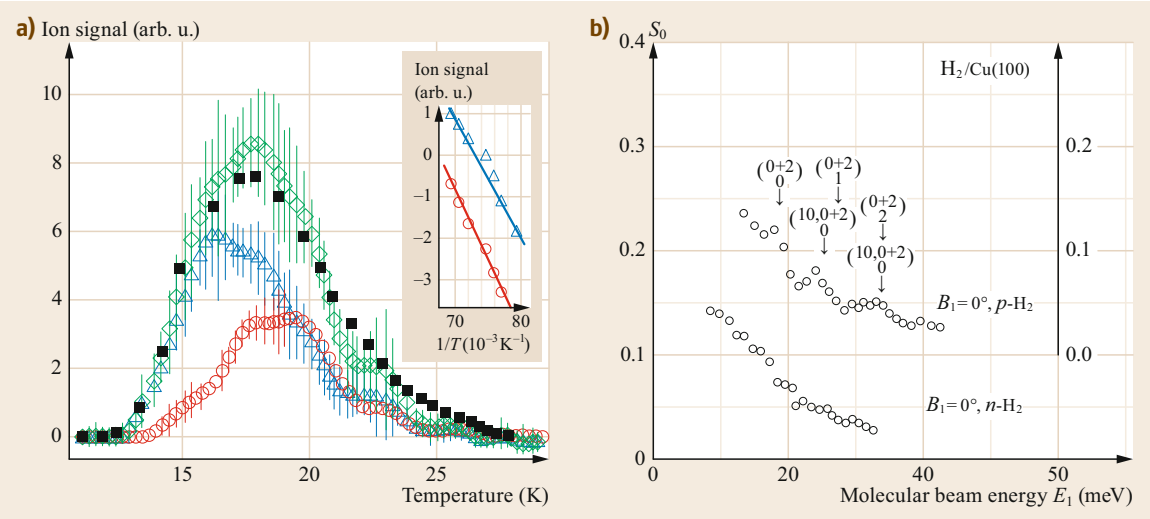

Fig. 32.6 **(a)** REMPI-TPD spectra for $J = 0$ of H_2 (*open triangles*) and $J = 1$ of H_2 (*open circles*) measured ≈ 30 s after 0.2 L dosage of H_2 on Ag(111) at 10 K with a heating rate of 2.5 K/s. The sum of the $J = 0$ and $J = 1$ REMPI-TPD spectra (*open diamonds*) and a QMS-TPD spectrum (*filled squares*) are shown for comparison. *Inset*: Arrhenius plots of the leading edge of the $J = 0$ and the $J = 1$ REMPI-TPD spectra. The *solid lines* are linear fits. **(b)** Initial sticking probability, S_0, versus molecular beam energy E_1, of *n*-H_2 and *p*-H_2 on Cu(100) at normal incidence. *p*-H_2 was produced via online conversion of the normal gases by use of a nickel-silicate catalyst kept at 25 K by a cool helium gas. The surface is kept at ≈ 10 K, such a low temperature is needed due to the very low adsorption energy for physisorbed H_2 (Reprinted with permission from [32.33, 35]. Copyright (2014) by the American Physical Society)

9]. Since then, molecular orientation effects have been studied in several chemical reactions [32.11, 13]. Recently, beam focusing and manipulation of a molecule using the Stark effect, the so-called hexapole technique, have been applied in a sophisticated way to excited CO molecules, OH radicals, NH_3, etc. [32.38–40]. Several groups have employed the hexapole technique in surface science studies.

NO is a simple molecule which has been studied most extensively regarding the stereodynamics of surface processes with and without a hexapole technique. Clear molecular orientation effects depending on the strength of the molecule–surface interaction were found in the scattering of NO from metal surfaces [32.12, 41–44]. The first demonstration of oriented NO scattering from a surface was carried out on NO/Ag(111), a weakly bound system [32.41].

The angular distribution of the scattered NO in Fig. 32.7 demonstrates that the adsorption probability is higher if the molecule approaches the Ag(111) surface with the O-end closer to the surface than the N-end. These results can be understood based on a strong anisotropic or orientation-dependent repulsion, resulting in preferential, rotationally mediated, adsorption for O-end incidence conditions [32.12].

While O-end incidence favors rotationally mediated adsorption for the weakly interacting system

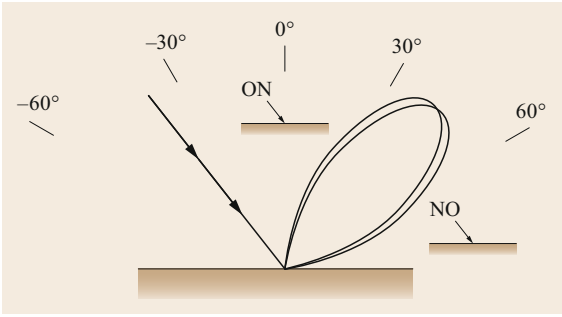

Fig. 32.7 Angular distributions for direct scattering of oriented NO from Ag(111) (after [32.41])

NO/Ag(111) [32.12, 41], the N-end approach is favored for the strongly interacting NO/Pt(111) system [32.43, 44]. The highly reactive preference for the N-end approach was also observed in other strongly adsorbed systems, such as NO/Al(111) [32.45], NO/Ni(100) [32.46], and NO/Pt(100) [32.47]. Even for a semiconductor surface such as Si(111), the N-end approach promotes the occurrence of surface reactions [32.48].

The hexapole technique can also be applied for orienting more complex polyatomic molecules such as N_2O [32.50] and CH_3Cl. Systematic studies of scattering of oriented alkyl halide molecules from highly

oriented pyrolytic graphite (HOPG) were performed in the early 1990s, and it was concluded that the steric effects depend on the alkyl chains and the halogens of the alkyl halide molecules [32.49, 51–53].

The obtained results are summarized in Table 32.1. They demonstrate the existence of steric effects for various polyatomic molecules having more degrees of freedom than NO. The alkyl halide molecules interact weakly with HOPG. The sign of the steric effect (with respect to the direction of the dipole vector relative to the surface normal) differs from one case to another. The negative end of the molecule sticks preferentially in some cases, while the positive end is preferred in others. Thus, the origins of the steric effects in the weak interaction of polyatomic molecules with surfaces have not been clarified yet.

The role of molecular orientation in the adsorption of CH_3Cl on strongly interactive Si(100) [32.54–56] and weakly interactive Si(111) [32.57] and HOPG [32.49, 52, 58, 59] has been intensively studied, revealing that the Cl-end collision is the favored one.

Here, we review the principles of focusing and orientation by using an electrostatic hexapole and a uniform field in front of the crystal surface. Since detailed reviews have already been published [32.12, 21, 60, 61], we briefly describe here the focusing of CH_3Cl, a typical symmetric-top molecule with a large dipole moment, 6.24×10^{-30} C m, which can be state selected and focused by a hexapole technique as explained below [32.62].

The experimental setup at Osaka University in Japan is shown schematically in Fig. 32.8. The apparatus consists mainly of three parts. The first part contains the nozzle and buffer chamber, generating a pulsed supersonic molecular beam (PSSMB). The second part contains the hexapole state selector with a beam stop and guiding electrodes. The third part hosts the ultrahigh-vacuum (UHV) chamber for analyzing surface-reaction processes. Detailed descriptions of such apparatuses are available elsewhere [32.62].

32.1.4 Rotational State Selection

The force exerted by the electric field $\boldsymbol{E}$ on molecules possessing a permanent dipole, $\boldsymbol{\mu}_{el}$, inside the electrostatic hexapole is radial and follows the derivatives of the Stark energy U_{Stark} [32.6]. The interaction energy U_{Stark} of a symmetric top molecule depends on the total angular momentum $\boldsymbol{J}$ and its projections onto the body-fixed molecular axis ($\boldsymbol{K}$) and onto the space-fixed axis defined by the electric field ($\boldsymbol{M}$). The force due to the inhomogeneous field of the state selector equals the derivative of the interaction energy U_{Stark} with respect to the radial distance r from the hexapole central axis

$$F_r = -\frac{dU_{Stark}}{dr} = \mu_{el}\frac{KM}{J(J+1)}\frac{dE}{dr}\,. \tag{32.8}$$

Here, J, K, and M are the quantum numbers corresponding to $\boldsymbol{J}$, $\boldsymbol{K}$, and $\boldsymbol{M}$, respectively; B, h, and c are the rotational and Planck constants, and the velocity of light, respectively; γ is the angle formed by $\boldsymbol{\mu}_{el}$ and $\boldsymbol{E}$. The values of μ_{el} and E stand for $|\boldsymbol{\mu}_{el}|$ and $|\boldsymbol{E}|$, respectively. The force remains radial because the azimuthal angular derivative $dU_{Stark}/d\phi$ vanishes for a linear Stark effect in a hexapole field.

Peak A and B in each panel correspond to the states $|JKM\rangle = |111\rangle$ and $|212\rangle$ (Reproduced from [32.54]. Copyright © 2005 The Japan Society of Applied Physics)

For a field $E = 3V_0r^2/R^2$ in the hexapole state selector, the force is

$$F_r = -\frac{dU_{Stark}}{dr} = \frac{6\mu_{el}V_0}{R^3}\frac{KM}{J(J+1)}r\,, \qquad (32.9)$$

where V_0 is the absolute value of the voltages applied to the hexapole. The negative and positive voltages are applied to every other pole of the hexapole; R is the radius of the circle inscribed within the surfaces of the rods. From 32.9 it follows that, for states with a positive Stark effect (i.e., $KM < 0$), $F_r < 0$ and the molecule will be deflected towards a region with low field strength on the axis of the PSSMB. This force shows a linear dependence on r, thus the motion of the CH_3Cl molecules focused using the hexapole deflector is sinusoidal. The molecule moves at a uniform velocity along the hexapole axis. Thus, by adjusting V_0, the focal length of the molecule can be controlled.

The state selection achieved using the hexapole is primarily verified by measuring the intensity I_B with the quadrupole mass spectrometer (QMS) as a function of voltage on the rods of the hexapole, obtaining the so-called focusing curve. By tuning the hexapole voltage, optimal focusing is easily achieved in the signal I_B on the detector.

Figure 32.9a,b shows the focusing curves for PSSMBs with $E_i = 120$ (CH_3Cl (25%)/Ar SSMB) and 65 meV (CH_3Cl (25%)/Kr SSMB) impinging directly upon the QMS, respectively. Here, the intensity I_B is plotted as a function of the absolute value of the voltages applied to the rods of the hexapole. There are several peaks in the focusing curves shown in Fig. 32.9.

To assign the peaks to the correct rotational states, trajectory simulations of CH_3Cl molecules were performed [32.62]. As a result of such simulations, peak A and B in Fig. 32.9 can be assigned to $|JKM\rangle = |111\rangle$ and $|212\rangle$ states, respectively.

32.1.5 Orientation

Molecules in a single KM state become oriented in a uniform electric field. Such a field is applied to obtain a beam of preferentially oriented CH_3Cl molecules. When a state-selected beam is introduced adiabatically into a uniform electric field, the orientation distribution for a molecule with the rotational state can be expanded into a series of Legendre polynomials $P_n(\cos\gamma)$ [32.63]

$$P_{JKM}(\cos\gamma) = \frac{2J+1}{2}\sum_{n=0}^{2J} C_n(JKM)P_n(\cos\gamma)\,. \tag{32.10}$$

Here, the coefficient C_n is given in the $3j$ symbolic description and γ is the angle between the orientation field and the permanent dipole of CH_3Cl. In real experiments, it is not feasible to select only a single state of molecules. Thus, the orientation distribution of the state-selected molecules can be described as the sum over the individual states weighted by the population of each state. As a result, the orientation distribution function $W_V(\cos\gamma)$ at a given hexapole voltage V_0 can be obtained once we know the distribution $W_V(JKM)$ of the $|JKM\rangle$ states at V_0 [32.64]

$$W_V(\cos\gamma) = \sum_{JKM} P_{JKM}(\cos\gamma)W_V(JKM)\,, \tag{32.11}$$

where $P_{JKM}(\cos\gamma)$ is given in (32.10).

Based on the simulation, we can obtain the state distribution function $W_V(JKM)$ of the $|JKM\rangle$ states at fixed V_0, and thus the orientation distribution function $W_V(\cos\gamma)$ in (32.11). The obtained $W_V(\cos\gamma)$ for the 120 meV CH_3Cl SSMB are shown in a polar plot for the Cl-end distribution, together with the random orientation distribution, in Fig. 32.10. $\bar{P}_1$ and $\bar{P}_2$ correspond to the average orientation and alignment, respectively. The Legendre moment $P_n = P_n(\cos\gamma)$ of $W(\cos\gamma)$ for the $|111\rangle$ state at 120 meV is determined as follows, taking the state purity into consideration: $\bar{P}_0 = 1$, $\bar{P}_1 = 0.47$, and $\bar{P}_2 = 0.06$, the higher terms being negligibly small.

For $|212\rangle$ at $E_i = 120$ meV, the moments $\bar{P}_n$ of $W(\cos\gamma)$ are $\bar{P}_1 = 0.33$ and $\bar{P}_2 = 0.11$, respectively. When we reverse the electric field, the distribution corresponds to the CH_3-end distribution. $W_V(\cos\gamma)$ for the 65 meV SSMB was reported in [32.55, 62].

The Cl-end distribution of CH_3Cl is shown in the case of the indicated electric field. The *black circle* around the center corresponds to the random orientation distribution (Reprinted with permission from [32.54]. Copyright (2005) by the American Physical Society)

32.1.6 Molecular Orientation Effects of CH_3Cl on Surfaces

By using such a state-selected and oriented beam, we can measure the rotational state dependence and molecular orientation dependence of the molecular sticking probability on surfaces [32.54, 56, 60, 61].

Figure 32.11 shows the T_s dependence of S_{Cl}/S_{random} and S_{Cl}/S_{CH_3} for the $|111\rangle$ incidence (black open and solid circles) at $E_i = 120$ meV. S_{Cl}, S_{random}, and S_{CH_3} are the initial sticking probabilities (S_0) for the Cl-end, the random orientation, and the CH_3-end incidence, respectively. Above 280 K, an obvious orientation effect appears and its onset agrees well with the decrease of S_{random}.

It is quite interesting that, when the surface is exposed to molecules in the $|212\rangle$ state (Fig. 32.10), no similar orientation effects are observed, as shown in Fig. 32.11. The steric effect observed for the $|111\rangle$ state strongly couples with the desorption off the potential well of the precursor state. Desorption occurs under nonequilibrium conditions before the molecule can thermalize in the precursor state, dissipating energy by phonon and/or electron–hole pair excitations.

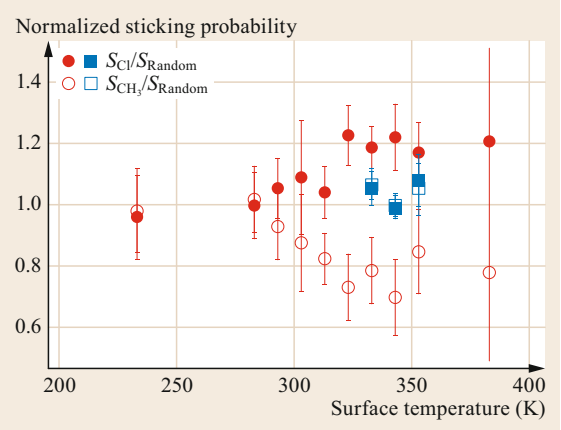

Fig. 32.11 T_s dependence of S_{Cl}/S_{random} and S_{CH_3}/S_{random} for CH_3Cl (*full* and *open circles*, respectively) and (*full* and *open squares*, respectively) incident at $E_i = 120$ meV (Reprinted with permission from [32.54]. Copyright (2005) by the American Physical Society)

For the $|212\rangle$ incidence, the first Legendre moment, corresponding to the orientation in the Legendre expansions of $W(\cos\gamma)$, is smaller than that for the $|111\rangle$ state. Moreover, as is apparent from the orientation distribution function shown in Fig. 32.10, the average orientation of the $|212\rangle$ state is closer to the stable precursor geometry and thus the steric effect is smeared out by the steering effect in the attractive well of the precursor state. We expect an effect of alignment for the $|212\rangle$ state due to the larger contribution of the second Legendre moment: this may account for the small offset of the data from 1 observed for the $|212\rangle$ state.

Figure 32.12 shows the T_s dependence of S_{Cl}/S_0 (full circles) and S_{CH_3}/S_0 (open circles) for the $|111\rangle$ (upper panel) and the $|212\rangle$ (lower panel) states at an incident energy of 65 meV. At variance with the results obtained at a kinetic energy of 120 meV for CH_3Cl incidence, when the kinetic energy is lowered to 65 meV, no clear orientation effects are observed for both the $|111\rangle$ and $|212\rangle$ states within experimental errors across the whole range of T_s. Steric effects thus disappear when lowering the kinetic energy, suggesting that strong steering effects reorient the slowly moving molecule into a more favorable orientation.

The steric effects in a shallow potential well (such as a precursor well) are confirmed in the scattering of CH_3Cl from HOPG [32.58, 59] and Si(111) [32.57]. Figure 32.13 shows the molecular orientation dependence of the TOF spectra for oriented 320 meV CH_3Cl incidence at $\theta_i = 45°$ (the detector being at $\theta_s = 45°$) on the Si surface at 300 K. Clearly, the scattering intensity for the CH_3-end collision is higher than that for the Cl-end collision at both temperatures. This result agrees well with the result obtained for HOPG.

In Fig. 32.13, the top panels also demonstrate that the molecular orientation effect appears in direct inelastic scattering. The profile of the difference spectrum between the CH_3-end and Cl-end collisions is in good agreement with the direct inelastic components obtained from the TOF spectra in an experiment performed for random incidence conditions. The higher trapping probability observed for the Cl-end collision on Si(111) is consistent with the molecular orientation dependence of the initial sticking probability reported for CH_3Cl on Si(100).

32.1.7 Alignment of O_2 by a Magnetic Hexapole

Kurahashi et al. developed a highly purified single spin-rotational state-selected ($(J, M) = (2, 2)$) O_2 beam by combining a supersonic oxygen beam with a magnetic hexapole field. The hexapole magnet is described in detail in previous reports [32.23, 65], so only a brief description is provided here. The strength of the inhomogeneous field $B(r)$ at a radial distance r in the gap between the poles of a hexapole magnet is given by

$$B(r) = B_0 \frac{r}{r_0} , \tag{32.12}$$

where r_0 is the Bohr radius and B_0 is the field strength at $r = r_0$. A molecule with an effective magnetic moment $\boldsymbol{\mu}_{\text{eff}}$ feels a deflection force towards the axis if $\mu_{\text{eff}} = |\boldsymbol{\mu}_{\text{eff}}| < 0$, but away from the axis if $\mu_{\text{eff}} > 0$. The force $F(r)$ can be expressed as follows if μ_{eff} is field independent

$$F(r) = 2\mu_{\text{eff}} \frac{B_0}{r_0^2} r . \tag{32.13}$$

This deflection force causes harmonic oscillation of a particle with $\mu_{\text{eff}} < 0$ and provides focusing of single rotational states of a molecule.

Figure 32.14 shows a schematic diagram of the apparatus used for the sticking probability measurements using state-resolved O_2. The beam line producing a state-selected O_2 consists of a beam source, a hexapole magnet, a spin flipper, and a Stern–Gerlach analyzer. The O_2 beam with $(J, M) = (2, 2)$ is generated by preparing a supersonic rotationally cold O_2

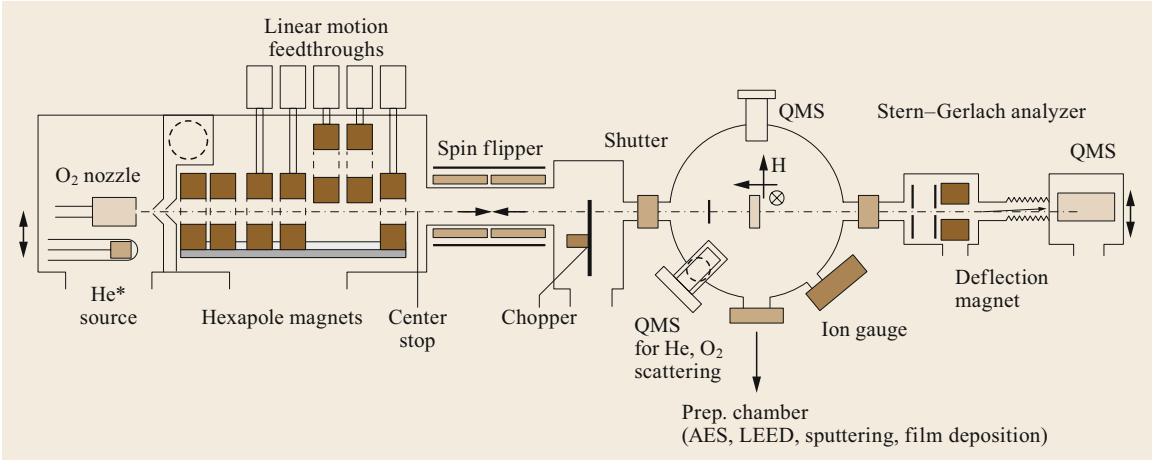

Fig. 32.14 Schematic diagram of experimental apparatus used for alignment- and spin-resolved O_2 sticking studies (Reprinted from [32.23], with permission from Elsevier)

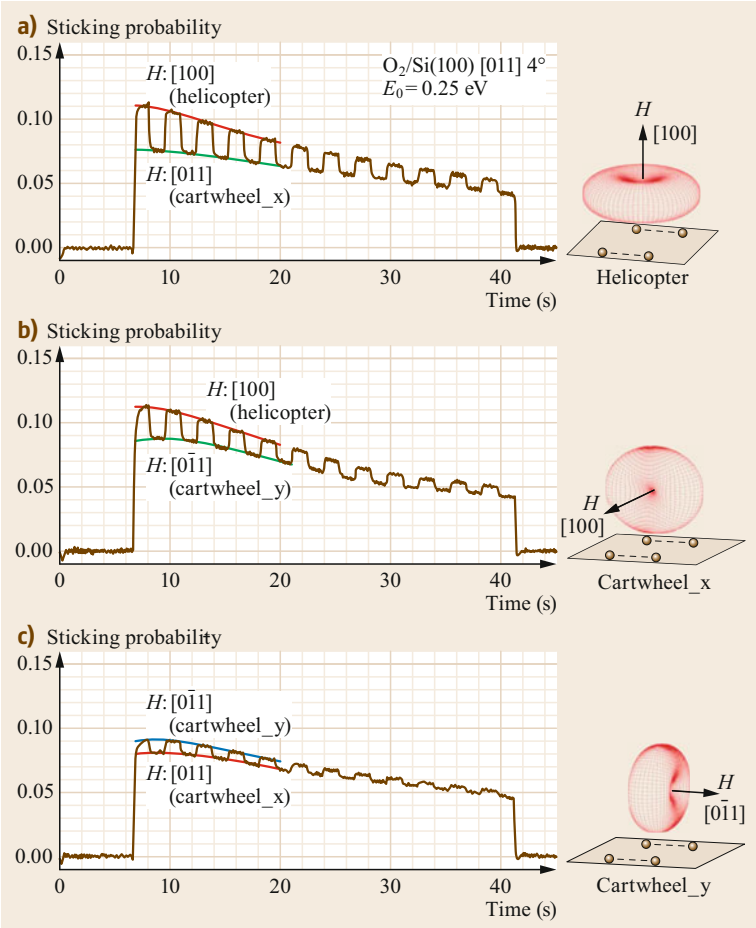

Fig. 32.15a–c Time evolution of sticking probability measured for a vicinal Si(100) surface at translational energy of 0.25 eV while alternating two of the three geometries shown in the *inset*. The dimers formed between two surface Si atoms are shown as short bars (Reprinted from [32.66], with the permission of AIP Publishing)

beam and selecting the (2,2) state of O_2 using the magnetic hexapole technique. Using this approach, control of both the molecular alignment and the spin direction relative to the magnetic field ($\boldsymbol{H}$) can be achieved [32.23, 65–69].

Since the O_2 molecular axis of $(J, M) = (2, 2)$ is dominantly perpendicular to the applied $\boldsymbol{H}$ direction, three different geometries can be realized by controlling the $\boldsymbol{H}$ direction at the sample, as shown in Fig. 32.15a–c.

By using such a state-selected molecular beam technique, the sticking probability for O_2 on Si(100)-(2×1) for different geometries of impingement was measured and a clear dependence of the sticking probability on the molecular alignment found [32.66]. The sticking probability is highest for the helicopter-like (HE) geometry (Fig. 32.15a), demonstrating the high preference for the side-on collision in dissociative adsorption. The two cartwheel-like (CW) geometries (Fig. 32.15b,c) reveal, on the other hand, the azimuthal dependence of the sticking probability, where O_2 is more reactive when its axis is perpendicular to the Si dimer [32.66].

Kurahashi and *Yamauchi* also measured the alignment dependence of the sticking probability of O_2 on Al(111) [32.68]. They clarified that O_2 reacts with its axis nearly parallel to the surface at kinetic energy < 0.2 eV and concluded that the abstraction process, which occurs when the O_2 axis is perpendicular to the surface, is a minor event at low kinetic energy.

The effect of spin in the dissociative adsorption of O_2 on a Ni(111) film was demonstrated by the same research group by using a state-selected molecular beam [32.69]. It was found that the sticking probability strongly depends on the relative spin directions of the Ni surface and the incoming O_2 in Fig. 32.16 and in particular that O_2 dissociates more efficiently when its spin is antiparallel to the majority spin direction of the Ni(111) film, a result relevant for spin-controlled surface chemical reactions.

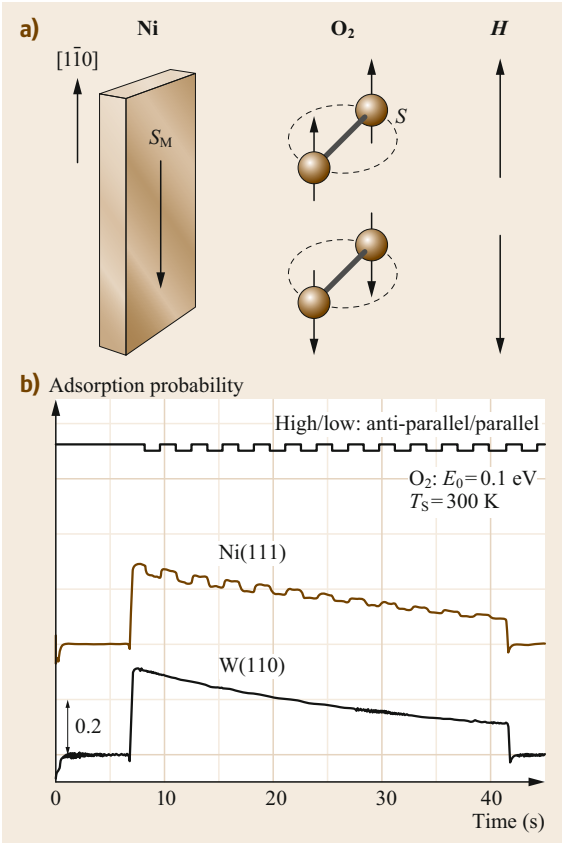

Fig. 32.16 (a) Control of the O_2 spin direction by the defining magnetic field. **(b)** Spin-dependent O_2 adsorption on a Ni(111) film surface. The adsorption probability is changed when the O_2 spin direction relative to the majority spin direction of the Ni film (S_M) is alternated. No spin-dependent effect is observed for O_2 adsorption on a nonmagnetic W(110) surface (Reprinted with permission from [32.69]. Copyright (2015) by the American Physical Society)

32.1.8 Collisional Alignment

Alignment and consequent molecular polarization can be induced by collisions in environments with anisotropic velocity distributions or temperature gradients. The occurrence of collisional alignment was firstly evidenced long ago in connection with the study of gaseous transport phenomena of paramagnetic molecules such as O_2 [32.70–72]. Subsequently, *Beenakker* et al. demonstrated that this phenomenon is common to nearly all diatomic gases, including diamagnetic molecules [32.73]. Collisional alignment in molecular beams, from supersonic nozzle sources, was anticipated by *Ramsey* [32.74] and first reported by *Steinfeld*, *Korving*, and coworkers [32.75, 76] in the 1970s.

The discovery of the dependence of the degree of alignment on the final speed for O_2 seeded in He [32.77], for N_2 [32.78], benzene [32.79], ethene [32.80], and acetylene [32.81], made it possible to perform experiments using aligned molecules both in the gas phase [32.82, 83] and at surfaces [32.84–90] by exploiting the velocity dependence of the collisional alignment [32.91, 92]. By seeding a few percent of such molecules in He (or Ne), hyperthermal beams are obtained.

Molecules in the beam are rotationally cold, due to the efficient energy transfer from the rotational degrees of freedom into translational energy made possible by the large number of collisions taking place in the nozzle region under the conditions of supersonic expansion. Notably, the low-speed tail of the velocity distribution has a statistical distribution of alignments, while the high-speed tail consists mainly of molecules in low-helicity states [32.93]. Molecules in orientations and rotational states that present a large collision cross section when viewed along the beam direction undergo a larger number of collisions during the supersonic expansion and thus end up with higher kinetic energy (fast tail), while the slowest molecules, which have undergone a smaller number of collisions, show no preferential alignment.

The strong dependence of the degree of alignment on velocity enables the use of a mechanical chopper (velocity selector) to select molecules in the slow or fast tail and to use them for gas-phase as well as adsorption experiments [32.94].

We have considered two different sets of systems:

a) Molecularly chemisorbed systems (such as $C_2H_4/O_2/Ag(001)$ [32.84, 87], $C_3H_6/Ag(001)$ [32.86], C_2H_4 on C-contaminated Cu(410) [32.21], $C_2H_4/Pd(100)$ [32.92])
b) Dissociative adsorption reactions (O_2 adsorption on bare and CO-precovered Pd(100) [32.85, 88–90], $O_2/Ag(001)$ [32.21].

A typical experiment is shown in Fig. 32.17. The slow tail (ST in the following) or the fast tail (FT in the following) is selected using an appropriately designed mechanical velocity selector. The degree of alignment for C_2H_4 as a function of velocity was obtained by scattering experiments with an inert gas target in Perugia using a high-resolution velocity selector. The selector used for adsorption studies has a lower resolution since a higher intensity is required to measure the sticking probability directly using the retarded reflector method of King and Wells. The concentration of CW estimated for the two-disk velocity selector operating in Genoa is 0.42 ± 0.03 for the ST

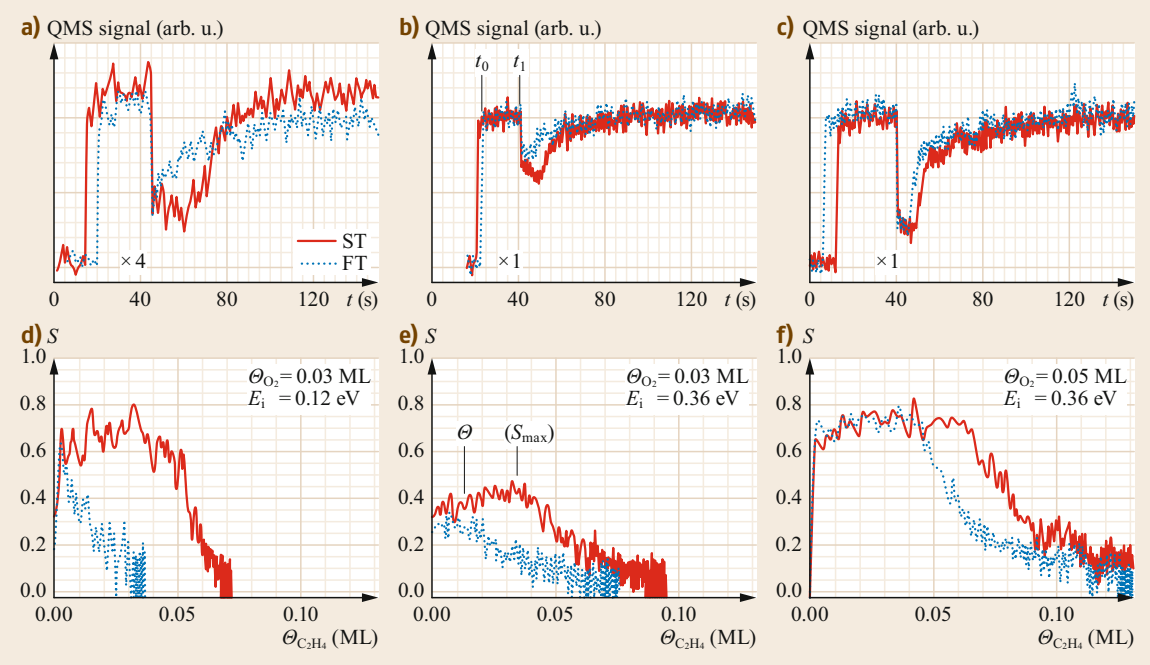

Fig. 32.17a–f KW traces **(a–c)** and $S(\Theta)$ curves **(d–f)** showing the results of ethene uptake experiments on O_2-precovered Ag(100). Different O_2 precoverages and C_2H_4 translational energies are reported (Reprinted from [32.21], with permission from Elsevier)

of the velocity distribution and 0.67 ± 0.05 for the FT.

Figure 32.17a–c shows the ethene partial pressure as a function of time for three different conditions. In all cases, the molecular beam enters the main chamber at $t \approx 20$ s, thus causing an increase in the quadrupole mass signal. As explained in the introductory paragraph, it is possible to obtain the coverage Θ by integrating $S(t)$ over time, thereby obtaining $S(\Theta)$. The result is shown in Fig. 32.17d–f. Inspection of the experimental data clearly shows that:

a) The initial sticking probability S_0 is independent of the polarization, being the same for ST and FT
b) With increasing surface coverage, a stereodynamical effect sets in above a certain coverage, which depends on the amount of preadsorbed oxygen molecules.

Above such ethene coverage, the sticking probability is higher for ST and FT, indicating that helicoptering molecules have a higher sticking probability than cartwheeling ones. We can thus safely conclude that, at the kinetic energies probed here, the interaction between ethene and the bare surface is not affected by the alignment of the impinging molecule. The same results have also been obtained for C_3H_6/Ag(001) and C_2H_4/C-Cu(410), thus indicating that the additional surface corrugation introduced by the presence of a preadsorbed species or by a regular array of steps is not sufficient to cause an observable effect of rotational alignment on the initial sticking probability. Possibly, despite the weakness of the bond, steering forces are still strong enough to suppress rotational effects in the low coverage limit, i.e., when only the interaction between the gas molecules and bare surface matters.

At higher coverage, a more complex scenario must be considered. Evidently, impinging helicopters have a higher chance to stick than cartwheels when they collide with preadsorbed species. Since the heat of adsorption decreases with increasing coverage, the onset of the stereodynamical anisotropy corresponds to the point at which steering is no longer strong enough to suppress the effect of the incoming alignment. The absence of any effect at all coverages for C_2H_4/Pd(100) [32.92], a more strongly bound chemisorption system with ethene molecules in a ff-bonded configuration, fits well with this picture.

Further consideration is needed regarding the relatively high magnitude of the steric effect at relatively low hydrocarbon coverage. If the anisotropy were to arise directly from the interaction between aligned gas-phase ethene and preadsorbed ethene molecule, it would not be possible to account for the huge difference in S of

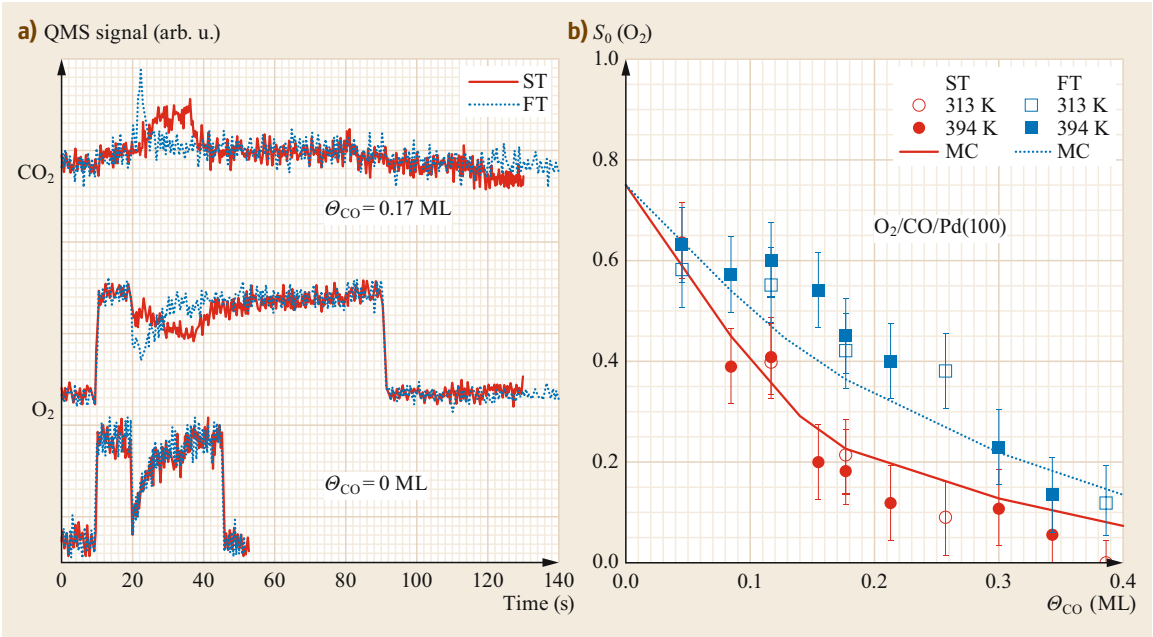

Fig. 32.18a,b O_2 partial pressure in the crystal chamber, measured by a QMS not in line of sight with the SMB, as a function of time for the ST and FT tails of oxygen SMBs interacting with the bare surface (*bottom traces*) and with Pd(100) precovered with 0.17 ML of CO (*middle traces*). The *top traces* show the signal due to CO_2 production during exposure (Reprinted from [32.21], with permission from Elsevier)

ST and FT observed for example at 0.05 ML at 0.12 eV and low O_2 precoverage. We must then conclude that C_2H_4 molecules that are not scattered immediately after the first hit with the surface must remain temporarily trapped as a mobile and nonthermalized precursor with a memory of its initial alignment so that, in this condition, CWs have a higher chance of being scattered back into the gas phase than HEs when colliding with already chemisorbed flat-lying C_2H_4 molecules.

No stereodynamical effects on the sticking probability S were observed for O_2/Ag(001) or O_2/Pd(001) (see Fig. 32.18 for $\Theta_{CO} = 0$): both its initial value and its coverage dependence resulted the same for ST and FT, within the attained experimental sensitivity [32.21].

When considering the interaction of O_2 with CO-precovered Pd(100), a more complex scenario is revealed. As is apparent from Fig. 32.18, the initial sticking probabilities S_0 for ST and FT are quite different in the presence of a significant CO precoverage ($\Theta_{CO} =$ 0.17 ML). In Fig. 32.18b, S_0 is plotted as a function of Θ_{CO} at two different temperatures for ST and FT. It is evident that:

a) S_0 decreases with increasing Θ_{CO} at both temperatures.
b) S_0 decreases more rapidly for ST than for FT. Since FT has a higher fraction of cartwheeling molecules (> 80%), this implies that cartwheeling molecules have a higher sticking probability in the presence of preadsorbed CO.

Point (a) is easily explained by the fact that, the higher Θ_{CO} is, the lower the number of free Pd sites available for the oxygen adatoms resulting from the dissociation of the incoming O_2. The fact that cartwheels have a higher sticking probability than helicopters at nonvanishing Θ_{CO} can be explained by considering in detail the array of empty sites needed for the landing and dissociation of helicoptering and cartwheeling O_2. A larger array is required for helicopters since, in a classical picture, their molecular axis is always parallel to the surface, thus explaining the more rapid decrease of S_0 for ST than FT. The reader is referred to the original papers for the details of the model; here we just underline that it can account in a quantitative way for the experimentally observed decrease (see lines in Fig. 32.18b).

A completely unexpected result was found for $\Theta_{CO} = 0.04$ ML (Fig. 32.19): despite the identical values of S_0 for ST and FT, a remarkably higher CO_2 yield was found for ST than for FT, both at 313 and at 393 K. It is clear that at least part of the oxygen atoms resulting from the dissociation of helicopters and cartwheels must end up at different sites to account for the observed large difference in reactivity.

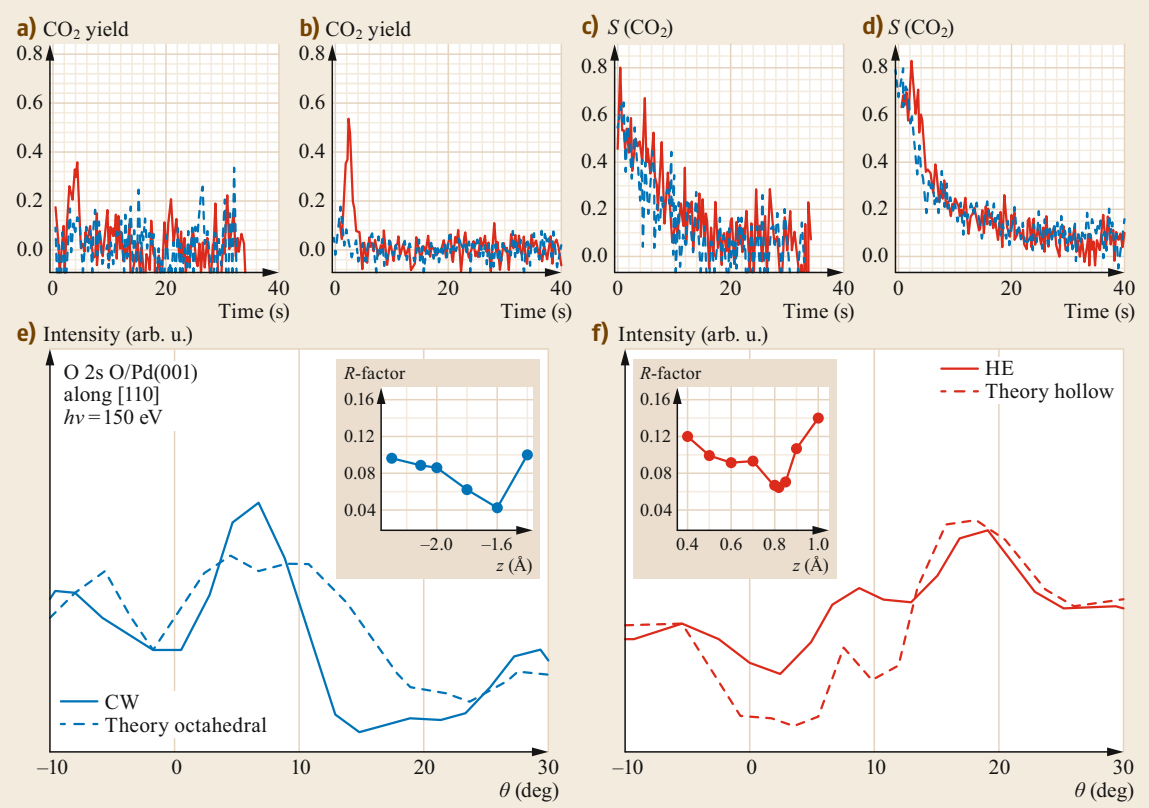

Fig. 32.19 **(a,b)** CO_2 yield and **(c,d)** O_2 sticking probability as functions of time for O_2 molecules from the ST (*red solid line*) and FT (*blue dashed line*) on Pd(001) precovered with 0.04 ML of CO at 313 K **(a,c)** and 394 K **(b,d)**. The traces for the CO_2 yield are corrected for the different ionization factor, so that the intensities can be directly compared. **(e,f)** Deconvoluted experimental XPD intensities of the O 2s level versus electron emission angle (*dot-dashed lines*) for HE **(f)** and CW **(e)**, compared with the theoretical fit using the model described in the text (*continuous line*). The photon energy is 150 eV, and the detection direction is along the ⟨110⟩ azimuth (Reprinted with permission from [32.88], © Wiley 2009)

X-ray photoelectron diffraction (XPD) experiments were then performed following adsorption of O_2 on Pd(100) in the absence of CO. Due to the proximity of the O 1s line to the Pd line, the photoelectron diffraction was performed for the O 2s line. The experimentally measured angle dependence of the diffracted intensity can be explained if the oxygen atoms resulting from the dissociation of the cartwheeling molecules occupy octahedral subsurface sites while the oxygen atoms resulting from the dissociation of helicopter-ing O_2 end up in fourfold hollow sites. Such assignments naturally account for the observed different CO_2 yield: since oxygen atoms occupying subsurface sites cannot react with adsorbed CO, the amount of CO_2 produced when the FT of the velocity distribution impinges onto a Pd(100) surface with 0.04 ML of CO is due to the fraction of helicopters present in FT.

A few experiments were also performed with higher nozzle temperatures [32.90]. While for $T_N = \mathrm{RT}$, almost all molecules populate the state with $K = 1$, at higher T_N a non-negligible fraction of O_2 populates higher rotational states with $K > 1$. Unfortunately, no experimental measurements of the degree of alignment have been performed for $T_N > \mathrm{RT}$. However, it is safe to assume that, with increasing T_N, higher rotational states start to be populated. Inspection of the O_2 uptake curves (Fig. 32.20) shows that molecules in higher rotational states behave differently with respect to rotationally cold ones with $K = 1$.

With increasing T_N, the amount of reactive O atoms produced with FT grows. This result indicates the propensity for rotationally hotter molecules in FT (i.e., for rotationally hotter cartwheels) to dissociate, yielding adatoms instead of oxygen atoms ending up at subsurface sites. Conversely, the lower amount of CO_2

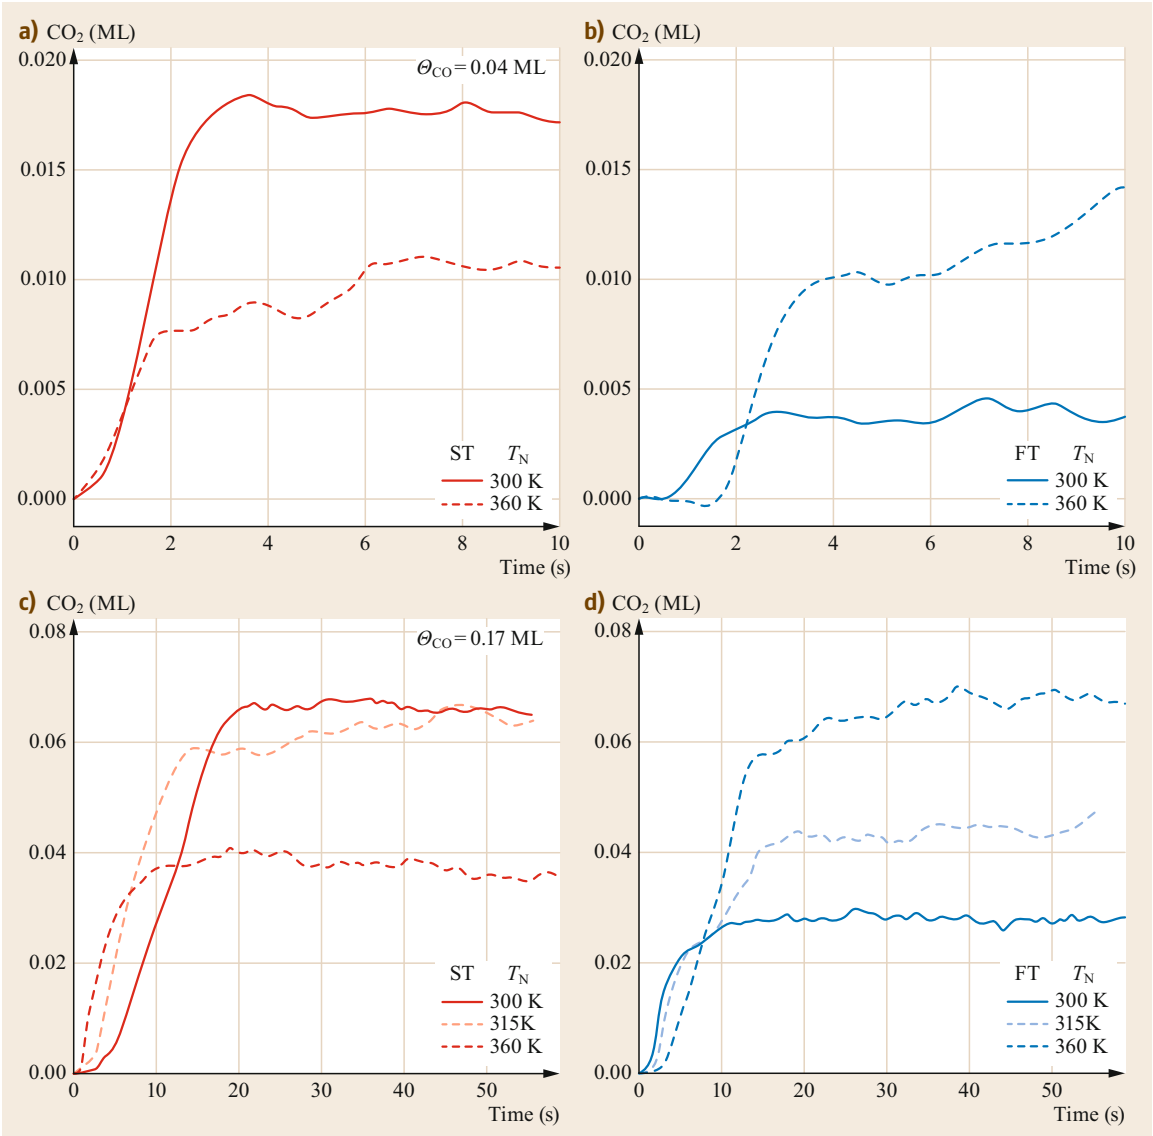

Fig. 32.20a–d Amount of CO_2 produced [in ML of the Pd(100) surface] versus time for a surface precoverage of $\Theta_{CO} = 0.04$ ML **(a,b)** and for $\Theta_{CO} = 0.17$ ML **(c,d)** for ST **(a,c)** and FT **(b,d)** while operating the source at different T_N (after [32.90])

produced by ST at higher T_N might indicate that non-reactive oxygen atoms are produced by the dissociation of the rotationally hotter molecules in ST (i.e., by rotationally hotter helicopters).

32.1.9 Laser-Based Methods

When using supersonic molecular beams, substantial rotational cooling occurs, so that molecules populate only low J states. Typical optical selection rules allow to change J only by 1 or 2 units, so that laser pumping of supersonic molecular beams cannot easily prepare molecules in states with predefined rotational quantum number [32.96]. Most results about rotationally hot molecules have indeed been obtained either by substantial annealing the nozzle so that a significant population of high rotational states may arise or by comparing the results of adsorption experiments using rotationally cold supersonic beams with effusive (i.e., rotationally hotter) beams.

As an example, we summarize here one of the few laser experiments reporting the effect of the rotational

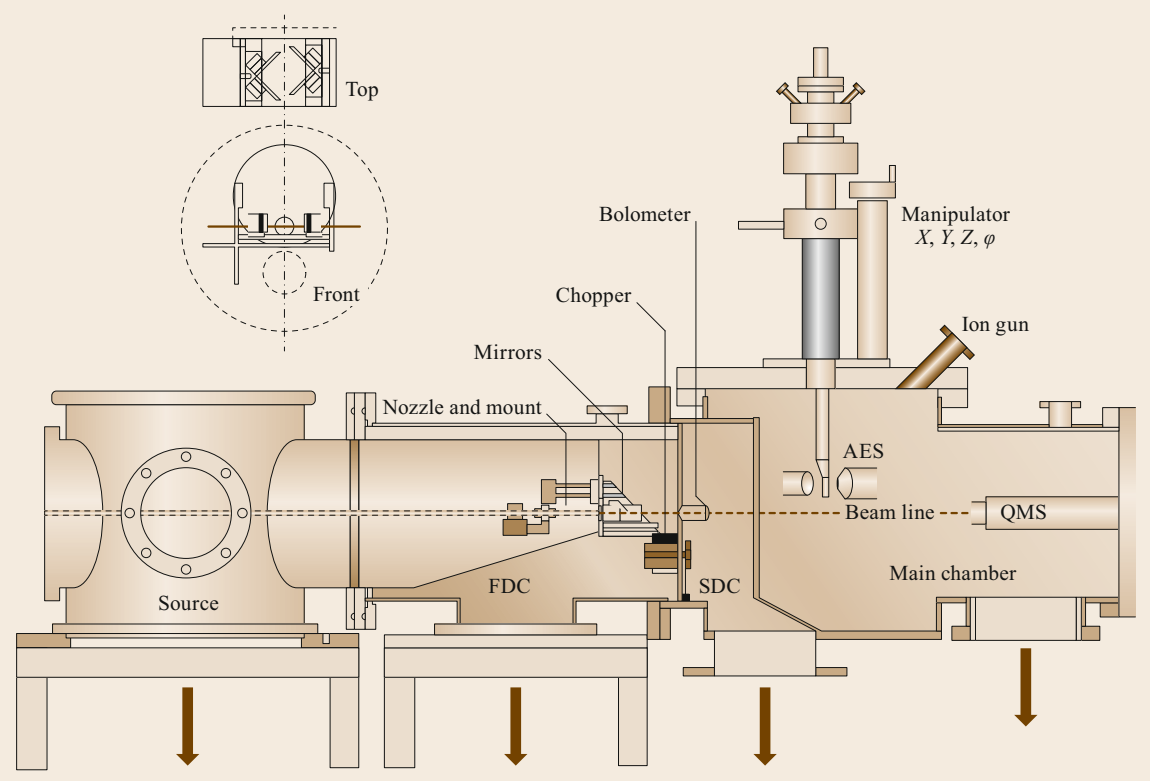

Fig. 32.21 Molecular beam–surface analysis chamber showing the four vacuum chambers, source, first differential pumping stage (FDC), second differential pumping stage SDC), and main surface analysis chamber (Reprinted from [32.95], with the permission of AIP Publishing)

state on the adsorption probability. The experimental setup is shown in Fig. 32.21.

Experimental results for methane excited from the ground state $\nu = 0$ to the first excited state $\nu = 1$ of the ν_3 antisymmetric CH stretching vibration are shown in Fig. 32.22. The total fraction of molecules excited in the beam is the product of the $\nu = 0, J''$ state population and the fractional excitation out of that state. Populations of levels ($\nu = 0$) in the molecular beam are calculated by scanning the infrared (IR) laser over $R(J'')$ transitions for all the J'' ($\nu = 0$) levels present in the beam, integrating the absorption signal, and normalizing for transition probability (see [32.95] for details).

The results for the initial sticking probability of vibrationally hot methane are shown in Fig. 32.22.

At first sight, rotational effects might be expected [32.18]; indeed, over the range of kinetic energy (from ≈ 0.1 to ≈ 0.5 eV) and of J values (up to $J = 3$) reported in that study, the timescale for rotation is comparable to the time the molecule spends in the effective range of the surface interaction potential. However, for this system, the initial sticking probability is independent of the rotational state, at least up to $J = 3$ and independently of the kinetic energy. On closer inspection, this result should not be surprising: adsorption of methane on Ni(100) occurs dissociatively, and vibrational excitation of the $\nu = 3$ mode is essential to obtain a high sticking probability, so that the dependence of the barrier on the rotational states (if present) becomes irrelevant.

32.2 Effect of Vibrational Energy on *S*

It is useful to address briefly also the relative role of kinetic and vibrational energy in determining the adsorption probability of a gas species at a surface. Polanyi suggested some simple rules to correlate the energy required for a chemical reaction and the shape of the potential energy surface (PES). For the reaction

$$\mathrm{A} + \mathrm{BC} \rightarrow \mathrm{AB} + \mathrm{C} \qquad (32.14)$$

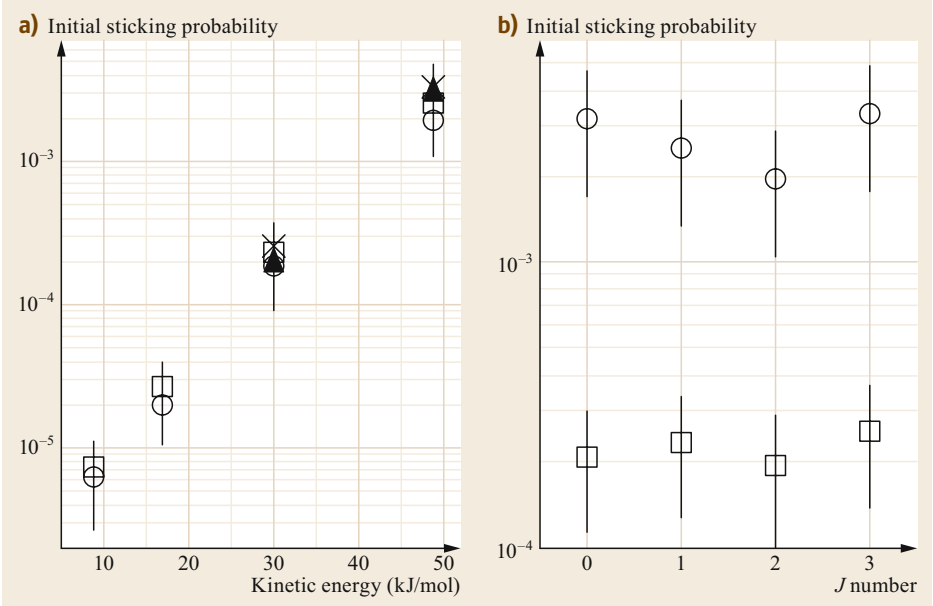

Fig. 32.22 **(a)** Initial sticking probability of methane on Ni(100) for $\nu = 1$ (ν_3) and different rotational states $J = 0$ (▲), $J = 1$ (□), $J = 2$ (◯), and $J = 3$ (×) as a function of kinetic energy. **(b)** Initial sticking probability for $\nu = 1$ (ν_3) as a function of J state for kinetic energy of 49 (◯) and 30 kJ mol^{-1} (□). Error bars show two standard deviations of convoluted uncertainties (Reproduced from [32.97] with permission of The Royal Society of Chemistry)

of an atom A with a diatomic molecule BC, basically two kinds of PES can be found (Fig. 32.23):

i) If the transition state separating the reactants from the products is located in the *entrance channel*, i.e., where the BC bond length has not yet increased, then a certain amount of kinetic energy is more effective than the same amount of vibrational energy in promoting adsorption.
ii) If, on the contrary, the transition state is located in the *exit channel*, then vibrational energy is more effective than kinetic energy.

These two ideal cases are often referred to as the early and late barrier cases, respectively. The validity of this idea was already confirmed in pioneering studies on gas–surface interactions [32.99].

Figure 32.24 shows experimental data for the initial sticking probability of D_2 on Cu(111) as a function of the kinetic energy associated with the motion in the direction normal to the surface, i.e., the so-called normal energy ($E\cos^2\theta$). Sets of data recorded for different nozzle temperatures T_N are shown. It is apparent that, at low normal kinetic energy, the sticking probability is remarkably higher for the data points obtained at the highest T_N, even if the kinetic energy is the same. This result indicates that both translational and internal energy play an important role in overcoming the barrier to adsorption. The difference is due unambiguously to the different internal energy content of the cold and hot beams. Even if the molecules are both rotationally and vibrationally excited, the enhancement of the adsorption probability was correctly ascribed to the vibrational energy.

The use of laser methods has allowed detailed investigation of the effect of vibrational excitation on the sticking probability. By experimentally studying the scattering probabilities of NO on clean and oxygen-covered copper (111) surfaces, it was found that highly excited ($\nu = 13$ and 15) NO molecules adsorb on clean copper (111) with a probability as high as 0.87, more than three orders of magnitude greater than the adsorption probability for ground-state NO [32.100].

It has even been shown [32.101] that highly vibrationally excited NO molecules can induce electron emission off Cs-covered Cu(111). This result has shown that, when the vibrational energy exceeds the surface work function, direct conversion of vibrational energy into electronic excitations can occur in surface scattering. Dedicated reviews have appeared [32.98, 102, 103] covering a relatively limited but growing literature [32.104–114].

Figure 32.26 shows the paradigmatic result obtained for the initial sticking probability of methane on Ni(100). By using lasers, molecules in defined vibra-

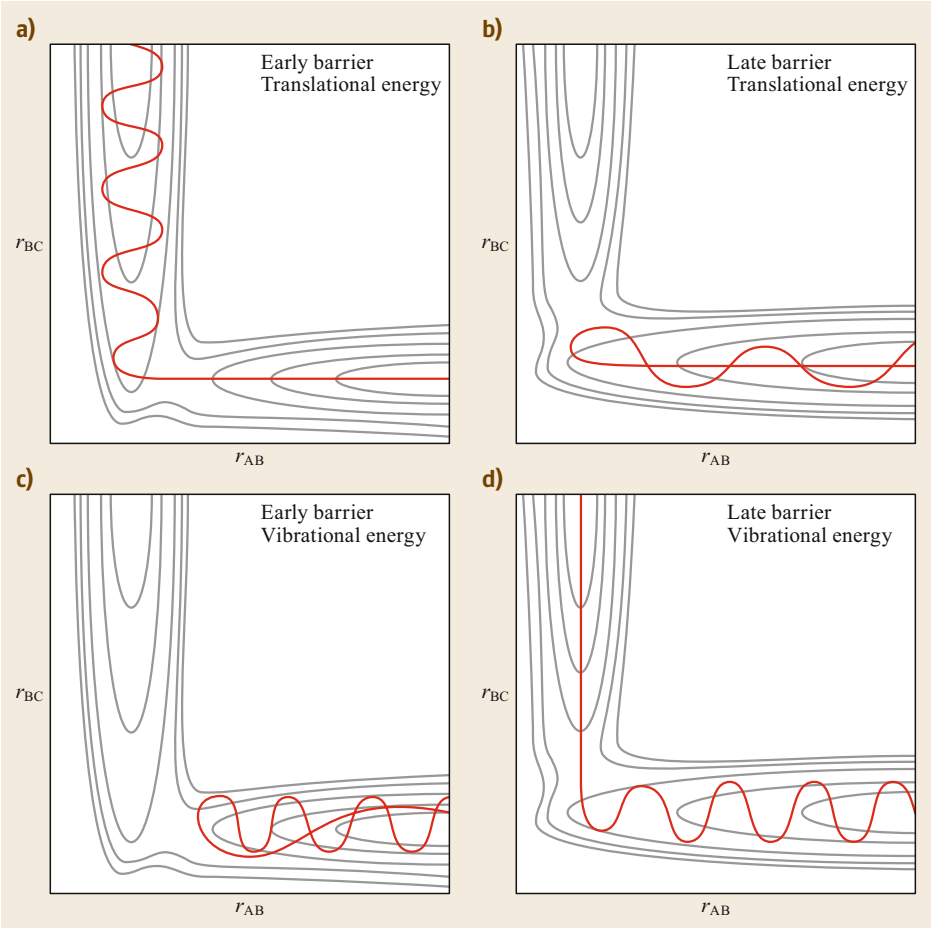

Fig. 32.23a–d Schematic potential energy surface for $A + BC \rightarrow AB + C$, showing the effect of adding translational energy **(a,b)** or vibrational energy **(c,d)** to the incident BC if the reaction has an early barrier **(a,c)** or late barrier **(b,d)** (Reproduced from [32.98] with permission of The Royal Society of Chemistry)

tional states are prepared (see the typical experimental setup in Fig. 32.25).

The amount of carbon (Fig. 32.26) produced by the cracking of methane is determined by inspection of the corresponding Auger signals after the exposure to beams of molecules in different vibrationally excited states and in the fundamental state (i.e., when the laser is turned off). By an appropriate calibration of the exposure, it is possible to obtain the sticking probability. The result of this experiment is shown in Fig. 32.26.

The data were fit using the equation for an S-shaped curve (32.7) applied to describe the energy dependence of S for activated systems. Independently of the exact mathematical definition of the barrier E_0, it is evident that the activation barrier decreases substantially when increasing vibrational excitation. It is thus apparent that CH_4 molecules in the second excited vibrational state ($2\nu_3$) have a sticking probability higher by more than one order of magnitude than molecules having the same kinetic energy in the fundamental vibrational state. The effectiveness of vibrational energy in promoting adsorption is moreover higher the lower the kinetic energy.

Similar results have been obtained for D_2O dissociation [32.110]. In order to determine the relative efficacy of translational and vibrational energy in overcoming the adsorption barrier it is instructive to compare the values of E_0 for $\nu_3 = 0$ and $\nu_3 = 1$. For methane dissociation, for example, the addition of 66 kJ mol^{-1} of translational energy increases S_0 for vibrationally cold molecule by the same amount as adding 72.1 kJ mol^{-1} of vibrational energy via the excitation of the $2\nu_3$ state.

It has also been shown that the reduction of the adsorption barrier $\Delta E_0 = E_0(\nu = 0) - E_0(\nu_i)$ produced by vibrational excitation depends on the identity of the reactant's quantum state. For methane dissociation on Pt(110), for example, ΔE_0 is 33.6 kJ mol^{-1} for the pure stretch ($2\nu_3$) but only 20.9 kJ mol^{-1} for the pure bend ($2\nu_2 + \nu_4$) modes [32.98]. This phenomenon is often referred to as vibrational state (or mode) specificity.

Utz and coworkers reported [32.103] a compilation of results showing the change in the adsorption barrier

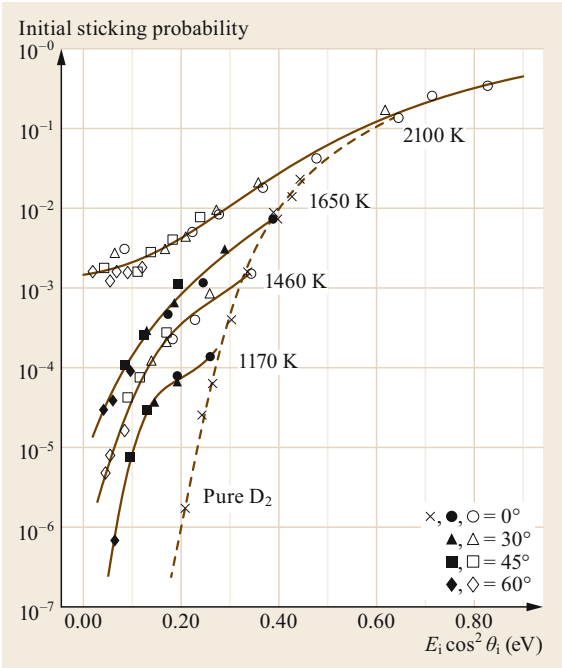

Fig. 32.24 Initial adsorption probability for D_2 on Cu(111) versus normal kinetic energy. Data obtained using seeded beams at four nozzle temperatures. Copyright (1992) by the American Physical Society)

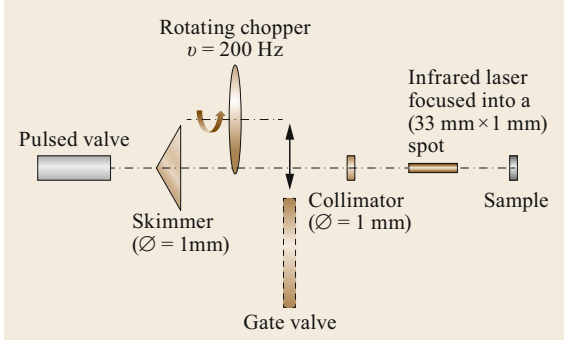

Fig. 32.25 Schematic of experimental setup. Methane seeded in H_2 is expanded, creating a pulsed supersonic molecular beam. The nozzle is opened by a valve operating at 20 Hz. The kinetic energy of the CH_4 molecules is controlled by the methane/H_2 ratio and by the temperature of the valve. A skimmer and a chopper control the profile of the beam and slice it into pulses. During its path to the sample (a single-crystal surface in these experiments), the molecular beam is irradiated by pulsed, tunable IR light to prepare a fraction (1–2%) in a specific rovibrationally excited quantum state. Sticking coefficients averaged over all vibrational states of methane populated in the beam were obtained from the ratio of the carbon coverage to the incident methane dose. Sticking coefficients for the state-selected CH_4 molecules were obtained from the difference between the coverages obtained with the laser on and off. (Data about the experimental setup taken from [32.105])

for different systems. These results are reported in Table 32.2.

Inspection of this table indicates that the excitation of the triply degenerate bending vibration $3\nu_4$ is much less effective than the excitation of the antisymmetric C–H ν_3, even though the amount of vibrational energy present in the former exceeds by 30% that available in the latter. These results contradict statistical theories of gas–surface reactivity and point to a central role for C–H stretching motion along the reaction path to dissociative chemisorption.

From this point of view, also the results shown for the adsorption of CH_4 on Ni(100) in Fig. 32.22 are not too surprising, since in this case the energy involved in the rotational motion is significantly lower than that provided by vibrational excitation.

The fundamentally nonstatistical nature of the phenomena is further proved by the experiment performed by *Killelea* et al. [32.115]. After exposing a clean Ni(111) surface to D atoms to preload the subsurface lattice sites with deuterium atoms, D adsorbed at the surface was removed (leaving only a residue of 0.03 ML) by recombinative desorption caused by the collision with Xe atoms. A surface prepared in this way is ready for testing with CHD_3 dissociation. The

Table 32.2 Compilation of experimental results about the efficacy of vibrational excitation of different quanta for CH_4 on different surfaces and for SiH_4 dissociation on Si(100) (1 × 2). The efficacy is defined here as the ratio between the change in the translational barrier ΔE_0 and the vibrational energy of the molecules (data taken from [32.103])

Molecule	State	E_{vib} (kJ mol^{-1})	Surface	ΔE_0 (kJ mol^{-1})	Efficacy

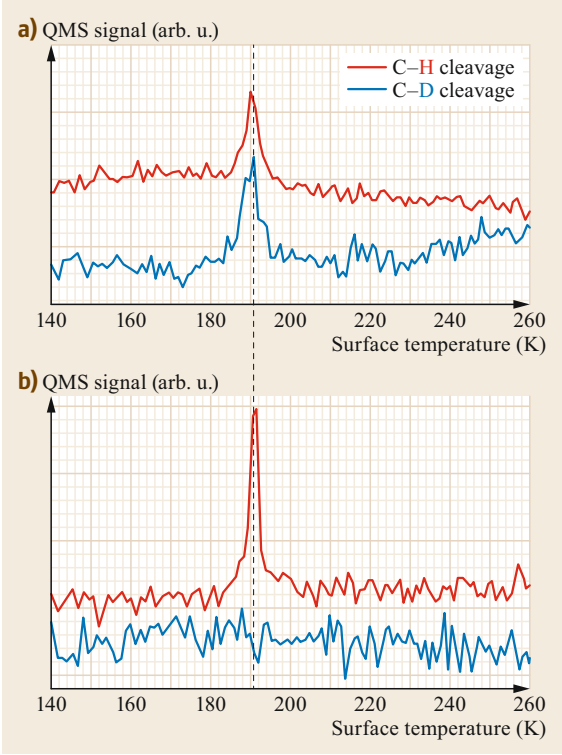

Fig. 32.27a,b Mass spectrometrically detected product yield for vibrationally mediated dissociative chemisorption of CHD_3 on Ni(111). **(a)** Yield of C–H and C–D cleavage products for a thermally populated ensemble of vibrational states. Approximately 40% of the molecules dissociated via C–H bond cleavage. In **(b)**, the product yield for CHD_3 molecules prepared in $\nu = 1$ of the ν_1 C–H stretching vibration is shown. At least 97% of the molecules dissociated via C–H bond cleavage (Reprinted from [32.103], with permission from Elsevier)

state-resolved experiments used a single-mode IR laser to excite CHD_3 to ν_1 ($\nu' = 1, J' = 2, K' = 0$) by the R(1)($\Delta K = 0$) transition at 3005.538 cm^{-1}. The vibrational energy (E_{vib}) is 36 kJ mol^{-1}, $\boldsymbol{J}'$ is the total angular momentum of the excited state, and $\boldsymbol{K}'$ is the projection of $\boldsymbol{J}'$ along the unique inertial axis.

The surface was exposed at 120 K, then temperature-programmed desorption was performed to check for the possible desorption products: D_2 (4 atomic mass units), CHD_3 (19 amu), and CD_4 (20 amu). During annealing, D atoms pre-embedded in the Ni lattice move to the surface, react with surface methyls, and form methane, which promptly desorbs. The integrated peak areas for 19 amu (CHD_3) and 20 amu (CD_4) provide a direct measure of C–D and C–H bond cleavage products, while Auger electron spectroscopy (AES) measurements were used to calibrate the coverage of desorbing species with respect to the surface coverage. The ratio of the two signals was used to quantify the branching ratio of C–D to C–H bond cleavage.

The product yields for C–H and C–D bond cleavage for thermal and state-resolved excitation of CHD_3 vibrations are compared in Fig. 32.27. In the upper panel (a), CHD_3 vibrations were thermally populated by keeping the source of the molecular beam at 600 K. The beam impinged on the surface with a kinetic energy of 57 kJ mol^{-1} and a vibrational energy of 5.9 kJ mol^{-1}. It was shown that about 40% of the reaction products were obtained from C–H bond cleavage while 60% were due to C–D bond cleavage. In the lower panel (b), the product yield for CHD_3 molecules prepared in $\nu = 1$ of the ν_1 C–H stretching vibration is shown. The vibrational energy is 36 kJ mol^{-1}, while the kinetic energy is still 57 kJ mol^{-1}, the total energy now being 93 kJ mol^{-1}. Since the yield of C–D bond cleavage products was below the detection limit (3%) of the total product yield, the authors could conclude that at least 97% of the molecules dissociated via C–H bond cleavage. The ratio between C–H and C–D bond cleavage was thus found to be higher than 30 : 1. In a complementary experiment, the authors compared this product ratio with that of another beam having the same total energy. By fixing the nozzle source at 830 K and using a 2% mixture of CHD_3 seeded in He, a beam with a ki-

netic energy of 80 kJ mol^{-1} and a vibrational energy of 14.4 kJ mol^{-1} for a total energy of 94 kJ mol^{-1} was obtained. Product yield measurements showed that 25% of the molecules dissociated via C–H bond cleavage. The corresponding C–H : C–D bond cleavage ratio was thus 1 : 3. Therefore, state-resolved excitation of the C–H stretching state altered the product ratio by nearly two orders of magnitude. This ensured that any differences in reactivity were not due to the total energy, but rather to the replacement of part of the incident kinetic energy with vibrational energy. The results of this experiment thus prove the nonstatistical nature of the underlying reaction mechanism.

A subsequent investigation using infrared spectroscopy extended this study to the chemisorption of all the partially deuterated methanes (CH_3D, CD_2H_2, and CHD_3) on Pt(111), reaching similar conclusions [32.116]. The results briefly reviewed here prove the relevant role played by vibrational energy in promoting methane dissociation and its nonstatistical nature. A key question now arises about the role of steric factors: does the orientation and or the alignment of the vibrationally excited molecule at impact influence its dissociation probability?

Circularly polarized light can be used to create an initially oriented sample where the population of the positive m levels is, for example, larger than that of the negative m levels, where m is the projection of $\boldsymbol{J}$ onto the quantization axis z. An aligned distribution can be prepared, on the other hand, by using linearly polarized light. Here, the population of the positive m level is the same as that of the negative m level while, for example, high $|m|$ levels are preferentially populated over low $|m|$ levels.

The possible transitions are classified into P, Q, and R branches according to the value of ΔJ (see top right panel in Fig. 32.28):

- $\Delta J = 0$ for the Q branch
- $\Delta J = -1$ for the P branch and
- $\Delta J = 1$ for the R branch.

We focus here on alignment, attainable by the adsorption of linearly polarized photons. Since a linearly polarized photon carries no angular momentum, the selection rule for the absorption of a linearly polarized photon is $\Delta m = 0$ and, for Q branch excitation only, $m \neq 0$.

Since the population of each m level in the excited state is the same, in the strong pumping limit (i.e., at high laser power) it is not possible to create an alignment using P branch excitation. On the contrary, both R and Q branch excitation are adequate to produce an initially aligned distribution, with $\boldsymbol{J}$ being aligned perpendicular to the laser polarization for R branch excitation and parallel to the laser polarization for Q branch excitation.

If weak pumping (i.e., a lower laser power) is used, the population transferred from the ground level to the excited level is proportional to the transition strength. Thus, it is possible to create alignment using P, Q, or R branch excitation.

The dependence of the initial chemisorption probability ($S_0(\theta)$) on the angle θ between the laser polarization and the plane of the surface is shown in Fig. 32.28. The aligned molecules were prepared through excitation of the ν_1 (C–H stretch) normal mode by linearly polarized IR light using rapid adiabatic passage. The alignment of the angular momentum causes also the alignment of the vibrational amplitude of the molecule, which for CHD_3 lies along the unique C–H bond.

When using Q branch excitation, both $\boldsymbol{J}$ and the C–H bond are aligned parallel to the polarization of the laser, while when using R branch excitation, the C–H bond is parallel and $\boldsymbol{J}$ is perpendicular to the polarization of the laser.

If the polarization of the laser is rotated, the alignment of the angular momentum $\boldsymbol{J}$ and of the C–H bond with respect to the plane of the surface are also modified. For R branch excitation, the sticking coefficient was found to decrease when the laser polarization was changed from parallel to perpendicular to the surface (Fig. 32.28a). The reactivity when the laser polarization is parallel to the surface (corresponding to $\theta = 0$) is up to 60% larger than when the laser polarization is aligned perpendicular to the surface ($\theta = 90°$).

The experiment was then repeated using Q branch excitation: the sticking probability was found to be larger when the laser polarization was parallel to the surface than perpendicular to it.

Since the direction of motion of the atoms due to the presence of the vibrational excitation is parallel to the laser polarization in both cases, while the direction of $\boldsymbol{J}$ is parallel to the polarization for Q branch excitation but perpendicular for R branch excitation, these experiments unambiguously demonstrate that the alignment effect is not due to the alignment of the angular momentum but to the alignment of the vibrational motion.

Yoder et al. also studied the alignment dependence of the dissociative chemisorption of CH_4 on Ni(100) when the ν_3 mode is excited. This mode corresponds to the antisymmetric C–H stretch normal mode, for which all four bonds vibrate with the same amplitude, although with different phases. Experiments show that the sticking probability is largest when the laser polarization is parallel to the surface, as shown in Fig. 32.28.

The Ni(100) surface was exposed to CH_4 molecules in a single rovibrationally excited state (one quantum of

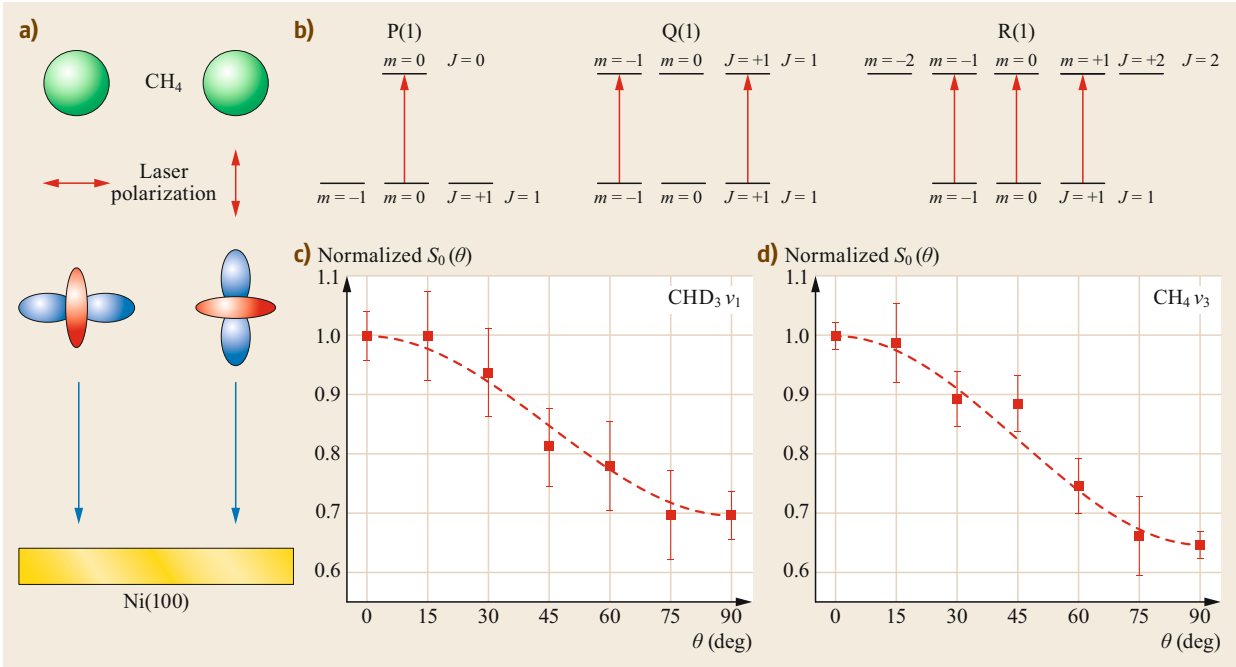

Fig. 32.28 **(a)** Schematic of the state-prepared and laser-aligned molecular beam deposition experiment. A molecular beam of CH_4 with initially isotropic spatial distribution of angular momentum $\boldsymbol{J}$ (*green spheres at top*) impinges on a Ni(100) surface at normal incidence (*yellow disc at bottom*). In their path towards the surface, the molecular beam is crossed by a continuous, linearly polarized laser beam focused in the direction of the molecular beam. Incident CH_4 molecules are prepared in a specific rovibrationally excited state by rapid adiabatic passage through the resonant laser beam. See [32.108] for details. The resulting probability distributions for $\boldsymbol{J}$ (*red*) and vibrational transition dipole moment $\boldsymbol{\mu}$ (*blue*) are shown for the case of R(0) excitation and two orthogonal polarization directions indicated by the *double-headed arrows*. **(b)** Scheme of the allowed transitions for P, Q, and R branch excitation for the absorption of a linearly polarized photon. **(c,d)** $S_0(\theta)$, normalized to the value measured when the laser polarization was parallel to the surface, as a function of the angle between the laser polarization and the surface (θ) for CHD_3 following ν_1 excitation **(c)** and CH_4 following ν_3 excitation **(d)**. The experimental data were obtained following R(0) excitation. The *line* is a guide to the eye (Reproduced from [32.98] with permission of The Royal Society of Chemistry)

the antisymmetric C–H stretch vibration ν_3 with aligned angular momentum $\boldsymbol{J}$ and with vibrational transition dipole moment in the laboratory frame) by using linearly polarized infrared radiation.

The preparation of the antisymmetric C–H stretch vibration ν_3 by using the R(0) transition at $3028.75\,\mathrm{cm}^{-1}$ ensures that alignment is attained by control of the laser polarization direction. Different laser polarization directions were employed, and the amount of C at the surface was then measured by Auger electron spectroscopy: the reactivity was found to be up to 60% higher with the laser polarization parallel to the plane of the surface than for perpendicular polarization.

If the preparation of the state is performed via the ν_3-P(1) transition, which produces no alignment of the excited molecules, no dependence of the reactivity on the direction of polarization is detected.

The dependence of the reactivity on the alignment of the vibrational motion demonstrates the absence of strong steering effects as the molecule approaches the surface: in the opposite case, the molecules would be turned when approaching the surface and S_0 would be independent of the angle of polarization of the laser.

Using similar experimental methods, the effect of vibrational energy on the physisorption of methane on Pt(111) has also been investigated [32.112]. It was found that vibrational excitation of the incident CH_4 with one quantum of ν_3 vibration does not produce any measurable effect on the trapping probability, in sharp contrast to the dissociative chemisorption process.

32.3 Conclusions

After briefly summarizing the main results obtained indirectly by use of detailed balance and by comparing experiments at different nozzle temperatures, we proceeded to highlight paradigmatic results obtained by preparing molecules in at least partially defined rotational and vibrationally excited states and measuring the sticking probability by the method of King and Wells.

We considered in particular:

a) Recent studies on chemical reactions of single-crystalline Si surfaces induced by oriented molecular beams prepared by the electrostatic hexapole technique. Steric effects were found in the dissociative adsorption of CH_3Cl on Si(100) surfaces. Trapping into a shallower precursor well plays an important role in the appearance of the observed steric effects. This conclusion is supported by the observation of steric effects in scattering processes in weakly bound systems of CH_3Cl on Si(111).
b) Recent studies on the adsorption of alignment-controlled molecular beams prepared by the magnetic hexapole technique. Precise control of the alignment (including spin) of a molecule is a new approach to the transition state for dissociative adsorption and for related chemical reactions.
c) Recent studies obtained by using collisional alignment of rotationally cold molecules in seeded beams. The latter method can be used for molecules having zero electric and magnetic moment, for which the former techniques cannot be applied. None of the systems investigated so far have shown steric anisotropy in the initial sticking probability on a bare surface, while large steric effects have been found at nonzero coverage. However, the possibility of tuning the final adsorption state by controlling the rotational alignment of the incoming molecule has been shown for O_2–Pd(100) as well as its effect on the reaction probability with preadsorbed CO.
d) State-of-the-art experiments in which molecules such as methane or water are prepared in well-defined vibrational states and their adsorption probability is measured as a function of kinetic energy. The dissociative adsorption probability turns out to be enhanced if appropriate vibrational modes are vibrationally excited, while the physisorption probability is not affected.
e) Dedicated experiments have shown the fundamentally nonstatistical nature of the role of vibrational energy in promoting dissociative adsorption (mode specificity).

Specific polarization (parallel to the surface) of the vibrational excitation is more effective than rotational alignment in promoting surface reactions when the vibrational excitation involves motion along the reaction coordinate.

We envisage two possible lines of development:

1) The use of oriented/aligned simple molecules to study and also control the selectivity of surface reactions and the synthesis of thin films.
2) The extension of these methods to more complex systems, such as model catalytic systems and biomolecular systems.

The coupling of such techniques with local probe microscopies [32.117] might in particular reveal new and still unexpected processes.

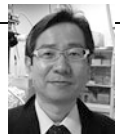
Osaka, Japan
okada@chem.sci.osaka-u.ac.jp



Michio Okada received his PhD from the University of Tokyo in 1993. He has worked at the University of Tennessee and Oak Ridge National Laboratory in the USA and at Osaka University in Japan, and is now a full professor at Osaka University. His research interests lie in the exploration of surface chemistry using molecular and ion beams.

Part H Chemical

Part H Chemical Reactions At Surfaces

Part H addresses the realm of surface reactions that occur under conditions similar to those present in catalytic industrial reactors. Surface reactions in the heterogenous phase can occur at either the gas–solid interface or the liquid–solid interface. The former case can be investigated under controlled ultrahigh-vacuum conditions; the latter by electrochemistry. The choice of catalyst for a particular product is dictated by not only thermodynamic and kinetic arguments but also—due to their impact in industrial processes—economic considerations, leading to a compromise between efficiency, selectivity, and costs.

It is necessary to underline that processes which can be investigated by surface science methods under controlled conditions are rather different from those that occur in industrial catalysis due to major differences in pressure and structure. The former arises because the typical pressure of an ultrahigh vacuum (UHV) is far lower than the atmospheric or higher pressures employed in reactors. The latter relates to the need to investigate single-crystal surfaces with very low defectivities to understand model systems and surfaces, even though these surfaces are quite different from those of the powders used in real catalysis. Studies performed at relatively high pressures (up to several mbar) and investigations of polycrystals have become feasible only very recently.

In electrochemistry, the application of a potential difference and the use of metallic electrodes introduces the possibility of adding energy to the system, thus facilitating endothermic reactions while exploiting the catalytic activity of the surface of the electrode. Experiments can be performed in highly controlled conditions, but additional variables are introduced since the nanoparticle morphology often depends on the external pressure, the concentrations of the reactants, and the pH of the environment.

Chapter 33 provides a synthetic overview of acidic, basic, oxidation, hydrogenation, and dehydrogenation catalysis utilizing metal, oxide, sulfide, and halide catalytic materials. The roles of promoters and stabilizers are explained. The catalytic system is often characterized by high complexity (it involves several components and different phases), which is difficult to address in fundamental surface science studies. As an example, the high-pressure steam reforming process for producing hydrogen from natural gas is described in detail. Attention is paid to the role of the Ni catalyst, as well as to the influence of the substrate that acts as a support. The roles of promoters and stabilizers are presented as well. These factors influence the choice of the reactor and the flow conditions to ensure the highest efficiency and selectivity.

Chapter 34 is devoted to electrocatalysis and focuses in particular on Pt and Au electrodes. Platinum (either pure or alloyed) is widely used in reactions relating to fuel cell technology, such as the hydrogen evolution reaction, hydrogen oxidation, oxygen reduction, and the oxidation of small organic molecules. Au electrodes are discussed for comparison. Starting from Faraday's law, the authors describe the correlation between the voltammetric behaviors of different solutions and the structure of the surface of the active electrode. The voltammetric signatures of several surface processes such as adsorption, surface reconstruction, faceting, and electrochemical reactivity are addressed, evidencing the roles of parameters such as the potential of zero charge and the maximum entropy.

33. From Surface Science to Industrial Heterogeneous Catalysis

Guido Busca

The different types of heterogeneous catalyst currently applied in the chemical industry are described. The catalytic activity is correlated to their main surface properties, which are the object of investigation based on surface science and theoretical calculations. Acidic, basic, oxidation, hydrogenation, and dehydrogenation catalysts are described. Metal, oxide, sulfide, and halide catalytic materials are considered. The practical need for promoters and stabilizers is underlined, frequently resulting in multicomponent and multiphasic catalytic systems. The complexity and multidisciplinarity of the field of heterogeneous catalysis research are emphasized, where collaboration among chemical engineers, material scientists, physical, inorganic, and organic chemists, and surface and material physicists is needed to fully understand phenomena and develop technologies. As a case study, the steam reforming process for producing hydrogen from natural gas is considered. The available data make it clear that knowledge on the molecular phenomena for most industrial processes is still largely incomplete and subject to debate. It is emphasized that surface science and surface chemistry, as well as computational studies, are needed to further improve existing technologies and to apply heterogeneous catalytic processes in the new era of industrial chemistry based on renewables.

33.1 Industrial Chemistry and Catalysis

Chemical technologies provide processes for the large-scale production of the materials (i.e., polymers, metals, semiconductors, etc.) and molecules (e.g., pharmaceuticals, cosmetics, detergents, etc.) that are essential for all other technologies (e.g., information and telecommunication technologies) and disciplines (e.g., medicine) as well as for household and personal life. In spite of the evident concerns associated with environment degradation, there is no doubt that industrial chemistry has been a major leading actor in the exponential technological development that has occurred over the last 150 years, allowing for the high level of wealth reached today by most of the population of developed countries. Unfortunately, this high level of wealth has not reached most of the population of less developed countries, as well as part of the inhabitants of industrialized countries. However, this is a matter of politics more than science and technology.

As first recognized by the Swedish chemist J. J. Berzelius in 1835 [33.1], catalysis is a phenomenon allowing a chemical reaction to occur faster when a nonreactant species is present. Catalysis gives rise to very relevant practical effects. In fact, such an increase in the rate of a reaction can in many cases result in practical feasibility. The acceleration of a desirable chemical conversion frequently allows it to be realized instead of other less desirable, competitive reactions, which become relatively slower. Thus, finding an appropriate catalyst to make the desired reaction faster than competing ones, as well as allowing it to be performed with high efficiency, is crucial to the development of industrial processes. For more than a century, heterogeneous catalysis has been a keystone of industrial chemistry [33.2].

33.2 Industrial Heterogeneous Catalysis and Catalysts

In practice, a large majority (likely $< 90\%$) of industrial chemical processes are catalyzed, and most of them are catalyzed by solids. World demand for catalysts is growing at a high rate, and the global market is expected to reach US $40B by 2022, up from US $28.6B in 2015, with a compounded average growth rate (CAGR) of 4.8% from 2016 to 2022 [33.3]. Refinery catalysts, environmental protection catalysts, polymerization catalysts, and chemical synthesis catalysts share the market.

The main reasons for using catalysts can be summarized as follows:

1. The use of a catalyst allows a desired reaction to become faster than competing reactions, thus allowing its practical realization.
2. For exothermic equilibrium reactions, the use of a catalyst also allows the reaction to be performed at a lower temperature at which it would be kinetically hindered otherwise. This allows the reaction to be realized in conditions where the thermodynamics is more favorable.
3. For endothermic equilibrium reactions, the use of a catalyst also allows the reaction to be performed at moderately high temperatures, where it would be kinetically hindered otherwise. This allows the reaction to be realized in conditions where the thermodynamics is already quite favorable with lower energy waste and using cheaper materials in the reactor.
4. For exothermic nonequilibrium reactions, the use of a catalyst allows reactions that are otherwise less favorable in terms of thermodynamics and kinetics to be realized instead of more favored and otherwise faster reactions.
5. The use of a better catalyst allows reactions to be performed in smaller flow reactors but with the same performance, or with better performance and fewer recycles of unconverted reactants in the same reactor, or even in shorter times in batch reactors.

In industry, solid catalysts are usually preferred over liquid catalysts because of their easier separation from the reaction fluid. Moreover, solid catalysts are

Table 33.1 Summary of some of the most relevant families of industrial catalysts and examples of their applications

Catalyst family	Reaction	Industrial catalyst	Catalyst functionality
Oxide catalysts			
Bulk single oxide	Alcohol dehydration to olefins and ethers	γ-Al_2O_3	Lewis acidic catalyst
Bulk mixed oxide	Aldol condensation	MgO-$MgAl_2O_4$ (calcined hydrotalcite)	Basic catalyst
Multicomponent oxide	Propane to acrylonitrile	V/Mo/Nb/Sb oxides	(Amm)oxidation
Oxide supported on oxide	*o*-Xylene to phthalic anhydride	V_2O_5/TiO_2	Selective oxidation
	Isobutane to isobutene	K_2O-Cr_2O_3/Al_2O_3	Dehydrogenation
Impregnated melt or liquid	SO_2 to SO_3	K_2SO_4-V_2O_5/SiO_2	Oxidation
	Olefin oligomerization	H_3PO_4/SiO_2 (*solid phosphoric acid*)	Protonic acid catalyst
Zeolite catalysts			
Protonic zeolite	Benzene + ethylene to ethylbenzene	H-BEA	Protonic acid catalyst
Cationic zeolite	N_2O decomposition/reduction	Fe-MFI (Mobil-5 zeolite)	Redox catalysts
Metal catalysts			
Bulk metals	Ammonia synthesis	Fe (CaO, K_2O, Al_2O_3, SiO_2 promoters)	Hydrogenation
Metal gauzes	Ammonia oxidation to NO	Pt (Rh stabilizer)	Selective oxidation
Supported metal	Acetylene hydrogenation in ethylene	Pd/Al_2O_3 (Ag promoter)	Preferential hydrogenation
	Car catalytic mufflers	Pt-Rh/Al_2O_3-CeO_2-ZrO_2	Combustion + NO red
	Alcohols to aldehydes	Pt/carbon	Liquid-phase oxidation
	Aromatization of paraffins	Pt/K-L zeolite	Dehydrog./aromatization
Sulfide catalysts			
Bulk sulfide	Bituminous sands to oil fractions	MoS_2	Deep hydrocracking
Supported sulfides	Gasoline treatment	NiS-MoS_2/γ-Al_2O_3	Hydrodesulfurization
Halide catalysts			
Bulk halides	Fluorination of chloroalkanes	CrF_3	Lewis acid catalyst
Supported halides	Ethylene and propene polymerizations	$TiCl_3/MgCl_2$	Stereospecific polymerization
	Aromatic alklylation	BF_3/γ-Al_2O_3	Lewis acidity
	Aldol-type condensations	KF/γ-Al_2O_3	Basic catalyst
	Ethylene to dichloroethane	$CuCl_2/\gamma$-Al_2O_3	Oxychlorination

frequently more environmentally friendly than liquid catalysts, and their manipulation is far safer. In practice, dangerous corrosive liquids characterized by unsafe manipulation procedures, difficult regeneration, and unsafe disposal (such as sulfuric acid, and $AlCl_3$-based Friedel–Crafts-type liquid acid, as well as concentrated soda solutions) and highly toxic and volatile compounds (such as hydrofluoric acid) have been replaced by environmentally friendly silicoaluminates and alkali-earth-containing solids. In parallel, the performance of such processes has also been remarkably improved.

Table 33.1 reports a summary of relevant industrial solid catalysts together with their applications. They mainly belong to four materials families: metals, metal oxides (including zeolites), metal sulfides, and metal halides. These categories refer to the main component, usually referred to as the *active phase*, whose presence is crucial for the catalytic effect.

33.3 On the Complexity of Industrial Catalytic Materials

A real industrial catalyst is frequently a very complex material, containing a number of components, whose functions are reported in Table 33.2. In fact, it has been found that inactive or almost inactive components can remarkably improve the catalytic activity or selectivity behavior of the main active phase(s). These components are generally referred to as *promoters* or *activators*. A promoting effect may frequently be observed for

Table 33.2 Components in industrial catalytic materials

7. Polymerization catalysis (Ziegler–Natta type)

a particular carrier in the case of supported catalysts. Thus, the carrier is chosen also (but not only) with respect to its effect on the catalytic activity of the active phase. In the final composition, additional promoters may be added in trace amounts but sometimes prevalent with respect to the active phase. As an example, the active palladium/alumina catalyst for acetylene hydrogenation in treatment of the C2 steam cracking cut may contain 0.03 wt% Pd (active phase) and 0.18 wt% Ag (promoter) over a γ-Al_2O_3 support. Similarly, typical catalysts for denitrification of waste gases from power stations (selective catalytic reduction of NO_x by ammonia) may contain 1–3 wt% V_2O_5 (active phase) and 10 wt% WO_3 MoO_3 (the promoter) over an anatase TiO_2 support, which also has a promoting effect on vanadia.

The activity-promoting mechanism can have different origins: from electronic promotion due to a slight modification of the electronic state of the active phase by a promoter that must be in electronic contact, to structural promotion where the activator induces or stabilizes particular structures or morphologies of the active phase, e.g., favoring dispersion or surface roughness.

Activity promotion sometimes occurs in parallel with stabilization, as stabilizers reduce deactivation, allowing high catalytic activity to be retained during time in-stream. Stabilizers are components that inhibit sintering and solid-state reactivity (e.g., reactivity between the support and the supported phase or among different components, including their volatility). Also, species which act as inhibitors of poisoning and coking act as stabilizers.

Selectivity promoters may act electronically or as structural promoters, but are frequently specific poisons for the active sites of unwanted parallel/successive by-reactions. In some complex cases (e.g., Ziegler–Natta-type polymerization catalysts), a cocatalyst is needed to promote the active phase and act in some way as a reaction chain initiator. Additional components are needed to build extrudates (binding materials), in particular in the case of fluidized bed catalysts, and to favor diffusion in complex catalytic materials.

On the other hand, in several cases, multifunctional catalytic materials are needed for processes which involve treatment of complex feeds (e.g., broad hydrocarbon fractions or complex raw materials such as biomasses) and imply the occurrence of a number of different catalytic reactions simultaneously; this is the case, e.g., in fluid catalytic cracking of heavy oils and catalytic reforming of gasolines.

Table 33.3 reports the different categories of industrial catalyst applications in terms of chemical functionality.

33.4 Surface Science, Surface Chemistry, and Industrial Heterogeneous Catalysis

As is typical in the chemical industry, several relevant processes using catalysts, in particular heterogeneous catalysts, were industrially developed early on (Table 33.4 [33.4–6]), when knowledge of the phenomena occurring at the molecular level was still incomplete. Surface chemistry and surface science developed in more recent years, thanks to the introduction of sometimes very sophisticated experimental techniques, and even more recently with the application of high-level computational technologies enabled by modern fast electronics and computers. One of the main objectives of surface science consists in the identification of the *active site* of the catalytic reaction, and its working mechanism [33.7]. This is a very important achievement, but really represents only one of the various relevant aspects of the development of better catalysts. As mentioned above, real catalysts are very frequently complex and *multifunctional* materials, with a number of different functionalities working synergistically or in series. Their catalytic activity is frequently (although not always) associated with defect surface sites (edges, corners, and vacancies), contact points between phases,

Table 33.4 Starting year of industrial processes using heterogeneous catalysis

1880	SO_2 oxidation to SO_3 on platinum (Winkler in Freiberg, Germany, and Squire and Messel in England)
1880	Cl_2 from HCl oxidation on $ZnCl_2/CuCl_2$ (Deacon process)
1887	H_2S and SO_2 to S over bauxite (Claus process, Chance)
1889	Formaldehyde production by methanol oxidation on platinized asbestos (Trillat)
1902	Liquid-phase hydrogenation of fatty oils on Ni (Sabatier)
1906	Ammonia oxidation to NO over Pt (Ostwald nitric acid process, Bochum, Germany)
1911	Cottonseed oil hydrogenation over Ni (Procter & Gamble)
1913	Ammonia synthesis over Fe (Haber–Bosch process, BASF, Oppau, Germany)
1913	Water gas shift over Fe_2O_3-Cr_2O_3 (BASF, Oppau, Germany)
1913	Bioethanol dehydration to ethylene on alumina (Elektrochemische Werke, Bitterfeld, Germany)
1916	Naphthalene oxidation to phthalic anhydride on V_2O_5 (BASF)
1919	Coal liquefaction to liquid hydrocarbons by hydrogenation over Fe sulfide (Bergius process, Th. Goldschmidt AG, Germany)
1920	Oxidation of aromatics to aldehydes and anhydrides on V_2O_5
1923	Syngas conversion to methanol over ZnO-Cr_2O_3 (BASF, Leuna, Germany)
1930	Hydrogen cyanide by methane ammoxidation over Pt-Rh (Andrussow process)
1930s	Hydrocracking of gasoils over metals (Standard Oil, Baton Rouge, USA)
1931	Steam hydrocarbon reforming over Ni (Standard Oil, Baton Rouge, USA)
1932	Olefin oligomerization over *solid phosphoric acid* (UOP)
1933	Benzene oxidation to maleic anhydride on V_2O_5-MoO_3 (National Aniline and Chemical Co.)
1935	Syngas conversion to liquid hydrocarbons over Co/ThO_2-MgO catalyst (Fischer–Tropsch process, Ruhrchemie, Germany)
1937	Catalytic cracking on clays (Houdry process, Socony-Vacuum, Marcus Hook, PA, USA)
1937	Ethylene oxidation to ethylene oxide on Ag/Al_2O_3 (Lefort catalyst, Union Carbide)
1939	Vinylchloride from acetylene and HCl over $HgCl_2$/charcoal-based catalysts (I.G. Farben and Wacker, Germany)

and the dispersion of atoms from one phase into another.

The set of experimental techniques allowing information on real catalytic materials to be obtained is frequently called *surface chemistry*. It implies the application of a series of complementary techniques to real catalytic materials, most commonly in the form of fine powders. When possible, spectroscopic measurements are performed in the conditions of the catalytic reactions, i.e., in *operando* conditions, at high temperatures, sometimes high pressures, in contact with complex reactant mixtures while measuring the conversion, selectivities, and yields. The techniques most typically applied to real catalytic materials are summarized in Table 33.5 [33.8].

On the other hand, to obtain as detailed an understanding of the catalytic behavior of the reactant + catalyst system as possible, it is useful to simplify the picture by separating the phenomena and looking at the simplest materials (pure compounds, high crystallinity, or monocrystals), using focused and sophisticated techniques [33.9] applied in their own most appropriate conditions (sometimes very low temperature, high vacuum). This is the typical original approach of *surface science*.

It is evident that both a *material gap* and a *conditions gap* (mostly a *pressure gap*) may exist between surface science on one side and surface chemistry and catalysis on the other side. However, attempts have been made recently to reduce these gaps [33.10–15] by applying surface science techniques in more realistic conditions and by preparing materials with intermediate properties (stepped monocrystal surfaces, doped materials, and planar model catalysts). Although this approach has not always been successful, in many cases it has provided deeper knowledge of real catalysts.

In any case, surface science and surface chemistry have long offered fundamental support for the management and enhancement of early technologies as well as the development of new ones [33.16].

33.5 Surface Acido-basicity and Heterogeneous Acido-basic Catalysts

Acidity and basicity are, to some extent, two sides of the same coin. Acid catalysis is a main player in the fields of refinery and primary petrochemistry [33.17, 18]. Basic catalysts are largely used in the field of fine chemistry. Additionally, acido-basic materials have wide applications as supports for metal catalysts. Typ-

Table 33.6 Catalysts and conditions of industrial solid-acid-catalyzed reactions

Reaction	Catalyst	Reaction conditions	
Isobutane alkylation by isobutene	Ultra stable type Y (USY) zeolite	90 °C/10 bar	Liquid phase
Light paraffin isomerization	Chlorided alumina	150 °C	Gas phase
	Sulfated zirconia, tungstated zirconia	200 °C	Gas phase
	H-mordenite zeolite	250 °C	Gas phase
Light olefin oligomerization	Amberlite (sulfonated PS-PDV)	100 °C/40 bar	Liquid phase
	Solid phosphoric acid or zeolites	200 °C/30 bar	Gas phase
Benzene alkylations	H-BEA (beta)- or MCM-22 zeolites	200 °C/30–40 bar	Liquid phase
Diethyl ether and dimethyl ether syntheses	γ-Al_2O_3	300 °C	Gas phase
Light olefin isomerization	H-ferrierite zeolite	350 °C	Gas phase
	γ-Al_2O_3 (silicated or borated)	450 °C	Gas phase
Isomerization or transalkylation of xylenes	H-MFI zeolite	450 °C	Gas phase
Catalytic cracking	Rare-earth-containing H-faujasite zeolites	700 °C	Gas phase

ical acid catalytic materials are summarized in Table 33.6, with some of their most typical industrial applications.

33.5.1 Surface Acidity and Solid Acid Catalysts: Brønsted Type

According to the definitions of *Brønsted* [33.19] and *Lowry* [33.20], an acid is any hydrogen-containing species that is able to release protons, while a base is any species capable of combining with protons. In this view, acid–base interactions consist in the equilibrium exchange of a proton from an acid HA to a base B (which may be the solvent, e.g., water), generating the conjugated base of HA, i.e., A^-, plus the conjugated acid of B, i.e., HB^+ (e.g., the hydroxonium ion H_3O^+) thus

$$HA + B \rightleftharpoons A^- + HB^+$$

This theory, valid in dilute water solutions, was extended to concentrated and nonaqueous solutions by *Hemmett* in the 1930s [33.21].

Solid Brønsted acids are materials whose surface contains active protons that are able to protonate molecules that exhibit some basicity. They can be used in contact with water solutions but, even more commonly, in contact with nearly water-free liquid or vapor phases. Even weak Brønsted acids can protonate strong and medium-strength bases, such as n-bases, i.e., those having free electron pairs in nonbonding orbitals (such as oxygenated, nitrogenated, and sulfided organics).

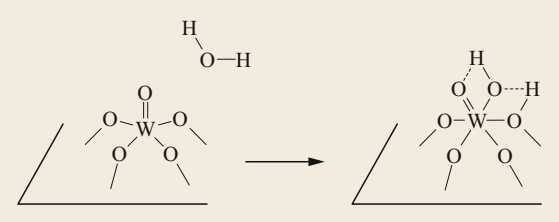

Fig. 33.1 Schematics of Brønsted acidic surface wolframate species on oxides

Strong to very strong acids and a nearly water-free environment are needed to protonate π-type bases (i.e., olefinic and aromatic hydrocarbons, whose bonding π-type orbitals are available for protonation) and also σ-type bases, i.e., paraffins.

Families of strong solid Brønsted acids contain surface species that are similar to homogeneous Brønsted acids; this is the case, e.g., of sulfated and tungstated zirconia, whose acidity is mainly due to the strong acidity of sulfuric and tungstic acids, although some properties (semiconducting character, slight reducibility) of zirconia also have an activating effect on protonic centers. Similarly, the medium-strong acidity of the so-called solid phosphoric acid (Kieselguhr silica impregnated by phosphoric acid) is due to the acidity of H_3PO_4. As in the case of homogeneous acids, the surface Brønsted acidity of sulfate-, tungstate-, and phosphate-containing solids is also associated with the presence of high-valency elements that are covalently bonded to a large number of oxygen atoms over which the anionic charge of the dissociated acid can be delocalized (Fig. 33.1). Another family of very strong solids acids is that of chlorided aluminas, i.e., γ-Al_2O_3 powders deliberately contaminated by chlorine, which actually contain $AlCl_3$ and adsorbed HCl [33.22].

Protonic zeolites today represent the most prominent family of solid strong Brønsted acids applied in refineries and petrochemistry [33.17, 23, 24]. Zeolites are natural and synthetic silicoaluminates characterized by a microporous crystal structure constituted by open channels and cages (Fig. 33.2). Substitution of aluminum for silicon in such a covalent silica network leads to a $[Si_{1-x}Al_xO_2]^{x-}$ negatively charged framework. This charge must be compensated by *extraframework* cations. In natural and *cationic* zeolites, alkali or alkali-earth metal cations located in the cavities play the role of compensating species. However, using different synthetic procedures, protons can substitute for metal cations, giving rise to protonic zeolites. In spite of the covalency of the resulting O–H bond of *bridging silanol groups*, the presence of the cavity and the structural features of the silicoaluminate framework make the protons of protonic zeolites exceptionally strong

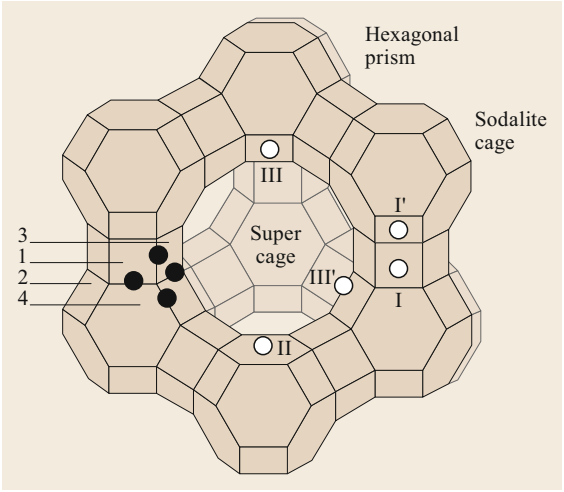

Fig. 33.2 Structure of faujasite zeolite. *Full circles*: position of the four crystallographic different oxygen positions. *Empty circles*: position of Na cations in dry Na-faujasites

Brønsted acids [33.25]. The spectra of adsorbed pyridine (a widely used basic probe molecule, Fig. 33.3) provides evidence of the formation of pyridinium ions (with ring stretching bands at 1633 and 1544 cm^{-1}). Looking at the OH stretching region, it is clear that protonation is related to the band at 3603 cm^{-1} due to OH stretching of *bridging* silanol groups.

The formation of this group (not found in non-microporous materials [33.26]), as well as its strong acidity, are certainly influenced by the cavities typical observed in zeolite structures. The hyperconjugation effect, i.e., the $n_O \rightarrow \sigma^*_{Si-O}$ (vicinal) interaction, a bonding interaction between an oxygen lone pair and the antibonding orbital of the vicinal Si–O bond, is very likely a key feature stabilizing the anionic charge of dissociated sites, thus justifying the strong Brønsted acidity [33.27, 28]. The delocalization of the negative charge of dissociated bridging silanols on the siloxane bridges, as well as the stabilization of the protonated species by interaction with the cavity wall, both contribute to the stabilization of the products of the proton transfer, thus increasing the Brønsted acidity (Fig. 33.4). In this case, it is evident that the surface is not flat, and such curvature may have an effect, as may also occur in the case of other porous systems.

33.5.2 Surface Acidity and Solid Acid Catalysts: Lewis Type

In 1923, the same year as the definitions of Brønsted and Lowry, *Lewis* [33.29] proposed a different approach to acidity and basicity. In his view, an acid is any species that, because of the presence of an incom-

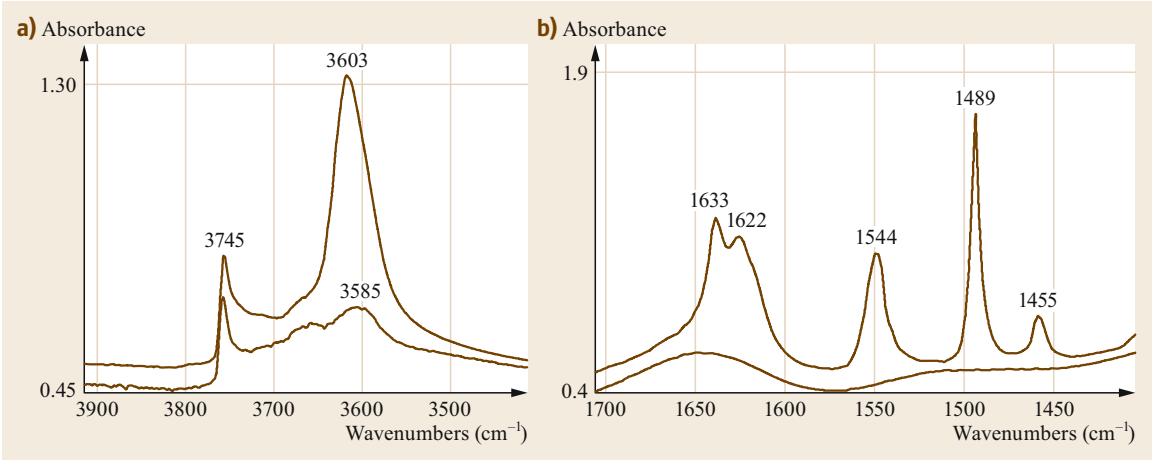

Fig. 33.3 **(a)** Infrared spectra of activated H-mordenite (lower spectra) and of the same material after adsorption of pyridine and outgassing at 100 °C. The band at 3745 cm^{-1} is due to weakly acidic external terminal OH, while the band near 3600 cm^{-1} is due to strongly acidic bridging silanols. **(b)** The bands at 1633 and 1544 cm^{-1} are due to pyridinium ions, those at 1622 and 1455 cm^{-1} are due to coordinated pyridine on Lewis acid sites, and the band at 1489 cm^{-1} to both species [33.23]

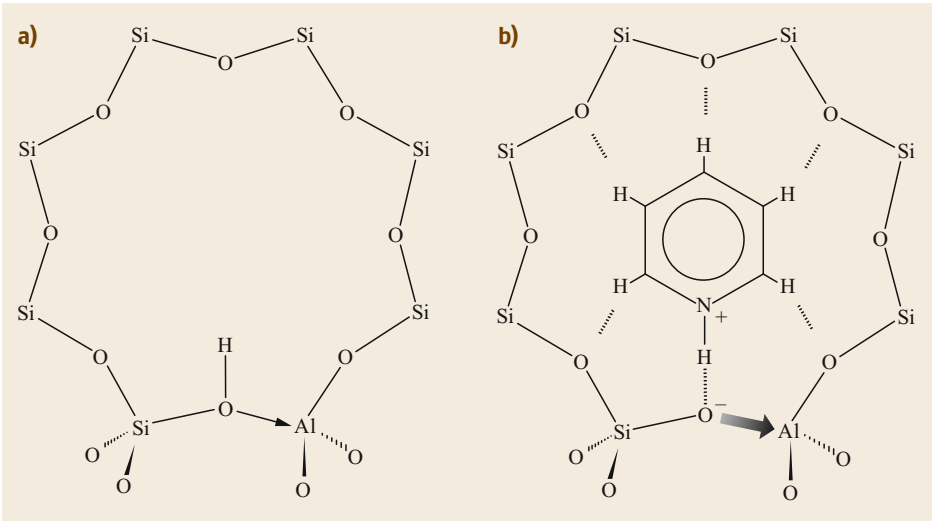

Fig. 33.4a,b Schematics of surface Brønsted sites in zeolites **(a)** and on pyridine protonation thereon **(b)**

plete electronic grouping, can accept an electron pair, thus forming a dative or coordination bond. Conversely, a base is any species possessing an electron pair which can be donated to form a dative or coordination bond. The Lewis-type acid–base interaction can thus be denoted as

$$B: + A_L \rightleftharpoons {}^{\delta+}B \rightarrow A_L^{\delta-}$$

In agreement with the Lewis definition, not only the proton H^+ but also metal cations ionically bonded to weakly basic anions are acidic. The most typical strong *Lewis acids* are metal compounds such as Al and B trihalides, as well as the halides of other cations such as $FeCl_3$, $ZnCl_2$, $TiCl_4$, $SnCl_4$, SbF_5, $BiCl_3$, etc. Several of these compounds, however, are liquid and volatile and easily hydrolyzed in mild conditions. They are also not environmentally friendly materials, giving rise to easy evolution of hydrogen halides and corrosion problems and being unsafe when disposed of.

As oxygen is the most electronegative element besides fluorine, the metal–oxygen bond is highly ionic. Thus, at the surfaces of metal oxides, the ionicity of the M–O bond results in coordinatively unsaturated cations

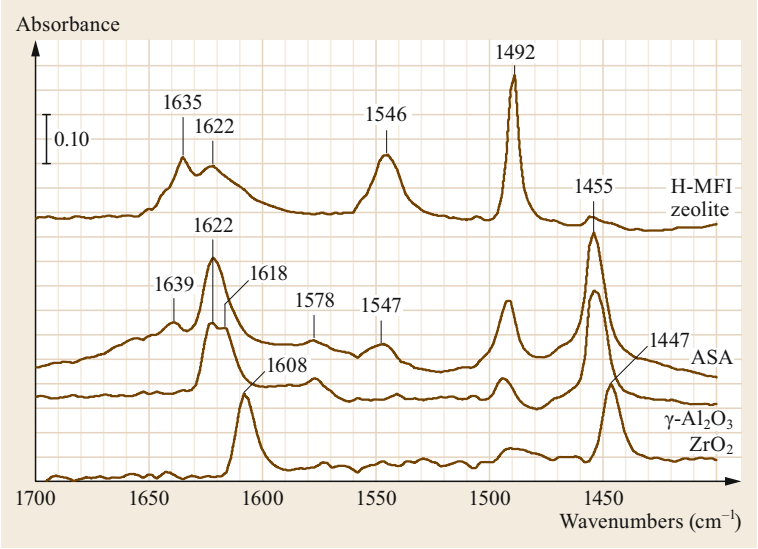

Fig. 33.5 Infrared spectra of pyridine adsorbed on catalysts. The bands at 1635 and 1546 cm^{-1} are due to pyridinium ions, those at 1625–1600 and 1455 cm^{-1} are due to coordinated pyridine on Lewis acid sites, and the band at around 1490 cm^{-1} to both species

and anions, with Lewis acidity of the cations and basicity of the anion. The balance between Lewis acidity and basicity depends on the size (radius, r) and charge (C) of the cation, i.e., its polarizing power (either C/r or C/r^2), as well as on its overall coordination. The smaller, the more charged, and the less coordinated the surface cation, the greater its Lewis acidity [33.17, 30].

The best Lewis acid solids in terms of activity, stability, and environmental friendliness are the so-called *transitional* aluminas [33.31], in particular γ-Al_2O_3, δ-Al_2O_3, η-Al_2O_3, θ-Al_2O_3, all containing the ionically bound and very small Al^{3+} species. These are metastable polymorphs with respect to the stable form, α-Al_2O_3 or *corundum*. Corundum is a very stable material whose surface is quite inert, likely due to the relatively high overall coordination of its ions also at the surface. In contrast, transitional aluminas are very active in adsorption and catalysis, due to the presence at the surface of low-coordination ions. While monocrystals of α-Al_2O_3 can be produced and their surface characterized by classical surface science techniques [33.32], this cannot be easily done with transitional aluminas, which have mostly been investigated using conventional surface chemistry techniques [33.31] as well as theory [33.33]. However, thin films of alumina have been prepared on the surface of selected single-crystal faces and are commonly used as a model for alumina to investigate its properties as a catalyst or support for catalysts [33.11, 34]. These materials can be analyzed using typical surface science techniques such as low-energy electron diffraction (LEED), high-resolution electron energy loss spectroscopy (HREELS), and infrared reflection absorption spectroscopy (IRAS), together with scanning tunneling microscopy (STM). Studies on these surfaces have essentially confirmed results coming from previous powder characterization.

The spectrum of pyridine adsorbed on transitional aluminas (Fig. 33.5) does not show the bands of pyridinium ion, indicating that the Brønsted acidity of alumina's OHs is weak. In contrast, the ring stretching bands of molecular pyridine at 1622 and 1614 cm^{-1} (well shifted up with respect to the value for free pyridine of 1588 cm^{-1}) and at 1455 cm^{-1} (shifted up from the 1440 cm^{-1} liquid-phase value) provide evidence of the presence of at least two families of strong Lewis acid sites. In the case of zirconia, the same bands are found at 1608 and 1447 cm^{-1}, indicating the presence of weaker Lewis acid sites with respect to transitional aluminas.

The Lewis acid sites of transitional aluminas have been characterized to be the strongest among binary metal oxides. However, in many cases, anion–cation couples work synergistically. To improve the thermal stability without losing acidity, aluminas may be additivated using small amounts of silica (silicated aluminas). The Lewis acido-basicity of γ-Al_2O_3 is associated with its *dispersing* ability for surface species, making it an excellent support for metallic catalysts as well as for sulfide catalysts.

Other very strong Lewis solid acids that are widely used in fluorine chemistry [33.35], i.e., for activating F_2 in the fluorination of chlorocarbons, are aluminum and chromium fluorides, which are high-melting-point solids.

33.5.3 Surface Basicity and Solid Basic Catalysts

According to both the Brønsted and Lewis definitions, bases are species that are characterized by their ability to bond with acids. Molecules having available electron pairs are both Brønsted and Lewis acidic, being at least in principle able to interact both with protons and with metallic cationic species. They are also nucleophilic, i.e., able to interact with electrophilic carbon atoms of organic molecules, and of CO_2 as well [33.30].

Basic solids have wide applications as catalysts and adsorbents in fine chemistry and environmental chemistry [33.36–38] (Table 33.7). As mentioned above, in the case of ionic oxides, the smaller and more charged the surface cation, and the lower its coordination, the stronger its polarizing power, i.e., its electron-withdrawing power and, consequently, its Lewis acidity. As a result, it bonds more strongly with basic oxide anions, thus decreasing their basicity. In contrast, the larger and less charged the cation, the weaker its Lewis acidity and, consequently, the stronger the basicity of the oxide anions. Thus, alkali and alkali-earth oxides, whose cations are large and low charge, are more basic, the larger and heavier the cation.

The surface basic reactivity of oxides of alkali metals is so high that they are essentially unstable in usual conditions, i.e., in the presence of water vapor, which is sufficient to convert them into the corresponding hydroxides, and of CO_2, which converts them into carbonates. Thus, bulk alkali-metal oxides cannot normally be used as basic catalytic materials. However, alkali-metal oxides can be supported or deposited on carriers, such as high-surface-area oxides (silica, alumina, titania, zirconia, magnesia, and zeolites) or activated carbons, by impregnation/calcination or vapor deposition procedures. They are also frequently introduced as dopants on the surface of transition-metal oxides and also of metal catalysts, to introduce basicity or reduce acidity. Potassium is frequently preferred over sodium, possibly because of its definitely larger ionic size that limits reactions with supports and formation of bulk salts. The basicity also tends to increase with cationic size, thus the Cs cation gives rise to extremely high basicity.

The alkaline-earth oxides (except BeO), whose cations are definitely large in size, are among the strongest solid bases that may be stable as such in practical conditions. They crystallize with rock-salt-type *periclase* structure, with octahedral coordination of both cation and anion. Increasing the size of the cation results in an increased unit cell size as well as decreasing Madelung potential, thus destabilizing the oxide anions.

Magnesium oxide is a stable material which can be prepared with different morphologies and crystal sizes. It has been the object of a large number of investigations from typical powder characterization to monocrystal studies and theoretical investigations. The presence of a number of different surface structures has been proposed as active sites, including differently coordinated oxide and hydroxide sites as well as combinations thereof [33.10, 39–41].

Actually, as for alkali oxides, alkaline-earth oxides are also so reactive that, when prepared as fine powders, they are largely converted into hydroxides and carbonates, at least at the surface, upon exposure to ambient air. Thus, high-temperature treatments are needed for their activation. On BaO, full desorption of carbonates is only obtained at 900 °C.

Mixed oxides containing alkali and alkali-earth cations may also exhibit strong basicity. Sr and Ba ions are involved in the formation of mixed oxides with less compact packing for oxide anions, such as perovskites and β-aluminas. Additionally, Sr and Ba ions may be supported on typical oxide carriers such as alumina and titania, forming quite stable basic materials. In fact, materials belonging to the $BaO\text{-}Al_2O_3$ and $K_2O\text{-}Al_2O_3$ systems find applications as traps for nitrogen oxides in lean NO_x trap-NO_x storage and reduction (LNT-NSR)

Table 33.7 Catalysts and conditions of industrial solid-base-catalyzed reactions

Reaction	Catalyst	Reaction conditions
$CH_3CHO + HCHO \rightarrow H_2C{=}CH{-}CHO + H_2O$	$NaOH\text{-}SiO_2$	300–320 °C
Butadiene from ethanol	$MgO\text{-}SiO_2$	370–390 °C
Crotonic condensation of 2-butanone	Na_2O/SiO_2, Cs_2O/SiO_2	325–400 °C
Acetone to methyl isobutyl ketone	(Pt)-$MgO\text{-}Al_2O_3$ (calcined hydrotalcite)	120–250 °C
Methyl methacrylate from methylpropionate + formaldehyde	Cs_2O/SiO_2	320–380 °C
Phenyl-1-propanone from benzoic acid with propionic acid	$CaO\text{-}Al_2O_3$	440–520 °C
2,4-Dimethyl-3-pentanone from isobutyric acid	ThO_2 or ZrO_2	430 °C
Biodiesel (FAME) by transesterification	$ZnAl_2O_4$	200–250 °C
Epoxide ring-opening/oxyethylation alcohol to polyethoxylates	$MgO\text{-}Al_2O_3$ (calcined hydrotalcite)	4–5 bar, 150–180 °C

technology for purification of waste gases from Diesel cars [33.42].

On the contrary, the size of Mg^{2+} is sufficiently small to enter close packing of oxygen ions. For this reason, Mg ions can participate in the formation, e.g., of mixed oxides such as spinels and ilmenites, whose oxygen packings are cubic close packed (ccp) and hexagonal close packed (hcp), respectively. In this regard, deposition of Mg ions at the surface of normal carriers such as alumina may give rise to poor stability due to the reaction producing Mg aluminate. Another way to provide stability for alkali-earth oxides is to mix them with more stable components. This is essentially what occurs when using hydrotalcite, a layered double hydroxide of magnesium and aluminum, with formula $Mg_6Al_2(OH)_{16}CO_3 \cdot 4H_2O$, available commercially [33.43]. It is a natural anionic clay having interesting basic properties. Its structure is formed by brucite-like $[Mg_6Al_2(OH)_{16}]^{2+}$ layers with carbonate ions and water molecules in the interlayer region. It is also a commercial synthesis product, used in medicine as a stomach antiacid, as well as an environmentally friendly, nontoxic, and heavy-metal-free filler for halogenated polymers (such as polyvinyl chloride (PVC)) to scavenge acid byproducts, and a heterogeneous catalyst. Hydrotalcite (HT) decomposes, releasing CO_2 and water, from 260 to 300 °C, thus acting as a flame-retardant and smoke suppressant. Thermal decomposition of hydrotalcite gives rise to a mixed oxide whose virtual composition is $5MgO \cdot MgAl_2O_4$, although these phases may give rise to mutual solid solubility, depending on the decomposition temperature. In fact, calcined HTs are intimate mixtures of rock-salt- and spinel-type solid solutions which retain the strong basicity of MgO with enhanced stability and high surface area due to the alumina or spinel.

33.6 Solid Catalysts for Oxidation Reactions

Three kinds of oxidation reaction are practiced commercially [33.44]:

i) Total oxidation to remove pollutants from waste gases [33.45, 46]
ii) Catalytic combustion of gaseous fuels for energy production [33.47]
iii) Partial (or *selective*) oxidation to produce chemicals [33.48, 49].

Total oxidation or combustion may be performed uncatalytically in air, but in this case high temperatures (> 1000 °C) are produced and, in parallel, nitrogen oxides will be formed, thus generating polluting waste gases. Catalytic combustion, i.e., total oxidation performed in the presence of solid catalysts, results in lower reaction temperatures (300–800 °C), thus avoiding the formation of substantial amounts of NO_x.

In the case of partial oxidation, catalysts are needed to make the desired reaction faster with respect to the total oxidation reaction and other possible partial oxidation reactions of the same substrate. To achieve this, the temperature of the catalytic bed must be controlled. Multitubular cooled reactors or cooled fluid bed reactors are mostly used.

Air is the cheapest oxidant in industrial processes. The use of pure oxygen as the oxidant is a second choice, when the presence of nitrogen generates drawbacks. When using both air and pure oxygen as the oxidant, O_2 is the stoichiometric oxidant molecule. In less favorable cases, other conditions (e.g., liquid phase and homogeneous catalysis) and/or other oxidants, such as hydrogen peroxide, ozone, or nitrous oxide (N_2O), must or can be applied.

33.6.1 Adsorption/Reaction/Activation of Oxygen

Upon catalysis, oxygen is supposed to adsorb and be *activated* over the catalyst surface, where it reacts with the substrate. According to early literature, a variety of different *adsorbed* or surface oxygen species can be obtained on solid surfaces, which have been identified mostly by vibrational spectroscopies (IR, Raman, or EELS) and electron spin resonance and are summarized in Table 33.8. Most of them have an intermediate redox state between dioxygen and the most reduced species, the oxide anion, O^{2-}. Thus they are, at least potentially, oxidizing species and are electrophilic. They are considered to be possibly involved in total oxidations. On the other hand, their formation from O_2 also implies the oxidation of a metal species, which can also act as an oxidizing species. The oxide anions, instead, are nucleophilic, and are assumed to be the main players in selective oxidations. When interacting with reducible cations, they act as oxygen insertion sites. In this case, the high-valency metal cations act as the oxidizing species, which reduce to a lower valency state by inserting oxide species into the reacting substrate.

Metals and other elements in very high oxidation states can give rise to element–oxygen *double*

Table 33.8 A summary of possible surface oxygen species

Formula	Oxidation state	Name	Properties	Possible structure
O^{2-}	–II	Oxide	Coordinatively unsaturated	
		Doubly bonded		
O^{-}	–I		Radical anion	
O_2^{2-}	–I	Peroxide	Side-on	
			Bridging	O_2^{-}	–0.5	Superoxide	Radical anion, end-on, bent				Bridging	O_2	0	Neutral dioxygen		
O_2^{+}	+0.5	Dioxygen cation	Radical cation	

bonds in their oxides, i.e., very short bonds. This is the case of vanadyl(V), niobyl(V), molybdenyl(VI), chromyl(VI), and wolframyl(VI) groups, characterized by very high M=O oxygen stretching frequencies in vibrational spectroscopies (IR and Raman). Cations with short M=O double bonds are usually considered to be active in oxygen insertion into the substrates, even if it has been determined that the oxygen atom inserted is not that involved in the double bond. Among these elements, one can cite Mo^{6+}, Cr^{6+}, W^{6+}, and V^{5+}, which in fact are the key elements in important families of oxidation catalysts (molybdates, chromates, wolframates, and vanadates).

The mechanisms involving adsorbed oxygen species can be of Eley–Rideal type (adsorbed or surface oxygen reacting with a gas-phase substrate) or Langmuir–Hinshelwood type (both species react while adsorbed at the catalyst surface).

In a mechanism usually attributed to Mars and Van Krevelen, the catalyst acts between two oxidation states. In the higher oxidation state, the catalyst surface acts as the oxidant for the substrate, reducing itself to a lower oxidation state. Oxygen reoxidizes in situ the catalyst surface from its lower to higher oxidation state. The Mars–Van Krevelen mechanism (also referred to as the *redox* mechanism) actually implies that oxygen is adsorbed and activated in the form of oxide anions.

33.6.2 Metal Versus Metal Oxide Oxidation Catalysis

Transition metals and/or their oxides are typical catalysts used in heterogeneously catalyzed oxidations (Tables 33.9, 33.10). The question that arises is the actual state of the catalyst during the reaction.

According to thermodynamics, metal oxides are stable at low temperature while they tend to decompose to the corresponding metals at high temperature, depending on the oxygen pressure and the redox properties of the element. In most cases, however, melting of the oxide occurs in milder conditions than decomposition. Actually, base metals and most transition-metal elements are stable as oxides even under high vacuum up to their melting point, frequently occurring at high temperature. Thus, when these oxides are charged into an oxidation reactor, they are stable as oxides and act as catalytic oxides. Some high-oxidation-state transition-metal oxides may undergo partial decomposition to lower oxides, at moderate temperature, before melting (e.g., $Co_3O_4 \rightarrow CoO$ at $\approx 940\,^{\circ}C$, $CuO \rightarrow Cu_2O$ at $\approx 1000\,^{\circ}C$). Thus, different oxide phases may be active in oxidation catalysis.

A few transition-metal oxides, usually having high oxidation states, have quite low melting points. In a few cases, the catalyst can work in a partially melted state.

Table 33.9 Catalytic oxidations on noble-metal catalysts

Reaction	Catalyst	Reaction conditions
CO oxidation to CO_2	Au/ZrO_2	0 °C
	0.3% Pt–0.03% Fe/γ-Al_2O_3	100 °C
Vinyl acetate synthesis	Pd-Au/SiO_2	180 °C
Ethylene epoxidation	Ag/α-Al_2O_3	250 °C/20 bar
Methanol oxydehydrogenation to formaldehyde	Ag/α-Al_2O_3 or Ag gauzes	650 °C
Ammonia oxidation to NO (nitric acid synthesis)	Pt(Rh) gauzes	800–900 °C, 1–12 bar
Ammonia oxidation to N_2 (ASO, ammonia slip oxidation)	Promoted 0.5% Pt/γ-Al_2O_3	275 °C
Methane ammoxidation to HCN (Andrussow process)	Pt(Rh) gauzes	1100 °C
Methane partial oxidation to syngas (low-contact-time CPO)	Rh/α-Al_2O_3	1000 °C, $\tau^* = 5$ ms
Catalytic combustion of methane for energy production	5% PdO/α-Al_2O_3	650–850 °C
Catalytic combustion of VOCs	0.3% Pd/θ-Al_2O_3	500 °C
Gasoline engine aftertreatment	Pt-Rh(Pd)/CeO_2-ZrO_2-Al_2O_3/cordierite	400 °C

τ^* = contact time; CPO = catalytic partial oxidation; VOC = volatile organic compound

Table 33.10 Catalytic oxidations on transition-metal oxide catalysts

Reaction	Catalyst	Reaction conditions
SO_2 to SO_3	$V_2O_5/(Cs,K)_2SO_4/SiO_2$	400–500 °C
o-Xylene to phthalic anhydride	V_2O_5/TiO_2 (anatase)	400 °C
n-Butane to maleic anhydride	$(VO)_2P_2O_7$	350 °C
Methanol oxidation to formaldehyde (Formox)	$MoO_3/Fe_2(MoO_4)_3$	300 °C
Propene oxidation to acrolein	Bi-Mo (Fe,Co,Ni) multicomponent oxides	320 °C
Acrolein oxidation to acrylic acid	Mo-W-V-Fe oxides	280 °C
Propene ammoxidation to acrylonitrile	Bi-Mo (Fe,Cr,Ni,Co,Mg) multicomponent oxides	350 °C
Propane ammoxidation to acrylonitrile	U-Sb (Ti,Sn,Al,Fe,W,Te) multicomponent oxides	450 °C
Catalytic abatement of oxygenated VOCs	MnO_x/θ-Al_2O_3	400–500 °C
Catalytic abatement of chlorinated VOCs	CrO_x/θ-Al_2O_3	400–500 °C
Butene oxidative dehydrogenation to butadiene	$(Zn,Mg)Fe_2O_4$	550 °C
HCl oxidation to Cl_2	RuO_2/TiO_2 (rutile), RuO_2/SnO_2	300 °C

One of the most interesting case is $V_2O_5/K_2SO_4/SiO_2$ catalysts for SO_2 oxidation, where the V_2O_5/K_2SO_4 system with a low-melting eutectic forms and acts as a supported liquid catalyst.

For noble-metal oxides, decomposition to the metal may occur at quite low temperatures, also in an oxidizing atmosphere, frequently well below melting. On the other hand, noble metals are charged, sometimes, after a previous reducing pretreatment, thus being in metallic form. Metal oxidation to the oxide is kinetically hindered at low temperature, even when the oxide is the thermodynamically stable form. On metallic surfaces, adsorption of oxygen at low temperature produces superoxo (O_2^-) and peroxo (O_2^{2-}) molecular species. At higher temperature, atomic or dissociative adsorption occurs, producing surface and subsurface oxide species as an intermediate state towards the formation of the bulk oxide.

Gold and silver are the metal elements having the least stable oxides. Gold and silver oxides tend to decompose in the range of 100–250 °C and thus when heterogeneous catalysis most generally occurs.

For CO oxidation on supported gold nanoparticles, occurring at very low temperatures (down to 200 K), it is supposed that gold is indeed in the form of metallic clusters with low-coordination sites where CO and O_2 can adsorb cooperatively [33.50, 51], but with the possible participation of the support, at least in the case of Au/CeO_2 catalysts [33.52].

Silver catalysts are used in particular for the ethylene epoxidation reaction with oxygen or air, realized in the 200–300 °C temperature range. Today, authors agree that metallic silver with a high oxygen loading (a surface oxide layer) is needed for high selectivity to EO [33.53]. According to *Rocha* et al. [33.54], up to five different atomic oxygen species can exist over silver in conditions near those of real catalysis. A weakly bound electrophilic surface oxygen, $O^{\delta+}$, is suggested to enable selective epoxidation by directly attacking the C=C π-type electrons. In contrast, strongly bound nucleophilic surface oxygen, $O^{\delta-}$, is supposed to give rise to a oxometallacycle (OMC) surface intermediate, whose evolution can also produce EO but with lower selectivity, together with acetalde-

hyde and combustion to CO_2. Real catalysts contain a set of promoters, such as Cs, Re, and an oxo-ion, and work in the presence of some chloride hydrocarbon, which improves either the conversion or selectivity. The mechanism of such activation is still a matter of debate [33.55].

For Pd, in 1 mbar O_2, the $PdO \rightleftharpoons Pd + 1/2\,O_2$ transition is expected to occur at approximately 570 °C. Accordingly, PdO is known to decompose in practice into Pd metal in the range of 650–800 °C, depending on the O_2 partial pressure and reactive gas mixture composition. Combustion catalysts for methane are mostly supported on stabilized supports such as La-alumina, with loadings of a few wt% Pd. The transformation of PdO into Pd is reported to negatively affect the catalytic reaction by lowering the conversion, although the CH_4 combustion activity is reversibly restored upon reoxidation of Pd to PdO. The nature of the support is reported to influence strongly the reoxidation of Pd metal. The active catalyst is mostly considered to actually consist of a mixture of PdO and Pd or an intermediate species [33.56, 57].

33.6.3 Supporting Metal Catalysts

In most industrial applications, metal catalysts are supported over carriers. This is done for several reasons: it allows the production, in some cases, of very reactive nanoparticles, whose surface is rich in steps, edges, corners, kinks, and defects, thus being very reactive and active as catalysts. The interaction with the support may also stabilize strongly metal particles against sintering. Additionally, a very high surface-to-bulk ratio is obtained, thus allowing the amount of active metal to be limited sometimes to very low concentrations (sometimes even less than 0.1 wt% on the overall catalyst). This may be very important when precious metals are used.

The following materials are most commonly used industrially for supporting catalysts:

- *Aluminas*: When applications require a relatively low reaction temperature (< 500 °C), high-surface-area γ-, δ- or η-Al_2O_3 are common industrial catalyst supports ($S_{BET} > 150\,m^2/g$). These are typically highly ionic and highly dispersing catalyst carriers. These supports, however, are characterized by high acidity and reactivity and are thus not applicable when very reactive compounds are present in the reactant mixture. They are also unstable at temperatures > 500 °C, tending to convert into θ-Al_2O_3 or even α-Al_2O_3 with loss in surface area. For these reasons, less reactive and more stable lower-surface-area aluminas are used in several applications, such as θ-Al_2O_3 ($S_{BET} = 50–100\,m^2/g$) or α-Al_2O_3 ($S_{BET} < 10\,m^2/g$).
- *Metal aluminates*: Mg and Ca aluminates, with spinel and α-alumina structures, are also widely used as refractory, stable, and quite unreactive carriers for high-temperature applications such as steam reforming, partial oxidation, autothermal reforming, and catalytic total oxidations. The surface area of these materials may be low or very low, and the dispersion of their surface is frequently not high.
- *Silicas*: According to their ionic character, these are typically nondispersing carriers in spite of their high surface area. They have usually give rise to medium-sized supported metal particles. These supports have quite high thermal stability and high chemical inertness.
- *Titanias and zirconias*: These are supports with weak redox properties, medium acido-basicity, high dispersing ability, and high reactivities towards the metal, giving rise to strong metal–support interaction (SMSI) effects. Titania (anatase) and monoclinic zirconia (baddeleyite) have limited thermal stability, tending to convert to the more stable rutile and tetragonal/cubic zirconia phases.
- *Ceria*: Ceria is a typical support or support component characterized by redox properties and oxygen storage capacity, useful for redox reactions. This, however, also gives rise to some instability. However, ceria has a high dispersing ability for metal sites and some surface basicity.
- *Zinc oxide*: Zinc oxide has some hydrogenation/dehydrogenation activity. It is widely used as an activating support, in particular for copper and palladium hydrogenation catalysts. It gives rise to some kind of activating effect. Reduced Zn is supposed to have a synergy with copper metal for methanol synthesis and water gas shift, while the formation of Pd-Zn alloy is very likely in the case of the corresponding Pd-based catalysts.
- *Magnesia*: This strongly basic support is quite unstable in the presence of CO_2 and water. As a catalyst support, it suffers from quite low surface area and poor mechanical strength. In spite of this, it is reported to be an excellent support for some metal catalysts.
- *Zeolites*: Zeolites (Sect. 33.7) have high dispersing ability for cations. After reduction, the size of the metal particles may be limited by the size of the cavity. This may allow metal catalysis with shape selectivity. They also enable metal and strong protonic acid catalysis, or even metal and basic or neutral acid–basic catalysis when alkali-cationic zeolites are used (e.g., Pt-K-zeolite catalysts for aromatization reactions).

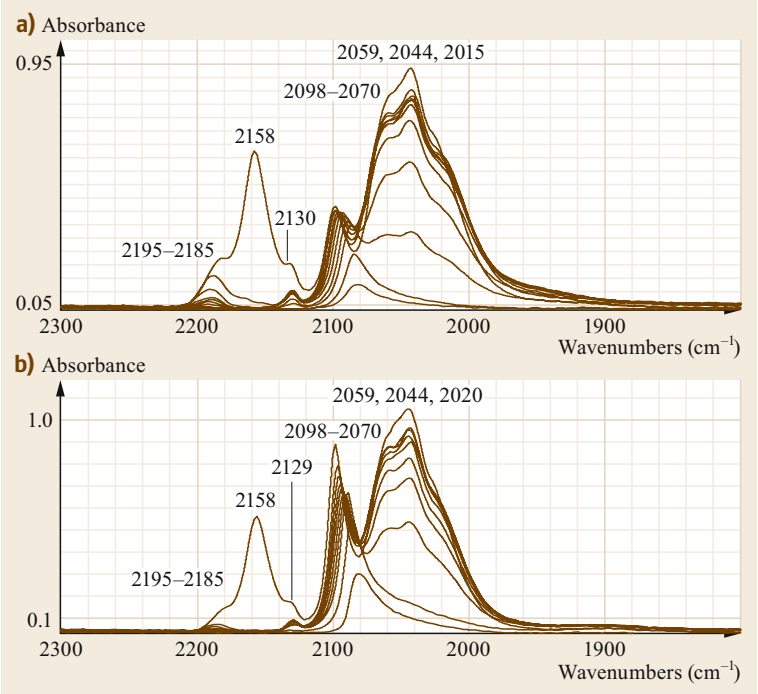

Fig. 33.6a,b IR spectra of CO adsorbed at low temperature on two Ni-alumina catalysts: **(a)** Ni 5%/Al_2O_3, **(b)** Ni 16%/Al_2O_3. While the band at 2098–2070 cm^{-1}, shifting down upon desorption, is due to CO on Ni particles, those at ca. 2130, 2060, 2045, and 2020 cm^{-1} are due to polycarbonyl species on isolated Ni metal centers

- *Carbons*: Different forms of carbon, such as activated carbons, graphite, etc., are used as supports mainly for noble-metal catalysts. They are used mainly for low-temperature liquid-phase applications, or gas-phase applications in reducing atmospheres. Their dispersing ability may be tuned, depending from the carbon pretreatment (oxidizing or reducing).
- *Calcium carbonate and barium sulfate*: These are supports for Pd in the so-called Lindlar catalysts Pd-Pb/$CaCO_3$ and Pd-Pb/$BaSO_4$, applied in organic chemistry for selective hydrogenations of C≡C bonds to C=C bonds.

Actually, in the case of most noble-metal-based industrial catalysts, the amount of metal is small or even very small. In this case, the dispersion of the metal may be very high and the size of the metal particles very small. Thus, supported metal particles cannot always be well characterized even by using transmission electron microscopy, and they are not always evident from x-ray diffraction analysis.

The presence of these particles justifies comparison with data obtained on monocrystal faces as well as theoretical calculations performed with periodic methods on metal crystal faces. The only limit, frequently somehow incorrectly neglected, is that, although these particles may expose the typical low-index faces well known to physicists and theoreticians, they have a very high density of defects, such as edges and corners between faces, whose behavior is more difficult to study.

Additionally, in the case of supported catalysts, isolated and very highly dispersed metal centers, such as small metal clusters, also usually strongly interacting with the supports, may form. This is evident from IR spectra, as shown in Fig. 33.6. In this case, the band of carbon monoxide adsorbed on top on flat nickel metal particles (2098–2070 cm^{-1}, typically shifting down with decreasing coverage) is observed together with a nonshifting multiplet (2130, 2059, 2044, and 2015 cm^{-1}), typically due to polycarbonyl species on isolated metal centers or small clusters. These highly dispersed centers, whose relative amount is greater on low-loading samples, may escape several characterization techniques (e.g., XRD and TEM) but have relevance in catalysis.

Theoretical studies reported on the stabilization of highly uncoordinated Pt and Pd metal centers by alumina reveal a relevant difference between alumina-supported catalysts and bulk metal surfaces [33.59]. The state of Pt and Pd is also dependent on the hydroxylation/dehydroxylation of the support: metal centers become positively charged when deposited on hydroxylated alumina faces, while they would be neutral or even negatively charged over dry surfaces. Other studies report on the existence of Pd particles decorated with a thin layer of an aluminate phase on Pd/Al_2O_3-supported catalysts [33.60]. The existence

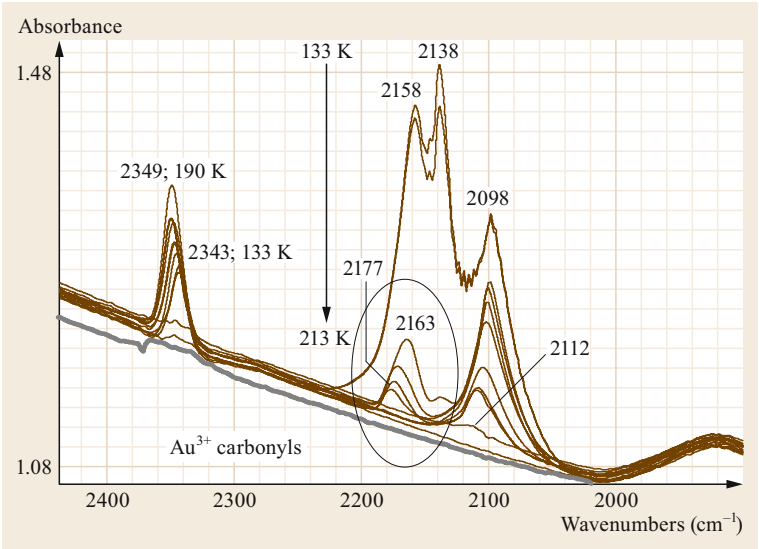

Fig. 33.7 IR spectra of CO adsorbed at low temperature on Au/Nb_2O_5 catalyst. While the band at 2098 cm^{-1}, shifting up upon desorption, is due to CO on Au particles, that at 2163 cm^{-1} is due to CO adsorbed on oxidized Au centers [33.58]

and likely catalytic activity of isolated centers have recently been proposed for CO oxidation and water gas shift on Pt/Al_2O_3-and different oxide-supported Pd catalysts [33.56, 61, 62] and also on gold catalysts [33.58]. Appropriate procedures indeed allow the preparation of atomically dispersed metal centers that exhibit catalytic activity and are even supposed to represent the real active sites in reactions such as CO oxidation and water gas shift [33.63, 64]. In Fig. 33.7, evidence is provided for the presence of isolated Au^{3+} centers on the surface of Au/Nb_2O_5 catalysts [33.58]. While the band shifting up from 2098 to 2112 cm^{-1} is typical of CO adsorbed on top of gold metal particles, the band at 2163 cm^{-1} is due to CO interacting with oxidized gold centers. As a result of this interaction, the band of CO_2 produced by CO oxidation on oxidized gold is observed growing at 2340–2350 cm^{-1}. In the case of Pd/CeO_2 catalysts, evidence for the possible introduction of palladium ions into the ceria lattice, producing a $Pd_xCe_{1-x}O_{2-x-\delta}$ solid solution, at the contact of palladium and cerium oxide nanoparticles, has been provided [33.65]. Indeed, the situation in the case of highly dispersed metals on oxide carriers may be even more similar to that of mixed oxides than of supported metal particles.

33.6.4 Activation of the Substrate upon Catalytic Oxidation

Oxidation catalysts are generally thought not only to activate oxygen but also to activate the substrate to be oxidized. Among hydrocarbons, the most reactive towards oxidation are functionalized molecules such as aromatics, with the activation of both ring positions as well as of benzylic positions. Also oxidation of olefins is very relevant industrially, with the possibility of oxidation at the C=C double bond or at the allylic position. The activation of unsaturated C=C bonds is frequently achieved by π-bonding over noble- or transition-metal centers. Alternatively, they can be activated by electrophilic attack. Activated saturated carbon atoms such as those at benzylic and allylic positions are activated by Lewis acid sites, which can abstract hydride species, or in a radical mode. Cations such as Sb^{3+}, Bi^{3+}, and Te^{4+}, i.e., having nonbonding electron pairs, are generally thought to be active in H abstraction from allylic positions [33.48, 49].

Heteroatom-containing molecules such as oxygenates, nitrogenated and halogenated compounds, which are in fact n-bases and more reactive to oxidation, are activated more easily. Activation likely involves the previous coordination of the molecules on Lewis acid sites using the lone pairs on heteroatoms. In Table 33.10, some relevant oxide oxidation catalysts are summarized.

33.6.5 Fixed Bed versus Fluidized Bed Catalytic Oxidations

Fixed bed multitubular reactors are mostly used for selective oxidations. Temperature is controlled by refrigeration fluids from the external surface of the catalytic tubes. These reactors have heavy drawbacks, in particular due to the difficult and long tube-charging operation, and possible preferential ways for the reactant mixtures when some tubes are not perfectly packed. Fluidized bed reactors allow much easier and faster charging and possibly also better temperature control. However, catalysts for fluid beds must be shaped as spheres that are resistant to abrasion. This is not always possible, depending on the catalyst composition.

33.7 Solid Catalysts for Hydrogenation and Dehydrogenation Reactions

33.7.1 Hydrogenations and Dehydrogenations

Hydrogenation reactions are exothermic equilibrium reactions, thus being performed at the lowest temperature allowed by the catalyst activity, and at medium to high pressure. Most of them are performed in the presence of solid metal-based catalysts, most frequently in multiple fixed beds with interbed cooling by heat exchange or quenching, in gas/solid or gas/liquid/solid conditions, or in slurry conditions, depending on the volatility of the reactants as well as the reaction temperature and pressure. In recent years, catalytic distillation processes have been developed, where the reaction occurs in distillation towers partly packed with a catalyst bed.

Catalytic activity in hydrogenation is associated with the ability of the catalytic material to adsorb hydrogen dissociatively, either heterolytically or homolytically, thus converting H_2 into atomic active forms.

Dehydrogenation reactions are endothermic equilibrium reactions, thus being performed at moderately high temperature and at low pressure, usually not far from ambient pressure. They are performed industrially in the presence of either metal-based catalysts or oxide catalysts, most frequently in single or multiple fixed beds with previous or interbed heating. Being reactions that occur at relatively high temperature and in the presence of organics and a reducing environment, catalyst coking may occur upon dehydrogenations. Reactor configurations must take this into account, allowing frequent or continuous regeneration. For this reason, several optional configurations have been developed: semi-regenerative processes, cyclic regenerative processes, and moving bed and continuous regenerative processes.

Most dehydrogenation catalysts are based on metals, mostly being the same as used also for hydrogenations, which are in fact the reverse reactions (Table 33.11). However, several oxides (such as chromia–aluminas and zinc oxide) also show catalytic behavior for some dehydrogenation reactions. Activity in dehydrogenation is driven by the ability of the catalyst to adsorb hydrogen as well as the unsaturated compound coming from dehydrogenation.

Catalysts that catalyze an equilibrium reaction also catalyze the reverse reactions. However, while hydrogenations are carried out at low temperature, dehydrogenations are carried out at high temperature. Thus, dehydrogenation catalysts may contain the same active phases as hydrogenation catalysts, but must be much more resistant to sintering and phase transformations than hydrogenation catalysts. As an example, catalysts for CO methanation work at 300–500 °C: they may be based on Ni on high-surface-area γ-Al_2O_3 [33.66]. The reverse reaction is methane steam reforming (see later). The latter reaction is realized at 800 °C: the catalysts are based on Ni supported on low-surface-area α-Al_2O_3 or metal aluminates (Sect. 33.8).

Table 33.11 Catalytic hydrogenations and dehydrogenations on metal catalysts

Reaction	Catalyst	Reaction conditions
Hydrogenation of nitrogen (ammonia synthesis)	Fe(K, Si, Al, Ca, Mg) Ru/graphite	400 °C, 200 bar, gas phase 300 °C, 100 bar, gas phase
Hydrogenation of CO, CO_2 (methanol synthesis)	55% Cu/ZnO/$ZnAl_2O_4$	250 °C, 100 bar, gas phase
Hydrogenation of CO, CO_2 (methanation)	25% Ni/γ-Al_2O_3 0.3% Ru/γ-Al_2O_3	250 °C, 20–50 bar, gas phase 170 °C, 20–50 bar, gas phase
Hydrogenation of CO, CO_2 (to hydrocarbons, LT Fischer Tropsch)	Co/γ-Al_2O_3	200 °C, 20–30 bar, slurry
Hydrogenation of CO, CO_2 (to hydrocarbons and oxygenates, HT Fischer Tropsch)	Fe-Fe_5C_2/SiO_2	300 °C, 20–40 bar, slurry
Hydrogenation of acetylene (C2 cut treatment)	0.03% Pd, 0.18% Ag/α-Al_2O_3	80 °C, 20 bar, gas phase
Hydrogenation of acetylenics	0.5% Pd/α-Al_2O_3	15 °C, 20 bar, liquid phase, fixed bed
Benzene saturation to cyclohexane	Ni Raney	200 °C, 50 bar, slurry
Hydrogenation of vegetable oils to margarine	Ni/SiO_2	200 °C, 5 bar, liquid phase
Light paraffin dehydrogenation to olefins	Pt/Li-Al_2O_3	550 °C
Heavy paraffin dehydrogenation	Pt/Li-Al_2O_3	475 °C, 2.5 bar
Aromatization	Pt/K-L zeolite	500 °C
Catalytic reforming of gasoline (aromizing)	Pt/K-L zeolite	500 °C
Dehydrogenation of alcohols to carbonyl compounds	Cu-ZnO-Al_2O_3 $CuCr_2O_4$	200–400 °C 200–400 °C

33.7.2 Hydrogenation Catalysts

Many metals, including platinum group metals, nickel, cobalt, iron, copper, etc., are active in hydrocarbon hydrogenation (Table 33.11). However, some noble metals are far more active, but quite easily deactivated, in particular by sulfur compounds. For these reasons, the catalyst composition for hydrocarbon hydrogenation is strongly dependent on the amount of sulfur impurities in the feed. Palladium, and to a lesser extent platinum, are the catalysts of choice for hydrogenation of clean feeds, while nickel is mostly used for hydrogenation of medium sulfur-containing feeds. Bimetallic noble-metal catalysts or other modified noble-metal catalysts may also have interesting resistance to medium/low concentrations of sulfur.

Metal sulfides are active in hydrogenations (Table 33.12) and are usually stable in sulfur-containing environments, needing sulfur in the feed to stay stable in a sulfided state. They are therefore the catalysts of choice for hydrodesulfurization and hydrocracking, and can be used for hydrogenation of hydrocarbons in sulfide-containing atmospheres.

Some metal oxides are also active in adsorbing hydrogen and can be used as catalysts for hydrogenation: in particular, some of them are used for hydrogenations of oxygenated compounds.

33.7.3 Adsorption of Hydrogen on Metals

There is general agreement that hydrogen adsorbs dissociatively and very quickly on almost all relevant metal surfaces, where the dissociation of hydrogen is only weakly activated or even barrierless [33.67]. As an example, it has been found that, when an H_2 molecule chemisorbs on a Pt surface, the antibonding σ^* orbital of H_2 is completely filled by electrons from platinum. Thus, nonactivated dissociative adsorption occurs; i.e., the adsorption step is not kinetically hindered. Only on group 11 metals (Cu, Ag, and Au) is hydrogen dissociation significantly activated [33.68] and may be endothermic. On-top, bridge or hollow sites can be occupied by atomic hydrogen species on metal surfaces. Such different coordinations for atomic hydrogen can be distinguished by vibrational spectroscopies, being surface metal hydride species (hydrogen on on-top sites) characterized by M–H stretchings in the $2000\,cm^{-1}$ region, while vibrations of hydrogen on bridge and hollow sites are detected at much lower frequencies [33.67, 69]. The formation of subsurface atomic hydrogen is also possible, usually via an endothermic and/or a slightly activated process. Tetrahedral and octahedral subsurface sites are occupied in this case. Only in the case of palladium is migration of hydrogen into the interior of the bulk apparently exothermic too, due to a very large binding energy ($-2.5\,eV$). This agrees with data showing that only in the case of Pd can a significant population of subsurface hydrogen occur and bulk hydrides also form.

33.7.4 Adsorption of Organic Substrates on Metals

Surface metal atoms, according to their coordinative unsaturation, present both Lewis acidity towards n-bases, as well as π-bonding activities towards unsaturated hydrocarbons. In fact, heteroatom-containing molecules such as saturated oxygenated compounds (including water), amines (including ammonia), sulfur compounds (including hydrogen sulfide), and halogens are supposed to interact by donation of their full n-type orbitals with empty d-type orbitals of transition-metal

Table 33.12 Catalytic hydrogenations and dehydrogenations on nonmetallic catalysts

Reaction	Catalyst	Reaction conditions
Hydrodesulfurization gasolines	Ni-MoS_2	300 °C, 20 bar, gas phase
Hydrodesulfurization gasoils	Ni-Co-MoS_2	350 °C, 50 bar, trickle bed
Hydrodenitrogenation of hydrocarbons	NiS-WS_2/Al_2O_3	350 °C, 50 bar, trickle bed
Hydrocracking heavy oils and residues	NiW-USY zeolite	400 °C, 150 bar, slurry
Deep hydrocracking (bottom of the barrel treatments)	MoS_2	450 °C, 200 bar, slurry
Hydro-deoxygenation of vegetable oils to green Diesel	CoS-MoS_2/Al_2O_3	250 °C, 50 bar, slurry
Hydrogenation of CO, CO_2 (HP methanol synthesis)	ZnO-$ZnCr_2O_4$	350 °C, 340 bar
Hydrodeoxygenation of carboxylic acids to aldehydes	Cr_2O_3-ZrO_2, CeO_2	310–400 °C, 1–30 bar
Hydrodealkylation of toluene	Cr_2O_3/Al_2O_3	600 °C, 50 bar
Dehydrogenation of light paraffins to olefins	K_2O-Cr_2O_3/Al_2O_3	550 °C
Dehydrogenation of ethylbenzene to styrene	K_2O-Fe_3O_4	600 °C, steam
Aromatization of light paraffins	Ga-ZSM5 zeolite	500 °C
Aromatization of light olefins	Zn-ZSM5 zeolite	500 °C

atoms, on-top. On the other hand, olefins, dienes, and aromatics are thought to adsorb on metal centers by electron donation from their full π-orbitals to empty d-type orbitals of transition metals with simultaneous electron back-donation from full d-type orbitals of transition metal to empty π^*-antibonding orbitals. This interaction with olefinic double bonds can be rapidly converted into di-σ-bonding and σ-alkyl groups [33.10, 70], while in the case of acetylene a tetra-σ-bonding or a threefold parallel-bridge configuration [33.71] is likely formed. In the case of aromatic rings, several σ-bondings are thought to form on the surface of active hydrogenation metals such as Pt(111) [33.72]. The picture for real catalysts is however possibly more complex due to the formation of carbonaceous matter on the metal surfaces, which can allow further adsorption mechanism to be active [33.10]. Sequential addition of single hydrogen atoms to the adsorbed hydrocarbon intermediate are thought to occur.

33.7.5 Metal Sulfides as Hydrogenation Catalysts

A number of metal sulfides act as hydrogenation catalysts [33.73, 74]. The most widely used sulfides for hydrogenations are based on MoS_2 and WS_2, pure or as solid solutions, with Co and/or Ni as activators. They are used either as bulk materials or supported, mainly on alumina [33.75, 76] (Table 33.12).

Molybdenum and tungsten sulfides, MoS_2 and WS_2, are isostructural layered phases. The tetravalent element forms a layer sandwiched between two two-dimensional hexagonal sulfide layers stacked over each other in an eclipsed fashion. Thus, the coordination around the metal is trigonal prismatic. Each sulfur center is pyramidal, being connected to three Mo centers.

Two main polymorphs of MoS_2 and WS_2 are reported to exist, due to the different relative position of the slabs. α-MoS_2 (molybdenite) hexagonal (space group $P63/mmc$), the most stable, is the most common and well-studied polymorph, and the natural form is isostructural with α-WS_2 tungstenite. β-MoS_2 and β-WS_2 are the rhombohedral modifications (space group $R3m$). Both sulfides may also be prepared in the form of fullerene-like particles as well as nanotubes, nanorods, nanostrips, nanowires, nanoflowers, nanoflakes, nanospheres, and nanohexagonal plates.

According to the most well-accepted theory, originally developed for supported MoS_2 catalysts, the catalytic chemistry of these materials should occur at the lateral termination (edges) of the MS_2 slabs. Two kinds of termination should exist for stoichiometric MoS_2, viz. the S edge ($\bar{1}010$ face), where coordinatively unsaturated sulfur is located for stoichiometric MoS_2, and the Mo edge ($10\bar{1}0$ face), where coordinatively unsaturated Mo species are expected in stoichiometric MoS_2.

The promoters Ni and Co introduce further defects and disorder into the structure, perturbing the stacking of the layered sulfides, introducing curvatures and non-stoichiometry. Additionally, or more importantly, they are mostly supposed to locate at the edges decorating them, increasing edge reactivity. In particular, most authors suggest that the promoters substitute for Mo or W at the edges of the $(Mo,W)S_2$ slabs, producing the most active sites for reaction.

For the Co-Mo-S system, other studies [33.77] have reported that the catalytic activity is directly proportional to the increase of the surface area of the two separate sulfide phases, Co_9S_8 and MoS_2. This suggests that the activity is directly connected with an increase of the contact surface area between the two sulfide phases. This approach has found further support, suggesting that the catalytic sites are located at the interface between cobalt sulfide crystallites and the stacks of MoS_2 slabs [33.78].

On the other hand, it has been underlined that, for fully saturated MoS_2, a metallic state extends over the slab basal (0001) plane, generating possible *brim* sites [33.79]. In fact, unsaturated molecules such as butadiene, thiophene, benzothiophene, pyridine, quinoline, benzene, and naphthalene may adsorb on the basal plane via van der Waals interactions. Additionally, it was recently shown that fully saturated MoS_{2+x} without any coordinative unsaturation can activate hydrogen and catalyze hydrogenation [33.80]. Thus, it seems that the details of the reaction mechanisms on unsupported sulfides remain to be completely defined.

Among other metal sulfides having relevant hydrogenation activities, much interest has been focused on ruthenium sulfides.

33.7.6 Adsorption of Hydrogen on Metal Sulfides

Two kinds of dissociation mechanism are supposed to exist, potentially, over sulfide surfaces: heterolytic dissociation, producing a molybdenum hydride species and a thionyl species, and homolytic *reducing* dissociation, producing two sulfidryl species and reduced molybdenum centers (Fig. 33.8).

To our knowledge, however, while the formation of thionyl SH groups has been directly detected by spectroscopic methods (e.g., bands at 2500 cm^{-1}, ν-SH, and 650 cm^{-1}, δ-SH, in inelastic neutron scattering spec-

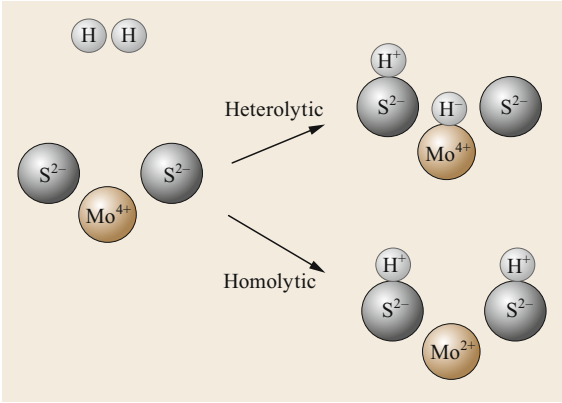

Fig. 33.8 Schematics of the mechanisms of dissociation of hydrogen on MoS_2

tra), no experimental evidence for molybdenum hydride species has been provided so far on MoS_2- or WS_2-based catalysts [33.81, 82].

Theoretical investigations suggest that heterolytic and homolytic dissociation of hydrogen may both occur, depending on the conditions and on the exposition of the Mo sites: heterolytic dissociation tends to occur on highly exposed Mo–S couples [33.83].

Interestingly, hydride species have been observed by inelastic neutron scattering on another catalytically active sulfide phase, RuS_2, thus providing evidence of a heterolytic dissociative adsorption mechanism there [33.84].

33.7.7 Supported Metal Sulfide Hydrogenation Catalysts

Transition-metal sulfide catalysts used in refineries for hydrotreatments are mostly molybdenum or tungsten sulfides supported on γ-Al_2O_3 and promoted by Co or Ni. The optimal promoter atomic ratio: $Co(Ni)/(Co(Ni) + Mo(W))$ is between 0.2 and 0.4. $CoMo/Al_2O_3$ catalysts are very efficient in the hydrodesulfurization (HDS) process [33.85] but are less active for hydrodenitrogenation (HDN) or aromatic hydrogenation. The degree of staking in MoS_2 and Co-Mo-S structures can be engineered by carefully controlling the properties and preparation parameters of the support. The formation of small stable single slabs of MoS_2 on alumina supports has been achieved. Conversely, NiMo phases are better HDN and hydrogenation catalysts and are preferred in order to treat feedstock with a high concentration of unsaturated compounds. NiW catalysts are highly effective for aromatic hydrogenation reactions but have higher cost. Other elements, such as phosphorus, boron, and titanium, are sometimes added to the alumina support, improving the catalytic activity. In particular, phosphorus improves the selectivity toward hydrogenolysis versus hydrogenation.

After sulfidation, crystallites of the MS_2 phase in the form of slabs form on the alumina surface. These crystallites may have different shapes, such as hexagonal, triangular, and truncated triangular, and may interact differently with the alumina surface. Promoter atoms (Co, Ni) are supposed to locate mainly in substitution of Mo (W) atoms at the edges of the slabs.

33.7.8 Metal Oxides in Hydrogenation and Dehydrogenation Reactions

A number of oxides significantly adsorb hydrogen and show useful activity as catalysts for hydrogenation and dehydrogenation reactions (Table 33.12). Adsorption of hydrogen on such materials is mostly reported to be heterolytic, occurring on exposed cation–oxide couples. Well-evident surface hydride species have been observed by vibrational spectroscopies (in particular infrared techniques) on ZnO [33.86–89], Cr_2O_3 and $ZnCr_2O_4$ [33.90], as well as on Ga_2O_3 [33.91] and ZrO_2 [33.92]. However, according to *Syzgantseva* et al. [33.93], on zirconia, hydrogen could dissociate via a different mechanism, adsorbing on two Zr^{3+} ions with a neighboring oxygen vacancy (νO), leading to formation of two Zr^{4+}–H hydride species.

On ZnO, surface hydride species cannot be observed in well-controlled single-crystal ultrahigh-vacuum (UHV) experiments, while they are detected on powders and at significant hydrogen pressure. At higher temperature, these species disappear, while contact with hydrogen can produce reduction of the surface.

A different mechanism, i.e., homolytic reductive adsorption, seems to occur in other cases, in particular on ceria [33.94]. The adsorption of hydrogen on ceria has been studied by density functional theory (DFT) calculations [33.95]. These studies have shown that H_2 may adsorb dissociatively on $CeO_2(111)$ with a relatively low activation barrier (0.2 eV) and strong exothermicity. Hydrogen homolytic dissociation is supposed to lead to two OH groups. Indeed, during the hydrogenation reaction, increased absorption in the OH stretching region of the IR spectra bands was observed [33.96]. Ceria is reported to be active in hydrodeoxygenation reactions, such as reduction of carboxylic acids to aldehydes, as well as in the hydrogenation of alkynes to alkenes.

It can be supposed that inverse mechanisms with the same intermediate states can be applied in the case of dehydrogenation reactions. These species will give rise to gaseous hydrogen after abstraction of a proton.

33.8 A Case Study: Steam Methane Reforming (SMR) for the Production of Hydrogen

33.8.1 Industrial Steam Reforming Processes: Some History

As summarized by *Rostrup-Nielsen* years ago [33.97], studies on the reaction of steam with hydrocarbons started in the last half of the nineteenth century [33.98]. The first patent on nickel catalysts for steam reforming was issued to BASF in 1913, while, apparently, the first detailed paper dealing with catalytic reforming of methane dates from 1924 [33.99]. Standard Oil started producing hydrogen by hydrocarbon steam reforming in the USA in 1931. As frequently occurs, chemical technology was fast to develop processes well before science was able to explain and describe in detail the phenomena at the molecular level. However, further technological improvements and plant management have taken much advantage of more recent scientific developments, allowing better understanding of the chemistry and physics of such systems, in particular through modeling [33.100]. Today, steam reforming of methane or natural gas is a very prominent technology for hydrogen and syngas production [33.101, 102].

33.8.2 Steam Methane Reforming: Thermodynamics

Steam reforming processes are endothermic equilibrium reactions performed to convert organics and water to syngases, i.e., hydrogen and CO_x mixtures. The most common application today is steam methane reforming (SMR) or reforming of natural gas. The main reaction is endothermic.

$$\mathrm{CH_4 + H_2O \rightarrow CO + 3\,H_2}$$
$$\Delta H^\circ_{298} = +206.63\,\mathrm{kJ/mol}$$
$$\Delta S^\circ_{298} = +214.63\,\mathrm{J/(K\,mol)}$$

The reaction, more favored at higher temperature and lower pressures, is practically performed at 700–900 °C, usually under 30–50 bar. This moderate pressure is used to reduce the reactor size and improve the efficiency of the overall process, despite the unfavorable thermodynamics of the reaction step.

In reaction conditions, also the so-called water gas shift equilibrium is established or approached

$$\mathrm{CO + H_2O \rightarrow CO_2 + H_2}$$
$$\Delta H^\circ_{298} = -41.16\,\mathrm{kJ/mol}$$
$$\Delta S^\circ_{298} = -42.08\,\mathrm{J/(K\,mol)}$$

Thus, the resulting product gas, denoted as syngas, is a mixture mainly containing H_2, CO, CO_2, and unreacted methane and water. In most cases, SMR processes are followed by one or more water gas shift steps, where CO is converted by reacting with water almost completely to CO_2, thus producing more hydrogen. Finally, hydrogen is separated from CO_2 and purified.

33.8.3 SMR: Metal Catalysts

Most transition metals are active in steam reforming. Platinum group metals, such as ruthenium, rhodium, iridium, and, possibly to a lower extent, palladium and platinum, are very active in SMR [33.103]. Nickel, if loaded at the same amount on the supports, is definitely less active than Ru and Rh, and more prone to deactivation. However, due to its much lower price, it can be charged on catalysts at much higher loadings (up to 50% instead of, e.g., $< 1\%$). Thus, nickel catalysts loaded at the level of 10–30 wt% are sufficiently active, cheap, stable, and robust to represent the best choice for SMR catalysis in practice.

33.8.4 SMR on Nickel: Surface Science and Computational Studies on the Reaction Mechanism

The mechanism of the SMR reaction over Ni metal surfaces was approached long ago by surface scientists [33.104] and, more recently, by theoreticians [33.105, 106], although full agreement has still not been reached.

Water activation on metallic nickel is supposed to produce hydroxyl and oxide species [33.107]. Most data suggest that methane is activated mostly on steps or edges of Ni particles, producing successively methyl (CH_3), methylene (CH_2), methine (CH), and carbide species by progressive dehydrogenation. A competition between methane and water adsorption has been reported [33.108].

However, methane can also be adsorbed and activated on oxide and/or hydroxyl sites, thus producing oxygenated intermediates. A further alternative consists in the reaction of water with CH_x adsorbed intermediates, producing oxygenated intermediates too. The final reaction step is the decomposition of such oxygenated intermediates, finally producing hydrogen and carbon monoxide.

33.8.5 SMR on Nickel: Kinetics

Kinetic modeling of SMR over Ni takes advantage of the above mechanistic considerations [33.109, 110]. The reaction order is close to one for methane and definitely negative for steam, with a weak positive effect of hydrogen [33.111–113]. The main data show that the rate-determining step in the overall process is most likely the first methane adsorption and dissociation step [33.108, 112], although some studies suggest that the decomposition of the surface oxygenated intermediates is rate determining [33.114]. Although scattered data are reported on activation energies, most authors [33.115] report a value of $\approx$ 100 kJ/mol, consistent with the values calculated for the C–H bond activation of CH_4 on Ni monocrystal surfaces [33.116].

33.8.6 SMR on Nickel: Managing the Problems

Sintering of Nickel Particles

As shown by surface chemistry studies, methane and water activation very likely occurs mostly at steps or kinks on Ni nanocrystals. On the other hand, the reaction conditions are certainly very demanding: high temperature, moderately high pressure, presence of large amounts of steam, and required lifecycles of several years. Taking into account that pure nickel melts at 1455 °C (1728 K), atomic mobility may already be active at such reaction conditions. In fact, the temperature for starting atom mobility in the solid state (the so-called Tammann temperature) is evaluated to be around half of the absolute melting temperature. For nickel, this temperature is consequently about 865 K. This means that sintering of Ni nanoparticles is possible. Sintering will obviously reduce the surface area of metallic nickel and the density of active step and corner sites. Thus, the catalyst composition (support and additives) must be chosen to reduce the sintering rate as much as possible. Ni–OH is assumed to dominate nickel transport at nickel surfaces in the presence of steam and hydrogen, as Ni–OH has the lowest combined energies of formation and diffusion compared with other potential nickel transport species [33.117].

Poisoning by Sulfur

Ni catalysts are rapidly deactivated by sulfur poisoning, due to the formation of inactive nickel sulfide [33.118, 119]. In practical SMR applications, this problem is solved by removing sulfur upstream. A hydrodesulfurization step with stoichiometric hydrogen over Ni-promoted MoS_2/Al_2O_3 catalysts at 350 °C is followed by an absorption step using ZnO at 400 °C [33.97, 101].

Formation of Carbon Deposits

Carbon matter forms at the reaction conditions on Ni catalysts [33.120], much more than for platinum group metal catalysts. A number of different forms of carbon are revealed by analysis of spent catalysts. The most evident one is represented by carbon whiskers [33.121], actually constituted by mulitiwalled carbon nanotubes whose formation is catalyzed by Ni surfaces (Fig. 33.9). It has been found that the (111) Ni faces are mostly responsible for the formation of this kind of carbon species. This carbonaceous matter tends to detach Ni crystals from the support. This form of carbon does not really deactivate the catalyst, at least during the first stages of formation. However, the whiskers occupy void spaces in the catalyst bed, causing pressure drops that worsen with time.

Other forms of carbon species can also be detected, such as gums and pyrolytic coke. In any case, all of these result in progressive catalyst deactivation. Most of the carbon species are formed by decomposition/dehydrogenation of higher hydrocarbons (butanes, propane) that are usually present in some amount in the feed. Pre-reforming beds allow specific reforming of higher hydrocarbons, whose reaction with water is

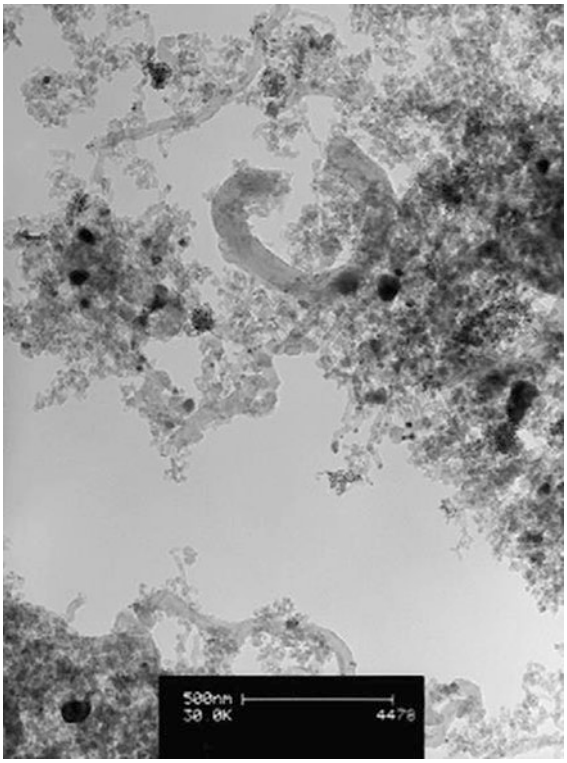

Fig. 33.9 TEM image of carbon whiskers formed on a Ni-Co/ZrO_2 steam reforming catalyst. From [33.122]. Reprinted with permission from AAAS

thermodynamically much more favorable than that of methane, at 500–600 °C. This limits the formation of carbon matter in the SMR tubes. Another way to reduce the formation of carbon matter consists in feeding a large excess amount of steam. In fact, the steam-to-carbon ratio typically applied in the SMR process is 3 : 6, compared with the S/C stoichiometric ratio of 1 for the main reaction. However, slow formation of C matter seems to be almost unavoidable and critical for the lifetime of the catalyst bed and also of the tubes. The formation of carbon matter can also be reduced by an appropriate choice of the support and of activators/stabilizers for Ni catalysts.

33.8.7 SMR on Nickel: The Choice of the Support

The SMR reaction is performed at high temperatures (700–900 °C) in the presence of a large amount of steam. The catalyst should be substantially stable for operation 24 h a day for several years. Thus, the catalysts must have an important refractory character. Typical methane steam reforming catalysts contain 10–25 wt% Ni, 70–85 wt% Al_2O_3, or aluminate supports and up to 5% K, Ba, Ca. The support phase is in fact a refractory oxide such as α-alumina (corundum), Mg aluminate spinel $MgAl_2O_4$, calcium aluminate $CaAl_{12}O_{19}$, and calcium-potassium aluminate $CaK_2Al_{22}O_{35}$. Metal aluminates, corundum, and Mg-, Ca- and K-aluminates, with spinel and β-alumina structures, are in fact refractory and high-melting-point materials. The surface area of these materials may be low (a few tens of m^2/g) or very low and dispersion of Ni on their surface is frequently not high, typically giving rise to Ni particles with sizes of 20–50 nm.

The presence of alkali and alkali-earth cations is associated with a significant basicity of these materials, which is needed to inhibit the formation of carbon matter on the support itself. These components can also act as activators or stabilizers of the nickel active phase.

The nature of the support, the amount of loaded metal, the nature and amount of promoters and stabilizers, and the preparation procedures are all factors that influence the crystal size and shape of the nickel nanoparticles on the catalyst. It seems that the best crystal size lies in the range of 20–50 nm (see Fig. 33.10 for a heavily charged Ni-Co/ZrO_2 catalyst). Actually, polycrystalline particles mainly form. Atoms at steps, edges, and defects are usually found to be the most reactive and probably represent the predominant active sites in the reaction.

33.8.8 SMR on Nickel: Promoters and/or Stabilizers

As mentioned above, catalyst components can influence the catalytic activity, poisoning, sintering, and carbon forming activity of nickel catalysts. According to the open literature, elemental analyses of industrial steam reforming catalysts indicate the presence, besides nickel and aluminum, of one or more alkali and alkali-earth elements, i.e., K, Mg, Ca, and Ba. These elements may be involved at least in part in the formation of aluminate phases, such as spinels and/or β-aluminas. They make the support stable at high temperature and under hydrothermal conditions. However, they also contribute by modifying the interaction between the nickel metal particles and the support itself. They may also modify the behavior of nickel and reduce the activity of the bare support surface. In particular, potassium has a very positive effect in reducing the formation rate of carbon species, with the drawback of slightly reducing the catalytic activity of the catalyst [33.120]. On the other hand, alkali-earth ions are reported to limit nickel dispersion, resulting in easier reducibility of nickel species [33.123, 124]. In the case of Ca, however, the behavior strongly depends [33.125] on the amount of Ca and the nature of the support. Other elements frequently cited as components of the catalysts are zirconium and rare earths, in particular lanthanum and cerium [33.126, 127]. La is reported to increase the catalytic activity [33.128] and aid in the removal of some of the carbon deposits more effectively by gasification [33.129].

The copresence of lanthanum and cobalt has been reported to be beneficial, at least for dry reforming activity [33.130]. Boron is also considered to act as an excellent structural promoter to obtain small Ni particles [33.129], but its behavior may depend on the impregnation procedure used [33.124].

The presence of small amounts of silica is also sometimes reported. Silica can stabilize the support as well as limit the dispersion of nickel, forming larger aggregates and reducing the amount of isolated nickel species [33.131].

Addition of Mo is also cited in literature: it is reported to decrease the surface metal area but increase the specific activity of the active sites [33.132].

Alloying of Ni with small amounts of other metals, in particular noble metals, is also considered to be useful [33.122], although it can also increase the cost of the catalyst. Ni-Au, Ni-Ag, Ni-Sn, Ni-Cu, and Ni-Co alloys are reported to exhibit superior catalytic performance in the methane steam reforming, i.e., high activity, high resistance to carbon formation and sintering of metal particles, and high selectivity to H_2 product [33.133]. In general, Co is reported to increase the catalytic activity of Ni in steam reforming reactions [33.134, 135]. Alloying Ni with Rh is reported to stabilize the metallic particles [33.129]. Alloying Ni with noble metals is reported to prevent sintering [33.136] and to display an *intelligent* behavior, with suppression of deactivation phenomena in case of daily start-up and shut-down operation, typical in case of hydrogen and fuel cells for domestic use [33.137].

33.8.9 SMR on Nickel: The Choice of Reactor and Reaction Conditions

The SMR process is usually realized today at 30–50 bar pressure, in spite of the negative effect of increasing the pressure on the reaction thermodynamics. In fact, although the hydrogen yield is slightly reduced by increasing the pressure, a great reduction of the reactor size is obtained. Medium/high pressures are convenient also because the other steps of the overall process are then conveniently performed. Finally, higher pressures may also allow higher flow rates, thus allowing higher productivities.

The reaction is usually performed in special steel tubes, 10–20 cm large and 10–15 m long, filled with the catalyst extrudates, mostly downflow, placed into fired furnaces. For large plants up to 1000 tubes may be present, while for small size plants 10–20 tubes are present. The small diameter of the tubes is due to the need to reduce temperature gradients in the section. The length is associated with the contact time needed to approach equilibrium and obtain the highest productivity. The space velocities typical for industrial reactors are on the order of 2000–4000 h^{-1}, being dictated predominantly by the heat transfer and tube design. The temperature profile along the tube is increasing, from $\approx 500\,^{\circ}C$ at the inlet to $\approx 800\,^{\circ}C$ at the outlet. The maximum temperature is a compromise between the need to improve the thermodynamics (the reaction is endothermic) and the needs to limit the catalyst sintering, fuel combustion, and tube metal costs and increase the lifetime of the tubes.

Steam is fed in excess, in spite of its reducing effect on the reaction rate: the steam-to-carbon ratio is usually > 3, to push the thermodynamics and reduce the formation of carbon species.

33.8.10 SMR on Nickel: Shaping the Catalyst

As cited above, shaping is necessary to reduce the pressure drops and improve the fluid dynamics and heat transfer effects. Cube extrudates were first used in commercial SMR plants by ICI (now Johnson Matthey) [33.138]. They were later substituted by cylinders with a single hole (Raschig rings), then by four-hole cylinders, and finally by quadralobes. Through this development, the relative activity was doubled while the pressure drop was more than halved. The most recent development in this field is the application of cylindrical foil-supported module structures (CATACEL JM SSRTM) that allow a further strong increase in the activity and decrease of the pressure drop.

33.9 Conclusions

The present review underlines the complexity and multidisciplinarity of the field of heterogeneous catalysis, where collaboration among chemical engineers, material scientists, physical, inorganic, and organic chemists, and surface and material physicists is needed to fully understand phenomena and develop technologies. Although several technologies were applied industrially very early on, knowledge on the molecular phenomena remains largely incomplete and subject to debate. Surface science and surface chemistry, as well as computational studies, are needed to further improve existing technologies. On the other hand, it is clear that a revolution is approaching, with the abandonment of the extensive use of fossil raw materials and the progres-

sive increasing application of renewable raw materials for production of chemicals and fuels. Heterogeneous catalysis will continue to play a fundamental role, and surface science and surface chemistry will help in developing such new technologies which will achieve sustainability for our high-technology civilization.

Guido Busca has been Full Professor of Industrial and Technological Chemistry at the University of Genoa since 2000. He is now the Director of the Civil, Chemical and Environmental Engineering Department of his University. He has authored one book, twelve books chapters, more than 430 papers, which collected more than 32 000 citations. His h-index in Scopus is 89.

34. Electrochemical Behavior of Single Crystal Electrodes on Model Processes

Victor Climent, Enrique Herrero

Platinum is among the most catalytic metals for many electrochemical reactions of applied interest. In particular, platinum or platinum-based alloys are the most active for the typical reactions related to fuel cell technology, such as hydrogen evolution, hydrogen oxidation, oxygen reduction and oxidation of small organic molecules. For this reason, there is great interest in understanding at a fundamental level the principles underlying the phenomena of electrocatalysis in relation to this metal. One aspect that has been revealed of particular interest is the sensitivity of most electrocatalytic reactions to the surface structure of the catalyst. To study this aspect of electrocatalysis, it is important to understand the techniques and methodologies to work with single-crystal electrodes. It is equally important to learn how to interpret the electrochemical behavior of well-defined surfaces from the perspective of their surface reactivity. In this chapter, we first review the techniques for the preparation of single-crystal electrodes with well-defined surfaces. Although gold is less important from an electrocatalytic point of view, its interfacial behavior is, precisely for this reason, easier to interpret. Therefore, the chapter focuses on and compares the behavior of two metals, platinum and gold. Some methodological details particular to the work of these electrodes in an electrochemical environment are described. The different surface structures obtained with the materials will be associated with the voltammetric behavior recorded in different supporting electrolytes, with the aim of characterizing processes such as adsorption, surface reconstruction and faceting, and basic electrochemical reactivity, using both in situ and ex situ techniques. Important parameters that describe the properties of the interphase are the potential of zero charge and the potential of maximum entropy. Techniques and methodologies for their determination and interpretation will be briefly reviewed. Finally, some practical examples of surface-sensitive reactions will be described, focusing on the underpotential deposition of metals and the oxidation of carbon monoxide and some small organic molecules.

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-46906-1_34

The initial studies in the field of surface electrochemistry sought to gain the same level of knowledge previously achieved in the related but older fields of surface science and heterogeneous catalysis. In the first place, they aimed to establish relationships between surface structure and reactivity. Secondly, they tried to prove the effects of surface modification on electrocatalysis, to finally attain sufficient knowledge to attempt the rational design of optimal catalysts. When compared with the studies carried out in ultrahigh vacuum (UHV), the electrochemical media present some advantages. In the first place, the experimental procedures to attain comparable cleanliness conditions are easier in electrochemical environments (after you learn some basic precautions). Ultrapure water and high-quality chemicals, together with well-tested and defined cleaning procedures are the basic requirements to obtain a clean system. Also, the preparation (cleaning and ordering) of the single-crystal electrodes is easier and faster: a simple annealing (with a flame or induction oven) followed by cooling in an appropriate atmosphere is enough to attain high-quality surfaces. Second, the instrumentation involved in electrochemical studies is simpler and cheaper: a potentiostat with a signal generator, a signal recorder and a glass cell are the essential equipment in these studies. Finally, in electrochemical systems, there is an additional variable (alongside composition, temperature and pressure) that controls the reactivity of the surface: the electrode potential. When compared with temperature, the control and change of the electrode potential is straightforward and faster, which allows for greater versatility in the types of programs that can be used to modulate the change with time of this variable, providing a better understanding of the behavior of the systems. However, the presence of water (or any other solvent) in the electrochemical environment poses a major problem in the application of the techniques classically employed in UHV to probe the interfacial structure, particularly those based on electron spectroscopy. For this reason, in some of the first studies with single-crystal electrodes, the electrochemical system was coupled with a UHV chamber, so that the electrode, after its modification in the electrochemical system, was carefully transferred to the UHV chamber to analyze the surface and the possible adsorbates or intermediates. In this analysis, it was assumed that the loss of potential control and the modification of the environment (essentially the loss of the water layer and the supporting electrolyte in contact with the electrode) would not alter the system. This could be true in the case of strong adsorbing species, such as metal adatoms, but probably not in the case of other adsorbing molecules. The advent of synchrotron and scanning probe microscopy techniques enabled a comprehension of the surface modification processes similar to that reached previously in UHV, because they made possible the determination of the different surface structures and the composition of the topmost layer under in situ conditions. Multiple spectroscopic techniques have also been incorporated to the battery of methodologies used to interrogate in situ the electrochemical interphase. Fourier transform infrared reflection absorption spectroscopy (FTIRRAS) is one of the most common and available spectroscopic approaches. Other techniques like second-harmonic generation (SHG) and sum frequency generation (SFG) are also useful but require more complex and expensive instrumentation. Raman spectroscopy was largely limited to rough surfaces of coinage metals until the recent introduction of shell-isolated nanoparticle-enhanced Raman spectroscopy (SHINERS) [34.1, 2]. All these techniques provide information primarily about the composition of the interphase, although structural information is also provided indirectly. Thus, it was possible to establish, usually with a combination of methodologies, the key role of the solvent and supporting electrolyte in electrochemical systems, and to justify the differences with similar systems in UHV. In the following, some examples of the electrochemical systems studied with single-crystal electrodes will be reviewed. After a brief introduction of the experimental techniques typically employed in these studies, we summarize the voltammetric characterization of single-crystal surfaces of platinum and gold with increasing degrees of complexity. The initial stages of metal deposition (underpotential deposition of metals) are then described, ending with some examples of the electrocatalytic behavior of platinum.

34.1 Preparation of Single-Crystal Surfaces

The first step in the preparation of a well-defined single-crystal surface starts with the fabrication of a crystallographically well-defined single crystal. This is a piece of material composed of a single grain in which the positions of the atoms follow a coherent crystallographic network. There are many different methods to obtain a single crystal. They all have in common the slow formation of the solid phase in such a way that atoms

have time to adopt the right position in the crystallographic network. It can be solidification from the melted material, condensation from a vapor phase or even electrodeposition from a solution. The procedure described here, the so-called Clavilier method [34.3–5], is the one used in our laboratory, which is particularly interesting given its simplicity. It has been successfully applied to the fabrication of platinum, gold and rhodium single crystals. Fabrication of palladium crystals is more problematic with this method, given the ability of this metal to absorb gas, but it has also been reported in the literature [34.6]. The process consists of the formation of a small bead of the metal by melting the end of a high-purity wire with a torch. Butane/oxygen or hydrogen/oxygen flames are hot enough for this purpose. The rate of fusion/solidification can be controlled by slowly moving the flame up and down. It is better to move the torch and not the wire with the bead to avoid vibrations that would results in defects in the crystal structure. Alternatively, the temperature of the flame can be varied by regulating the flow of gases. The process of crystallization can be easily followed, since melt and solid phases have different brightness, resulting in an easy visualization of the front that separates the two phases. The size of the bead is limited by the surface tension that holds the drop of melted material hanging from the end of the wire. Typically, beads with diameters ranging from 2 to 4 mm can be obtained with a wire of 0.8 mm. By repeating the melting and solidification process several times, impurities in the metal tend to accumulate at the bottom of the bead (the last point to solidify), which have to be removed by treating the hot metal with aqua regia (a 3 : 1 mixture of HCl and HNO_3). The process is repeated several times until a single crystal bead of sufficient quality is obtained. The single-crystal nature of the bead can be checked by observing the facets formed on its surface. Typically, facets on the (111) directions are favored on the surface of the crystal and can easily be observed using a simple glass magnifier.

To accurately check the angle between the facets, which is a proof of the single-crystal nature of the bead, reflections of a laser beam on the facets can be used. When a laser beam is directed to the beam, reflections are formed pointing in the orientation of the facets. Usually, (111) and (100) facets give visible reflections. Then, to measure the angle between two facets, the angle between the two reflections is measured with great accuracy. For this purpose, the bead is mounted on a goniometer at the end of an optical bench, with the laser at the other end. The length of the bench gives the accuracy of the measurement. This procedure allows one not only to verify the single-crystal nature of the bead (comparing the obtained angles with the theoretical ones) but also to orient the crystallographic axis before cutting and polishing the piece to obtain a macroscopic surface with well-defined crystallographic orientation.

The orientation of the crystal prior to cutting is illustrated in Fig. 34.1 using stereographic projection. The crystal orientation process typically starts by locating two (111) facets and, after adequate rotations, placing their reflections in the horizontal plane. Starting from this position, we have access to the three basal planes and all stepped surfaces between (111) and (100) and between (111) and (110). To obtain stepped surfaces between (100) and (110) or other surfaces in the center of the stereographic triangle, two rotations are necessary, one to bring the surface to the horizontal plane and a second to bring it to the center [34.7]. Perpendicular to the center, the bench has a polishing disk that allows one to first cut and then polish the crystal in this orientation. Further details on the procedure are described in previous reviews [34.7, 8].

Prior to cutting and polishing, the crystal is protected with an epoxy resin to fix its position. Then the crystal is cut, typically until exposing a maximum diameter of the bead, using sandpaper of adequate grain size. The surface is then polished using either alumina or diamond paste of decreasing grain size, typically from 3 to 0.1 μm. Normally, a few hours of polishing at each grain size is necessary to obtain a high-quality mirror finished surface. The next step is to remove the epoxy resin to obtain a hemisphere-shaped electrode with an approximately circular flat surface with the desired crystallographic orientation.

The last step in the preparation of the crystal is the annealing of the bead at high temperature, close to the melting point of the material. At this temperature, the surface atoms have enough mobility to adopt positions that minimize the surface energy of the piece, usually following the nominal structure according to the angle in which the crystal was cut. For platinum, this can be easily achieved by holding the crystal in a Bunsen flame at red-hot temperature for ca. 20–30 min. The temperature of the Bunsen flame is sufficient to facilitate the ordering of the surface atoms but low enough to prevent melting of the platinum crystal. This is not the case for gold, which can be easily melted in a Bunsen flame, and therefore it has to be annealed with great care. Alternatively, annealing for several hours in a furnace at ca. 850 °C can be done without the danger of melting the crystal. The opposite situation holds for rhodium, which has a higher melting point and therefore requires a relatively oxygen-rich high temperature flame.

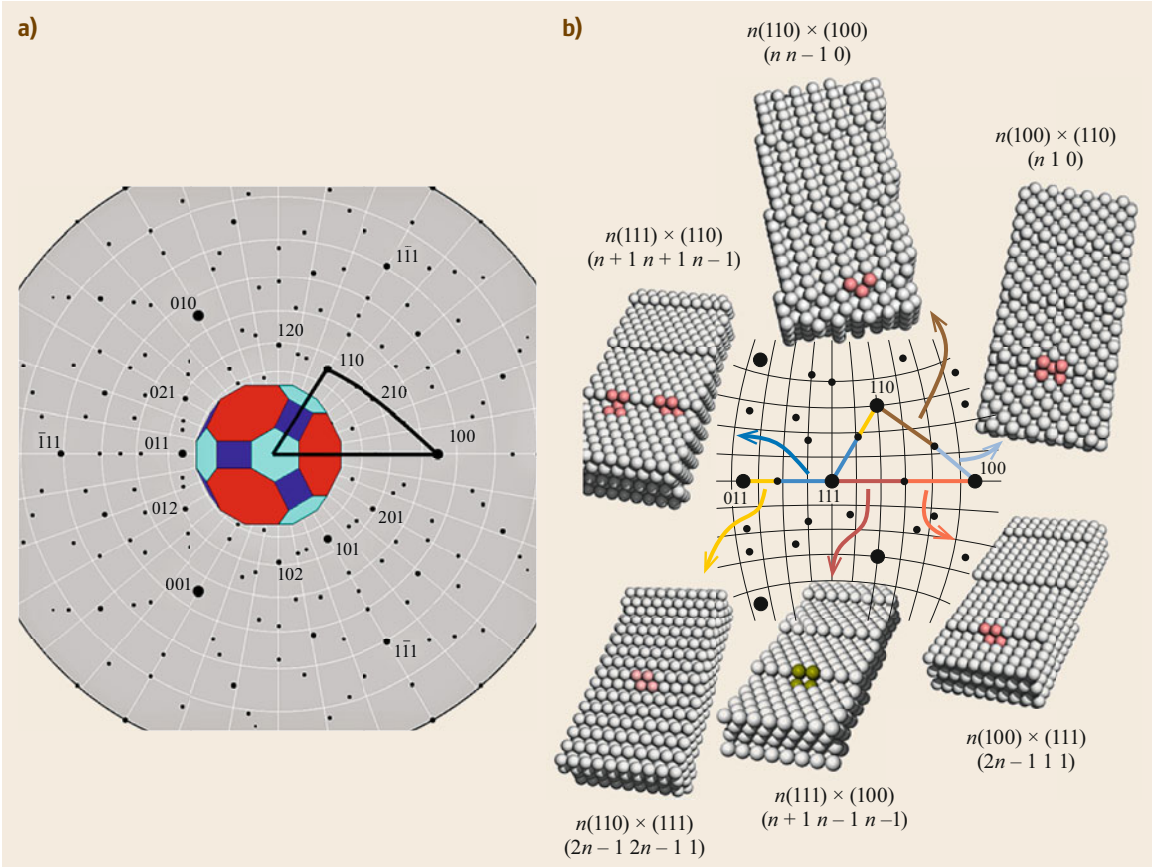

Fig. 34.1a,b Orientation of the crystal for the preparation of a well-defined electrode surface. **(a)** The crystal is oriented with two vertical (111) facets (*light blue*). One (110) facet (*dark blue*) is between the two (111) facets. One (100) facet (*red*) is also located vertical in the opposite direction. **(b)** Relation between the stepped surfaces, and their position in the stereographic projection. The *horizontal line* (011)-(111)-(100) indicates the stepped surfaces that can be prepared from the starting point represented in **(a)** by a single rotation. Other surfaces in the line (110)-(100) need two rotations. Labels in **(b)** give the relationship between the terrace length (n in the Lang, Joyner and Somorjai nomenclature, $n(hkl) \times (h'k'l')$) and the Miller indices (hkl) of the surface [34.9]

34.2 Some Remarks About the Experimental Procedures

Experiments in the investigation of surface electrochemical processes are particularly sensitive to the presence of small traces of contaminants. Organic contamination usually leads to the accumulation of molecular fragments irreversibly adsorbed on the surface of the electrode, deeply altering its electrocatalytic behavior. Inorganic contamination usually leads to specific adsorption of anions, which can be either reversible or irreversible, but in any case, also altering the electrochemical response of the material. Platinum and rhodium are usually more electroactive than gold, and therefore they are more sensitive to contaminants in solution. The sensitivity to contaminants also depends on the crystallographic orientation of the electrode surface: surfaces with a more open arrangement of atoms are usually more reactive.

We often encounter the following misconception: single-crystal surfaces are more sensitive to contamination than polycrystalline materials, and precautions can be relaxed to some extent when working with the latter. This is a dangerous misunderstanding. What really happens is that the response of a single-crystal electrode surface is better defined, and therefore, accumulation of contaminants is more easily detected. With polycrystalline materials, response is less defined and reproducible, and thus it is more difficult to discern whether differences in the electrochemical behavior are due to variations in the surface structure or to contam-

inants. However, this does not mean that, if there are impurities in the solutions, they will not affect the behavior of polycrystalline electrodes to the same extent as they do for single-crystal electrodes.

For the reasons outlined above, it is extremely important in surface electrochemistry to maintain the solution at a high level of purity. Deionized water of maximum quality should be used (18.2 MΩ cm). Also, all reactants must be of the maximum degree of purity. Glassware should be cleaned profusely before each experiment. Needless to say, detergents or surfactants are completely *forbidden* for this purpose. Cleaning is usually performed through a combination of strong oxidizing solutions, rinsing and boiling in water. Different oxidizing agents have been used for this purpose: chromic mixture (dichromate in concentrated H_2SO_4), Caro's acid (a 1 : 3 mixture of 30% H_2O_2 and concentrated H_2SO_4), peroxodisulfate solution (a 3 : 1 mixture of concentrated H_2SO_4 and HNO_3), a 10% HNO_3 solution or a potassium permanganate solution. Among them, the chromic mixture is not recommended because Cr(VI) is highly carcinogenic. Our favorite choice is the potassium permanganate solution ($\approx 2\,g\,L^{-1}$) in diluted H_2SO_4 (ca. 0.1 M). Glassware is left overnight in this solution. MnO_2 deposits formed on the surface of the glass can be easily removed by rinsing with 1% H_2O_2 in 0.1 M H_2SO_4 solution. Finally, the material is thoroughly rinsed with water and boiled in water (10−20 min) several times. The high temperature favors dissolution of contaminations that are later removed by rinsing. In cases where this mild treatment is not sufficient, boiling in 10% HNO_3 solution or even boiling in concentrated H_2SO_4 are more effective. However, the latter is particularly dangerous and detrimental to the different parts of the fume hood.

A stationary voltammogram with well-defined peaks, as shown later in Sects. 34.4 and 34.5, is a clear indication of good experimental conditions. Conversely, a continuous decrease in voltammetric current observed during potential cycling would be a clear symptom of surface fouling. Often, when the level of contamination is low but not negligible, the first voltammetric cycles are correct but the voltammogram later becomes increasingly distorted. Under these conditions, and depending on the time scale of the experiment, the results may range from slightly affected to completely wrong. As mentioned above, the same solution may appear *clean* for an electrode with a given crystallographic orientation but contaminated for a different electrode orientation. Low-coordinated atoms are usually more sensitive to contamination, since adsorption processes are favored on those atoms.

Another critical step in the electrochemical characterization of a surface is cleaning it while preserving the surface order. While the typical procedure for cleaning a (polycrystalline) electrode is to polish it, for instance with alumina, to renew the surface, such a procedure cannot be followed for a well-ordered surface, for obvious reasons. Repetitive cycles of surface oxidation and reduction have also often been used to clean the surface of platinum and gold single crystals. Again, this protocol cannot be followed with single crystals since, as will be shown below, oxide formation and subsequent reduction causes roughening of the surface.

Initial attempts to study well-ordered platinum surfaces used well-established procedures for surface preparation and characterization in UHV, followed by the transfer of the cleaned electrode to the electrochemical environment [34.10–17]. In this case, the problem was found in the transfer step, which turned out to be very difficult while preserving the cleanliness of the surface. Combination of UHV preparation followed by extensive surface oxidation and reduction was also attempted, but, as just mentioned, this process leads to defective surfaces [34.10, 12, 16, 17]. From a historical perspective, a key moment in the development of the field of surface electrochemistry was the introduction of the flame annealing technique for surface decontamination and reordering [34.3, 4, 18]. This includes the heating of the electrode in a flame (as described above for the reordering of the surface) followed by a rapid quenching of the electrode, while still hot, with water. In this way, the electrode is covered with a drop of water which protects the surface from possible contamination from the laboratory atmosphere (diffusion of contaminants is much slower in condensed media than in the gas phase). This gives enough time to transfer the electrode to the electrochemical cell while preserving the cleanliness of the surface. Following this methodology, completely new cyclic voltammograms were recorded for the three platinum basal planes [34.3, 4, 19, 20]. The voltammetry recorded for Pt(111) was particularly striking since it exhibited adsorption states at abnormally high potentials. Such adsorption states were called unusual adsorption states [34.21], although it was later demonstrated that there is nothing unusual about them (see full description of the voltammograms below). Although some controversy arose at the beginning about the validity of this methodology, it was soon demonstrated that surfaces prepared in UHV produce similar voltammograms when the transfer step is properly controlled [34.22]. This served as the definitive demonstration of the validity of the flame annealing procedure. Later, it was realized that the cooling atmosphere plays a crucial role in the ordering process and, for this reason, requires special control. In particular, it is important to avoid the oxidation of the surface during the quenching with water, since this process leads to its disordering. It was demonstrated that this point is less critical for Pt(111), because this highly packed

surface is more stable, but very important for the other, more open, surfaces [34.23]. To avoid oxidation of the surface during the quenching, the hot electrode can be cooled down in a reductive atmosphere (a 1 : 3 mixture of H_2 and Ar) and quenched with water in equilibrium with these gases. Other cooling atmospheres have also been tested. For instance, cooling the platinum electrodes in CO atmosphere results in the protection of the surface with this molecule, which is strongly adsorbed on platinum [34.24, 25]. In this case, the protection with the water drop is not necessary. The CO can be easily removed from the surface by electrooxidation (see below), resulting in a clean and ordered surface. Cooling in I_2 atmosphere has also been reported [34.26]. This molecule can be displaced with CO that can later be electrooxidized to give rise to a clean surface. However, CO and I_2 adsorption may produce faceted surfaces with structures that differ from the nominal one [34.27]. Flame annealing was initially proposed for platinum, but can also be used for other noble metals, such as gold and rhodium. While gold is not sensitive to the presence of O_2 in the cooling step, rhodium is very sensitive, and cooling in H_2/Ar is mandatory in this case.

The final point that deserves a comment is the way in which the electrode is contacted with the solution. Only the flat surface with the desired crystallographic orientation should be in contact with the solution, while the sides of the electrode, containing many other orientations, should not contact it. This is achieved with the so-called hanging meniscus configuration [34.28]. For this, the electrode is introduced in the solution and then raised above its level. The high surface tension characteristic of aqueous solutions facilitates the formation of a meniscus that wets only the flat surface. Sometimes formation of this meniscus is tricky, and a fraction of the sides of the electrode is also wet. This is usually noticed as a tilt in the voltammogram caused by the electrochemical contributions from the sides of the electrode taking place through a very thin layer of solution with a relatively high ohmic resistance. Also, oxygen (which is always present at trace level) can be reduced through the thin layer of solution at the sides of the electrode, resulting in additional tilt of the voltammogram at low potentials. The situation is particularly difficult when the electrode is hydrophilic (for instance, a gold electrode covered with a hydrophilic self-assembled monolayer (SAM)), when surface tension of the solution is decreased (for instance, in the presence of organic contaminants) or if the angle between the flat surface and the side of the electrode is $> 90°$.

34.3 Voltammetric Characterization

In cyclic voltammetry, the electrode potential is scanned linearly between two limits, at a given scan rate, while the current flowing through the potentiostat is recorded [34.29]. The graph of current as a function of potential is called a voltammogram. In the more general case, if an electroactive species is present in solution, current will flow when the electrode potential reaches a value sufficiently high (low) to produce its oxidation (reduction). For a simple process, current should keep increasing (in absolute value) as the difference between applied and equilibrium potentials increases. However, a maximum in the current is typically observed, beyond which the current starts to decrease, resulting in a peak in the voltammogram. The formation of this maximum can be due to two main reasons: (i) mass transport limitation or (ii) a decrease in the availability of surface sites for processes that involve adsorption. In this chapter, we are more concerned about adsorption processes, and hence the following discussion will explain the shape of the voltammetric peaks in this case. The reader is referred to the broad bibliography in the field to learn more about processes limited by mass transport [34.29–31].

For processes that involve electrosorption, the variation of the potential will drive a change in coverage of the electrosorbed species with current flowing in consequence. There is a direct relationship between coverage and charge, resulting from Faraday's law

$$q = -nF\Gamma_{\mathrm{ML}}\theta \,, \tag{34.1}$$

where n is the number of electrons exchanged in the adsorption process (positive for reductive adsorption of a cation and negative for the oxidative adsorption of an anion), F is the Faraday constant, Γ_{ML} is the maximum surface coverage and θ is the fractional coverage. For a reversible adsorption process, the coverage is directly determined by the electrode potential (at a given P, T and composition of the solution) according to a particular adsorption isotherm. In this case, we can write

$$\begin{aligned} j &= -nF\Gamma_{\mathrm{ML}}\left(\frac{\partial\theta}{\partial t}\right)_{P,T,\mu_i} \\ &= -nF\Gamma_{\mathrm{ML}}\left(\frac{\partial\theta}{\partial E}\right)_{P,T,\mu_i}\left(\frac{\partial E}{\partial t}\right) \\ &= -nF\Gamma_{\mathrm{ML}}v\left(\frac{\partial\theta}{\partial E}\right)_{P,T,\mu_i} \,, \end{aligned} \tag{34.2}$$

where $v = (\partial E/\partial t)$ is the scan rate and μ_i is the chemical potential of the specie i in the interphase. This equation demonstrates that the current is proportional to the scan rate for an adsorption process. This is a major difference with the voltammetric response for a process controlled by the diffusion of the reactants to the electrode surface, where the dependence of the peak current scales with the square root of the scan rate [34.29]. The exact shape of the voltammetric profile will depend on the nature of the adsorption isotherm, i.e., the functional relationship between the coverage and the electrode potential

$$\theta = f(E, P, T, \mu_i)\,. \tag{34.3}$$

For a Frumkin isotherm [34.31–33],

$$\frac{\theta}{1-\theta} = K\frac{c}{c^0}\exp\left(\frac{-nFE - r(\theta - 0.5)}{RT}\right), \tag{34.4}$$

where r is the lateral interaction parameter, K is the equilibrium constant, c the concentration in solution and c^0 is the concentration at the standard state. To obtain the current from such relationship, (34.4) should be differentiated with respect to the potential and the result introduced in (34.2). Figure 34.2 shows the voltammetric profile expected for an adsorption process that follows this isotherm for several values of the lateral interaction parameter. In this case, symmetrical peaks are obtained with the peak potential directly related to the energy of adsorption [34.31]

$$\Delta G^0_{\text{ads}} = -RT\ln(K) = -nFE_{\text{peak}} + RT\ln\left(\frac{c}{c^0}\right). \tag{34.5}$$

The width of the peak is controlled by the lateral interaction parameter. Positive values of r correspond to repulsion and result in broader peaks, while negative values indicate attractive interaction and result in narrower peaks [34.31–33]. Finally, the area under the peak gives a measure of the maximum coverage Γ_{ML}

$$\Gamma_{\text{ML}} = \frac{1}{nF}\int_{E_{\text{low}}}^{E_{\text{high}}}\frac{j}{v}\mathrm{d}E\,, \tag{34.6}$$

where E_{low} and E_{high} are the limit of the integration that should be chosen sufficiently below and above, respectively, to integrate the whole voltammetric peak. Equations (34.5) and (34.6) are general, and their validity is not limited to the Frumkin isotherm.

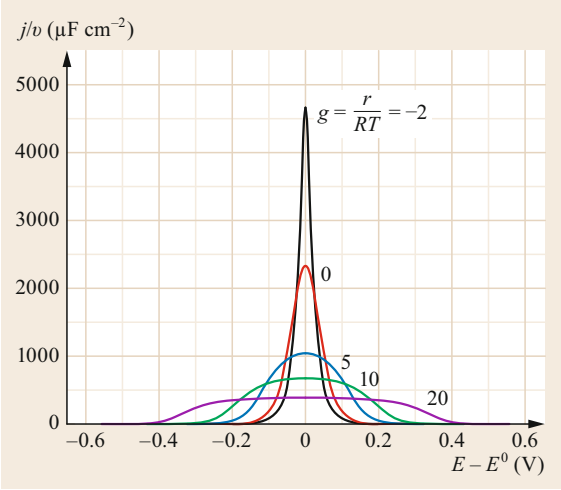

Fig. 34.2 Calculated voltammetric profiles expected for an electrosorption process following the Frumkin isotherm with different values of lateral interaction parameter, as indicated ($n = 1$, $c = 1\,\text{M}$ and $q_{\text{ML}} = 240\,\mu\text{C}\,\text{cm}^{-2}$)

In the case of a process with a limited reaction rate (the so-called irreversible or quasi-reversible processes), asymmetry appears in the peak that now depends on the scan rate. In this case, the peak separation between positive and negative sweeps is related to the rate constant. The latter can be obtained from a plot of peak potentials as a function of the logarithm of the scan rate [34.34].

The previous model applies to a homogeneous adlayer where local differences in the environment of adsorbates are not important. This is the mean-field approximation. In this case, the long-range order is not important. On the other hand, when strong lateral interactions lead to the formation of ordered adlayers, long-range order is very important, and the previous model does not apply. For this situation, Monte Carlo simulations are usually the way to analyze and predict the shape of the voltammetric profile [34.35].

Real voltammetric profiles recorded with platinum-group metals are usually composed of several peaks corresponding to different (most often competitive) adsorption process (hydrogen and anion adsorption) on different reactive sites on the surface (see later). In addition to electrosorption processes, the voltammetric profile also contains the capacitive response of the double layer. This usually has a smoother variation with potential, and in the scale of the other adsorption processes often appears as nearly constant. For gold electrodes, adsorption processes are less frequent, and variations in the differential capacity are more characteristic [34.36, 37].

34.4 Electrochemical Behavior of Gold Single-Crystal Surfaces

Figure 34.3 shows the cyclic voltammograms recorded with the three basal planes of gold in a perchloric acid solution. Perchloric acid is chosen as electrolyte because it is generally accepted that perchlorate anion adsorbs only weakly on metal surfaces. There are two regions in the voltammogram that can be clearly distinguished. Below 1.2 V, a relatively flat voltammetric profile signals the absence of adsorption processes. This is the so-called double-layer region. Above 1.2 V, the current sharply increases as a consequence of surface oxidation, resulting in a complex peak structure. Above 1.6 V, oxygen evolution takes place. Reduction of oxide takes place in the negative scan, resulting in a sharp peak, followed by one or more smaller peaks. The significant asymmetry between positive and negative scans is a clear indication of the irreversible nature of this process. In consequence, the voltammetric profile in the surface oxide region of gold is sensitive to the scan rate. The most important observation is that the voltammetric profile depends on the crystallographic structure, being like a fingerprint that enables the identification of the surface structure of the crystal. Enlargement of the double-layer regions reveals that current in this region also contains important features characteristic of the crystallographic structure of the surface [34.36–38].

According to the previous discussion, voltammetric characterization of gold single crystals can be done according to the profile obtained in the oxide region. Such characterization is often encountered in the literature. However, this method of characterization is not recommended since it is now well established that surface oxidation and subsequent reduction lead to formation of pits and islands resulting on a defective surface [34.39]. This conclusion was obtained from in situ scanning tunneling microscopy (STM) investigation of the surface [34.40]. With this technique, it is concluded that defects are formed during the desorption of the oxide. This observation is explained considering the existence of a place exchange mechanism in which oxygen atoms penetrate into subsurface positions. The subsequent extraction of such subsurface atoms drags gold atoms out of the equilibrium positions, resulting in the formation of pits and islands. The defective surface heals to some extent after prolonged potential cycling in the double-layer region, but it never recovers completely the initial state. For that reason, the voltammetric characterization should be limited to the double-layer region.

The electrochemical behavior of gold is dominated to some extend by the existence of surface reconstructions [34.41–43]. Such reconstructions are well known in UHV studies. For this environment, it is well established that the clean surface is terminated by a layer of atoms that occupy positions that are different from those corresponding to the normal truncation of the network in the bulk. The reason for this displacement of atoms is the existence of unbalanced bonds in the low-

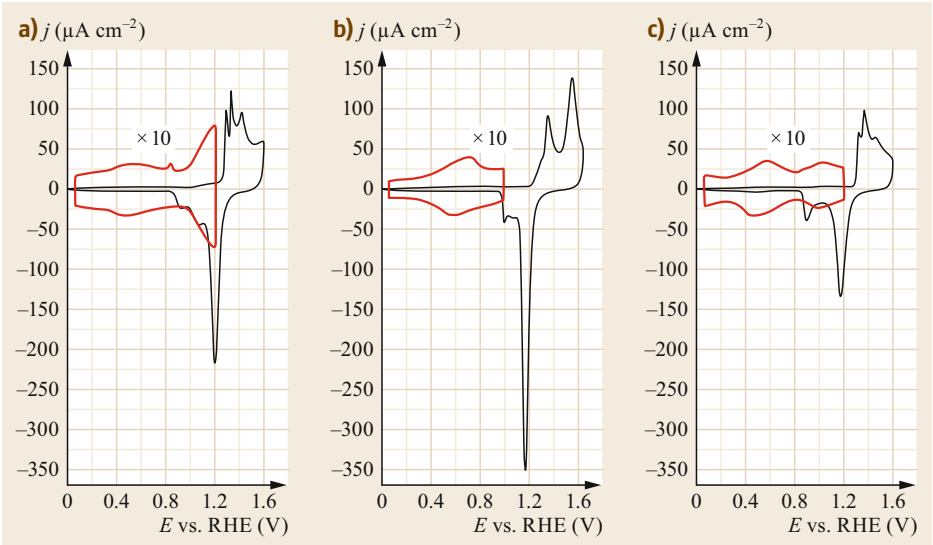

Fig. 34.3a–c Stationary cyclic voltammograms corresponding to the gold basal planes in 0.1 M $HClO_4$ solution: **(a)** Au(100), **(b)** Au(111), **(c)** Au(110). Scan rate: 50 mV s^{-1}. The *red curves* represent the magnification of the voltammetric profile measured in the so-called double-layer region and avoiding oxidation of the surface

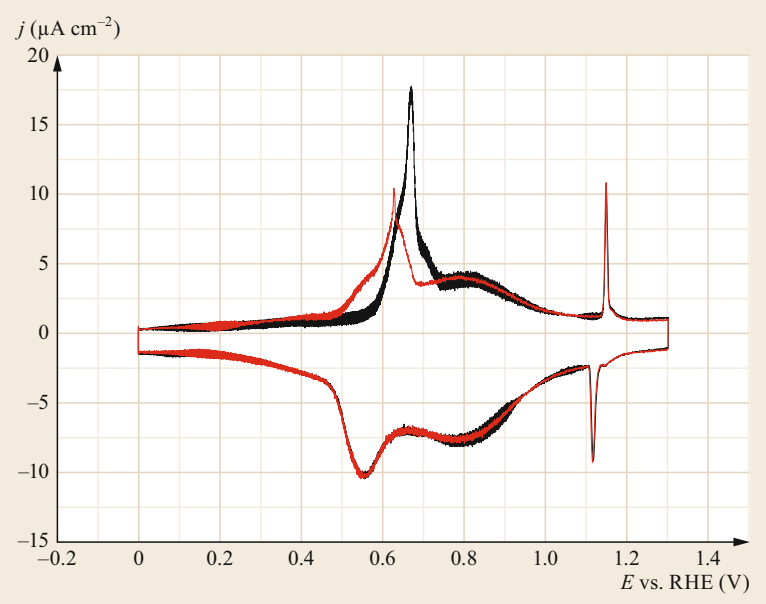

Fig. 34.4 Cyclic voltammograms of a Au(111) electrode in 0.1 M H_2SO_4. *Black curve*: first cycle after flame annealing and contacting the solution at 0.1 V; *red curve*: second cycle. Scan rate: 50 mV s^{-1}

coordinated atoms of the surface, as compared with atoms in the bulk. The surface reconstruction achieves a decrease in energy by increasing the atom density, thereby increasing the sharing of electron density in the low-coordinated atoms. Even the (111) surface of gold tends to reconstruct to form a higher-density $(\sqrt{3}\times 22)$ adlayer. Usually, adsorption eliminates reconstruction, since the adsorbate satisfies the necessity of surface atoms to share their electron density. In the electrochemical environment, the reconstructions are stabilized at lower potentials, where the higher electron density further destabilizes low-coordinated atoms at the surface in comparison with atoms in the bulk of the metal. The increased potential results in the disappearance of the reconstruction, usually linked to the onset of anion adsorption. The lifting of the reconstruction is usually coupled with a sudden change in the differential capacity, resulting in a relatively sharp peak in the voltammogram.

The voltammetric profile of Au(111) in 0.1 M H_2SO_4 shown in Fig. 34.4 is a good example to explain the phenomena described above. The electrode is contacted with the solution, after flame annealing, at low potentials, where the $(\sqrt{3}\times 22)$ reconstruction, formed during the annealing and cooling process, is stable. As the potential is increased, only a small capacitive current is recorded with a differential capacity of ca. 20 μF cm^{-2}. At ca. 0.54 V versus the reversible hydrogen electrode (RHE), sulfate adsorption starts to take place in a disordered way on the reconstructed surface. Immediately coupled with the onset of sulfate adsorption, reconstruction is suddenly lifted, resulting in a sharp voltammetric peak at ca. 0.6 V. Between 0.7 and 1.0 V, sulfate coverage keeps increasing. At ca. 1.15 V (RHE), sulfate coverage is large enough to trigger a disorder/order phase transition, which results in the formation of the $(\sqrt{3}\times\sqrt{7})$R19.1° sulfate adlayer [34.44, 45]. Such phase transition is signaled in the voltammogram by a very characteristic sharp spike. In the negative sweep, the order/disorder phase transition takes place at a slightly lower potential. This is followed by the slow desorption of sulfate that ends at ca. 0.45 V. Below this potential, the surface starts to reconstruct, driven by the increasing values of electron density. In this case, the reconstruction is not complete, because it is a slow process at room temperature. The fraction of the surface that is reconstructed depends on the time the electrode potential remains close to the lower end, which in turn depends on the scan rate. The red curve in Fig. 34.4 shows the second cycle. A strong difference can be observed in the peak corresponding to the lifting of the reconstruction between the first and second cycle, suggesting, as mentioned above, that the reconstruction was incomplete. Except for that, the first and second cycle are identical. The total charge integrated between 0.50 and 1.2 gives a measure of the amount of sulfate adsorbed.

On the other hand, the effects of surface oxidation on the structural integrity of the surface are shown in Fig. 34.5. In the first oxidation cycle, the oxidation of the surface is hindered by the rather compact sulfate adlayer formed after the sharp spike. This is why the

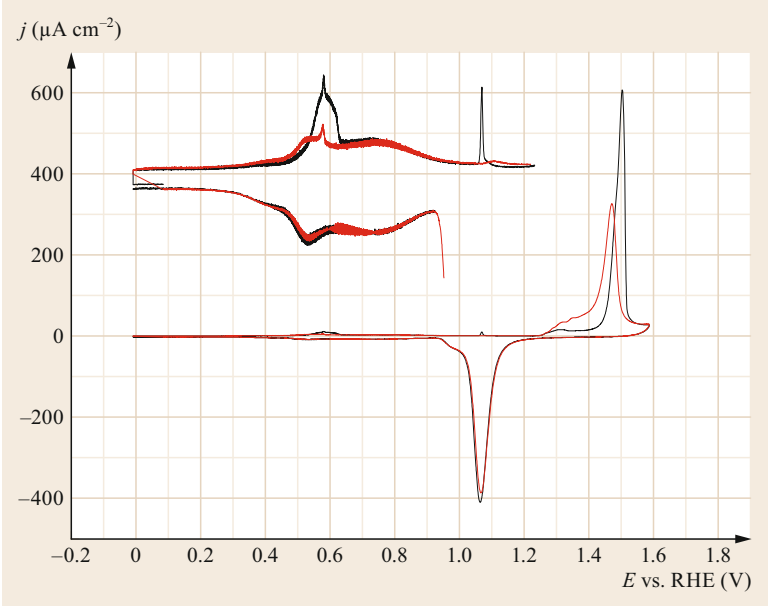

Fig. 34.5 Effect of surface oxidation on the voltammetric profile of Au(111) in 0.1 M H_2SO_4. *Black curves:* First cycle, before oxidation. *Red curves:* Second cycle, after oxidation. The *upper graphs* show an enlargement of the current in the double-layer region

peak corresponding to oxide formation is significantly shifted to higher potential values in comparison with the voltammogram in perchloric acid (see Fig. 34.3 for comparison). At some point, sufficient overvoltage is attained to replace the sulfate adlayer by oxide formation. As explained before, oxide formation is accompanied by the place exchange mechanism, resulting in subsurface oxygen. The subsequent reduction breaks the surface, resulting in the formation of pits and islands that disrupt the long-range order of the surface. This modification of the surface is reflected in the voltammetric profile of the second cycle. In this case, the amount of reconstructed surface significantly decreases, as deduced from the decreased magnitude of the peak at 0.63 V. However, the most significant effect is the almost complete disappearance of the sharp spike signaling the formation of the ordered $(\sqrt{3}\times\sqrt{7})$R19.1° sulfate adlayer. As explained above, formation of this ordered adlayer requires long-range order, and therefore the observation of the corresponding spike is a good indicator of the quality of the surface [34.46]. Another symptom of the disordering of the surface after the first oxidation/reduction cycle is the shift of the onset of the oxidation to lower potentials. This is a consequence of the formation of a defective sulfate adlayer, unable to prevent the surface oxidation as effectively as before. As mentioned above, there is a correlation between the onset of the lifting of the reconstruction and the strength of anion adsorption (Fig. 34.6). The voltammetric profile in the presence of bromide is very similar to that previously described for sulfate, but with all features shifted to lower potentials. Finally,

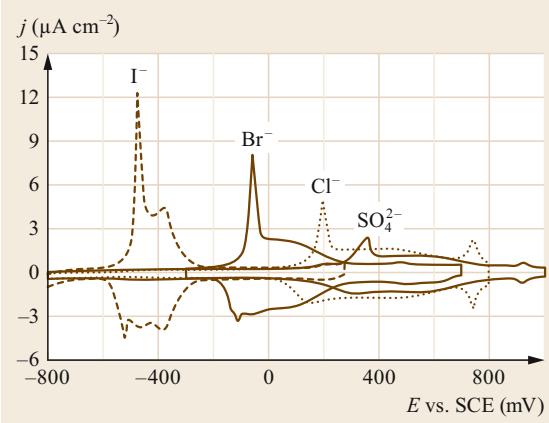

Fig. 34.6 Comparison of sulfate, chloride, bromide and iodide adsorption on the Au(111) electrode surface from 0.1 M $HClO_4 + 10^{-3}$ M K_2SO_4, KCl, KBr or KI solutions (SCE: saturated calomel electrode). Scan rate: 10 mV s^{-1}. Reprinted from [34.47], with permission from Elsevier

Fig. 34.7 shows the voltammetric profile for Au(100) in 0.01 M H_2SO_4. Similarly to what has been previously discussed for Au(111), this voltammogram is characterized by the observation of a very sharp peak signaling the lifting of a hexagonal reconstruction (also noted as (5×20)) that is observed for the clean surface in UHV and remains in an electrochemical environment at low enough potentials. As before, the magnitude of the peak is maximum after the flame annealing and, after a first scan, increases with the time spent at low potentials.

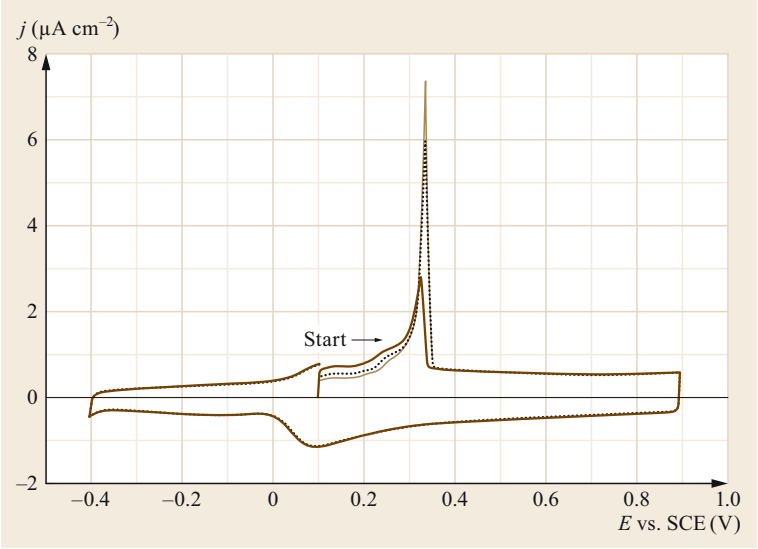

Fig. 34.7 Cyclic voltammograms for the unreconstructed, island-covered Au(100)-(1 × 1) surface in 10 mM H_2SO_4 after waiting at −350 mV for different lengths of time: 10 s (*thick line*), 60 s (*dotted line*) and 10 min (*thin line*) to allow potential-induced reconstruction. 34.5 Voltammetry of Platinum Single Crystals

Figure 34.8 shows a comparison of the voltammetric profiles recorded with the three basal planes of platinum in 0.1 M $HClO_4$ and 0.5 M H_2SO_4. As before, perchloric acid is chosen because perchlorate does not adsorb specifically on the surface of platinum (as will be demonstrated below). The potential scan is limited to the window between the onset of hydrogen evolution and the oxidation of the surface. In comparison with the voltammograms previously discussed for gold, current density is significantly higher for platinum, as a consequence of the existence of important adsorption processes. The first important observation is the significant sensitivity of the voltammetric profile to the crystallographic orientation of the electrode surface. Second, in the three cases, the effect of anion (sulfate) specific adsorption is to push adsorption states to lower potential values, resulting in sharper and higher peaks in sulfuric acid solution (red curves in Fig. 34.8). The key quantitative measure to analyze the voltammogram is the charge integrated according to

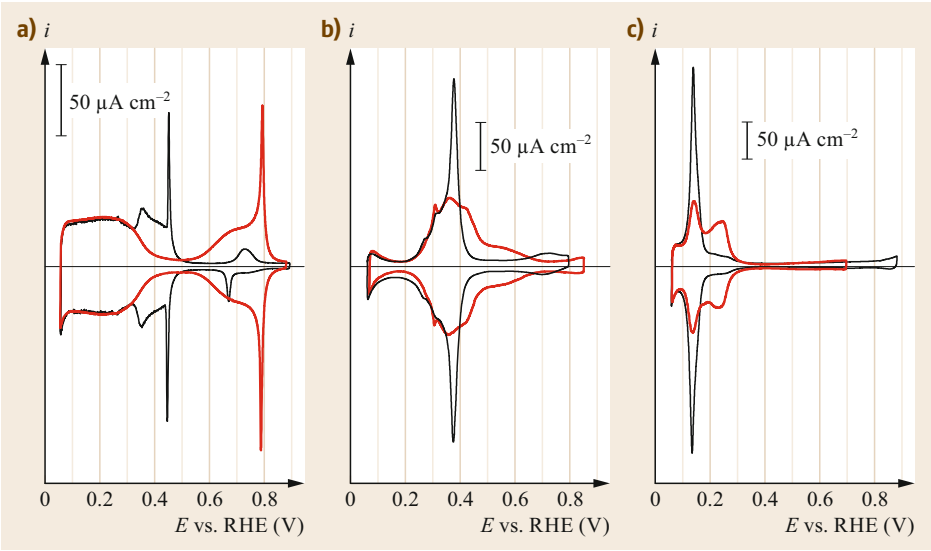

Fig. 34.8a–c Cyclic voltammograms of the three platinum basal planes in 0.1 M $HClO_4$ (*red curve*) and 0.5 M H_2SO_4 (*black curve*) for **(a)** Pt(111), **(b)** Pt(100) and **(c)** Pt(110) electrodes. Scan rate: 50 mV s^{-1}

Table 34.1 Values of the charge corresponding to a process exchanging one electron per surface atom (q) and atomic density (N) of the three basal planes of platinum and gold. Atomic diameters are calculated from the lattice parameter as $d = a/\sqrt{2}$: $a = 0.39236$ nm (for Pt) and $a = 0.40782$ nm (for Au) [34.49]

Miller index	S_{hkl}	Metal	q (μC cm^{-2})	N (cm^{-2})
(111)	$\sqrt{3}/2d^2$	Pt	240.3	1.50×10^{15}
		Au	222.5	1.39×10^{15}
(100)	d^2	Pt	208.1	1.30×10^{15}
		Au	192.7	1.20×10^{15}
(110)	$\sqrt{2}d^2$	Pt	147.2	9.19×10^{14}
		Au	136.2	8.50×10^{14}

$$q = \int_{E_1}^{E_2} \left(\frac{j}{v} - C_{\mathrm{dl}} \right) \mathrm{d}E \tag{34.7}$$

These charges have to be compared with the nominal values calculated for a reaction that involves one electron per surface atom, so that surface coverage can be determined. The nominal values can be calculated from the hard sphere model of the surface as

$$q_{hkl} = \frac{ne}{S_{hkl}}\,, \tag{34.8}$$

where n is the number of atoms in the unit cell, e is the unitary charge and S_{hkl} is the area of the unit cell of the surface with Miller indices (hkl). The values obtained for the three basal planes of platinum and gold, together with the expression for the surface of the unit cell as a function of the atomic diameter of both metals and the atomic density on the surface are given in Table 34.1.

For Pt(111) in 0.5 M H_2SO_4, the charge integrated between 0.06 and 0.6 V (after double-layer correction) amounts to ca 240 μC cm^{-2} (Table 34.2). This figure coincides outstandingly well with the value predicted by the hard sphere model for a one-electron process per platinum atom on this surface. This coincidence led to the initial hypothesis that the current in the whole potential range was due to a single process involving a single electron transfer and attaining a coverage close to 1. This process was thought to be hydrogen adsorption according to [34.21].

$$\mathrm{Pt} + \mathrm{H}^+ + \mathrm{e}^- \rightleftharpoons \mathrm{Pt{-}H} \tag{34.9}$$

However, there were several observations that soon casted doubts about this interpretation. First, the voltammogram in perchloric acid shows adsorption states at even higher potentials, above 0.5 V, too high to be due to hydrogen adsorption [34.55, 56]. Second, adsorption states below 0.3 V shift with pH of the solution, but they don't shift with (bi)sulfate concentration (using mixtures of $HClO_4$ and Na_2SO_4) [34.57]. Third, adsorption states above 0.3 V shift with (bi)sulfate concentration but not with pH [34.57]. The obvious conclusion from these observations is that there are two competitive processes in this case, hydrogen adsorption/desorption and (bi)sulfate adsorption/desorption. This latter process occurs according to

$$\mathrm{Pt} + \mathrm{HSO_4^-} \rightleftharpoons \mathrm{PtH_{1-}}_n\mathrm{SO_4^{z-}} + n\,\mathrm{H^+} + m\,\mathrm{e^-} \tag{34.10}$$

where m and n are the number of protons and electrons exchanged in the adsorption process, respectively. These processes partly overlap on Pt(111), although a minimum in the voltammetric current around 0.3 V

Table 34.2 Charges displaced by the potentiostatic adsorption of CO on the different platinum basal planes for different electrode potential and electrolyte composition. Total voltammetric charges (double-layer corrected) integrated in the voltammogram between the indicated potential limits are also given for comparison

Electrode	Electrolyte	Total charge (μC cm^{-2})	E vs. RHE (V)	Displaced charge (μC cm^{-2})	Reference
Pt(111)	0.1 M $HClO_4$	268 (0.06–0.90 V)	0.08	152	[34.50]
			0.40	−20	[34.50]
	0.5 M H_2SO_4	240 (0.06–0.55 V)	0.08	161	[34.51]
			0.50	−92	[34.51, 52]
Pt(100)	0.1 M $HClO_4$	256 (0.17–0.75 V)	0.10	196	[34.53, 54]
			0.50	−56	[34.53]
	0.5 M H_2SO_4	257 (0.18–0.80 V)	0.10	197	[34.51]
			0.45	−57	[34.51]
Pt(110)	0.1 M $HClO_4$	212 (0.06–0.40 V)	0.085	146	[34.50]
			0.34	−38	[34.50]
	0.5 M H_2SO_4	220 (0.06–0.50 V)	0.10	143	[34.51]
			0.34	−64	[34.51]

signals (at least formally) the transition from one process to the other. The situation is more complex on Pt(100) and Pt(110) where a single main peak is observed in the voltammogram, indicating that both processes are mainly coupled, i.e., sulfate adsorption pushes hydrogen desorption, and both processes take place as a single step.

$$\mathrm{Pt-H} + \mathrm{HSO_4^-} \rightleftharpoons \mathrm{PtH_{1-}}_n\mathrm{SO_4^{z-}} + (n+1)\,\mathrm{H^+} + m\,\mathrm{e^-} \qquad (34.11)$$

5 Therefore, additional information is required to separate and determine these contributions. This can be achieved with the charge displacement experiment discussed in the next section.

34.6 Charge Displacement Experiment

In this experiment, the current flowing during the potentiostatic adsorption of a neutral molecule is recorded as a measure of the interfacial charge at the potential of the experiment [34.58]. The adsorption of this molecule should be strong enough to displace all previously adsorbed species. It should also decrease the differential capacity of the interphase in such way that the charge at the end of the displacement can be considered negligible. The best displacing agent for platinum (and the one almost exclusively used for this purpose) is carbon monoxide. This molecule adsorbs very strongly on the platinum surface, displacing almost any other adsorbate. Besides, the interfacial charge on the CO-covered surface is very small, (although not always negligible; see below). Other advantages of this molecule are that the excess CO in solution can be easily removed just by argon bubbling, and that the free surface can be easily recovered by scanning the electrode potential to high values, which triggers the oxidation of the adsorbed molecules (see Sect. 34.10). This allows the experiment to be repeated several times without the need to exchange the solution or to clean the electrode surface again. Another displacing agent successfully used for platinum is iodine [34.59]. However, in this case, it is not possible to remove the iodine from the solution after the experiment is completed and requires changing the solution (and thoroughly cleaning the cell) in each repetition of the experiment. Moreover, the potential range where iodine is not electroactive is rather small, since it can be oxidized to iodate or reduced to iodide [34.59].

The advantage of using displacing agents in the gas state is that they can be easily introduced in the cell while avoiding the entrance of oxygen. In fact, the latter is the main experimental difficulty in the charge displacement technique. If a trace amount of oxygen accompanies the displacing agent, it will produce negative currents due to its reduction. This will interfere with the true displacement current, altering the measurement of the total charge. Thus, special care has to be taken to ensure the removal of any oxygen traces from the gas stream of the displacing agent.

Table 34.2 shows values of the displaced charge for the different platinum basal planes in different electrolytes. These values should be compared with the charges corresponding to the monolayer (one electron per platinum atom on the surface) in Table 34.1 and also with the charges integrated in the voltammogram. We observe that, at the onset of hydrogen evolution, nearly one monolayer of hydrogen is attained for Pt(100) and Pt(110) while only 2/3 of the monolayer are attained for Pt(111). Importantly, we observe that, in general, the maximum charge corresponding to hydrogen is always smaller than the total voltammetric charge, indicating that the latter includes some additional contribution, namely, anion adsorption. The definitive proof for this is the displacement of negative charges at higher potentials. In fact, there is no need to perform the displacement experiment at more than one potential since the difference between displaced charges at two potentials should always be equal to the integrated charge between these potential limits. In this way, from the charge displaced at one potential and the integration of the voltammogram, we can predict the charge that will be displaced at a second potential. This is further discussed in Sect. 34.8.

In the following, we describe in more detail the voltammetry of the different basal planes on the most typical media, under the light of the charge displacement results, but also considering complementary results of IR spectroscopy and STM microscopy.

34.6.1 Pt(111)

Let us discuss first the voltammetry of Pt(111) in 0.5 M H_2SO_4. Around 160 $\mu C\,cm^{-2}$ are displaced with CO at the onset of the hydrogen evolution (0.08 V), indicating that only 2/3 of the hydrogen monolayer are attained on this surface. Most likely, the maximum coverage is not attained in this case because hydrogen evolution starts before the monolayer is completed, limiting the effective potential range where the voltammogram can be recorded. Indeed, chronoamperommetric experiments

suggest that the monolayer is completed at lower potentials [34.60]. From the lower limit, if the potential is scanned positively, hydrogen will desorb oxidatively, resulting in positive currents. The voltammogram is rather flat in this region. In the framework of a Frumkin isotherm, the very broad peak can be understood as the consequence of rather strong repulsive interactions [34.31–33]. Small peaks at 0.12 and 0.26 V are sometimes observed. They signal the presence of (110) and (100) defects on the surface (see later) [34.61–64]. The absence of peaks in this region is an indication of a high-quality crystal (although it can also indicate a partial blockage of the surface by traces of contamination in the solution, because low-coordinated atoms at the defects are more susceptible to contamination). Around 0.3 V, the current starts to decrease as the surface concentration of hydrogen becomes very low. At this point, sulfate adsorption starts on the free surface that resulted from hydrogen desorption. Sulfate adsorption initially forms a disordered adlayer. At 0.44 V, a critical coverage is attained that triggers the transformation of the disordered adlayer into the $(\sqrt{3}\times\sqrt{7})$R19.1° ordered sulfate adlayer, as detected with STM [34.65–67]. As previously indicated, this adlayer has been observed for sulfate adsorbed on the (111) surface of gold [34.44, 45], platinum [34.65–67], palladium [34.68, 69], rhodium [34.70], iridium [34.71] and copper [34.72]. This seems to indicate that the structure of the adlayer is dominated by the matching interactions between the three oxygens in the tetrahedral structure of the sulfate ion with the trigonal arrangement characteristic of the (111) surface. The sharp spike that signals the disorder/order phase transition is very sensitive to the quality of the single crystal and to the purity of the solution. In this sense, a voltammogram like the one in Fig. 34.8 can be taken as a fingerprint of good experimental conditions.

One point that has aroused intense debate is the exact chemical nature of the adsorbed species, either sulfate or bisulfate. Spectroscopic investigation of the interphase should, in principle, be able to discern between those species since they have, in solution, easily distinguished vibrational spectra. The problem comes with the uncertainty about the effect of the chemical bond with the surface on the vibrational spectra. In this regards, the same spectral features have been interpreted by different research groups as clear indication of the presence of one or the other species on the surface [34.73–78]. Careful spectroscopic measurements using quantitative subtractively normalized interfacial Fourier transform IR spectroscopy (SNIFTIRS) [34.79] and a detailed thermodynamic analysis using solutions of different pH [34.80] seems to tip the balance in favor of sulfate as the adsorbed species. In this way, although the species that predominates in 0.5 M H_2SO_4 solution is bisulfate ($pK_a = 1.99$) [34.49], during the adsorption, the ion deprotonates. This trend is linked with the effect of the bond with the surface on the acid/base equilibrium of adsorbed acids. It seems that, in general, the bond with the metal surface has a withdrawing effect on the electron density that results in an increase in the acidity of adsorbed species [34.81–83].

Another controversial point is the nature of the small peak observed at ≈ 0.68 V. A thermodynamic analysis indicates a significant ($\approx 20\%$) increase in sulfate surface concentration associated with this process [34.84]. This led to the conclusion that this process could be associated with the restructuring of many different rotational domains present on the sulfate adlayer in the potential range between the spike and the small pair of peaks to form larger rotational domains [34.85]. The disappearance of domain boundaries would lead to this increase in sulfate coverage. However, STM observations have not corroborated this hypothesis. Different rotational domains are indeed observed at potentials lower than the pair of peaks [34.66, 67]. Nevertheless, at higher potentials, the ordered structure has not been observed [34.67]. Another interesting feature of this pair of peaks is its sensitivity to the nature of the alkaline cation present in solution, indicating that cations are coadsorbed with the sulfate adlayer in this potential region [34.85, 86].

Figure 34.9 shows the evolution of the voltammogram when the potential is scanned into the region of oxide formation. Similar to what happens with gold, the first cycle shows only capacitive currents up to a relatively high potential value. This behavior is associated with the protection of the surface by the ordered sulfate adlayer described above. A rather high potential is needed to trigger the substitution of sulfate by oxide. This oxidation implies place exchange, and when oxide is reduced, the surface becomes disordered, as can be deduced from the evolution of the voltammogram. The defective surface is oxidized at much lower potentials in the second cycle. After several cycles of oxidation and reduction, the resulting voltammogram is that characteristic of a disordered surface with mainly (110) defects, while the density of (100) defects is much lower. The onset for the replacement of sulfate by oxide depends on sulfate concentration and the pH of the solution [34.84].

When the voltammogram recorded in sulfuric acid is compared with the one recorded in perchloric acid, we observe that the two overlap perfectly below 0.30 V. This is also true in the presence of other anions: at low enough potentials, the anion is desorbed, and the current

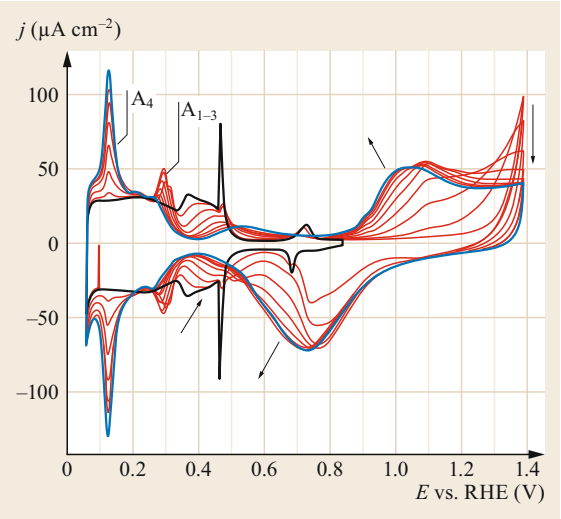

Fig. 34.9 Evolution of the voltammetric profile of the Pt(111) electrode in 0.5 M H_2SO_4 as the electrode potential is cycled at 50 mV s^{-1} between 0.06 and 1.40 V vs. RHE. The *black curve* indicates the initial voltammogram, the *red curves* indicate the evolution upon cycling and the *blue curve* corresponds to the profile attained after 12 cycles. *Arrows* indicate the evolution of the voltammogram. Reprinted from [34.87], with permission from Elsevier

becomes independent of the anion in solution [34.88, 89]. In accordance with this, the charge displaced at the onset of the hydrogen evolution is independent of the anion, since only hydrogen is displaced [34.90]. In perchloric acid, the hydrogen and anion adsorption regions are separated by a narrow double-layer region. In this region, current is mainly capacitive.

Regarding the adsorption process recorded above 0.55 V, it has been usually assumed that perchlorate is a poor Lewis base and therefore unable to adsorb specifically on the surface of platinum. This assumption was challenged based on spectroscopic observations [34.91, 92]. However, comparison of the voltammetry in the presence of other anions that do not adsorb specifically reveals that these adsorption states are not specific to the presence of perchlorate. Almost identical voltammetry is observed in HF/NaF mixtures [34.55, 77, 78] and in trifluoromethane sulfonic acid [34.93]. This supports the idea that these states correspond to the only common species in the three electrolytes: hydroxyl adsorption from water. These adsorption states are composed of a broad peak, which can be explained in terms of a Frumkin isotherm with rather large repulsive interactions, followed by a sharp peak at 0.8 V. The latter has been interpreted as indicative of phase transition in the hydroxyl adlayer [34.94]. However, the morphology of this peak is clearly different from the one observed in sulfuric acid, involving more charge. Besides, very low concentrations of different anions have interesting effects on the relative magnitude of the broad and sharp peak [34.95]. This led to a second interpretation of the two peaks, considering that they originate from two different kinds of water at the interphase: structured and unstructured water [34.95].

Increasing further the potential above 1.0 V reveals the existence of another peak that has been interpreted as the initial stages of the oxidation of the surface, i.e., transformation of OH into O [34.96, 97]. While for other surfaces of platinum, oxidation (and subsequent reduction) to this high potential value leads to the creation of defects, for Pt(111) in perchloric acid solution, scanning the potential up to 1.15 V does not induce changes in the surface, as deduced from the stability of the voltammetric profile [34.98]. Hence, it can be inferred that oxide formed in this initial peak does not involve place exchange.

We complete the picture of the electrochemical behavior of Pt(111) in different electrolytes with the examples shown in Fig. 34.10. Figure 34.10a shows the voltammograms recorded with this surface in solutions containing different anions, while Fig. 34.10b,c shows the voltammograms in solutions of different pH. To control the pH, an adequate buffer solution needs to be used. While phosphate adsorbs specifically on platinum (Fig. 34.10b), the mixtures of NaF/HF (Fig. 34.10c) are selected due to the absence of specific adsorption. Comparison of the voltammetry in halide-containing solution shows how the strength of adsorption increases in the order F < Cl < Br. Fluoride does not adsorb at all, as anticipated above, resulting in a voltammogram identical to that of perchloric acid (Fig. 34.10c). The increase in halide adsorption strength is signaled by a shift of adsorption states to lower potentials. Phosphate is another anion typically used to prepare electrolytes, especially for buffered solutions. At pH 2.2, the CV in phosphate-containing solution features a single, broad peak, similar to that of sulfate (at similar concentration) but without the characteristic spike. When the pH is increased, a rather complex voltammetric profile is obtained, featuring a number of peaks that varies with pH. These adsorption states involve the interconversion between phosphate species with different degrees of protonation [34.99, 100]. OH coadsorption is also likely to take place in this potential region at high pHs. It is worth pointing out the effect of the alkaline cation of the phosphate salt on the voltammetric profile [34.101]. While sharp peaks are measured with the sodium salt, more rounded features are measured when the potassium salt is employed.

On the other hand, the voltammograms of Fig. 34.10c show the effect of increasing the pH on the different adsorption states. Both hydrogen and hydroxyl adsorption regions shift by nearly 59 mV per pH unit (that is, the potentials are constant in the RHE scale) [34.102–104]. Such shift is in accordance with Nernst's law, which would be another way to express the Frumkin isotherm. However, there are some subtle changes when the pH is increased. First a broad feature is observed in the double layer when the pH is between 2–4. This process is overlapped with the hydrogen adsorption at pH 1, but is decoupled from it when hydrogen shifts to lower potential with the increase in pH, whereas this process is unaffected by the pH. Further increasing of the pH above 4 makes this process move into the hydroxyl region. The charge associated to this process is around 1 $\mu C\,cm^{-2}$. This process has been associated with the reorientation of water dipoles as the potential is increased [34.105]. As this process is displaced from the hydrogen region to the hydroxyl region, hydrogen charge decreases and hydroxyl charge slightly increases as a consequence of pH increase. In addition, hydroxyl adsorption, that is divided into two peaks, one broad and one narrow, is redistributed when the pH increases. The broad peak increases, while the narrow peak decreases. This could be due to the different role of anions to modify the structure of water at the interphase. In alkaline solution (Fig. 34.10b), the voltammogram of Pt(111) still contains the same main features. Hydrogen adsorption is slightly lower, while the sharp peak in the hydroxyl adsorption has disappeared completely and shows a total charge of ca. 170 $\mu C\,cm^{-2}$.

34.6.2 Pt(100)

We come back now to the voltammogram of Pt(100) in Fig. 34.8b. As previously discussed, the total charge in the voltammogram is well above that corresponding to the monolayer of hydrogen, evidencing the competitive adsorption of hydrogen and anions. The voltammograms measured both in perchloric and sulfuric acid overlap at potentials below 0.3 V, indicating that the anion is not adsorbed in this potential range. Moreover, the charge displaced at 0.1 V is the same in both electrolytes (ca. 200 $\mu C\,cm^{-2}$), approaching the value of the monolayer on this surface.

The quality of the (100) surfaces is influenced in great extent by the existence of surface reconstructions. Similar to what has been described before for gold, the (100) surface of platinum also forms a hexagonal reconstruction (Pt(100)-hex-R0.7°) leading to a distribution of atoms with an atomic density ca. 20% higher than that of the (1×1) surface [34.106–108]. This reconstructed adlayer is stable in a wide range of temperatures between 77 and 1450 K [34.107]. UHV studies show that different adsorbates such as H_2, O_2, CO or NO swiftly cause the disappearance of the reconstruction [34.109–113]. The perseverance of the reconstruction in aqueous solutions has been

discussed in the past [34.114, 115], but there is now general consensus that the reconstruction is completely eliminated after the contact with the solution [34.40, 116–118]. The disappearance of the reconstruction involves significant movement of atoms that leads to the formation of surface defects [34.24–26]. Studies with stepped surfaces (see below) reveal that the small peak at 0.30 V can be ascribed to adsorption processes on such defects. A small peak or shoulder around 0.27 V is often observed, also related to surface defects. The quality of this surface is also very sensitive to the annealing and cooling conditions [34.21, 119]. Cooling in the presence of oxygen leads to the formation of a highly defective surface, with a voltammogram in sulfuric acid solutions characterized by a main peak at 0.26 V and only small contributions reminiscent of the peak at 0.38 V. On the other hand, cooling in H_2/Ar leads to the voltammogram shown in Fig. 34.8, with the main peak in sulfuric acid at 0.38 V corresponding to adsorption on ordered terraces. Other annealing conditions have been tried. In particular, cooling in CO seems to produce the best ordered surface [34.24, 25], although, in our experience, the difference between H_2/Ar and CO is important only if the quality of the electrode is not high. STM characterization enables relationships to be established between the voltammetric features and the morphology of the surface obtained by the different cooling conditions, corroborating the description given above [34.24, 25]. Finally, the small process at 0.71 V is usually ascribed to the replacement of adsorbed sulfate by adsorbed hydroxyl. Scanning the potential above 1.0 V produces the disordering of the surface, as discussed above [34.120].

The description of the voltammogram in perchloric acid solution follows the same lines as the case of sulfuric acid. Starting from a monolayer of hydrogen at 0.1 V, the increase of the potential causes the desorption of hydrogen, initially from defect sites, peaking at ca. 0.3 V, and then, at slightly higher potentials, from terrace sites. In the absence of specific anion adsorption, the desorption of hydrogen spans over a broader potential range, signaling the existence of repulsive lateral interactions in the hydrogen adlayer [34.121]. The inflection at 0.50 V is usually taken as a change in the main process from hydrogen desorption to hydroxyl adsorption. Around 0.50 V, the two processes overlap. From CO displacement, it can be inferred that the maximum hydroxyl charge attained at 0.70 V is around 77 $\mu C\,cm^{-2}$, equivalent to 0.37 species per surface platinum atom [34.121]. To conclude this description of the Pt(100) surface, Fig. 34.11 shows the voltammogram obtained in 0.1 M NaOH. The voltammetric profile is significantly more complicated, with important differences from those recorded in acid media. The peak

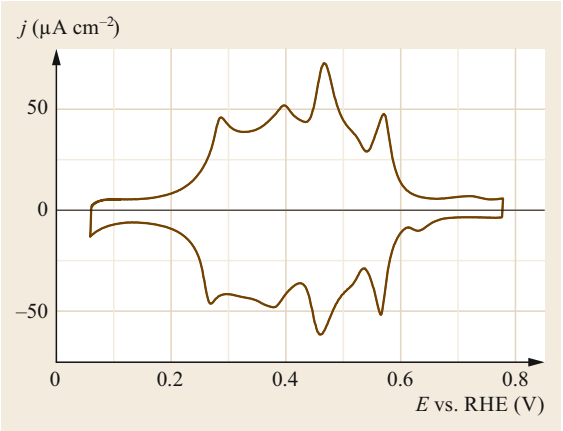

Fig. 34.11 Voltammetric profile for the Pt(100) electrode in 0.1 M NaOH. Scan rate: 50 mV s^{-1}

corresponding to surface defects now splits into two peaks at 0.28 and 0.38 V, while the peak corresponding to adsorption on the terraces shifts to 0.45 V [34.122]. Finally, a new peak at 0.56 V may be ascribed to hydroxyl adsorption. The charge displaced at 0.1 V is still close to that corresponding to the monolayer of hydrogen, and the total charge integrated in the whole potential range is close to the value obtained in acidic media (ca. 264 $\mu C\,cm^{-2}$).

34.6.3 Pt(110)

This is the most open surface among the three basal planes and therefore the most reactive and unstable. In UHV, the clean surface is reconstructed to form a (1×2) structure characterized by the disappearance of one every second row of atoms [34.43, 123]. Such structure minimizes the surface energy by creating (111) microfacets. This reconstruction has been studied extensively in UHV [34.123–125]. Similarly to what happens with the (100) surface, the adsorption of different adsorbates causes the lifting of the reconstruction [34.126–128]. It is also worth mentioning that other reconstructions with higher periodicity $(1\times n)$ have also been reported. Regarding the persistence of the reconstruction in an electrochemical ambient, it seems to depend very much on the preparation method and cooling conditions. Ex situ characterization of surfaces extracted from the electrochemical cell at different potentials indicated that the reconstruction may persist in the electrochemical environment [34.15, 129]. However, in situ measurements using STM cast some doubt on this result, since with this method, only (1×1) surface is observed [34.130–132]. In fact, the resulting topography, with a large number of small islands, is that expected after lifting of the reconstruction [34.24]. Finally, in situ surface x-ray

scattering (SXS) studies [34.133, 134] concluded that a fast cooling rate freezes the (1×1) structure obtained at high temperature (above 800 °C) in the flame, while slow cooling of the the electrode (in nitrogen) results in the (1×2) surface that persists in an electrochemical environment.

The voltammetric profile of this surface in different acidic solutions is shown in Fig. 34.8c. The voltammogram in H_2SO_4 shows a main peak at 0.145 V and a small shoulder at 0.16 V. The resolution of this shoulder seems linked to the quality of the crystal and it is better resolved when the electrode is cooled in CO after the flame annealing [34.24, 135]. This treatment gives wider (1×1) (110) terraces. In the absence of anion adsorption (0.1 M $HClO_4$), the peak and shoulder separate completely, giving rise to two peaks at 0.14 and 0.24 V. The surface cooled in CO gives rise to a complex number of peaks in the voltammogram recorded in 0.1 M $HClO_4$, which renders this surface particularly sensitive to the cooling conditions [34.135]. The charge displaced with CO at potentials close to the onset of hydrogen evolution is close to 150 $\mu C\,cm^{-2}$, therefore indicating that the monolayer of hydrogen is attained under these conditions [34.50, 51]. Also, displacement of negative charges at potentials higher than the voltammetric peak allows us to unambiguously assign this peak to the coupled desorption of hydrogen and the adsorption of anion, either sulfate or hydroxyl. Regarding the voltammogram in 0.1 M $HClO_4$, it is tempting to assign each of the two peaks observed in the voltammogram to each one of the processes taking place, namely, hydrogen and hydroxyl adsorption. However, the charge of the peaks does not match with the expected charges inferred from the CO displacement. Charge displaced at the onset of hydrogen evolution is close to 150 $\mu C\,cm^{-2}$, while the charge of the first peak is only around 110 $\mu C\,cm^{-2}$. Therefore, if the first peak (in the positive sweep) were hydrogen desorption, this process would extend 40 $\mu C\,cm^{-2}$ into the second peak. Most likely, both processes take place in a concerted way in each of the peaks, and the peak splitting seems to be related more to the existence of different atomic geometries on the surface than to the occurrence of different chemical processes [34.136].

34.7 Stepped Surfaces

Additional information about the relationship between the voltammetric profile and the surface structure can be obtained from the systematic study of stepped surfaces prepared by cutting the crystal at an angle between two basal planes. The different kinds of stepped surfaces that can be obtained and the relationship between surface structure and Miller indices has been summarized in Fig. 34.1. Figure 34.12 shows the corresponding voltammetric profiles of a selection of these surfaces. What turns out to be very interesting is that, in most cases, the voltammogram of a stepped surface can be understood as a combination of terrace and step

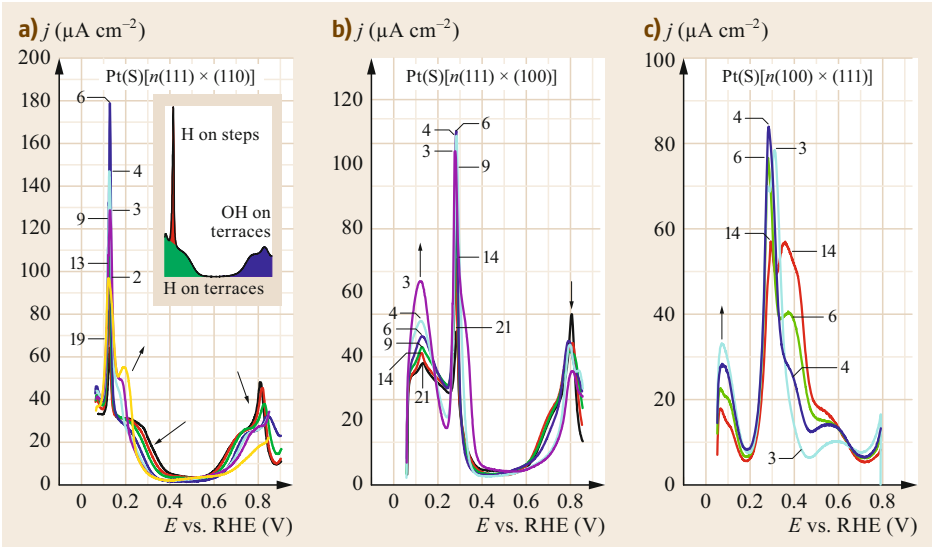

Fig. 34.12a–c Cyclic voltammograms for Pt stepped surfaces in 0.1 M $HClO_4$: **(a)** Pt(S)[$n(111) \times (111)$]; **(b)** Pt(S)[$n(111) \times (100)$] and **(c)** Pt(S)[$n(100) \times (111)$]. Numbers in each figure indicate the length of the terrace in atomic rows (n). *Inset* in **(a)** indicates the separation of different contribution to the charge. Scan rate: 50 $mV\,s^{-1}$

contributions [34.61, 62, 137, 138]. From the systematic variation of the step density, it is easy to infer which contribution corresponds to each kind of site. For instance, careful observation of the voltammograms in the $[1\bar{1}0]$ zone, i.e., Pt(S)$[n(111)\times(110)]$ surfaces, reveals that, as the length of the terrace (n) decreases, and therefore the step density increases, the voltammetric contribution assigned to hydrogen and anion adsorption on the (111) sites decreases, and a new contribution at 0.12 V builds up. According to this, contribution of step sites can be immediately associated with the new peak at 0.12 V. Moreover, the specific voltammetric profile obtained in this case allows us to separate terrace and step sites, taking a relatively unambiguous base line, as illustrated in the inset of Fig. 34.12a. The charge integrated in this way for different stepped surfaces can be compared with the hard sphere model to test the accuracy of the step/terrace description of the surface. It turns out that the measured charges fit quite well with the hard sphere model for Pt(S)$[n(111)\times(110)]$ and Pt(S)$[n(111)\times(100)]$. Deviations are observed in the latter case for the charge of the terrace, which can be attributed to the contribution from anion adsorption [34.139]. Also, deviations are observed for the step charge at large step densities. When steps are very close, the electronic perturbation from two adjacent steps overlaps, and the surface can no longer be considered a combination of terrace and step sites.

The previous analysis demonstrates that stepped surfaces can be prepared with a high degree of accuracy with a resulting structure close to the ideal one, at least for some corners of the stereographic triangle. STM studies also corroborate this [34.27, 54, 140]. In this way, the use of stepped surfaces in electrocatalytic studies has allowed us, in many different situations, to separate the contributions from the different geometric parts of the surface, resulting in a deeper understanding of the relation between surface structure and reactivity.

34.8 Potential of Zero Charge

The electrochemical interphase is, by definition, neutral, which does not imply that the electrode and the solution charge are zero. In fact, the charges of the electrode and solution have the same absolute value and opposite sign, that gives rise to a charge separation in the same way as in a capacitor. This charge is a function of the potential, pressure, temperature and solution composition. The existence of charge separations at the electrochemical interphase is one of its key distinctive characteristics in comparison with interphases in other contexts. The magnitude of the charge separation will have a great influence on the properties of the interphase and its reactivity under given conditions. The charge separation is responsible for the existence of the electric field, polarization of dipoles, inhomogeneous distribution of charges, etc. Despite its importance, charge is not the primary variable controlled in a standard electrochemical experiment, and the properties of the interphase are usually determined as a function of the electrode potential, measured with respect to a reference electrode. Therefore, for a deep understanding of the electrochemical reactivity, it is necessary to establish the relationship between electrode potential and interfacial charge.

The concept of the potential of zero charge (pzc), i.e., the potential at which the charge of the electrode is zero (and therefore the charge of the solution is also zero), was introduced in 1928 by Frumkin [34.141]. Knowledge of the pzc enables the determination of the electrode charge from the integration of the differential capacity or the voltammetric current. Without it, an integration constant is missing and only charge differences can be determined.

The dependence of the pzc on the crystallographic orientation of the electrode has been sufficiently demonstrated in those cases where this magnitude is easily accessible. This is the case of gold and silver electrodes, where the position of the pzc can be identified by locating the minimum in the differential capacity in diluted solutions, according to Gouy–Chapman–Stern theory of the double layer [34.142, 143]. It has been demonstrated that the dependence of the pzc on the crystallographic orientation follows the same trends as the work function in UHV, therefore demonstrating the intimate relationship between the two magnitudes [34.144–146]. For gold single-crystal electrodes, the effect of the selective introduction of steps on the surface has been studied extensively [34.38, 147–152]. In this case, the pzc decreases linearly with the density of steps, similarly to the work function. This decrease is rationalized in terms of the creation of surface dipoles due to the Smoluchowski effect [34.153] or the smearing of the electron density around the hard profile defined by the position of the atomic nuclei around the step. This results in an excess of electron density at the bottom of the step and a deficiency at the top, creating the surface dipole. From the slope of the decrease in either the work function or the pzc as a function of the step density, a value for such dipole can be estimated. The comparison of the dipole associated to the same step observed in UHV or in an electrochemical environment has relevant implications for the interaction of water with the surface [34.147].

Also, the effect of the temperature on the pzc provided interesting information on the entropy of formation of the interphase with important implication for the understanding of the interaction between water and the surface [34.38, 151, 152, 154–156]. These concepts are explained below in more detail for the case of platinum.

The unambiguous definition of the electrode charge requires the use of the concept of the ideally polarizable interphase. This implies the absence of charge transfer through the interface (Note: the interphase is the three-dimensional region of the space through which the properties change from those of the bulk metal to those of the bulk of the electrolyte; the interface is an imaginary two-dimensional plane that divides the interphase into two regions), which means that charged species can be unambiguously assigned to each side of it: electron density is assigned to the metal side, and ionic species are assigned to the electrolyte side. When charged species can circulate through the interface, the concept of charge is ill-defined. For such systems, the concept of the ideally nonpolarizable interface can be introduced [34.141]. In this case, the potential of the electrode cannot be changed without the simultaneous change in the composition of the solution. When charge transfer is limited to adsorption processes, the system shares properties between both situations, ideally polarizable and ideally nonpolarizable. It is ideally polarizable in the sense that the potential can be changed without changing the composition of the solution. However, it is nonpolarizable in the sense that the potential is fixed by the adsorption equilibrium and cannot be changed without changing the activity of the adsorbed species (at constant solution composition). Introduction of the concept of the total charge helps in adapting the thermodynamic equations to a situation with adsorption processes. The total charge can be defined as the charge that has to be supplied to the electrode when its surface is increased by one surface unit with the concentration of solution species remaining constant [34.141]. According to this definition, total charge also involves the charge flowing during the electrosorption process. For a platinum electrode that can adsorb hydrogen through (34.9) and an anion through equation

$$A^{z-} \rightleftharpoons A_{ads} + z\,e^- \,, \tag{34.12}$$

the relation between total charge, q and the true electronic charge density, σ_M (free charge in the following), is given by

$$q = \sigma_M - F\Gamma_H + z_A F\Gamma_A \tag{34.13}$$

where Γ_i is the amount of adsorbed species i. Total charge and not the free charge is what can be measured

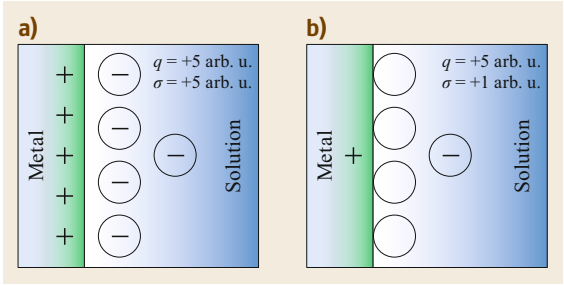

Fig. 34.13a,b Schematic representation of the interphase illustrating the relationship between total and free charge. **(a,b)** Two situations with equal total charge but different values of free charge

through the usual electrochemical experiment. It can be shown that the total charge is also the thermodynamic quantity that has to replace the charge density σ_M to adapt the electrocapillary equation to a situation that involves adsorption processes. The relationship between total and free charge is exemplified in the diagrams of Fig. 34.13. Both situations in Fig. 34.13 require the same supply of electricity from an external source for the creation of a new unit of surface. The difference between them requires only an internal reorganization of charge without external supply of electricity and therefore cannot be distinguished from the *external* observation of the system. The difference between both systems can also be explained by saying that, in the definition of total charge, the charge of the adsorbed species still counts as part of the solution, while in the definition of the free charge, it has been incorporated into the metal side, i.e., the definition of charge depends on the position of the interface.

The consequence of the previous definitions is that two different pzc should be distinguished in the presence of adsorption processes: the potential of zero total charge (pztc) and the potential of zero free charge (pzfc). Total charges, and therefore values for pztc, can be determined using the CO charge displacement experiment. The assumption implied in this is that no faradaic charge flows during CO adsorption, and therefore the charge integrated in the displacement process, $q_{dis}(E)$, can be equated with the difference between the charge present on the electrode before, $q_i(E)$, and after, $q_f^{CO}(E)$, the introduction of CO

$$q_{dis}(E) = q_f^{CO}(E) - q_i(E). \tag{34.14}$$

The desired quantity is $q_i(E)$. To calculate it from the measured value of $q_{dis}(E)$, the value of $q_f^{CO}(E)$ is required. The latter can be calculated from the integration of the differential capacity in the presence of CO if the value of the pzc of the surface covered with

CO is known. As a first approximation, $q_f^{CO}(E)$ can be neglected [34.63]. This assumption is based on the low magnitude of the differential capacity of the CO-covered electrode (ca. $14\,\mu F\,cm^{-2}$) when compared with the pseudocapacity of platinum (ca. $600\,\mu F\,cm^{-2}$ for Pt(111) in the hydrogen region). The estimation of $q_f^{CO}(E)$ can be improved if an approximate value of the pzc of the CO-covered electrode is known. Such estimation was given for Pt(111)-CO based on UHV measurements of work function values [34.157] and later determined experimentally for the same system by the immersion method [34.158]. The result obtained by both approaches coincides, within the experimental uncertainty, in a value around 1.0 V RHE. This gives a value for $q_f^{CO}(E)$ around $-13\,\mu C\,cm^{-2}$ at 0.1 V RHE. This remaining charge represents a correction of ca. 9%. Unfortunately, the value of $q_f^{CO}(E)$ is not known for surfaces different from Pt(111).

Once the charge at one potential is known, within the uncertainty explained in the previous paragraph, it can be calculated at any other potential from the integration of the voltammogram according to

$$q(E) = \left[q^{CO}(E^*) - q_{dis}(E^*)\right] + \int_{E^*}^{E} \frac{j}{v} dE \,, \qquad (34.15)$$

where E^* is the potential of the displacement experiment, j the voltammetric current and v the scan rate (with sign). When recording the voltammogram for the integration, a sufficiently low scan rate should be used to ensure a situation close enough to equilibrium. To ensure the consistency between displaced and voltammetric charges, the displacement experiment can be repeated at more than one potential. Then, a least squares method can be used to fit the voltammetric charge to the displaced charge values. The procedure is exemplified in Fig. 34.14.

The result of this analysis is a curve that relates total charge and potential. From this curve, the value of the pztc can be directly measured. Charge values at other potentials can be useful in coulometric analysis, when coverage of an adlayer is calculated from charge involved in its stripping. In this case, after the stripping of the adlayer, the bare surface should recover the charge that corresponds to the final potential, and this charge can be read from the charge–potential curve described here. This charge turned out to be very important in the calculation of CO coverage from its stripping (see later) [34.160].

The pztc of different platinum electrodes has been determined with this method, and the effect of crystallographic orientation, presence of specifically adsorbed anions, density of steps and pH has been analyzed.

Determination of free charge and pzfc for platinum electrodes is less straightforward. As mentioned above, usual charge measurements do not allow for separation of free charge from adsorption charge. One approach is to separate both contributions relying on their different time scale. Adsorption processes involving charge transfer are expected to be slower, while double-layer phenomena involving reorganization of ions at the interphase are likely to be faster. According to this, a fast perturbation of potentials would enable separation of both contributions. This has been achieved with impedance spectroscopy, although a very high-frequency modulation, above the normal range of common instrumentation, has to be used [34.161, 162]. The laser-induced potential temperature jump method mentioned below would also fall within the philosophy of this approach. Alternatively, one can measure a structural property of the interphase that is related to the electric field and therefore to the free charge. In this regard, the orientation of water dipoles can be inferred from their vibrational spectroscopic properties. The potential where dipoles change orientation is also related to the location of the pzfc [34.46, 163–165].

According to (34.13), at the pztc, adsorption charge compensates the free charge. If the pztc lies in the hydrogen region, $\Gamma_A = 0$, and therefore at the pztc

$$\sigma_M = F\Gamma_H \,. \qquad (34.16)$$

This means that free charge is positive at the pztc, and therefore the pzfc is located more negative than the pztc. The case of Pt(111) in $HClO_4$ is particularly interesting because, in this case, hydrogen and hydroxyl adsorption regions are separated. It is usually assumed that the region between them is purely capacitive. Therefore, in this potential region, free and total charge coincide; in consequence, the value of the free charge in this region is known. If the differential capacity of the electrode is also known, it can be combined with the known value of free charge in the capacitive region to calculate the free charge at any other potential. Two different approaches have been followed here. The more rigorous approach used a thermodynamic analysis based on the electrocapillary equation to separate total and free differential capacities from the dependence of the total charge with pH [34.104]. Such values of differential capacities can be combined with the known value of free charge at the double-layer region to locate the position of the pzfc [34.166]. However, the thermodynamic analysis that leads to the calculation of the differential capacity has only been performed in a narrow range of pH values. To extend the analysis to other pH values, an approximate approach has been followed consisting of the extrapolation of the charge in the double-layer region considering a constant double-layer differential capacity [34.102]. Interestingly, a constant value of the pzfc independent of pH was obtained with this approximate approach. Moreover, the study of Pt(111) in solutions of different pH demonstrated that, while in acid solution the pztc lies in the hydrogen region with the implication mentioned above, pzfc < pztc, for pH > 4 the pztc lies in the hydroxyl region and the pzfc > pztc. At pH 3, pzfc = pztc [34.103].

To conclude this section, we mention another approach that has proved very valuable in the investigation of the interfacial properties of single-crystal electrodes: the laser-induced temperature jump method. In this approach, pulsed laser irradiation is used to induce a sudden change in the temperature of the interphase. With the use of enough laser intensity, the temperature of the electrode surface can be increased by 10–20K in a few nanoseconds. By monitoring the change in the open-circuit potential during the decay of the temperature, information about the interphase can be obtained. Among the different contributions to the variation in the open-circuit potential with temperature, the most important is that due to the perturbation of the dipolar contribution from the orientation of the solvent. In this way, when free charge on the metal is positive, solvent dipoles will tend to orient with the negative end towards the metal, giving a negative contribution to the potential drop. Increasing the temperature will decrease the orientation of the dipoles, causing a decrease in this negative contribution, and therefore increasing the potential. The opposite is observed at negative charges. Thermodynamic arguments show that the thermal coefficient of the potential drop is related to the entropy of formation of the double layer [34.167–170]. A significant point is the potential where no net dipolar orientation is observed. This coincides with the potential of maximum entropy (pme) of double-layer formation and with a situation of zero change in the potential with the increase in temperature. This approach has been applied to study the interphase of mercury [34.171, 172], gold(111) [34.173], platinum basal planes [34.174], platinum stepped surfaces [34.175, 176], single-crystal electrodes modified with adatoms [34.177, 178] and single-crystal electrodes in ionic liquids [34.179, 180].

The resulting values of pme obtained for the three platinum basal planes are shown in comparison with the values of pztc in Fig. 34.15. For Pt(111), the pztc and pme nearly coincide. This is explained considering that, in this case, pztc lies in the double-layer region, and therefore pztc and pzfc are nearly identical. For Pt(100) and Pt(110), the pme is located at lower potentials than the pztc. This agrees with the argument that follows (34.16), and it shows that the pme can be taken as a good indicator of the position of the pzfc when this is located in a region where adsorption processes overlap with the purely capacitive charging of the double layer. Moreover, the pme of the three surfaces follows the order (111) > (100) > (110), which parallels the variation in the work function, again stressing the relationship between pme and pzfc.

34.9 Underpotential Deposition of Metals on Single-Crystal Electrodes

This was one of the first processes studied in detail on single-crystal electrodes. The general reaction for the deposition of a metal is given by

$$M^+ + e^- \rightleftharpoons M \qquad (34.17)$$

The equilibrium potential for this reaction is given by the thermodynamic Nernst equation, and at potentials more negative than this, bulk deposition of the metal occurs. However, it was found that the deposition of the first layer(s) of the metal onto a foreign substrate

$$S + M^+ + e^- \rightleftharpoons S{-}M \qquad (34.18)$$

can take place at potentials more positive than the equilibrium potential for the bulk deposition [34.181, 182].

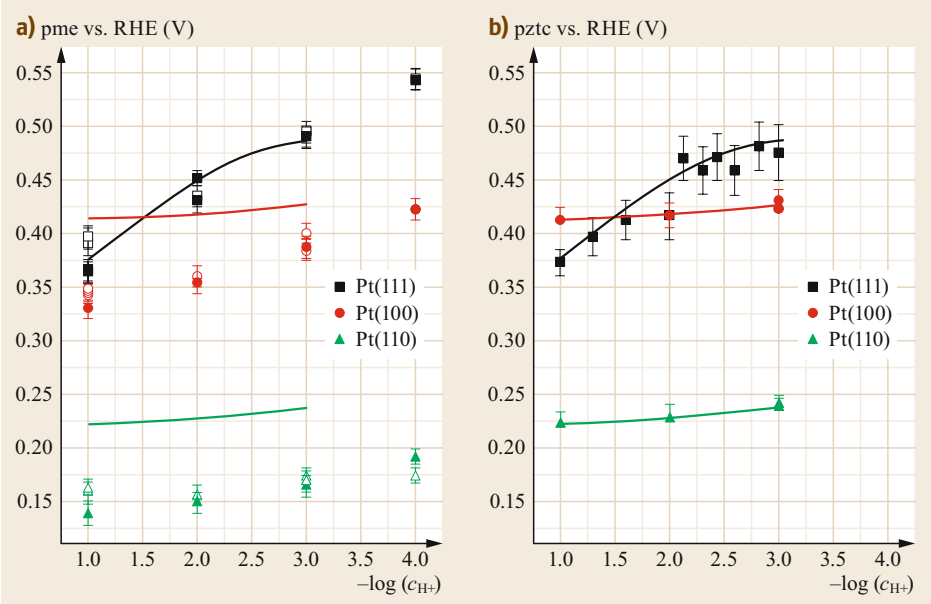

Fig. 34.15a,b Values of **(a)** uncorrected (*open symbols*) and corrected (*filled symbols*) pme values determined from the thermodiffusion potential, and **(b)** pztc values for Pt(111), Pt(100), and Pt(110) electrodes in $(0.1-x)$ M $KClO_4$ + x M $HClO_4$ solutions. *Lines* are drawn to indicate the tendencies of pztc values, and they are reproduced in **(a)** in order to facilitate the comparison with pme values. For this reason, this phenomenon was then termed as underpotential deposition (UPD). The explanation for the *apparent violation* of the thermodynamic laws of the process lays in the different interaction of the metal with the substrate. The equilibrium potential for the bulk metal deposition corresponds to the deposition of new metal atoms onto a bulk material of the same chemical nature and therefore involves the formation of new metal–metal bonds. However, when the metal is deposited on a foreign substrate, the initial stages of the deposition are governed by the substrate–metal interactions [34.183]. If these interactions are stronger than the metal–metal interactions, the initial deposition stages will take place at potentials more positive than the bulk metal deposition, due to the favorable metal–substrate interaction. Thus, the UPD of metals is normally restricted to the deposition of the first (and sometime second) layer.

From the initial studies, it was found that the work function differences between the metal and the substrate could be used to rationalize this phenomenon [34.181]. Thus, the UPD occurs when the work function of the metal substrate is larger than that of the deposited metal. Moreover, the difference between the potential for the UPD process and the bulk deposition potential was essentially the same as the difference between work functions. Given that, the UPD process is clearly controlled by the surface properties and should be structure-sensitive, and for that reason, as soon as single-crystal electrodes were introduced in electrochemistry, many different systems were thoroughly studied. There are several reviews that cover the topic in detail [34.184–186]. To illustrate the behavior of this electrochemical process, the results of copper UPD on gold single-crystal electrodes will be reviewed. These results exemplify how the surface structure, electrode potential and electrolyte composition affect the deposition process.

The first studies with gold single-crystal electrodes revealed the important effect of the surface structure on the process. As shown in Fig. 34.16, the voltammetric profiles for the Cu UPD on Au(111), Au(100) and Au(110) electrodes in sulfuric acid solution are very different [34.187–189]. Although the onset potential for the process is similar for all three electrodes, the shape of the voltammogram is not the same. Moreover, for the Au(111) electrode, the process splits into two main peaks, whereas for Au(110) and Au(100) electrodes, only one broad peak (with several shoulders) is observed. The presence of sharp peaks in the Cu UPD process on Au(111) electrodes suggests the formation of ordered adlayers, since sharp peaks with narrow widths are normally associated to order-disorder phase transitions. For the three electrodes, the bulk deposition of Cu took place at potentials below 0.3 V, which agrees with the thermodynamic value for the onset of bulk Cu deposition.

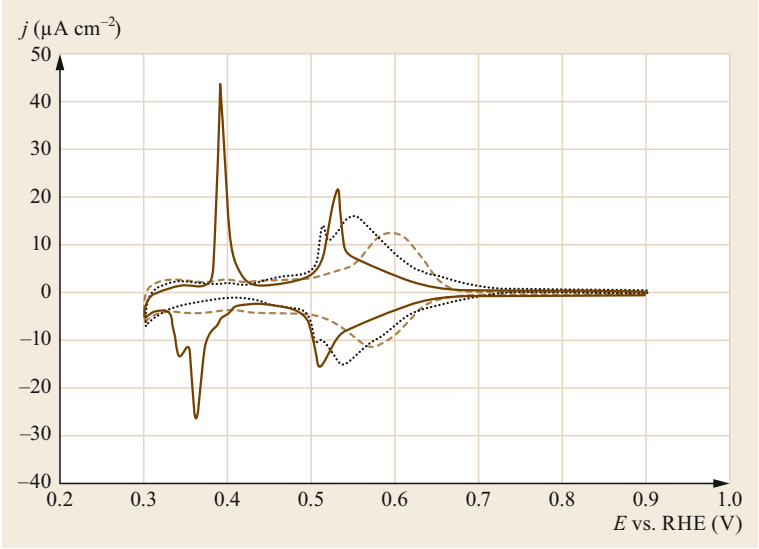

Fig. 34.16 Cu UPD on Au(111) (*solid line*), Au(110) (*dashed line*) and Au(100) (*dotted line*) in 0.05 M $H_2SO_4 + 10^{-3}$ M Cu^{2+}. Scan rate 5 mV s^{-1}

After the voltammetric profile for the process is recorded, normally, the first magnitude that is calculated is the charge associated to the deposition/dissolution process of Cu. Initially, it was supposed that charge processes that give rise to the voltammetric peaks correspond exclusively to the reduction of the Cu^{2+} ions. Thus, the charge measured in the deposition peak would give the Cu coverage. In the case of the Au(111) electrode, the charge measured was 450–460 μC cm^{-2} [34.190–194]. This value should be compared with the theoretical value for the deposition of a Cu atom per Au(111) surface atom in the unreconstructed surface (440 μC cm^{-2}) (see Table 34.1). The measured value is very close to the theoretical value, and thus it was supposed that the Cu layer formed a (1 × 1) isomorphic layer on the unreconstructed Au(111) surface. For the other two surfaces, the charge measurements also give values compatible with the formation of a (1 × 1) isomorphic layer.

It was soon confirmed that the UPD process was more complicated than this initial assignment of all measured charge to the Cu^{2+}/Cu redox process. It was already observed in the initial studies that there was an important dependence of the voltammetric profile on the anion present in solution (see Fig. 34.17 for the comparison when bromide is present in solution), a clear indication that the anion in solution plays a role in the whole deposition process. In the case of the sulfuric acid solution, the deposition process takes place on a surface which is partially covered by sulfate ions. Thus, Cu^{2+} ions, when deposited, should replace the sulfate ions and the sulfate coverage can change. The change in sulfate coverage on the surface also gives rise to a charge transfer, so that the measured charge in

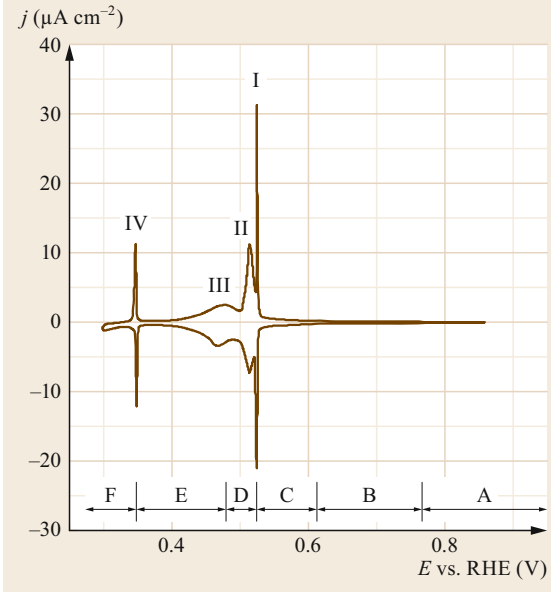

Fig. 34.17 Cu UPD on Au(111) in 0.1 M $HClO_4 + 1.0$ mM NaBr + 1.0 mM Cu^{2+}. Scan rate 1 mV s^{-1}

the voltammogram contains information not only from the Cu^{2+}/Cu redox process and on how the Cu coverage changes with electrode potential, but also on the change in the coverage of the surface-adsorbed anions. Two techniques were used to determine the coverage changes in sulfate anions and Cu with the potential during the UPD process: the electrochemical quartz crystal microbalance (EQCM) [34.190, 191] and chronoamperometry [34.192–194]. In the first one, mass changes during the deposition process are calculated using the

variation in the vibrational frequency of the quartz crystal on which the gold electrode is deposited. Those mass changes are then related to the measured charge, and Cu and sulfate coverage can be estimated. With the second technique, the effect of the anion and Cu^{2+} concentration on the measured charge for the process is evaluated using a thermodynamic approach, which allows the coverage of both species to be determined. Both techniques showed that the coverage of adsorbed sulfate on the electrode surface changed during the process. However, the final coverage of adsorbed sulfate at potentials close to the onset of bulk deposition was the same as that found on the bare Au(111) surface above 1.1 V (0.20) [34.192–194], which indicates that the net effect of the change in adsorbed sulfate coverage on the measured total charge was negligible, and a commensurate (1×1) Cu layer was formed on the electrode when the UPD process was completed. In fact, the surface structure for the adsorbed sulfate before and after the formation of the Cu adlayer was the same: the $(\sqrt{3} \times \sqrt{7})$R19.1° structure [34.195]. As mentioned above, the ordered adlayers formed by adsorbed sulfate on the (111) surfaces of Au [34.44, 45], Pd [34.69], Ir [34.71] and Pt [34.65, 66, 196] are identical. The only difference between the adlayers on the different metals is the potential at which this ordered adlayer is formed, which is related to the interaction of sulfate ions with the atoms on the surface. For Au, adsorption of sulfate starts at 0.5 V and the ordered adlayer is formed after the spike recorded at 1.1 V. Thus, the presence of the adsorbed sulfate adlayer on the Cu UPD layer indicates the large affinity of sulfate for the adsorption on Cu surfaces. Moreover, theoretical calculations indicate that the presence of adsorbed sulfate is the key element that stabilizes the (1×1) Cu adlayer [34.197].

The formation of a (1×1) Cu adlayer on the electrode prior to the bulk deposition (at 0.3 V) was first confirmed by UHV vacuum studies [34.198, 199]. If the electrode after the full deposition process was transferred to the UHV chamber, a (1×1) low-energy electron diffraction (LEED) pattern was found. Also, the presence of adsorbed sulfate was confirmed by Auger spectroscopy, although the coverage could not be accurately estimated due to the changes induced by the removal of the water layer, which is involved in the formation of the adlayer. The formation of the commensurate (1×1) layer was confirmed by in situ techniques, such as STM [34.200] and surface-extended x-ray absorption fine structure (SEXAFS) [34.201–203]. Moreover, the data obtained with SHG suggested that the Cu atoms were deposited on a 3-fold hollow site [34.204]. Additionally, detailed x-ray absorption near-edge structure (XANES) analysis revealed the polar character of the Cu–Au bond on the surface, in which Cu has charge deficiency [34.202, 205].

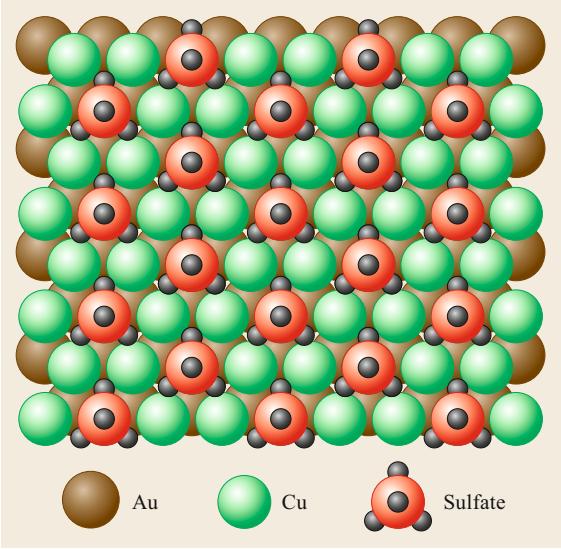

Fig. 34.18 Honeycomb structure formed for Cu UPD on Au(111) after the first deposition peak. Reprinted with permission from [34.206]. Copyright (2019) by the American Physical Society

For the adsorbed adlayer formed after the first UPD peak, that is at ca. 0.45 V, there was some initial controversy. Although charge measurements indicate that the Cu coverage was 2/3, the STM images revealed a $(\sqrt{3} \times \sqrt{3})$R30°, which is associated with a 1/3 coverage [34.190–194]. The detailed chronoamperometric analysis of the charge evolution with the concentration of sulfate and Cu^{2+} in solution also indicated that the Cu coverage was 2/3 and the sulfate coverage was 1/3 [34.192–194]. The correct interpretation of all this data was obtained after the in situ gracing incident X-ray analysis, which revealed a honeycomb structure (Fig. 34.18), in which the Cu coverage was 2/3, and that the sulfate was adsorbed in the center of the honeycomb structure [34.206, 207]. Thus, the structure observed with the STM images corresponds to the adsorbed sulfate on top of the Cu structure.

As mentioned above, the anion present in solution has a strong influence on the deposition process. This effect is clear, since the anion is adsorbed on top of the Cu layer, and therefore modifies the Cu–Au interaction. A clear example of this effect is the modification of the Cu UPD process on the Au(111) electrode in the presence of bromide anions [34.208, 209]. As can be seen in Fig. 34.17, the shape of the voltammogram is completely different from that observed in the presence of sulfate. Two sharp peaks can be easily distin-

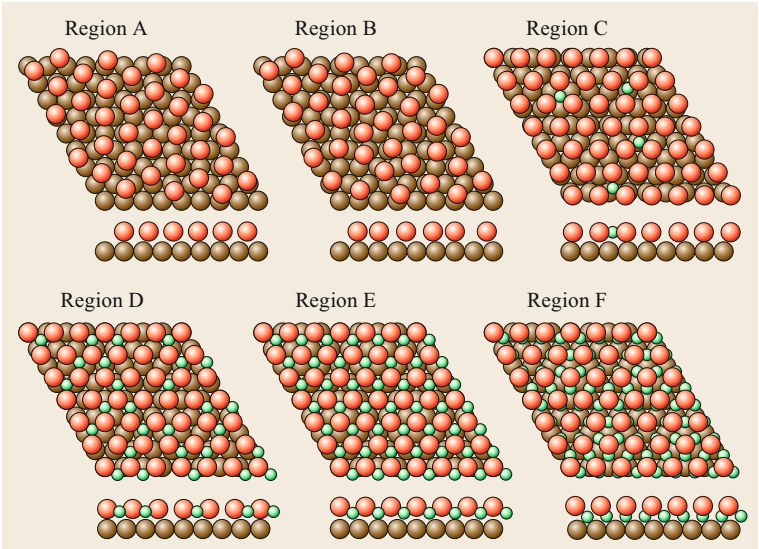

Fig. 34.19 Structures formed during the Cu UPD on Au(111) in 0.1 M $HClO_4$ + 1.0 mM NaBr + 1.0 mM Cu^{2+} in the different regions shown in Fig. 34.17 (Au atoms marked *brown*, Br atoms marked *red*, and Cu atoms marked *green*)

guished (peaks I and IV) and two additional shoulders (peaks II and III) appear around peak I. In situ detailed X-ray analysis of the process (both grazing incident X-ray diffraction and crystal truncation rods analysis) revealed changes in the structure as a function of potential and how bromide shaped the process [34.208, 209]. The analysis demonstrated that there were six different regions (as shown in Fig. 34.17) corresponding to six different adlayer structures (Fig. 34.19). At very positive potentials (region A), bromide is adsorbed on the electrode, forming a rotated and incommensurate hexagonal layer with a bromide coverage of 0.495 (defined as the number of bromide species per Pt surface atom). The structure of this adlayer is depicted in region A in Fig. 34.19 and is the same as the one observed in the absence of copper in solution [34.210, 211]. As the potential is decreased, bromide starts to desorb and the ordered adlayer disappears. However, as soon as the initial copper atoms are deposited at 0.56 V (onset of region C in Fig. 34.17), bromide anions are readsorbed, and a pseudo (4×4) incommensurate bromide structure with a coverage of 0.5 is observed (region C in Fig. 34.19). The fact that bromide is readsorbed as the potential is made more negative (which is an unexpected behavior) reveals the strong interaction between copper adatoms and bromide. As the deposition of Cu progresses, the bromide structure compresses until the commensurate (4×4) bromide structure is obtained (region D in Fig. 34.19) at the potential of peak I. The compression/relaxation and the changes in rotation angles with respect to the substrate orientation are processes that often occur in UPD reactions. From that point, the bromide adlayer does not change, but copper is progressively deposited between the Au(111) topmost layer and the bromide layer until the (1×1) Cu structure is formed after peak IV.

34.10 CO Adsorption and Oxidation on Platinum Single-Crystal Electrodes

CO is considered a model molecule to probe the properties of the surface. For this reason, it has been studied extensively in UHV. In electrochemical environments, it has also been used to determine the properties of the surface, as was shown previously in Sect. 34.6. In addition, its oxidative behavior is very important for practical purposes, especially in fuel cell technology. In this technology, hydrogen or other small molecules are oxidized in an electrochemical cell, generating electric energy. CO is present as a contaminant in the hydrogen sources coming from the reformate of organic molecules and, as will be shown in the next section, it also appears as an intermediate in the oxidation mechanism of small organic molecules such as formic acid, methanol or ethanol. For these reasons, its electrochemical behavior has also been widely studied in electrochemical environments.

The initial studies for adsorbed CO on platinum single-crystal electrodes attempted to determine the coverage, surface structure and adsorption modes of CO on the different surfaces. As expected, the CO adsorption/oxidation process was sensitive to the surface

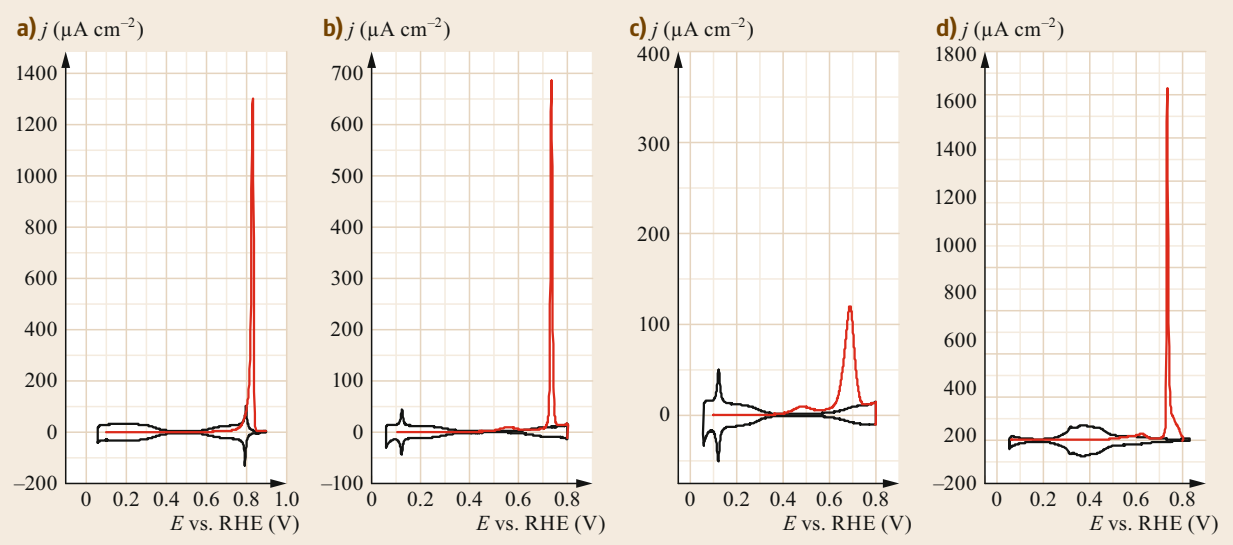

Fig. 34.20a–d Voltammetric profile for the oxidation of CO on the different Pt electrode surfaces in 0.1 M $HClO_4$: **(a)** Pt(111), **(b)** Pt(776), **(c)** Pt(554), and **(d)** Pt(100). Scan rate: 50 mV s^{-1}

structure of the electrode, as shown by the different peak position for the voltammetric profiles corresponding to the oxidation of an adsorbed CO layer on the different low-index electrodes (Fig. 34.20). From these profiles, the coverage could be easily determined by the charge integration of the oxidation peak obtained in the voltammetry [34.212, 213]. The major problem in this procedure was the determination of the correction to the charge to take into account the transferred charge in the processes taking place simultaneously with the CO oxidation process, that is, the changes in the surface charge and all the processes related to them [34.50]. Soon it was observed that there was a disagreement between the coverage determined depending on the corrections applied [34.214]. The discrepancies had arisen because there was still a lack of clarity regarding the nature of the so-called unusual adsorption states on the Pt(111). If the species responsible for these states was hydrogen adsorption on the surface, at 0.8 V, the potential at which CO is oxidized, hydrogen would be completely desorbed and thus no adsorption process would be contributing additional charge to the oxidation process. Thus, the only correction in the charge measurements would be that of the residual double-layer modification (which is a very minor correction). On the other hand, if anion adsorption processes give rise to these voltammetric features, anions should be readsorbed after CO adsorption, with the concomitant charge transfer. This would require a large correction of the measured charge. As mentioned in Sect. 34.6, the charge displacement measurements revealed that the unusual adsorption states correspond to an anion adsorption process with charge transfer involved in the process. Therefore, the calculation of coverage from CO oxidation should consider this value for a correct estimation of the coverage from the charge measurements. Following these arguments, the integrated charge for the whole oxidation process can be split into two contributions, the true faradaic charge for CO oxidation and the charge involved in the reorganization of the interphase

$$q_{\mathrm{raw}} = q_{\mathrm{far}} + q\left(E^{+}\right) - q^{\mathrm{CO}}\left(E^{-}\right), \qquad (34.19)$$

where q_{raw} is the total charge integrated in the voltammetric sweep, q_{far} is the true faradaic charge of CO oxidation, $q(E^{+})$ is the total charge at the higher limit of integration and $q^{\mathrm{CO}}(E^{-})$ is the charge present on the CO-covered surface at the lower limit of the sweep. The latter contribution is rather small, as discussed in Sect. 34.8; $q(E^{+})$ can be read in the curve relating total charge with potential, introduced in Sect. 34.8. This involves use of charge displacement data, as previously explained. It can be shown that, because the calculation of $q(E^{+})$ from CO displacement data also involves the term $q^{\mathrm{CO}}(E^{-})$ (34.14), both terms cancel, and the correction is sufficiently accurate without the need for any additional assumptions [34.215].

In parallel with the determination of the coverage, the surface structure of adsorbed CO was investigated. As in the case of the UPD, in the initial studies, the electrodes covered by CO were transferred from the electrochemical environment to the UHV chamber to examine the CO structure by LEED [34.216–218]. It

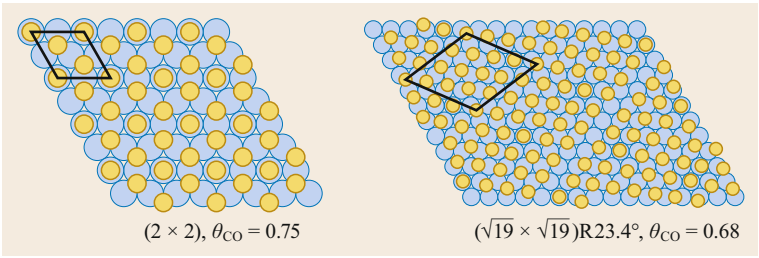

Fig. 34.21 CO structures on Pt(111) surfaces in acidic solutions

was revealed that the CO adlayers obtained in electrochemical environments have higher coverage than those obtained when CO was dosed under UHV conditions. This fact indicated the important role that water played in the adlayer formation process. As mentioned above, in the transfer process from the electrochemical environment to the UHV chamber, there is always the issue of the possible adlayer modification after the water removal process and the loss of potential control. To try to evaluate these possible modifications, the coverage values obtained from the measured structures and those obtained from the charge measurements were compared. Coverage values were in agreement after proper correction of the charge measurements [34.157, 214, 218, 219], which indicated that CO was not desorbed during the transfer process.

However, in situ STM measurements soon revealed the major effect of the electrode potential and water in the CO adlayer structure. STM images revealed three different adlayers formed on the Pt(111) surface, depending on the conditions [34.220, 221], which were later confirmed by grazing incidence x-ray diffraction (GIXD) measurements [34.47, 55–59]. These adlayers were different from those reported in the electrochemistry-UHV experiments, which, once more, highlighted the importance of the water on the adlayer. When CO was present in the solution, a (2×2)-3CO-$\theta_{CO} = 0.75$ structure was formed (Fig. 34.21A) [34.222–224]. This coverage value is significantly higher than that measured in UHV (0.5) [34.214]. The adlayer is only stable when CO is present in solution and requires long ordered domains, that is, the presence of steps reduces the stability of the adlayer [34.225]. A second structure was observed when CO was removed from solution after CO adsorption. In these conditions, the adlayer has a $(\sqrt{19}\times\sqrt{19})$R23.4°-$\theta_{CO} = 0.68$ structure (Fig. 34.21) [34.220, 226]. This coverage is in agreement with the values determined from the voltammetry [34.64, 214]. An additional structure is also formed at very mild dosing conditions: a $(\sqrt{7}\times\sqrt{7})$R19.1°-$\theta_{CO} = 0.56$ structure could also be detected [34.220].

The infrared spectra of the different electrode surfaces have also been studied in detail. In general, two peaks corresponding to the C–O stretching vibration appear on the spectra for the single-crystal electrodes, one at ca. 2030–2070 cm^{-1} for atop CO, and a second one at 1850–1870 cm^{-1} for bridge-bonded CO [34.227–229]. In the case of the (2×2)-3CO-$\theta_{CO} = 0.75$ structure on the Pt(111) electrode, the latter peak is replaced by one at ca. 1800 cm^{-1}, which corresponds to multicoordinated CO [34.220, 225, 230]. In all cases, the peak at 2030–2070 cm^{-1} is the dominant feature in the spectra. However, as shown in Fig. 34.21, atop CO is not the dominant species in the CO structures: for the (2×2)-3CO-$\theta_{CO} = 0.75$ adlayer, multicoordinated CO is more abundant than atop CO, whereas bridge-bonded CO predominates for the $(\sqrt{19}\times\sqrt{19})$R23.4°-$\theta_{CO} =$ 0.68 structure. Theoretical calculations demonstrate that there is a strong energy transfer from the band at low wave numbers to the band at high wave numbers, so that the atop CO band dominates in the spectra [34.220, 230].

In the case of the Fourier transform infrared (FTIR) spectra obtained in electrochemical conditions, the band position is dependent not only on the coverage and surface structure, but also on the electrode potential. Peak positions shift to higher wave number values as the potential is made more positive, in what is known as the Stark effect. The changes in the electronic populations of the metal or the electric field as the potential is made more positive have been postulated as the origin of the Stark effect. Detailed density functional theory (DFT) calculations have shown that field-dependent back-donation is the main contribution of the observed Stark effect on platinum metals [34.231–235].

The kinetics of the oxidation of CO has also been studied in detail, because of its technological relevance. CO oxidation follows a Langmuir–Hinselwood (L-H) mechanism in which adsorbed CO requires an adjacent adsorbed OH to produce CO_2 as a final product. Once the oxidation of the CO adlayer has started on specific sites, the progression of the oxidation can take place according to two different kinetic models. The first one is the nucleation and growth mechanism, in which the oxidation progresses from the initial points and extends over the whole surface, following the Bewick–Fleischmann–Thirsk model [34.236]. In the second kinetic model, the mobility of CO on the surface is fast, so that a random CO distribution is obtained through-

out the surface, following the mean-field L–H equation [34.237]. When the current transient at constant potential or the voltammetric peaks for CO oxidation in acidic media are analyzed, they are found to follow the mean-field equation [34.238–247], suggesting a large mobility of the adsorbed CO molecules on the surface.

On the other hand, in alkaline solutions, the situation is much more complex. Several differences between the behavior of the oxidation of CO adlayers in acidic and alkaline solutions are observed. In acidic solutions, the voltammetric oxidation shows only one peak for (111) stepped surfaces, whereas multiple peaks are observed in alkaline solutions [34.248–254]. The peaks are related to the presence of steps and kinks on the surface. Moreover, the transients do not follow the mean-field equation [34.249, 252]. Although other explanations have been proposed, the most probable justification of the differences is related to a change in the mobility of CO on the surface. In the case of alkaline solutions, the mobility of CO is negligible, explaining the peak multiplicity for stepped surfaces and the different kinetic equation for the current transients [34.252–254]. Additionally, the kinetic analysis of the transient has allowed us to calculate rates and to establish the role of steps and defects on the CO adlayer structure. It has been found that the presence of steps on the surface [34.245, 247] and of defects on the adlayer catalyze the oxidation [34.241, 254, 255]. The steps or defects in the adlayer are the initiation sites for the oxidation from where it propagates throughout the surface.

34.11 Oxidation of Small Organic Molecules on Platinum Single-Crystal Electrodes

The electrocatalysis of the oxidation of small organic molecules is a very relevant technological issue, since it is directly linked to the economic viability of fuel cell technology. Several molecules have been proposed for use in this technology, but the most studied are formic acid, methanol and ethanol. To reach the efficiency goals in the oxidation of these molecules for practical uses, the oxidation should take place at the lowest possible overpotential with the highest current, especially because the catalysis of these oxidation reactions requires the use of noble metals. In fact, platinum is the pure metal which shows the highest activity for these oxidation reactions. However, its activity is still low for practical uses, and thus, alloys and other modifications of platinum have been tested as electrocatalysts.

34.11.1 Formic Acid Oxidation Reaction

Formic acid oxidation reaction is the simplest reaction of these types of molecules. In the oxidation to CO_2, only two electrons are exchanged.

$$HCOOH \rightleftharpoons CO_2 + 2\,H^+ + 2\,e^- \qquad (34.20)$$

Apparently, the reaction is very straightforward, since only of two bonds, H–C and O–H bonds, need to be broken to form CO_2. The O–H bond breaking is involved in the acid base equilibria of formic acid, and thus, it is a facile reaction, whereas the cleavage of the H–C bond requires the use of a metal that has good dehydrogenation properties, such as platinum or palladium [34.256]. This reaction route would be the *natural* reaction mechanism for the oxidation. However, it was soon realized that the reaction was more complex than the simple mechanism proposed above. A blocking intermediate was soon detected when the reaction was studied on platinum [34.256], and identified using IR spectroscopy as adsorbed CO [34.257]. The formation of CO indicates that the reaction also proceeds with a different route in which H–C and C–OH bonds are broken. The formation of CO is also a major problem in the oxidation reaction, since it is strongly adsorbed, blocking the surface, and it is only oxidized at high potentials. Thus, the formic acid oxidation reaction involves a complex mechanism with two parallel pathways, one going through CO, which is regarded as a poisoning intermediate and the second one, going directly to CO_2 through an active intermediate, as shown in the following reaction scheme.

$$HCOOH \begin{cases} \nearrow \text{Active intermediate} \searrow \\ \searrow \text{CO} + H_2O \nearrow \end{cases} CO_2 + 2\,H^+ + 2\,e^- \qquad (34.21)$$

This parallel pathway mechanism was confirmed using isotopically labeled formic acid and differential electrochemical mass spectrometry (DEMS) [34.258]. In general, the electrocatalysis of this reaction seeks to increase the reaction rate through the active intermediate and the inhibition of CO formation.

In the initial studies of the reaction with single-crystal electrodes, it was soon realized that the reaction was very sensitive to the surface structure [34.259],

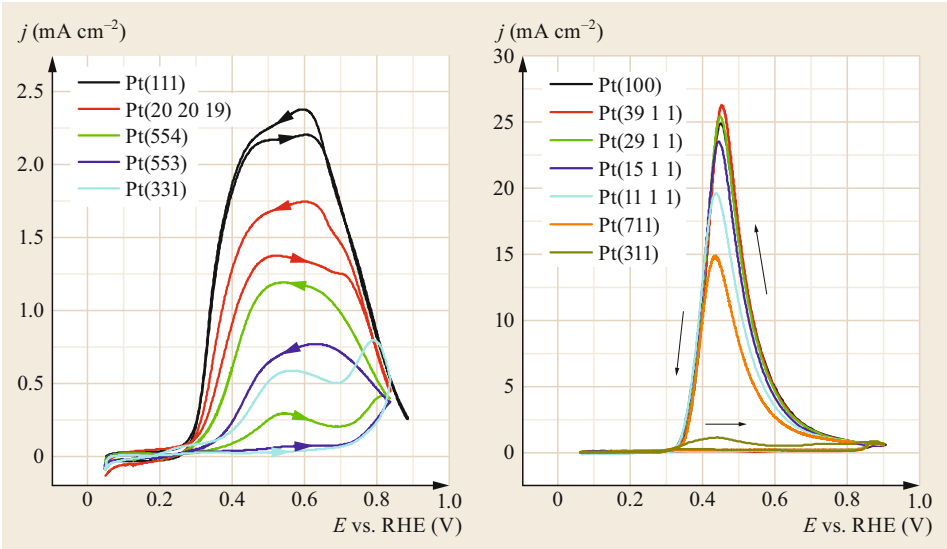

Fig. 34.22 Formic acid oxidation on different single-crystal electrodes in 0.1 M HCOOH + 0.5 M H_2SO_4. Scan rate: 50 mV s^{-1}

as shown in Fig. 34.22. Current densities and onset potentials for the oxidation depend on the surface structure. Moreover, the voltammetric profiles of the three basal planes show a distinct hysteresis between positive and negative scan directions. The formation of CO was responsible for this difference in the scan directions [34.260–262]. CO is formed at low potentials and partially blocks the electrode surface [34.261, 262]. The presence of CO leads to small currents in the positive scan direction. At 0.7 V, CO is oxidized, liberating surface sites, and when the scan is reversed, higher activity is recovered because no poison species are blocking the surface. Thus, CO formation rates can be qualitatively assessed by the difference in currents between the positive and negative scan directions, whereas the activity through the direct pathway can be estimated using the maximum currents in the negative scan direction. For both reaction paths, the activity order is Pt(100) > Pt(110) > Pt(111).

Once the qualitative behavior of the reaction was understood, the detailed mechanism for both reaction paths was studied. First, the variation in the solution composition allowed us to determine the active species in the reaction. For a fixed total formic acid/formate concentration, the maximum activity is proportional to the concentration of formate, indicating that solution formate is the active species in the reaction [34.263–265]. As any other anion, formate can be adsorbed on the surface, and in fact, it has been detected on polycrystalline electrodes [34.266–269] and on the Pt(111) electrode [34.270]. However, the actual role of this species has been subject to controversy. Recent studies suggest that this species is not the active intermediate, because, as DFT calculation indicates, the activation energy for the cleavage of the C–H bond in this configuration is very high [34.271]. However, the presence of adsorbed formate enables the adsorption of an additional formate species with a C–H bond directed toward the surface. In this configuration, the activation energy for the cleavage of the C–H bond is low [34.271], yielding CO_2 as final product. A kinetic model derived from this proposed mechanism was able to reproduce the voltammetric behavior, validating this reaction scheme [34.263, 270].

Reaction rates for both pathways were studied using pulsed voltammetry, which is a transient technique that allows one to determine the activity of the reaction in the absence of CO formation as well as the CO formation rate [34.272, 273]. When the different behavior of the electrodes was analyzed, it was clear that the Pt(111) surface has a very distinct behavior. First, it was shown that CO formation rate on this electrode was negligible [34.273–275]. In fact, the decoration of the Pt(111) and vicinal electrodes with adatoms indicated that the formation of CO on these surfaces was associated with the presence of steps or defects [34.261, 276–280]. Thus, on an ideal Pt(111) surface, the reaction would take place only through the active intermediate route and would produce no adsorbed CO, as happens in the UHV environment [34.281]. For the other surfaces, the formation of CO takes place in the potential region where the presence of adsorbed species on the surface is minimum, that is, in the vicinity of the potential of zero total charge [34.273–275]. The quantitative analysis of the data produced the following order in reactivity: (100) terraces ≈ steps on (100) terraces > (111) terraces > (110) steps on (111) terraces > (100) steps on (111) terraces.

34.11.2 Methanol and Ethanol Oxidation Reactions

Methanol and ethanol oxidation reactions have been widely studied for their possible use in fuel cells [34.282]. When compared with hydrogen or formic acid oxidation reactions, the other proposed fuels, their specific energies are significantly higher, which would favor their potential use. However, methanol and ethanol oxidation reactions are significantly more complex than the formic acid oxidation reaction, since 6 and 12 electrons are exchanged in the final oxidation to CO_2. The complexity of the reactions is due not only to the large number of electrons exchanged, but also to the type of bonds that have to be broken and formed in these reactions. For the methanol oxidation reaction, the mechanism involves dehydrogenation steps to gave rise to adsorbed CO. Although platinum is regarded as an excellent dehydrogenation catalyst, the oxidation of CO requires the transfer of an oxygen group (see Sect. 34.9), which is not favorable on platinum electrodes. For this reason, currents and onset potentials for the oxidation are higher. In the case of ethanol, the cleavage of the C–C bond should also take place in addition to the dehydrogenation processes, ending up with two adsorbed CO molecules, which should be oxidized to CO_2. If the C–C bond is not broken, acetic acid is formed, a molecule which is very difficult to oxidize. In general, the behavior of the different single-crystal electrodes for both reactions follows the same general scheme. Pt(111) is the less active electrode, but also has a lower onset potential for the reaction [34.283–286]. Moreover, this surface is inactive for the cleavage of the C–C bond [34.285, 286]. The addition of steps catalyzes the oxidation of these molecules, and higher currents are obtained, although at higher potentials due to the formation of CO [34.285–287]. In order to catalyze these reactions, Ru or Sn, which catalyze the oxidation of CO, or Rh for catalyzing the cleavage of the C–C bond, are generally used.

34.12 Concluding Remarks

Intense progress over the past few decades in the field of surface electrochemistry has brought it to the stage where attaining detailed control of surface structure at an atomic level becomes a reality. Such control enables the comprehension of catalytic processes with unprecedented detail. As already discussed, the electrocatalytic phenomena is intimately related to the existence of specific interaction between reactants and intermediates with the electrode surface. Attempting the study of such phenomena using complex polycrystalline surfaces would complicate enormously the interpretation of results. Conversely, the combination of methodologies that work with single-crystal electrodes with well-defined surfaces, and spectroscopic and microscopic techniques providing structural information, sometime at atomic-level resolution, has paved the way toward a situation where rational design of new catalytic materials can be based on deep comprehension of the processes taking place. In addition, the increasing power of computing capabilities experienced in recent years enables the rationalization of some experimental results from first-principles calculations. Future trends in this field should attempt exploiting even more the synergies between theory and experiments. In this regard, we stress how important it is for corroborating theoretical results to have access to high-quality experimental results under strictly controlled conditions.

Another question is how to bridge the gap between the knowledge acquired under such controlled conditions and the real situation under true applied conditions. Such distance can be decreased with the use of dispersed catalysts if the preparation of the catalysts is still done with careful control of experimental conditions. An example of this is the use of platinum and gold nanoparticles with preferential shapes, where the surface of the nanoparticles contains preferential surface sites similar to those of the different basal planes. While laboratory conditions in experiments with nanoparticles are still far from the real conditions of applied interest, particularly when it comes to purity of solutions employed, they can be taken as model systems closer to real applications.

In this review, we have given methodological clues to work with single-crystal electrodes of gold and platinum and to understand their electrochemical behavior. In particular, we showed how cyclic voltammetry can be used to characterize the structure of the single crystal with simple instrumentation. The importance of the charge separation to describe the interphase has been stressed, and the use of CO displacement has been described to obtain charge values for platinum electrodes. Finally, some important reactions in the field of surface electrochemistry and electrocatalysis have been reviewed, namely, underpotential deposition of metals, carbon monoxide oxidation and formic acid and methanol oxidation.

Future trends will most likely involve the use of increasingly complex surface composition involving al-

loys of several metals while maintaining comparable degree of control of the surface structure. Another trend in the field involves the use of nonaqueous solutions. In particular, in recent years, notable interest has arisen in the field of ionic liquids and their use in electrocatalysis. It is obvious that our comprehension of the interfacial properties in contact with such solvents is very far from the one achieved in water, so there is plenty of space for progress in this direction.

Victor Climent

Instituto Universitario de Electroquímica
Universidad de Alicante
San Vicente del Raspeig, Alicante, Spain
victor.climent@ua.es

Victor Climent obtained his PhD at the University of Alicante (2000). After a postdoctoral period at the University of Oxford (UK), he returned to the University of Alicante in 2003 where he is currently professor. His main research interest is the investigation of the relationship between the structure of the electrode surface, its composition and its electrochemical reactivity.

Enrique Herrero

Instituto Universitario de Electroquímica
Universidad de Alicante
San Vicente del Raspeig, Alicante, Spain
herrero@ua.es

Enrique Herrero received his PhD from the University of Alicante in 1995. After a two years of postdoctoral stay at Cornell University, he returned to the University of Alicante, where he is currently professor. His research focusses on the understanding of fundamental aspects of electrochemistry, especially those associated with the effect of the interfacial structure on the reactivity.

Part I Current T

Part I Current Topics In Surface Science

Part I is devoted to topics which, in the opinion of the Editors, must be covered to ensure that this Handbook is comprehensive. These topics relate to the current frontiers of surface science research but do not fit easily into the other sections. So, instead of general surface properties, the present section focuses on some new low-dimensional materials (graphene, silicene, and carbon clusters) as well as nanotribology and nuclear investigation methods.

Chapter 35 considers contact mechanics and nanotribology. The chapter explores the theory of contact mechanics and stick-slip motion at the nanoscale. In the theoretical part, analytical predictions regarding contact mechanics for lengths spanning several orders of magnitude are attempted based on morphology and material properties. The ultimate limits of friction measurements are illustrated for the sliding of an atomically sharp tip over a crystal lattice.

The next two chapters focus on the properties of two-dimensional materials and complement the information given in Chap. 9.

Chapter 36 deals with graphene. It describes its structure, possible defects, methods of preparation, peculiar electronic properties, and chemical reactivity in detail. The properties of graphene may be influenced by the substrate on which it is deposited, as highlighted by a comparison of single layers grown on different materials. The chapter also addresses the role of doping and the possibility of using adsorption to tune the band gap.

Chapter 37 describes the structural, electronic, and vibronic properties of monolayer silicene as well as the growth and electronic properties of multilayer silicene. The chapter also reviews the fabrication procedures for the first field-effect transistors based on this material, and reports on exotic forms of silicon for zero-dimensional (benzene-like nanodots) and one-dimensional (pentasilicene-like nanoribbons) materials.

Chapter 38 describes the use of supersonic cluster beam deposition (SCBD) to grow carbon (nsC) thin films with controlled nanostructures. The growth conditions ensure that incoming particles land on the growing interface and do not diffuse significantly. Due to the absence of stress, it is possible to grow films with a wide range of thicknesses. Their low density and high surface roughness make them promising materials for the fabrication of several devices (electrolyte-gated transistors, supercapacitors, photocatalytic systems, etc.).

Chapter 39 reviews the use of nuclear methods in ion beam analysis at high energies. It covers Rutherford backscattering spectrometry (RBS), elastic recoil detection analysis (ERDA), and nuclear reaction analysis (NRA). Because of the very short interaction time involved, inelastic collisions can be neglected, so the cross-section is determined by nuclear properties alone. Hence, the intensity of the signal is not affected by environmental factors, meaning that these methods can be used to quantify the elemental compositions of samples, including hydrogen, which is often not possible with other techniques.

35. Selected Topics in Contact Mechanics and Nanotribology

Enrico Gnecco

Driven by recent developments in nanotechnology and materials modeling and simulations, our understanding of contact mechanics, and more specifically of solid friction down to the nanometer scale, is experiencing a period of exceptional growth. Since a dedicated handbook would be not enough to summarize the latest experimental and theoretical achievements, we focus on two selected topics, which will hopefully stimulate the reader to examine the specialized literature in the growing field of nanotribology. These topics are the contact mechanics theory, recently developed by B.N.J. Persson, and the stick–slip motion on the nanoscale. While the first theory, to the best of our knowledge, is the first one embracing the contact between rough surfaces over length scales of several orders of magnitude, and making analytical predictions based on the morphology and material properties of the constituent materials, the second topic concerns the ultimate limits of friction measurements, i.e., the sliding of an atomically sharp tip over a crystal lattice. The two topics are not yet well related, but the situation may change in the near future. For this reason, it is also of interest to mention basic attempts in modeling stick–slip of multi-asperity contacts, as done in an intermediate section of this chapter. Last but not least, the dissipation accompanying the motion of a nanoslider in close proximity to but not touching a solid surface, and oppositely, of a similar object penetrating and scraping the surface, is briefly discussed, as it can be investigated with the most important technique available for this kind of study, i.e., atomic force microscopy.

Friction is a very important subject in surface science, as well as in everyday life. On one hand, friction is not only beneficial, as one can easily realize when driving on an icy road, but even vital, since life would be very difficult on planet Earth if the friction forces between meteorites and atmospheric particles were not strong enough to pulverize the former. On the other hand, friction is usually an annoying phenomenon, as proven by uncountable examples in engineering applications. Beyond that, it is estimated that a consistent part of the GDP of industrialized countries is consistently eroded by our ignorance of basic friction mechanisms. Friction may lead to abrasive wear over the long term, and ultimately to failure of many mechanical components, with more damage than that caused by fracture and plastic deformation. The situation is even worse in contacts formed on small length scales. Let us consider an object with linear dimension L. Since the fraction of atoms at the surface increases as $1/L$ when the size of the body is reduced, it is not surprising that friction forces play a key role in the dynamics of tiny objects ranging from microelectromechanical systems (MEMS) to microorganisms.

A compact and exhaustive treatment of friction phenomena is clearly impossible. Rather than following this approach, the chapter will thus focus on two selected topics which, in the author's opinion, have experienced significant progress in recent years. These topics are (i) the contact mechanics of rough surfaces as modeled in the continuum theory by B.N.J. Persson and (ii) the stick–slip motion of an atomically sharp tip elastically driven on a crystal surface. Both of these should be relevant for anyone interested in modern tribology. The corresponding two sections are joined by an *interlude* introducing the multiscale concept of stick–slip. Finally, nanotribology experiments under extreme loading conditions are mentioned. Traditional lubrication techniques and many other topics in *classical* tribology are deliberately ignored.

35.1 Contact Between Rough Surfaces

Any surface of practical use is ultimately rough. Assuming that the surface height is described by a function $h(\boldsymbol{r})$, where $\boldsymbol{r} \equiv (x, y)$ defines the position on a reference plane, as a fundamental quantity describing the surface roughness we can introduce the standard deviation $h_{\mathrm{rms}} = \langle (h - \overline{h})^2 \rangle^{1/2}$, where $\langle \ldots \rangle$ denotes averaging on the plane, and $\overline{h}$ is the mean height of the surface, which in the following will be assumed equal to zero. Nevertheless, two surfaces may be characterized by the same value of h_{rms} and appear very different. This is due to the different degree of *correlation* between locations at a given distance on the surface. This concept can be made quantitative by introducing the *self-correlation function*

$$C(\Delta \boldsymbol{r}) = \overline{h(\boldsymbol{r} + \Delta \boldsymbol{r}) h(\boldsymbol{r})} \, .$$

Essentially, $C(\Delta \boldsymbol{r})$ measures the *memory* that the surface has of its own features over a distance $\Delta \boldsymbol{r}$. If the surface is isotropic, the function C depends only on the module of the vector $\Delta \boldsymbol{r}$. Without loss of generality, we will simply refer to this module also as r. Alternatively, a solid surface can be described by its *power spectrum*, which can be defined as the Fourier transform of the correlation function

$$S(k) = \frac{1}{(2\pi)^2} \int C(\boldsymbol{r}) \mathrm{e}^{-\mathrm{i}\boldsymbol{k}\boldsymbol{r}} \mathrm{d}^2 r \, .$$

In the context of modern contact theories, the use of $S(k)$ is often more practical than that of $C(r)$.

When two bodies are pressed against each other, their surface profiles are unavoidably changed according to the elastic and plastic properties of the contacting materials. Additionally, the contact response will vary with the rate by which stresses or strains are applied, if viscoelastic or viscoplastic processes are effective. We begin with the easiest case of pure elastic surfaces. For two contacting spheres with radii R_1 and R_2, the problem was brilliantly solved by *Hertz* in 1885 [35.1]. In this case, based on energy considerations, it can be proven that the contact circle has a radius

$$a_0 = \left(\frac{3 F_{\mathrm{N}} R}{4 E^*} \right)^{1/3} \, , \tag{35.1}$$

where F_{N} is the normal (loading) force, $R^{-1} = R_1^{-1} + R_2^{-1}$, and the effective elastic modulus E^* is defined by the relation

$$\frac{1}{E^*} = \frac{1 - \nu_1^2}{E_1} + \frac{1 - \nu_2^2}{E_2} \, , \tag{35.2}$$

with E_i and ν_i $(i = 1, 2)$ the Young's modulus and the Poisson ratio of each material, respectively. Furthermore, the penetration depth $\delta = a^2/R$. Thus, the contact area A is not proportional to F_{N}, but it scales as $F_{\mathrm{N}}^{2/3}$. If the (kinetic or static) friction f is supposed to be proportional to the contact area, we reach the conclusion that $f \propto F_{\mathrm{N}}^{2/3}$. This is in contrast to most experimental observations on real surfaces, which show that friction is proportional to the normal load (so-called *Amontons' law*).

The paradox is only apparent, since real surfaces, including spherical ones, are usually rough, but it was a long time before a convincing explanation was proposed. A key step was the model developed by *Greenwood* and *Williamson* (GW) in the 1960s [35.2]. In this model, the authors considered a distribution of independent spherical asperities with the same radius R in elastic contact with a rigid half-space. If the height distribution of the asperities decays exponentially as $\mathrm{e}^{-\lambda h}$, it is easy to see that

$$A(F_{\mathrm{N}}) = \frac{\sqrt{\pi R \lambda}}{E^*} F_{\mathrm{N}} \, , \tag{35.3}$$

consistently with the Amontons' law. The same conclusion approximately holds in the more realistic case of a Gaussian height distribution. However, in spite of its popularity, the GW model has severe limitations. First, assuming that a surface can be approximated as an ensemble of similar asperities is not realistic. Second, the model does not consider the interaction between two asperities, which is unavoidable if the asperities are not far from each other. It was *Persson* who proposed a solution to this problem in the first years of the new millennium [35.3]. Starting from the general description of the surface roughness introduced in Sect. 35.1, he was indeed able to conclude that, if the contact is elastic and the loading force is not too high, the Amontons' law is verified on almost *any* surface of practical interest.

The Persson theory is based on the concept of *magnification*. Suppose that, from the power spectrum $S(k)$ of a given surface, all components above a certain threshold value k are cut off. The surface corresponding to the new spectrum so obtained has features down to the wavelength $\lambda = 2\pi/k$. If L is the linear size of the original surface, the quantity $\zeta = L/\lambda$ may be called the magnification degree (Fig. 35.1). Without loss of generality, it can be proven that when the surface is pressed against a rigid half-space with a loading force F_{N}, the stress distribution $P(\sigma, \zeta)$ satisfies the diffusion-like equation

$$\frac{\partial P}{\partial \zeta} = D(\zeta) \frac{\partial^2 P}{\partial \sigma^2} \, , \tag{35.4}$$

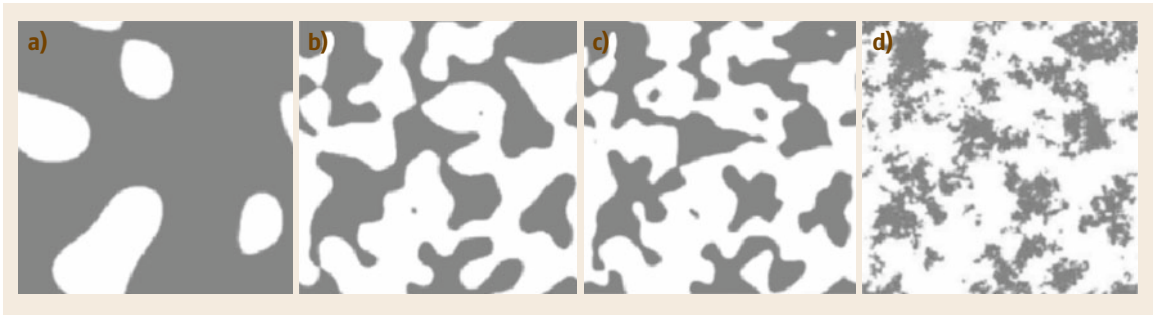

Fig. 35.1a–d Contact region between a rough rigid substrate and an elastic block at different magnifications **(a)** $\zeta = 3$, **(b)** $\zeta = 9$, **(c)** $\zeta = 12$ and **(d)** $\zeta = 648$. When $\zeta \approx 12$, the non-contact region percolates. (From [35.4] © IOP Publishing. Reproduced with permission. All rights reserved)

where ζ and σ take the roles of time and distance, respectively. In contrast to the well-known Fick's law, the *diffusion coefficient* in (35.4) is not constant, but depends on the magnification as $D(\zeta) = G'(\zeta)$, where the quantity

$$G(\zeta) = \frac{\pi}{4} E^{*2} \int_{k_0}^{2\pi\zeta/L} k^3 S(k) \mathrm{d}k \tag{35.5}$$

is defined by the surface power spectrum. Thus, all elastic and morphological properties of the undeformed surface are contained in (35.5). The boundary conditions of (35.4) are given by the simple fact that, in the absence of adhesion, the surfaces detach when $\sigma = 0$ and, on the other hand, that the stress cannot become anywhere infinite in a finite contact area. In this way, (35.4) can be solved. Since the contact area at the magnification ζ is $A(\zeta) = A_0 P(\zeta)$, where A_0 is the nominal contact area, the load dependence of the friction force (which is assumed to be proportional to A) can be estimated. The result is shown in Fig. 35.2a. If F_N is sufficiently low, the relation is a simple proportionality

$$A(F_\mathrm{N}) = \frac{F_\mathrm{N}}{\sqrt{\pi G_1}}\,, \tag{35.6}$$

where G_1 is the value of $G(\zeta)$ corresponding to $\zeta = 1$. Equation (35.6) generalizes (35.3) including all possible length scales.

Note that the Persson theory can also be applied to elastic-plastic and viscoelastic contacts. In the former case, the stress distribution P must be zero when σ equals the yield strength Y of the material. The latter case requires that the elastic constant is generalized according to the *correspondence principle* [35.7]

$$E^* \to \int E^*\left(t - t'\right) \frac{\mathrm{d}}{\mathrm{d}t'} \ldots \mathrm{d}t'\,; \tag{35.7}$$

(note that this principle is only applicable if the contact is growing with time). As a result, the area of contact is found to increase with time, as seen in Fig. 35.2b. Applications beyond contact mechanics are also possible, since the Persson theory can be used to study heat transfer and electrical conductivity through a contact formed by rough surfaces. Interestingly, it is found that in general, friction has a negligible influence on the thermal and electrical contact resistance. Very important for practical applications is also the influence of the contact structure on the flow of a liquid confined between two surfaces. The simple observation of Fig. 35.1 shows that a flow, let's say from the bottom edge to the top edge of the image, is only possible above a threshold value ζ_c, which can be numerically evaluated from the relation $A(\zeta_\mathrm{c}) \approx 0.4 A_0$ [35.4]. Depending on the loading force, the threshold is changed.

Adhesive effects were introduced in the Hertz theory by *Johnson* et al. [35.8]. In the *JKR model* so established, the contact radius is expected to increase, for a given normal load F_N, as

$$a^3 = a_0^3 \left[1 + \frac{3\Delta\gamma\pi R}{F_\mathrm{N}} + \sqrt{\frac{6\Delta\gamma\pi R}{F_\mathrm{N}} + \left(\frac{3\Delta\gamma\pi R}{F_\mathrm{N}}\right)^2} \right], \tag{35.8}$$

where $\Delta\gamma$ is the local change in surface tension when the contact is formed. The contact becomes unstable when a reaches a critical value given by

$$a_\mathrm{c} = \left(\frac{9\pi\Delta\gamma R^2}{8E^*}\right). \tag{35.9}$$

This value corresponds to a critical force

$$F_\mathrm{c} = -\frac{3\pi}{2}\Delta\gamma R, \tag{35.10}$$

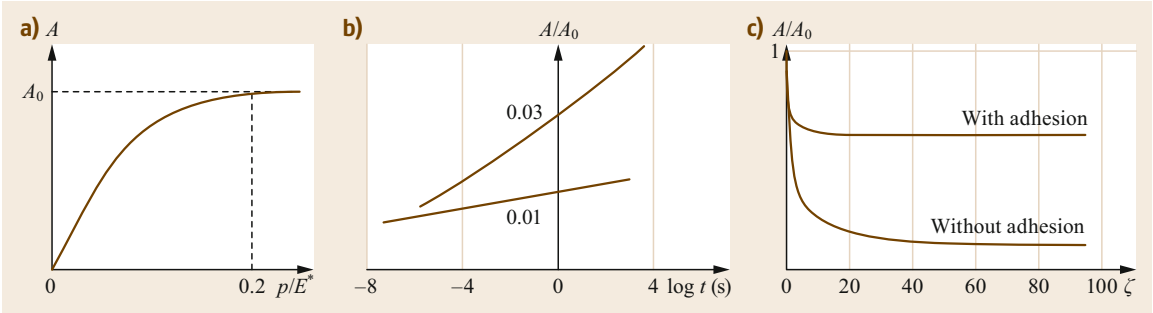

Fig. 35.2a–c Applications of the Persson contact mechanics theory. **(a)** Apparent contact area between an elastic rough surface and a rigid half-space as a function of the squeezing pressure. the opposite of which can be considered as the *adhesion force* F_{adh} of the contact. Note that the JKR model is applicable only to large compliant contacts. In the opposite case

$$a^3 = a_0^3\left(1 + \frac{2\pi\Delta\gamma R}{F_{\mathrm{N}}}\right) \tag{35.11}$$

is a more accurate approximation [35.9], whereas intermediate cases can be treated within the Maugis–Dugdale model [35.10]. Also in this case, an extension to rough contacts has been proposed by *Persson* [35.6]. The analysis occurs through a series of consecutive steps. For a given surface with power spectrum $S(k)$, an effective surface tension γ_{eff} is first defined. This quantity is related to the adhesion force F_{adh} that is experienced by a rigid sphere of radius R pressed against the surface (at the magnification ζ) as

$$\gamma_{\mathrm{eff}} = \frac{2F_{\mathrm{adh}}}{3\pi R}\,. \tag{35.12}$$

The largest stress at the magnification ζ is then obtained using the Griffith theory for crack propagation

$$\sigma_a(\zeta) = \sqrt{\frac{2\gamma_{\mathrm{eff}}(\zeta)E^*k}{\pi^2}}\,. \tag{35.13}$$

Finally, (35.4) is solved with the boundary condition $P(-\sigma_a(\zeta),\zeta) = 0$. As expected, the adhesion increases the contact area considerably, as shown in Fig. 35.2c.

35.2 Macroscopic Sliding Friction

Having described how the problem of determining the pressure distribution in the contact between two surfaces can be elegantly solved within the Persson theory, it makes sense to ask how the previous relations change, and the friction force evolves, when the surfaces start sliding past each other. However, a general solution for sliding friction based on the Persson theory does not yet exist. A satisfying analytical treatment exists only for simple geometries, with most results coming from the past century [35.11]. Suppose that, besides the normal loading force F_{N}, a tangential force F_{x} is applied at the contact between two elastic spheres. In this case the shear stress distribution in the contact circle is given by

$$\tau(r) = \frac{\tau_0}{\sqrt{a^2 - r^2}}\,, \tag{35.14}$$

where $\tau_0 = F_{\mathrm{x}}/2\pi a^2$. This stress becomes infinite, and therefore not bearable, at the perimeter of the circle. As a result, a ring-shaped part of the circle must be necessarily detached. The radius c of the remaining part is related to F_{x} by the formula

$$c = a\left(1 - \frac{F_{\mathrm{x}}}{\mu F_{\mathrm{N}}}\right)^{1/3}\,, \tag{35.15}$$

where μ is the coefficient of static friction. When F_{x} increases, c becomes progressively smaller, until the sphere is fully detached when $F_{\mathrm{x}} = \mu F_{\mathrm{N}}$. Similar results hold in the case of a cylindrical contact (with the detachment occurring on the trailing edge). What happens after the detachment? If the lateral force is large enough to overcome the kinetic friction, a shear stress with the same distribution of the Hertzian pressure is

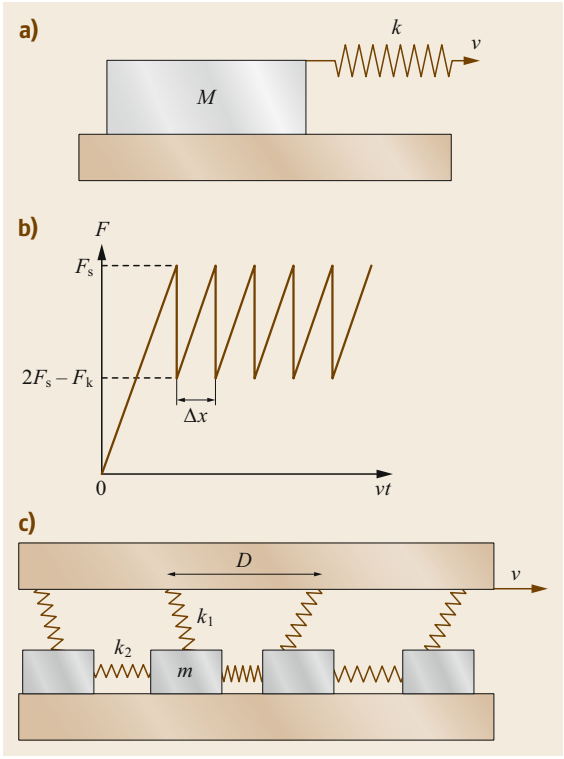

Fig. 35.3 **(a)** A block of mass m sliding on a flat substrate; **(b)** time dependence of the spring force in the quasi-static limit $v \to 0$; **(c)** schematics of the Burridge–Knopoff model

kept at the contact while sliding. Otherwise, the surfaces will *stick* again.

The *Stick-slip* process is a very general phenomenon, and can be better understood in the simple case of a block of mass M pulled by a spring (constant k), the free end of which moves with constant velocity v, as shown in Fig. 35.3a. If the static and kinetic friction have the constant values F_s and F_k, respectively, with $F_s > F_k$, it is not difficult to prove that the block will also move through alternate stick and slip phases, in which the block remains in contact with the surface or abruptly detaches and is quickly stopped again. When the stick time

$$t_{\text{stick}} = \frac{2(F_s - F_k)}{kv} , \tag{35.16}$$

the slip time is given by

$$t_{\text{slip}} = \frac{2}{\omega_0} \arctan\left(\frac{\omega(F_s - F_k)}{kv}\right) , \tag{35.17}$$

where $\omega_0 = \sqrt{k/m}$ is the resonance frequency of the linear oscillator. If v is very low and the oscillations immediately following the detachment are quickly damped (so-called *quasi-static* case), then $t_{\text{stick}} \gg t_{\text{slip}} \approx \pi/\omega_0$, and the spring force F essentially varies with time following the sawtooth profile in Fig. 35.3b. It is also interesting to study the same problem under the assumption that F_s increases with the time of contact (so-called *contact aging*). In this case, stick–slip can also be observed, but only if the initial rate of increase of the static friction is low enough

$$\left.\frac{dF_s}{dt}\right|_{t\to 0} > k . \tag{35.18}$$

If this is not the case, sliding occurs steadily.

The simple stick–slip model can be extended in several ways. As an example, Fig. 35.3b shows several similar blocks connected to one another by springs k. The blocks are driven altogether by a series of springs K that are connected to a much larger rigid block moving with a constant velocity v. The importance of the *Burridge–Knopoff* (BK) *model* so defined [35.12] is given by the fact that it can also be treated analytically, and its solution gives a good understanding of thermally activated effects that are also expected in real-life situations (e.g., in earthquakes). In the BK model, it can indeed be proven that the motion of each small block is prevented by an energy barrier $\Delta E \propto (F_s^2 - F^2)$, where F is the force acting on the large block, and the coefficient of proportionality is determined by the values of K and k. In the course of time, the value of F increases and ΔE decreases. Neglecting thermal fluctuation, a block detaches when $\Delta E = 0$, but at a finite temperature T, one can introduce the probability p that the block remains stuck and observe that, according to the Kramers rate theory, the time variation of this quantity is given by the *master equation*

$$\frac{dp}{dt} = -f_0 \exp\left(-\frac{\Delta E}{k_B T}\right) p(t) . \tag{35.19}$$

In (35.19), f_0 is a prefactor (depending on ω_0, the damping coefficient γ and the average distance between two consecutive blocks). As a result, the friction force is found to increase with the logarithmic sliding velocity. This is also the case if the contact area is as small as the junction formed by an atomically sharp tip driven on a crystal surface, which is discussed in the next section.

35.3 Sliding Friction on the Atomic Scale

The *Prandtl–Tomlinson* (PT) *model* [35.13] differs from the model in Fig. 35.3a for the fact that (i) the block is replaced by a point mass m, and (ii) the mass is driven on a periodic (crystal) surface. For sake of simplicity, we limit the discussion to the one-dimensional motion on a sinusoidal potential with period a and amplitude U_0 and, again, consider the quasi-static limit only. Introducing the parameter

$$\eta = \frac{4\pi^2 U_0}{ka^2} \tag{35.20}$$

it is easy to see that, if $\eta < 1$, the mass m follows the driving spring continuously in a *steady sliding* with negligible friction [35.14]. If $\eta > 1$, the motion consists in an alternation of long *stick* phases and rapid *slip* events between consecutive minima of the potential. In this case the static friction force is

$$F_s = \frac{ka}{2\pi}\sqrt{\eta^2 - 1}\,. \tag{35.21}$$

The kinetic friction force F_k can be estimated as the ratio between the potential drop ΔU observed in the slip phase and a. A simple analytical expression for F_k is not possible, but it is interesting to observe that in a first approximation, $F_k \propto (\eta - 1)$ when $\eta \to 1$, and $F_k \propto \eta$ when $\eta \gg 1$. These conclusions hold if the damping coefficient γ is so high that m is pinned in the first minimum encountered after slip. If this is not the case, *long jumps* (corresponding to integer multiples of a) are possible, the occurrence of which can be related numerically to the values of η, γ and the temperature T. Various extensions to two-dimensional energy landscapes, with the symmetries of natural or artificial crystal surfaces, are available in the literature. Their validity is confirmed from lattice-resolved lateral force maps, which nowadays can be routinely acquired using *atomic force microscopy* (AFM). In this technique, a sharp probing tip is scanned over a solid surface in a sequence of parallel scan lines. The tip is located at the end of a flexible microcantilever, the bending of which is determined by the normal force F_N on the tip, whereas its torsion corresponds to the lateral force F_L. In this way, the friction force acting on the tip can be recorded as a function of the normal loading and the sliding velocity v, and mapped over an entire selected scan area. Examples of molecular-scale resolution achieved across monatomic step edges [35.15], on Moiré patterns [35.16, 18] and on molecular thin films on mineral surfaces [35.17] are given in Fig. 35.4. Note that this resolution is usually only possible in ultrahigh vacuum (UHV) conditions or with the probing tip completely embedded in water (in ambient conditions high resolution being prevented by the formation of a water meniscus between tip and sample).

The PT model can also be used to estimate how atomic-scale sliding friction varies with the velocity and temperature. In order to do that, one has again to consider the energy barrier ΔE preventing a slip event. On a sinusoidal potential ΔE depends on the spring force F as $\Delta E \propto (\text{const} - F)^{3/2}$. The higher the velocity, the lower the number of attempts to overcome the barrier, and, again using the Kramers rate theory, it is found

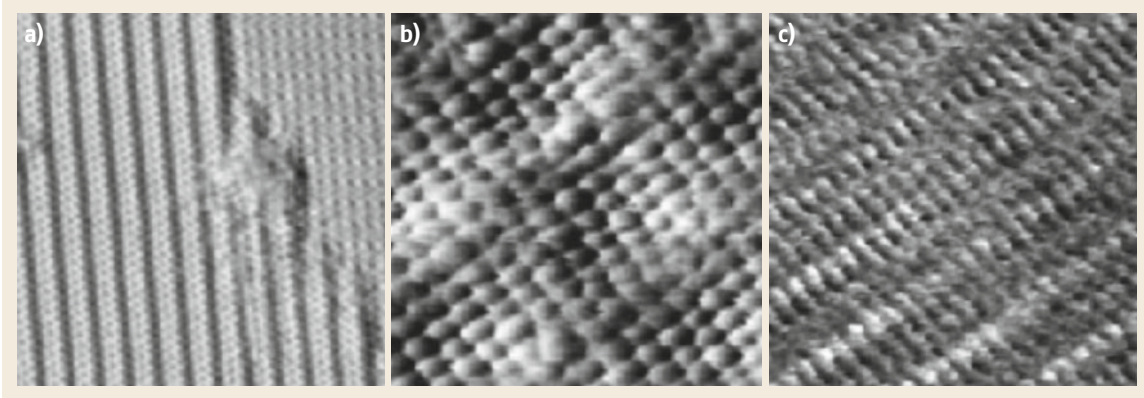

Fig. 35.4a–c Lateral force maps of **(a)** a (2×1) reconstructed Ge(001) surface. **(b)** A KBr monolayer grown on NaCl(001), **(c)** parallel stacks of perylene diimide derivative molecules on a dolomite cleavage surface. These results, corresponding to scan areas of a few nm^2, can be well reproduced with the PT model. (**(a)** Reprinted with permission from [35.15]. that the friction should increase logarithmically with the sliding velocity [35.19]. However, this is only true if the contact area and the related contact stiffness do not change in the stick phase. If this is not the case, an opposite trend is expected, which has indeed been observed on SiO_2 and NaCl at cryogenic temperatures [35.20, 21]. The origin of the contact aging processes on the basis of this trend can be traced back to the formation and rupture of chemical bonds, and it obviously depends on the system. The rate theory combined with the PT model can also be used to prove that the friction force decreases if the temperature increases. This can be understood by simply observing that, the higher the temperature, the larger the number of attempts to overcome the energy barrier. This prediction has also been confirmed experimentally [35.22].

The motion of a point mass elastically driven on a crystal surface is the starting point for more complex friction models focusing on finite but still tiny contact areas. In some analogy with the BK model (Sect. 35.2), one can consider a chain of point masses connected by springs k_1 and driven by an external spring k on a periodic potential. Several combinations are possible. In the simplest case, corresponding to the so-called *edge-driven Frenkel–Kontorova* (FK) *model*, the external spring is connected to the point mass at the leading edge of the chain (a detailed review of the FK model is given in [35.23]). Recent nanomanipulation experiments performed by *Kawai* et al. on polyfluorene chains [35.24] and graphene nanoribbons [35.25] on a gold surface could indeed be reproduced using the edge-driven FK model. These experiments were performed in the so-called *noncontact mode*, with the probing tip oscillating in close proximity to the substrate but without *touching* it. From the variation in the resonance frequency of the cantilever, mechanical force gradients (in the normal direction) can be estimated and related to the friction forces through the potential energy landscape determined by integration. Stick-slip motion of single-stranded DNA chains on graphene [35.26] has also been investigated numerically by molecular dynamics combined with the FK model.

35.4 Ultimate Limits of Nanotribology: From Noncontact Friction to Abrasive Nanowear

How to reduce friction? Here we will try to give partial answers considering only *physical* methods applicable on the nanoscale. We begin by noting that the logarithmic velocity strengthening (without aging) does not occur at very low velocities, where *back-jumps* become efficient and cause that, in the limit $v \to 0$, the lateral force tends to zero [35.27]. Nevertheless, due to the very low velocity values where such effect (so-called *thermolubricity*) is expected, this is not a practical method for reducing friction. According to (35.21), the friction is also negligible when the PT parameter $\eta \to 1$. In this case the transition from stick–slip to steady sliding can be observed experimentally [35.28], but only with very low normal force values F_N in the order of 1 nN. Nevertheless, the energy barrier ΔE preventing slip can also be reduced (on average) if F_N oscillates. In this way, the transition to steady sliding can be easily observed if the excitation frequency f_{exc} is close to the resonance frequency of the tip in contact with the sample surface [35.29]. Note that in this case the average value $\overline{F}_N$ can be considerably higher than the (steady) value of F_N causing the transition without oscillations. Similar results are obtained if the tip oscillates parallel to the sample [35.30]. On finite contact areas, friction is significantly reduced if the two contacting surface lattices are *unmatched*, i.e., they are incommensurate or, if they are commensurate, their principal crystallographic directions are not parallel. Depending on the reciprocal orientation and/or the ratio between the lattice constants, stick–slip or *structural lubricity* [35.31] can be observed. Note that the last one is often called *superlubricity*, but this term is not universally accepted. Experimental verification of this effect also came from AFM measurements performed with a dedicated setup [35.32] and, more recently, from nanomanipulation experiments [35.33]. In this context, it should be pointed out that exceptionally low dissipative forces (in the order of 10−100 aN) can be measured when two surfaces move past each other in UHV without forming a real (repulsive) contact. Among the possible mechanisms leading to these effects, one has to distinguish between van der Waals, electrostatic and phononic *friction*. To detect *noncontact friction*, one of the two surfaces is usually oscillated, then the excitation is stopped and the time decay of the oscillations is measured. The resulting damping coefficients can be as small as 10^{-13} kg/s, although *giant* noncontact friction of 10^{-5} kg/s has been reported on charge density wave systems [35.34].

Last but not least, it is also worth mentioning what happens in the opposite limit of *high* loading forces (usually of a few tens of nN), where abrasive wear occurs. In contrast to friction, abrasive wear is still poorly explained in a satisfactory analytical way, but,

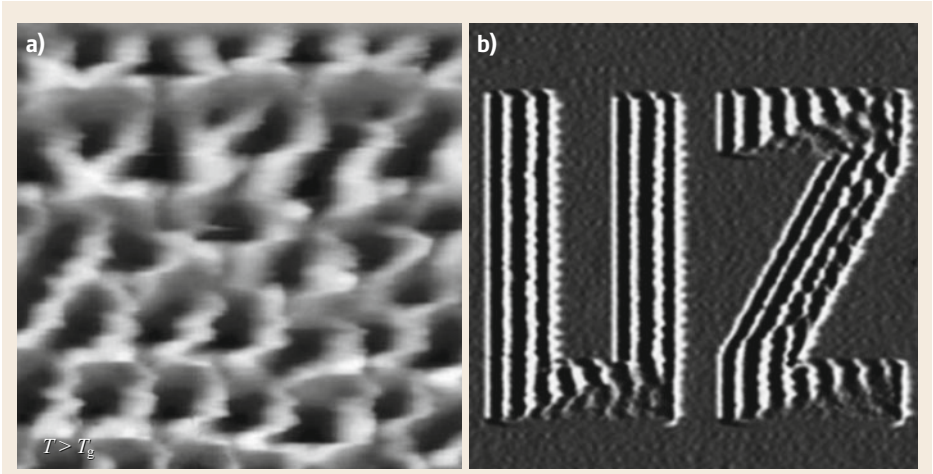

Fig. 35.5 **(a)** Abrasive wear patterns on polysulfone above T_g ($\approx 220\,^{\circ}\mathrm{C}$). AFM scan size: $1\,\mu\mathrm{m}$. (Reprinted by permission from [35.35]. similar to friction, AFM in UHV offers the possibility to investigate its time evolution in the *cleanest* possible conditions. As an example, in an early experiment of this kind it was found that when a groove is scraped by an AFM tip on a brittle KBr surface, the removed material recrystallizes in a periodic hilly pattern surrounding the groove [35.37, 38]. Interestingly, this result is not unique to alkali halides, but was also reported on semiconductors [35.39] and especially on polymer surfaces [35.40]. The regular *ripple* features formed in the abrasive process can also be modeled invoking the PT mechanism [35.41]. In this case, the surface profile plays the role of variable surface potential. The longer the tip sticks at a given place on the surface, the deeper is the potential well formed there. Assuming that at time $t = 0$ the surface is perfectly flat, a ripple pattern may develop or not depending on the values of the lateral stiffness k, indentation rate N, sliding velocity v and linear size of the tip a. The condition for ripple formation is

$$v < C\frac{N}{ak}\,, \tag{35.22}$$

where the parameter C is of the order of unity. Also, in this case, abrasive wear can be suppressed by mechanical oscillations applied during sliding, and the effect is more pronounced in the proximity of the contact resonance frequency [35.42]. In spite of its simplicity, surface rippling can develop in more complex *mogul* patterns (in polymers above the glass transition temperature T_g) or can be *tuned* by changing the scan conditions with dedicated scripts (Fig. 35.5).

35.5 Conclusions

To summarize, this short review has attempted to give a *flavor* on two topics of current research in macro- and nanotribology. Many questions are still open. What are the lower limits of continuum mechanics? How does the value of the friction coefficient depend on quantum effects involving the electron clouds of the contacting atoms? How reliable is molecular dynamics when used to understand phenomena extended over several length and time scales? The answers that the reader can find in the specialized literature are only partial, and they are often based on *guessing* rather than on rigorous mathematical proofs. This is not necessarily a negative conclusion, but should rather help to stimulate further experimental and theoretical research on this fascinating multidisciplinary subject.

Enrico Gnecco is Professor of Physics at Friedrich Schiller University Jena. He received his PhD from the University of Genova, and worked as Postdoctoral Researcher at the University of Basel and as independent Group Leader at IMDEA Nanoscience, Madrid. His research focuses on nanoscale friction, scanning-probe manipulation of metal clusters and nanocrystals, nanomechanics of abrasive wear in polymers and glasses, and the influence of ultrasonic vibrations on friction.

36. Graphene

Ado Jorio, Edmar Avellar Soares, Roberto Paniago, Mario Rocca, Luca Vattuone

This chapter presents a review on different aspects of graphene (Gr), the one-atom-thick two-dimensional sp^2 bonded carbon system. It starts by describing the pristine structure of graphene, including strain, layer stacking, and defects. Atomic and interlayer vibrations are also discussed. Next, the synthesis of graphene is addressed, including growth by segregation, using silicon carbide, molecular-beam epitaxy, and chemical vapor deposition, the latter depending on the substrate, including Ni(111), Ir(111), Rh(111), and Ru(0001). The substrate effects are considered, addressing graphene on metals, on Gr/Ni(111) (strongly n-doped), and on Gr/Rh(111) and Gr/Ru(0001) (strongly corrugated Moiré patterns). Finally, the chapter addresses metal intercalation and reactivity in graphene, ending with a summary and perspectives.

This chapter addresses the basic aspects of graphene. It is organized as follows: Section 36.1 describes the structure of graphene, considering the pristine lattice and the effect of strain (Sect. 36.1.1). Then defects are considered (Sect. 36.1.2), as well as vibrations (Sect. 36.1.3), both intra- and interlayer. Section 36.2 addresses graphene synthesis, considering growth by segregation (Sect. 36.2.1), from silicon carbide (Sect. 36.2.2), molecular-beam epitaxy (MBE) (Sect. 36.2.3), and chemical vapor deposition (CVD) (Sect. 36.2.4). Section 36.3 discusses the dependence of the CVD-grown structure on different substrates, namely Ni(111)—Sect. 36.3.1, Rh(111), and Ru(0001)—Sect. 36.3.2, Ir(111)—Sect. 36.3.3. Section 36.4 addresses metal atom intercalation under graphene. Section 36.5 deals with the reactive properties of graphene, and Sect. 36.6 provides a summary and perspectives.

The term graphene was coined in 1962 by *Boehm* et al. [36.2] to describe a one-atom-thick planar sheet of sp^2-bonded carbon atoms, densely packed in a two-dimensional (2-D) honeycomb crystal lattice, basically a single atomic layer of graphite. Graphene has been recognized as one of the most important materials for next-generation technology applications [36.3] due to its unique electronic (carrier mobility up to $200\,000\,\mathrm{cm^2\,V^{-1}\,s^{-1}}$, at electron densities of $\approx 2\times 10^{11}\,\mathrm{cm^{-2}}$ [36.4] 100 times better than silicon), mechanical (Young's modulus 1 TPa, i.e., 5× larger than stainless steel [36.5]), and optical (already some percentage absorption in the optical range for the monolayer) [36.6] properties. An isolated (single-layer) graphene, as first demonstrated in 2004 by *Noselov* et al. [36.7], can be obtained by peeling an already existing bulk graphite crystal. The fact that it could be produced by that surprisingly simple exfoliation

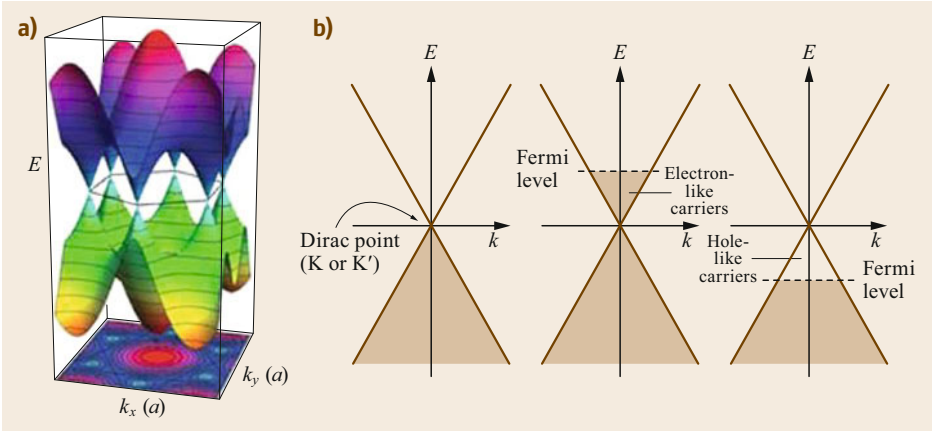

Fig. 36.1 **(a)** Calculated band structure of graphene showing the occupied (*yellow–green*) and unoccupied (*blue–red*) states, which touch each other without an energy gap at six K points in the first Brillouin zone; **(b)** simplified band structure near the K points and Fermi level-dependent charge carrier concentration. n- or p-type doping can create electron-like or hole-like charge carriers. (From [36.1] © IOP Publishing. Reproduced with permission. All rights reserved)

method has stimulated much research on this material, both fundamental and device-related.

One aspect that makes graphene so unique is that the out-of-plane p orbitals hybridize touching only at the Dirac points (K and K′ points of the two-dimensional Brillouin zone) and have a linear dispersion (Fig. 36.1). Thus the Fermi level falls at the Dirac point for freestanding pristine graphene, making it a gapless semiconductor. The carrier concentration may be easily modified, either by doping the layer with electron donors or acceptors, or applying electric fields or adsorbing gases.

36.1 Structure

Graphene is a one-atom-thick, perfectly two-dimensional system made of carbon atoms arranged in a honeycomb structure, where the atoms are bound to each other by sp^2 bonds. The strong $sp^2\sigma$ bonds allow unprecedented manipulation of this purely surface material [36.8]. This section describes the structure of the pure freestanding material, followed in the next sections by the study of its interactions with the surface of supports.

36.1.1 Pristine Graphene

In an isotropic environment, monolayer graphene exhibits a hexagonal symmetry belonging to the space group $P6/mmm$ (D^1_{6h}), with two inequivalent C atoms in the unit cell, sitting at sites usually named A and B [36.9]. The graphene unit cell, defined by the vectors $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$, is illustrated in the left sketches of Fig. 36.2a,b. Small modifications in the graphene structure may lead to different symmetry groups, as indicated by the other schematics in Fig. 36.2a,b, sometimes related to other 2-D materials [36.10]. For example, starting from hexagonal graphene (left panel in Fig. 36.2a) and inducing a compressive strain along the $\hat{\boldsymbol{x}}$-direction leads to a symmetry change to the space group D^{19}_{2h} (middle panel in Fig. 36.2a), which is commonly observed for graphene under strain. Subsequently, stronger uniaxial compression may drive graphene into the space group D^7_{2h} (right panel in Fig. 36.2a), where the light and dark gray atoms are in different levels along the $\hat{\boldsymbol{z}}$-direction, a structure naturally observed in phosphorene (black P). A biaxial compressive homogeneous strain on hexagonal graphene (Fig. 36.2b) may lead to a phase transition to the D^3_{3d} space group (right panel in Fig. 36.2b). Again, light and dark gray atoms correspond to different levels along the $\hat{\boldsymbol{z}}$-direction. Such structure is also observed in phosphorene (blue P).

When stacking graphene to form many-layer systems, the most common is the so-called AB (Bernal) stacking, where one sheet is displaced with respect to the other, with corresponding carbon atoms moving from sites A and B when moving from one layer to the next. N-layer graphene (N = number of layers) has $2N$ atoms in the unit cell. Graphite ($N \to \infty$) has four atoms in the unit cell, usually in the AB stacking

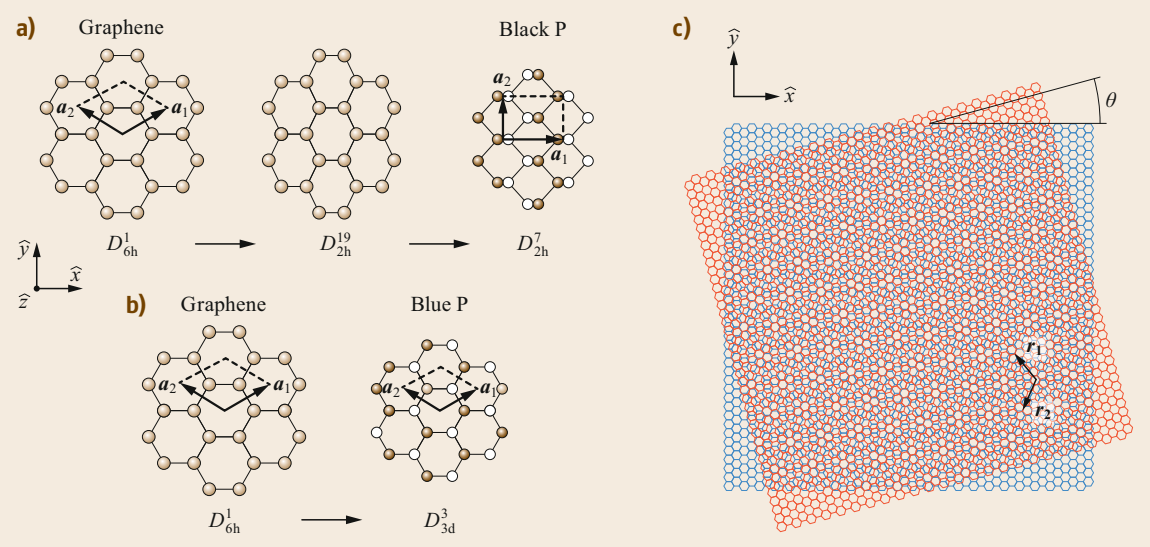

Fig. 36.2a–c Atomic structure of graphene and the effect of lattice distortions, uniaxial in (a) and hydrostatic in (b) [36.10]. Vectors $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$ indicate the unit cell, where the two atoms are located on sites A (*left*) and B (*right*). The space group symmetries are given below the respective structures. When *light* and *dark gray* atoms are used, they indicate C atoms at different levels along the $\hat{z}$-direction. arrangement. The point group symmetries for N-layer graphene, with N even or odd, are the same as for bilayer and trilayer graphene, respectively, which are D_{3d} for N even and D_{3h} for N odd [36.9]. The main symmetry operations distinguishing these structures are (i) the horizontal mirror plane, absent for N even, and (ii) the inversion, absent for N odd.

Another interesting structure is generated by stacking two graphene layers with a mismatch rotation angle θ between the lattice structures in each layer, building the so-called twisted bilayer graphene (tBLG) [36.11–16]. The mismatch angle θ produces a superstructure that creates a Moiré pattern, which generates many other interesting phenomena. The superstructure exhibits a θ-dependent periodicity described by the two vectors

$$\boldsymbol{r}_1(\theta) = -\frac{a}{4}\left[\sqrt{3} + \cot\left(\frac{\theta}{2}\right)\hat{\boldsymbol{x}}\right] - \frac{a}{4}\left[1 - \sqrt{3}\cot\left(\frac{\theta}{2}\right)\hat{\boldsymbol{y}}\right]$$

and

$$\boldsymbol{r}_2(\theta) = \frac{a}{4}\left[\sqrt{3} - \cot\left(\frac{\theta}{2}\right)\hat{\boldsymbol{x}}\right] - \frac{a}{4}\left[1 + \sqrt{3}\cot\left(\frac{\theta}{2}\right)\hat{\boldsymbol{y}}\right].$$

36.1.2 Defective Graphene

From a topology standpoint, defects in two-dimensional (2-D) systems can be either one-dimensional (1-D, Fig. 36.3a–c; [36.17, 18]) or zero-dimensional (0-D, Fig. 36.3d; [36.19]). 0-D defects in the 2-D graphene lattice are vacancies, dopants, functional chemical groups, crystallographic variations, such as 7-5-7 Stone–Wales defects; 1-D defects in 2-D graphene are dislocations, sequence of 7-5-7-structures, and crystallite borders which appear during growth, thus enclosing a crystallite area, or simply the edge of a graphene flake [36.20–22]. This simple geometrical distinction changes defect functionality and their influence on graphene properties. Moreover, defects in the sp^2 honeycomb carbon lattice dictate structural amorphization from pristine graphene or three-dimensional (3-D) graphite down to more complex structures, such as amorphous carbon, carbon black, charcoal, biochar or, to a greater extent, organic molecules [36.23–25]. The example of sp^3 formation induced by strain in graphene will be discussed later.

36.1.3 Lattice Vibrations

The two unit-cell atoms in pristine monolayer graphene moving in three-dimensional space generate six phonon branches—three acoustic (A), with in-phase displace-

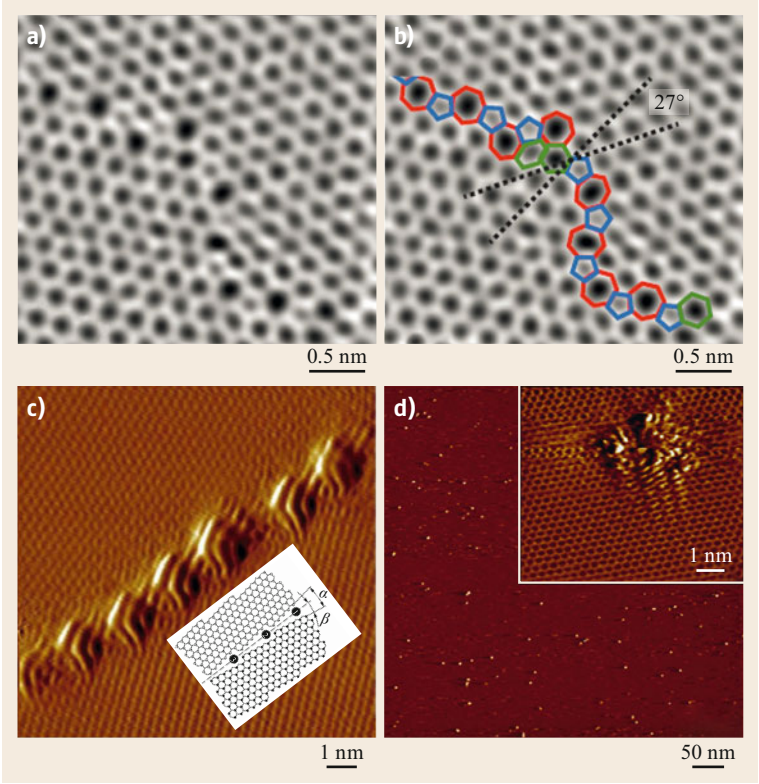

Fig. 36.3a–d Transmission electron microscopy (TEM **(a)** and **(b)**) and scanning tunneling microscopy (STM **(c)** and **(d)**) images of defects in graphene [36.17–19]. **(a–c)** are line defects [36.17]. The schematic in **(c)** shows the atomic structure responsible for the measured electronic disturbance [36.18]. **(d)** Point defects produced by Ar^+ ion bombardment on the top graphene layer in a highly oriented pyrolytic graphite (HOPG) [36.19]. ments of the two unit-cell atoms, and three optical (O), with out-of-phase displacements of the two unit-cell atoms. The atomic displacements in the graphene plane (i for in-plane) can be longitudinal (L) or transverse (T) with respect to the phonon wavevector direction. The atomic displacements perpendicular to the graphene plane (o for out-of-plane) are transverse (T) phonons, and they generally exhibit lower frequencies because the out-of-plane restoring forces are much weaker than the in-plane ones [36.26, 27].

Vibrations within the two-dimensional graphene plane are usually characterized by relatively large frequencies, and the stacking of multiple layers has minor importance. The in-plane longitudinal optical (iLO) and the in-plane transverse optical (iTO) phonons are degenerate, representing the only first-order Raman-active mode of graphene, called G band, belonging to the double-degenerate irreducible representation E_{2g}, appearing at $1584\,\mathrm{cm}^{-1}$ [36.26–29]. The relatively high frequency of this optical phonon ($\approx 0.2\,\mathrm{eV}$) allows the use of Raman spectroscopy to probe small environmental perturbations, including variations in strain [36.30], doping [36.31], and temperature [36.32]. The out-of-plane transverse optical (oTO) mode at the Γ point is active in infrared absorption spectroscopy [36.9]. However, the polar character of this vibration is very weak because graphene is monatomic, and infrared spectroscopy is mostly used to measure the vibrations from functionalization agents and other contaminants in graphene [36.33, 34], in addition to direct electronic effects near the K point [36.35, 36].

Interlayer vibrations exhibit much lower frequencies, because the interlayer coupling in two-dimensional materials is governed by van der Waals bonds, which are much weaker than the in-plane bonds [36.37, 38]. The physics of interlayer vibrations is independent of the specific in-plane symmetry, being general for two-dimensional materials with two layers or more, and can be used to monitor the number of layers and to study the evolution from the two-dimensional system to the bulk form [36.9]. There are two main types of interlayer vibrations, corresponding to shear (in-plane) and breathing (out-of-plane) motion of adjacent layers [36.39–45].

Experimentally, due to momentum conservation requirements necessary for achieving scattering by phonons in the interior of the Brillouin zone, most measurements rely on either neutron or x-ray inelastic scattering to probe phonon dispersion [36.37, 38, 46]. The so-obtained dispersion is shown in Fig. 36.4.

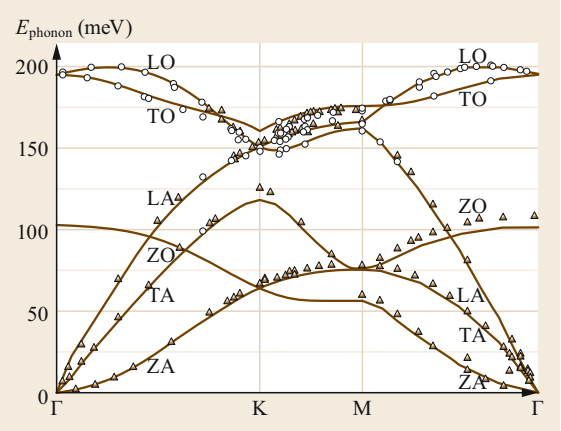

Fig. 36.4 Phonon dispersion for graphite as obtained from inelastic x-ray scattering. *Triangles* and *circles* correspond to two different sets of data, while the *continuous line* indicates density functional theory (DFT) calculations ([36.38] for details). (Reprinted with permission from [36.38]. Copyright (2007) by the American Physical Society)

Graphene, however, has a combination of factors that give rise to unique effects, making it possible to probe the phonon dispersion with inelastic light scattering in the visible range [36.11, 15, 16, 48–50].

Figure 36.5a shows a Raman spectrum obtained from an ion-bombarded graphene sample [36.19, 47]. This spectrum shows the first-order allowed G band ($\approx 1584\,\mathrm{cm}^{-1}$) and the second-order (or two-phonon) G′ ($\approx 2700\,\mathrm{cm}^{-1}$, also called 2-D band in the literature) and 2-D′ ($\approx 3120\,\mathrm{cm}^{-1}$) bands. The spectrum also shows three additional disorder-induced bands, namely the D band ($\approx 1350\,\mathrm{cm}^{-1}$), the D′ band ($\approx 1620\,\mathrm{cm}^{-1}$), and the combination D+D′ ($\approx 2970\,\mathrm{cm}^{-1}$) [36.19, 26–28, 47]. The origin of the unlabeled feature near $2450\,\mathrm{cm}^{-1}$ has been a matter of debate in the literature [36.51–53].

It has been shown [36.19] that the D to G peak area ratio (A_D/A_G) increases when increasing the number of defects, reaching a maximum value when there is defect coalescence. After this point, the A_D/A_G ratio decreases with the increasing number of defects, and the line widths increase even more significantly. The right panel of Fig. 36.5 shows a Raman-based diagram where the A_D/A_G ratio is plotted as a function of the G-band line width (Γ_G) [36.54]. Actually, A_D/A_G is normalized by multiplying the measured values by the fourth power of the excitation laser energy (E_L^4), which is known to turn the D to G area ratio independently of the excitation energy (E_L) utilized to generate the Raman scattering [36.55]. Since both A_D/A_G and Γ_G are known to depend differently on the amount of point versus line defects [36.19, 47, 56], the phase diagram was shown to span the possible amorphization trajectories for graphene, from pristine (left-hand side of the plot and $(A_D/A_G) = 0$) to highly amorphous (right-hand side of the plot). The solid line is the trajectory for purely one-dimensional defects, while the dashed line is the trajectory for purely zero-dimensional defects [36.54].

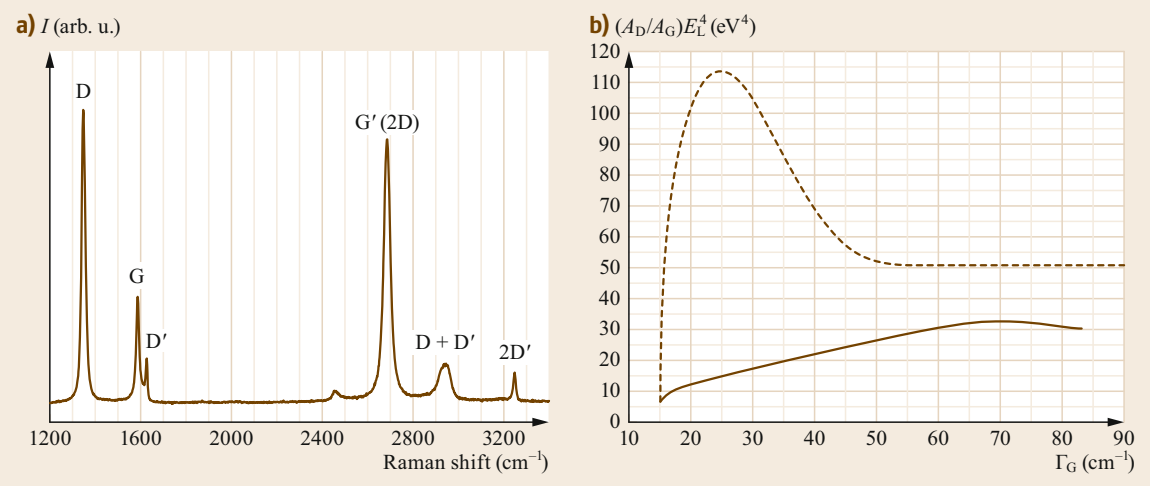

Fig. 36.5 **(a)** Raman spectrum obtained from an ion-bombarded graphene sample with average distance between point defects $L_D \approx 5\,\mathrm{nm}$ [36.47]. **(b)** Raman phase diagram for graphene amorphization. The *left-hand side* of the plot at $(A_D/A_G) = 0$, with A_D and A_G the areas of D and G peaks, respectively, corresponds to the pristine structure. Fully amorphous material appears on the *right-hand side* of the plot. The *solid/dashed lines* provide the amorphization trajectories for 1-D/0-D defects. 36.2 Growth

Since mechanical exfoliation of graphite only produces micrometer-sized graphene flakes, great effort has been dedicated to producing graphene through different methods. Epitaxial growth is an attractive alternative, but achieving large graphene domains is still a challenge. One of the first observations of the epitaxial growth of graphene dates back to 1975 [36.57]. Heating silicon carbide in ultrahigh vacuum (UHV) causes silicon sublimation, and the nucleation of carbon atoms forming a graphene layer occurs. More recently, chemical vapor deposition (CVD), molecular-beam epitaxy (MBE), and surface segregation methods have been developed to synthesize graphene mostly on top of transition-metal surfaces. Optimization of those methods seeks high-quality graphene which should generally present large area and high crystallinity (few defects), and in most cases should also be transferable onto any substrate.

Here we focus on methods in which graphene is prepared (grown) directly on surfaces. That implies that either carbon already exists inside the substrate (diluted or a substrate constituent, as in SiC) or is added by deposition (CVD or MBE). Such methods have several advantages: they are reproducible, they do not depend on a pre-existing graphite crystal and, most importantly, they permit the production of large areas, not to mention the possibility of graphene functionalization, oxidation, doping, and intercalation, which can be done during or after the growth process. In the following section, we discuss the main methods for graphene growth on polycrystalline and on single-crystalline substrates, and also give some examples of metal–graphene intercalation to form interfaces.

36.2.1 Graphene Growth by Segregation

Traces of carbon are inevitably present in most bulk metals, and thermal annealing can drive carbon impurities to the surface, a phenomenon known as segregation. This carbon can be used to grow graphene without the need for any external carbon source, as demonstrated for Ni, Co, Fe, and Cu-Ni polycrystalline films [36.58]. The mechanism of graphene formation has been described as occurring in three steps: thermally induced diffusion of dissolved carbon to the surface; creation of growth nuclei by trapping of carbon atoms at grain boundaries (2-D-defects) and at step edges; and finally, graphene growth around those centers by lowering the temperature. The carbon segregation method also has the ability to produce multilayered graphene, in contrast to the single-layer limitation of the CVD method. Ni, Co, and Fe show very efficient growth by this method due to their high carbon solubility, while Cu, with very low maximum carbon solubility (0.04%), does not. In some experiments using single crystals, interstitial carbon enrichment is accomplished by hydrocarbon (mostly ethylene) exposure at very high temperatures. Eventually, the hydrocarbon source is closed, and the substrate is slowly cooled in order to promote graphene nucleation. Growth by carbon segregation has been obtained on single-crystalline Ru(0001) [36.59–61] (Fig. 36.6a,b) and Pt(111) [36.62], among others. For Ru(0001), it has been shown that at 850 °C, a graphene island starts its growth and, in a time scale of 90 s, achieves a length of ca. 30 μm. Two-layer-thick graphene has also been observed on ruthenium, the second layer showing weak electronic coupling to the metal.

36.2.2 Silicon Carbide

When a silicon carbide substrate is annealed at high temperature, Si atoms (or species) selectively desorb from the surface, causing its carbon enrichment, and under appropriate conditions, graphene is formed (Fig. 36.7a). Because SiC is a wide-bandgap semiconductor, graphene on commercial SiC substrates could in principle be used for electronics applications. Films grown in this way can be patterned using standard nanolithography, making them very promising for large-scale applications. This technique has been developed to grow epitaxial graphene monolayers on SiC(0001), the Si-face of silicon carbide, typically at 1200 °C and in a UHV environment [36.64, 65]. Mono-, bi-, tri-, etc., layers are formed, depending on growth parameters like temperature, heating rate, and pressure. Nevertheless,

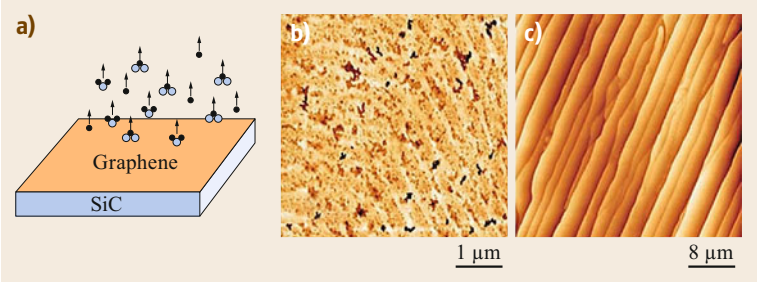

Fig. 36.7 **(a)** Growth of epitaxial graphene on SiC, via selective sublimation of Si species (Si atoms marked *blue*, C atoms marked *black*). Atomic force microscopy image of graphene grown on SiC(0001) by annealing **(b)** in UHV at 1280 °C and **(c)** in Ar environment at 1650 °C. (From [36.63])

as compared with exfoliated graphene, SiC graphene usually presents large numbers of defects, and consequently a much lower electron mobility. It is also possible to grow graphene at the Si(0001) face (so-called C-face), although in the literature, authors claim it is more difficult to control the number of layers. This aspect has to be further investigated. Even though the thermal decomposition of SiC in UHV appears promising for large-scale production, this method usually produces small grains (30–200 nm) with variable thickness. The high annealing temperature needed to provoke sublimation moreover causes drastic morphological changes at the surface. Some attempts have been made to obtain morphologically superior graphene layers, for example by using high-pressure argon (1 bar) and annealing SiC at 1650 °C [36.63]. Despite the higher temperature, this reduces the Si evaporation rate, because part of the silicon atoms are reflected back to the surface, delaying graphene formation, and allowing surface reconstruction by the enhanced surface diffusion. This method has enabled substantial surface quality improvement to be achieved (Fig. 36.7b,c).

36.2.3 Growth by MBE

Graphene formation has also been obtained on silicon carbide substrates by molecular-beam epitaxy using a solid carbon source on both SiC basal-plane surfaces [36.66, 67]. Because of the lower substrate temperatures used, this method has the advantage of not altering the SiC crystals, in contrast to the conventional graphitization method in UHV. Carbon can be generated by sublimation from a heated graphite filament [36.66] or from an effusion cell containing C_{60} [36.68], with the substrate held in the 850–1100 °C temperature range. It has been shown that by using vicinal SiC surfaces, well-ordered graphene nanoribbons (10 nm wide) are grown [36.69], in that case with carbon atoms supplied by heating resistive carbon plates at 2200 °C. Graphene growth was also successfully realized by MBE on h-BN [36.70], Al_2O_3(0001) [36.71], Pt(111), and Au(111) [36.72]. The growth of graphene from different solid carbon sources, such as polymeric films, has been demonstrated as well. By spin-coating poly(methyl methacrylate) (PMMA) thin films and heating the substrate (800–1000 °C) with a reductive gas flow (H_2/Ar), both pristine and N-doped graphene were grown [36.73].

36.2.4 Growth by CVD

A very promising way to produce large areas of high-quality graphene is the chemical vapor deposition (CVD) method, which relies on the catalytic decomposition of hydrocarbons on hot metal surfaces. The mechanism of graphene growth by CVD (Fig. 36.8) involves:

(i) Decomposition at the substrate surface
(ii) Graphene nucleation
(iii) Expansion.

However, the first step can be different for metals having high carbon solubility (such as Ni and Fe), since in that case it will diffuse into the hot substrate. As the substrate cools, the dissolved carbon will segregate to the surface, and grow graphene. Several transition-metal substrates catalyze the formation of graphene.

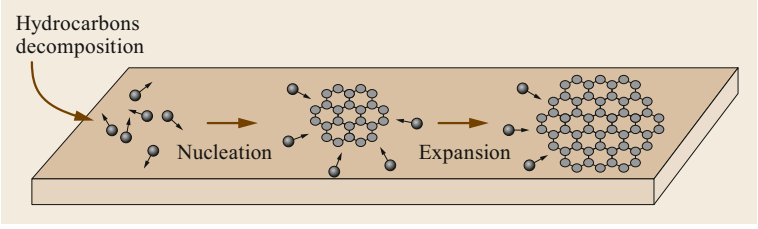

Fig. 36.8 CVD growth mechanics on transition-metal surfaces

Successful CVD growth has been reported, e.g., for Ni, Co, Ru, Ir, Pt, and Cu. The catalytic potential of transition metals is considered to be related to their partially filled d-orbitals and the formation of intermediate carbon compounds. Furthermore, growth mechanisms should be substrate-specific, and also dependent on several substrate characteristics, such as carbon solubility, tendency for carbide formation, grain boundaries, surface crystallography, and surface cleanliness. In fact, very little is established about the influence of all these factors, such as the role of transition-metal carbides in graphene formation. Nickel-carbide, which is metastable in bulk, can form an ordered surface carbide phase. It has been observed that on Ni(111), an atomic-layer-thick Ni_2C phase competes with graphene growth [36.74]. On the other hand, it has been argued that graphene growth by CVD on group IVB–VIB metals is facilitated by carbide formation [36.75]. Optimization of graphene growth is achieved by tuning several variables, including the flow of hydrocarbon gases, use of additional flow gases (e.g., Ar, H_2), substrate temperature, and cooling rate. Efforts have been made to obtain highly crystalline graphene on polycrystalline Ni and Cu. Because of the wide availability and low cost, the use of copper foils has been a standout in graphene synthesis by CVD, producing large-area and one-layer-thick graphene with excellent quality. Temperatures ranging from 800 to 1050 °C and hydrocarbons ethylene and methane are usually employed. Despite exhibiting very low reactivity with carbon, the copper surface can bind weakly to carbon atoms. Because of the low carbon solubility and because the graphene film acts as a diffusion barrier for other carbon atoms, graphene formation on Cu is regarded as predominantly a surface process. Not only is the thickness restricted to a single monolayer on polycrystalline copper, but annealing promotes larger grains. It has been observed that the highest-quality monolayer graphene is grown on the (111)-facets, with higher area coverage and short growth time in comparison with the (100)-facet or higher-index facets [36.76]. This has been attributed to the higher diffusion and improved adsorption of carbon-containing species on Cu(111). The state-of-the-art single-crystalline graphene obtained by CVD are grains with lateral size of about 1 mm and just 1 h of synthesis [36.77].

36.3 Graphene on Metal Surfaces

The epitaxial growth of large-area graphene sheets on metal surfaces is one of the most promising methods for technology applications. A thorough understanding of the atomic and electronic properties of the graphene–metal interface is therefore essential. The main driving forces of these properties are the strength of the carbon–metal interaction at the interface and the mismatch between the graphene and the metal surface lattice constants [36.78–80].

Several metal surfaces have been used as support for graphene growth, most of them having hexagonal symmetry. The local high-symmetry adsorption sites for an fcc(111) surface are presented in Fig. 36.9. In the atop geometry, the center of the graphene hexagon lies on top of the surface metal atoms, and the carbon atoms sit on the substrate fcc- and hcp-hollow sites. In the hcp configuration, the hexagon's center is on top of the second-layer metal atoms (hcp-hollow), and the carbon atoms are on atop and fcc-hollow sites, respectively. The center of the carbon–carbon bond lies on top of the topmost surface metal atom in the bridge geometry. Finally, the carbon atoms are respectively on atop and hcp-hollow sites in the fcc geometry. If there is no mismatch between the graphene and the underlying substrate, these sites define the (1×1) structures; otherwise they appear locally in the Moiré structure.

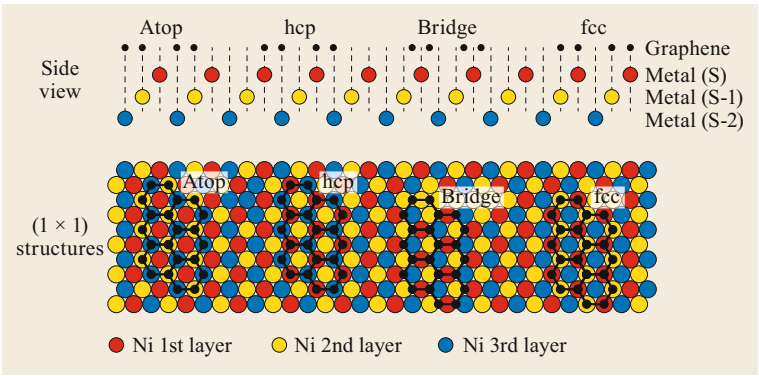

Fig. 36.9 Local adsorption sites of graphene on fcc(111) and hcp(0001) metallic surfaces

36.3.1 Graphene on Ni(111)—Strongly n-doped

Among the most commonly used single-crystalline substrates for graphene synthesis is Ni(111), with a surface lattice constant of 2.49 Å. Nickel therefore has the smallest lattice mismatch with graphene (2.46 Å). This enables a commensurate epitaxial relationship between graphene and the underlining substrate. Graphene growth by CVD on metallic single crystals usually requires previous in situ UHV surface preparation by cycles of ion sputtering (most commonly Ar^+) and annealing at high temperature. After an atomically clean and well-ordered Ni(111) is obtained, graphene can be prepared via thermal hydrocarbon decomposition at the surface. This is typically done by establishing a partial pressure (10^{-7}–10^{-6} mbar range) of propene (C_3H_6) in a UHV chamber for ca. 10 min with the crystal kept at 550 °C, resulting in a complete graphene monolayer [36.81]. It has been observed that epitaxial growth can be achieved up to 650 °C, with higher temperatures usually leading to the highest-quality graphene epitaxy, while at temperatures below 500 °C, undesired nickel carbide is formed. Growth at still higher temperatures (between 650–800 °C) is achieved only if the carbon content in the substrate is first enhanced. At these temperatures there is a significant increase in the number of rotated domains, as observed by low-energy electron diffraction (LEED) [36.82].

In the case where propene is deposited at room temperature and Ni(111) is post-annealed at temperatures between 350 and 550 °C, graphene islands are grown instead of complete coverage of that substrate [36.83]. Such graphene islands are observed to be commensurate (1×1) with Ni(111) and show either triangular or hexagonal shapes, depending on the reaction temperature. Some edges appear as zigzags, while others exhibit reconstructions, as demonstrated by atomically resolved STM images [36.84]. Evidence of a one-to-one relationship between edge type, graphene stacking, and orientation of the graphene islands has been noted.

As already pointed out, due to the small mismatch between the graphene and the Ni(111) lattice constants (about 1.3%), graphene grows assuming the substrate periodicity resulting in a (1×1) structure. Most experimental and theoretical investigations on the structure of Gr/Ni(111) have considered six possible structural models, which are presented in Fig. 36.10.

The first structural determination of the Gr(1×1)/Ni(111)(1×1) interface was performed by *Gamo* et al. [36.86] using LEED. In this work, the hcp model was the one that best fit the experimental LEED-IV curves. However, first-principles calculations based on the DFT approximation, including the van der Waals interactions, predicted that hcp and bridge models were energetically degenerate and that both structures could coexist on the surface [36.87]. The first experimental evidence of this coexistence came from a high-resolution x-ray photoemission spectroscopy (HR-XPS) study [36.88]. The graphene domains in the fcc structure were also observed on the surface in STM experiments [36.89] and in a subsequent XPS study [36.90], where the relative coverage of

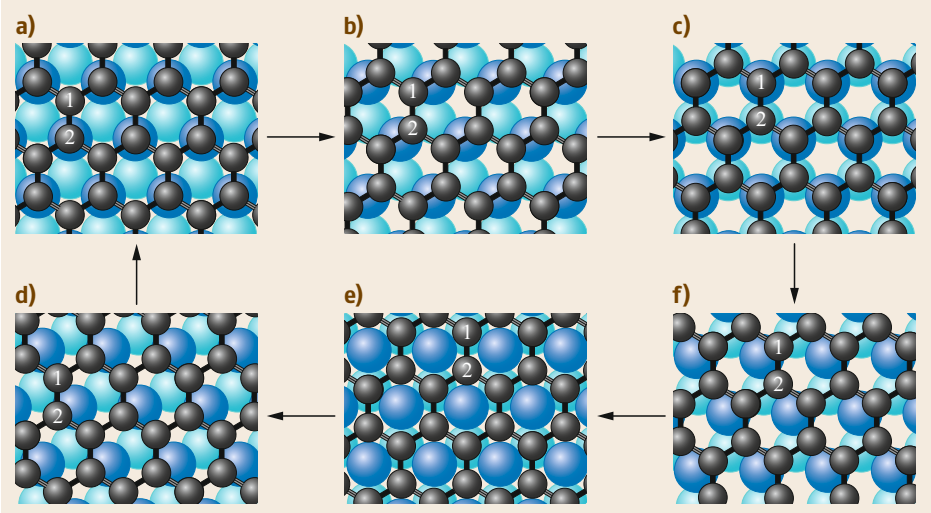

Fig. 36.10a–f Possible structural models for graphene on Ni(111): **(a)** top-fcc (hcp), **(b)** bridge-top (bridge), **(c)** top-hcp (fcc), **(d)** bridge-hcp (bridge-hcp), **(e)** hcp-fcc (atop), and **(f)** bridge-fcc (bridge-fcc). The models are obtained by shifting the graphene layer with respect to the Ni(111) surface in a direction along a C–C bond

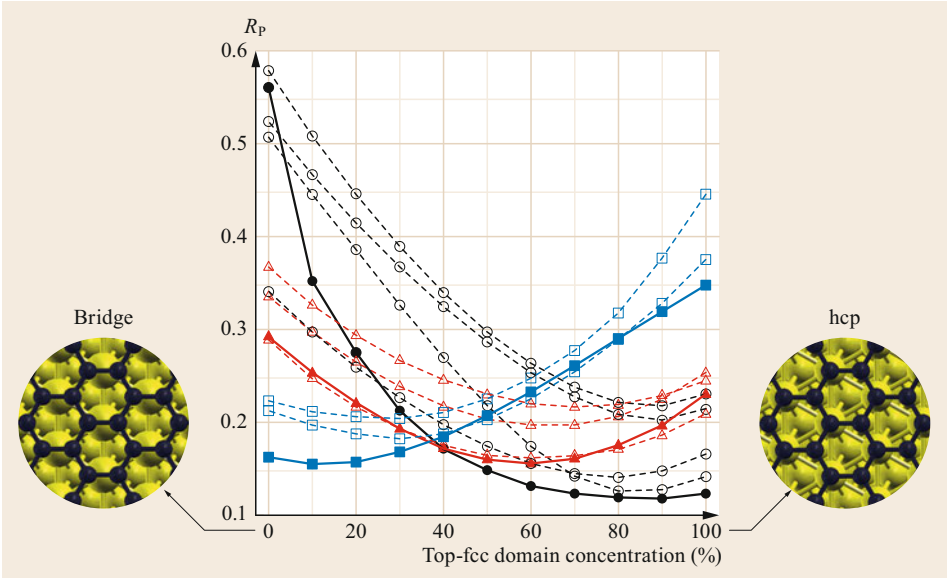

Fig. 36.11 Pendry R-factor R_P as a function of the hcp domain concentration for the 12 different LEED experiments. (Reprinted with permission from [36.85]. Copyright (2014) by the American Physical Society)

the different structures was shown to depend strongly on the details of the graphene preparation procedure. In a more recent structural determination combining LEED, photoelectron diffraction (PED), and DFT calculations, the hcp and bridge domains were found to coexist, and the structures of both were successfully determined [36.85]. The R_P-factor (a quantity defined to quantify the agreement between the experimental and theoretical LEED-IV curves) [36.91] as a function of the hcp domain concentration is presented in Fig. 36.11 for the 12 different LEED experiments. The best-fit models range from pure hcp domains (black lines) to pure bridge domains (blue lines). The experiments where a coexistence of both domains better reproduces the experimental LEED-IV curves are plotted in red. No evidence of the fcc structure was observed in this study.

A summary of the Gr(1×1)/Ni(111)(1×1) structural parameters is presented in Table 36.1 and Fig. 36.12. The main structural features are the interlayer distance between graphene and the topmost Ni layer of 2.11 Å, and the very small height difference (0.05 Å) between the two carbon atoms of the graphene sublattices. This small interlayer distance, compared with graphite interlayer distances, is a consequence of the strong interaction between C and Ni atoms at the interface. In particular, there is strong n-doping of graphene due to electron transfer from the Ni 4s to the Gr π states, and angle-resolved photoemission electron spectroscopy (ARPES) experiments performed on this interface clearly show a gap opening on the Gr π band [36.78].

36.3.2 Graphene on Rh(111) and Ru(0001)

Graphene growth on Rh(111) is also possible by CVD by exposing it to hydrocarbons (e.g., ethyne: C_2H_2) in UHV. However, for this system, the temperature window is much narrower (740–780 °C), with lower-temperature synthesis inducing rhodium carbide growth. STM images exhibit large graphene domains crossing several substrate steps without visible defects and also forming a Moiré structure caused by the lattice mismatch [36.92, 93]. The corrugation of graphene/Rh(111) measured by STM and AFM was between 0.5 and 1.5 Å, depending on the imaging conditions. The growth of high-quality single-layer

graphene on rhodium has also been reported by low-pressure CVD (2×10^{-7} mbar, 90 L exposure) using 3-pentanone ($CH_3-CH_2-CO-CH_2-CH_3$) with the substrate at 790 °C [36.94].

Growth of graphene on Ru(0001) is usually performed by carbon segregation [36.60], firstly exposing a clean Ru(0001) surface to 10^{-7} mbar of ethylene or propylene at room temperature, followed by annealing to 1030 °C [36.95]. Due to the large misfit between the graphene and the surface lattice constants and the strong interaction of carbon and metal atoms at the high-symmetry adsorption sites, the growth of graphene on Ru(0001) always leads to the formation of strongly corrugated Moiré patterns [36.60, 78, 79, 96, 97]. For the Gr/Ru(0001) interface, the lattice mismatch is about 9.0%, and most of the structural details have been revealed by LEED, surface x-ray diffraction (SXRD), STM, and ab initio calculations [36.59, 98–105]. Nowadays, the widely accepted structure is the Gr(25×25)/Ru(0001)(23×23), which means that 25 graphene unit cells are contained in 23 Ru(0001) surface unit cells. All the structural studies agree that graphene has considerable corrugation of about 1.5 Å (from the LEED analysis), and the minimum graphene–metal distance is about 2.1 Å. A summary of the results reported in the literature for this complex system is presented in Fig. 36.13.

The large modulation exhibited by the Gr(25×25)/Ru(0001)(23×23) interface has been used as a template for self-organized growth of different types of nanostructures [36.106]. The regions in the Moiré structure at different heights with respect to the underlying substrate have different surface potentials and behave differently with regard to nucleation centers. A textbook case is the deposition, at room temperature, of C_{60} molecules on the Gr(25×25)/Ru(0001)(23×23) interface. In the low-coverage range of 0.04–0.4 ML, STM images reveal the successive occupation of the adsorption sites within the Moiré structure. First, individual molecules populate the hcp valley sites, followed by an additional six molecules in a close-packed arrangement. Next, the fcc valley sites are occupied, followed by the Moiré hill sites. Around 0.4 ML, six additional close-packed molecules are imaged around the hill sites [36.107]. A correlation between the site occupation and the variation in the absorption energies between the different sites in the Moiré structure can be established.

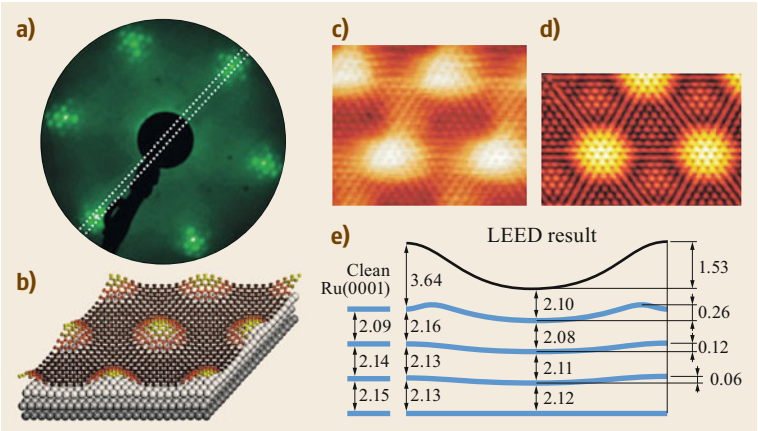

Fig. 36.13a–e Summary of results reported in the literature for the Gr(25×25)/Ru(0001)(23×23) interface. **(a)** LEED pattern at 112 eV showing single-domain graphene with superstructure spots due to Moiré pattern. **(b)** A three-dimensional surface structure model. **(c)** Experimental STM image acquired at 0.05 V bias voltage and 1 nA tunnel current. **(d)** Simulated STM image, and **(e)** schematic drawing of graphene and Ru-surface layers derived from LEED I(V) analysis, values are given in Å (Reprinted from [36.79], with permission from Elsevier)

Another good example of self-organized growth at the Gr/Ru(0001) interface is the deposition of iron phthalocyanine (Fe-Pc) molecules [36.108]. At lower coverage, the Fe-Pc molecules preferentially adsorb in the fcc valley sites. After saturation of the fcc sites, the molecules adsorb at the edge of the Moiré sites, avoiding the hcp valley hollows.

36.3.3 Graphene on Ir(111)

The growth of epitaxial graphene on Ir(111) was investigated extensively by *Coraux* et al. [36.109, 110] using STM, employing two preparation procedures: (i) room-temperature ethyne (C_2H_2) adsorption followed by thermal decomposition (600–1200 °C), and (ii) direct exposure of the hot substrate (600–1050 °C). The morphologies are distinct, the first route leading to graphene nanoislands with controllable size, depending on the growth temperature. The second route enables 100% coverage and very high structural quality above 930 °C. Because of the 9% surface lattice mismatch with Ir(111), both routes result in single-layer graphene with a Moiré superstructure, so that the positions of the C atoms relative to the underling metal atoms change periodically. The interaction between graphene and Ir(111) is very weak, which may cause the appearance of misoriented domains. In general, synthesis at lower temperatures leads to rotated domains, while higher growth temperature induces preferred orientation, forming the Moiré structure with periodicity of (10×10)/(9×9), as shown in Fig. 36.14. In comparison with other metal substrates, Ir(111) shows one of the highest graphene–substrate separations (3.4 Å), characterizing a weakly interacting system. For strongly interacting metals such as Ni(111), Rh(111), and Ru(0001), the graphene–metal separation is about 2.2 Å. That is also a reason why the graphene is shown crossing step edges on the Ir(111) substrate while maintaining structural coherency.

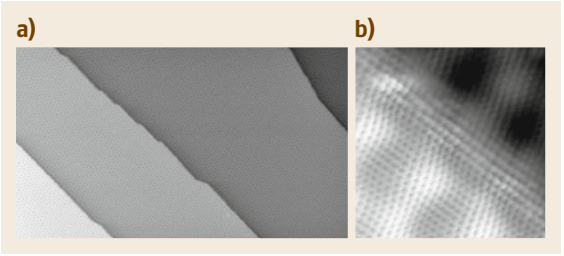

Fig. 36.14 **(a)** STM image (2500 Å × 1250 Å, 0.10 V, 30 nA) of graphene/Ir(111), showing Moiré superstructure crossing several Ir steps. **(b)** Atomically resolved STM (50 Å × 50 Å, 0.04 V, 30 nA) across a step edge. 36.4 Metal Intercalation

The intercalation of a different material layer between the graphene and substrate can lead to the fabrication of novel low-dimensional structures, in many cases significantly altering the interface interaction. That has been evidenced, for example, by interfacial reaction with oxygen, which decouples the graphene from Ru(0001) [36.111], originally exhibiting a strong interaction at the graphene–metal interface. Therefore, intercalation can in some cases result in quasi-freestanding graphene, which could potentially be transferred to another material.

An epitaxial interface with a certain metal, onto which graphene does not grow directly, can be produced by metal intercalation. It has been observed for the graphene/Ni(111) system intercalated by Au that the π bands recover the typical linear dispersion near the K point, resembling a nearly free layer [36.112]. Cs intercalation between graphene and Ni(111) has the effect of enlarging the distance between the graphene sheet and the substrate, achieving quasi-freestanding graphene as well [36.113, 114]. It was also shown that the intercalation of Al between the graphene layer and Ni(111) surface is able to detach the graphene from the substrate. After intercalation, the graphene/Al/Ni(111) interface shows a (2×2) reconstruction [36.115].

One of the obstacles to the effective use of graphene in electronics is the lack of an energy gap. It has been shown that bandgap opening can be obtained by epitaxial growth on a SiC substrate [36.116], or by the patterned adsorption of atomic hydrogen onto the Moiré superlattice positions of Gr/Ir(111) [36.117]. There are several examples of Gr/metal-intercalated systems showing substantial gap opening at the Dirac point of graphene, including Gr/Cu/Ir(111) [36.118], Gr/Pb/Pt(111) [36.119], Gr/Bi/Ir(111) [36.120], and Gr/Ag/Ni(111) [36.121]. Moreover, the graphene binding energy can be altered by means of alkali metal and halogen intercalation, which induces n-doping and p-doping of graphene, respectively. It has been shown that the Dirac point can be tuned almost continuously between strong n-type doping for Li, and strong p-type doping for F [36.122].

Protection of metal surfaces is another well-known property of graphene/metal systems. It has been

demonstrated both experimentally and theoretically that graphene layers on Cu, Ni, and Cu/Ni alloys protect the underling substrate from corrosion. The possibility of intercalating different metallic layers between graphene and an original substrate opens up a wide range of options in this matter and in interface magnetism as well. In general, metal intercalation produces modifications of the crystallographic and electronic structure of the system.

The intercalation of metal monolayers such as Au, Ag, Cu, Fe, and Sn underneath a graphene sheet grown on Ni(111) has been the object of several investigations. The intercalation of one or two Fe monolayers (ML) is accomplished by deposition of this nominal thickness on freshly prepared graphene/Ni(111), followed by annealing at 320 °C for 15 min [36.123]. At this temperature (and heating time), interfacial alloying effects are negligible, leading to a graphene/Fe/Ni(111) intercalated system. The mechanism of metal–atom intercalation is not completely understood, but it is believed to occur through grain boundaries and structural defects. For 1- and 2 ML films, iron atoms assume commensurate fcc stacking on the Ni layer, with graphene maintaining the same registry as for graphene/Ni(111). Moreover, the carbon distance to the last iron layer for graphene/Fe/Ni(111) is very similar (2.1 Å) to the graphene/Ni(111) system [36.123]. Fe-intercalation was also produced on graphene/Pt(111); in that case the iron strongly modified the graphene band structure by lifting its band spin degeneracy [36.124]. Co-intercalation has also been obtained for graphene on Ir(111) [36.125]. This graphene-covered system showed unconventional magnetic properties, much different from pristine cobalt films, suggesting magnetic interaction with graphene.

36.5 Chemical Reactivity of Graphene

The reactive properties of graphene were recently reviewed [36.1]. Adsorption of gases is important in fabricating highly sensitive sensors, removing undesired molecules in environmental applications, or inducing a gap opening for electronic applications. The importance of this topic is manifested in the growing number of papers in the literature each day.

36.5.1 Adsorption of Gases at Freestanding Graphene

Due to its electronic configuration, graphene is expected to be chemically inert. However, pioneering experiments [36.126] have demonstrated that it can be used as a very sensitive sensor for various simple gases, and that the latter can be regenerated by annealing to 423 K. The nature of the adsorption site on graphene may well be connected to defects or dopants rather than to adsorption at pristine sites, since the sensing activity was demonstrated to be suppressed after removing the contaminants introduced by the use of nanolithography [36.127].

Several theoretical papers have addressed the gas–graphene interaction, calculating for this purpose the adsorption energy of simple molecules such as CO, H_2O, NO, and NH_3 on freestanding graphene. While the actual result depends on the adsorption site, molecular orientation, and critically on the calculation method used (see [36.128] for H_2O), the values obtained are always quite low, at most 47 meV for H_2O, 31 meV for NH_3, 14 meV for CO, 67 meV for NO_2, and 29 meV for NO [36.129]. Nevertheless, the charge transfer for the different gases, albeit small, came out with the correct sign, whereby H_2O and NO_2 behave as electron acceptors, and NH_3, CO, and NO as donors. This small charge transfer causes significant n- or p-doping of graphene [36.1] because of the vanishingly low carrier concentration at the Dirac point. Doping therefore results in a measurable change in the resistivity.

The adsorption energy of the simple molecules mentioned above on unsupported graphene should be significantly larger at doped sites and at defects [36.130]. For example, for NO and NO_2 at N-doped sites, the adsorption energy is predicted to be 341 and 325 meV, respectively [36.131]. Similarly, doping with Al increases the latter values significantly for CO, CO_2, and O_2. In general, doping with heteroatoms such as Al, Cr, or Mn has a larger effect for O_2 than N- or B-doping [36.132].

The adsorption energy of simple gases is also predicted to be larger at di-vacancies: for example, it should be as high as −8.44, −4.53, −13.83, and −3.86 eV for O_2, N_2, B_2, and CO, respectively [36.133]. Another theoretical paper suggested that graphene vacancies could be healed by sequential exposure to CO and NO. The former gas would thereby adsorb at the vacancy, while NO would react with it to NO_2, leaving a C atom which could eventually repair the vacancy. Similarly, controllable N-doping should be achievable by vacancy creation (e.g., by an electron beam) and subsequent exposure to NO at room temperature [36.134].

As an example of an environmental application, we cite the use of graphene for the removal of bisphenol A (BPA), a monomer used for the production of epoxy resins and harmful to living organisms, from aqueous solutions, with the remarkable adsorption capacity of 182 mg/g [36.135]. The process is exothermic by 34 kJ/mol but, thanks to the entropic contribution to the free energy, adsorption can also take place spontaneously around room temperature. The large adsorption affinity of graphene for BPA was explained by the interaction of its single-layer planes with aromatic rings and the residual oxygen-containing groups, which can form π–π and hydrogen bonds with the benzene rings and the hydroxyl groups of BPA.

Graphene powders obtained from the reduction of graphene oxide have demonstrated a hydrogen adsorption capacity of the order of 0.1 wt% at 298 K. The latter is expected to increase up to 0.72 wt% at 100 bar given a measured isosteric heat of adsorption value between 4 and 5.9 kJ/mol [36.137].

At least one review paper has recently appeared that covers the topic of environmental application of graphene composites for water remediation and gas adsorption [36.138]. The material employed, however, is often not graphene, but graphene oxide, which is much more reactive than graphene itself and has very different electronic properties. For example, experiments have shown that NH_3 can be effectively removed by modifying graphene oxide with polycations or nanoparticles. These materials are undoubtedly promising for applications.

Adsorption of organic molecules on graphene flakes has also been investigated. In this case, low values of the chemisorption energy are found (Table 36.2).

In Fig. 36.15, the adsorption enthalpy versus increasing surface coverage is shown for three organic molecules. It was found to decrease with exposure and to become independent of coverage above ≈ 2% coverage. This process was modeled theoretically, simulating the graphene layer with a coronene molecule. About 60% of the adsorption energy was found to be provided by dispersive forces, while the second major contribution came from electrostatic interactions.

Table 36.2 Experimentally determined adsorption enthalpies for several organic molecules on graphene flakes [36.136]

Molecule	ΔH_{ads} (kcal/mol)
Acetone	-8.2 ± 0.3
Acetonitrile	-7.6 ± 0.3
Dichloromethane	-5.9 ± 0.5
Ethanol	-7.3 ± 0.7
Ethyl acetate	-11.5 ± 0.2
Hexane	-12.2 ± 0.2
Toluene	-13.5 ± 0.3

As long as freestanding graphene is considered, strong chemisorption at pristine graphene sites can be obtained only in solution for highly reactive radicals (e.g., aryl), in vacuum for atomic hydrogen or using plasmas.

36.5.2 Reactivity of Supported Graphene Layers

Most studies on graphene reactivity have been performed for layers grown on a reactive substrate or transferred on a support by different methods. Such layers may thus show effects associated with mechanical strain and are influenced by the possibly strong interaction with the support.

Effect of Mechanical Strain

Mechanical strain can be applied to graphene by stretching the supporting substrate. The effect on the reactivity was probed with three different aryl molecules: 4-nitrobenzenediazonium (4-NBD), 4-bromobenzenediazonium (4-BBD), and 4-methoxybenzenediazonium (4-MBD) [36.139]. The reaction occurs in two steps: first, a delocalized electron from an occupied level of graphene is transferred into an unoccupied level of the diazonium cation, giving rise to an aryl radical; the latter then binds to the graphene lattice, modifying the local hybridization state from sp^2 to sp^3. Such modification causes an increase in the defect-related D band in the Raman spectrum (Sect. 36.1.2). The ratio of the intensities of the D and G bands can thus be used to monitor the process. Since functionalization induces doping, the Raman spectrum also exhibits a shift of G and 2-D peaks (see table in the inset of Fig. 36.16b). We remind the reader here that p-type doping causes an upshift of the frequencies, while n-type doping has the opposite effect, for both G and 2-D modes (see Fig. 36.16). It is apparent that the increase in the ratio of the peak intensities I_D/I_G with functionalization dose occurs more rapidly for the strained sample, and also that the final concentration of the functionalized sites is then larger, thus proving that straining effectively modifies the reactivity of graphene with respect to covalent functionalization.

Mechanical strain can also be obtained by depositing nanoparticles on the substrate. For this purpose, monolayer graphene was deposited on a Si wafer decorated with SiO_2 nanoparticles (NPs) and then exposed to aryl radicals. Using micro-Raman mapping, the latter were found to selectively react with the regions of graphene strained by the underlying NPs [36.140].

Role of the Support in Determining the Chemical Reactivity of Graphene

Since in real systems graphene is rarely freestanding and is almost always supported on a substrate, the question that naturally arises is whether the interaction with the substrate can affect the reactivity of the graphene layer.

Burghaus and coworkers [36.141] investigated adsorption of water on graphene supported on Cu and on SiO_2 under controlled UHV conditions. In Fig. 36.17 we show the temperature desorption spectroscopy (TDS) rates recorded by these authors after different exposures to water for graphene on silica (Fig. 36.17a) and on a Cu foil (Fig. 36.17b).

The following are apparent: (a) For graphene/SiO_2, the only TDS feature shifts initially to lower temperatures with increasing exposure (see the red dashed line in Fig. 36.17a) and then remains constant. The leading edges at low temperature and low coverage are not aligned, yielding a straight line with positive slope in an Arrhenius plot (not shown), indicating deviation from zero-order kinetics. The latter is restored at higher exposures, since water then starts to condense. (b) Also, for graphene/Cu, only one TDS peak is evident. It shifts slightly to greater temperatures, however, with increasing exposure. The exponential rise of the peak at low temperature and the common leading edges are indicative of ice sublimation and zero-order kinetics.

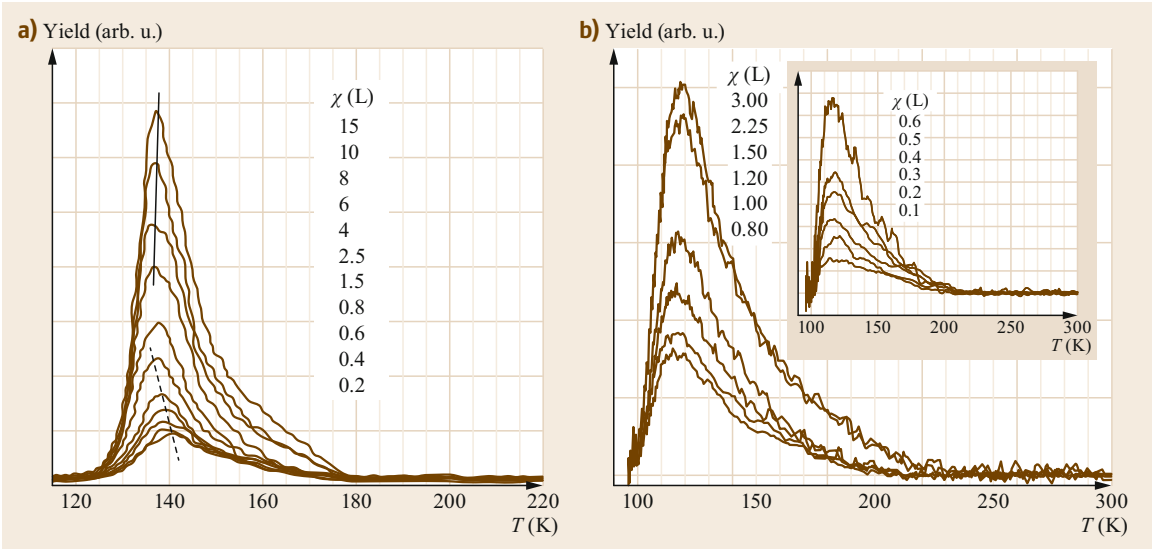

Fig. 36.17a,b TDS of water ($m/e = 18$) as a function of water exposure on hydrophilic graphene/SiO_2 **(a)** and on graphene/Cu **(b)**. Data for lower exposures are shown in the *inset*. (Reproduced from [36.141] with permission of The Royal Society of Chemistry)

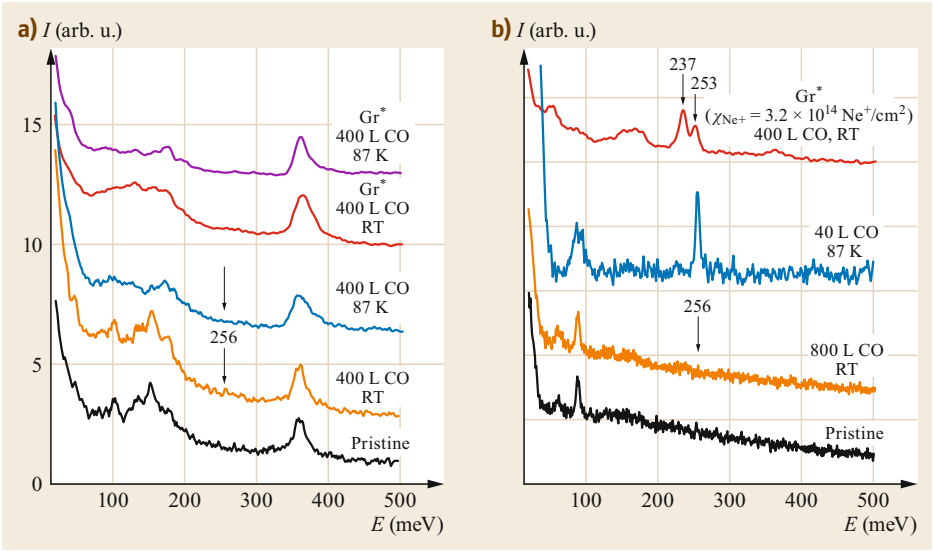

Fig. 36.18a,b High-resolution electron energy loss spectra recorded after exposure to CO graphene grown on **(a)** polycrystalline Cu and **(b)** Ni(111) under different conditions

The deviation from zero-order desorption kinetics for water adsorption on graphene/SiO_2 at lower exposures is indicative of a hydrophilic interaction and of surface wetting. On the contrary, water adsorption on graphene/Cu is consistent with hydrophobic interactions, similar to the case of water on graphene/Ru [36.142]. The authors concluded that graphene wettability is inversely correlated with the wettability of the support, i.e., if the support is hydrophobic, graphene shows wetting behavior, and if the support is hydrophilic, it shows nonwetting behavior.

The influence of the substrate on graphene reactivity was also investigated using CO as a probe under controlled UHV conditions [36.143]. The results are summarized in Fig. 36.18.

It is apparent that in the high-resolution energy loss (HREEL) spectra:

1. No signature of CO adsorption is observed upon exposure of pristine graphene at room temperature (RT).

2. On the contrary, at liquid nitrogen temperature, a loss at 256 meV forms, corresponding to the CO stretch mode, which is apparent upon exposure of graphene grown on Ni(111) but not on polycrystalline Cu. The additional losses present for the latter system are due to incomplete dehydrogenation of the molecules used to produce the graphene layer and are also present before CO exposure (see lowest trace).
3. If isolated defects are introduced in the graphene layer by a small ion bombardment dose with 100 eV Ne^+ ions (Gr^*), the subsequent exposure to CO at RT generates two electron energy losses for graphene grown on Ni(111), but not for graphene on Cu.

These results clearly indicate that graphene on Cu is inert with respect to CO adsorption, while graphene on Ni(111) is reactive.

If the sample is heated, the CO-related features disappear at quite different temperatures in the absence and in the presence of defects. In the former case, the heat of adsorption is estimated to be 0.35 eV/molecule at 1/3 ML, and 0.58 eV/molecule in the low-coverage limit. These values, the presence of the molecule-surface stretch, and the redshift of the CO stretch frequency with respect to the gas phase value provide evidence of weak molecular chemisorption. Out of the different configurations that Gr can take on Ni(111), the top-fcc (hcp) configuration (Sect. 36.3.1) was proven to have the highest reactivity to CO. The active site was identified with the carbon atom placed in the fcc position [36.144].

The reactivity of graphene on Ni(111) has also been investigated experimentally using water as probe gas. Following exposure at RT, decomposition and hydrogen production occur [36.145].

The interpretation of the results for CO adsorption on sputtered graphene is not straightforward. Two CO stretch features are present in the HREEL spectra, suggesting the existence of both single (loss at 253 meV) and doubly coordinated (loss at 237 meV) CO admolecules. If the vacancy itself were reactive, as suggested by several theoretical investigations for freestanding graphene [36.129], adsorption should also occur for sputtered graphene on Cu, contrary to experimental evidence.

Both energy losses of CO on Gr^*/Ni(111) disappear upon annealing between 350 and 400 K. Indeed, this temperature range and the observed vibrational frequencies compare well with those of CO/Ni(111). It was thus concluded that CO adsorption does not occur *at the vacancy* itself, but that, thanks to the presence of the vacancy, CO has intercalated between graphene and the Ni substrate. This straightforwardly explains the inertness of Gr^* on Cu, since the heat of adsorption of CO on this metal is too low to allow for stable adsorption.

Interestingly, if the Gr^*/Ni(111) system is annealed to induce CO desorption and then is exposed again at RT, the newly obtained CO coverage is smaller than for the first uptake. This indicates that part of the vacancies were repaired in the previous cycle and are therefore unreactive. For this reason, it was suggested that a Boudouard reaction between two adsorbed CO molecules takes place on the Ni substrate, producing CO_2 (which desorbs) and leaving one carbon atom that can repair the vacancy. This process is enabled with high efficiency thanks to the confinement of the CO admolecules in the space between the graphene layer and nickel surface, providing an example of a reaction under cover (see dedicated section below). The role of vacancies in the chemistry of graphene is thus not as straightforward as was suggested by pioneering theoretical studies for freestanding graphene. The substrate does indeed play a key role in determining the chemical reactivity of the graphene layer.

Other results indicate an active role of vacancies for functionalization. For example, enhanced reactivity toward selective oxidation of the amino group and the subsequent integration of the nitrogen atom within the graphene network was reported for graphene deposited on SiC [36.146]. The effect was ascribed to the excess charge at carbon dangling bonds at single-atomic vacancies. Graphene deposited on silicon carbide thus behaves differently from graphene on metals. The difference is presumably due to the formation of bonds between the C at the edge of the vacancy and the metallic substrate.

For water adsorption, theory predicts a different reactivity for vacancies drilled on graphene grown on Cu and Pt [36.147]. The C atoms close to the vacancy backbond to the metallic substrate in both cases, but since the Pt–C bond is stronger than the Cu–C bond, it is energetically convenient for H_2O to dissociate at the vacancy site of graphene on Cu, but not when the substrate is Pt.

The role of the substrate in graphene reactivity is also evident in the efficacy of covalent functionalization. The presence of large surface charge fluctuations induced by the substrate, for example, enhances the reactivity of aryl diazonium molecules with graphene supported on SiO_2 and Al_2O_3 [36.148], while adsorption is negligible on alkyl-terminated and hexagonal boron nitride (hBN) surfaces.

A review on the functionalization of graphene derivatives, including graphene oxide (GO), hydrogenated graphene (graphane), and graphene fluoride (fluorographene), was recently published [36.149].

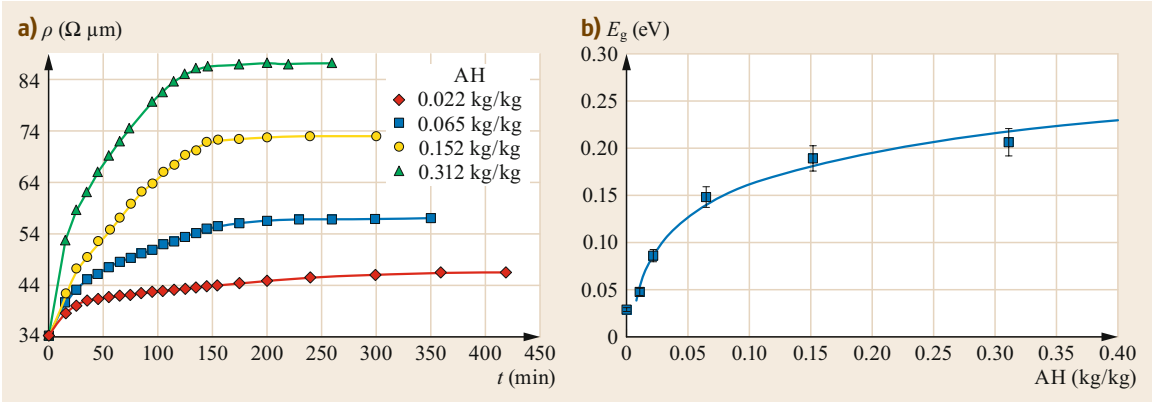

Fig. 36.19 **(a)** Change in resistivity ρ for a graphene film as a function of time for different absolute humidity. **(b)** Bandgap (E_g) as a function of absolute humidity (AH, given in kg water vapor in kg air). The bandgap increases sharply with humidity, saturating at a level of ≈ 0.206 eV. (Reprinted with permission from [36.150])

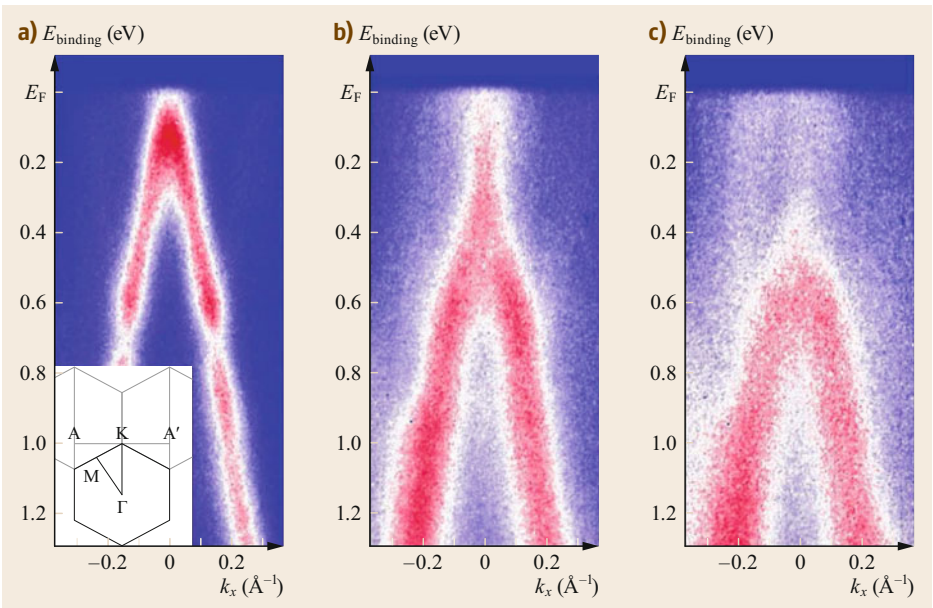

Fig. 36.20 **(a)** Photoemission intensity along the A-K-A′ direction of the Brillouin zone for clean graphene on Ir(111), **(b,c)** graphene exposed to 30 and 50 s of atomic hydrogen, respectively. The corresponding estimated coverage is of the order of some tenths of a monolayer. The *inset* shows the Brillouin zone of graphene. (From [36.117])

Controlling the Bandgap by Adsorption

It is well established that the absence of a bandgap is one of the major factors preventing the direct use of graphene in nanoelectronic devices. A bandgap can be artificially engineered through the introduction of defects [36.151], doping with adatoms [36.152], electrical gating [36.153–155], or the adsorption of gases [36.156].

The latter case was demonstrated using ambient humidity [36.150]. Graphene adlayers were grown by chemical vapor deposition (CVD) on copper (Cu) and coated with a thin poly(methyl methacrylate) (PMMA) film. The Cu substrate was eventually chemically dissolved and the graphene film transferred onto a Si substrate with an approximately 300 nm-thick insulating SiO_2 layer. Photolithography was then used to pattern four electrodes (Ti/Au, 3/30 nm) on the top surface of the transferred graphene film. The experimentally measured change in resistance with time for different absolute humidities (measured in weight of water content with respect to weight of air) is shown in Fig. 36.19. It is apparent that the resistance increases with time

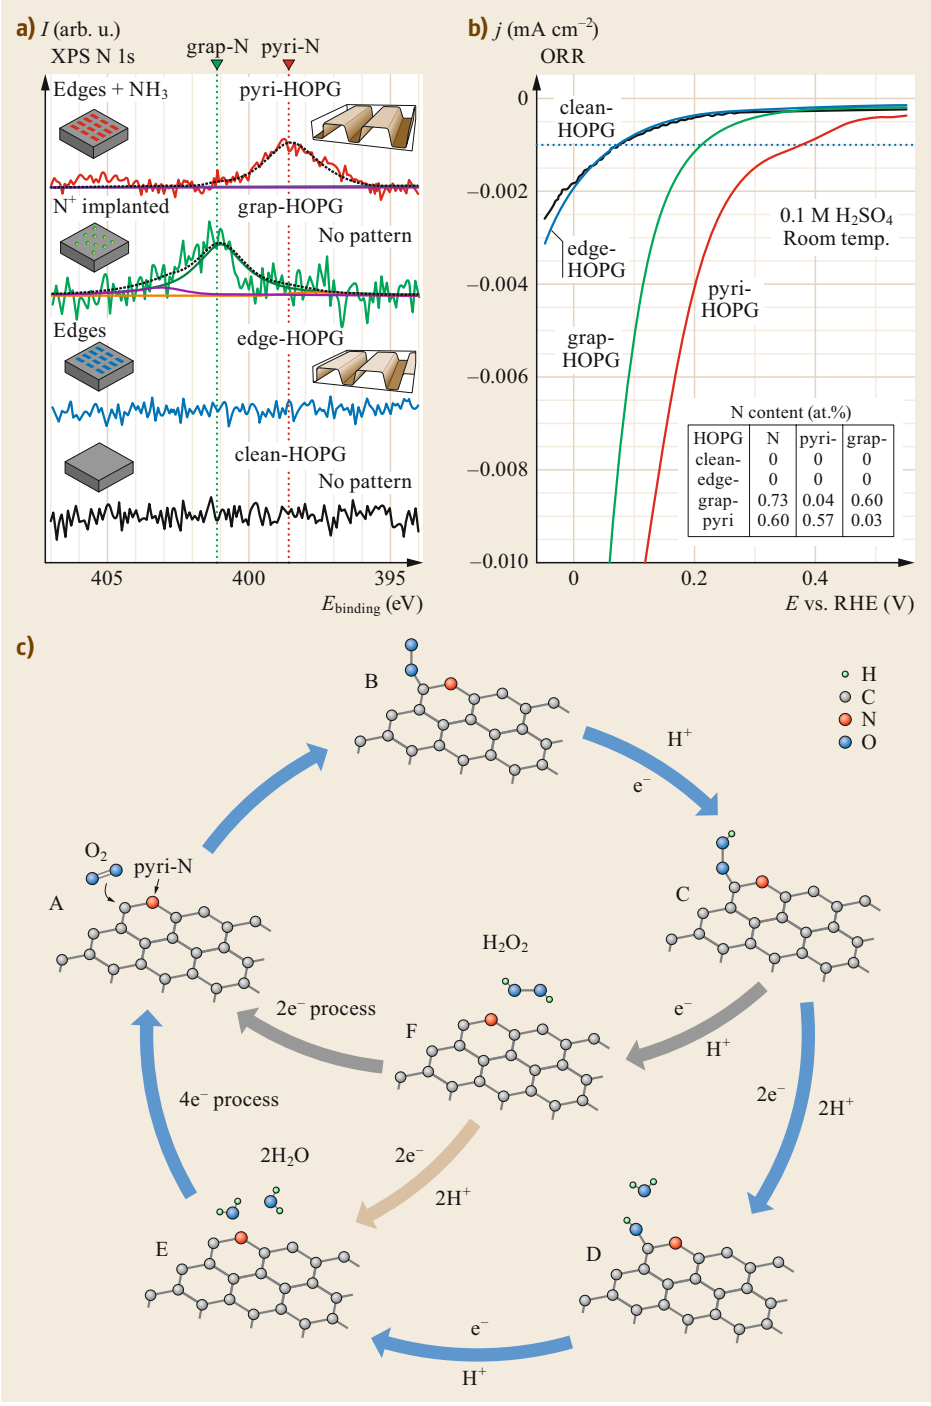

Fig. 36.21a–c N 1s XPS spectra of the different model catalysts **(a)** and the corresponding ORR results **(b)** obtained by cyclic voltammetry. **(c)** Schematic pathways for the ORR for the pyri-HOPG case. (From [36.157]. Reprinted with permission from AAAS)

and that the increase is greater the higher the humidity. Interestingly, water adsorption occurs reversibly. To prove the opening of a bandgap, the authors measured the conductivity at a fixed humidity level as a function of temperature, obtaining the gap values shown in the right panel of Fig. 36.19.

Theory also predicts the possibility of obtaining a tunable bandgap by introducing a periodic modula-

tion of the graphene lattice [36.159]. The feasibility of this approach was demonstrated [36.117] by exposing graphene on Ir(111) to atomic hydrogen. This system exhibits a Moiré pattern that survives H adsorption, as demonstrated by STM. Photoemission experiments have shown the opening of a bandgap upon H adsorption, as shown in Fig. 36.20.

36.5.3 Chemical Reactivity of Doped Graphene

Despite the presence of a large body of theoretical work suggesting the role of doping in promoting chemical reactivity, only a few experimental investigations have been performed. Two examples, addressing the role of n-doping for the oxygen reduction reaction (ORR) and for the stabilization of adsorbed CO, will be discussed.

For the former reaction, the electrochemical performance was investigated for pristine and N-doped highly oriented pyrolytic graphite (HOPG) and for graphene nanosheets (NGS). The results are shown in Fig. 36.21. Clean HOPG and edge HOPG indicate the undoped pristine and defect-rich surfaces, respectively, while grap-HOPG and pyri-HOPG correspond to substitutional and pyridinic N dopants. Cyclic voltammetry (CV) under oxygen saturation conditions shows that the pyri-HOPG sample provides the highest current density. The scheme in the lower part of the same figure shows that two alternative mechanisms are active for the reaction, involving four or $2+2$ electrons, respectively. O_2 initially adsorbs at the C site next to pyridinic N. In the four-electron mechanism, a proton attaches to the O_2, forming O−OH. Two further protons then react, leading to water formation by cleavage of the O–OH bond leaving OH groups at the surface, which are then reacted away by the fourth H. In the other reaction mechanism ($2+2$ electrons), an H_2O_2 intermediate forms due to the reaction of O−OH with a proton, which is then reduced to water by two further protons upon readsorption.

In another experimental investigation, the effect of N-doping in promoting adsorption was studied for CO chemisorption at graphene supported on Ni(111). N doping was attained by low-energy ion bombardment [36.161], and the so-obtained layer was exposed to CO in UHV conditions at low temperature. HREELS inspection demonstrated that in the presence of N, a further CO moiety, characterized by a CO stretch at 238 meV, forms in addition to the one vibrating at 256 meV also present for pristine graphene/Ni(111) [36.158] (Fig. 36.18). Such species is characterized by a higher desorption energy (0.85 eV/molecule) than that of CO adsorbed at pristine graphene sites (0.54 eV/molecule), as indicated by the temperature evolution of the spectra upon annealing, shown in Fig. 36.22. The stabilization of adsorption

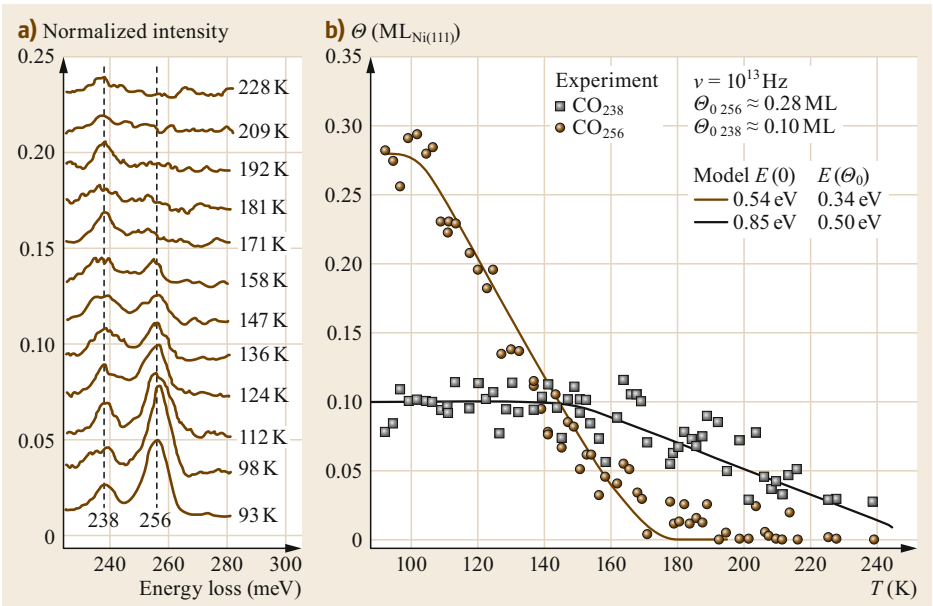

Fig. 36.22 (a) Evolution of HREEL spectra in the region of the CO stretch upon annealing after exposing N-doped graphene/Ni(111) to CO. Two losses are apparent: the one at 256 meV is also present for pristine graphene/Ni(111), while the one at 238 meV forms only for N-doped layers. (b) Coverage of the two CO species (CO_{238} and CO_{256}) as a function of annealing temperature. (Reprinted from [36.158], with permission from Elsevier)

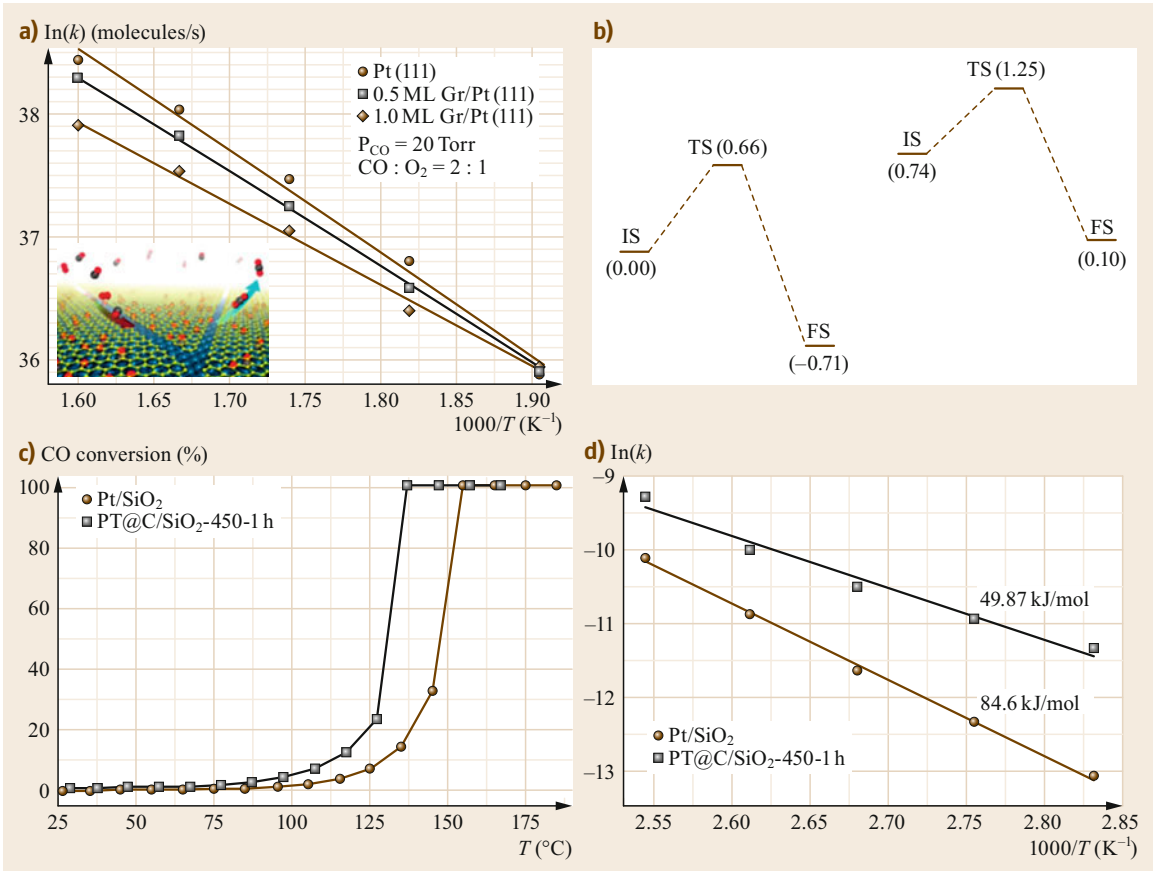

Fig. 36.23 **(a)** Arrhenius plots of the CO_2 formation rate k on the Pt(111) surface and graphene/Pt(111) from 525 to 625 K. The reaction gas mixture consists of 20 Torr CO and 10 Torr O_2. **(b)** Calculated reaction barriers for the oxidation of CO on Pt(111) (*left*) and Gr/Pt(111) (*right*), respectively. Values in brackets are in electron volts. **(c)** CO conversion as a function of reaction temperature over the Pt nanoparticles on SiO_2 and graphene-covered Pt nanoparticles at SiO_2 catalysts; **(d)** Arrhenius plots of the CO oxidation reaction rate (between 80 and 120 °C) over the Pt nanoparticles at SiO_2 and graphene-covered Pt nanoparticles at SiO_2. provided by N doping is effective not only at low coverage, but also at saturation. The adsorption energy at N sites is then 0.50 eV/molecule, i.e., 0.16 eV/molecule more than at pristine graphene sites.

36.5.4 Reactions Under a Graphene Cover

Reactions occurring *under cover* are particularly interesting, since the space between graphene and the catalytically active support acts like a *nanoreactor*, where chemistry takes place with a hindered ability for the reactants to desorb. The activation barriers of the reactions may be reduced as well. An example of a reaction under cover was mentioned above for defective graphene on Ni(111), where the Boudouard reaction was shown to proceed with much higher efficiency than for CO adsorption on bare Ni(111) [36.162].

In Fig. 36.23, the results for the CO oxidation reaction on bare Pt(111) and under graphene cover on Pt(111) are compared [36.160, 163–165]. It is apparent that, while the formation rate is always higher on Pt(111), the slope of the Arrhenius plot, i.e., the activation barrier, is lower for the monolayer graphene-covered Pt(111) surface (Fig. 36.23a). Theory confirms a reduction of the activation barrier from 0.66 to 0.51 eV (Fig. 36.23b). The comparison becomes even more interesting for bare and graphene-covered Pt nanoparticles (Fig. 36.23c,d), since the activation barrier is then reduced from 85 to 50 kJ/mol, and the reaction rates are always higher for Gr-covered nanoparticles.

36.6 Summary and Perspectives

The fascinating physical properties of graphene have established its reputation as the most famous two-dimensional crystalline structure. Given its only one-atomic-layer thickness and outstanding mechanical and electronic properties, one can only imagine how vast its use will be in the future, replacing existing technologies and materials. Considering applications in areas such as electronics, composites and coatings, sensors, spintronics, photovoltaics, and even biomedical devices, a good understanding not only of pristine graphene but also of defective and interactive graphene is indispensable. This need has stimulated the development of various preparation methods, growth on top of different substrates and in different forms, and functionalization and interfacing with various materials. In pursuit of a detailed characterization of its physical properties, continuous improvements in both experimental and theoretical surface science methods have taken place.

Very recently, the importance of twisted bilayer graphene with very low rotation angle (near 1 degree and below) has increased significantly. A low twist angle between the two stacked crystal networks in bilayer graphene enables self-organized lattice reconstruction with the formation of a periodic domain, the presence of strain solitons, topological points [36.166], and the eventual observation of strong correlation and superconductivity [36.167]. The control of the interlayer twist angle in two-dimensional van der Waals (vdW) heterostructures falls into a new reserach field baptized twistronics.

The ways that electronic, chemical, and magnetic properties are influenced by different substrates, dopants, and forms (nanoribbons, edge structures, etc.) are hot topics at the moment. In addition, graphene has generally served as a prototype material for the development of nanometrology. Thus it is used as a reference material for the detailed study of the the properties of nanotools. As the basics of graphene science are being established, engineers will continue to engage in expanding the development of graphene-based applied science and technology.

Ado Jorio

Departamento de Física
Universidade Federal de Minas Gerais
Belo Horizonte, Brazil
adojorio@gmail.com

Ado Jorio is a professor of Physics at the Federal University of Minas Gerais (UFMG), from where he earned a doctoral degree in 1999. He works with research and development of scientific instrumentation in optics for the study of nanostructures with applications in new materials and biomedicine. He was a postdoctoral fellowship at MIT (2000-2001), a visiting Professor at ETH Zurich (2013) and at Freie Universitat Berlin (2016).

Edmar Avellar Soares

Departamento de Física
Universidade Federal de Minas Gerais
Belo Horizonte, Brazil
edmar@fisica.ufmg.br

Edmar Soares is an associate professor at the Physics Department of Federal University of Minas Gerais (Brazil) where he received his PhD in 1998. He was a visiting researcher at University of Warwick-UK, LBNL-USA and CEA/ESRF Grenoble-France. His research has focused on the determination of atomic-scale structure and bonding at solid surfaces and in nanostructures, in order to better understand the atomistic basis of surface science, nanoscience and their many technological applications.

Roberto Paniago

Departamento de Física
Universidade Federal de Minas Gerais
Belo Horizonte, Brazil
paniago@fisica.ufmg.br

Roberto Paniago received his PhD in Physics at the University of Kassel (Germany) and is currently full professor of condensed matter physics at the Federal University of Minas Gerais (Brazil), with focus on Surface Science. His research activity aims at understanding the correlation of structural, electronic and magnetic properties of ultrathin-epitaxial films and nanostructures.

Mario Rocca

Dipt. di Fisica
Università di Genova
Genova, Italy
rocca@fisica.unige.it

Mario Rocca received his PhD in Physics at the University of Aachen (Germany) and is currently full professor of condensed matter physics at the University of Genova (Italy), where he leads a joint research group on Surface Science with CNR-IMEM. His major scientific achievements are on gas-surface interaction, ultrathin film growth, surface phonons and acoustic surface plasmons.

Luca Vattuone

Dipt. di Fisica
Università di Genova and IMEM-CNR Unità di Genova
Genova, Italy
vattuone@fisica.unige.it

Luca Vattuone received his PhD from the University of Genoa in 1994, worked as postdoc at Cambridge University (1995) and at Genoa University (1996–1999). In 1999 he became Staff Researcher and in 2012 Associate Professor of Condensed Matter Physics at Genoa University. His research activity focuses on the experimental investigation of gas–surface interactions and surface plasmons.

37. Silicene

Eric Salomon, Daniel Beato-Medina, Paola De Padova, Thierry Angot, Guy Le Lay

We introduce silicene, the Si-based analog of graphene, an emerging two-dimensional topological insulator, and its realization by epitaxial growth on the favored silver (111) substrate. We describe the structural, electronic and vibronic properties of monolayer silicene, and the growth and electronic properties of multilayer silicene. We next address the hydrogenation and oxidation of these new silicon allotropes. We further report the fabrication of the first field-effect transistors made with a silicene channel. Finally, we discuss exotic forms of silicon at zero and one dimension, namely benzene-like nanodots and pentasilicene-like nanoribbons, before drawing enticing perspectives.

The 2016 Nobel Prize in Physics was awarded to David J. Thouless, F. Duncan M. Haldane and J. Michael Kosterlitz "for theoretical discoveries of topological phase transitions and topological phases of matter" [37.1]. The subject of this chapter, *silicene*, is a hallmark of an emerging new two-dimensional (2-D) topological state of quantum matter, an atom-thin 2-D elemental topological insulator (TI) characterized by the quantum spin Hall effect (QSHE) [37.2, 3]. It is made solely of silicon atoms arranged in a low-buckled honeycomb structure, as shown in Fig. 37.1 for freestanding silicene [37.4–6], similar to but different from graphene, which is basically flat [37.7].

Topological insulators represent a fascinating recently discovered class of quantum states of matter with insulating bulk but helical conducting surface or edge states. *Topological* refers to a mathematical concept that describes the invariant property of objects during an adiabatic evolution process. Typically, as pedagogical classical examples, an orange cannot be deformed continuously into a donut (with, per se, a hole), but you can transform a donut into a mug. The topology of an object is characterized by an integer associated with the integral of its curvature. A trivial insulator (like vacuum) has an integer value of zero; a TI (equivalently, a quantum spin Hall insulator (QSHI)) has a value of one.

It turns out that the quantum mechanical wave functions in momentum space of crystals have properties similar to the curvature of a donut. Within a bulk energy gap, TIs possess gapless boundary states, spin-locked due to the protection of the time-reversal symmetry: the propagation direction of the surface electrons is robustly linked to their spin orientation, as illustrated in Fig. 37.2.

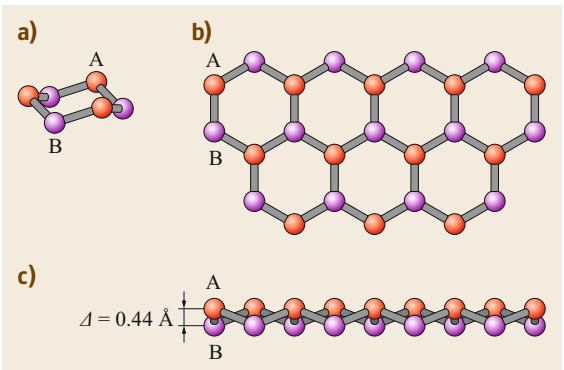

Fig. 37.1 (a) Perspective, (b) top and (c) side views of freestanding silicene. A and B represent the two sublattices, vertically displaced by $\Delta = 0.44$ Å, the buckling ►

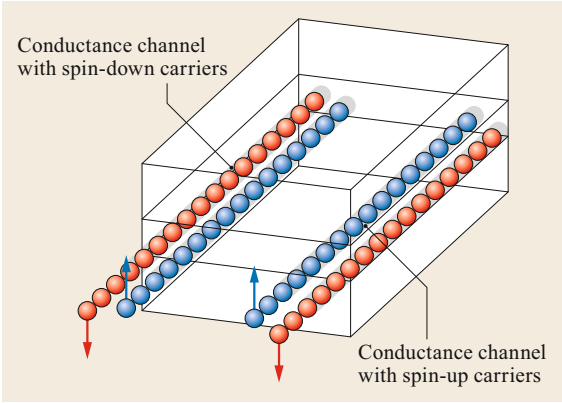

Fig. 37.2 Edge states in the quantum spin Hall insulator. Schemes of the spin-polarized edge channels (From [37.8]. Reprinted with permission from AAAS)

Graphene was the first material proposed to be such a QSHI governed by spin–orbit coupling (SOC) [37.10], opening a bandgap in such 2-D Dirac semimetals. It exemplified a theoretical toy model already proposed in 2-D honeycomb lattice systems by *Haldane* in 1988 [37.11]. However, the spin–orbit interaction in graphene is so weak ($\approx 10^{-3}$ meV) that the QSHE can only occur at unrealistically practical low temperatures, at variance with silicene, with a SOC gap value of 1.55 meV [37.3, 12], which makes it a robust TI up to ≈ 15 K.

As further stated by *Ma* and coworkers [37.13], 2-D TIs are immune to all the scattering of electrons in the presence of nonmagnetic impurities, leading to dissipation-less transport edge channels, while Majorana fermions, which besides their fundamental physical importance may play an important role in topological quantum computation schemes, should appear when the material comes in contact with a superconductor.

Moreover, as emphasized by *Persichetti* et al. [37.14], silicene, like graphene, is a Dirac material in which electrons near the K and K′ points of the Brillouin zone behave as relativistic massless particles because of the linear dispersion around the Fermi level. The velocity of the charge carriers, estimated to be of the order of 10^5–10^6 m/s [37.5], is also comparable to that in graphene. However, silicene (and germanene) shows peculiar physical properties that make it better suited than graphene in the race for ultimate thickness scaling of nanoelectronic devices [37.9]. Indeed, it offers perfect compatibility with the current Si-based technology of semiconductor processing, and more importantly, its buckled structure makes it more flexible than that of graphene because of the absence of strong π-bonds enforcing planarity. This buckling, along with the resulting much larger SOC, makes it easier to create a required energy bandgap in such a Si (and Ge) 2-D crystal without degrading its electronic properties.

As seen in Fig. 37.3, to pursue Moore's law, and to push scaling towards the 5 nm gate length in the fabrication of field-effect transistors (FETs), the use of low-dimensionality materials, especially channels based on *intrinsically* 2-D structures to mitigate so-called short channel effects and related power dissipation issues, could be imperative [37.9, 15].

Such reasons explain why, boosted by the first realizations of silicene in 2012 [37.16–18], the research on silicene has become the hottest front in physics after the Higgs boson, the neutrino and gravity ones, according to a Thomson Reuters citation-based study covering the years 2011 to 2014, as seen in Table 37.1.

In this chapter, we will present the basic concepts on silicene, its synthesis by epitaxial growth, the characterization of its structural, electronic and vibrational properties on the favored silver (111) template, and then the growth and electronic properties of multilayer silicene. Next, we will address the hydrogenation and oxidation of these Si-based nanostructures and the fabrication of the first FETs made with a silicene channel. Finally, novel exotic forms of low-dimensional silicon will be described, before drawing conclusions and offering intriguing perspectives.

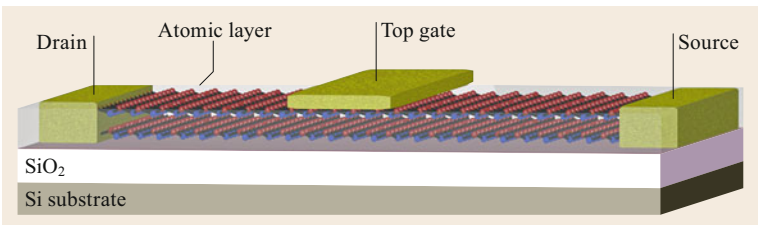

Fig. 37.3 The reduction of the channel thickness is at the center of the nanoelectronic device scaling scenario. Ultimate thickness downsizing with atomically thin layers could be one of the most important options for aggressive scaling beyond the 5 nm technology node, offering excellent electrostatic control (From [37.9] © IOP Publishing. 37.1 The Concept: Freestanding Silicene

Ten years before the isolation of graphene, two pioneers had already shown, through density functional theory (DFT) calculations, the "possibility of stage corrugation in Si and Ge analogs of graphite" [37.4], in other words of freestanding silicene, so coined in 2007 [37.5], and germanene, the germanium counterpart. The stability of the low-buckled structure with respect to phonons was demonstrated in 2009 [37.6], together with the cone-like dispersion of the π and π^* states near the Fermi level at the corners of the 2-D Brillouin zone, as shown in Fig. 37.4. For silicene, the 0.44 Å buckling corresponds to a bond angle of $\theta = 116.2°$, which gives a sp^D degree of hybridization ($D = -1/\cos(\theta) = 2.27$) closer to sp^2, as in graphene, than to sp^3 in normal crystalline silicon [37.20].

For nearly two decades, until the very first synthesis of silicene on Ag(111) in 2012 [37.16], practically no one believed in the possibility of graphene-like silicon: a spectacular illustration is given in Fig. 37.5, which shows, according to the Web of Science (WOS), upon searching for silicene for the period from 2007, when the term silicene was introduced [37.5], to the end of November 2016, a sudden jump in the number of papers and citations in 2012/2013.

As underlined in the introduction, the SOC opens a bandgap at the Dirac point of silicene and its group 14 cousins, namely germanene and stanene (also sometimes called tinene), which exhibit SOC of respectively 1.55, 23 and 73 meV (compared with only 8 μeV for graphene), facilitating the 2-D material transition from semimetallic to a QSH insulator [37.21, 22]. Other properties are worth mentioning. We stress, to name a few, the electrically tunable bandgap [37.23], a possibility of phonon-mediated superconductivity [37.24], and the predicted very high mobility for both electrons and holes (μ_e and μ_h) at room temperature (RT), as shown in Table 37.2 [37.25].

37.2 Silicene Synthesis and Characterization

The first synthesis of silicene on a silver (111) single-crystal surface proceeds from earlier investigations of the inverse system, namely Ag/Si(111), during the study of the growth mechanisms of the noble metal/semiconductor heterostructures, i.e., Ag, Au/Si(111), Ge(111), as illustrated in Fig. 37.6. Ag/Si(111) is the most prototypical system, growing in the Stranski-Krastanov mode. The interface is atomically abrupt, and, past the formation of a Si(111)-$(\sqrt{3}\times\sqrt{3})$R30° 2-D superstructure, three-dimensional Ag(111) islands develop in parallel epitaxy with a *magic* relationship: four Ag–Ag nearest-neighbor distances in the Ag(111) contact plane matching nearly exactly three Si–Si nearest-neighbor distances within the Si(111) surface plane [37.26]. This inspired the idea to try to grow silicene the other way around.

Success came when depositing Si onto a Ag(111) surface held at about 200 °C. Such a process results in the observation of a highly ordered 2-D layer, with the aspect of a very nice *flower pattern* in scanning tunneling microscopy (STM) imaging, which did not appear directly at all as a graphene-like arrangement but which could be interpreted as revealing a hidden honeycomb structure (Fig. 37.7).

Table 37.2 Predicted mobility at 300 K (10^5 cm^2/V s) along the zigzag and armchair directions (Reprinted by permission from [37.25], © RSC 2014)

Material	Electron mobility	Hole mobility
Graphene	3.39	3.22
	3.20	3.51
Silicene	2.58	2.23
	2.57	2.22
Germanene	6.09	6.39
	6.24	6.54

Typically, three unit lattice vectors of silicene matched perfectly four unit lattice vectors of the Ag(111) surface, forming a Ag(111)-(4×4) reconstruction with respect to the silver substrate, but a puckered (3×3) superstructure in terms of silicene. In a seminal paper published in 2012, we name this archetype, most energetically favorable silicene phase, in short, $(3\times3)/(4\times4)$ [37.16]. A linearly dispersing band, with possibly a gap opening, was measured in angle-resolved photoelectron spectroscopy (ARPES) experiments at the K/K′ points of the surface Brillouin zone and thence eventually assigned to a branch of a Dirac cone. Later, however, it was shown to be a hybridized band resulting from a significant interaction of the monolayer silicene sheet with the Ag(111) surface [37.27–29].

The $(3\times3)/(4\times4)$ silicene phase on Ag(111) was soon confirmed [37.17]. Further diffraction studies by reflection high-energy positron diffraction (RHEPD) showing that 95% of the surface of the substrate was covered by this unique structure [37.30], by dynamical low-energy electron diffraction (LEED) [37.31], and lastly by grazing incidence x-ray diffraction [37.32], firmly established the proposed atomic geometry, initially proposed by Vogt et al., following DFT calculations [37.16].

Other superstructures are formed on the Ag(111) surface at higher temperatures. A $(\sqrt{7}\times\sqrt{7})/(\sqrt{13}\times$

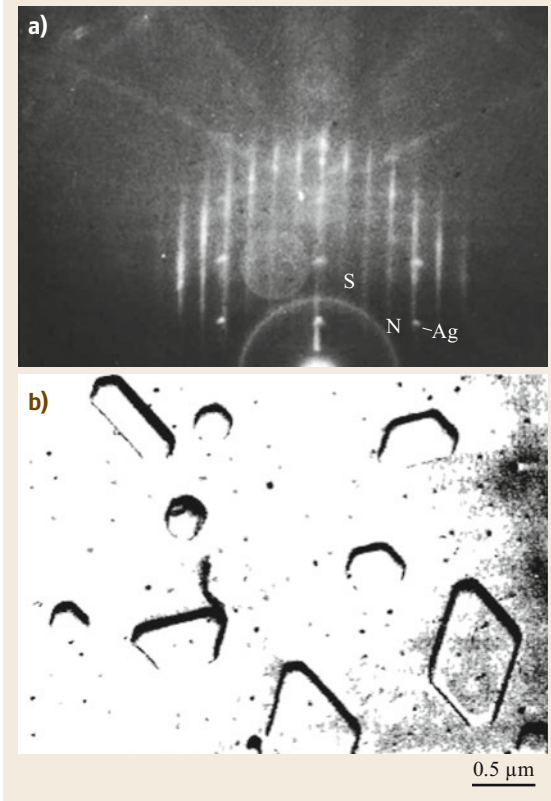

Fig. 37.6a,b Ag(111) crystallites in parallel orientation on the Ge (or, similarly, Si). **(a)** (111)-$(\sqrt{3}\times\sqrt{3})$R30°-Ag surface superstructure detected in situ by reflection high-energy electron diffraction (RHEED): pattern along the $\langle 11\bar{2}\rangle$ azimuth (*N*: normal substrate streaks, *S*: 1/3 order superstructure streaks). **(b)** In situ-prepared carbon replica observed ex situ after extraction in HF solution by transmission electron microscopy (TEM): one observes the imprints of (111) Ag crystallites, which have been attacked by HF, on the Si(111) substrate (Reprinted from [37.26], with permission from Elsevier)

$\sqrt{13}$) one, using the same notation convention as for the $(3\times3)/(4\times4)$ phase, is also a slightly expanded silicene phase, existing by symmetry in four equivalent domains as depicted by *Resta* et al. [37.33] and shown in Fig. 37.8.

Interestingly, at low temperatures, a vortex-like appearance is manifested in such domains upon STM imaging (Fig. 37.9) [37.34]. Still, the continuity of the honeycomb array is preserved, but with very different local buckling configurations [37.35]. We tentatively assign this spectacular behavior to the very different thermal expansion coefficients of the silver substrate, which behaves normally upon cooling from the growth temperature of ≈ 493 to ≈ 4 K, and that of the silicene overlayer, initially slightly stretched, which most probably possesses a negative thermal expansion coefficient at low temperatures [37.36], and consequently behaves like a synergetic combination of silicon atoms and graphene-like structure, both silicon and graphene having negative thermal expansion coefficients. Then, the vortex pattern would result from a complex buckling relaxation process of the strain accumulated upon cooling.

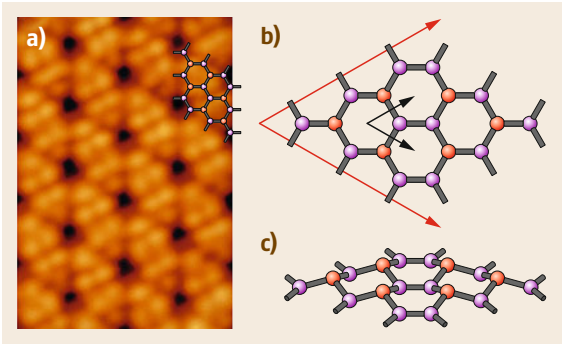

Fig. 37.7 **(a)** The *flower pattern* appearance of the archetype $(3\times3)/(4\times4)$ silicene phase formed on Ag(111) at $\approx 200\,^{\circ}$C. **(b)** Top and **(c)** perspective views of the atomic structure of the puckered silicene sheet

A distorted 2-D sheet forming a pseudo "$(2\sqrt{3}\times 2\sqrt{3})$" reconstruction with respect to the Ag(111) substrate, with local honeycomb appearance in STM imaging, is covering most of the surface at high temperatures [37.37]. It is at the verge of a dewetting process with formation of three-dimensional (3-D) silicon crystallites [37.38], and might possibly correspond to a surface alloy [37.39].

Just two months after the publication of the seminal paper on the archetype $(3\times3)/(4\times4)$ silicene phase on Ag(111), another important silicene phase, formed this time by segregation of Si atoms through a metallic ZrB2 thin film epitaxially grown on a Si(111) template, was reported [37.18]. This is a $(\sqrt{3}\times\sqrt{3})$ reconstructed silicene monolayer matching a (2×2) reconstructed ZrB2 (0001) surface; in our notation it is a $(\sqrt{3}\times\sqrt{3})/(2\times2)$ phase. Such a $(\sqrt{3}\times\sqrt{3})$ silicene reconstruction, now matching a $(\sqrt{7}\times\sqrt{7})$ supercell, i.e., a $(\sqrt{3}\times\sqrt{3})/(\sqrt{7}\times\sqrt{7})$, was also found on an iridium (111) surface [37.40]. Later, 2-D Si nanosheets with local hexagonal structure were reported on a MoS_2 surface [37.41]. However, the very high buckling, leading to a metallic nature, makes an assignment to silicene questionable. Instead, the formation of germanene on the same substrate appears more reliable [37.42]. Clearly, the growth of silicene (and germanene or stanene) on a semiconductor or an insulator is highly desirable for practical applications

in electronics. Yet, even though predictions have been made on the stability of van der Waals (vdW) heterostructures made of silicene, germanene or stanene with hexagonal boron nitride (h-BN) [37.43], such hybrid structures have not been convincingly realized until now.

37.3 Multilayer Silicene

Beyond the first $(3\times3)/(4\times4)$ monolayer (ML), at the same growth temperature of $\approx 200\,°\text{C}$, a layered arrangement in successive flat terraces is observed, as displayed in Fig. 37.10 [37.44]. All terraces possess the apparently same $(\sqrt{3}\times\sqrt{3})\text{R}30°$ reconstruction with respect to freestanding silicene seen in the corresponding LEED pattern. Topographic profiles recorded on the $(\sqrt{3}\times\sqrt{3})\text{R}30°$ reconstruction point to a periodic lattice constant of $0.64\pm0.01\,\text{nm}$, meaning that there is in reality a $\approx 4\%$ contraction of the reconstructed cell with respect to $(\sqrt{3}\times\sqrt{3})$ times that of the unit cell of freestanding silicene [37.44–46].

Profiles along the dashed white lines in the figure also indicate a step height between successive terraces, from the second to upper ones, of $\approx 0.3\,\text{nm}$. If growth is performed at slightly higher temperatures, where the first ML shows an admixture of $(3\times3)/(4\times4)$ and $(\sqrt{7}\times\sqrt{7})/(\sqrt{13}\times\sqrt{13})$ phases, the next layers still possess the $(\sqrt{3}\times\sqrt{3})$ reconstruction, but with different orientations, as seen in Fig. 37.11 [37.47]. These orientations follow those of the domains of the initial first ML already displayed in Fig. 37.8. It is thus likely that each first layer within each domain is reconstructed upon growth of the second and further layers on top of it.

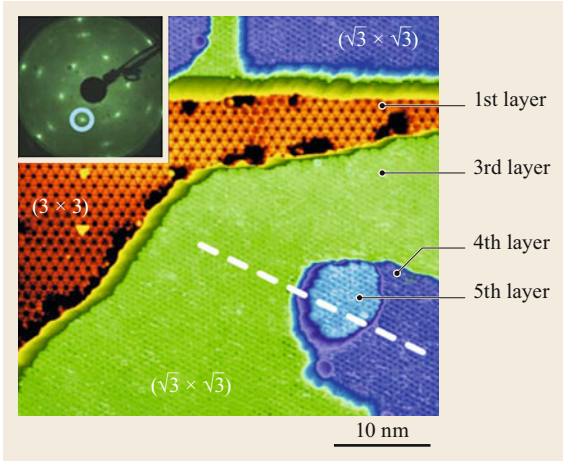

Fig. 37.10 STM topographic image ($44 \times 44\,\text{nm}^2$, $U_{\text{bias}} = -1.14\,\text{V}$, $I = 0.54\,\text{nA}$), after deposition of several MLs of Si onto the $(3\times3)/(4\times4)$ first-layer silicene sheet. Three well-ordered terraces can be seen showing the $(\sqrt{3}\times\sqrt{3})\text{R30}^\circ$ arrangement. The first $(3\times3)/(4\times4)$ silicene layer is still visible at the bottom. *Top-left inset*: corresponding LEED pattern clearly dominated by the $(\sqrt{3}\times\sqrt{3})\text{R30}^\circ$ spots (Reprinted from [37.44], with the permission of AIP Publishing)

The actual nature of the $(\sqrt{3}\times\sqrt{3})$ reconstruction of multilayer silicene has been, and still is, in strong debate. On the one hand, several groups state that the so-called multilayer silicene is just a Si(111) thin film grown with silver atoms at its very surface acting as a surfactant [37.48–51]. Then the $(\sqrt{3}\times\sqrt{3})$ structure would be just the well-known Si(111)-$(\sqrt{3}\times\sqrt{3})\text{R30}^\circ$-Ag surface reconstruction completed at 1 ML coverage, represented by the honeycomb-chained-triangle (HCT) model at room temperature (Fig. 37.12a,b), following dynamical fluctuations of the most energetically favorable inequivalent triangle (IET) configuration obtained at low temperatures [37.52].

On the other hand, the first ARPES measurements obtained by *De Padova* et al. on a multilayer silicene exhibit a cone-like band structure and a reported Fermi velocity of $0.3\times10^6\,\text{m s}^{-1}$, a value much lower than the $1.3\times10^6\,\text{m s}^{-1}$ measured in the case of Si(111)-$(\sqrt{3}\times\sqrt{3})\text{R30}^\circ$-Ag [37.54, 55]. Also, several STM measurements showed that the in-plane lattice parameter of multilayer silicene (around 6.4 Å) is a few percent smaller than the expected one for the Ag-terminated Si(111) surface reconstruction (6.65 Å) [37.47, 53, 56–59]. Furthermore, a very recent work performed by *Li* et al., and based on scanning tunneling microscopy and spectroscopy as well as Raman spectroscopy, demonstrates that a silicene multilayer can be grown with an atomically resolved buckled honeycomb structure (Fig. 37.12c,d), excluding the possibility of a Ag-terminated Si(111) surface [37.53]. Hence, the controversial sets of data raising the question about the possibility of growing a new layered silicon allotrope were clarified.

Finally, the issue was recently solved by *De Padova* et al. [37.46], who carried out energy-dispersive grazing incidence x-ray diffraction (ED-GIXRD) and Raman spectroscopy measurements comparing multilayer thin films to Si(111)-$(\sqrt{3}\times\sqrt{3})\text{R30}^\circ$-Ag samples used as a reference.

Figure 37.13 displays a summary of the ED-GIXRD data recorded for three different samples. In the case of the $(\sqrt{3}\times\sqrt{3})$ multilayer film grown at $\approx 200\,^\circ\text{C}$, the first-order in-plane reflection appears at $q_{xy} = 0.970 \pm 0.005\,\text{Å}^{-1}$, demonstrating a cell size of the multilayer film of 6.477 ± 0.015 Å, in fair agreement with the STM determination. Interestingly, in the case of both the film grown at 300 °C and the Si(111)-$(\sqrt{3}\times\sqrt{3})\text{R30}^\circ$-Ag sample, the in-plane first-

order reflection appears at $q_{xy} = 0.944 \pm 0.005\,\text{Å}^{-1}$, i.e., a cell size of 6.655 ± 0.015 Å. All this demonstrates that the multilayer film grown at low temperature possesses an in-plane lattice parameter markedly different from and smaller than that of a usual diamond-type Si(111) arrangement, whether terminated by a Si(111)-($\sqrt{3} \times \sqrt{3}$)R30°-Ag superstructure or even by an intrinsic Si(111)-($\sqrt{3} \times \sqrt{3}$)R30° reconstruction ($a_{\text{Si(111)-}\sqrt{3}} = 6.655 \pm 0.015$ Å) [37.60, 61]. Hence, these measurements, along with a systematic shift of the main Raman peak with respect to Si(111)-($\sqrt{3} \times \sqrt{3}$)R30°-Ag, have demonstrated the existence, in this low-temperature growth regime, of a new layered metastable structure of silicon, which we call multilayer silicene [37.44, 46]. If, instead, growth is performed at higher temperatures approaching 300 °C, diamond-type Si(111) crystallites terminated by the Si(111)-($\sqrt{3} \times \sqrt{3}$)R30°-Ag superstructure are effectively formed [37.48, 62–65].

Hence, the conflicting issues described above are somehow reconciled: whether multilayer silicene is formed on Ag(111) substrates depends crucially on the actual growth temperature, a parameter which is, unfortunately, often not very well controlled. This is also observed during annealing experiments. An in situ Raman spectroscopy study clearly demonstrates that a structural phase transition from epitaxial $(3 \times 3)/(4 \times 4)$ silicene takes place at ≈ 300 °C (Fig. 37.14) [37.66], in agreement with earlier results [37.37, 67].

This is obvious from the disappearance of the A modes found at 175 and 216 cm^{-1}, as well as the E mode found at 514 cm^{-1} at RT described in [37.68] and

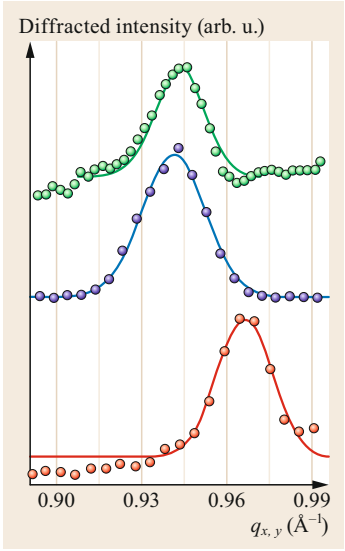

Fig. 37.13 ED-GIXRD pattern recorded from a $(\sqrt{3}\times\sqrt{3})$ multilayer film (10 ML in thickness) grown on Ag(111) at $\approx 200\,^{\circ}$C and Gaussian fits (*bottom*), $(\sqrt{3}\times\sqrt{3})$ multilayer film (10 ML in thickness) grown on Ag(111) at $\approx 300\,^{\circ}$C and Gaussian fits (*middle*) and Si(111)-$(\sqrt{3}\times\sqrt{3})$R30°-Ag and Gaussian fits (*top*)

its replacement by a dominant L(T)O bulk silicon mode at 520 cm^{-1}, due to the formation of Si 3-D crystallites observed by atomic force microscopy (AFM).

Here it is worth mentioning that a single-domain epitaxial monolayer silicene sheet with $(\sqrt{3}\times\sqrt{3})$ structure was recently obtained on $ZrB_2(0001)$ templates [37.69]. As could be anticipated, further growth on top generated pure $(\sqrt{3}\times\sqrt{3})$ layered films, indeed, without the issues raised with the Ag(111) substrates [37.70].

37.4 Functionalization and Encapsulation

The intrinsic low buckling in freestanding silicene preserves the massless Dirac fermion character of the charge carriers and their extremely high mobility. Yet, SOC and symmetry breaking of the A and B sublattices (Fig. 37.1), as well as reconstructions, which are observed until now on all metallic substrates, can eventually open a bandgap. Indeed, the opening of a bandgap is further facilitated by the reactivity of silicene due to its buckled or puckered structures, with intermediate sp^2/sp^3 hybridizations. A striking example is given by the in situ hydrogenation of the $(3\times3)/(4\times4)$ monolayer phase on Ag(111). Figure 37.15 displays an STM image of monolayer silicene after atomic hydrogen exposure [37.71]. Interestingly, upon hydrogen adsorption, the $(3\times3)/(4\times4)$ periodicity is preserved, but the symmetry between the two rhombi halves is broken, as depicted in Fig. 37.15.

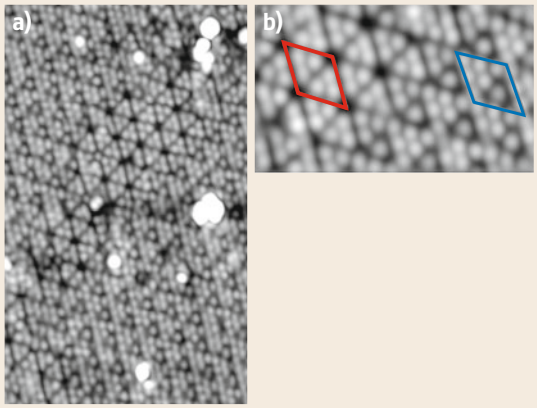

Fig. 37.15 **(a)** 11 nm × 18 nm STM image of $(3\times3)/(4\times4)$ silicene exposed to cracked molecular hydrogen at room temperature for 480 s; $I_{tunnel} = 0.55$ nA, $U_{bias} = -515$ mV (filled states). **(b)** 4 nm × 7 nm zoom-in; the asymmetric unit cell is enclosed in the *blue rhombus*, while the symmetric one is highlighted by the *red rhombus*

In effect, a new reconstruction, labeled γ-(3×3), formed by the repetition of asymmetric unit cells (see the blue rhombus in Fig. 37.15a) is visible. Their minor diagonals split those rhombi into two different triangles. One of them is entirely occupied by six bright protrusions, whereas the other one only displays one bright protrusion located at its center. The explanation behind the new structure probably relies on modified buckling and would be evidence of a structural phase transition from the silicene-(3×3)-α phase to the silicene-(3×3)-β phase, more stable after hydrogenation, as first demonstrated by *Qiu* et al. [37.72]. In addition, let us mention that upon adsorption, the surface corrugation increased by approximately 10 pm, reflecting a modification of the Si buckling [37.71].

Another stimulating point is that for relatively high hydrogen exposure doses, the surface can be fully passivated with respect to oxidation, as demonstrated by high-resolution electron energy-loss spectroscopy (HREELS) measurements. As exhibited in Fig. 37.16, the HREELS spectrum of silicene exposed to low doses of hydrogen (60 s) is dominated by peaks at 98 meV (790 cm^{-1}) and 249 meV (2009 cm^{-1}), which can be readily attributed to the Si–O and Si–H stretching, respectively. This demonstrates that the silicene-(3×3)

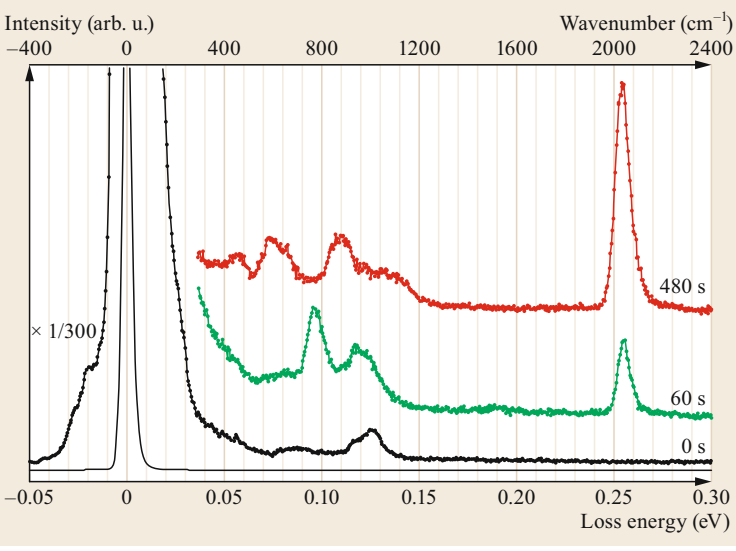

Fig. 37.16 HREELS spectra of hydrogenated monolayer $(3\times3)/(4\times4)$ silicene for different exposure times to atomic hydrogen

surface is reactive and could easily be contaminated during the experiment. On the other hand, after a longer exposure time (480 s) to hydrogen, the spectrum no longer exhibits peaks related to the Si–O, but only the Si–H modes [37.71]. This shows that the silicene-(3×3) can be fully passivated and that it is possible to protect it from contamination, or at least oxidation, through exposure to atomic hydrogen.

Controlled hydrogenation or halogenations should allow bandgap tuning and, furthermore, could lead to ferromagnetic properties [37.73–75]. Indeed, the tuning of a sizable energy gap is on the wish list to push Moore's law beyond the 5 nm node, where 2-D material channels most likely will become indispensable [37.9, 76].

Regarding oxidation, on the one hand, *Du* et al. reported a quasi-freestanding silicene layer that could be successfully obtained through oxidization of bilayer silicene on the Ag(111) surface, the oxygen atoms intercalating into the underlayer silicene, resulting in isolation of the top layer of silicene from the substrate [37.77]. On the other hand, thicker multilayer silicene films were shown by *De Padova* et al. to be resistant to ambient air exposure for at least 24 h: protected by an ultrathin native-oxidized skin, the rest of the body underneath is fully protected [37.78].

Although not as resistant, monolayer epitaxial silicene on Ag(111) can be efficiently preserved by Al- and Al_2O_3-based encapsulation [37.79].

37.5 Devices

The encapsulation of the first silicene layer has been crucial for the successful fabrication of the first-ever field-effect transistors with ambipolar characteristics based on a monolayer silicene channel and operating at room temperature [37.80]. This achievement was made possible by the smart fabrication process depicted in Fig. 37.17.

Remarkably, the derived mobility of the charge carriers for both electrons and holes was about $100\,cm^2\,V^{-1}\,s^{-1}$, which is quite low compared with estimated intrinsic values for freestanding silicene ($\approx 10^5\,cm^2\,V^{-1}\,s^{-1}$) [37.25]. However, it is of the same order of magnitude as the carrier mobility in single-layer MoS_2 [37.81], which suggests that the devices are promising candidates for 2-D transistors. The low mobility is attributed to strong scattering from acoustic phonons and to grain boundary scattering.

It was emphasized that plenty of room remained to achieve higher mobility and better device performance, for example by optimizing silicene growth, engineering and characterizing the interfaces, and tuning and enlarging the bandgap (e.g., by surface adsorption), fabricating and protecting the monolayer silicene gate (which is exposed to air in the present devices), and probably using multilayer instead of monolayer silicene [37.82]. It turns out that in the last case, mobility twice as large was obtained, $\approx 200\,cm^2\,V^{-1}\,s^{-1}$, but somewhat to the detriment of the I_{On}/I_{Off} ratio because of the semimetallic Dirac character of the material [37.83].

In spintronics, exciting possibilities have been proposed. One is the design for a silicene-based spin filter that should enable the spin-polarization of an output current to be switched electrically, without switching external magnetic fields [37.84]. Another one suggests very promising applications by edge-state manipulations, leading typically to a giant magnetoresistance and a perfect spin filter [37.85].

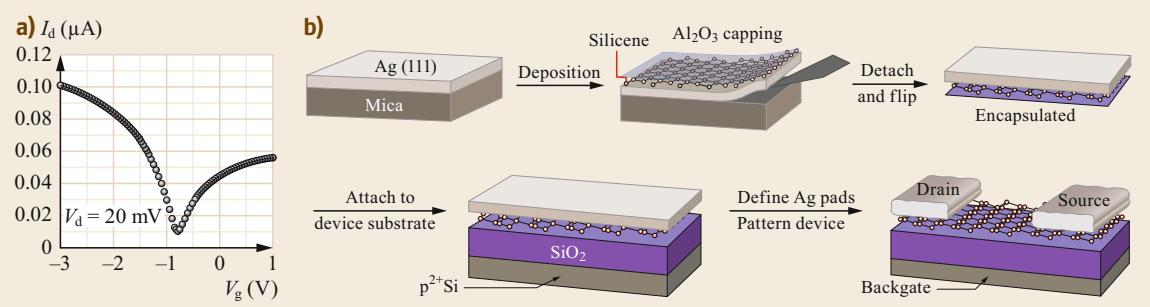

Fig. 37.17 **(a)** The transfer characteristics of a back-gated field-effect transistor with a silicene channel exhibiting ambipolar behavior. **(b)** Schematic of the fabrication process of the silicene device with source/drain contacts defined in the native silver film (From [37.80])

37.6 Exotic Forms of Silicon in Zero and One Dimension

When using a silver (110) substrate exposing a lower-symmetry surface with a rectangular 1×1 unit cell to deposit a submonolayer amount of silicon at room temperature, one obtains two types of perfectly defined novel Si nano-objects, whose atomic structures have remained elusive for more than a decade. As seen in Fig. 37.18, identical zero-dimensional Si nanodots (SiNDs) coexist with an ensemble of highly perfect, massively parallel one-dimensional Si nanoribbons (SiNRs) with the same width of just 0.8 nm, all aligned along the $[1\bar{1}0]$-direction of the surface. While the SiNDs possess the symmetry of the (110) surface, the SiNRs obviously break this symmetry, showing a $\times 2$ reconstruction along the $[1\bar{1}0]$-direction, but with a glide shift of their two rows of protrusions.

Recently, thorough DFT calculations have unveiled the hidden atomic structures [37.86]. The SiNDs sit on two Ag vacancies and consist of a hexasilabenzene-like molecule to which 4 Si atoms are symmetrically attached, as shown in Fig. 37.19. Here we stress that to the best of our knowledge, a hexasilabenzene molecule, i.e., the silicon analog of benzene, has never been synthesized up to now.

The presence of the two vacancies points to the propensity of the noble metal (110) surfaces to reconstruct. Typically, the Au(110) surface is spontaneously reconstructed with a 2×1 superstructure explained by a missing row model, while Ag(110) is unreconstructed, but just at the verge of a missing row reconstruction [37.87]. Each SiNR generates such a missing row by changing the silver surface free energy. It is lying over the missing row with a unique, striking arrangement of Si pentagonal tiles, creating an unprecedented strip of pentasilicene, which we named a single strand, as seen in Fig. 37.20. Again, to the best of our knowledge, this is the first time that a pentasilicene-like structure, i.e., of the Si counterpart of a strip of pentagraphene [37.88], has been synthesized. Remarkably, the amazing atomic arrangement theoretically proposed for the single-strand SiNRs was very rapidly confirmed by synchrotron radiation grazing incidence x-ray diffraction measurements on a highly perfect array of double-strand SiNRs, all 1.6 nm in width [37.89], obtained by lateral compaction of single-strand ones upon deposition (or annealing) at $\approx 200\,^{\circ}\mathrm{C}$, realizing a 5×2 grating with a pitch of just 2 nm [37.90].

Finally, let us quickly mention that several works have reported on the functionalization of SiNRs using atoms or molecules. While adsorption of atomic hydrogen results in an etching of the surface, adsorption of molecules appears to modify the electronic properties of the SiNRs by opening a bandgap depending on the molecular species [37.91–94]. These results, in different ways, appear to be potentially interesting from the perspective of future nanoelectronic devices.

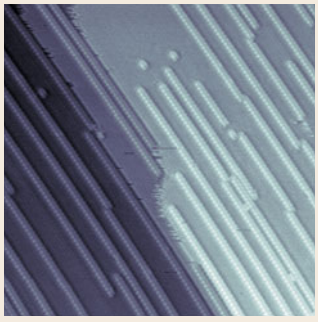

Fig. 37.18 40 nm × 40 nm STM image of a collection of Si nanoribbons with sparse Si nanodots upon deposition of Si onto the Ag(110) at room temperature. $I_{\mathrm{tunnel}} = 0.35$ nA, $U_{\mathrm{bias}} = -50$ mV (filled states)

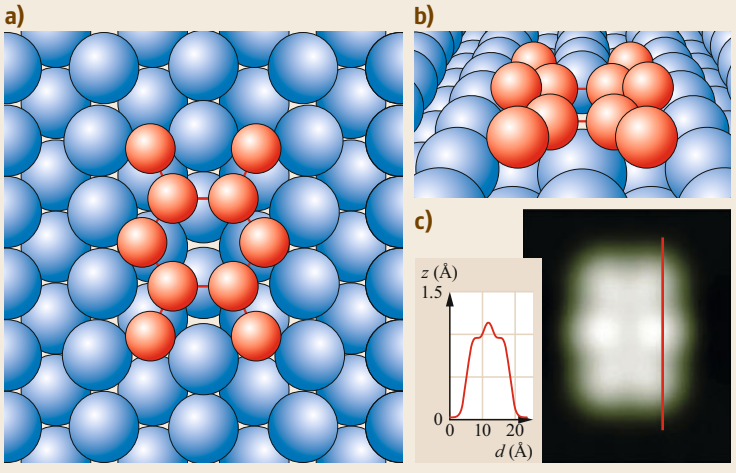

Fig. 37.19 (a,b) Top and perspective views of the nanodot structure with 2 Ag vacancies. (c) Simulated STM topographic image and line profile along the *solid line* (From [37.86])

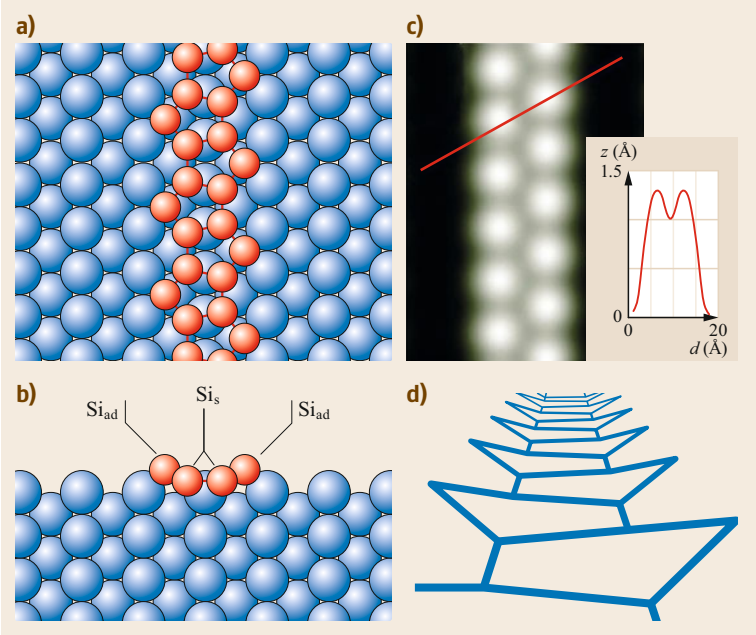

Fig. 37.20a–d Optimized geometry of the pentagonal missing row model. **(a–c)** Top, side and simulated topographic STM image for the SiNR phase prepared at room temperature. **(d)** Perspective view of a pentasilicene strand without the silver surface. (From [37.86])

37.7 Perspectives and Conclusion

Beyond graphene, which descends from graphite, researchers have initially looked for existing semiconductor lamellar crystals that could be peeled to the ultimate monolayer limit, typically transition metal dichalcogenides. The first fabrication of a transistor with a 2-D single-layer MoS_2 channel was realized in 2011 [37.81]. Next, black phosphorus, a layered elemental P allotrope, was rediscovered [37.95], leading to high-performance field-effect transistors based on few-layer crystals with thickness down to a few nanometers [37.96].

However, it was only in 2012 that the first artificial elemental analog of graphene, namely silicene, was synthesized [37.16–18]. Soon after, boosted by this discovery, a cornucopia of novel elemental synthetic 2-D materials including germanene, stanene, plumbene, borophene, blue phosphorene, arsenene, antimonene and bismuthene were shown to possibly exist, and have been eventually realized [37.97]. Strikingly, just three years after the advent of silicene, the first FETs with a monolayer silicene channel were fabricated [37.80].

All this opens exciting prospects, indeed, especially for silicene, and the group 14 novel synthetic 2-D materials, which are directly compatible with the Si-based electronics industry [37.98]. Because these emerging artificial elemental 2-D materials are so young, their properties and potential applications are barely explored [37.99]. Yet, we think that several of them are meant for a bright future, as they will offer fascinating prospects for future nanoelectronics, optoelectronics, spintronics, for quantum computing and flexible devices.

Will one of them be the next silicon? Silicene, the novel 2-D silicon allotrope, and its elemental cousins are clearly in the race.

thierry.angot@univ-amu.fr

Thierry Angot is Professor at Aix-Marseille University. He has worked in the field of surface science for more than 25 years, with a particular interest in the interaction of hydrogen (atoms, ions and plasmas) with metal surfaces, semiconductors and 2-D materials.

Guy Le Lay

PIIM CNRS Campus de Saint-Jérôme
Aix-Marseille University
Marseille, France
guy.lelay@univ-amu.fr

Guy Le Lay, Professor, Aix-Marseille Université, PIIM-CNRS Laboratory, graduated as an Engineer from the School of Mines in Nancy (France) in 1968, and in Marseille (France) received two Doctorates, one in Engineering and one in Physics at the University of Provence, in 1972 and 1977, respectively. He was the French PI of the European Collaborative Project "Two-Dimensional Nanolattices", and in Marseille pioneered the first synthesis of silicene.

38. Cluster-Assembled Carbon Thin Films

Luca Giacomo Bettini, Massimiliano Galluzzi, Alessandro Podestà, Paolo Piseri, Paolo Milani

The supersonic cluster beam deposition (SCBD) of neutral carbon clusters produced in a pulsed microplasma cluster source (PMCS) is an effective technique for producing nanostructured carbon (nsC) thin films with controlled nanostructures. The use of carbon clusters as building blocks allows the synthesis of carbonaceous materials with structural properties that are determined not only by the characteristics of the clusters but also by their organization upon deposition. NsC films produced by SCBD/PMCS grow in a ballistic deposition regime where incoming particles land on the growing interface and do not diffuse significantly. This growth regime leads to remarkable statistical scale invariance of the evolving interface at which the carbon clusters aggregate in larger and larger superunits. Due to negligible stress accumulation during the low-energy deposition process, nsC films with thicknesses of between a few tens of nanometers and a few micrometers can be routinely deposited onto and will adhere to almost any kind of surface. This deposition approach enables the production of carbon thin films characterized by low density, high surface roughness, and high porosity, making them promising materials for use in the fabrication of devices such as electrolyte-gated transistors, supercapacitors, and photocatalytic systems for sustainable energy technologies.

Carbon is one of the most versatile elements. Its valence atomic orbitals can hybridize into alternative orbitals (commonly known as sp^1, sp^2, and sp^3 hybrid orbitals), and it can aggregate in many different allotropic forms exhibiting a variety of different physicochemical properties [38.1, 2]. Besides the bulk forms of sp^2- and sp^3-bonded carbon atoms, i.e., graphite and diamond, there are a vast number of intermediate forms of carbon in which sp^1-, sp^2-, and sp^3-hydridized carbon coexist, such as fullerenes, graphene, carbon nanotubes, and carbynes [38.1, 3].

Carbon-based materials fabricated by assembling carbon nanoobjects (nanostructured carbons) are considered among the most promising systems for a wide variety of applications, ranging from energy production and storage to catalysis and biomedicine [38.4, 5]. The increasing use of nanostructured carbons in real-world applications is due mainly to their high surface area, nanoscale porosity, chemical inertness, and low cost [38.6].

The need for nanostructured carbons with optimized characteristics integrated into complex devices calls for the development of synthesis technologies that enable not only the fabrication of materials with tailored nanostructures but also the deposition of nanostructured carbons in the form of thin films, as this allows nanostructured carbons to be integrated into platforms produced with planar fabrication methods.

Supersonic cluster beam deposition (SCBD) is a versatile bottom-up approach for the synthesis of cluster-assembled nanostructured carbon (nsC) thin films with controlled structural properties [38.3, 7, 8]. Depositing clusters from a supersonic beam makes it possible to grow nanostructured materials in which the physicochemical properties of the pristine clusters are preserved [38.9]. This *memory effect* is ob-

tained when the kinetic energy of the clusters in the supersonic molecular beam is low enough to avoid significant structural reorganization upon deposition but high enough to activate cluster bonding to the substrate and prevent cluster diffusion. In this low-energy cluster beam deposition regime, the growth of thin films can be viewed as the random stacking of particles (just as for ballistic deposition), leading to materials that exhibit granular and porous nanostructure and low density [38.10].

38.1 Supersonic Cluster Beam Deposition

The supersonic cluster beam deposition (SCBD) of carbon clusters produced in the gas phase is a well-established approach for the production of carbon thin films [38.3, 7, 11, 12]. Owing to the so-called memory effect, the meso- and nanostructure of the resulting thin films are reminiscent of those of the free clusters [38.3, 7, 11, 12]. Moreover, the ballistic deposition regime typical of the SCBD process enables the growth of nsC with high porosity and surface corrugation, low density, and well-controlled thickness [38.7, 11, 13, 14].

The growth of nsC thin films using SCBD is typically achieved using two differentially evacuated chambers operating in the high-vacuum regime, as depicted in the sketch shown in Fig. 38.1a. The deposition process involves four main steps: (i) carbon cluster formation, (ii) cluster extraction, (iii) cluster transport, and (iv) cluster deposition [38.7, 11, 12, 14, 15]. The carbon clusters are typically produced in a pulsed microplasma cluster source (PMCS) coupled to the SCBD apparatus, as shown in Fig. 38.1a [38.7, 15]. The PMCS, which is presented schematically in Fig. 38.1b, is a cluster source based on the pulsed vaporization of bulk electrodes. In order to form carbon clusters, a rod of the graphite to be vaporized is inserted into the small cavity inside the ceramic body of the PMCS. A pulsed valve injects an inert gas such as helium into the cavity to promote an electrical discharge between the cathode (i.e., the graphitic rod) and a copper anode placed inside the source. The discharge, driven by a high-voltage pulse (typically between 600 and 800 V), lasts 60–90 ms and results in the ablation of a very small region of the graphite target. The gas-phase carbon atoms from the sputtered target are then quenched by collisions with the helium gas, nucleate, and condense inside the cavity of the source, forming an aerosol of carbon clusters that is eventually transported out of the PMCS in a seeded supersonic expansion [38.11, 14]. The separation effects attainable in aerosol flow dynamics permit the cluster size distribution produced in the PMCS to be refined, and the particles are concentrated by a series of aerodynamic lenses [38.11, 12, 14]. After passing through the aerodynamic focusing system, the carbon cluster aerosol undergoes supersonic free-jet expansion and enters the expansion chamber, forming a molecular beam. Finally, the central part of the beam is selected by a skimmer and eventually reaches a substrate placed on the sample holder in the deposition chamber [38.11, 14].

38.2 Surface Morphology of Cluster-Assembled Carbon Thin Films

Figure 38.2a shows a representative topographic map, acquired by atomic force microscopy (AFM), of a nsC film of thickness 220 nm (the thickness is measured with high precision by scanning the AFM tip across a sharp step on the film produced by masking the substrate during cluster deposition). The surface morphology of the nsC film is characterized by high specific area and roughness and by the presence of a fine raster of nanometer-sized grains, which are typical of cluster-assembled films deposited by SCBD [38.16–18]. The rough and granular nature of the film is a consequence of the deposition of the building blocks (the carbon clusters), which are typically nanosized according to their mass distribution [38.19]. Clusters impact with low kinetic energies per atom on the growing interface, thus avoiding substantial fragmentation [38.19]. Upon deposition, the more unstable and reactive carbon clusters may undergo aggregation and/or coalescence [38.10]. The resulting morphology is statistically scale invariant (self-affine) across several orders of magnitude in length: from the size of the pristine clusters produced by gas-phase aggregation inside the cluster source and the size of the surface grains formed after deposition and film growth right up to the size of the largest morphological features observed in Fig. 38.2a (which are micrometer-sized for the thickest films shown in Fig. 38.2b) [38.18, 20]. The rms roughness R_q, calculated as the standard deviation of the surface heights (typically measured from AFM scan traces extending over an area of $5\,\mu m \times 5\,\mu m$), generally increases with film thickness, as clearly shown in Fig. 38.2b (from bottom to top). The roughening of the growing interface is known to be regulated by scaling laws (the Family–Vicsek scaling relations) that are typical of a variety of growing interfaces [38.21–24] and result in a statistically scale-invariant topography. The scaling laws govern the evolution of morphological parameters such as the rms roughness and the lateral correlation length, i.e., in practical terms, half the maximum (average) size of the largest morphological features that develop during film growth, such as the supergrains visible in the AFM maps of Fig. 38.2b [38.21].

Despite the disordered surface morphologies of cluster-assembled carbons, as well as the randomness of the deposition process, the existence of a scaling law for roughness evolution allows precise control over the morphological properties of the nsC thin films. This is achieved by simply adjusting the deposition time, since the film thickness increases linearly with the deposition time at a constant deposition rate. Quantitative analysis of AFM topographies has shown that the evo-

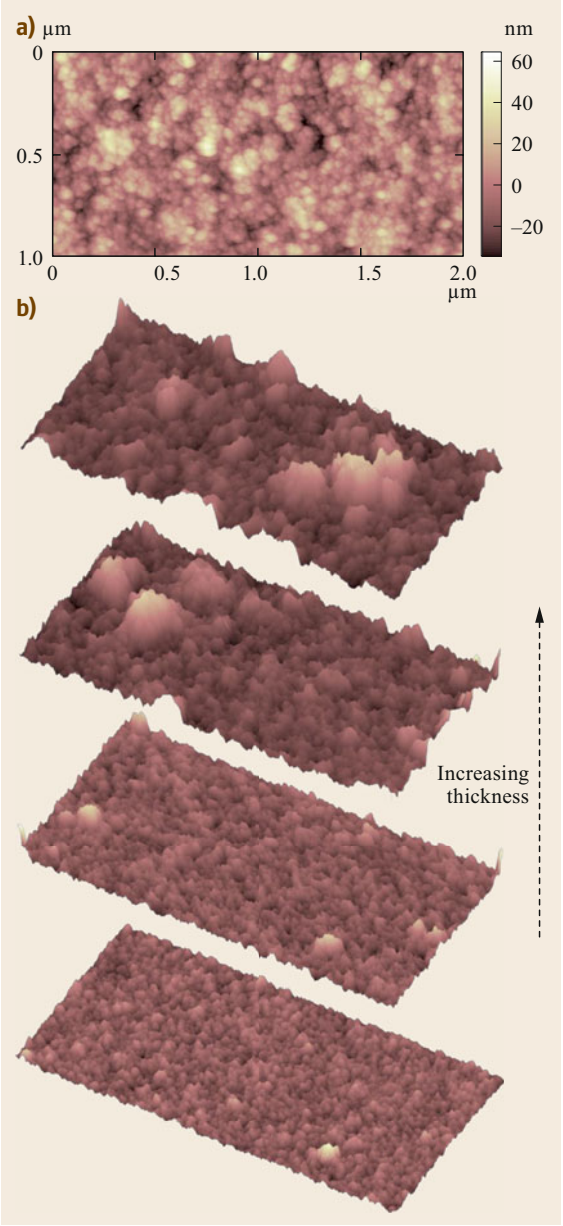

Fig. 38.2 **(a)** A representative 2-D view of the surface morphology of a nsC film of thickness 220 nm. A fine raster of surface nanometer-sized grains is visible. **(b)** Images depicting how the surface rms roughness of the nsC film varies as a function of increasing film thickness (the thickness varies from 36 to 500 nm and the rms roughness varies from 9 to 65 nm from the *bottom* to the *top* image; the scan area in each image is $2\,\mu m \times 1\,\mu m$, and the vertical range is 600 nm) ►

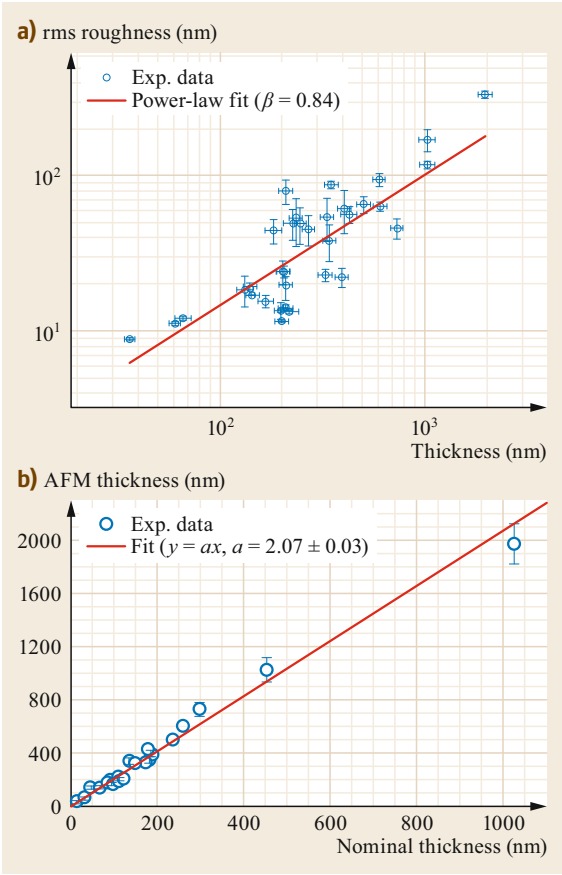

Fig. 38.3 **(a)** Scaling of the rms roughness of the surface of a nsC film deposited via SCBD. The linear fit obtained for the log–log plot highlights the power law character of the evolution of roughness with film thickness (deposition time). The evolution of the surface roughness conforms to a scaling law that is compatible with the ballistic deposition regime; **(b)** nsC film thickness as measured by AFM versus the film thickness measured by QCM assuming a material density of 1 g/cm^3 ◄

lution of the rms roughness R_q with the thickness h of the nsC film obeys the power law $R_q \approx h^\beta$, with $\beta = 0.84 \pm 0.19$ (Fig. 38.3a). The value of the growth exponent β is larger than expected for a purely ballistic deposition growth model (for which $\beta = 0.33$), which is typical of deposition processes in which the added particles land on and stick to the growing interface without diffusing significantly [38.21, 24]. Incidentally, the growth of cluster-assembled metal oxide films deposited by SCBD (either titania or zirconia) obeys the scaling laws of the ballistic deposition regime [38.16, 17]. Pinning and quenched noise mechanisms may be key to understanding the scaling of nsC film morphological properties, in contrast to nanostructured metal oxides [38.23]. It has indeed been observed that larger clusters can act as pinning locations, locally quenching the evolution of the growing interface [38.20].

The surface granularity revealed by the AFM maps shown in Fig. 38.2 reflects the structure of the bulk material, which exhibits a low density, is highly porous, and has a high surface area. The density of the nsC film was calculated by comparing the nominal film thickness measured by a quartz crystal microbalance (QCM, configured assuming a nominal material density of 1 g/cm^3 and that the acoustic impedance data of graphite are applicable) placed close to the sample during deposition with the film thickness measured ex situ by AFM (Fig. 38.3b). Assuming that the same mass of nsC per unit area is deposited on the QCM and the sample, and that the AFM provides an accurate measurement of the film thickness, the inverse of the slope of the curve shown in Fig. 38.3b was found to represent the correction factor to the nominal density assumed for the QCM measurement. A density of about 0.5 g/cm^3 was therefore estimated for nsC. This is about one-fourth of the density of graphite (≈ 2.2 g/cm^3), confirming the porous nature of the nsC deposited by SCBD. This explains why nsC is attracting considerable interest in the context of functional devices where high porosity at the nanoscale and a large specific surface area are beneficial.

38.3 Cluster-Assembled Carbon Nanocomposites

The preservation of cluster nanostructure when the clusters land on the growing interface during SCBD enables the deposition of a wide variety of carbon nanocomposites by the controlled introduction of heterospecies into the cluster-assembled carbon matrix. Cluster-assembled thin films of carbon nanocomposites have been effectively produced via different approaches based on the SCBD/PMCS method, including (i) the application of He-based gas mixtures as sputtering gases instead of pure He [38.25, 30], (ii) the utilization of a PMCS equipped with a multicomponent cathode [38.27, 31], and (iii) the use of multiple simultaneous SCBD processes to deposit clusters of different materials produced in separate sources [38.29]. The aforementioned strategies provide high versatility in terms of the variety and the concentrations of materials embeddable in the nsC, thus enabling the highly tunable introduction of nanoparticles, dopant atoms, and graphitization catalysts into the carbon matrix, which in turn allows the structural and electrical properties

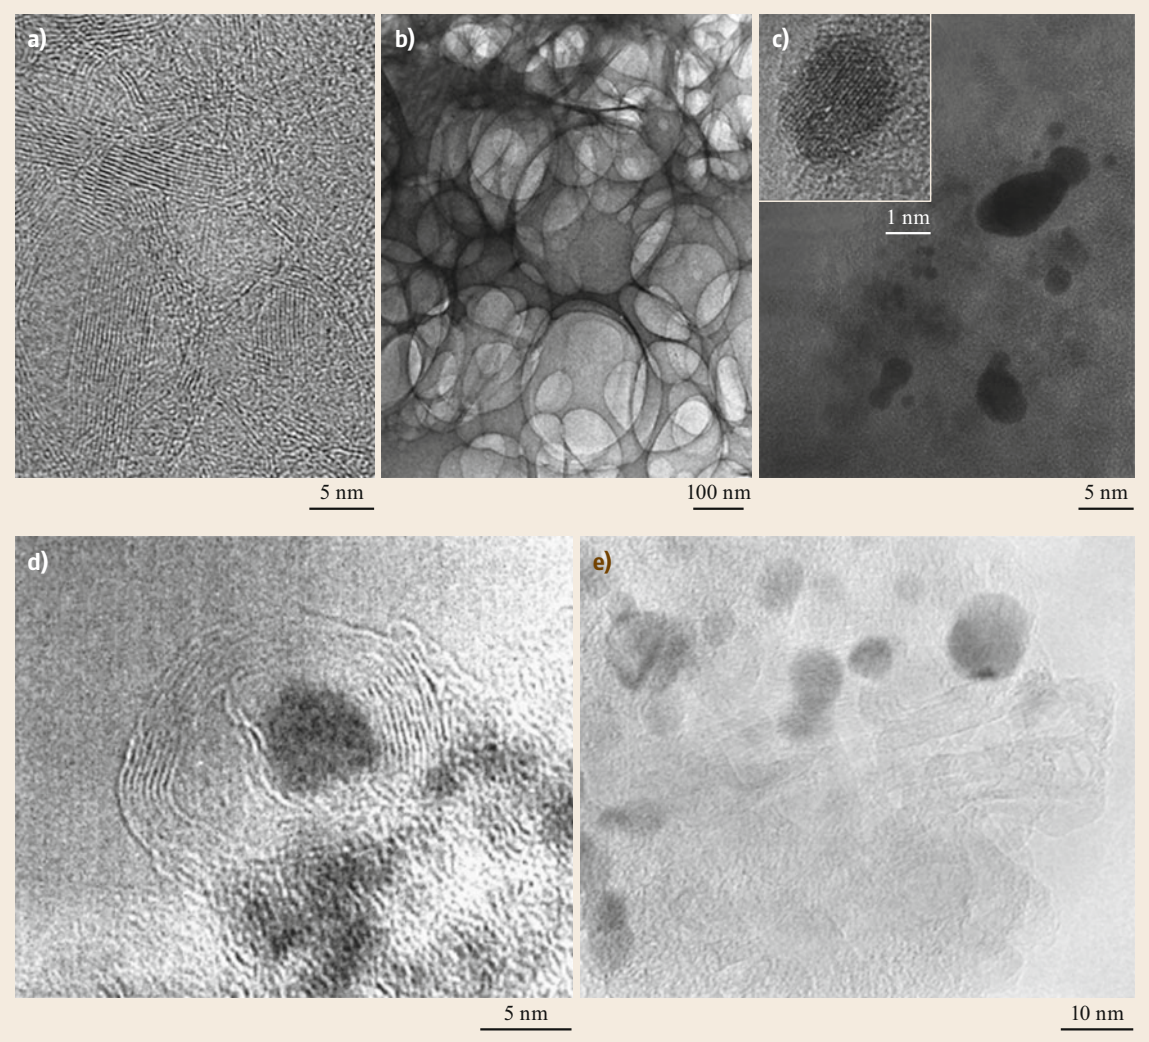

Fig. 38.4 **(a)** Densely packed graphitic planes and onion-like particles present in a nsCN_x film obtained by mixing NH_3 and He (reprinted from [38.25], with permission from Elsevier), **(b)** foam-like carbon obtained by adding metallorganic Mo to the He (from [38.26]), **(c)** TiO_x nanoinclusions dispersed in the nsC matrix (reprinted from [38.27], with the permission of AIP Publishing), **(d)** Ni nanoparticles embedded in nsC and surrounded by equally spaced graphitic shells (reprinted with permission from [38.28]. Copyright (2003) by the American Physical Society), and **(e)** tubular onion-like carbon structures consisting of concentric curved graphitic sheets that formed in Ni-containing nsC thin films upon mild thermal treatment (From [38.29]. © IOP Publishing. Reproduced with permission. All rights reserved)

of nsC thin films to be tailored according to requirements.

Dopant inclusion in nsC films has been achieved by operating the PMCS with nitrogen-containing gases, such as N_2 and a He-NH_3 mixture instead of pure He [38.25], and by mixing metallorganic compounds such as molybdenum(V) isopropoxide and cobalt(II) methoxyethoxide with the He carrier gas before it enters the source [38.30]. In this way, molecules in the buffer gas are cracked by the electric discharge and add N, Mo, and Co atoms to the condensing carbon vapor, favoring the growth of carbon clusters with a higher degree of organization than seen for undoped clusters. The availability of nitrogen atoms in the reaction chamber of a PMCS operated with a graphite target leads to the formation of a cluster-assembled CN_x film with a nanostructure characterized by the coexistence of interwoven graphitic planes, onion-like nanoparticles, and multiwalled nanotubes embedded in an amorphous carbon matrix (Fig. 38.4a; [38.25]), whereas supplying

a very low concentration of Mo or Co produces nsC thin films rich in spongy schwarzite structures consisting of fully connected 3-D sp^2 networks with a topology typical of negatively curved graphene layers (Fig. 38.4b) and with pore sizes that depend on the metallic precursor (e.g., narrower and larger pores were reported for Co and Mo doping, respectively) [38.30].

The loading of metal and metal oxide nanoparticles into nsC thin films has been obtained by either operating a PMCS with a carbon-metal composite cathode or using two cluster sources, one with a carbon and one with a metal cathode. In the former case, a mixed supersonic beam seeded with both carbon and metal clusters is produced; in the latter, two incident supersonic beams are formed, and the carbon and metal clusters are finally mixed on a substrate located at the intersection of the beam trajectories. Mixed cluster beams obtained using metal-graphite composite cathodes have been successfully used to uniformly disperse noble and transition metals into nsC in order to realize thin films with different metal abundances, particle sizes, and dilutions [38.31]. Nanocomposite nsC thin films containing noble metals such as Au, Pt, and Pd at concentrations of between 2 and 20 at.% and with metal nanoparticle diameters between 1 and 15 nm show very similar structures and carbon networks to those of of pure nsC thin films. Conversely, the inclusion of transition metals (e.g., Ti and Ni) drastically alters the nsC matrix as these metals catalyze the formation of crystalline sp^2 nanostructures. Titanium-containing nsC thin films show the presence of TiO_x nanoinclusions; the size of these nanoinclusions increases according to the Ti content in the film, ranging from a few nm for the lowest concentration (ca. 3 at.%) up to 10–15 nm for higher concentrations (9–11 at.%). Titanium-containing nsC thin films also exhibit more ordered carbon structures—open and defective graphitic cages—than pure nsC (Fig. 38.4c; [38.27, 31]). Interestingly, these thin films undergo significant metallization under exposure to a focused vacuum UV photon beam, enabling complex metallic patterns to be drawn with submicrometric resolution on the films [38.27, 32]. More of the ordered graphitic structures are formed when the carbon clusters are grown in the presence of <2 at.% Ni atoms, and the resulting nanocomposite Ni:nsC films contain sp^2-hybridized ribbon-like, onion-like, and cage nanostructures with small (2–7 nm) metal particles embedded (Fig. 38.4d; [38.28, 31]). Ni:nsC nanocomposites with different volumetric Ni concentrations (0–35%) have also been deposited by appropriately adjusting the relative intensities of nickel and carbon-cluster beams produced in different PMCSs [38.29]. Due to the low-energy deposition regime applied, the inclusion of preformed Ni nanoparticles in the nsC does not increase the graphitic order of the carbon matrix. Nevertheless, upon mild thermal treatment at 300 °C, the embedded metals promote the formation of curved graphitic sheets, and the Ni:nsC thin films become rich in tubular onion-like structures with lengths of up to several tens of nanometers (Fig. 38.4e; [38.29]).

38.4 Cluster-Assembled Carbon Thin Films for Energy Applications

Nanostructured materials with high surface-to-volume ratios have enhanced interfacial properties that are beneficial in a number of emerging energy storage and conversion technologies (e.g., photovoltaics, batteries, fuel cells, and photocatalytic systems) where the device performance is typically governed by surface-mediated physicochemical processes [38.33]. The synthesis of nanostructured materials with controlled structural and morphological properties is the key to understanding these processes, and paves the way for the development of efficient and green energy technologies [38.33, 34]. The need to transition to a sustainable energy scenario is currently being accelerated by the Internet of Things paradigm in which an enormous number of smart devices and sensors are linked together in communication networks; this requires efficient energy management, often including energy harvesting and storage functions [38.35]. The ability to produce and deposit functional materials with well-controlled nanostructures is crucial to the development of devices that integrate systems capable of harvesting energy from the environment, storing it, and delivering the power required to switch on functional units such as sensors and transceivers.

Electrochemical cells are important enabling technologies for renewable energy as well as energy management, conversion, and storage [38.36]. These technologies rely on interfacial processes that strongly depend on the morphological characteristics of the interfaces between electrodes and electrolytes. Electrochemical cell development would thus benefit from the fabrication of nanostructured electrodes with engineered interfacial properties.

Carbon thin films with high surface-to-volume ratios are used extensively as electrode materials in a number of emerging electrochemical systems due to their chemical inertness, high electrical conductivity, low density, and relatively low cost [38.6]. These

systems typically take advantage of the large specific surface area of the employed carbons to promote the storage and/or exchange of charge at the electrode–electrolyte interface. However, the techniques commonly used to fabricate porous carbons are not readily compatible with thin film deposition processes and/or micropatterning techniques, and are therefore unsuitable for the development of micro and on-chip integrated energy devices, as required by the rapidly growing market of autonomous miniaturized electronic systems. The use of aggressive chemical and thermal treatments to improve the carbon porosity is another issue that limits the integration of carbon electrodes into diverse substrates that would greatly increase their range of applications, such as polymers and paper.

The miniaturization and integration of carbon electrodes requires an ability to synthesize porous carbon thin films by high-throughput techniques that allow fine control over the physicochemical characteristics of the material and compatibility with standard microfabrication processes and substrates.

The assembly of carbon clusters via SCBD is a promising approach with demonstrated applicability to the production of carbon-based materials and electrodes with structural and morphological properties that are beneficial for electrochemical applications. Moreover, the deposition of nsC thin films at room temperature and under clean high-vacuum conditions, which is characteristic of the SCBD method, leads to novel opportunities in the context of integrating highly porous carbon electrodes into diverse platforms.

38.4.1 Microsupercapacitors

Electric double-layer capacitors, also known as supercapacitors (SCs), are energy storage devices that play an important role in encouraging the widespread adoption of renewable energy sources. SCs store energy in the electric double layer formed upon the electrostatic separation of charges at the interface between a polarizable (and typically carbon-based) porous electrode and an ion-conducting electrolyte [38.37]. Due to the reversibility and speed of the double-layer formation mechanism, SCs can be quickly and almost endlessly charged and discharged, offering a much higher power density and much longer cycle life than electrochemical batteries [38.38]. SCs are extensively used in a variety of applications, such as electric vehicles and grid storage, and have great potential to replace batteries or to be used in combination with energy harvesters to power microelectronic devices and develop self-sustaining miniaturized devices [38.39]. The integration of microsupercapacitors into more complex systems that include energy harvesters and functional devices is a valuable strategy for developing autonomous systems. However, the fabrication of porous carbon electrodes with controlled and optimized properties (e.g., shape, thickness, porosity, morphology, and structure) remains a challenge.

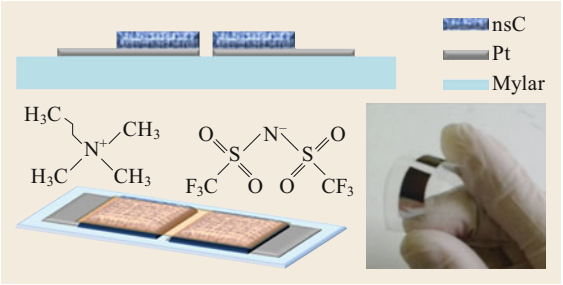

Fig. 38.5 Schematic of a planar microsupercapacitor fabricated by the SCBD of nsC electrodes on a flexible Mylar substrate (Reprinted from [38.41], with permission from Elsevier)

The deposition of nsC thin films by SCBD is an effective approach to the synthesis of carbon electrodes with promising electrochemical energy storage properties [38.29, 40–42]. NsC thin films with thicknesses in the range between 100 nm and 1 μm have been reported to exhibit an electric double-layer capacitance of about 80 F/g in the aqueous and organic electrolytes commonly employed in the production of SCs [38.42, 43], and similar capacitances have been measured upon soaking the nsC in ionic liquids featuring a bis(trifluoromethanesulfonyl)imide anion and imidiazolium- or ammonium-based cations [38.40, 41]. NsC thin films have been also successfully integrated into prototype microsupercapacitors fabricated by SCBD on glass and polymeric substrates [38.40, 41, 44]. As reported in Fig. 38.5, SCBD-generated microsupercapacitors consist of two coplanar nsC electrodes that are deposited using stencil masks and have areas of 0.2–1 cm^2 and thicknesses in the range between 100 and 500 nm. The electrodes are then soaked with a thin layer of ionic liquid serving as electrolyte. The resulting devices exhibit a specific capacitance of about 10 F/cm^3 and have been demonstrated to operate in a flat or bent configuration at 3 V with long cycling stability (over 2×10^4 cycles) even at temperatures up to 80 °C, as well as to have a volumetric specific power and energy of 10–14 W/cm^3 and 2.5–10 mWh/cm^3, respectively [38.40, 41].

Although they are nonoptimized prototypes, the energy storage performance of microsupercapacitors based on nsC thin films is of interest for different devices that, if properly designed and connected, could bring about miniaturized autonomous systems [38.45]. Moreover, compared to other forms of carbon that

have been employed as electrode materials in microsupercapacitors (e.g., carbide-derived carbons, onion-like carbons, and graphenes [38.39]), nsC thin films have the key advantage of being inherently porous and depositable in a single step, avoiding the need for complicated postdeposition processing, such as sintering, chemical activation, and binder mixing.

38.4.2 Electrolyte-Gated Transistor

In the race to produce autonomous electronic devices, electrolyte-gated transistors (EGTs) are attractive platforms owing to their very low voltage operation [38.46]. EGTs make use of electrolytes instead of conventional gate dielectrics and exploit electrolyte–channel interfaces with high electrical double-layer capacitance to modulate currents across several orders of magnitude at relatively low gate voltages. The use of porous carbon-based material with a high specific surface area as the gate electrode enables operation below 1 V and renders the presence of an external reference electrode to monitor the channel potential unnecessary, thus simplifying the structure of the device [38.47, 48]. Indeed, carbon gate electrodes with high capacitance can electrostatically store an amount of charge that can, if counterbalanced in the transistor channel, lead to channel doping and current modulation [38.47, 48]. Moreover, the integration of porous carbon gate electrodes into EGTs enables these systems to be used as energy storage structures, resulting in a class of devices known as transcaps, where the charge stored at the gate interface permits the transistor to be operated without an external power supply [38.49]. The coupling of a transistor with a capacitor within the same structure could therefore yield a very interesting energy device for autonomous electronic and bioelectronic systems, but this remains a challenging approach due to the lack of effective fabrication techniques that enable the deposition and integration of porous carbon thin films into EGTs [38.49].

Recently, cluster-assembled nsC thin films with a thickness of about 750 nm were successfully integrated as gate electrodes into planar and flexible poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS)-based organic electrochemical transistors patterned by orthogonal lithography on a Mylar substrate using poly(sodium 4-styrenesulfonate) (PSSNa) gel as an electrolyte [38.50]. The large specific surface area of a nsC thin film deposited by SCBD allows a considerable amount of charge to be stored in the electric double layer formed at the gate–electrolyte interface, enabling the doping/dedoping of the transistor channels by the counterbalanced charge at the channel–electrolyte interface. The electrical characteristics of the devices

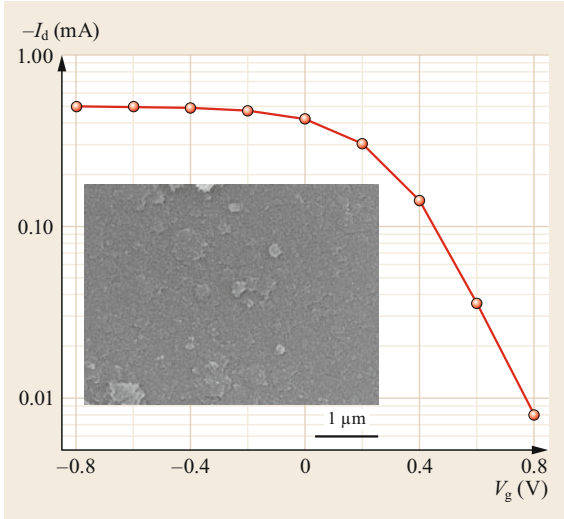

Fig. 38.6 Transfer curve of an electrolyte-gated transistor that is based on a PEDOT:PSS channel and employs a nsC thin-film gate electrode and a PSSNa-based gel electrolyte. The *inset* of the figure is a SEM image of the nsC gate electrode. (Reprinted by permission from [38.50])

present very good drain-source current modulation at low voltages (the gate voltage was varied between −0.8 and 0.8 V) with an on/off ratio of about 60 (Fig. 38.6). Moreover, due to the high electric double-layer capacitance of nsC thin films, the device can also act as a hybrid supercapacitor with efficient charge retention and satisfactory energy storage characteristics. The resulting system can maintain the applied voltage for a short period of time (ca. 10 s), allowing the operation of the transistor and the modulation of the current without an external power supply [38.50]. This demonstrates that the deposition of carbon clusters by SCBD is a suitable approach for the fabrication of flexible EGTs and transcaps featuring carbon-based gate electrodes.

38.4.3 Photocatalytic Systems

Photocatalytic processes are extensively used in a variety of applications, such as hazardous waste remediation, hydrogen production, and photoelectrochemical energy conversion [38.51]. Metal oxide semiconductors (e.g., TiO_2, WO_3, ZnO) are among the most thoroughly investigated photocatalysts due to their ability to use photogenerated charge to initiate redox reactions in adsorbed species, their high chemical stability, and their low cost [38.52]. Although the photocatalytic activity of these materials results from a synergistic effect of several physicochemical properties, considerable effort is being directed into enlarging their surface-to-volume

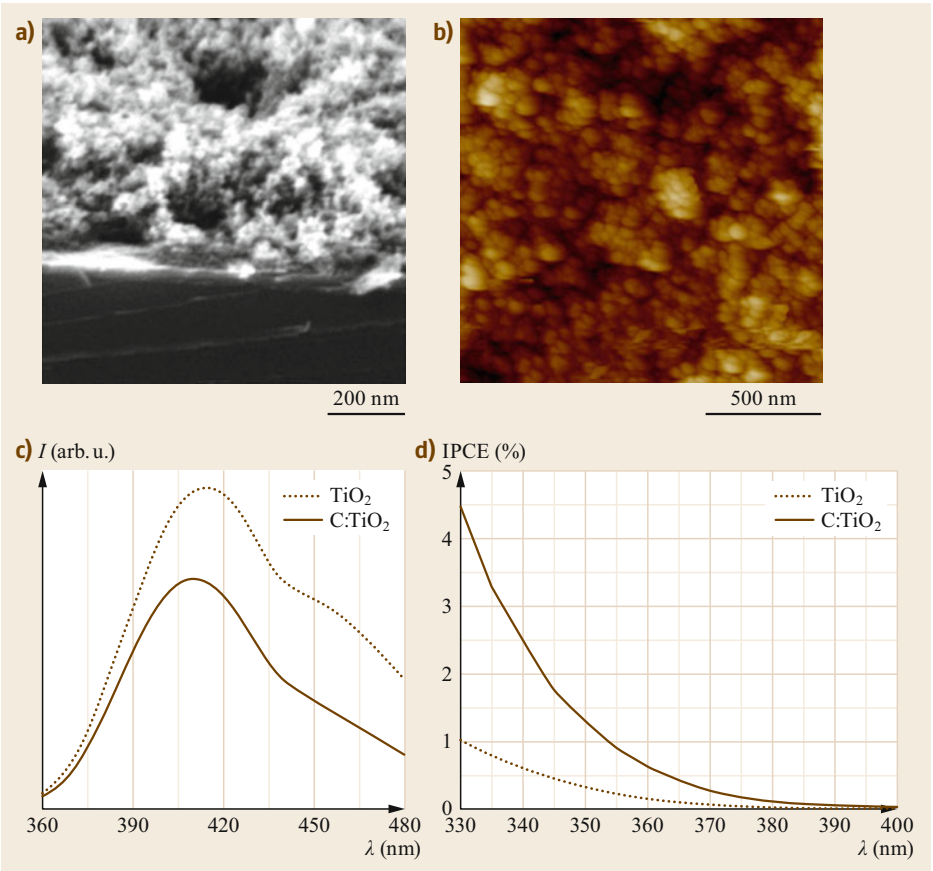

Fig. 38.7 **(a)** SEM and **(b)** AFM images of the cluster-assembled TiO_2:C nanocomposite formed using a nsC thin film as substrate for the deposition of TiO_2 nanoparticles, **(c)** fluorescence spectra of salicylic acid solution in contact with illuminated cluster-assembled TiO_2 and TiO_2:C films, and **(d)** incident photon-to-current efficiency spectra acquired under monochromatic illumination in 1 M KOH electrolyte and without external bias using cluster-assembled TiO_2 and TiO_2:C as photoanodes

ratio via nanostructuring to favor the adsorption of the compounds to be reduced and/or oxidized.

To use a nanosized photocatalyst practically, it must be embedded into an appropriate support material with a high surface area (e.g., a porous membrane): so to maximize the mass-transfer to the catalyst, to allow photons reach the active material, and to minimize the loss of catalyst into the environment [38.53]. Moreover, as nanoparticle-based metal oxide materials typically suffer from poor electronic connectivity due to the relatively high number of grain boundaries present in the system [38.54], conductive support materials are needed to facilitate the transport of the electric charge at the interface with the photocatalyst. Carbon thin films with high specific surface areas and electric double-layer capacitance are promising support materials for metal oxide photocatalysts [38.55].

The use of cluster-assembled nsC thin films of thickness 200 nm as substrate layers for the deposition of TiO_2 nanoparticles was recently reported to be an effective strategy for the fabrication of TiO_2-based materials with high photocatalytic activity. This approach yields TiO_2:C nanocomposite thin films with high surface corrugation (Fig. 38.7a,b) and greater surface roughness and electric double-layer capacitance than materials that consist of the same amount of TiO_2 nanoparticles only and are deposited using the same technique on flat substrates [38.56]. The beneficial effect of the structure of the nanocomposite on its photocatalytic activity was proven by the significantly increased activity of the TiO_2 nanoparticles embedded in the nsC in the oxidative photodegradation of salicylic acid (Fig. 38.7c) and the production of hydrogen via photoelectrochemical water splitting (Fig. 38.7d; [38.56]).

These improvements demonstrate that the SCBD-based fabrication of photocatalytic materials through the deposition of TiO_2 nanoparticles on nsC thin films not only allows the surface morphology and porosity of the nanoparticle-assembled TiO_2 to be adjusted to enhance mass transport to the surface of the photocatalyst, but it also improves the electrical properties of the photocatalyst, thus facilitating the transfer of the photogenerated charge from the TiO_2 nanoparticles to the adsorbed species.

38.5 Conclusions

The assembly of carbon clusters produced in a pulsed microplasma cluster source (PMCS) and deposited by supersonic cluster beam deposition (SCBD) has emerged as a very effective approach for growing carbon thin films. SCBD enables neutral carbon clusters to be manipulated through supersonic expansion and aerodynamic focusing, thus permitting the deposition of carbon thin films with controlled nanostructures. Precise control over the conditions applied during cluster production, extraction, and deposition is crucial not only in basic research but also to meet the requirements imposed by applications. Cluster-assembled carbon thin films produced via SCBD exhibit low density, high surface roughness, and high porosity—characteristics that potentially make these films useful in a wide range of devices, such as electrolyte-gated transistors, supercapacitors, and photocatalytic systems. These properties, together with the compatibility of SCBD with standard planar microfabrication processes, are key to the development of energy storage and conversion devices that require the integration of extremely thin films of nanostructured carbon.

Materials Interfaces Center
Shenzhen, China
galluzzi@siat.ac.cn

Massimiliano Galluzzi is a research scientist at the Shenzhen Institutes of Advanced Technology, Chinese Academy of Science, China. He received his MSc (2011) and PhD (2015) in physics from the University of Milan. His research mainly focuses on the AFM-based characterization of the morphological, mechanical, and electrical properties of polymeric soft matter, biological specimens (living cells and membranes), ionic liquids, and nanostructured interfaces.

Alessandro Podestà

CIMaINa and Dipartimento di Fisica "Aldo Pontremoli"
Università degli Studi di Milano
Milano, Italy
alessandro.podesta@mi.infn.it

Alessandro Podestà is an associate professor at the Department of Physics of the University of Milan. His research focuses on the investigation of systems and interfaces at the nanoscale using scanning probe techniques, and is supported by the development and implementation of AFM-based techniques and protocols.

Paolo Piseri

CIMaINa and Dipartimento di Fisica "Aldo Pontremoli"
Università degli Studi di Milano
Milano, Italy
paolo.piseri@fisica.unimi.it

Paolo Piseri is an associate professor at the Department of Physics of the University of Milan. He has contributed to the development of the supersonic cluster beam deposition technique for synthesizing nanostructured materials since it was first conceived. His research largely focuses on the development of advanced characterization techniques for free clusters, in particular the investigation of gas-phase clusters with short-wavelength probe radiation from synchrotron and FEL sources.

Paolo Milani

CIMaINa and Dipartimento di Fisica "Aldo Pontremoli"
Università degli Studi di Milano
Milano, Italy
paolo.milani@mi.infn.it

Paolo Milani is a full professor at the Department of Physics of the University of Milan and Director of the Interdisciplinary Centre for Nanostructured Materials and Interfaces (CIMAINA). His research focuses on cluster-assembled materials and their integration into microfabricated platforms via supersonic cluster beam deposition technology. He is active in the field of nanostructured systems and devices for stretchable electronics and optics, biotechnology and medicine, and energy production and storage.

39. Nuclear Methods in Surface Science

Daiichiro Sekiba

Some techniques in ion beam analysis (IBA), profoundly related to surface science, interfaces, and thin films, are introduced. In particular, this chapter details Rutherford backscattering spectrometry (RBS) and elastic recoil detection analysis (ERDA) as well as their high-resolution varieties, and nuclear reaction analysis (NRA), as well as recent progress that has allowed, e.g., the extension of the realm of applications to ambient conditions. These techniques have a long history that overlaps with the development of nuclear and elemental particle physics. Indeed, one could say that IBA is a byproduct of these branches of physics. Therefore, the principles of linear accelerators are also briefly mentioned in this chapter. The advantages of IBA derive from the *swiftness* of the probe ion beams produced by particle accelerators. The resulting very short interaction time ensures a precise description of differential cross section in RBS and ERDA while neglecting inelastic collisions since no chemical reactions can occur. Similarly, the cross section of NRA is well determined by nuclear physics and is not affected by environmental factors. These characteristics allow the *absolute* quantification of elemental compositions, including of hydrogen, on as well as under solid surfaces without the need to refer to any standard sample. Finally, it is noteworthy that IBA intrinsically offers nanoscale depth resolution because of the stopping power of the target material, which is an important concept defined in this chapter also in relation to the recent development of particle radiotherapy for oncological treatments.

39.1 Methods Employing Swift Ion Collisions

The most widely used ion beam analysis (IBA) techniques employing *swift* ions for solid-state physics are particle-induced x-ray emission (PIXE), particle-induced γ-ray emission (PIGE), Rutherford backscattering spectrometry (RBS), elastic recoil detection analysis (ERDA), and nuclear reaction analysis (NRA). Among these, RBS, ERDA, and NRA offer good depth resolution and can be easily applied to surface and interface studies, provided that the experiment is designed appropriately. In particular, RBS is sensitive to the relatively heavy elements present in the sample, while ERDA and NRA are suitable to detect light elements

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-46906-1_39

including hydrogen. Therefore, ERDA and/or NRA investigations are usually performed simultaneously with RBS due to the complementary information that can be retrieved. These techniques are compatible, since the detector used for RBS does not affect ERDA and NRA measurements.

Despite their long history, such methods are still undergoing improvements in terms of their depth resolution and detection limits. The reason why these traditional methods remain important is that IBA offers the unique advantage of enabling *absolute* quantification of elemental composition without the need for calibration samples. These techniques thus enable the identification of novel compounds in solid chemistry samples and the derivation of information on their surface properties.

This chapter does not cover low-energy ion scattering (LEIS), also known as ion scattering spectroscopy (ISS), even though this technique plays an important role in surface science studies. The most distinct difference between ISS and the other above-mentioned IBA techniques is that it makes use of low-kinetic-energy ions (up to some keV), which makes the interaction time with the target atoms long enough to enable chemical interactions, inhibited for swift ions. For this reason, the scattering process in ISS is usually inelastic, and information can be retrieved only by comparison with trajectory simulations. ISS data interpretation is still being improved, e.g., by including the electronic interaction between probe ions and targets. From the experimental side, a recent development is the use of spin-polarized beams (SP-ISS) for surface investigation, which delivers valuable information on materials that exhibit a substantial spin–orbit interaction. ISS has been recently reviewed by *Brongersma* et al. [39.1]. For information on SP-ISS, the papers by *Suzuki* [39.2, 3] are recommended.

39.2 Accelerators

In IBA, an electrostatic accelerator, with a terminal voltage of 0.1−10 MV, is used. Synchrotrons or cyclotrons, which can accelerate charged particles up to ≈ 100 MeV, are rarely employed in IBA for materials science applications, while they are often used for medical purposes, such as oncological therapy [39.4]. The latter takes advantage of the knowledge and experience gathered in the long history of IBA. The study of particle radiotherapy from the physics viewpoint is therefore useful not only for medical doctors but also for IBA scientists.

Two types of accelerator are usually employed for IBA: the tandem type (Fig. 39.1a) and the single-end type (Fig. 39.1b) [39.5]. The former is suitable for high-energy beams, while the latter is used for relatively low energies when a high beam current is required. Most IBA apparatuses consist of an ion source, a terminal shell kept at a high positive voltage, and a measurement system (target and detectors). We first describe the tandem-type accelerator setup. Since the ion source creates negative ions and IBA users are interested in many different elements of the Periodic Table, the task of the ion source is to produce negative ions of each desired element; For example, in the case of oxygen (O) or chlorine (Cl) beams, one can use a sputtering-type ion source, which consists of an oven, employing usually cesium (Ce), an ionizer, and a target (Fig. 39.1c). Solid Ce is inserted into the oven, and Ce vapor is generated by sublimation when heating the oven. The hot ionizer creates Ce^+ ions that are attracted toward the target (often called the cathode) in which the desired element is included. When the Ce^+ ions sputter the cathode, negative ions of the desired element are produced and then accelerated by the repulsive force due to the negative electric voltage applied to the cathode. When the negative ions reach the external part of the ion source, they are further affected by the negative voltage applied on the ion source. Usually, this negative voltage lies in the range from −50 to ≈ −100 keV. Compared with photon sources used, e.g., in photoemission, the disadvantage of an ion source is its instability. The user must accurately control the heating power of the Ce oven and ionizer to stabilize the ion beam current.

If the user wants to employ inert gases such as He or Ne, other specific ion sources are used. The principles of operation of such ion sources for inert gases are completely different from those of the sputtering type. The ion source for the inert gas has a Li oven to generate Li vapor by sublimation, although sometimes alkali metals other than Li are used instead. Negative ions of inert gases are usually produced by direct collision of an electron beam with the Li vapor. After negative ions of the inert gas are generated, the acceleration mechanism is the same as for the solid cathodes used for other elements. At many facilities, the accelerators have several ion sources to enable various types of experiment.

The negative ions are guided by magnets toward the entrance of the accelerator. The accelerator is usually contained in a large tank of SF_6 gas at ≈ 0.8 MPa to avoid discharge. A part called the *terminal shell* is placed at a high (positive) voltage at the center of the accelerator and connected to its entrance and

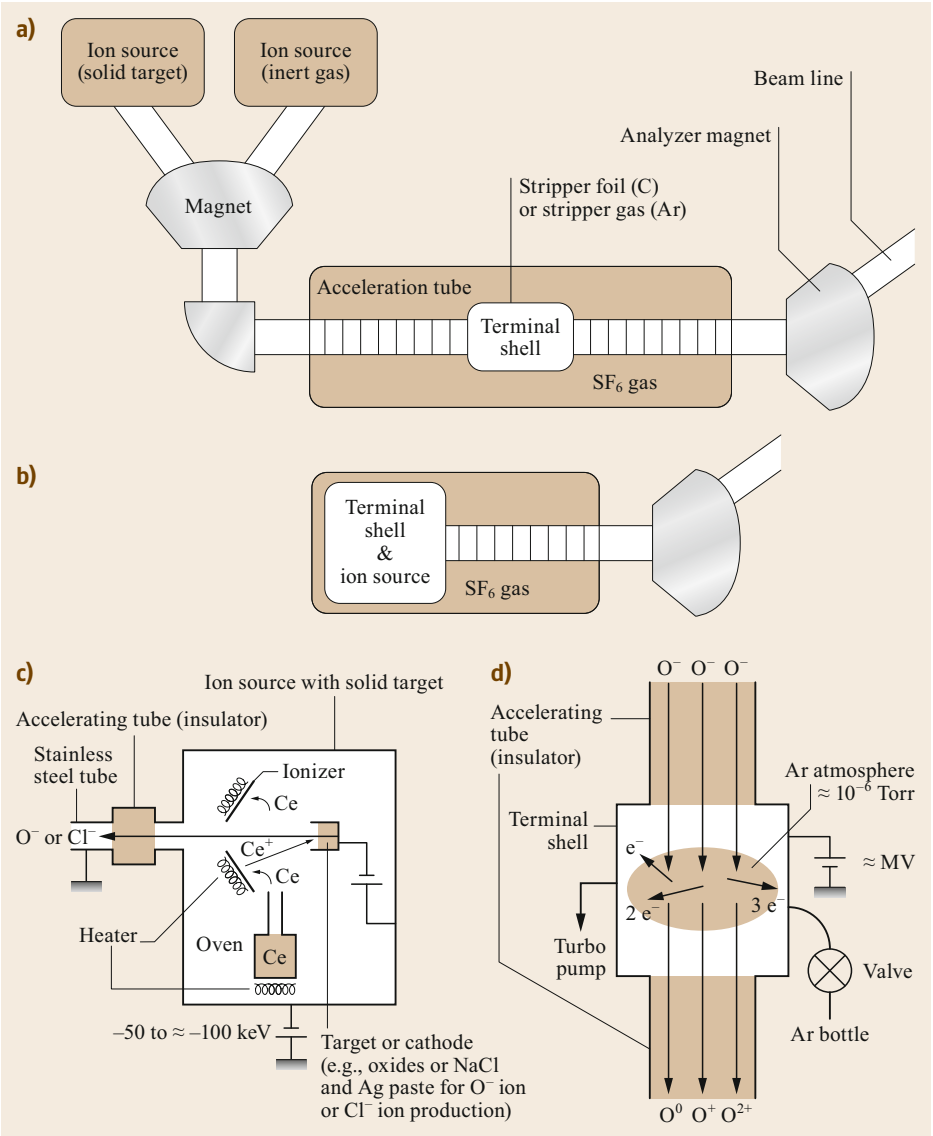

Fig. 39.1
(a) Tandem-type electrostatic accelerator, **(b)** single-end-type electrostatic accelerator. **(c)** Schematics of ion source with solid target, which generates the desired negative ions. **(d)** Schematics of charge conversion process in the terminal shell

exit by acceleration tubes, which are usually made of ceramic with resistor divider circuits. When the negative ions reach the entrance of the accelerator, they start being accelerated by the attraction to the positive voltage of the terminal shell. In the terminal shell, several electrons are removed from the negative ions by a stripper foil (carbon) or stripper gas (Ar) (Fig. 39.1d). The particles then become positive ions and are again accelerated by the repulsive force from the terminal shell. This process is called charge conversion. Thus, by using this trick of charge conversion, a tandem-type accelerator can provide a high-energy beam starting from a single terminal shell.

Any IBA technique usually requires monochromatic beams. The user must thus pay attention to the fact that ions with various valences can coexist after the occurrence of charge conversion. They have, of course, different energies. Therefore, an analyzer magnet (Fig. 39.1a,b) is inserted downstream of the accelerator so that users can select the desired energetic particles.

On the other hand, a single-end-type accelerator contains an ion source in a terminal shell. The ion source produces positive ions instead of the negative ones produced by a tandem-type accelerator. This represents a great advantage from the point of view of

the beam current, because in most cases, the creation of positive ions is much easier than that of negative ions.

There are two methods to obtain the high voltage applied to the terminal shell, viz. Van de Graaf and Cockcroft–Walton type accelerators [39.6–8]. Both methods are still in common use for a wide range of terminal voltages. Nowadays, in particular the Van de Graaf type is operated using a pellet chain [39.9] instead of a rubber band.

39.3 Stopping Power

The intrinsic high depth resolution of RBS, ERDA, and NRA is based on the stopping power of the target materials towards the probe ions. The typical value for common materials (semiconductors and/or metals) is several keV/nm. When selecting energies of ≈ 100 keV, referred to as medium energy in this field, the stopping power becomes an order of magnitude larger. In RBS and ERDA, the depth resolution is determined by the combination of the energy resolution of the detector, the stopping power, and the relative angle between the surface normal and the beam incidence direction. For NRA, the key factors are the resonance energy width and the energy straggling of the incident beam.

There is no established general theory to calculate the stopping power. It is a complicated function of the electronic stopping power and the nuclear stopping power. When the incident ions are swift enough, the electronic stopping power dominates. Usually, RBS, ERDA, and NRA are performed in this energy region, in which the electronic stopping power varies almost linearly and moderately, so that the user can easily convert an ion energy loss into a depth from the surface. If the target region is limited to a shallow subsurface region or to an interface below a thin film, the change of the stopping power is negligible and it can be treated as constant. The nuclear stopping power becomes important when the velocity of the incident beam is small; e.g., the sputtering process in secondary-ion mass spectroscopy (SIMS) [39.10] and/or the efficiency of radiotherapy are greatly affected by the nuclear stopping power. Practically, in RBS, ERDA, and NRA, one uses tabulated values of experimentally measured stopping powers. Today, such data are well known and users can easily extract the necessary stopping power using the Stopping and Range of Ions in Matter (SRIM) code [39.11].

When users need the stopping power of a new compound, it can be obtained by Bragg's rule to a good approximation [39.12] under the condition that the electronic stopping power is dominant. Briefly, the stopping power of a compound is calculated by the summation of each element included with a weight connected to the particle density. This calculation can also be performed by the SRIM code [39.11].

While measurements on devices with operation have been intensely developed in many fields, an accurate database of stopping powers for gas atmospheres and liquids is required for the field of IBA. Indeed, efforts are still being devoted to the measurement of the stopping power for various gas and liquid phases [39.13–15]. These data are also important for the medical field, e.g., for particle radiotherapy.

39.4 Principles of RBS and ERDA

Most nuclear methods in surface science employ an energetically monochromatic ion beam accelerated by an electrostatic accelerator. Usually ions with energies from several hundred keV up to MeV are used. One can choose the desired elements as accelerated ions, as mentioned above. RBS is one of the oldest methods using high-energy particles. When *Rutherford* and his collaborators found the nucleus of gold (Au) by the incidence of α particle, the principle of RBS was almost established [39.16]. As often used in kinematic explanations (Fig. 39.2), the parallel beam produced by a double-slit system is guided to a scattering chamber. Suppose that the masses and kinematic energies of the incident and target particles in the laboratory frame are M_1, E_0, and M_2, 0, respectively, before the collision.

After the collision, the kinematic energy of the scattered particle E_1 becomes as follows in the laboratory system, where the factor in front of E_0 is often called the k-factor. The scattering angle θ is measured with respect to the beam incident angle.

$$E_1 = \left(\frac{M_1 \cos\theta + \sqrt{M_2^2 - M_1^2 \sin^2\theta}}{M_1 + M_2} \right)^2 E_0 \equiv \mathrm{k}E_0$$

One of the most useful advantages of RBS is that the differential cross-section $\sigma(E, \theta)$ is almost independent

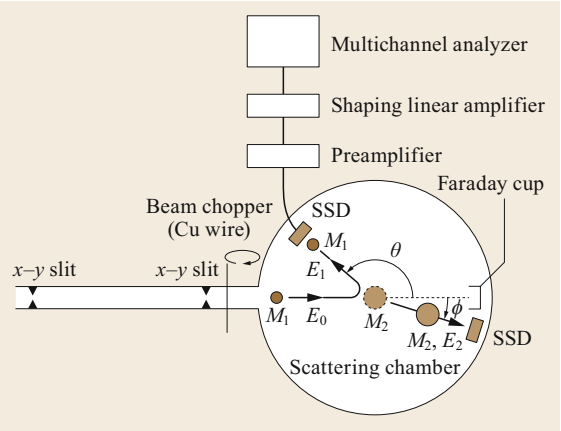

Fig. 39.2 Schematics of elastic collision with Coulomb potential and measurement of particle energies. The probe beam comes from the left through the double x–y slit system, which reduces its angular divergence. The beam current is monitored by a beam chopper to normalize the number of incident probe particles. In the case of the author's laboratory, a simple combination of a rotating Cu wire (3 Hz) and a digital current integrator is used. The current read on the Cu wire is calibrated using a Faraday cup placed at the end of the beam line. Both scattered and recoiled particles are usually detected by a solid-state detector (SSD) or surface barrier detector (SBD). The SSD measures the particles' energies from the electric current pulses that are proportional to the number of electron–hole pairs created inside the p–n junction of the SSD. The electric current pulses are treated in series by a preamplifier and shaping linear amplifier, then finally read by a computer through a multichannel analyzer (current digitizer). The principle of SSD is described in detail in [39.17]

of the chemical composition of the target. This is due to the swiftness of the incident particle, which does not have enough time to form chemical bonds with the target materials. In other words, RBS, ERDA, and other nuclear methods can be used to determine the absolute elemental compositions without any other information except the stopping power data table, which is well established. The differential cross-section can thus be written as a function of the atomic number of the incident (Z_1) and target (Z_2) particles as

$$\sigma(E,\theta) = \left(\frac{Z_1 Z_2 e^2}{2E}\right)^2 \frac{1}{\sin^4\theta} \times \frac{\left(\cos\theta + \sqrt{1-(M_1/M_2)^2\sin^2\theta}\right)^2}{\sqrt{1-(M_1/M_2)^2\sin^2\theta}} .$$

It is apparent that RBS is more sensitive to the heavier elements present in the sample. However, due to the increase of the cross section at low energy, it is necessary to pay attention to the beam energy: if the velocity of the incident particle is not large enough, the measurement could be destructive. Nondestructiveness is indeed one of the main advantages of RBS, ERDA, and NRA. While RBS is affected by small statistics errors if the mass of the target particles is heavier than the matrix, ERDA is more useful to quantify lighter elements in the matrix. The fundamental kinematics of ERDA is common to that of RBS (Fig. 39.2). The kinematic energy of the recoil particle with mass of M_2 is written as

$$E_2 = \frac{4M_1M_2\cos^2\phi}{(M_1+M_2)^2}E_0 \equiv k_{\text{recoil}}E_0 .$$

Here, the recoil angle ϕ is measured from the beam incident direction. The differential cross-section is also almost matrix independent and described as

$$\sigma(E,\phi) = \left(\frac{Z_1 Z_2 e^2\,(M_1+M_2)}{2M_2E}\right)^2 \frac{1}{\cos^3\phi} .$$

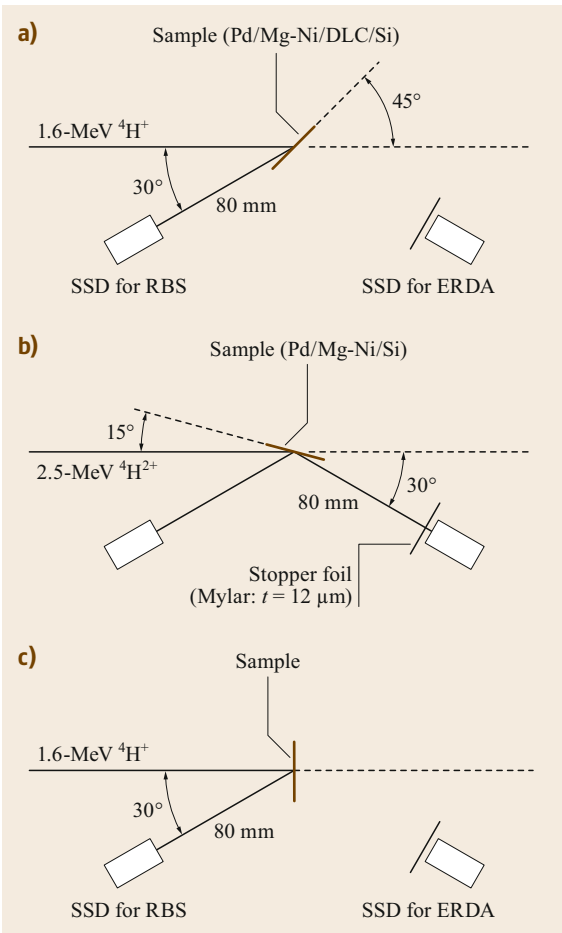
A difficulty in ERDA is the choice of an appropriate stopper foil to be placed in front of the SSD or SBD. As can be easily imagined, usually other, nonrelevant, particles enter the detector for ERDA, for example, forward scattered incident particles and recoils of other elements in the matrix. To remove such noninteresting particles, one uses a stopper foil, taking advantage of the different stopping powers of the different elements in the material of the stopper foil. As a typical case, to observe hydrogen on the surface and in subsurface regions, 2.5-MeV He ions are used. In this case, Al foil with $t = 10\,\mu\text{m}$ or Mylar foil with $t = 12\,\mu\text{m}$ are typically used as stoppers [39.18]. The author recommends Mylar foil, because Al thin foil sometimes has pinhole defects.

It is noteworthy that the differential cross-sections for RBS and ERDA described above are based on Rutherford scattering due to the Coulomb potential. When the atomic numbers of both the incident beam and target are small, the Coulomb barrier is overcome and the interaction occurs between the nuclei. In this limit, the non-Rutherford cross-section should be applied. Non-Rutherford cross-sections have been determined experimentally for the most widely used situations and are available on the Internet [39.19]. As an example, the author often uses the cross-sections determined experimentally by *Baglin* et al. [39.20] and *Besenbacher* et al. [39.21] to quantify the amount of H and D (deuterium), respectively, by ERDA with 2.5-MeV He^{2+} beam [39.22]. IBA users should thus make a simple estimate before performing an experiment to determine whether the Coulomb barrier can be overcome or not.

RBS and ERDA are usually performed simultaneously in the same measurement. By doing so, one can determine the ratio of heavy metals and light elements precisely after first determining the solid angle ratio between the two detectors for RBS and ERDA by using well-known materials.

39.5 Application of RBS and ERDA

Here, an example of RBS and ERDA from the author's experience is summarized. The metal compound formed by Mg and Ni is known to be a hydrogen-absorbing material. Apart from the high concentration of hydrogen, a metal–insulator transition also occurs due to hydrogen absorption and desorption [39.23–25]. However, after repeated absorption–desorption cycles, the ideal properties are lost. The change in the Mg-Ni thin film after repeated hydrogen absorption–desorption cycles was thus investigated by RBS and ERDA [39.26]. Figure 39.3a shows the RBS setup using 1.6-MeV $^4He^+$ ions as the probe beam. The results and schematics of the sample are shown in Fig. 39.4.



Even though the thin films deposited by the sputtering process are similar to each other, the well-separated depth profile and the change in each of the elements C, O, Si, Mg, Ni, and Pd can be observed. This sensitivity can be understood based on the k-factor in the kinematics equation, which implies that the heavier elements contribute in the higher energy region. After repeated hydrogen absorption–desorption cycles, mainly the width (or thickness) of the Mg depth profile is modified. Furthermore, a small amount of oxygen appears in the degraded sample. A simple analysis using simulations and ERDA measurements (mentioned below) demonstrates that these changes are induced by the formation of Mg hydride and Mg oxide under the Pd cap layer. For the analysis with simulations, the SIMNRA code may be useful for both RBS and ERDA as well as NRA [39.27].

The reader may wonder why the angle of incidence of the beam onto the sample is set at 45° (Fig. 39.3a): This technique is used to obtain higher depth resolution by increasing the track length of both the incident and scattered particle. In other words, grazing incidence and grazing emission are needed.

When investigating the elemental composition of a single-layer film, a simple arrangement such as that

Fig. 39.3a–c Setup of simultaneous RBS-ERDA measurements. **(a)** RBS setup for relatively high depth resolution, that is, with grazing incidence and grazing emission. Both the probe particle and the scattered particles pass the long track, so that the energy deposition per unit depth is increased. There is no special meaning for the value of the energy (1.6 MeV) of the incident beam, except that the accelerator of the author's laboratory is then stable. **(b)** Typical setup for RBS-ERDA simultaneous measurements. Although in this schematic the beam incident angle and the recoil emission angle with respect to the surface normal are identical, this is not a compulsory requirement. The beam energy (2.5 MeV) is rather critical when He ions are used as probe particles. This value is useful to avoid the detection of forward scattered He ions thanks to the stopper foil placed in front of the SSD for recoil (in this case, H ions). **(c)** The simplest setup for RBS. The advantages of this setup are that a probe beam with a large diameter (i.e., large beam current) can be used while the energy separation for each element in the sample is large ◄

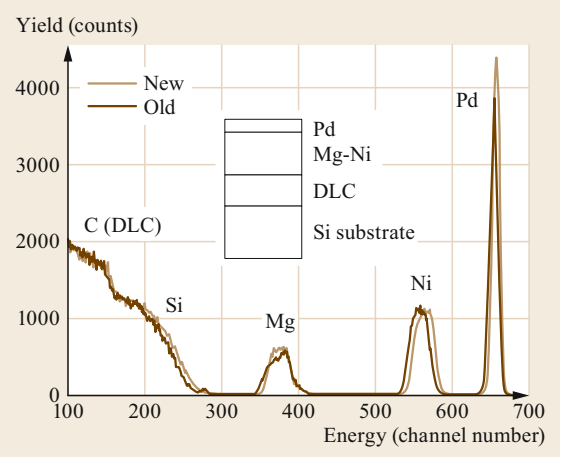


Fig. 39.4 RBS spectrum taken on the Mg-Ni metal compound before and after repeated hydrogen absorption–desorption cycles. The setup shown Fig. 39.3a was used, so that the grazing incidence (of the probe ion) and grazing emission (of the scattered ion) enable high depth resolution (see the caption of Fig. 39.3a). shown in Fig. 39.3c is sufficient. When the thickness of the Mg-Ni film is relatively small (≈ 40 nm), the change of the depth profile after repeated hydrogen absorption–desorption cycles can be well distinguished using the setup shown in Fig. 39.3a.

Figure 39.5 shows the ERDA and RBS spectra simultaneously recorded for samples as shown in the inset in Fig. 39.4. The experimental setup is changed as shown in Fig. 39.3b. One can see that the depth resolution becomes worse when changing the setup, but hydrogen quantification is now attained. The results reveal that a lot of hydrogen is included in the degraded sample after repeated hydrogen absorption–desorption cycles. Comparison of the simultaneously recorded RBS and ERDA measurements enables a direct determination of the hydrogen concentration in the degraded film. More details can be found in [39.26].

39.6 Advanced ERDA

In conventional ERDA, various different operational modes may be implemented, known as dE–E telescope ERDA and ToF–E telescope ERDA, where *ToF* signifies *time of flight*, while E indicates the kinetic *energy* of the recoils. Both techniques are used mainly for the identification of light elements. In principle, ERDA (and also RBS) can distinguish the elements in the sample based on the energy deposited into the detector. However, such measurements are often carried out on samples containing several different light elements such as Li, B, C, N, O, and F. Because the energy of recoil depends on both the atomic number and the depth from

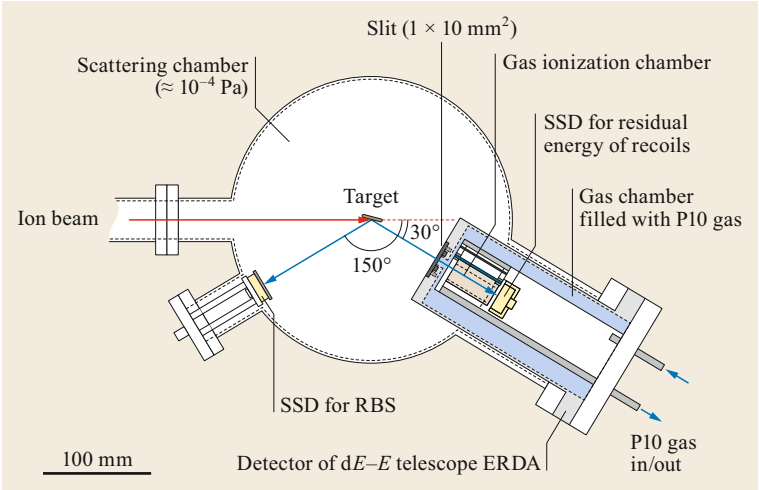

Fig. 39.6 Setup of a simultaneous RBS and dE–E telescope ERDA system with ≈ 40-MeV $^{35}Cl^{7+}$ beam. P10 gas is a mixture of 90% argon and 10% methane (Reprinted from [39.28], with permission from Elsevier)

the sample surface, it is difficult to identify the elements from the recoiling particle energy alone. Telescope-type ERDA determines the element and particle energies by using two detectors, so even if the recoils of different elements, for example, O and N, have the same kinetic energy, the element and kinetic energy can still be determined at the same time. In the case of dE–E telescope ERDA, the recoils penetrate a first detector (gas ionization chamber) and deposit about 5−10% of their kinetic energy, indicated by ΔE or dE. Then the particles that penetrate the gas ionization chamber are stopped by a second detector (an SSD in the case shown in Fig. 39.6), which determines the residual kinetic energy. Therefore, $\Delta E + E_{\mathrm{res}}$ is often also called the total energy (E_{total}). The point is that elemental identification now becomes possible based on the different interactions with the Ar gas. In other words, even though N and O have the same kinetic energy, they generate a different number of Ar^+ and e^- pairs during their penetration through the gas ionization chamber. For the first detector, usually ionization chambers filled with Ar gas are used. Sometimes, a thin SSD is used to separate H and D from relatively thick samples [39.29]. Because the interaction between the Ar gas and the recoil of each element is different, one can distinguish the elements from the ΔE values even when the E_{total} values are the same.

Figure 39.6 shows schematics of the author's setup for simultaneous RBS and dE–E telescope ERDA analysis [39.28]. This system was developed for measurements of metal oxynitride thin films on various substrates. The length of the gas ionization chamber is 50 mm. The energy resolution of a typical gas ionization chamber is 100−200 keV. Therefore, the energy loss difference between O and N during their penetration of the gas ionization chamber filled with 6000 Pa Ar should be greater than 500 keV. The length of the gas ionization chamber was determined to satisfy this condition. When using 40-MeV $^{35}Cl^{7+}$ as the incident beam, the typical kinetic energy of O and N recoils is ≈ 25 MeV. Thanks to the simulation, the length of the gas ionization chamber is determined unambiguously. Usually the multianion or multiligand system consists of a relatively heavy metal at the center of the unit cell and some surrounding light elements. As may be imagined, the ratios between the metal and light elements are determined by simultaneous RBS and dE–E telescope ERDA measurements. Figure 39.7 shows some example two-dimensional dE–E histograms taken on oxides and multianion systems [39.30–36].

On the other hand, while dE–E telescope ERDA can identify the difference between the interactions of the individual elements with the Ar gas, ToF–E telescope ERDA allows one to distinguish the light elements by the recoil. In general, if the mass (or element) of recoil is different, the velocity is also different, even though some recoils may have the same kinetic energy. Figure 39.8a shows a two-dimensional map of energy versus time of flight taken on a sample containing multiple light elements [39.37]. Improving the mass and depth resolution of such measurements has attracted much attention over the years. In Fig. 39.8a, the isotopes ^6Li and ^7Li show well-separated lines. By extracting the lines of each element, one can reproduce their depth profiles individually, as shown in Fig. 39.8b. In the same paper, readers can find a depth profile with depth resolution of ≈ 1 nm. Figure 39.8c, d shows a typical setup for ToF–E telescope ERDA, where the velocities of the recoils are acquired by measuring the time of flight between the two detectors.

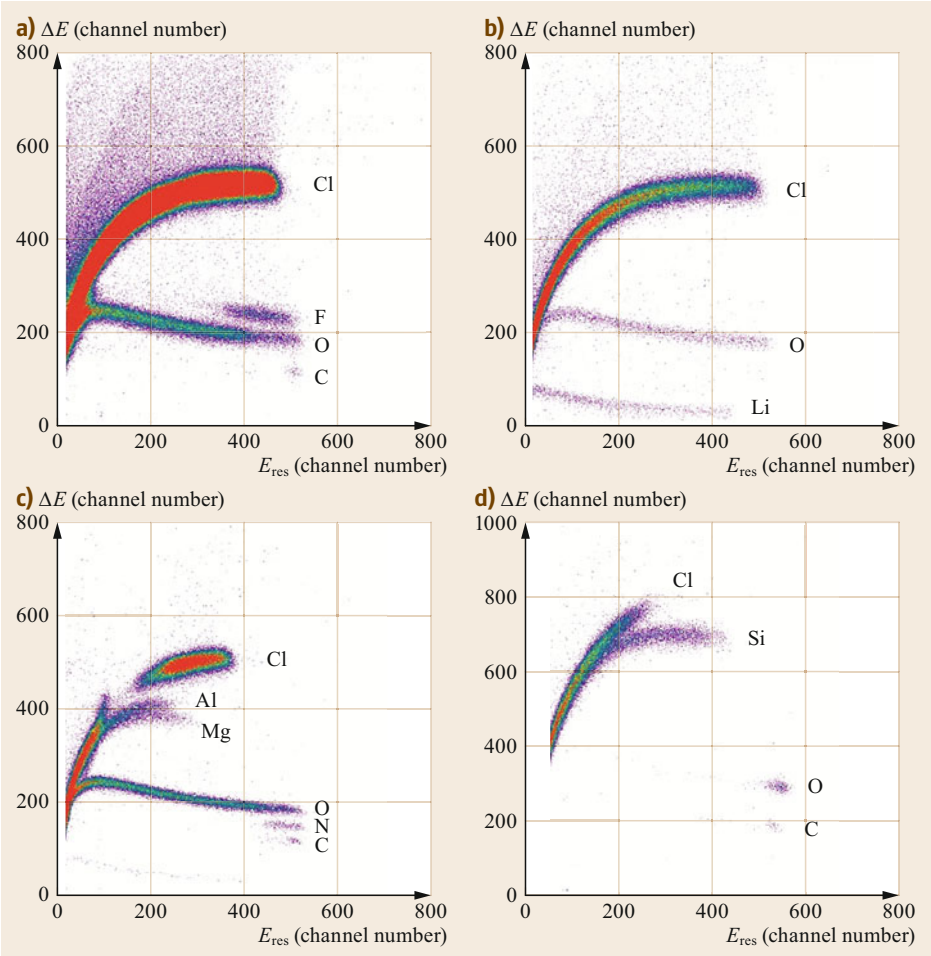

Fig. 39.7a–d dE–E histograms taken on **(a)** InO_xF_y film ($t = 125$ nm) deposited on Y:ZrO_2 substrate; **(b)** thick $LiTaO_3$ plate; **(c)** CoO_xN_y film ($t = 90$ nm) deposited on $MgAl_2O_4$ substrate, and **(d)** SiO_2 film ($t = 47$ nm) deposited on Si wafer. Here, E_{res} means ($E_{total} - dE$) and t indicates the film thickness (Reprinted from [39.28], with the permission of AIP Publishing)

The ToF detectors usually consist of a carbon foil, electrostatic mirror, and microchannel plate (MCP). Recently, very thin (50–100 nm) SiN membranes have been used instead of carbon foils. The SiN membranes usually have a coating of low-work-function material to enhance the secondary-electron emission. MCPs detect the secondary electrons emitted from the carbon foil due to the recoil penetration. The detections of the secondary electrons by the two detectors are used as the *start* and *stop* signals. Compared with dE–E telescope ERDA, ToF–E telescope ERDA measurements can be performed with lower-energy probe ions. It is noteworthy that, even though H is also well detected in Fig. 39.8a, the data obtained for H by ToF–E telescope ERDA are not suitable for accurate quantification. The detection efficiency of H in ToF–E telescope ERDA is not stable and depends on the condition of the carbon foil and/or SiN membrane surfaces [39.37, 38]. Recently, the combination of ToF–E and dE–E has also been suggested to achieve better mass and depth resolution near surfaces [39.39, 40].

39.7 Outline of HRBS, HERDA, and MEIS

Followingthe development of smaller transistors and thin insulator layers, ion beam analyzers equipped with higher depth resolution have been suggested. As mentioned above, the determination of the elemental depth profile in ion beam analysis, in general, is performed based on the stopping power. In this respect, the strategy to improve the depth resolution involves the flowing steps:

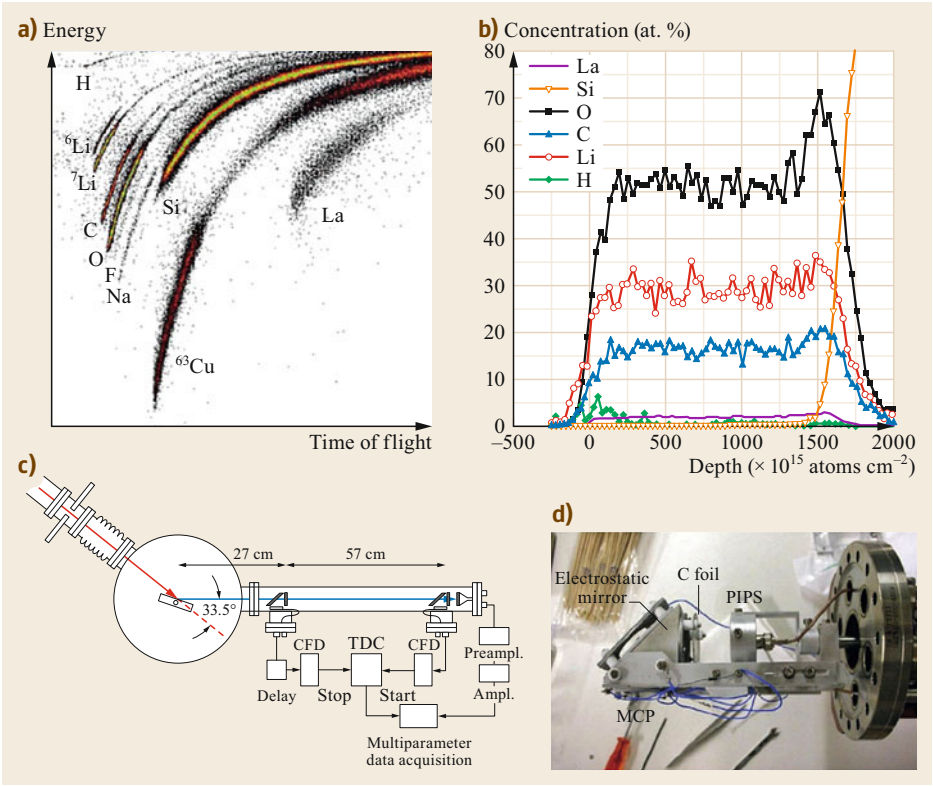

Fig. 39.8 **(a)** Two-dimensional map of energy versus time of flight taken on LiLaO by ToF–*E* telescope ERDA with 16-MeV ^{63}Cu beam. **(b)** Depth profile of each element extracted from data reported in panel **(a)**. **(c)** Overview of ToF–*E* telescope ERDA setup (CFD: constant fraction discriminator, TDC: time-to-digital converter). **(d)** Picture of second time detector and SSD, written as PIPS (passivated implanted planar silicon). 1. Maximize the energy loss of the incident and/or emitted particles per unit depth. For this purpose, there are two possibilities: using grazing incidence of the primary ions or grazing emission of the scattered ions or recoils. Another practical solution is to make use of so-called medium-energy (100–500 keV) projectiles.
2. The detection of scattered ions (in RBS) and recoils (in ERDA) should be improved to ≈ 0.5 keV. The group of Mannami and Kimura have proposed the combination of a 90° sector magnetic spectrometer with a position-sensitive detector (PSD) for both RBS [39.41] and ERDA [39.42]. Usually a position-sensitive microchannel plate (MCP) is employed as the PSD. The setups for high-resolution RBS (HRBS) and high-resolution ERDA (HERDA) are quite similar. In the case of HRBS, scattering angles of 60°–90° are often used, while recoil angles of 25°–30° are suitable for HERDA, as shown in Fig. 39.9 [39.43]. The user can determine the appropriate detection angle mainly by increasing the cross-section while avoiding interference between the target elements in the spectra. In the case of HERDA, the degradation of the depth resolution due to kinematic broadening becomes crucial, so a small electrostatic quadrupole lens (singlet lens is enough) is placed in front of the 90° magnetic sector lens to compensate for the broadening [39.42, 43]. The group of Mannami and Kimura achieved monolayer depth resolution on the PbTe(001) surface by RBS (Fig. 39.10), and the author's group proved that nearly monolayer depth resolution can be attained for H on an amorphous carbon film by HERDA [39.43]. In the case of Mannami and Kimura, the exit angle of the scattered ion is set at 2° from the surface plane, and the 300-keV ^{4}He$^+$ beam is generated by a single-end accelerator. This study demonstrated unambiguously that the topmost layer of PdTe(001) is Te rich.

Medium-energy ion scattering (MEIS) is a method quite similar to HRBS, and the energy region of the

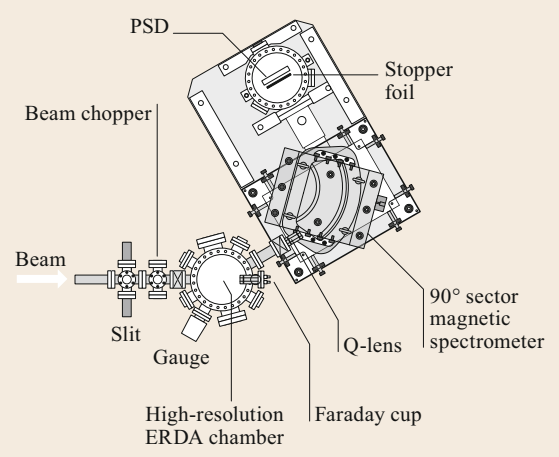

Fig. 39.9 Arrangement of HERDA system. The recoil angle is set at 30° from the beam incident angle (Reprinted from [39.43], with permission from Elsevier)

projectile is common to these techniques. Traditionally, the two methods are distinguished according to the detection type. One method employs a magnetic lens for the detector and is called HRBS, while the technique using an electrostatic lens is usually called MEIS. MEIS was developed first. In a sense, HRBS is a kind of variation of MEIS. The advantage of MEIS, in which an electrostatic lens is used, is that it can use a set of toroidal lenses and a two-dimensional PSD as shown in Fig. 39.11 [39.44], which enables the blocking condition to be found easily. MEIS was originally developed with the intention of surveying the crystallographic structure of surfaces by scanning the channeling and blocking patterns, as briefly explained in the next section. The reader can find details on the MEIS setup and principles in the good review by *van der Veen* [39.45]. Recently, MEIS has often been used as HRBS or HERDA to determine the depth profile of light elements at interfaces.

39.8 Ion Channeling and Blocking in MEIS, HRBS, and RBS

The channeling effect is frequently used in the framework of RBS to determine the surface relaxation and/or strain of lattices, not only along the surface normal but also in the surface plane. Channeling is induced when the beam incident angle lies within the acceptance angle with respect to some crystallographic direction. In this case, the incident particle is guided by multiple forward scattering into the bulk. Therefore, the RBS yield is extremely reduced under channeling conditions [39.47].

Before discussing surface strain, it is worth introducing a simple but still impressive and famous example concerning channeling and blocking, i.e., the direct observation of surface melting by MEIS [39.46]. Figure 39.12a shows how to proceed. When the surface and subsurface region is a well-ordered crystalline lattice, a sharp scattering yield from the topmost layer, the so-called surface peak, is present. On the other hand, if some molten layer exists at the surface, the surface peak

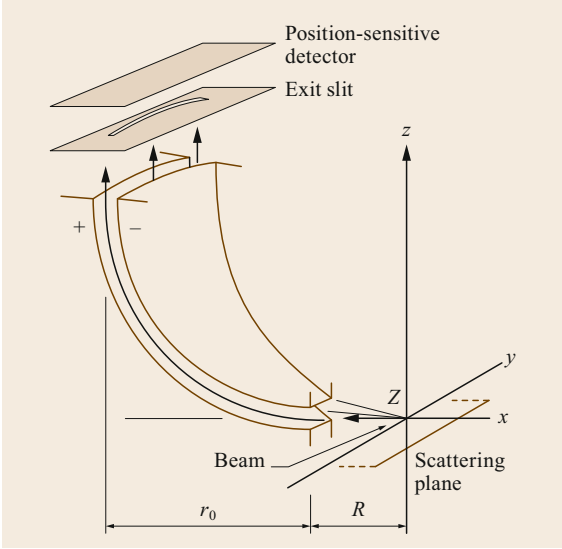

Fig. 39.11 Schematic view of toroidal analyzer and PSD (Reprinted from [39.44], with permission from Elsevier)

broadens to a width corresponding to the melted layer thickness. *Frenken* and *van der Veen* carried out MEIS experiments on the Pb(110) surface [39.46]: a significant and rather abrupt broadening of the surface peak at 600 K (Fig. 39.12c, 600.5-K curve) was observed, indicating the occurrence of surface melting. Since the line shape could not be adequately reproduced by a simple Monte Carlo simulation including more than 40 Pb layers (see the dashed line in Fig. 39.12c notated as M), the superposition of M and of the shifted 561-K curve, noted as I, was tested, revealing that such a superposition well reproduces the 600.5-K curve in Fig. 39.12c. This finding implies that the topmost and/or second layer start to melt already at 560 K (Fig. 39.12c, 561-K curve), and that such an intermediate or interface layer always exists between the solid region and the completely melted region. The melting layer constructing line M included ≈ 16.5 molten Pd layers. It was thus clearly revealed that the solid–liquid transition at the surface starts at ≈ 40 K below the bulk melting point of Pb.

Using MEIS and HRBS, it is also possible to observe strain. While scanning the beam incident angle around the channeling directions, one can find dips in the RBS yield for each channeling axis. Figure 39.13 shows the simple explanation for the relationship between the surface relaxation and/or strain and the shift of the channeling dip angle [39.48]. The same effect is caused also by blocking of the scattered ion in the framework of MEIS [39.47, 49]. This method thus qualifies as a powerful tool to investigate lattice strain in semiconductor devices and improve their development.

Figure 39.14a shows the role of the Si(001) surface oxidation method in determining the blocking around the [111] axis by comparing O_2^+ ion implantation and subsequent annealing with thermal oxidation [39.49]. It is apparent that the method employing ion implantation induces larger blocking dip shifts. From the energy loss observed in MEIS and HRBS spectra, it is possible to extract the dependence of strain on depth. Figure 39.14b

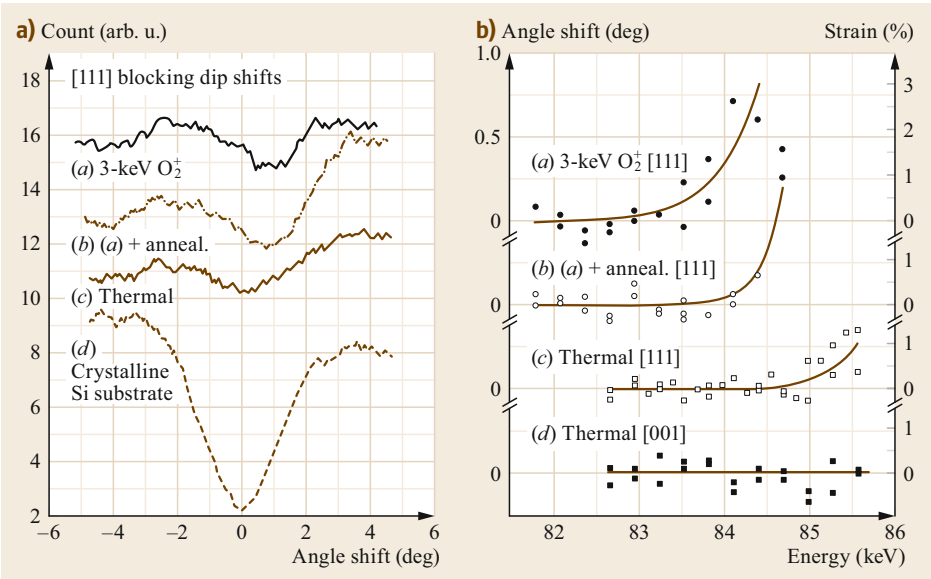

Fig. 39.14 **(a)** Shift of blocking dip at $Si_2/Si(001)$ interface observed by MEIS with various oxidation conditions. **(b)** The estimated strains in the bulk near the interfaces as a function of distance from the interfaces (Reprinted from [39.28], with the permission of AIP Publishing)

shows the lattice strain determined on the samples as a function of distance from the interface. One can see that the lattice strain near the interface obtained by ion implantation is larger by up to 3% and that it is not significantly removed by the subsequent annealing. The lattice strain present after thermal oxidation is, on the contrary, much less pronounced.

A similar experiment was performed by HRBS on the $HfO_2/Si(001)$ surface and interface [39.50]. Figure 39.15a shows the series of channeling dips, instead of the blocking dip seen in Fig. 39.14a, recorded when sweeping the beam incident angle around the [111] channeling axis. Each line shows the channeling dip corresponding to a different depth. As seen, the bottom position in angle shifts depending on the depth. The depth profile of the strain is summarized in Fig. 39.15b. There is strong compressive strain of up to $\approx 1\%$ in the vertical direction, and the strain is released and the lattice constant returns to the bulk value at a distance of $\approx$ 4 nm from the interface. It was thus shown that the strain distribution is rather larger than expected. In devices such as metal–oxide–semiconductor field-effect transistors (MOSFETs), the carrier (electron and/or hole) moves in the semiconductor side near the interface (at a distance of several nanometers from the interface). The results shown in Figs. 39.14 and 39.15 indicate that the region where the carriers move is strongly strained and the electronic band structure is also strongly modified. This information is valuable and should be taken into consideration in the design of such devices.

Related to the insulator–semiconductor system, an interesting case was presented by *Kido* et al., who reported the existence of the surface peak for an amorphous SiO_2 film deposited on the Si(001) substrate as shown in Fig. 39.16 [39.51]. In general, the charged state of a swift ion in a material is expressed as an equilibrium charge, which is a function of the velocity of the ion and does not strongly depend on the material.

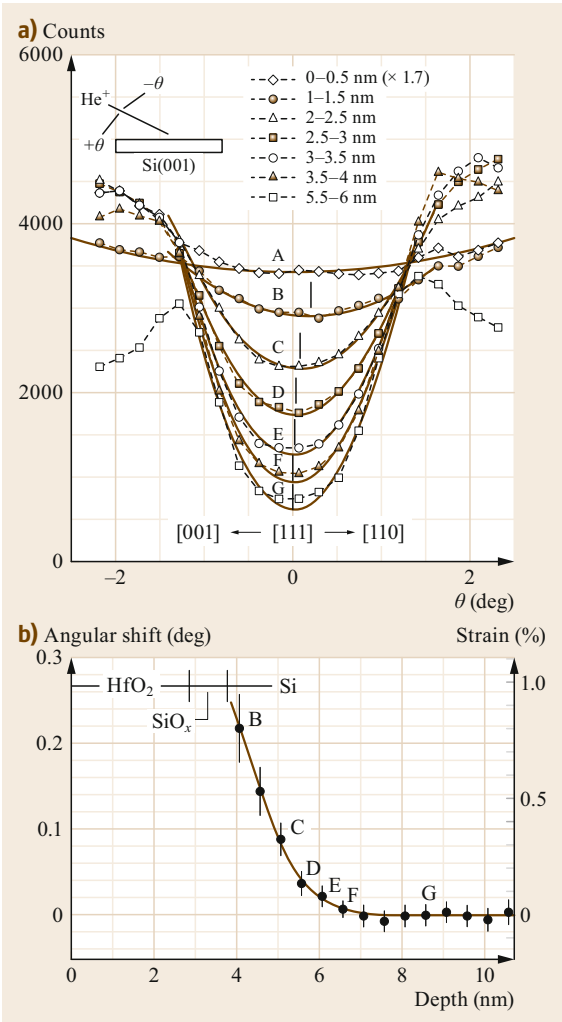

Fig. 39.15 **(a)** Series of channeling dips taken on $HfO_2/Si(001)$ interface as a function of the distance from the interface. **(b)** Depth profile of strain extracted from the series of channeling dips (Reprinted from [39.50], with the permission of AIP Publishing)

Furthermore, the charged state is usually not integer, because the incident ion may catch and release electrons from and to the target atoms, in processes such as $He^+ + e^- \rightarrow He^0$ and the reverse process $He^0 \rightarrow He^+ + e^-$. The process starts immediately. However, one could argue about the meaning of "immediately." The surface peak appearing in Fig. 39.16 can be assigned to the transient state of the charged state of the incident He ions. In other words, the He particles scattered from the topmost layer include both He^+ and He^0 at the moment of collision, and the stopping power of materials towards these two different charged states is different. As a result, the kinetic energies of scattered He^+ and He^0 can

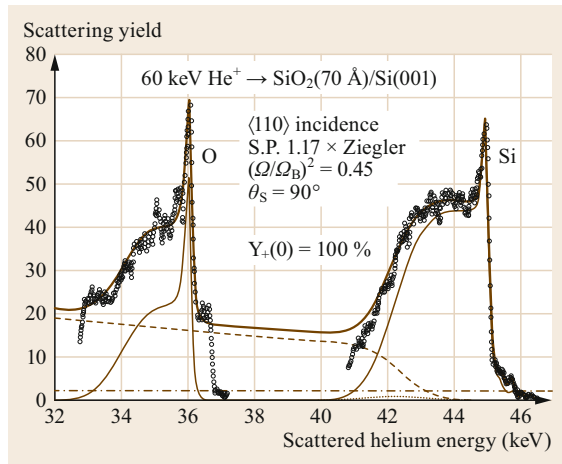

Fig. 39.16 Backscattering spectra in MEIS from Si and O of SiO_2 (70 Å) layer on Si(001) for 60-keV He^+ incident along [011] axis and backscattered at 90° (Reprinted with permission from [39.51], © 1999 by the American Physical Society)

be resolved when the energy resolution (corresponding to the depth resolution) is extremely high. Thus, the high resolution of MEIS enables observation of the nonequilibrium state of ion–surface interactions just at the moment when the ions collide with the solid surface.

Here, another impressive work on RBS channeling and blocking can be introduced. When N atoms are implanted in a shallow region of the Cu(100) surface and annealing is eventually performed, a two-dimensional array of square patches (Fig. 39.17a) spontaneously forms. RBS channeling and blocking measurements by *Cohen* et al. confirmed that this self-organized structure is induced by the lattice strain due to the adsorption of nitrogen at the topmost layer both in the plane and along the vertical direction, obtaining not only qualitative but also quantitative agreement between model and experiment [39.52]. Figure 39.17b shows the blocking dip around the 130° axis taken on stage 1 and stage 2, which correspond to a surface with a two-dimensional array of patches and the N-saturated surface, respectively. On both surfaces, the bottom positions of the blocking dips are significantly shifted from the 135° direction. The dashed and solid lines in Fig. 39.17b show the dip patterns simulated based on the Cu atom displacement shown in Fig. 39.17c. One can thus conclude that the lattice strain is induced not only at the topmost layer but also in the relatively deep subsurface region. Following this report, the authors undertook a detailed study of the electronic structure of the Cu(100)-N surface by photoemission and found a modification of the band structure both at the surface and in the subsurface region [39.53, 54].

39.9 Introduction to NRA

One of the most useful aspects of the ion beam technique or ion beam analysis is that they are sensitive to protons at or in materials. Dissociatively adsorbed hydrogen always exists as a proton, because its only electron is involved in the chemical bond with neighbors. Therefore, techniques that use inner-shell electrons as probes, such as x-ray photoemission and/or Auger electron spectroscopy, are blind to the amount of hydrogen at surfaces or subsurface sites. Despite the existence of different nuclear reactions to observe the presence of hydrogen, the $^{1}H(^{15}N, \alpha\gamma)^{12}C$ reaction between 6.385-MeV ^{15}N and a proton is the most frequently used in surface science, because of its very high cross section (≈ 1.65 b) and very narrow (≈ 1.85 keV) resonant width. The latter property enables the investigation of the dynamics of hydrogen at surfaces and subsurface sites. This reaction emits an α-particle and a γ-ray. Usually, the characteristic 4.43-MeV γ-rays, which can easily penetrate through the vacuum chamber wall, are detected by scintillators outside the chamber. $Bi_4Ge_3O_{12}$ (BGO) scintillators are often used because, although they do not have very good energy resolution

for γ-rays, their detection efficiency is better for 4-MeV γ-rays than most other common crystals. Once the effective solid angle of the detector (usually a scintillator) has been determined, the γ-ray yield is proportional to the quantity of hydrogen (or proton) in the corresponding depth region. Of course, NRA is useful not only for observation of hydrogen but also to detect other light elements. A study using ^{16}O and ^{18}O detection is introduced below; regarding other reactions, with B etc., the reader is redirected to specific IBA textbooks [39.55].

39.10 Application of NRA for H at the Surface and in the Subsurface Region

The H absorption–desorption properties of Pd have attracted much attention for a long time and remain a hot topic. As for the bulk properties, the author lists some textbooks as references [39.56, 57]. During absorption and desorption of hydrogen, entrance and exit occur at the surface of Pd. The microscopic behavior of hydrogen atoms at the Pd surface and in the subsurface region, in particular at subsurface sites, is not yet completely understood. In thermal desorption spectroscopy (TDS), hydrogen at subsurface sites desorbs first, followed by hydrogen at on-surface sites. Figure 39.18a shows an NRA profile taken on the Pd(100) surface at 100 K. All the sample preparations and measurements were performed in ultrahigh vacuum (UHV) as for any other surface science study [39.58]. One can see a peak at a depth of 0 nm, corresponding to hydrogen adsorbed at the Pd(100) surface. There are also a shoulder and a tail up to depth of ≈ 8 nm, corresponding to subsurface hydrogen. The dark filled circles shown in Fig. 39.18b are the TDS spectra for this system. There are two peaks, seen just below 200 and at ≈ 320 K. These peaks can be clearly assigned based on the temperature dependence of the NRA yields. According to the NRA results, the subsurface (≈ 6 nm depth) hydrogen disappears just below 200 K, while the NRA yield at the surface (0 nm depth) does not change at this temperature. The hydrogen on the surface desorbs at the temperature at which the second TDS peak appears (≈ 320 K). In other words, the subsurface hydrogen desorbs first, followed by surface hydrogen at much higher temperature. This phenomenon is commonly seen also on other metal surfaces. It is still a great puzzle to explain how hydrogen atoms in the subsurface or at shallow bulk sites can find a partner and desorb as H_2 without visiting a surface adsorption site.

39.11 Application of NRA for H in Nanoclusters on the Surface

It is often said that the discrepancy between industrial catalysis and surface science studies may result from the nanosize of the metal particles used in industrial conditions. The hydrogen absorption properties of Pd nanoclusters seem to be different from those of well-defined Pd surfaces. *Wilde* et al. studied the hydrogen concentration on and in well-defined Pd nanoclusters self-organized on the Al_2O_3/NiAl(110) surface [39.59]. The typical dimensions of the Pd nanocluster are ≈ 10 nm width and ≈ 2 nm height. Figure 39.19a shows NRA profiles taken on Pd nanoclusters (0.59 nm)/Al_2O_3/NiAl(110) at 90 K in an H_2 atmosphere with pressure of 2×10^{-5}, 6×10^{-4}, and 2×10^{-3} Pa, respectively. With increasing H_2 pressure, the amount of absorbed hydrogen (blue line) increases while the concentration on the Pd nanoclusters (orange Gaussian) remains constant. These results are rather obvious and not very interesting. The problem is the stability of hydrogen in the Pd nanoclusters against temperature (or heat). Figure 39.19c shows the temperature dependence of the NRA yields taken at the surface (open circles) and inside (blue filled circles) of the Pd nanoclusters when keeping the H_2 pressure at ≈ 10^{-3} Pa. The amount of surface hydrogen becomes half as large at ≈ 350 K, while that of absorbed hydrogen decreases by a factor of two already at ≈ 250 K. This tendency for surface hydrogen to be more stable than absorbed hydrogen is similar to the tendency observed on the extended surface. However, the desorption temperature of absorbed hydrogen of ≈ 250 K is much higher than the value on the single-crystal Pd(100) surface, which is ≈ 180 K. This could be attributed to the scenario that the lattice relaxation of Pd due to the nanosize effect stabilizes α-phase hydrogen in the Pd nanoclusters.

39.12 Hydrogen Embrittlement Studied by Microbeam NRA

Hydrogen embrittlement of metal structures is a serious problem in architecture and civil engineering. While many macroscopic phenomenological models have been established, there are still open questions about the microscopic mechanism. IBA may not always be useful to study hydrogen embrittlement, because the diffusion coefficient of atomic hydrogen or protons in metals is very large. On the other hand, the typical time resolution of IBA is from several minutes to several tens of minutes. However, IBA techniques such as NRA can make some contributions by detecting clues regarding the hydrogen embrittlement process.

In this regard, fatigue-fractured surfaces of glassy alloys $Zr_{50}Cu_{37}Al_{10}Pd_3$ and $Zr_{50}Cu_{40}Al_{10}$ have been studied [39.60]. For both samples, the fracture started from the region surrounded by the white broken lines visible in Fig. 39.20a,e. The hydrogen accumulation or concentration was surveyed by NRA with a lateral resolution given by the beam diameter of 150 μm over a $3 \times 3\,mm^2$ area. NRA in-plane mapping was performed at three depths of ≈ 2.5, ≈ 8, and ≈ 20 nm (Fig. 39.20). Note that, in the shallow region, accumulations are seen just below the area where the fatigue fractures started (area A in Fig. 39.20b and D in Fig. 39.20f). Similar accumulations were also found in deeper regions on the $Zr_{50}Cu_{40}Al_{10}$ but not $Zr_{50}Cu_{37}Al_{10}Pd_3$ sample. This difference can be ascribed to the existence of a small amount of Pd in the $Zr_{50}Cu_{37}Al_{10}Pd_3$. Further studies are needed to obtain a more detailed interpretation.

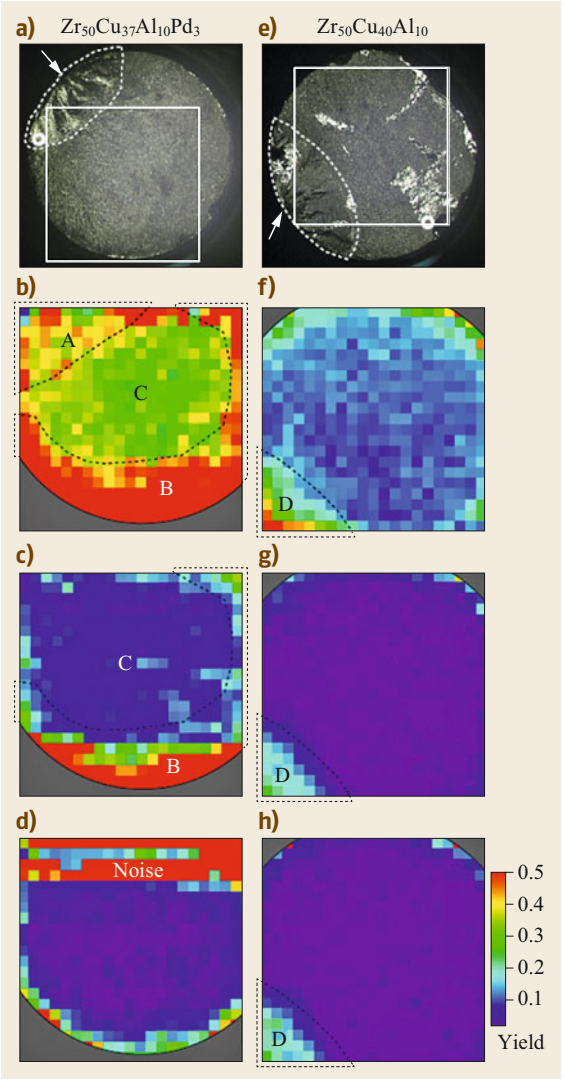

Fig. 39.20 **(a,e)** Optical microscopy images of the alloys $Zr_{50}Cu_{37}Al_{10}Pd_3$ and $Zr_{50}Cu_{40}Al_{10}$, The other panels show the in-plane distribution of the γ-ray relative yield taken at three different depths on $Zr_{50}Cu_{37}Al_{10}Pd_3$ **(b–d)** and $Zr_{50}Cu_{40}Al_{10}$ **(f–h)** at ≈ 2.5, ≈ 8, and ≈ 20 nm, respectively (Reprinted from [39.60], with permission from Elsevier) ►

39.13 NRA to Study Oxide Film Growth

As mentioned above, various NRA techniques can be used to quantify light elements. Here an isotope tracing method for ^{18}O with the 151-keV $^{18}O(p,\alpha\gamma)^{15}N$ resonance is introduced [39.61]. Sensitivity to only one specific isotope is a main advantage provided by IBA. $Hf^{16}O_2$ films were deposited first on Si(100) wafers using $HfCl_4$ and H_2O, then the films were exposed to an $^{18}O_2$ atmosphere at 100 mbar and 800 °C. The results revealed that the ^{16}O in the initial HfO_2 film was easily replaced by $^{18}O_2$ from the gas phase and that O defects were repaired. Figure 39.21a,b shows the ^{18}O depth profiles taken on HfO_2 films with different thicknesses of 3.5 and 7.5 nm, respectively. These two figures indicate that, after applying an annealing process in vacuum or N_2 atmosphere, the exchange process of oxygen between the gas and solid phases is considerably suppressed. The degree of suppression seems to depend on the HfO_2 film thickness. For the thinner film ($t = 3.5$ nm), the suppression was not so significant after N_2 annealing at 425 °C, while it was substantial

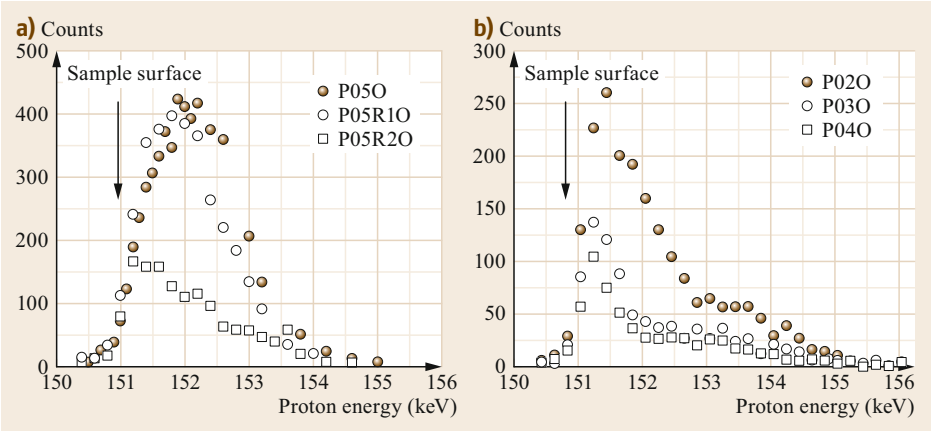

Fig. 39.21a,b NRA profiles of 151-keV $^{18}O(p,\alpha\gamma)^{15}N$ resonance taken on **(a)** 3.5-nm and **(b)** 7.5-nm HfO_2 thin films oxidized in $^{18}O_2$ atmosphere at 425 °C just after deposition (*filled circles*), postdeposition N_2 annealing at 425 °C (*open circles*), and postdeposition N_2 annealing at 800 °C (*open squares*). The details for each sample can be found in [39.61, Table 1]. (Reprinted from [39.61], with permission from Elsevier)

after N_2 annealing at 800 °C. On the other hand, on the thicker films ($t = 7.5$ nm), any type of N_2 annealing suppressed the oxygen exchange except for the surface and subsurface regions. This results implies that the crystallographic change or damage of HfO_2 film at the interface depends not only on the N_2 annealing condition but also on the thickness of the film. While the origin of this effect has not been understood yet, accumulation of lattice strain depending on the film thickness could be one of the possible causes. Thus, the isotope tracing method based on IBA is useful to assess the origin of elements in desired functional films.

39.14 Conclusions

IBA techniques with swift ions were reviewed in this chapter. Because of its intrinsic ≈ nm depth resolution, IBA is suitable to investigate surfaces, interfaces, and thin films. In particular, RBS, ERDA, and NRA allow the determination of the *absolute* elemental composition and yield a depth profile. Sufficient sensitivity to hydrogen or protons in materials is another distinctive property of IBA techniques. Although the basis of most IBA techniques was established almost 100 years ago, they are still developing fast. One of the reasons is the recent progress in MOSFETs using wide-gap semiconductors such as GaN, SiC, and diamond, for which IBA information has proved to be crucial. Accurate control of the interface content of light elements is indeed mandatory for such devices. Another reason is connected to the new strategy for functional materials synthesis, for which thin films without rare metals are required.
