Gian P. Brivio (deceased)

Gian Paolo Brivio was a Professor at the University of Milano-Bicocca(Italy) in Physics of Matter. His research focused on theoretical problems in surface and materials science. Specifically the investigation of magnetic effects in the interaction of molecules with graphene and adsorption of organic molecules on solids focusing on spectroscopic properties, excited states, and their lifetimes. He founded the European Doctoral Network in Physics and Chemistry of AdvancedMaterials (PCAM) in 2006. He had been Adjunct Professor at University Southern Denmark since 2015.

Guido Fratesi

Physics Department
University of Milano
Milano, Italy
guido.fratesi@unimi.it

Guido Fratesi is Associate Professor in Physics of Matter, the University of Milano. His research addresses surface systems and two-dimensional materials from first-principles theoretical approaches, especially for the properties of adsorbed organic molecules in relation to electron core-level techniques. He was co-organizer of the 17th Workshop on Dynamical Phenomena at Surfaces (2016) and of the 23rd and 24th Workshops of the European Theoretical Spectroscopy Facility (2018 and 2019).

Collective Part D

Part D Collective And Single Particle Excitations

Part D deals with collective and single-particle excitations at the surfaces of conductors. These excitations determine responses to photon and electron beams, energy transfer, and screening. As such, they impact on photoemission intensities and optical properties. Collective excitation at a surface is known as a surface plasmon (SP), which—in contrast to volume plasmons—corresponds to a transversally polarized mode. As such, the SP dispersion mixes with the light cone, giving rise to surface plasmon polaritons (SPPs) that are characterized by a lower group velocity (and hence a shorter wavelength) than light. SPPs may be excited by photons whenever the missing momentum is provided by a grating or surface disorder. They determine the Mie resonance at nanosized noble-metal particles, which produces the bright colors of the glass used in medieval cathedrals. SPPs are at the heart of plasmonic applications, including surface plasmon resonance spectroscopy and energy harvesting in solar cells.

Electronic excitations at metallic surfaces are important deexcitation channels for adsorbate vibrations and are responsible for nonadiabatic effects in adsorption processes, thus influencing chemical reactions. In contrast, SPs are too high in energy to contribute to energy dissipation under normal conditions. A notable exception is the recently discovered acoustic surface plasmon, which corresponds to the counterphase motion of the electrons of a Shockley surface state or a two-dimensional material such as graphene and an underlying three-dimensional electron gas. This mode is characterized by a much lower group velocity than polaritons, and therefore extends over a larger volume of phase space.

Chapter 17 is devoted to the theoretical underpinnings of the dielectric responses of quasi two-dimensional crystals to incident electron and photon beams, and covers a wide set of electronic and optical phenomena, such as the excitation of monopole, multipole, two-dimensional, and acoustic surface plasmons. First, the conventional formalism of the energy-loss functions is introduced, after which it is shown that a more general approach that takes into account the kinematics of the probing particle in the excitation process is required. Finally, the role of nonlocality in the response is addressed. This nonlocality leads to strong enhancement of the microscopic electric field at the surface, thus providing an explanation for photoyield data and multipole plasmon excitations.

Chapter 18 introduces the concepts of SP propagation and localized SP resonance. The surface plasmon frequency is determined by the bulk electron density, which typically leads to ultraviolet wavelengths. On the other hand, SP dispersion at wavelengths much smaller than those of light is dictated by surface properties, particularly the position of the induced charge with respect to the geometric surface plane. Since the latter sits outside the surface, the SP energy decreases with wavevector. The opposite happens for noble metal surfaces, as interband transitions displace the SP to lower frequencies, and this effect becomes less efficient with wavevector. Nanostructuring and adsorption-induced reconstructions are shown to affect the SP dispersion as well.

Chapter 19 covers plasmons in one- and two-dimensional (1-D and 2-D, respectively) systems. In contrast to ordinary surface plasmons of metallic bulk materials, the energy of a plasmon in a 1-D or 2-D system vanishes in the long wavelength limit, thus covering all energies from terahertz to the near-infrared, while the wavelength ranges from mesoscopic to nanometric. In the first part of the chapter, plasmons in 2-D systems are reviewed, including acoustic surface plasmons, which have a linear rather than a square-root-like dispersion. In the second part of the chapter, plasmon excitations in 1-D (linear chains) are presented, and it is shown that the slope of the dispersion is affected by the nature of the substrate and the separation between neighboring monoatomic chains.

Chapter 20 explores the theory of interband transitions, focusing on state-of-the-art ab initio methods with an emphasis on semiconductor surfaces. After providing a general theoretical framework for surface spectroscopies, the chapter reviews the main ab initio approaches based on density functional theory (DFT), Green's function (many-body theory or the GW method), the Bethe–Salpeter equation, and time-dependent DFT. Many examples of calculated spectra that are relevant to experimental electron spectroscopy of clean and modified surfaces of several semiconductors are included. Attention is also paid to the differences involved in extracting exciton binding energies using the GW, Bethe–Salpeter, and time-dependent DFT approaches. Despite theoretical and experimental difficulties, it is possible to match the surface interband transition spectrum to the surface morphology with high levels of accuracy and sensitivity to reconstructions.

17. Electron Energy-Loss and Photoelectron Spectroscopies of Surfaces and Two-Dimensional Crystals

Vladimir U. Nazarov, Eugene E. Krasovskii, Vyacheslav M. Silkin

Dielectric response of crystal surfaces and quasi two-dimensional (Q2-D) crystals to incident electrons and photons underlies a variety of electronic and optical phenomena, such as the excitation of monopole, multipole, two-dimensional (2-D), and acoustic plasmons, which have vast implications for optical and electron spectroscopies. This chapter covers model and electronic structure approaches to dynamic dielectric screening and discusses the development of the field from the pioneering works by R.H. Ritchie and P. Feibelman up to recent ab-initio developments. Starting with the quantum-mechanical expression for the microscopic dielectric response (Sect. 17.1), we explain the emergence of surface plasmon modes and discuss their structure based on simplified model systems. We further introduce an ab-initio approach to calculate the response function for realistic systems. We discuss how the excitations manifest themselves in the inelastic scattering of electrons reflected from a solid surface or a Q2-D crystal (Sect. 17.2), at first confining ourselves to the conventional formalism of energy-loss functions. We then demonstrate the necessity to go beyond this formalism and present the theory of the inelastic scattering of electrons, which takes into account the effect of the kinematics of the probing particle on the excitation process (Sect. 17.3). Finally, we show how the nonlocal response to the incident light leads to a strong enhancement of the microscopic electric field at the surface and how the total exciting field can be included into an ab-initio one-step photoemission theory to describe photoyield enhancement (Sects. 17.6 and 17.7).

17.1 Probing Solid Targets with Electrons and Light: What Kind of a Theory Do We Need?

Electron energy-loss spectroscopy (EELS) has by now developed into a very powerful experimental method for studying objects ranging from bulk solids (mimicked by sufficiently thick films), through thin films and surfaces of semi-bulk materials, to nano-objects of two and lower dimensionality. In the literature, the term EELS refers to two experimental techniques that are very different in their instrumental implementation. These are the more traditional high-resolution electron energy-loss spectroscopy (HREELS) [17.1, 2] and the newer version of the EELS in the transmission electron microscope (TEM) [17.3]. Fundamentally, both methods employ electron beams incident onto a target, which, after the inelastic scattering, are analyzed with respect to energy and momentum. In HREELS, electrons reflected from a solid surface are collected, with the incident energies usually ranging from several to several hundred eV. On the other hand, EELS in TEM employs incident energies in the range from tens to hundreds of keV, and it uses the transmission regime of electron scattering. Application of HREELS can be divided, in its turn, into two principal categories: those studying *electronic* excitations (with the energy losses roughly on the scale of 0.1−10 eV) and those concerned with *phononic* processes (with the losses roughly of the order of 10 meV). In the following, we will be exclusively dealing with electronic excitations, referring the reader interested in phonons to the corresponding literature (see [17.4–7], where the impact regime of the HREELS of surface phonons is considered).

The theory has almost always considered electronic excitations in HREELS and in the transmission EELS in TEM from very different perspectives. HREELS was traditionally treated within the concept of the *dipole* regime of scattering, while EELS in TEM was described within the *impact* regime. The former is characteristic of the inelastic scattering outside a target via long-range Coulomb interaction, while the latter concerns the short-range collisions with electrons of the target [17.8]. A notable exception from this picture has, however, been promoted in an approach founded in [17.9–11], which takes account of both the inelastic and elastic aspects of electron scattering at a solid target and, by this, does not require the artificial division of the scattering into the two different categories. Below, we adopt the latter approach and show that the two regimes can both be treated on the same footing, once a general expression for the double differential cross section of the electron scattering has been derived [17.9], from which those regimes follow as specific cases. Moreover, this approach reveals situations when the dipole and impact regimes intermix, thereby losing their distinct meaning, while the general formula holds and produces a consistent description of EELS [17.12, 13].

The methodology of this chapter is top down. In particular, results are not presented in chronological order. We first derive our main general expression for the inelastic double differential cross section of a charged projectile (electron, in particular) scattering on a solid (or atomic) target. We then demonstrate how this general result reduces to the known quantities (bulk and surface energy-loss functions, etc.) for particular targets and scattering geometries. We also emphasize cases when such a reduction is impossible and the scattering formalism must be used in its full extent. We will use atomic units ($\hbar = e = m = 1$) unless otherwise stated.

17.2 Inelastic Scattering of Electrons: General Formalism

The purpose of this section is to derive the differential cross section of an electron inelastic scattering on an arbitrary many (or few)-body system, representing it *in terms of the density-response function*. For simplicity, below we consider the zero temperature case. The interacting density-response function $\chi(\boldsymbol{r}, \boldsymbol{r}', \omega)$ determines the linear response of the particle density $n^{(1)}(\boldsymbol{r}, \omega)$ to the externally applied potential $v^{(1)}_{\rm ext}(\boldsymbol{r}, \omega)$, and it is defined by

$$n^{(1)}(\boldsymbol{r}, \omega) = \int \chi(\boldsymbol{r}, \boldsymbol{r}', \omega) v^{(1)}_{\rm ext}(\boldsymbol{r}', \omega) {\rm d}\boldsymbol{r}' \,. \qquad (17.1)$$

Below we will need an expression for χ in terms of the complete set of the eigenfunctions $|n\rangle$ and eigenvalues E_n of the many-body system under consideration, which, for self-containedness, we shortly derive as follows. We write down the Liouville equation [17.14]

$${\rm i}\frac{\partial \hat{\rho}}{\partial t} = \left[\hat{H}, \hat{\rho}\right], \qquad (17.2)$$

where

$$\hat{H} = \sum_{i=1}^{N}\left[-\frac{1}{2}\Delta_i + v_{\rm ext}(\boldsymbol{r}_i, t)\right] + \sum_{i<j}^{N}\frac{1}{|\boldsymbol{r}_i - \boldsymbol{r}_j|} \qquad (17.3)$$

is the time-dependent many-body Hamiltonian, and $\hat{\rho}$ is the many-body density matrix. Assuming the

time-dependent part of the external potential to be weak and assuming it to be monochromatic $v_{\rm ext}^{(1)}(\boldsymbol{r},t) = v_{\rm ext}^{(1)}(\boldsymbol{r},\omega)\mathrm{e}^{-\mathrm{i}\omega t}$, we linearize (17.2) to

$$\omega\hat{\rho}^{(1)} = \left[\hat{H}^{(0)},\hat{\rho}^{(1)}\right] + \left[\hat{H}^{(1)},\hat{\rho}^{(0)}\right], \tag{17.4}$$

where

$$\hat{H}^{(0)} = \sum_{i=1}^{N}\left[-\frac{1}{2}\Delta_i + v_{\rm ext}^{(0)}(\boldsymbol{r}_i)\right] + \sum_{i<j}^{N}\frac{1}{|\boldsymbol{r}_i-\boldsymbol{r}_j|}\,, \tag{17.5}$$

$$\hat{H}^{(1)} = \sum_{i=1}^{N} v_{\rm ext}^{(1)}(\boldsymbol{r}_i,\omega)\,. \tag{17.6}$$

Taking matrix elements of (17.4) between the many-body states $\langle n|$ and $|m\rangle$, we find for the perturbation of the density matrix

$$\langle n|\hat{\rho}^{(1)}|m\rangle = \frac{\delta_{m0}-\delta_{n0}}{E_m-E_n+\omega+\mathrm{i}\eta}\langle n|\hat{H}^{(1)}|m\rangle\,, \tag{17.7}$$

where an infinitesimal imaginary quantity $\mathrm{i}\eta$ has been added to the frequency to ensure the proper decay of the perturbation at $t=-\infty$.

The density perturbation is the trace (spur) of the density operator

$$\hat{n}(\boldsymbol{r}) = \sum_{i=1}^{N}\delta(\boldsymbol{r}_i-\boldsymbol{r}) \tag{17.8}$$

taken with the perturbation of the density matrix of (17.7). Therefore,

$$\begin{aligned} n^{(1)}(\boldsymbol{r},\omega) &= \mathrm{Sp}\left[\hat{\rho}^{(1)}\hat{n}\right] \\ &= \sum_{nm}\frac{\delta_{m0}-\delta_{n0}}{E_m-E_n+\omega+\mathrm{i}\eta}\langle m|\hat{n}(\boldsymbol{r})|n\rangle\langle n|\hat{H}^{(1)}|m\rangle \\ &= \int\sum_{nm}\frac{\delta_{m0}-\delta_{n0}}{E_m-E_n+\omega+\mathrm{i}\eta}\langle m|\hat{n}(\boldsymbol{r})|n\rangle\langle n|\hat{n}(\boldsymbol{r}')|m\rangle \\ &\quad\times v_{\rm ext}^{(1)}(\boldsymbol{r}',\omega)\mathrm{d}\boldsymbol{r}'\,. \end{aligned} \tag{17.9}$$

Comparing (17.9) and (17.1), we conclude that

$$\chi(\boldsymbol{r},\boldsymbol{r}',\omega) = \sum_{nm}\frac{\delta_{m0}-\delta_{n0}}{E_m-E_n+\omega+\mathrm{i}\eta} \times\langle m|\hat{n}(\boldsymbol{r})|n\rangle\langle n|\hat{n}(\boldsymbol{r}')|m\rangle\,, \tag{17.10}$$

which can be split into the reactive and the absorptive parts

$$\chi(\boldsymbol{r},\boldsymbol{r}',\omega) = \chi^{\rm R}(\boldsymbol{r},\boldsymbol{r}',\omega) + \mathrm{i}\chi^{\rm A}(\boldsymbol{r},\boldsymbol{r}',\omega)\,, \tag{17.11}$$

$$\chi^{\rm R}(\boldsymbol{r},\boldsymbol{r}',\omega) = \mathcal{P}\sum_{nm}\frac{\delta_{m0}-\delta_{n0}}{E_m-E_n+\omega} \times\langle m|\hat{n}(\boldsymbol{r})|n\rangle\langle n|\hat{n}(\boldsymbol{r}')|m\rangle\,, \tag{17.12}$$

$$\chi^{\rm A}(\boldsymbol{r},\boldsymbol{r}',\omega) = \pi\sum_{nm}(\delta_{n0}-\delta_{m0})\delta(E_m-E_n+\omega) \times\langle m|\hat{n}(\boldsymbol{r})|n\rangle\langle n|\hat{n}(\boldsymbol{r}')|m\rangle\,, \tag{17.13}$$

where $\mathcal{P}$ denotes the principal value. If, as we will always assume below, there is no magnetic field involved, $|n\rangle$ and $|n\rangle^*$ are eigenfunctions with the same eigenenergies E_n, from which it follows that

$$\chi^{\rm R}(\boldsymbol{r},\boldsymbol{r}',\omega) = \mathrm{Re}[\chi(\boldsymbol{r},\boldsymbol{r}',\omega)]\,, \tag{17.14}$$

$$\chi^{\rm A}(\boldsymbol{r},\boldsymbol{r}',\omega) = \mathrm{Im}[\chi(\boldsymbol{r},\boldsymbol{r}',\omega)]\,, \tag{17.15}$$

and

$$\chi(\boldsymbol{r}',\boldsymbol{r},\omega) = \chi(\boldsymbol{r},\boldsymbol{r}',\omega)\,. \tag{17.16}$$

17.2.1 Distorted-Waves Approach

The problem of the inelastic reflection of electrons at the surface cannot be solved within the Born approximation, since the reflection of electrons is the result of interaction with the lattice, which cannot be treated as weak.

Let us consider the scattering process schematically shown in Fig. 17.1. A projectile is elastically scattered by an atom or ion of the solid, and then it escapes into vacuum. While passing in the solid, it can suffer an inelastic scattering at the electron subsystem. We write down the many-body Hamiltonian of the target–projectile (the latter is assumed to be electron) system as

$$\hat{H} = \hat{H}_{\rm T} + \hat{H}_{\rm P} + \hat{H}_{\rm TP}\,, \tag{17.17}$$

$$\hat{H}_{\rm T} = \sum_{i=1}^{N}\left[-\frac{1}{2}\Delta_i + v_{\rm ext}(\boldsymbol{r}_i)\right] + \sum_{i<j}^{N}\frac{1}{|\boldsymbol{r}_i-\boldsymbol{r}_j|}\,, \tag{17.18}$$

$$\hat{H}_{\rm P} = -\frac{1}{2}\Delta + v_{\rm ext}(\boldsymbol{r})\,, \tag{17.19}$$

$$\hat{H}_{\rm TP} = \sum_{i=1}^{N}\frac{1}{|\boldsymbol{r}-\boldsymbol{r}_i|}\,. \tag{17.20}$$

In (17.18)–(17.20), $\boldsymbol{r}_i$ and $\boldsymbol{r}$ are positions of the electrons of the target and of the projectile, respectively.

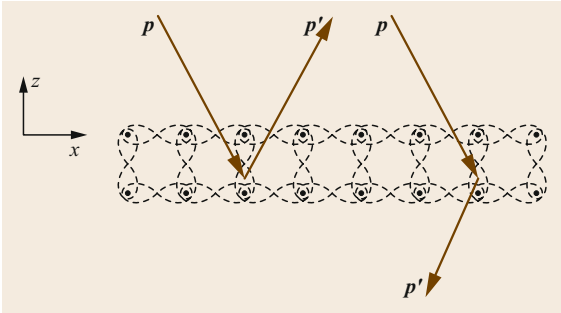

Fig. 17.1 Reflection and transmission geometries of the EELS experiment

Let us write down the differential cross section for an electron scattered from $|\boldsymbol{p}\rangle$ into $|\boldsymbol{p}'\rangle$ state with the transition of the solid from the ground state into an excited state of a complete orthonormal set of the eigenstates of the many-body system $|n\rangle$ [17.15]

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\boldsymbol{p}'}(\boldsymbol{p}', n \leftarrow \boldsymbol{p}, 0) = \frac{(2\pi)^4}{p}\delta(E' - E)|\mathbf{t}(\boldsymbol{p}', n \leftarrow \boldsymbol{p}, 0)|^2 , \tag{17.21}$$

where E and E' are the total energies of the system before and after the collision, and $\mathbf{t}$ is the T-matrix on the energy surface [17.15] corresponding to the Hamiltonian (17.17). (The concept of $\mathbf{t}$-matrix is basic to the theory of both elastic and inelastic scattering [17.15]. Without going too much into theoretical details, for us it is important that (i) the differential cross section is quite generally expressed by the $\mathbf{t}$-matrix on the energy shell ($E = E'$) by (17.21), and (ii) $\mathbf{t}$-matrix itself can be conveniently expressed in the distorted-wave approximation by (17.25).) Let us assume that:

(i) The problem of the single-particle (elastic) scattering of the projectile can be solved exactly or to some good approximation with the Hamiltonian

$$\hat{H}_\mathrm{P}^0 = -\frac{1}{2}\Delta + V^0(\boldsymbol{r}) = -\frac{1}{2}\Delta + v_\mathrm{ext}(\boldsymbol{r}) + v^0(\boldsymbol{r}) . \tag{17.22}$$

At this point, we do not specify the potential $v^0(\boldsymbol{r})$, deferring this until later.

(ii) The potential

$$V^1 = \sum_{i=1}^{N} \frac{1}{|\boldsymbol{r} - \boldsymbol{r}_i|} - v^0(\boldsymbol{r}) \tag{17.23}$$

can be considered *weak*.

Then, according to (17.17),

$$\hat{H} = \hat{H}_\mathrm{T} + \hat{H}_\mathrm{P}^0 + V^1 . \tag{17.24}$$

We will consider V^1 as a perturbation and will solve the scattering problem in the first Born approximation with respect to V^1. Then, accounting for the perturbation of the first order, we obtain in the distorted-waves approximation [17.15]

$$\mathbf{t}(\boldsymbol{p}', n \leftarrow \boldsymbol{p}, 0) = \mathbf{t}^0(\boldsymbol{p}', n \leftarrow \boldsymbol{p}, 0) + \langle(\boldsymbol{p}', n)^{-0}|V^1|(\boldsymbol{p}, 0)^{+0}\rangle , \tag{17.25}$$

where $\mathbf{t}^0$ is $\mathbf{t}$ with the perturbation V^1 neglected,

$$|(\boldsymbol{p}, n)^{\pm 0}\rangle = \Omega_\pm|(\boldsymbol{p}, n)\rangle ,$$

where $\Omega_{\pm 0}$ are the Möller's operators of the scattering problem without perturbation [17.15], and $|\boldsymbol{p}\rangle$ are plane waves.

From here on, we will be interested in the scattering into the inelastic channel $|n\rangle \neq |0\rangle$ only. Then, since the solid is excited by the external perturbation, the first term in (17.25) is zero. Furthermore, if there is no perturbation, the scattering of the electron at the target does not depend on the electron subsystem, which leads to

$$|(\boldsymbol{p}, n)^{\pm 0}\rangle = |\boldsymbol{p}^\pm\rangle|n\rangle , \tag{17.26}$$

where $|\boldsymbol{p}^\pm\rangle$ are solutions of the Lippmann–Schwinger equation [17.15]

$$|\boldsymbol{p}^\pm\rangle = |\boldsymbol{p}\rangle + G^0\left(\frac{p^2}{2} \pm i0_+\right)V^0\,|\boldsymbol{p}^\pm\rangle . \tag{17.27}$$

Here, G^0 is the Green's function of a free particle. We can write by the use of (17.25) and (17.23)

$$\mathbf{t}(\boldsymbol{p}', n \leftarrow \boldsymbol{p}, 0) = \int \frac{\rho^*(\boldsymbol{r})\langle n|\hat{n}(\boldsymbol{r}')|0\rangle}{|\boldsymbol{r} - \boldsymbol{r}'|}\mathrm{d}\boldsymbol{r}\mathrm{d}\boldsymbol{r}' , \tag{17.28}$$

where

$$\rho(\boldsymbol{r}) = \langle \boldsymbol{r}|\boldsymbol{p}^+\rangle^* \langle \boldsymbol{r}|\boldsymbol{p}'^-\rangle . \tag{17.29}$$

Substituting (17.28) into (17.21), we have

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\boldsymbol{p}'}(\boldsymbol{p}', n \leftarrow \boldsymbol{p}, 0) = \frac{(2\pi)^4}{p}\delta\left(\frac{p'^2}{2} + E_n - \frac{p^2}{2} - E_0\right) \times \int \frac{\rho^*(\boldsymbol{r})\langle n|\hat{n}(\boldsymbol{r}')|0\rangle}{|\boldsymbol{r} - \boldsymbol{r}'|}\frac{\rho(\boldsymbol{r}_1)\langle 0|\hat{n}(\boldsymbol{r}_1')|n\rangle}{|\boldsymbol{r}_1 - \boldsymbol{r}_1'|}\mathrm{d}\boldsymbol{r}\mathrm{d}\boldsymbol{r}'\mathrm{d}\boldsymbol{r}_1\mathrm{d}\boldsymbol{r}_1' , \tag{17.30}$$

where E_n are the energies of the electron subsystem in the corresponding states.

Regardless of the final state of the solid, the differential cross section is obtained from (17.30) by the summation over $|n\rangle$. This gives

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\boldsymbol{p}'}(\boldsymbol{p}' \leftarrow \boldsymbol{p}) = \frac{(2\pi)^4}{p} \sum_n \delta\left(\frac{p'^2}{2} + E_n - \frac{p^2}{2} - E_0\right) \times \int \frac{\rho^*(\boldsymbol{r})\langle n|\hat{n}(\boldsymbol{r}')|0\rangle}{|\boldsymbol{r}-\boldsymbol{r}'|} \frac{\rho(\boldsymbol{r}_1)\langle 0|\hat{n}(\boldsymbol{r}_1')|n\rangle}{|\boldsymbol{r}_1-\boldsymbol{r}_1'|} \mathrm{d}\boldsymbol{r}\mathrm{d}\boldsymbol{r}'\mathrm{d}\boldsymbol{r}_1\mathrm{d}\boldsymbol{r}_1' \,. \tag{17.31}$$

On the other hand, with the use of (17.13), we can write

$$\chi^{\mathrm{A}}(\boldsymbol{r},\boldsymbol{r}',\omega) = \pi \sum_n \delta(E_n - E_0 + \omega)\langle n|\hat{n}(\boldsymbol{r})|0\rangle\langle 0|\hat{n}(\boldsymbol{r}')|n\rangle - \pi \sum_n \delta(E_0 - E_n + \omega)\langle 0|\hat{n}(\boldsymbol{r})|n\rangle\langle n|\hat{n}(\boldsymbol{r}')|0\rangle \,,$$

or, for $\omega > 0$ and taking into account that $E_n > E_0$,

$$\chi^{\mathrm{A}}(\boldsymbol{r},\boldsymbol{r}',\omega > 0) = -\pi \sum_n \delta(E_0 - E_n + \omega) \times \langle 0|\hat{n}(\boldsymbol{r})|n\rangle\langle n|\hat{n}(\boldsymbol{r}')|0\rangle \,. \tag{17.32}$$

Combining (17.31) and (17.32) with (17.15) and (17.16), we can write

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\boldsymbol{p}'}(\boldsymbol{p}' \leftarrow \boldsymbol{p}) = -\frac{16\pi^3}{p} \times \mathrm{Im}\left(\int \frac{\rho^*(\boldsymbol{r})\chi(\boldsymbol{r}',\boldsymbol{r}_1',\omega)\rho(\boldsymbol{r}_1)}{|\boldsymbol{r}-\boldsymbol{r}'||\boldsymbol{r}_1-\boldsymbol{r}_1'|}\mathrm{d}\boldsymbol{r}\mathrm{d}\boldsymbol{r}'\mathrm{d}\boldsymbol{r}_1\mathrm{d}\boldsymbol{r}_1'\right), \tag{17.33}$$

where

$$\omega = \frac{p^2 - p'^2}{2} \,.$$

Equation (17.33) can be rewritten in the form of the double differential cross-section

$$\frac{\mathrm{d}^2\sigma}{\mathrm{d}\omega\mathrm{d}\Omega}(\boldsymbol{p}' \leftarrow \boldsymbol{p}) = -\frac{16\pi^3 p'}{p} \times \mathrm{Im}\left(\int \frac{\rho^*(\boldsymbol{r})\chi(\boldsymbol{r}',\boldsymbol{r}_1',\omega)\rho(\boldsymbol{r}_1)}{|\boldsymbol{r}-\boldsymbol{r}'||\boldsymbol{r}_1-\boldsymbol{r}_1'|}\mathrm{d}\boldsymbol{r}\mathrm{d}\boldsymbol{r}'\mathrm{d}\boldsymbol{r}_1\mathrm{d}\boldsymbol{r}_1'\right), \tag{17.34}$$

where $\mathrm{d}\Omega$ is the element of the solid angle. Equation (17.34) is the main result of this section. It is instructive to note that, since (17.34) relates the differential cross section of the inelastic scattering of the projectile to the absorption part of the density-response function, it is a variant of the fluctuation-dissipation theorem [17.16]. Another observation is that in (17.34), $\rho(\boldsymbol{r})$, given by (17.29) and (17.27), plays a role of a complex-valued charge density, which both excites our system and experiences the effect of its excitation.

At this point, we make a connection to the pretime-dependent density functional theory (TDDFT) literature on the inelastic diffraction [17.17–21] based on the concept of the mixed dynamic form factor (MDFF) [17.17]. We note that:

(i) Equation (17.34) can be also written in terms of MDFF rather than χ. Although the two forms are equivalent, expression via χ is of paramount importance for us, allowing us to invoke the linear-response TDDFT, for which χ is the key quantity [17.22].
(ii) For three-dimensional (3-D) crystals, (17.33) and (17.34) reduce to the results of [17.20], but their applicability is broader, permitting, in particular, their use in the Q2-D case, in the Laue (17.79), rather than Bloch function representation.

Up to this point we have not specified the potential $v^0(\boldsymbol{r})$ of (17.22), which has been added and subtracted from the total Hamiltonian. Since $v^0(\boldsymbol{r})$ is introduced to make the perturbation V^1 of (17.23) weak, one choice can be the Hartree potential. Another convenient choice of $v^0(\boldsymbol{r})$ is the sum of the Hartree and exchange-correlation potentials of the density functional theory (DFT). In the latter case, the single-particle Hamiltonian of (17.22) becomes the Kohn–Sham Hamiltonian [17.23], and the states $|\boldsymbol{p}^+\rangle$ and $|\boldsymbol{p}'^-\rangle$ of the projectile electron are obtained on the same footing as those of the electrons of the target.

17.3 Energy-Loss Functions

The traditional interpretation of the EELS of a bulk medium is known to be in terms of the bulk energy-loss function [17.24]

$$L_{\mathrm{b}}(\boldsymbol{q},\omega) = -\mathrm{Im}\left(\frac{1}{\epsilon(\boldsymbol{q},\omega)}\right), \tag{17.35}$$

where $\epsilon(\boldsymbol{q},\omega)$ is the wavevector and frequency-dependent dielectric function of the medium. In (17.35), $\boldsymbol{q}$ is the momentum, and ω is the energy transferred in the scattering event.

On the other hand, the reflection EELS at a surface of a semi-infinite medium is usually described with the

$g(\boldsymbol{q}_\parallel, \omega)$ function [17.25], where $\boldsymbol{q}_\parallel$ is the parallel-to-the-surface component of the transferred momentum. Deferring the definition of the g-function until below, here we write the surface energy-loss function in the long-wave limit as

$$L_s(\omega) = -\mathrm{Im}\left(\frac{1}{1+\epsilon(\omega)}\right) = -\frac{1}{2}\mathrm{Im}\left[g(\boldsymbol{q}_\parallel = \boldsymbol{0}, \omega)\right]. \tag{17.36}$$

In particular, (17.36) states that in *the long-wave limit*, the surface energy-loss function is determined by the bulk quantity $\epsilon(\omega)$. This, however, is not the case at $\boldsymbol{q}_\parallel \neq \boldsymbol{0}$, i.e., it would be meaningless to substitute the wavevector-dependent dielectric function into (17.36).

Since our equation (17.34) is general, the quantities of (17.35) and (17.36) must appear naturally from it at the corresponding conditions of the EELS setup. The purpose of this section is to demonstrate that it is, indeed, the case, which will give us insight into the general properties of our solution as well as set constraints on the applicability of the conventional approaches relying on the formulas of (17.35) and (17.36).

17.3.1 Bulk Scattering

Let us consider the transmission EELS through a film that is sufficiently thick, although penetrable, so that the surface scattering is of secondary importance, as schematized in Fig. 17.2. Let us neglect the projectile–ions interaction, considering only the scattering on the electron subsystem of the target. The reader can legitimately ask why this approximation can be made. If the target is a metal modeled with jellium and occupying the whole space, this is not an approximation, since, in this case, there is no crystal potential. Otherwise, it is difficult to justify this approximation a priori, and only a comparison with the results of the full theory of (17.34) can tell how important the effects of the elastic scattering on ions are. We, however, emphasize that the common use of (17.35) is based, most often implicitly, on the neglect of elastic scattering. Therefore, in (17.27), we now set $V^0(\boldsymbol{r}) = 0$, which leads to

$$\langle \boldsymbol{r}|\boldsymbol{p}^+\rangle = \langle \boldsymbol{r}|\boldsymbol{p}\rangle = \frac{\mathrm{e}^{\mathrm{i}\boldsymbol{p}\cdot\boldsymbol{r}}}{(2\pi)^{3/2}}\,,$$
$$\langle \boldsymbol{r}|\boldsymbol{p}'^-\rangle = \langle \boldsymbol{r}|\boldsymbol{p}'\rangle = \frac{\mathrm{e}^{\mathrm{i}\boldsymbol{p}'\cdot\boldsymbol{r}}}{(2\pi)^{3/2}}\,, \tag{17.37}$$

and, by (17.29),

$$\rho(\boldsymbol{r}) = \frac{\mathrm{e}^{\mathrm{i}(\boldsymbol{p}'-\boldsymbol{p})\cdot\boldsymbol{r}}}{(2\pi)^3}\,. \tag{17.38}$$

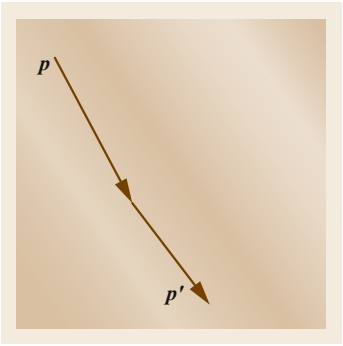

Fig. 17.2 Inelastic electron scattering in the bulk of a solid

Substituting (17.38) into (17.34), we have

$$\begin{aligned}\frac{\mathrm{d}^2\sigma}{\mathrm{d}\omega\mathrm{d}\Omega}(\boldsymbol{p}' \leftarrow \boldsymbol{p}) &= -\frac{p'}{4\pi^3 p}\mathrm{Im}\left(\int \frac{\chi(\boldsymbol{r}_1', \boldsymbol{r}', \omega)\mathrm{e}^{\mathrm{i}(\boldsymbol{p}'-\boldsymbol{p})\cdot(\boldsymbol{r}_1-\boldsymbol{r})}}{|\boldsymbol{r}-\boldsymbol{r}'||\boldsymbol{r}_1-\boldsymbol{r}_1'|}\mathrm{d}\boldsymbol{r}\mathrm{d}\boldsymbol{r}'\mathrm{d}\boldsymbol{r}_1\mathrm{d}\boldsymbol{r}_1'\right)\\ &= -\frac{4p'}{\pi p|\boldsymbol{p}-\boldsymbol{p}'|^4}\mathrm{Im}\left(\int \chi(\boldsymbol{r}_1, \boldsymbol{r}, \omega)\mathrm{e}^{\mathrm{i}(\boldsymbol{p}'-\boldsymbol{p})\cdot(\boldsymbol{r}_1-\boldsymbol{r})}\mathrm{d}\boldsymbol{r}\mathrm{d}\boldsymbol{r}_1\right)\\ &= -\frac{32\pi^2 p'}{p|\boldsymbol{p}-\boldsymbol{p}'|^4}\mathrm{Im}\left[\chi(\boldsymbol{p}-\boldsymbol{p}', \boldsymbol{p}-\boldsymbol{p}', \omega)\right],\end{aligned} \tag{17.39}$$

where the double Fourier transform of χ is

$$\chi(\boldsymbol{q}, \boldsymbol{q}', \omega) = \frac{1}{(2\pi)^3}\int \chi(\boldsymbol{r}, \boldsymbol{r}', \omega)\mathrm{e}^{\mathrm{i}(-\boldsymbol{q}\cdot\boldsymbol{r}+\boldsymbol{q}'\cdot\boldsymbol{r}')}\mathrm{d}\boldsymbol{r}\mathrm{d}\boldsymbol{r}'\,, \tag{17.40}$$

and in (17.39) χ is taken at $\boldsymbol{q} = \boldsymbol{q}' = \boldsymbol{p} - \boldsymbol{p}'$.

Equation (17.39) is the final result for a target of an arbitrary structure under the neglect of elastic scattering. We now consider a specific case of a uniform target occupying a box with a large size L with periodic boundary conditions. Then,

$$\chi(\boldsymbol{r}, \boldsymbol{r}', \omega) = \chi(\boldsymbol{r}-\boldsymbol{r}', \omega) \tag{17.41}$$

and

$$\chi(\boldsymbol{q}, \boldsymbol{q}', \omega) = \frac{\delta_{\boldsymbol{q}\boldsymbol{q}'}L^3}{(2\pi)^3}\chi(\boldsymbol{q}, \omega)\,, \tag{17.42}$$
$$\chi(\boldsymbol{q}, \omega) = \int \chi(\boldsymbol{r}, \omega)\mathrm{e}^{-\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{r}}\mathrm{d}\boldsymbol{r}\,. \tag{17.43}$$

Substituting (17.42) into (17.39), we have

$$\frac{\mathrm{d}^2\sigma}{\mathrm{d}\omega\mathrm{d}\Omega}(\boldsymbol{p}' \leftarrow \boldsymbol{p}) = -\frac{4p'}{\pi|\boldsymbol{p}-\boldsymbol{p}'|^4 p}L^3\mathrm{Im}\left[\chi(\boldsymbol{p}-\boldsymbol{p}', \omega)\right]. \tag{17.44}$$

After dividing the differential cross section of (17.44) by the area $S = L^2$, we obtain the probability of the scattering per $\mathrm{d}\omega\mathrm{d}\Omega$ interval at the path length of L. Further division by L yields the probability to be scattered into the above interval per unit path length. In other words,

$$\frac{\mathrm{d}^3P}{\mathrm{d}\omega\mathrm{d}\Omega\mathrm{d}l}(\boldsymbol{p}' \leftarrow \boldsymbol{p}) = -\frac{4\mathrm{e}^2m^2p'}{\pi|\boldsymbol{p}-\boldsymbol{p}'|^4p}\mathrm{Im}\left[\chi(\boldsymbol{p}-\boldsymbol{p}',\omega)\right], \tag{17.45}$$

or taking account of the relation between the density-response function and the dielectric function

$$\frac{1}{\varepsilon(\boldsymbol{q},\omega)} = 1 + \frac{4\pi}{q^2}\chi(\boldsymbol{q},\omega), \tag{17.46}$$

we can write

$$\frac{\mathrm{d}^3P}{\mathrm{d}\omega\mathrm{d}\Omega\mathrm{d}l}(\boldsymbol{p}' \leftarrow \boldsymbol{p}) = -\frac{p'}{\pi^2|\boldsymbol{p}-\boldsymbol{p}'|^2p}\mathrm{Im}\left(\frac{1}{\varepsilon(\boldsymbol{p}-\boldsymbol{p}',\omega)}\right). \tag{17.47}$$

Equation (17.47) is the justification of the concept of the bulk energy-loss function, introduced in (17.35), the prefactor being a smooth function of p and p'.

17.3.2 Surface Scattering

In this section, we will introduce the concept of *dipole scattering* in the reflection EELS [17.25] (in the geometry of Fig. 17.3) and, following our methodology, we will show how it arises from the general formula of (17.34) as a specific case.

We define the dipole regime as a scattering during which the projectile (its wavefunction) does not enter the electron charge density of the target, so that the interaction is only via Coulomb forces at a distance (of course, the interaction is always via Coulomb forces, but we will see that *at a distance* makes a big difference).

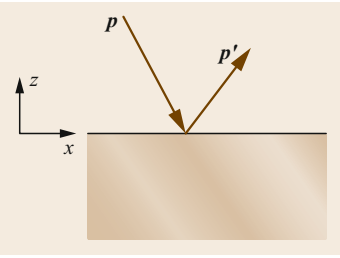

Fig. 17.3 Inelastic electron scattering from a semi-infinite solid in the reflection geometry

Let us assume that the target solid is uniform in the xy plane; we use the notation $\boldsymbol{r} \equiv (\boldsymbol{r}_\parallel, z)$. Then,

$$\langle \boldsymbol{r}|\boldsymbol{p}^+\rangle = \frac{\mathrm{e}^{\mathrm{i}\boldsymbol{p}_\parallel\cdot\boldsymbol{r}_\parallel}}{2\pi}\langle z|p_z^+\rangle,$$
$$\langle \boldsymbol{r}|\boldsymbol{p}'^-\rangle = \frac{\mathrm{e}^{\mathrm{i}\boldsymbol{p}'_\parallel\cdot\boldsymbol{r}_\parallel}}{2\pi}\langle z|p_z'^-\rangle, \tag{17.48}$$

and, by (17.29),

$$\rho(\boldsymbol{r}) = \frac{\mathrm{e}^{\mathrm{i}(\boldsymbol{p}'_\parallel-\boldsymbol{p}_\parallel)\cdot\boldsymbol{r}_\parallel}}{(2\pi)^2}\rho(z), \tag{17.49}$$

where

$$\rho(z) = \langle z|p_z^+\rangle^*\,\langle z|p_z'^-\rangle. \tag{17.50}$$

Substituting (17.49) into (17.34) and integrating over $\boldsymbol{r}_\parallel$ and $\boldsymbol{r}_{1\parallel}$, we have

$$\frac{\mathrm{d}^2\sigma}{\mathrm{d}\omega\mathrm{d}\Omega}(\boldsymbol{p}' \leftarrow \boldsymbol{p}) = -\frac{4\pi p'}{p}\mathrm{Im}\int \mathrm{e}^{-\mathrm{i}\boldsymbol{q}_\parallel\cdot\boldsymbol{r}'_\parallel}\mathrm{e}^{-q_\parallel|z-z'|}\rho^*(z)\chi(\boldsymbol{r}',\boldsymbol{r}'_1,\omega) \times \mathrm{e}^{\mathrm{i}\boldsymbol{q}_\parallel\cdot\boldsymbol{r}'_1}\mathrm{e}^{-q_\parallel|z_1-z'_1|}\rho(z_1)\mathrm{d}z\mathrm{d}\boldsymbol{r}'\mathrm{d}z_1\mathrm{d}\boldsymbol{r}'_1, \tag{17.51}$$

where $\boldsymbol{q}_\parallel = \boldsymbol{p}'_\parallel - \boldsymbol{p}_\parallel$, or

$$\frac{\mathrm{d}^2\sigma}{\mathrm{d}\omega\mathrm{d}\Omega}(\boldsymbol{p}' \leftarrow \boldsymbol{p}) = -\frac{4\pi p'}{p}\mathrm{Im}\int \mathrm{e}^{-q_\parallel|z-z'|}\rho^*(z)\chi(z',z'_1,q_\parallel,\omega) \times \mathrm{e}^{-q_\parallel|z_1-z'_1|}\rho(z_1)\mathrm{d}z\mathrm{d}z'\mathrm{d}z_1\mathrm{d}z'_1, \tag{17.52}$$

where, because of symmetry, $\chi(\boldsymbol{r},\boldsymbol{r}',\omega) = \chi(z,z',\boldsymbol{r}_\parallel - \boldsymbol{r}'_\parallel,\omega)$, and the 2-D Fourier transform was performed.

We now consider the case when the projectile never enters the charge density of the electrons of the target. We realize this by assuming that

$$\chi(z',z'_1,q_\parallel,\omega) = 0, \text{ if } z' > 0 \text{ or } z'_1 > 0, \tag{17.53}$$
$$\rho(z) = 0, \text{ if } z < 0. \tag{17.54}$$

Then, by (17.52),

$$\frac{\mathrm{d}^2\sigma}{\mathrm{d}\omega\mathrm{d}\Omega}(\boldsymbol{p}' \leftarrow \boldsymbol{p}) = -\frac{2q_\parallel p'}{p}\left|\int \mathrm{e}^{-q_\parallel z}\rho(z)\mathrm{d}z\right|^2\mathrm{Im}\left[g(q_\parallel,\omega)\right], \tag{17.55}$$

where the so-called g-function is defined by [17.25]

$$g(q_\parallel,\omega) = \frac{2\pi}{q_\parallel}\int \mathrm{e}^{q_\parallel z}\chi(z,z',q_\parallel,\omega)\mathrm{e}^{q_\parallel z'}\mathrm{d}z\mathrm{d}z'. \tag{17.56}$$

Furthermore, considering the definition of the density-response function χ, we can give the g-function of (17.56) the following interpretation. Let us apply to the system the external potential

$$v_{\text{ext}}(\boldsymbol{r},t) = \mathrm{e}^{\mathrm{i}\boldsymbol{q}_\parallel\cdot\boldsymbol{r}_\parallel + q_\parallel z - \mathrm{i}\omega t} \,. \tag{17.57}$$

Then, according to (17.56), the induced potential at large $z > 0$ outside the system is

$$g(q_\parallel,\omega)\mathrm{e}^{\mathrm{i}\boldsymbol{q}_\parallel\cdot\boldsymbol{r}_\parallel - q_\parallel z - \mathrm{i}\omega t} \,. \tag{17.58}$$

Having accurately introduced the concept of the dipole-scattering regime, it would be timely to address the question: What is, within our formalism, its opposite, known in the literature as the impact regime [17.25]? A simple answer reads: the impact regime takes place when there is no restriction on the incident electron to enter the electron density of the target. Then, formulas (17.34) and (17.29) must be used, examples of which we will see in Sects. 17.4.2 and 17.4.3.

Local-Response Model

Let us further see the simplifications arising within the approximation of the local response.

Let the $z > 0$ (region I) and $z < 0$ (region II) half-spaces be filled with vacuum and a medium of the dielectric function $\varepsilon(\omega)$, respectively, as schematized in Fig. 17.4. The boundary is assumed abrupt, and the dielectric function is wavevector independent. This model is referred to as local.

For this model, we can easily evaluate the g-function. Indeed, let the external potential be that of (17.57). The Poisson equation holds

$$\Delta v_{\text{ext}}(\boldsymbol{r},\omega) = -4\pi\rho_{\text{ext}}(\boldsymbol{r},\omega) \,, \tag{17.59}$$

where ρ_{ext} is the density of the external charges creating v_{ext}. Equations (17.59) and (17.57) lead to

$$\rho_{\text{ext}}(\boldsymbol{r},\omega) = 0 \,. \tag{17.60}$$

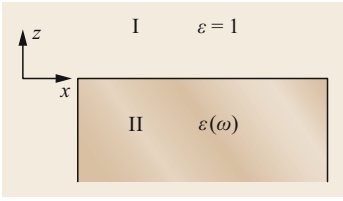

Fig. 17.4 Model of local response of a semi-infinite solid with the dielectric function $\varepsilon(\omega)$

On the other hand, it follows from the Gauss theorem

$$\nabla\cdot\boldsymbol{D}(\boldsymbol{r},\omega) = 4\pi\rho_{\text{ext}}(\boldsymbol{r},\omega) = 0 \tag{17.61}$$

and the material equation $\boldsymbol{D}(\boldsymbol{r},\omega) = \varepsilon(\omega)\boldsymbol{E}(\boldsymbol{r},\omega)$ that

$$\nabla\cdot\boldsymbol{E}(\boldsymbol{r},\omega) = 0 \,, \tag{17.62}$$

which holds in both regions I and II. Since $\boldsymbol{E}(\boldsymbol{r},\omega) = -\nabla v(\boldsymbol{r},\omega)$, in both regions we have

$$\Delta v(\boldsymbol{r},\omega) = 0 \,. \tag{17.63}$$

In our system, the $\boldsymbol{q}_\parallel$ component is conserved and, therefore, the solution of (17.63) can only be

$$v(\boldsymbol{r},\omega) = \mathrm{e}^{\mathrm{i}\boldsymbol{q}_\parallel\cdot\boldsymbol{r}_\parallel}\begin{cases}\mathrm{e}^{q_\parallel z} + A(\omega)\mathrm{e}^{-q_\parallel z}, & z > 0 \,,\\ B(\omega)\mathrm{e}^{q_\parallel z}, & z < 0 \,,\end{cases} \tag{17.64}$$

where $A(\omega)$ and $B(\omega)$ are constants in space, and the attenuation of the solution into the solid has been imposed. Then,

$$E_z(\boldsymbol{r},\omega) = -q_\parallel\mathrm{e}^{\mathrm{i}\boldsymbol{q}_\parallel\cdot\boldsymbol{r}_\parallel}\begin{cases}\mathrm{e}^{q_\parallel z} - A(\omega)\mathrm{e}^{-q_\parallel z}, & z > 0 \,,\\ B(\omega)\mathrm{e}^{q_\parallel z}, & z < 0 \,,\end{cases} \tag{17.65}$$

and

$$D_z(\boldsymbol{r},\omega) = -q_\parallel\mathrm{e}^{\mathrm{i}\boldsymbol{q}_\parallel\cdot\boldsymbol{r}_\parallel}\begin{cases}\mathrm{e}^{q_\parallel z} - A(\omega)\mathrm{e}^{-q_\parallel z}, & z > 0 \,,\\ \varepsilon(\omega)B(\omega)\mathrm{e}^{q_\parallel z}, & z < 0 \,.\end{cases} \tag{17.66}$$

Applying the boundary conditions of the continuity of $\boldsymbol{E}_\parallel$ (or, equivalently, of v) and of D_z at $z = 0$ [17.26], we find

$$A = \frac{1-\varepsilon(\omega)}{1+\varepsilon(\omega)} \,, \tag{17.67}$$

$$B = \frac{2}{1+\varepsilon(\omega)} \,. \tag{17.68}$$

Combining (17.67), (17.64), and (17.58), we arrive at

$$g(\omega) = \frac{1-\varepsilon(\omega)}{1+\varepsilon(\omega)} \,, \tag{17.69}$$

which is the final justification of formula (17.36).

17.4 Application to EELS of Metal Surfaces

Here, we will apply the formalisms introduced above to describe EELS from metal surfaces within models of increasing order of sophistication.

17.4.1 Dipole Scattering

Within the jellium model of a simple metal surface [17.28] and using the approximation of the dipole scattering (i.e., in terms of the g-function), *Tsuei* et al. [17.27] interpreted the multipole plasmon mode in alkali metals, which they detected experimentally. Their results for K and Na metals are reproduced in Fig. 17.5. As seen from the inset in Fig. 17.5a, the amplitude of the multipole plasmon is drastically underestimated compared to the experiment.

Another shortcoming of the purely dipole scattering theory is the oversimplification of the geometry of the experiment, including the incidence energy dependence of the EEL spectra. Indeed, according to (17.55), the $\boldsymbol{q}$ and ω dependence basically factorize in the expression for the differential cross section (apart from $p' = \sqrt{p^2 - 2\omega}$, which usually has an insignificant effect). This leads to dipole-mode spectra differing from each other at the same momenta and energy loss but at different geometries, by overall factors only, which does not matter, considering that the intensity scale is arbitrary.

We will see below that the unified theory of EELS, which does not separate the dipole and impact scatterings, lifts the above limitations.

17.4.2 Reflection of Electrons Under the Surface

The simplest possibility to go beyond the dipole regime is to allow for the incident electron penetration into the surface region, where the electron density of the target is nonzero or even into the bulk, doing this, however, simplistically by imposing an impenetrable potential barrier at a given depth under the surface. This pathway was implemented in [17.10] within the jellium model of a metal surface [17.28]. In this setup, the complex valued charge density is

$$\rho(z) = \left\{ \frac{\exp[\mathrm{i}q_\mathrm{f}(z-c)]}{\cos\theta_\mathrm{f}} + \frac{\exp[\mathrm{i}q_\mathrm{i}(z-c)]}{\cos\theta_\mathrm{i}} \right\} \frac{\Theta(z-c)}{4\pi} , \tag{17.70}$$

where $\Theta(z) = 0, 1$ if $z \lesseqgtr 0$, $q_{\mathrm{f,i}} = \pm(p' - p - q_\parallel \sin\theta_{\mathrm{f,i}})/\cos\theta_{\mathrm{f,i}}$ θ_i and θ_f are the angles of incidence and reflection, respectively, and $z = c$ is the position of the plane of reflection.

In [17.10], $\rho(z)$ of (17.70) was used in (17.52). The bulk, surface, and multipole plasmons, including their

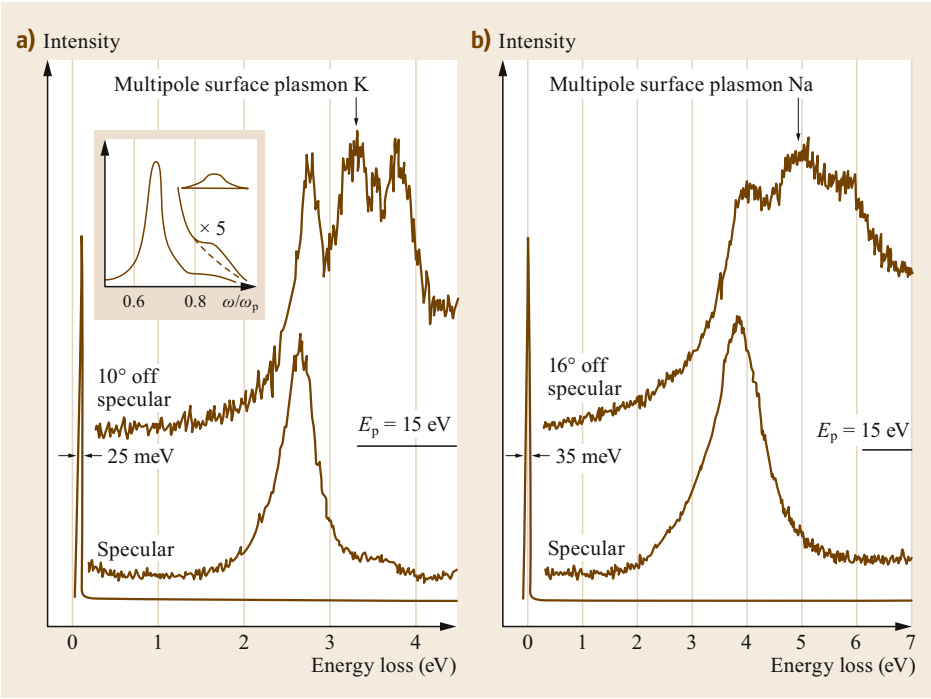

Fig. 17.5a,b EEL spectra for **(a)** K and **(b)** Na. Fig. 17.6 Energy-loss function calculated for the K surface ($r_s = 5$) for reflection at different distances c from the jellium edge. The *inset* shows the positions of the penetration depths c inside the charge-density distribution profile at the surface; $E_p = 15\,\text{eV}$, $\theta_i = 50°$, and $\theta_f = 60°$. (Reproduced from [17.10])

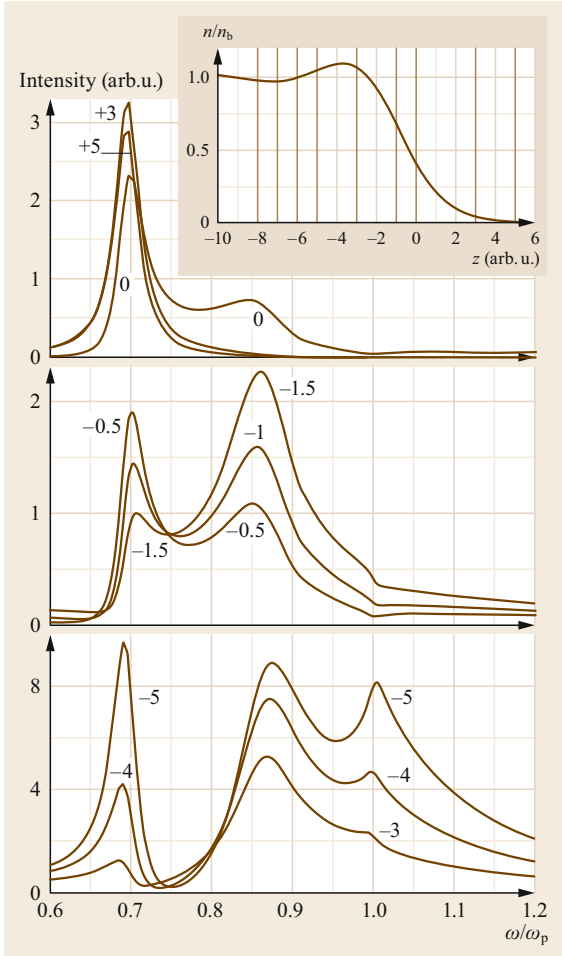

Fig. 17.7 Energy-loss function calculated for Na ($r_s = 4$) surface; $E_p = 15\,\text{eV}$, $\theta_i = 44°$, and $\theta_f = 60°$. (Reproduced from [17.10])

amplitudes, were found to be in good agreement with experiment, as can be seen from the comparison of Figs. 17.6 and 17.7 with Fig. 17.5.

This model was further improved by considering the elastic scattering of electrons within the kinematic theory of diffraction [17.11].

17.4.3 Target and Incident Electrons Treated on the Same Footing: EELS of the Ag Surface

It is obvious that the full implementation of the theory based on (17.34) and (17.29) in the case of the surface of a crystal would require a 3-D calculation of both the density-response function χ and the elastically scattered waves $|\boldsymbol{p}^+\rangle$ and $|\boldsymbol{p}'^-\rangle$, which, in this case, are the low-energy electron diffraction (LEED) wavefunctions. This ambitious program was fulfilled later in the case of the graphene target [17.13]. In this section, we will consider a step in that direction made in the calculation of EELS at the surface of silver [17.12].

Compared with the approach of [17.10], the improvement in [17.12] was to use the wavefunctions of the incident and reflected electron dictated by the crystal potential at the surface and in the bulk rather than those corresponding to the reflection from an infinite barrier at a fixed position. Therefore, the same Schrödinger, or rather Kohn–Sham, equations were solved both for the impinged electron and for the electrons of the target, the latter being necessary for calculation of the density-response function χ.

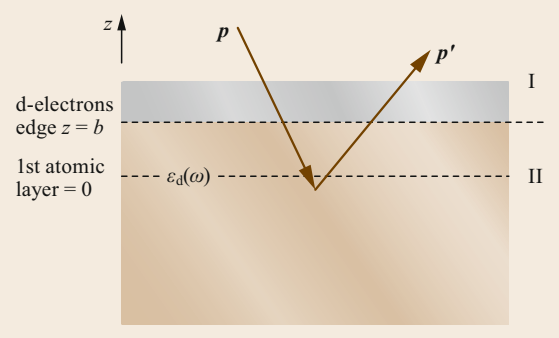

Fig. 17.8 Model used in the calculation of EELS from the Ag surface. (Reproduced from [17.12])

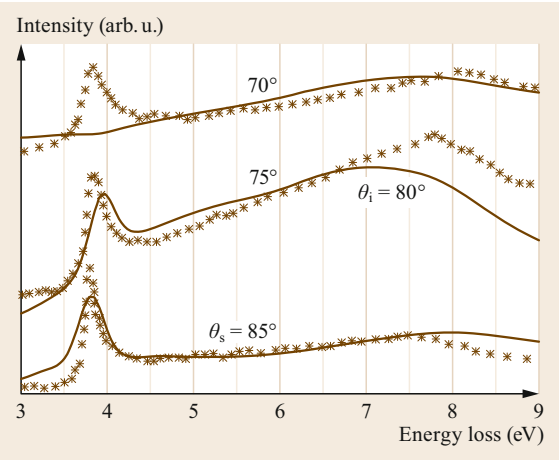

Fig. 17.9 High-resolution electron energy-loss spectra of the Ag(111) surface calculated within the framework of our theoretical approach in Sect. 17.4.3 (*solid lines*) compared to the experimental spectra of ten monolayers of Ag on the Ni(111) surface, the latter compiled from [17.29] (*symbols*). The energy of electrons in the incident beam is $E_p = 40\,\text{eV}$. (Reproduced from [17.12])

In order to facilitate calculations, a one-dimensional (1-D) model of the surface and the bulk crystal was used. An unfortunate artifact of this model is that it does not account for d-electrons of the Ag crystal, which significantly affects the dielectric response. To compensate for this deficiency, d-electrons were included

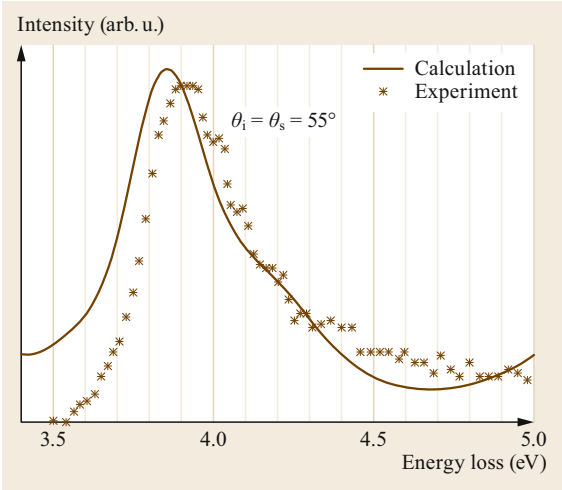

Fig. 17.10 High-resolution electron energy-loss spectrum of the Ag(111) surface calculated within the framework of our theoretical approach in Sect. 17.4.3 (*solid line*) for the specular reflection $\theta_i = \theta_s = 55°$. (Reproduced from [17.12])

phenomenologically through a background dielectric function $\varepsilon_d(\omega)$, as explained in detail in [17.30]. On the other hand, s-electrons were treated fully quantum-mechanically. The geometry of the model is shown in Fig. 17.8.

Within the aforementioned assumptions, the density-response function $\chi(z, z', q_\parallel, \omega)$ was obtained self-consistently, and then (17.52) was used to calculate the electron energy-loss spectrum.

The clear advantage of this approach is that it provides a means to study dependence of the EEL spectra on the experimental conditions, i.e., on the angles of incidence and reflection, and on the primary energy of the electrons. Representative calculated spectra are compared with the experiment in Figs. 17.9 and 17.10. While the comparison is, in general, satisfactory, the theory does not follow the experiment with larger wavevector transfer (Fig. 17.9, the spectrum with the angle of scattering of 70°). This is analyzed in detail in [17.12] and is attributed to the failure of the d-electrons' background dielectric function model at large wavevectors.

17.5 EELS of Q2-D Materials: Important Particulars

With the discovery of graphene [17.31], interest in Q2-D materials (materials macroscopic in two dimensions and microscopic in the third one) has grown, while EELS has become one of the important experimental techniques of their investigation [17.32]. It must be emphasized that our general formalism based on (17.33) and (17.34) remains fully applicable to Q2-D systems, and, moreover, it can be expected to be better suited in this case, considering that the first Born approximation for the inelastic scattering should hold

the more accurately the thinner a target is. While we defer the full theory until Sect. 17.5.4, for pedagogical reasons we start the considerations within the concept of energy-loss functions. In this section, we will limit ourselves to the description of the energy losses within the dipole regime, the latter having been introduced in Sect. 17.3.2. Below, we will focus on the distinctive features characteristic to Q2-D systems.

17.5.1 Supercell Method

To handle Q2-D crystals, calculations are generally performed with the use of the *supercell* method, which means that Q2-D layers are periodically replicated in space at a given distance d from each other, as shown in Fig. 17.11, and then standard 3-D solid-state methods are used for the resulting formally 3-D-periodic system. However, an important problem arises: in the calculation, the copies of the layers interact with each other and, therefore, the results obtained for the array of layers are not, generally speaking, the same as they would be for a single one. Moreover, it turns out that a simple increase of the interlayer distance d does not solve the problem, since, at sufficiently small $q_\parallel$ (long-wave response), the interaction between the copies remains strong. On the other hand, to give up the supercell approach and handle a single Q2-D system is usually computationally prohibitively expensive.

Fortunately, the elimination of the spurious interlayer interaction within the supercell method can be rigorously and efficiently performed in the following way. Let $\tilde{\chi}(\boldsymbol{q}_\parallel,\omega)=\tilde{\chi}_{\boldsymbol{G}\boldsymbol{G}'}(\boldsymbol{q}_\parallel,\omega)$ be the density-response function of the artificial supercell system, which includes the spurious interlayer interaction ($\boldsymbol{G}$ are the supercell reciprocal vectors). Then, the genuine density-response function of the single Q2-D system $\chi(\boldsymbol{q}_\parallel,\omega)$ free from the interlayer interaction can be restored as [17.33]

$$\chi(\boldsymbol{q}_\parallel,\omega)=\tilde{\chi}(\boldsymbol{q}_\parallel,\omega)\left[1+\mathbf{C}(\boldsymbol{q}_\parallel)\tilde{\chi}(\boldsymbol{q}_\parallel,\omega)\right]^{-1}\,, \tag{17.71}$$

where the matrix $\mathbf{C}_{\boldsymbol{G}\boldsymbol{G}'}$ is given by

$$\mathbf{C}_{\boldsymbol{G}\boldsymbol{G}'}(\boldsymbol{q}_\parallel)=F_{G_zG'_z}(|\boldsymbol{G}_\parallel+\boldsymbol{q}_\parallel|)\delta_{\boldsymbol{G}_\parallel\boldsymbol{G}'_\parallel}\,, \tag{17.72}$$

$$F_{G_zG'_z}(p)=\frac{4\pi(p^2-G_zG'_z)}{pd(p^2+G_z^2)(p^2+G_z'^2)} \times\cos\left(\frac{(G_z+G'_z)d}{2}\right)(1-\mathrm{e}^{-pd})\,, \tag{17.73}$$

and we have used the notation $\boldsymbol{G}\equiv(\boldsymbol{G}_\parallel,G_z)$.

17.5.2 The True Energy-Loss Function of a Q2-D Crystal

It must be emphasized that the correct energy-loss function to be used in the reflection EELS of Q2-D structures (as long as we are limited to the dipole regime), according to (17.55) and (17.56), is [17.33]

$$L_{\text{Q2-D}}(\boldsymbol{q}_\parallel,\omega)=-\frac{1}{2}\mathrm{Im}\left[g_{\text{Q2-D}}(\boldsymbol{q}_\parallel,\omega)\right], \tag{17.74}$$

where

$$g_{\text{Q2-D}}(\boldsymbol{q}_\parallel,\omega)=\frac{2\pi}{q_\parallel}\int \mathrm{e}^{q_\parallel z}\chi_{\mathbf{0}\mathbf{0}}(z,z',\boldsymbol{q}_\parallel,\omega)\mathrm{e}^{q_\parallel z'}\mathrm{d}z\mathrm{d}z'\,, \tag{17.75}$$

and not

$$-\mathrm{Im}\left(\frac{1}{\epsilon_{\text{Q2-D}}(\boldsymbol{q}_\parallel,\omega)}\right), \tag{17.76}$$

where

$$\frac{1}{\epsilon_{\text{Q2-D}}(\boldsymbol{q}_\parallel,\omega)}=1+\frac{2\pi}{q_\parallel}\int\chi_{\mathbf{0}\mathbf{0}}(z,z',\boldsymbol{q}_\parallel,\omega)\mathrm{d}z\mathrm{d}z'\,, \tag{17.77}$$

although the opposite is often assumed without justification. The latter energy-loss function is pertinent to the in-plane energy dissipation in the Q2-D system [17.33]. In the above equation, the subscripts at the response functions denote the zero in-plane reciprocal lattice vectors and select the long-wave response to the long-wave perturbation.

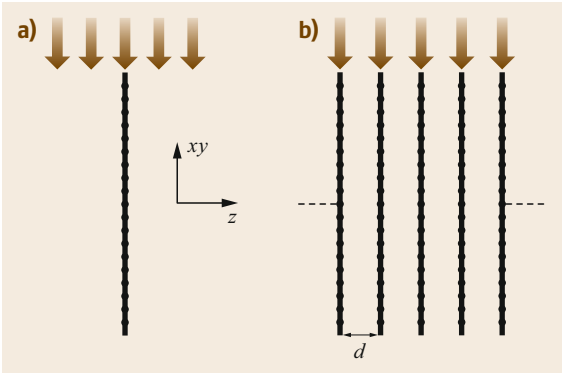

Fig. 17.11a,b 2-D material under an external field. **(a)** 2-D single-layer geometry and **(b)** 3-D super-cell geometry. (Reproduced from [17.33])

17.5.3 Results for Single-Layer and Multilayer Graphene

In [17.33], calculations using formulas (17.74)–(17.77) were performed. Results for monolayer pristine graphene are presented in Figs. 17.12 and 17.13.

A comparison of the theory with HEELS experiment for monolayer and bilayer graphene is shown in Fig. 17.14. We first note that the agreement between theory and experiment is much better in the case of the π-plasmon (upper panels) rather than for the $\pi+\sigma$ one. When making the comparison, we must take the following factors into account. As will be shown in Sect. 17.5.4, where we implement the theory that does not separate the dipole and impact mechanisms, the $\pi+\sigma$ plasmon is much more sensitive to the details of the elastic scattering than the π-plasmon is, the latter being well reproduced within the dipole mechanism. Since, on the one hand, the theory in this section is the dipole one, it is not surprising that for the $\pi+\sigma$ plasmon we have a worse agreement with experiment. On the other hand, the experiment in [17.34] was carried out with graphene on a substrate (of SiC (0001)) rather than with a standalone graphene. This would make the comparison of these experimental data to our full theory of Sect. 17.5.4 meaningless, the latter being sensitive to the details of the elastic scattering, which is very different for the standalone and the substrate-supported systems. The full theory with inclusion of the substrate is still to be built in the future.

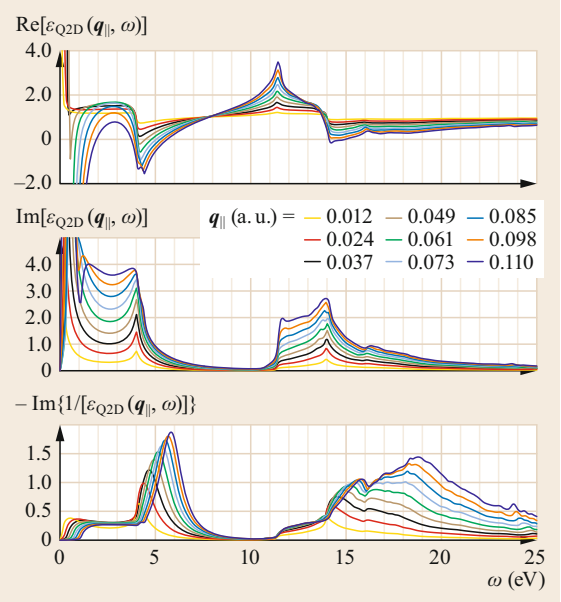

Fig. 17.12 Dielectric function of the pristine monolayer graphene obtained with (17.77) and the corresponding energy-loss function. Momentum $\boldsymbol{q}_\parallel$ is varied along the ΓM direction. (Reproduced from [17.33])

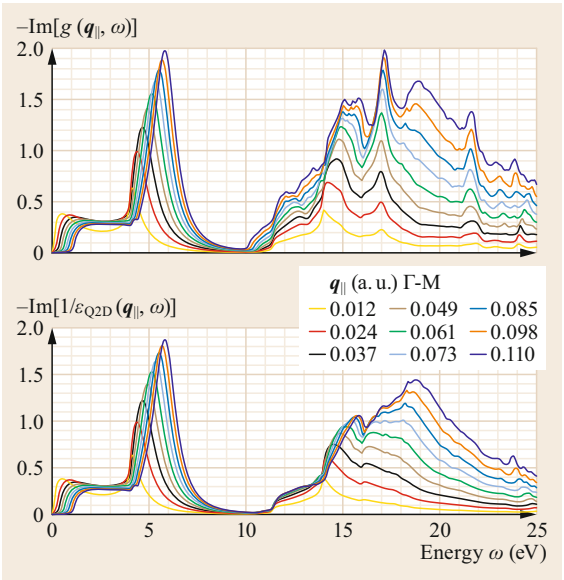

Fig. 17.13 The EELS-related energy-loss function $-1/2\mathrm{Im}\left[g_{Q2\text{-}D}(\boldsymbol{q}_\parallel,\omega)\right]$ (*upper panel*) compared to the energy-loss function $-\mathrm{Im}\left[1/\varepsilon_{Q2\text{-}D}(\boldsymbol{q}_\parallel,\omega)\right]$ (*lower panel*) for pristine monolayer graphene. (Reproduced from [17.33])

We note that all specific calculations considered above have required the knowledge of the interacting electrons density-response function $\chi(\boldsymbol{r},\boldsymbol{r}',\omega)$. The nontrivial methods of its numerical evaluation will be considered in Sects. 17.6.3 and 17.7.

17.5.4 Theory of EELS of Q2-D Crystals Beyond the Energy-Loss Functions Formalism

The one-step combined inelastic and elastic scattering theory, developed in Sect. 17.2.1 and resulting in expression (17.34) for the double differential cross section is best suited for applications to the HEELS of Q2-D crystals. This happens for two particular reasons. First, in the medium energy range of incident electrons ($\approx 10-100$ eV), the role of the elastic scattering grows very importantly, leading, in particular, to the appearance of the elastic *scattering resonances*, which were first predicted in [17.35] and then observed and studied experimentally [17.36–39]. Elastic scattering, therefore, can no longer be considered as constituting a smooth background to the sharp features due to inelastic processes, and both kinds of scattering must be included in the theory in their interrelations [17.13].

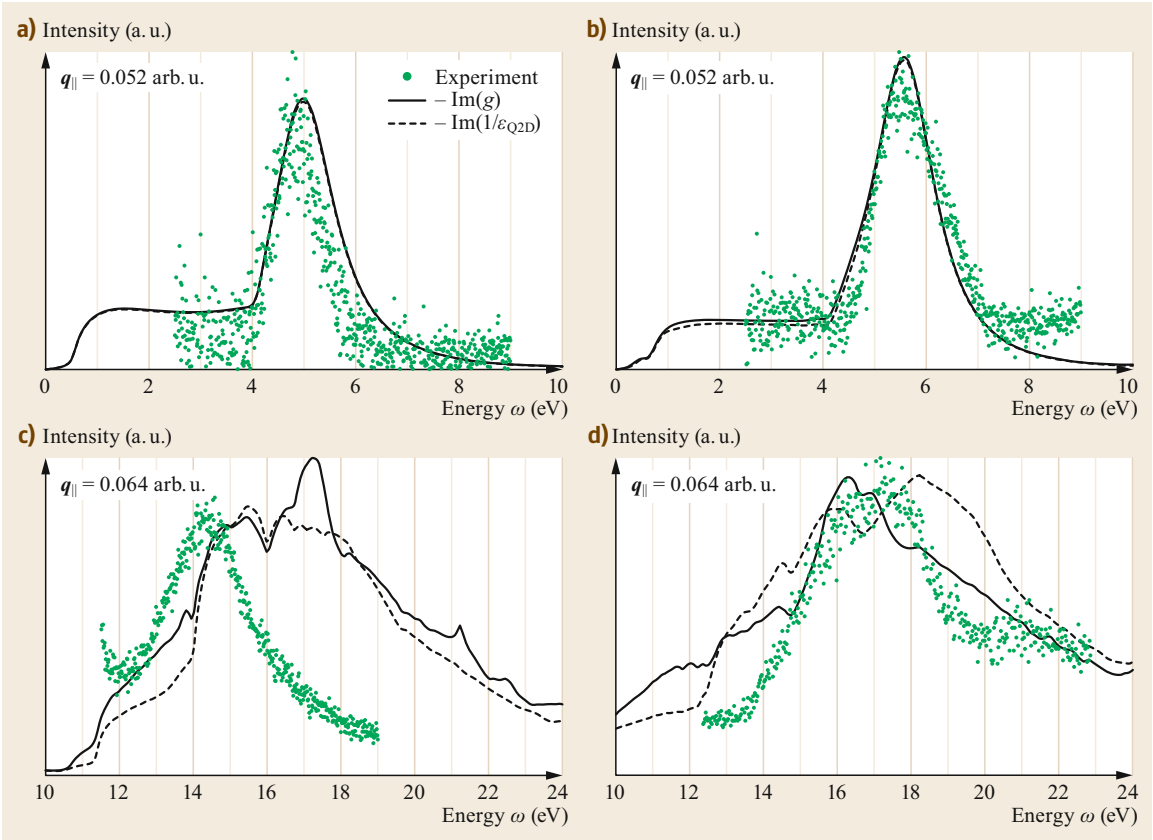

Fig. 17.14a–d The reflection EELS energy-loss function $-\mathrm{Im}\left[g_{\mathrm{Q2\text{-}D}}(\boldsymbol{q}_\parallel,\omega)\right]$ of (17.75) (*solid lines*) and the energy-loss function $-\mathrm{Im}\left[1/\varepsilon_{\mathrm{Q2\text{-}D}}(\boldsymbol{q}_\parallel,\omega)\right]$ of (17.77) (*dashed lines*) for monolayer **(a,c)** and bilayer **(b,d)** graphene in the energy range of π **(a,b)** and $\pi+\sigma$ **(c,d)** plasmons. *Green symbols* are the experimental HREELS data of [17.34]. The theoretical spectra have been roughly normalized to the experimental ones. (Reproduced from [17.33])

Secondly, in contrast to the surfaces of semi-infinite solids, Q2-D materials are the systems for which the method of Sect. 17.2.1 can be implemented without resorting to any sort of additional phenomenological ingredients. Indeed, the description of the energy losses in a semi-infinite solid necessarily requires the introduction of the *optical potential*. This is because we need a mechanism restricting electrons' exit to vacuum after penetrating arbitrarily deep into the target, without which mechanism the probability of the bulk losses diverges, leading to the break down of the first Born approximation for inelastic scattering [17.12]. In experiments, this restriction is ensured by the higher-order inelastic processes, which, however, cannot be included in the theory in the ab-initio fashion. The latter problem does not arise in the case of Q2-D materials, due to their microscopic thickness, making them ideal objects to be studied with the use of the theory of Sect. 17.2.1.

We proceed by noting that in a Q2-D crystal, the in-plane component of the wavevector is conserved to within a reciprocal lattice vector $\boldsymbol{G}_\parallel$. As a consequence, the density-response function becomes a matrix in the reciprocal lattice vectors $\chi_{GG'}(z,z',\boldsymbol{q}_\parallel,\omega)$, where $\boldsymbol{q}_\parallel$ belongs to the 2-D Brillouin zone (2-DBZ). Equation (17.34) can then be conveniently transformed to

$$\begin{aligned}
&\frac{1}{S}\frac{\mathrm{d}\sigma}{\mathrm{d}\omega\mathrm{d}\Omega}(\boldsymbol{p}'\leftarrow\boldsymbol{p})\\
&=-\frac{64\pi^5 p'}{p}\mathrm{Im}\left[\sum_{\substack{G\tilde{G}\\ G'\tilde{G}'}}\int \chi_{GG'}(z_1,z_1',\boldsymbol{q}_\parallel,\omega)\right.\\
&\times\frac{\mathrm{e}^{-|\boldsymbol{G}+\boldsymbol{q}_\parallel||z_1-z|}\mathrm{e}^{-|\boldsymbol{G}'+\boldsymbol{q}_\parallel||z_1'-z'|}}{|\boldsymbol{G}+\boldsymbol{q}_\parallel||\boldsymbol{G}'+\boldsymbol{q}_\parallel|}a^{+*}_{\boldsymbol{p},\boldsymbol{G}+\tilde{\boldsymbol{G}}}(z)a^{-}_{\boldsymbol{p}',\tilde{\boldsymbol{G}}+\boldsymbol{G}_0}(z)\\
&\left.\times a^{+}_{\boldsymbol{p},\boldsymbol{G}'+\tilde{\boldsymbol{G}}'}(z')a^{-*}_{\boldsymbol{p}',\tilde{\boldsymbol{G}}'+\boldsymbol{G}_0}(z')\,\mathrm{d}z\mathrm{d}z'\mathrm{d}z_1\mathrm{d}z_1'\right], \qquad (17.78)
\end{aligned}$$

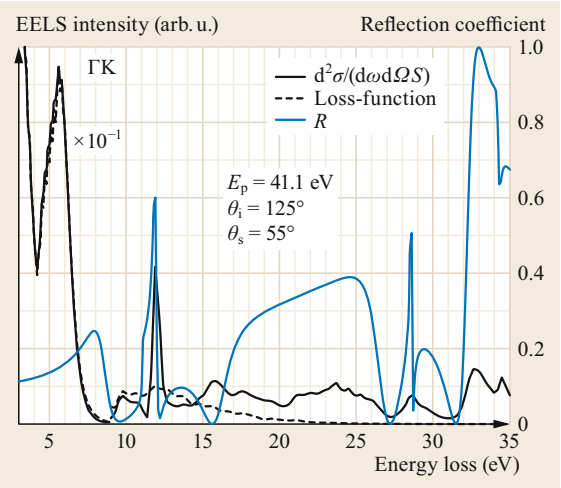

Fig. 17.15 Calculated EEL reflection spectrum of monolayer graphene (*thick black line*, full theory, (17.34)), the one calculated with the use of the surface loss function (*dashed line*, (17.55), (17.56)), and the coefficient of reflection (*thin blue line* plotted against the right *y*-axis). For better visualization, EEL spectra are split into two parts, the low-energy one is scaled by 0.1. See Fig. 17.16 for the definition of angles. (Reproduced from [17.13])

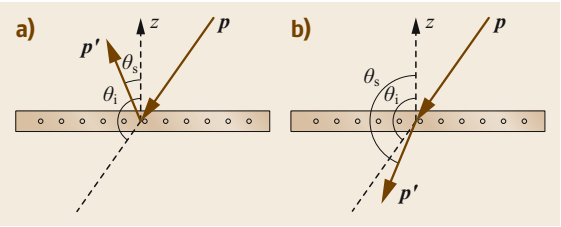

Fig. 17.16a,b Reflection **(a)** and transmission **(b)** geometries of the EELS experiment on a Q2-D crystal with the definition of angles. (Reproduced from [17.13])

where $a^{\pm}_{\boldsymbol{p},\boldsymbol{G}}(z)$ are the Fourier coefficients in the expansion (Laue representation [17.40])

$$\langle \boldsymbol{r}|\boldsymbol{p}^{\pm}\rangle = \sum_{\boldsymbol{G}} a^{\pm}_{\boldsymbol{p},\boldsymbol{G}}(z) \mathrm{e}^{\mathrm{i}(\boldsymbol{G}+\boldsymbol{p}_{\parallel})\cdot\boldsymbol{r}_{\parallel}} \,, \tag{17.79}$$

S is the normalization area, and $\boldsymbol{G}_0$ reduces the parallel component of the transferred momentum to the first Brillouin zone: $\boldsymbol{p}_{\parallel} - \boldsymbol{p}'_{\parallel} = \boldsymbol{q}_{\parallel} + \boldsymbol{G}_0$.

In [17.13], the approach based on (17.78) was implemented for Q2-D crystals and applied to monolayer and bilayer freestanding graphene. In Fig. 17.15, results corresponding to the experimental setup of HREELS are presented, where the reflection EEL spectrum of graphene calculated with the use of the present theory is plotted together with the reflection coefficient (the latter changing with $\boldsymbol{p}'$, while $\boldsymbol{p}$ is fixed). The energy of the incident electrons is $E_p = 41.1$ eV (the nonround primary energy in eV is due to the specific energy mesh in the wavefunction calculations), the angle of incidence is $\theta_i = 125°$, and the angle of scattering is $\theta_s = 55°$ (polar angles are relative to the positive z-axis, Fig. 17.16). It is instructive to note how the influence of the elastic scattering changes the spectrum in the energy range of the $\pi + \sigma$ plasmon, the latter extending broadly from about 10 to 25 eV within the energy-loss function approach [17.33]. A sharp peak in the reflection coefficient due to the diffraction resonance [17.35] at ≈ 11.9 eV leads to a peak in the EELS intensity at this energy. The same happens at ≈ 28.5 and 33 eV. Generally, the EEL spectrum becomes a product of the interplay of inelastic and elastic processes. At the same time, it would be an oversimplification to conclude that the EEL spectrum just follows the reflectance: In (17.34), the reflectance coefficient does not factorize and, therefore, the influence of the elastic scattering on the EELS is not straightforward. This can be observed in Fig. 17.15, considering a maximum in the EEL spectrum at ≈ 15.7 eV, where reflectance has a minimum.

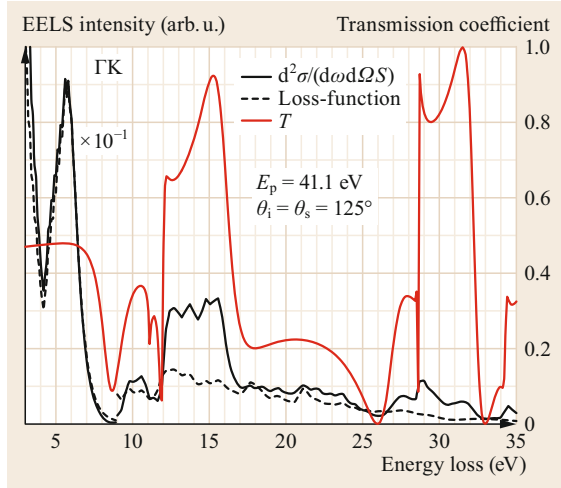

Fig. 17.17 Calculated EEL transmission spectrum of monolayer graphene (*thick line*, full theory, (17.34)), the one calculated with the use of the bulk loss function (*dashed line*, (17.47)), and the coefficient of transmission. See Fig. 17.16 for the definition of the angles. (Reproduced from [17.13])

Similar observations can be made from the EELS in the transmission geometry in comparison with the coefficient of transmission, as presented in Fig. 17.17. We conclude that the elastic scattering affects the EEL spectra dramatically, especially so in the region of the $\pi + \sigma$ plasmon and at higher energies. Different parts of

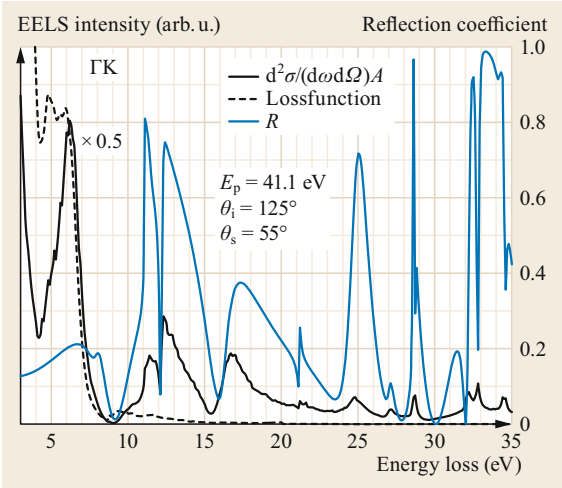

Fig. 17.18 Calculated EEL reflection spectrum of bilayer graphene (*thick black line*), the loss function (*dashed line*), and the coefficient of reflection (*blue*). In contrast to the monolayer case, the π-plasmon loss intensity is also influenced by the inclusion of the elastic scattering. (Reproduced from [17.13])

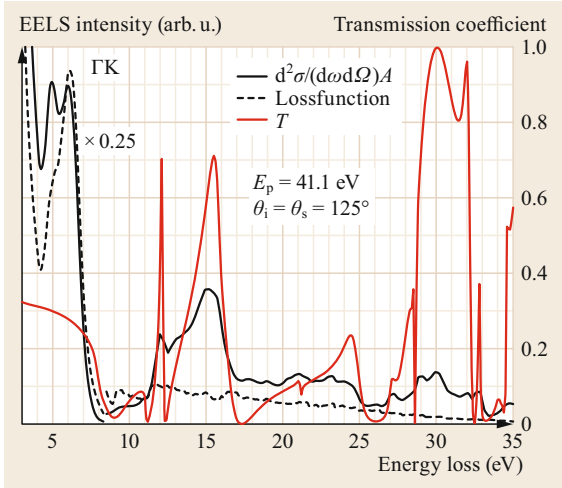

Fig. 17.19 Calculated EEL transmission spectrum of bilayer graphene (*thick black line*), the loss function (*dashed lines*), and the coefficient of transmission (*red*). In contrast to the monolayer case, the π-plasmon is also influenced by the inclusion of the elastic scattering. (Reproduced from [17.13])

the spectra are strongly enhanced and suppressed in the reflection and transmission regimes, which is mainly due to the presence of the diffraction resonances. These conclusions are supported by the spectra of the bilayer graphene in Figs. 17.18 and 17.19.

We argue that overcoming the limitations of the energy-loss functions formalism, the one-step simultaneous inelastic and elastic scattering approach can be expected to replace the former as a standard theoretical tool in the EELS of mesoscopic crystals.

17.6 Dielectric Screening in Photoemission

The alternating electric field of the light excites the electrons in the solid, and the electron promoted to a state with the energy higher than the surface potential barrier can leave the crystal, which is known as the photoelectric effect [17.41]. Apart from the probability to be excited, the probability of the photoelectron being detected with the same energy in vacuum depends on whether it would reach the surface without losing energy in inelastic collisions and on whether it would transmit through the surface or reflect back into the solid. The probability of inelastic scattering is expressed by the electron mean free path λ or electron lifetime τ, and the elastic scattering by the surface is reduced to time-reversed electron diffraction [17.42–45]. These aspects will be briefly discussed in Sect. 17.6.1. The excitation probability depends on the frequency and polarization of the incident light and also on the spatial structure of the electric field inside the solid, which may be strongly modified by the dielectric response of the electronic system, as we will discuss in Sects. 17.6.2 and 17.6.3.

Dielectric screening is most important at low photon energies, and this spectral region has recently become of special interest in angle-resolved photoemission spectroscopy [17.46–50], where a reduced inelastic scattering of the photoelectrons at low energies implies higher bulk sensitivity. A related issue is the design of laser-driven photocathodes of high quantum efficiency for free-electron lasers [17.51, 52]. Another rapidly growing field is laser-assisted time-resolved photoemission [17.53–58] based on the superimposed ultraviolet pulse and the laser pulse of $\omega = 1.7$ eV. In particular, in the streaking technique [17.53–57] the wave packet excited by the high-frequency pulse is accelerated by the laser field, and the energy shift of its spectrum is measured. In this relation, it is important to know how deeply the laser field penetrates into the solid and what its spatial structure is.

17.6.1 The Essence of the One-Step Photoemission Theory

If the interaction of the outgoing electron with the hole left behind can be neglected (the so-called sudden approximation [17.59]) and if the one-particle approach is adopted then the photocurrent is given by optical transitions from the initial states—eigenfunctions of the crystal Hamiltonian—to the time-reversed LEED states [17.42–44]. Indeed, it follows from the time-dependent perturbation theory that if an electron of initial energy E_i is excited by a harmonic perturbation $\hat{O}$ of frequency ω, the photoelectron wavefunction is

$$\Psi(\boldsymbol{r}) = \int \mathrm{d}\boldsymbol{r}'\, G^+(\boldsymbol{r},\boldsymbol{r}',E_\mathrm{f})\,\hat{O}\,\psi(\boldsymbol{r}')\,, \quad E_\mathrm{f} = E_\mathrm{i} + \omega\,. \tag{17.80}$$

This wave $|\Psi\rangle$ propagates in all directions, and it describes both external and internal photoemission. If we are interested in the probability of detecting the photoelectron outside the crystal at $\boldsymbol{r} \to +\infty$, then G^+ as a function of $\boldsymbol{r}'$ satisfies the Schrödinger equation everywhere in the half-space containing the crystal (but not the detector), and its asymptotic behavior at large $\boldsymbol{r}'$ can be inferred from the free-space Green's function G_0^+

$$G_0^+(\boldsymbol{r},\boldsymbol{r}',E) = -\frac{\exp\left(\mathrm{i}\sqrt{E}|\boldsymbol{r}-\boldsymbol{r}'|\right)}{2\pi|\boldsymbol{r}-\boldsymbol{r}'|} \tag{17.81}$$

and the resolvent identity [17.15, 42]

$$G^+(\boldsymbol{r},\boldsymbol{r}',E) = G_0^+(\boldsymbol{r},\boldsymbol{r}',E) + \int G_0^+(\boldsymbol{r},\boldsymbol{r}'',E)\,V(\boldsymbol{r}'')\,G^+(\boldsymbol{r}'',\boldsymbol{r}',E)\,\mathrm{d}\boldsymbol{r}''\,, \tag{17.82}$$

where $V(\boldsymbol{r})$ is the crystal potential. (We follow the arguments of *Adawi* [17.42] closely.) For $r \gg r'$, the dependences on $\boldsymbol{r}$ and $\boldsymbol{r}'$ of the free-space Green's function (17.81) factorize

$$G_0^+(\boldsymbol{r},\boldsymbol{r}',E) \to -\frac{\exp(\mathrm{i}kr)\exp(-\mathrm{i}\boldsymbol{k}\boldsymbol{r}')}{2\pi|\boldsymbol{r}|}, \quad \text{with } k = \sqrt{E} \quad \text{and } \boldsymbol{k} = k\frac{\boldsymbol{r}}{|\boldsymbol{r}|}\,. \tag{17.83}$$

From (17.82) and (17.83), the asymptotic formula for $G^+(\boldsymbol{r},\boldsymbol{r}',E)$ at $\boldsymbol{r} \to +\infty$ is

$$G^+(\boldsymbol{r},\boldsymbol{r}',E) = -\frac{1}{2\pi}\mathrm{e}^{\mathrm{i}kr} \times \left[\mathrm{e}^{-\mathrm{i}\boldsymbol{k}\boldsymbol{r}'} + \int G^+(\boldsymbol{r}',\boldsymbol{r}'',E)\,V(\boldsymbol{r}'')\,\mathrm{e}^{-\mathrm{i}\boldsymbol{k}\boldsymbol{r}''}\,\mathrm{d}\boldsymbol{r}''\right], \tag{17.84}$$

where we have used the identity $G^+(\boldsymbol{r}',\boldsymbol{r}'',E) = G^+(\boldsymbol{r}'',\boldsymbol{r}',E)$. For $\boldsymbol{r}'$ far from the crystal and $\boldsymbol{r}''$ inside the crystal, the function $G^+(\boldsymbol{r}',\boldsymbol{r}'',E)$ in the integrand contains only outgoing waves (in accord with its use in (17.80)). Thus, the expression in brackets contains a single *incoming* beam $\exp(-\mathrm{i}\boldsymbol{k}\boldsymbol{r}')$ coming from the detector and the outgoing beams due to the integral. The wavefunction that satisfies these conditions in vacuum is the LEED state $|\Phi\rangle$, cf., (17.37). Thus, the photocurrent J depends upon the probability of the transition from the initial state $|\mathrm{i}\,\boldsymbol{k}_\parallel\rangle$ to the *time reversed LEED state* $|\mathrm{f}\,\boldsymbol{k}_\parallel\rangle$

$$J(\omega,\boldsymbol{k}_\parallel) \approx \sqrt{E_\mathrm{f}-E_\mathrm{vac}}\left|\langle \mathrm{f}\,\boldsymbol{k}_\parallel|\,\hat{O}|\mathrm{i}\,\boldsymbol{k}_\parallel\rangle\right|^2\,, \tag{17.85}$$

where $\langle \boldsymbol{r}|\mathrm{f}\,\boldsymbol{k}_\parallel\rangle = \langle \boldsymbol{r}|\Phi\rangle^*$, and the notation $|\mathrm{i}\,\boldsymbol{k}_\parallel\rangle$ and $|\mathrm{f}\,\boldsymbol{k}_\parallel\rangle$ emphasizes that both initial and final states have a well-defined crystal momentum parallel to the surface $\boldsymbol{k}_\parallel$, but there is no translational invariance perpendicular to the surface. The initial states that belong to the $\boldsymbol{k}_\parallel$-projected bulk continuum are standing waves, which in the depth of the crystal, $z \to -\infty$, where the crystal potential is periodic, are a superposition of the incident wave and the Bloch waves reflected from the surface. (However, close to the surface the initial state wavefunction may have a more complicated structure). In the $\boldsymbol{k}_\parallel$-projected band gaps there may exist surface states, whose asymptotics at $z \to -\infty$ is a sum of evanescent Bloch waves, i.e., the waves with complex crystal momenta projections $k_\perp$. The initial state also has a band index, because there may be several degenerate states with the same $\boldsymbol{k}_\parallel$ and E_i, but here we drop it for brevity.

Photoemission is known to be a surface-sensitive phenomenon, which, in particular, manifests itself in the fact that the photocurrent from the surface state has the same order of magnitude as from the bulk bands (where the number of electrons is proportional to the thickness of the sample). The reason is the inelastic scattering of the outgoing electrons. In the one-step photoemission theory [17.42–45], the surface sensitivity is allowed for by the evanescent behavior of the LEED state, which is achieved by adding an absorbing potential $-\mathrm{i}V_\mathrm{i}$ to the Hamiltonian in the crystal half-space. Because the energy E is kept real, the imaginary optical potential forces the function $|\mathrm{f}\,\boldsymbol{k}_\parallel\rangle$ to decay in space, so that the wavevectors $k_\perp$ of all Bloch constituents of the LEED state become complex.

Computational methods for electron scattering by surfaces are based either on the layer KKR (Korringa–Kohn–Rostoker) multiple scattering technique [17.60–62] or on the Bloch-waves approach [17.63, 64]. In the latter case, one first determines the complex band structure of the semi-infinite substrate, i.e., finds for given E

and $\boldsymbol{k}_\parallel$ a number of relevant Bloch solutions with different $k_\perp$ and then connects a superposition of these partial waves to a plane-wave expansion in vacuum across the surface [17.65]. If the electron absorption is neglected, i.e., $V_\mathrm{i} = 0$, a finite number of the wavevectors $k_\perp$ are purely real, and they constitute the real $\boldsymbol{k}_\parallel$-projected band structure (propagating waves). Apart from that, for each E and $\boldsymbol{k}_\parallel$, there exists an infinite number of complex $k_\perp$, which constitute the complex band structure (evanescent waves) [17.66, 67]. For $V_\mathrm{i} \neq 0$, all $k_\perp$ become complex, and, similarly to the notion of the transmitted current, each partial wave can be ascribed *partial absorbed current* [17.68] according to the formula

$$j^\lambda = 2V_\mathrm{i} \int \left|\psi(k_\perp^\lambda, \boldsymbol{r})\right|^2 \mathrm{d}\boldsymbol{r}\,, \tag{17.86}$$

where the integration extends over the entire volume of the crystal. In the limit $V_\mathrm{i} \to 0$, (17.86) transforms into the usual expression for the transmitted current for the propagating waves ($\mathrm{Im}(k_\perp) \to 0$) and vanishes for the genuinely evanescent states (e.g., in a projected band gap, with $\mathrm{Im}(k_\perp)$ being the elastic decay rate). From the point of view of (17.85), the complex $k_\perp$ imply a broadening of the direct (crystal momentum conserving) transitions, and when the inelastic decay rate becomes comparable with the elastic one, the direct transitions picture becomes inapplicable [17.69].

17.6.2 The Optical Perturbation

The perturbation operator due to the optical electric field is expressed in terms of the vector potential $\boldsymbol{A}$ as

$$\hat{O} = \frac{1}{2c}\left[\boldsymbol{A}(\boldsymbol{r},\omega)\cdot\hat{\boldsymbol{p}} + \hat{\boldsymbol{p}}\cdot\boldsymbol{A}(\boldsymbol{r},\omega)\right], \tag{17.87}$$

where $\hat{\boldsymbol{p}} = -\mathrm{i}\nabla$ is the momentum operator. For photon energies up to far ultraviolet, the light wavelength is much larger than the dimensions of the crystal unit cell, so if the perturbing field in the solid has the same structure as in vacuum, then its spatial variations can be neglected, $\hat{\boldsymbol{p}}\cdot\boldsymbol{A} \approx 0$, and the perturbation operator would reduce to $\hat{O} = (1/c)\boldsymbol{A}\cdot\hat{\boldsymbol{p}}$. This is referred to as the dipole approximation. It may be sufficient at high enough photon energies, at which the electronic system virtually does not respond to the perturbation, $\epsilon \approx 1$. At lower energies, the effects of light refraction must be taken into account, and, in some cases, it is sufficient to include it via the macroscopic Fresnel equations based on the position-independent bulk dielectric constant of the solid [17.70–72].

Fresnel equations combined with the dipole approximation imply a certain form of the dependence of the photoemission intensity on the angle of incidence θ of the electromagnetic wave, which follows from the simple $\boldsymbol{A}(\theta)\cdot\boldsymbol{P}$ structure of the perturbing operator, where $\boldsymbol{P} = \langle \mathrm{f}\,\boldsymbol{k}_\parallel | -\mathrm{i}\nabla | \mathrm{i}\,\boldsymbol{k}_\parallel \rangle$ depends only on the initial and the final states, and $\boldsymbol{A}(\theta)$ depends on the macroscopic dielectric response. In many cases, pronounced deviations of $J(\theta)$ from this simple behavior were observed [17.73, 74], which pointed to the presence of another term in the perturbation operator. One term not included in the dipole approximation arises from the spatial inhomogeneity of the vector potential $\boldsymbol{A}(\boldsymbol{r},\omega)$ at the surface due to the simple fact that the field must change from its vacuum value to the asymptotics in the depth of the crystal given by macroscopic electrodynamics. This gives rise to the term $(1/2c)\hat{\boldsymbol{p}}\cdot\boldsymbol{A} = (-\mathrm{i}/2c)\,\mathrm{div}\,\boldsymbol{A}$, which may cause an asymmetric shape of the spectral peaks due to direct transitions [17.75, 76], or may lead to unexpectedly high intensity at the grazing incidence angle of p-polarized light [17.74], or may contribute to the circular dichroism [17.77, 78].

In the model considerations of [17.73–76], the vector potential was simply assumed to monotonically vary from its vacuum to its bulk value over a few angstroms wide surface region. A more refined treatment of the spatial inhomogeneity of $\boldsymbol{A}(\boldsymbol{r},\omega)$ requires a knowledge of the dielectric response in the surface region. The pronouncedly broken translational symmetry makes microscopic calculations very difficult, so the theoretical effort has been limited to simplest model systems. Nevertheless, the gross manifestations of the surface dielectric response in photoemission are well understood, as we show in the next section.

17.6.3 Nonlocal Dielectric Response

It has been known since the seminal works by *Feibelman* [17.79–81] that in metals, below the plasmon energy ω_p the microscopic fields generated at the surface by p-polarized light greatly enhance the emission intensity. Later, a vast experimental evidence of the enhancement of total photoyield ω_p was accumulated for simple metals [17.82–85]. Low-energy angle-resolved spectra in the constant initial state (CIS) mode were first reported for Al(100) [17.86, 87] and then for Be(0001) [17.88] and Al(111) [17.89].

Qualitatively, the emission enhancement is due to the excitation of a multipole surface plasmon [17.25, 91, 92], which was first predicted in 1970 by *Bennett* [17.93]. The multipole mode is a result of the nonlocal dielectric response at the surface. It was first calculated by *Feibelman* [17.79, 80] in the random phase approximation (RPA) for the response function in a jellium model. The local-field enhancement and the power absorption at the surface are analyzed in

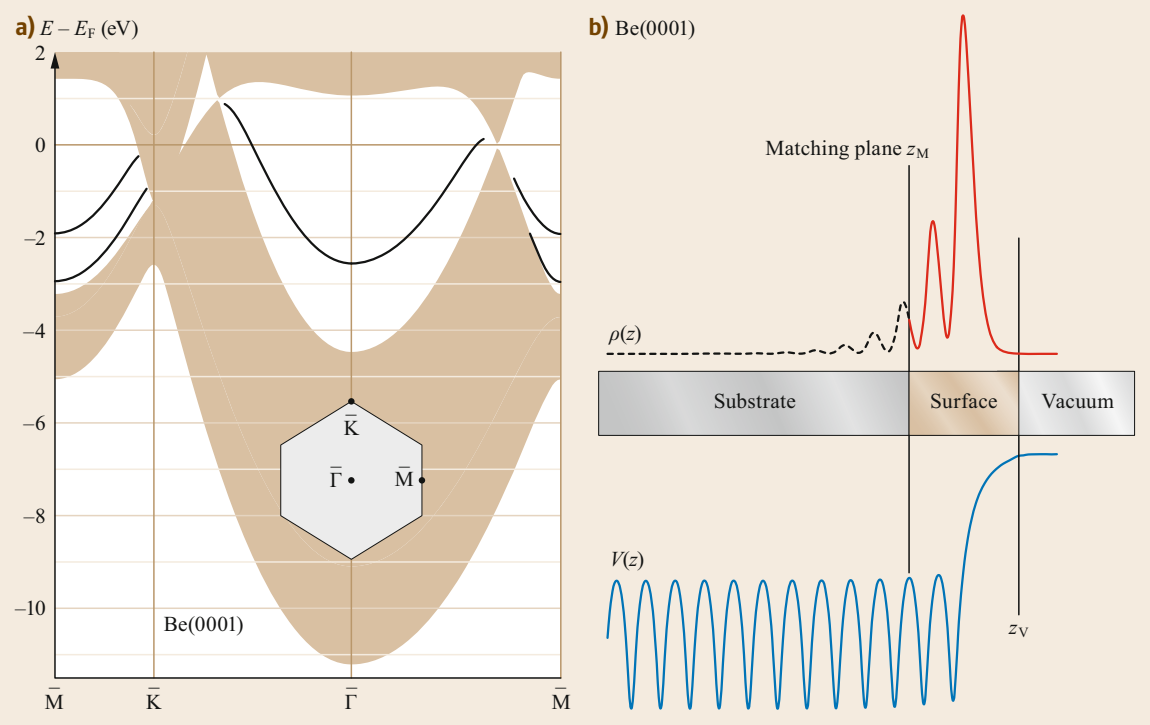

Fig. 17.20a,b Surface electronic structure of Be(0001). **(a)** The *shaded area* shows the $k_{\parallel}$ projected bulk band structure, and *lines* show calculated surface states. **(b)** Density profile $\rho(z)$ of the surface state at $\bar{\Gamma}$ and schematically shown crystal potential profile $V(z)$. The bulk band structure is calculated with a full-potential linear augmented plane wave method [17.90], and surface states are calculated with the embedding method of [17.65]; a fragment of a finite-thickness slab (from z_M to z_V) is embedded between a semi-infinite substrate and vacuum

detail in [17.81]. In metals with high electronic density, such as Al and Be, the multipole plasmon is only weakly manifested in electron energy-loss spectra [17.10] because it is blurred by a strong surface monopole plasmon, but it has a dramatic effect on photoemission intensities.

We will now introduce a quasi 1-D model to treat the nonlocal response within RPA and for Be(0001) demonstrate that the resulting total electric field combined with the (fully 3-D) one-step theory of photoemission fairly accurately describes the experimentally observed photoemission intensities. Beyond the jellium model, the present description includes (i) the nonfree-electron character of the photoemission initial and final states, (ii) the effect of optical absorption due to interband transitions on the *classical* Fresnel field, and (iii) the effect of crystallinity on the nonlocal dielectric response. The latter aspect allows for the damping due to electron-hole excitations (albeit underestimated) and eliminates the uncertainty of the jellium model [17.25] in locating the edge of the positive background relative to the crystal surface. The discussion below follows our work [17.94].

To calculate the self-consistent RPA response function χ, the Be(0001) surface is represented by a finite-thickness slab (60 atomic layers) inhomogeneous only along the direction z normal to the surface [17.95]. The model crystal potential $V(z)$ was constructed in [17.96, 97] so as to give the correct parameters of the gap at $\bar{\Gamma}$ and the location of the surface state (Fig. 17.20). (The scheme can be straightforwardly generalized to a true 3-D crystal potential, but this would require an enormous computational effort.)

In the quasi 1-D approach the z component of the electric field is the solution of the 1-D integral equation

$$\int \epsilon^{zz}(z,z',\omega)\mathcal{E}_z(z',\omega)\,\mathrm{d}z' = \mathcal{D}_z = \mathcal{E}_z^{\mathrm{vac}} \,. \quad (17.88)$$

The classical field in vacuum $\mathcal{E}_z^{\mathrm{vac}}$ is derived from the Fresnel equations using the experimental dielectric function ϵ_{mac} from [17.98], and the spatially varying total field inside the solid is obtained from the approximate microscopic theory. We thereby take into account the properties of the actual material in the bulk response but neglect the effect of the surface response on

reflection. Following the approach by *Samuelsen* and *Schattke* [17.99], we reduce the calculation of the response to the transverse field to the response to a scalar field, with the external scalar field taken as an evanescent wave

$$\phi^{\mathrm{ext}}(\boldsymbol{r}) = -\frac{2\pi}{q_\parallel}\exp(\mathrm{i}\boldsymbol{q}_\parallel \boldsymbol{r}_\parallel + q_\parallel z)\,. \tag{17.89}$$

The limit $q_\parallel \to 0$ is ensured by the numerical convergence of the results for $2\pi/q_\parallel$ much larger than the lattice constant.

The response of the electronic system to the external scalar field ϕ^{ext} is determined by the equation

$$\int \mathrm{d}z'\,\chi^0(z,z',q_\parallel,\omega)\phi^{\mathrm{tot}}(z',q_\parallel,\omega) = \int \mathrm{d}z'\,\chi(z,z',q_\parallel,\omega)\phi^{\mathrm{ext}}(z',q_\parallel,\omega)\,, \tag{17.90}$$

where ϕ^{tot} is the total self-consistent field, and the functions χ^0 and χ are the 2-D Fourier transforms of the noninteracting and interacting density-response functions, respectively. The noninteracting response function is derived from the single-particle eigenfunctions ψ_n, which, in the geometry of thick repeated slabs, are standing waves in the direction perpendicular to the surface, and they are independent of the Bloch vector $\boldsymbol{k}_\parallel$ parallel to the surface

$$\chi^0(z,z',q_\parallel,\omega) = 2\sum_{nm}\psi_n(z)\psi_m^*(z)\psi_n^*(z')\psi_m(z') \times \sum_{\boldsymbol{k}_\parallel}\frac{f_{\boldsymbol{k}_\parallel n} - f_{\boldsymbol{k}_\parallel+\boldsymbol{q}_\parallel m}}{E_{\boldsymbol{k}_\parallel n} - E_{\boldsymbol{k}_\parallel+\boldsymbol{q}_\parallel m} + \omega + \mathrm{i}\eta}\,. \tag{17.91}$$

Here, the sum over n and m comprises both occupied and unoccupied states, and $f_{\boldsymbol{k}_\parallel n} = \Theta(E_{\mathrm{F}} - E_{\boldsymbol{k}_\parallel n})$ are the Fermi occupation factors.

Within RPA, the interacting response function χ is the solution of the integral equation

$$\chi(z,z',q_\parallel,\omega) = \chi^0(z,z',q_\parallel,\omega) + \int \mathrm{d}z_1 \int \mathrm{d}z_2\,\chi^0(z,z_1,q_\parallel,\omega)v(z_1,z_2,q_\parallel)\chi(z_2,z',q_\parallel,\omega)\,, \tag{17.92}$$

where $v(z_1,z_2,q_\parallel)$ is the 2-D Fourier transform of the bare Coulomb interaction. In the present approach, the integral equation reduces to a linear algebra matrix equation (more details of the calculations are given in [17.95]). Finally, the solution of (17.88) $\mathcal{E}_z(z',\omega)$ is obtained from the solution ϕ^{tot} of (17.90) as its gradient $-\mathrm{d}\phi^{\mathrm{tot}}/\mathrm{d}z$ scaled so as to equal the z projection of the electric field of the electromagnetic wave in vacuum $\mathcal{E}_z^{\mathrm{vac}}$.

In jellium, light is absorbed only at the surface, and the absorbed power is proportional to the imaginary part of the centroid of the induced density $d_\perp(\omega)$ [17.81]. In a crystal, owing to the bulk local fields, the induced microscopic dipole moment extends to macroscopic distances, and surface and bulk absorption cannot be unambiguously separated. The surface absorption is, however, clearly seen in the energy-depth distribution $P(z,\omega)$ of the absorbed power; the results for 1-D crystal and jellium models of Be(0001) for p-polarized light incident at 45° are shown in Fig. 17.21 along with field intensity $I(z,\omega)$, which is the relevant quantity for photoemission. Above ω_{p}, bulk plasmons are excited, the momentum being provided by the surface; the plasmon wavevector increasing with energy is clearly seen for the jellium model, but for the crystalline Be, it is blurred by the stronger crystal fields. Below ω_{p}, the surface absorption peaks at the multipole plasmon energy $\omega_{\mathrm{m}} \approx 0.8\omega_{\mathrm{p}}$ in perfect agreement with the earlier jellium theory [17.81].

17.6.4 Photoemission from a Surface State

To see how the inclusion of the total exciting field into the perturbation operator $\hat{O}$ of (17.85) affects photoemission intensity, let us consider the emission from the surface state at $\bar{\Gamma}$ on Be(0001), see Fig. 17.20. Because it is located in a wide energy gap, its signal does not overlap with the bulk emission. The surface state is almost entirely localized within two outermost atomic layers (Fig. 17.20), so its spectrum cannot be understood in terms of direct transitions, and the evanescent part of the complex band structure is expected to play an important role. In addition, in spite of the small atomic number of Be, its unoccupied band structure is not free-electron-like, see Fig. 17.22a, as evident from the high-energy structures B–E in the $J(E)$ curve in Fig. 17.22b. Figure 17.22a relates these maxima to the complex band structure of the LEED states in the AΓA interval of the bulk Brillouin zone; the intensity is distributed over several conducting branches (i.e., partial waves that affect the escape of the photoelectron, see Sect. 17.6.1), and the observed spectrum results from a superposition of transition amplitudes to different Bloch waves. (For technical details of the calculation, see [17.94]).

Because we are interested in photoemission intensities we should pay attention to the effect of the absorbing potential $-\mathrm{i}V_{\mathrm{i}}(E)$, which controls the surface sensitivity in the calculations. In principle,

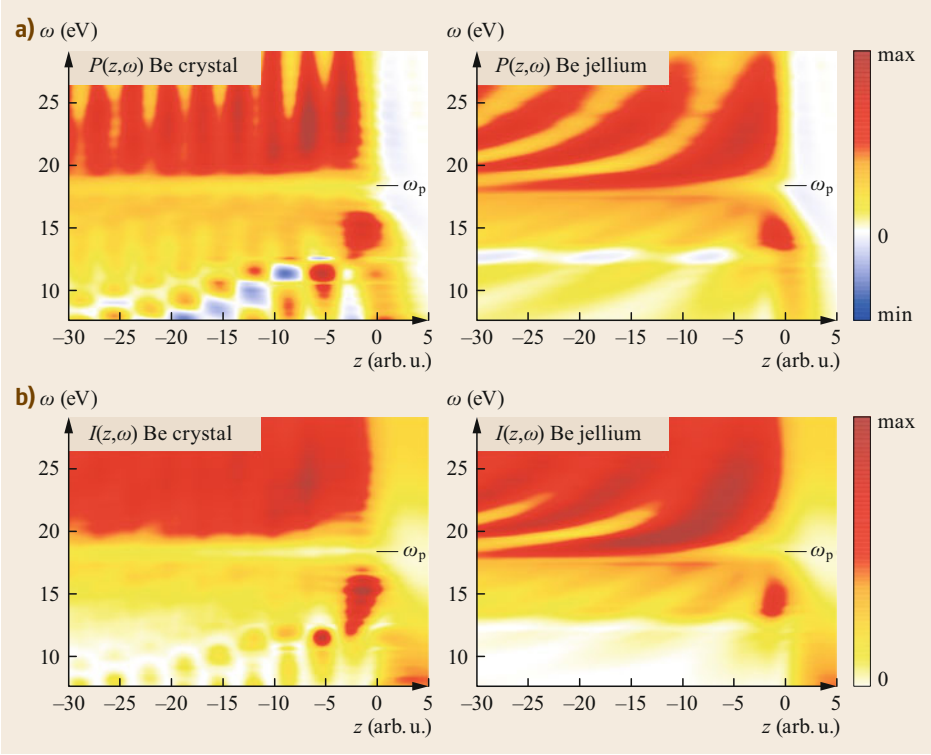

Fig. 17.21a,b Frequency-dependent spatial distribution of the electric field at the surface Be(0001). **(a)** Power absorption density $P(z,\omega) = [\omega/(4\pi)]\,\mathrm{Im}[\mathcal{D}_z E_z^*(z,\omega)]$ and **(b)** intensity $I(z,\omega) = |\mathcal{E}_z(z,\omega)|^2$. Calculations are for $q = 0.02$ (arb. u.)$^{-1}$. (Reproduced from [17.94])

this parameter can be obtained as the expectation value of the imaginary part of the self-energy operator [17.100], which can be calculated within the *GW* approximation [17.101, 102] from the ab-initio band structure [17.103]. However, for such a complicated electronic structure as that of Be, a reliable ab-initio calculation is still very difficult. In the present theory, V_i is the only unknown parameter, which, however, is known to be not strongly material dependent [17.104, 105] and to have a common behavior: V_i is close to zero at the Fermi energy, it increases sharply at the bulk plasma frequency ($\omega_p = 18.4$ eV for Be) and then steadily grows with energy. Assuming this shape, we deduced the function $V_i(E)$ (see the inset in Fig 17.22b) from the results for Al(100) [17.105] with an expected uncertainty of ± 0.5 eV (shown by shading). The variations of the emission intensity due to the uncertainty in V_i are shown by the shading of the $J(E)$ curve in Fig. 17.22b, and they are seen to be quite small compared to the intensity variations over the spectrum. Such weak sensitivity to the optical potential is a consequence of the strong spatial localization of the initial state.

The strongest peak A is at $\omega = 15$ eV, and it is entirely due to the enhancement of the exciting field caused by the multipole plasmon. Above ω_p, the higher intensity of the emission caused by the total field rather than by the incident field (dashed curve) is due to the classical response (described by the Fresnel formulas). In particular, when the reflected field is in phase with the incident field, a classical resonance occurs, which, for the incidence angle of 45°, is at $\omega_p\sqrt{2} = 26$ eV. However, in Be the classical resonance is very broad, and maximum B is, actually, a final state effect. For the comparison with the experiments [17.88], we scaled the $J(\omega)$ spectrum so as to match the measured curve over the interval 25–45 eV, the solid line in Fig. 17.22a. The theory rather accurately describes the intensity variation by two orders of magnitude in the interval 10–50 eV, which proves that the calculated exciting field is quite realistic, as well as are the final states. (The slow decrease of intensity above 50 eV may be due to experimental conditions.) We may conclude that the present model for the dielectric response, which is based on RPA and on 1-D crystallinity, is adequate for real surfaces.

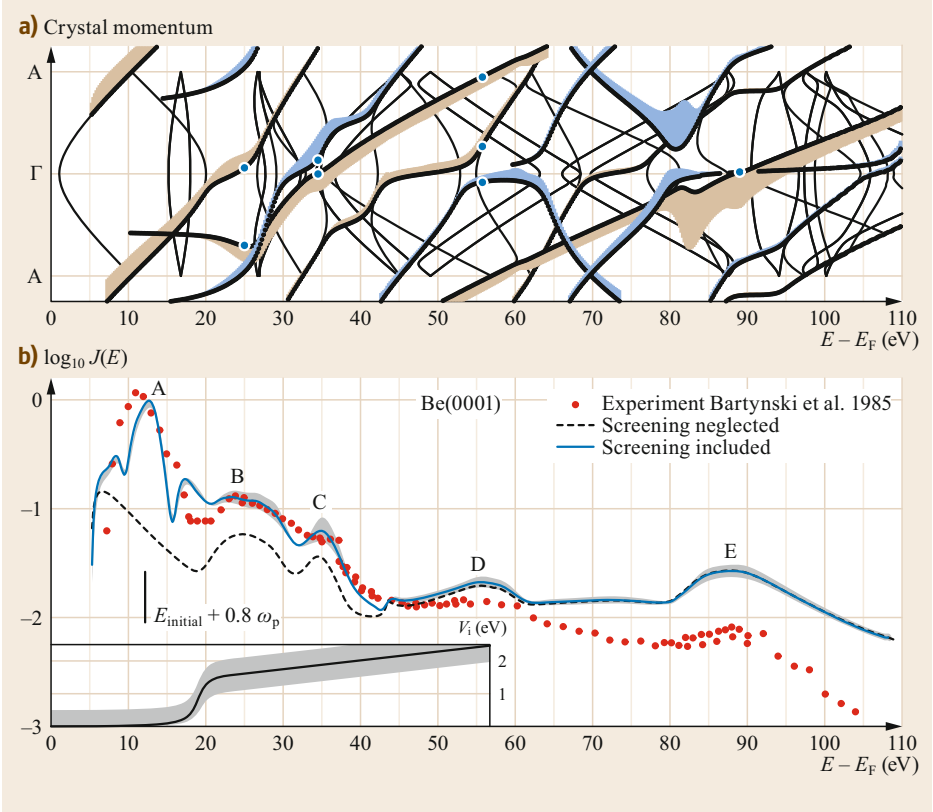

Fig. 17.22a,b Band structure analysis of the photoemission from the surface state at $\bar{\Gamma}$ on Be(0001). **(a)** Complex band structure of Be(0001) along the AΓA interval: *thin lines* are the (real) bulk band structure, $\mathrm{Im}(k_\perp = 0)$. *Thick lines* show Bloch waves that contribute to LEED states. Note that of the real band structure only the waves that move towards the surface contribute to the outgoing wave (which makes the thick lines asymmetric with respect to Γ). The vertical extent of the *shading* is proportional to the modulus (not squared) of the contribution to the matrix element from the individual partial wave. *Circles* indicate $k_\perp$ vectors of the Bloch waves at the maxima B–E. **(b)** Experimental [17.88] semilogarithmic intensity profile $\log_{10} J(\omega)$ (*circles*) of the $\bar{\Gamma}$ surface-state emission compared to the theory with (*solid line*) and without screening (*dashed line*). The *vertical bar* at $E - E_\mathrm{F} = 12\,\mathrm{eV}$ indicates the excitation energy of $0.8\omega_\mathrm{p}$. *Inset*: optical potential $V_\mathrm{i}(E)$. *Shading* shows the estimated uncertainty of V_i and in graph **(b)** the related intensity uncertainty. (Reproduced from [17.94])

17.7 Calculation of Response Functions

Here, we introduce an ab-initio method of the calculation of the response function for realistic systems with full inclusion of the electronic band structure. Also, we give some details of a simplified approach based on a 1-D model potential that simulates key features of the surface electronic structure.

17.7.1 Ab-initio Model

According to the time-dependent density-functional theory [17.106], the response function of interacting electrons χ is related to that of noninteracting electrons χ^0 through the integral equation

$$\chi(\boldsymbol{r},\boldsymbol{r}',\omega) = \chi^0(\boldsymbol{r},\boldsymbol{r}',\omega) + \int \mathrm{d}\boldsymbol{r}_1 \int \mathrm{d}\boldsymbol{r}_2\, \chi^0(\boldsymbol{r},\boldsymbol{r}_1,\omega)[v(\boldsymbol{r}_1,\boldsymbol{r}_2) + K^\mathrm{xc}(\boldsymbol{r}_1,\boldsymbol{r}_2,\omega)]\chi(\boldsymbol{r}_2,\boldsymbol{r}',\omega)\,, \quad (17.93)$$

where $v(\boldsymbol{r}_1,\boldsymbol{r}_2)$ is the Coulomb interaction potential, and $K^\mathrm{xc}(\boldsymbol{r}_1,\boldsymbol{r}_2,\omega)$ takes into account dynamical exchange-correlation effects. Many approximate forms for K^xc have been proposed. The simplest and most common approximation is RPA, in which K^xc is simply set to zero.

At the surface, the translational symmetry in the direction perpendicular to the surface is broken, and a direct application of (17.93) with full inclusion of the band structure would be a formidable task. One way to solve this problem is to resort to so-called repeated-slab geometry, where one constructs an artificial 3-D lattice with a unit cell containing a slab of a finite number of atomic layers representing the crystal surface of interest sandwiched between two vacuum spaces (cf., supercell geometry of Sect. 17.5.1). This cell is periodically repeated in the direction normal to the surface. For such geometry, one can perform 3-D Fourier transformation of all quantities and employ the computational codes developed for 3-D lattices. The only difference here is that the 2-DBZ is used, since the cell size in the direction perpendicular to the surface is substantially larger than its in-plane size.

For a 3-D periodic system, the integral equation (17.93) for χ transforms into a matrix equation, which for a given in-plane momentum transfer $\boldsymbol{q}_\parallel$ reads

$$\begin{aligned}&\chi_{GG'}(\boldsymbol{q}_\parallel,\omega)\\&=\chi^0_{GG'}(\boldsymbol{q}_\parallel,\omega)+\sum_{G_1}\sum_{G_2}\chi^0_{GG_1}(\boldsymbol{q}_\parallel,\omega)\left[\upsilon_{G_1}(\boldsymbol{q}_\parallel)\delta_{G_1G_2}\right.\\&\quad\left.+K^{\mathrm{xc}}_{G_1G_2}(\boldsymbol{q}_\parallel,\omega)\right]\chi_{G_2G'}(\boldsymbol{q}_\parallel,\omega)\,.\end{aligned}\tag{17.94}$$

The matrix elements of the response function of noninteracting electrons χ^0 are given by

$$\begin{aligned}&\chi^0_{GG'}(\boldsymbol{q}_\parallel,\omega)\\&=\frac{2}{S}\sum_{\boldsymbol{k}_\parallel}^{\text{2-DBZ}}\sum_{nn'}\frac{f_{\boldsymbol{k}_\parallel n}-f_{\boldsymbol{k}_\parallel+\boldsymbol{q}_\parallel n'}}{E_{\boldsymbol{k}_\parallel n}-E_{\boldsymbol{k}_\parallel+\boldsymbol{q}_\parallel n'}+(\omega+\mathrm{i}\eta)}\\&\quad\times\left\langle\psi_{\boldsymbol{k}_\parallel n}\right|\mathrm{e}^{-\mathrm{i}(\boldsymbol{q}_\parallel+\boldsymbol{G})\cdot\boldsymbol{r}}\left|\psi_{\boldsymbol{k}_\parallel+\boldsymbol{q}_\parallel n'}\right\rangle\\&\quad\times\left\langle\psi_{\boldsymbol{k}_\parallel+\boldsymbol{q}_\parallel n'}\right|\mathrm{e}^{\mathrm{i}(\boldsymbol{q}_\parallel+\boldsymbol{G}')\cdot\boldsymbol{r}}\left|\psi_{\boldsymbol{k}_\parallel n}\right\rangle,\end{aligned}\tag{17.95}$$

where the factor 2 accounts for spin, S is the normalization area, and the second sum runs over the band structure for each wavevector $\boldsymbol{k}_\parallel$ in the 2-DBZ, $f_{\boldsymbol{k}_\parallel n}=\{\exp[(E_{\boldsymbol{k}_\parallel n}-\mu)/T]+1\}^{-1}$ is the Fermi factor, with μ and T being the chemical potential and temperature of the electron gas, respectively; $E_{\boldsymbol{k}_\parallel n}$ and $\psi_{\boldsymbol{k}_\parallel n}$ are the one-particle eigenvalues and eigenfunctions, and η is a positive infinitesimal. For the evaluation of $E_{\boldsymbol{k}_\parallel n}$ and $\psi_{\boldsymbol{k}_\parallel n}$, one can employ a variety of methods developed within the framework of DFT. However, the computational cost of the evaluation of the matrix elements in (17.95) may be very different for different methods. The most efficient and simple computational realization is achieved in the plane-wave representation for the wavefunctions $\psi_{\boldsymbol{k}_\parallel n}$, but this limits the consideration to relatively simple elementary solids.

The evaluation of the χ^0 matrix is the most time-consuming part of the 3-D response calculations. In order to save computational time, one can first calculate [17.107, 108] the absorptive part of the χ^0 function according to (17.13), which, at $T=0$, takes the form

$$\begin{aligned}&\chi^{0A}_{GG'}(\boldsymbol{q}_\parallel,\omega)\\&=-\frac{2\pi}{S}\sum_{\boldsymbol{k}_\parallel}^{\text{2-DBZ}}\sum_{n}^{\text{occ}}\sum_{n'}^{\text{unocc}}\delta(E_{\boldsymbol{k}_\parallel n}-E_{\boldsymbol{k}_\parallel+\boldsymbol{q}_\parallel n'}+\omega)\\&\quad\times\left\langle\psi_{\boldsymbol{k}_\parallel n}\right|\mathrm{e}^{-\mathrm{i}(\boldsymbol{q}_\parallel+\boldsymbol{G})\cdot\boldsymbol{r}}\left|\psi_{\boldsymbol{k}_\parallel+\boldsymbol{q}_\parallel n'}\right\rangle\\&\quad\times\left\langle\psi_{\boldsymbol{k}_\parallel+\boldsymbol{q}_\parallel n'}\right|\mathrm{e}^{\mathrm{i}(\boldsymbol{q}_\parallel+\boldsymbol{G}')\cdot\boldsymbol{r}}\left|\psi_{\boldsymbol{k}_\parallel n}\right\rangle,\end{aligned}\tag{17.96}$$

where the sum over n (n') is limited to occupied (unoccupied) states. Another important problem is related to the long-range Coulomb interaction between oscillating charges in different slabs, which may introduce spurious effects in the response function χ. For instance, the plasmon dispersion is distorted in the long-wavelength limit. This issue is especially crucial, if one is interested in the dispersion of a 2-D plasmon [17.109]. Several recipes were proposed to solve this problem. One of the approaches [17.33] is described in Sect. 17.5.1. Implementation of this recipe in the first-principles calculations of the plasmonic structure of thin Pb(111) films demonstrated [17.110] its efficiency in the elimination of the spurious long-range Coulomb interaction between different slabs.

The ab-initio method to evaluate the response functions with full inclusion of the electronic band structure still has to be incorporated into the theories of the inelastic scattering of electrons and photoemission presented in previous sections. The recent progress in the numerical evaluation of response functions from first principles by different groups promises that this can be done in the nearest future. One of the main advantages of the ab-initio approach over the simple models based on a free-electron approximation is its ability to correctly describe both the energy and the lifetime of collective electronic excitations at the surfaces. The surface plasmon properties obtained with the surface response function evaluated with a full inclusion of the surface electronic structure demonstrated its efficiency: such calculations are able to reproduce the dispersion of the plasmon energy and lifetime for clean surfaces of the simple metals Mg(0001) [17.111–113], Al(111) [17.112], Be(0001) [17.114–116], and Pb(111) [17.110] very closely to the energy-loss experiments [17.117–119]. Moreover, since in this approach, the valence d electronic states are taken into account, the surface plasmon properties of the noble metals Cu(111) [17.120], Ag(111) [17.120, 121], and Au(111) [17.120, 122]

are well described as well, in agreement with the experiment [17.2]. Similar calculations were performed for Si(001) [17.123] and for surfaces with adsorbed layers, such as p(2×2)K/Be(0001) [17.124, 125], p(2×2)K/graphite [17.126], graphene/SiC(0001) and graphene/Al(111) [17.127], and H/Ag(111) [17.121] and monolayer and bilayer graphene [17.113, 127–133].

17.7.2 One-Dimensional Model

The results presented in this chapter are based on the response function χ^0 obtained with a simplified model, in which the band structure effects are included via the model potential of [17.97]. In contrast to the potential of the frequently used jellium model, the potential of [17.97] reproduces the key features of the surface band structure, namely the energy gap in the $\boldsymbol{k}_\parallel = 0$-projected bulk band structure and the energy of the surface state and the first image state. For simplicity, this model assumes the translational invariance and a free-electron-like dispersion for the electronic states in the plane of the surface. As a result, the wavefunctions are

$$\psi_{\boldsymbol{k}_\parallel n}(\boldsymbol{r}) = \frac{1}{\sqrt{S}} \mathrm{e}^{\mathrm{i}\boldsymbol{k}_\parallel \cdot \boldsymbol{r}_\parallel} \psi_n(z) \,, \tag{17.97}$$

and the corresponding single-particle energies are

$$E_{\boldsymbol{k}_\parallel n} = E_n + \frac{k_\parallel^2}{2m_n} \,, \tag{17.98}$$

where the energy E_n is obtained by solving the 1-D Schrödinger equation with the model potential, and m_n is the effective mass of the n-th energy band, which, in principle, may be different from unity (using the effective masses partially compensates for the averaging of the potential in the xy plane).

In this representation, the calculation of $\chi^0(\boldsymbol{r}, \boldsymbol{r}', \omega)$ reduces to the calculation of $\chi^0(z, z', q_\parallel, \omega)$ [17.134, 135], and the expression (17.95) for the response function of noninteracting electrons χ^0 becomes (17.91). In order to proceed one can expand the wavefunctions $\psi_n(z)$ in a Fourier series, again using a slab geometry for the surface description [17.134]. In this case, the Fourier representation of the noninteracting density-response function χ^0 takes the following form

$$\begin{aligned}
&\chi^0(z, z', q_\parallel, \omega) \\
&= \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \chi^{0+}_{mn}(q_\parallel, \omega) \cos\left(\frac{2\pi m}{d} z\right) \cos\left(\frac{2\pi n}{d} z'\right) \\
&\quad + \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \chi^{0-}_{mn}(q_\parallel, \omega) \sin\left(\frac{2\pi m}{d} z\right) \sin\left(\frac{2\pi n}{d} z'\right) ,
\end{aligned} \tag{17.99}$$

where d is the width of the unit cell composed of the atomic layers and the empty space.

Within the framework of RPA, the 2-D Fourier transform $\chi(z, z', q_\parallel, \omega)$ of the density-response function of an interacting electron system is obtained by solving the integral equation (17.92). All quantities entering (17.92) can be represented in the form of (17.99), which yields the following matrix equation for the coefficients $\chi^{\pm}_{m,n}(q_\parallel, \omega)$

$$\begin{aligned}
\chi^{\pm}_{mn}(q_\parallel, \omega) = \chi^{0\pm}_{mn}(q_\parallel, \omega) + \sum_{m', n'} \big[&\chi^{0\pm}_{mm'}(q_\parallel, \omega) v_{m'n'}(q_\parallel) \\
&\times \chi^{\pm}_{n'n}(q_\parallel, \omega) \big],
\end{aligned} \tag{17.100}$$

with $v_{mn}(q_\parallel)$ being the coefficients of the bare Coulomb interaction $v(z, z', q_\parallel)$. Further computational details of this approach can be found in [17.95].

17.8 Conclusions and Perspectives

We have reviewed the main challenges arising in the development of the theoretical approaches to the electron and photoemission spectroscopies of bulk, surface, and quasi 2-D solid systems. Over the years, the general trend of the transfer from model to ab-initio approaches have been clearly identified.

We have discussed the current state-of-the-art of the theory of EELS up to its very recent developments. A fundamental limitation of the traditional picture of the inelastic scattering of electrons at solid targets has been revealed. That is the neglect of the simultaneous *potential scattering* at the crystal lattice, which turns out to be critically important, especially for quasi 2-D materials in the energy range of incident electrons of $\approx 10-100$ eV, corresponding to the values used in high-resolution EELS. We have shown how this shortcoming can be overcome by the construction of the theory of one-step combined inelastic and elastic electron scattering. These results open a path to the *theoretically interpretable* application of HREELS for studying Q2-D materials with meV resolution, an unachievable limit with the presently available EELS in the TEM technique.

We have analyzed the results obtained with the new theory, which show a strong coupling between inelastic and elastic channels in monolayer and bilayer graphene in the HREELS regime. In particular, the excitation of

the $\pi + \sigma$ plasmon is dramatically affected by the scattering in the elastic channel. These theoretical findings constitute a strong motivation for performing HREELS experiments on free-standing Q2-D crystals, especially so in view of the recent advances in the HREELS techniques.

In our example calculations, we used the local-density approximation (LDA) to DFT for the ground-state calculations and RPA for the dynamic response calculations, respectively. This was done consciously for the sake of simplicity and considering that our goal was highlighting the coupling between inelastic and elastic processes, rather than studying the many-body effects in Q2-D materials, the latter problem having been addressed in a large body of literature ([17.136] and references therein). The basis of our approach, (17.78), however, remains valid at any level of (TD)DFT, allowing future inclusion of the many-body effects within the framework of this theory. At the same time, it must be noted that the supercell method might encounter difficulties in the presence of the long-range xc [17.137], in which case the *native* approaches [17.138] (considering a single Q2-D crystal from the very beginning) will be necessary. The well-known shortcomings of LDA and RPA [17.16] are the likely source of the remaining discrepancies between our calculations and experiment in the energy range of the $\pi + \sigma$ plasmon.

Finally, we argued that overcoming the limitations of the presently generally adopted energy-loss functions formalism, the theory of the simultaneous inelastic and elastic electron scattering can be expected to replace the previous approaches as a standard theoretical tool in the EELS of mesoscopic materials.

waxslavas@ehu.es

Vyacheslav Silkin received his PhD from the Institute of Strength Physics and Material Science of the Russian Academy of Science at Tomsk, Russia (1990). He worked in the Institute of Strength Physics and Material Science in Russia, at the University of the Basque Country (Spain), and at Donostia International Physics Center (Spain). He is currently working on the dynamics of one-particle and collective electronic excitations in metals and their surfaces.

18. Surface Plasmons and Plasmonics

Mario Rocca

Surface plasmons (SPs) correspond to self-sustaining excitations of the electron gas of metals or semiconductors, i.e., to modulations of the density of such gas occurring at the surface of the body generating electric fields propagating along the surface and decaying exponentially perpendicular to it. Since the electric field at a metal surface is directed perpendicular to it, the SP corresponds to a transversely polarized wave. As such it may interact with light giving rise, in the long wavelength limit, to SP polaritons (SPPs) which are promising for plasmonics applications, i.e., SP-based electronics, since at any given frequency their wavelength is shorter than the one of light and may thus allow for a miniaturization of photonic devices. Excitation of SPPs by light requires matching of energy and wavevector and is thus possible only for rough surfaces or in the presence of gratings. As for bulk plasmons, the SP frequency is dictated by the electron density and falls typically between a couple and some tens of eV. Surface plasmons, therefore, cannot be excited thermally nor interact significantly with lattice vibrations but play a role whenever electronic degrees of freedom are involved as in electron and ion-surface scattering. Surface plasmon dispersion is dictated by surface properties and may depend on crystallographic surface and propagation direction. For small particles, resonant light absorption occurs whenever a closed path along the surface coincides with multiples of the SP wavelength (Mie resonance). If it falls in the visible range it determines the bright colors of metallic nanoparticles and can be exploited in energy harvesting in solar cells. SP resonances are, moreover, responsible for the amplification of the local electric field in nanoantennas and in surface-enhanced Raman spectroscopy, allowing Raman signals even for single isolated molecules to be recorded. Furthermore, the SP resonance influences the optical reflectivity and can therefore be easily monitored. Since the latter depends on the refractive index of the medium, surface modifications resulting from adsorption can be monitored in vacuum and electrochemical environments.

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-46906-1_18

Surface plasmons are coherent excitations of the free-electron gas occurring at the interface of two materials. They are polarization waves propagating along the interface and evanescent normal to it, whereby the electromagnetic fields associated with the additional charge fall exponentially away from the interface.

Surface plasmons were first predicted by *Ritchie* in 1957 [18.1] and extensively studied in the following decades by *Raether* [18.2], *Kretschmann* [18.3], and *Otto* [18.4].

At variance with bulk plasmons, which correspond to longitudinal oscillations of the electron gas, SPs have transverse character and may therefore interact with light, a property which makes them attractive for applications. For this same reason at small wavevectors, where the SP dispersion crosses the light line, hybridization with electromagnetic radiation occurs giving rise to a mixed excitation: the surface plasmon polariton (SPP) (see [18.5] for a recent review of this topic). Direct excitation of an SP by light is, however, possible only when energy and wavevector match, a condition that is satisfied only for rough surfaces or in the presence of a grating which provides the missing momentum.

Evanescent light waves can be produced with a prism (a technique known as attenuated total reflection, Fig. 18.1). Above a certain angle of incidence, on the inside wall of the prism light undergoes total reflection, but the associated electromagnetic field spills over and reaches the metallic foil placed above it. Whenever energy and momentum match a SP, light is absorbed and the reflectivity decreases abruptly.

The metallic foil usually consists of the noble metals Au or Ag, since they have the sharpest resonances [18.7–9]. Shifts in the angle at which the resonance occurs may be induced by changes in the optical density close to the noble metal film. This effect forms the basis of surface plasmon resonance spectroscopy, a technique applied to monitor adsorption and desorption of molecules especially for the investigation of biointerfaces [18.6] and appreciated for its real-time and noninvasive nature.

SPs may otherwise be excited by charged particle beams, such as the swift electrons of a transmission electron microscope. Momentum transfer causes thereby a deflection in the trajectory and an energy loss as shown schematically in Fig. 18.2b for a 50-keV beam shot through Ag foils of different thickness. The electron energy-loss (EEL) spectra are shown in Fig. 18.2a. The lowest EEL peak at ≈ 3.63 eV corresponds to the excitation of the surface plasmon. The loss intensity is independent of film thickness since this mode can be excited only as long as the electron is *outside* of the foil. Conversely, the EEL at 3.78 eV is associated with the excitation of the bulk plasmon. Its intensity indeed scales with film thickness since it can be excited only while the electrons move *inside* the material. Energy and wavevector conservation allow the dispersion curve of both modes to be traced.

More recently, surface plasmon dispersion has been investigated with low kinetic energy electrons (kinetic energy of tens to hundreds of eV) for which the penetration into a metal surface is limited to just a few monolayers (MLs) [18.11–18] and the retrieved information is therefore highly surface sensitive. Such high-resolution electron energy-loss spectroscopy (HREELS) investigations allowed for a careful determination of the SP dispersion with wavevector, validating the theoretical forecast of a negative slope for simple metals [18.11, 19, 20] and stimulating new theory for noble metals where the dispersion was determined to be positive [18.21, 22]. The dispersion of the SP explains the size dependence of the Mie resonance in clusters [18.23–25], and impacts on the understand-

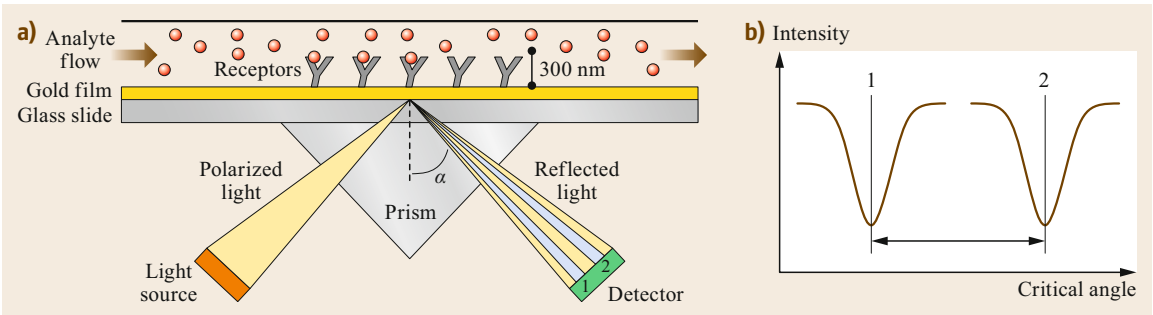

Fig. 18.1 **(a)** Kretschmann configuration used for biochemical sensing. A thin gold film is evaporated on a prism and put into contact with receptors and an analyte. The latter changes the refraction index in the thickness range of about 300 nm above the gold surface thereby causing a shift in the angular position at which absorption of light, caused by the excitation of SPPs, takes place. **(b)** Intensity of the reflected radiation versus angle with 1 and without 2 analyte. (Reprinted from [18.6], with permission from Elsevier)

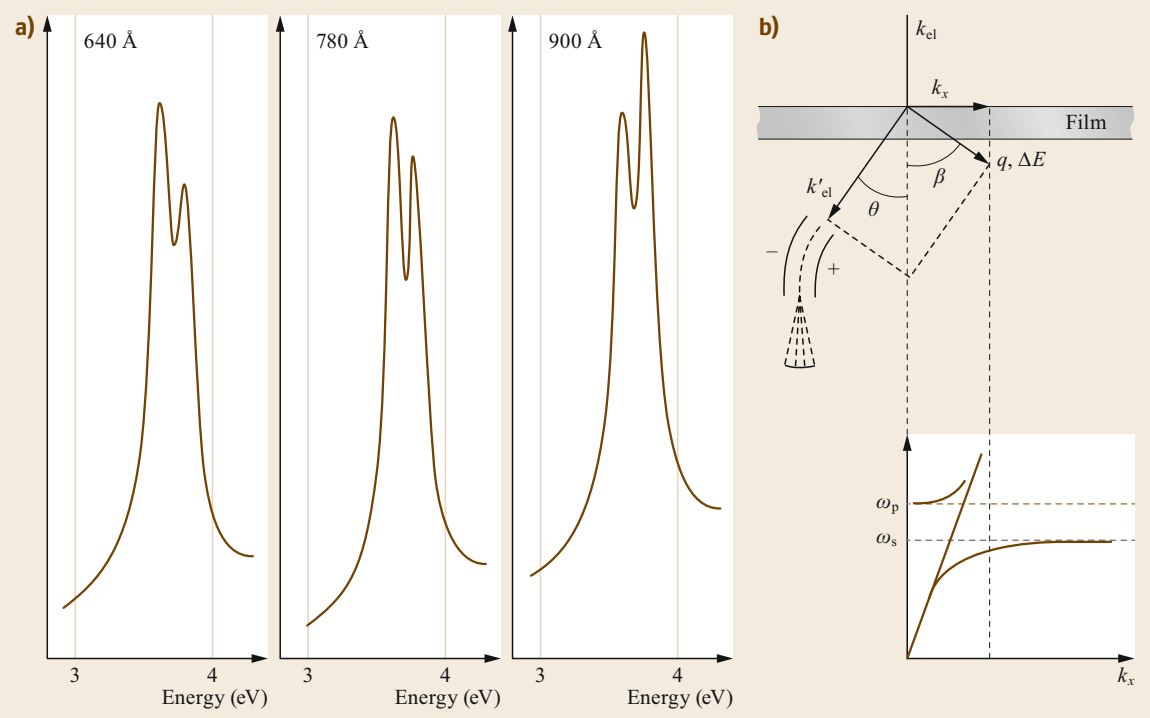

Fig. 18.2 **(a)** Electron energy-loss spectra recorded by swift electrons (kinetic energy 50 keV) moving through a thin Ag foil. The losses correspond to surface (3.63 eV) and bulk (3.78 eV) plasmon excitations. **(b)** Geometry of the experiment. The beam hits the foil along the surface normal and the electrons are recorded in transmission. The loss intensity of the bulk plasmon scales with the foil thickness. The *lower right panel* reports the dispersion of transverse modes with transferred momentum parallel to the surface k_x on a wavevector scale comparable to the one of photons in the visible range, i.e., 10^{-3} Å^{-1}. The hybridization of SPs and light gives rise to the SPP. (Reprinted by permission from **(a)** [18.10] and **(b)** [18.2], © Springer 1967, 1980)

ing of surface photoyield (PY), deexcitation mechanisms of adsorbates, and the origin of van der Waals forces [18.19, 21, 22].

A typical HREEL spectrum for an Ag surface showing the SP loss is reported in Fig. 18.3. It does not correspond to optimal investigation conditions since the impact energy of the electrons used in this experiment is relatively high implying an important integration of the inelastic signal over reciprocal space but it has been recorded over a wide energy-loss range. As one can see, the spectrum is dominated by a single peak. The bulk plasmon does not contribute appreciably to the inelastic signal and an important tail is present on the large energy-loss side due to the excitation of interband transitions. Changing the scattering geometry by moving out-of-specular within the dipolar cone allows for an accurate recording of the dispersion of the surface plasmon for wavevectors that are large compared to those of the light cone (Fig. 18.2b), a region which can only be accessed by optical methods.

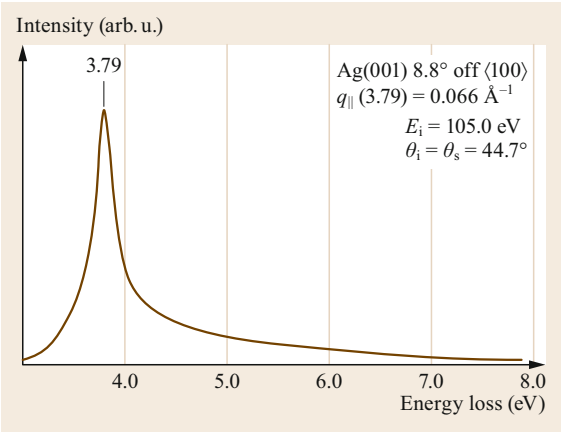

Fig. 18.3 Electron energy-loss spectrum recorded at a relatively large impact energy evidencing the loss due to the surface plasmon and the tail associated with interband transitions. (Reprinted from [18.22], with permission from Elsevier)

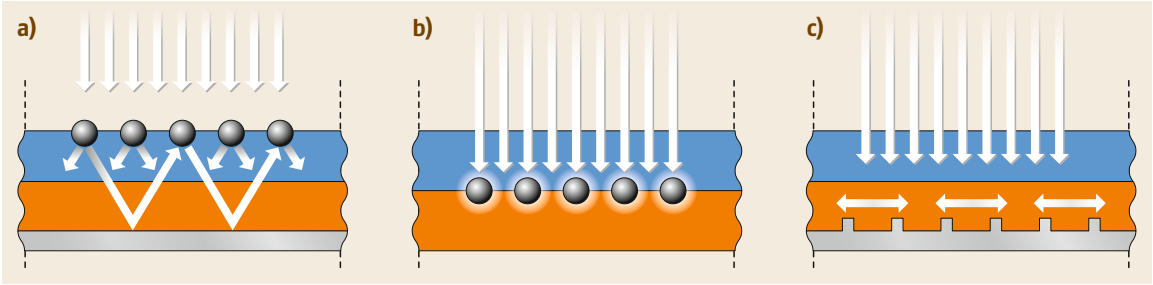

Fig. 18.4a–c Energy harvesting in plasmonic solar cells. Plasmonic nanoparticles are added to the junction in order to reduce the thickness of the cell to a few μm and save precious material while reducing the recombination of the charge carriers prior to their collection by the p-n junction. **(a)** Plasmonic particles at the surface reflect the light trapping it into the cell; **(b)** plasmonic particles at the interface trap the light by excitation of localized SPs; **(c)** SPPs are excited at the metal semiconductor interface. Fig. 18.5 The Lycurgus Cup (Reprinted by permission from [18.27], © Springer 2007)

The importance of SPs in applications grew over the years eventually giving rise to a new field of research called plasmonics. A search under the keyword *surface plasmon* yields some 64 000 papers over the past 20 years, while inserting the keyword *plasmonics* results in over 1000 papers appearing every year.

The interest in SPs and SPPs is motivated by their interaction with electromagnetic radiation which allows light to be squeezed in regions much smaller than the wavelength of the corresponding photon [18.28–30] and by energy harvesting in solar cells [18.26, 31]. Localization of light allows it to pass through subwavelength holes [18.32] and is promising for the construction of SP-based optoelectronic devices with nanosized dimensions [18.33, 34]. Finally, SP-based antennas are currently under investigation and look very promising for the generation of very high local electric fields. Results were reported for SP coupling to optical emitters [18.35–37], SP focusing [18.38, 39], building optical antennas at the nanoscale [18.40], SP-based integrated circuits [18.41, 42], SP-enhanced light-emitting diodes [18.43], as well as on negative refractive index materials [18.44–46].

In Fig. 18.4, schemes are reported for SP-based energy harvesting by light scattering of nanoparticles placed at the surface of a solar cell, at the p-n junction, and for SPP coupling by the corrugation introduced by a grating drawn in a metal back surface of the cell.

Two-dimensional (2-D) materials, such as graphene, can also sustain plasmons. This topic will not be treated here since it is reviewed in Chap. 19.

Surface plasmon-based nanotechnology is in reality an old technology, though it is now developed with knowledge-based insight. For example, the bright colors of the windows of Medieval cathedrals are due to Au and Ag nanoparticles of different diameter, embedded in the glass. The technique originates from late Roman times as witnessed by the magnificent Lycurgus Cup (now at the British Museum), which changes color when illuminated from the back (red) and front

(green) because of light absorption by localized SPs at the surface of the Au and Ag nanoparticles (Fig. 18.5).

The topic of SP dispersion has been summarized in 1995 [18.22]. Plasmonics applications in photovoltaic devices were reviewed more recently by *Atwater* and by *Polman* [18.26, 31]. An introduction to the surface plasmon topic may also be found in the some textbooks, see, e.g., [18.47].

18.1 Dynamical Screening at Surfaces

The dynamical screening of electric fields by a material is described by its dielectric response function ε which links the electric displacement field $\boldsymbol{D}$, generated by external charges only, with the electric field $\boldsymbol{E}$ to which all charges, i.e., including polarization charges, contribute. The response is thereby determined by the dependence on time t and space $\boldsymbol{r}$ of the external field $\boldsymbol{D}(t, \boldsymbol{r})$; $\boldsymbol{\varepsilon}$ is, in general, a tensor if the solid shows some anisotropy. Instead of performing complicated integrations over time delay and space distribution of the charges it is more convenient to look at the problem in reciprocal space performing a Fourier transform and reasoning in terms of frequency ω and wavevector $\boldsymbol{q}$ of the fields. The relationship between $\boldsymbol{D}$ and $\boldsymbol{E}$ simplifies then to the tensor product

$$\boldsymbol{D}(\omega, \boldsymbol{q}) = \boldsymbol{\varepsilon}(\omega, \boldsymbol{q})\, \boldsymbol{E}(\omega, \boldsymbol{q}) \,. \tag{18.1}$$

By definition, the component D_z normal to the interface is continuous across it while the one of the electric field E_z is discontinuous. If the only charges present at the interface are due to polarization, $\boldsymbol{E}$ will revert its direction across the interface, as schematically drawn in Fig. 18.6. A solution will then be possible at the particular frequency at which $\boldsymbol{\varepsilon}(\omega, \boldsymbol{q})$ also reverts its sign when crossing the interface.

If the interface is between a metal and a vacuum, an electric field generated by polarization charges may be sustained at the surface of the metal when the dielectric function of the metal $\varepsilon(\omega, q) = -1$. Such a condition is associated with the resonant excitation of an SP, a mode which propagates parallel to the interface in wavelike fashion and is characterized by a wavevector $q_\parallel$ (or by a wavelength $\lambda = 2\pi/q_\parallel$), an angular frequency, $\omega_{\mathrm{sp}}(q_\parallel)$, and a propagation velocity $v = \mathrm{d}\omega/\mathrm{d}q_\parallel$ parallel to the surface.

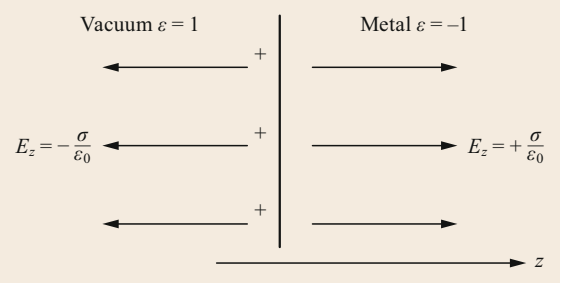

Fig. 18.6 Electric field across an interface with positive polarization charges. E is discontinuous while the field $D = \varepsilon E$ is continuous. Matching is possible only if ε changes sign across the interface

The electric fields associated with the polarization charges decrease exponentially away from the interface as $\mathrm{e}^{-|q_\parallel|z}$. Their penetration into the material is thus large at large wavelengths and very limited at large wavevectors. Excitation of surface plasmons makes up a very efficient screening mechanism for high-frequency external electric fields and determines thus to a large extent the high-frequency optical properties of surfaces.

For a free-electron gas one can easily demonstrate that the dielectric function is given by

$$\varepsilon(\omega) = 1 - \left(\frac{\omega_\mathrm{p}}{\omega}\right)^2 \,, \tag{18.2}$$

with ω_p plasma frequency. At ω_p, $\varepsilon(\omega) = 0$ so that according to (18.1) electric fields may exist in the bulk of the material even in the absence of external sources. This resonance condition corresponds to the excitation of volume or bulk plasmons, i.e., longitudinal waves with frequency ω_p, given by

$$\omega_\mathrm{p} = \sqrt{\frac{ne^2}{m^* \varepsilon_0}} \,, \tag{18.3}$$

in the international system units; n is thereby the density of the electron gas, e the elementary electric charge, m^* the effective mass of the involved electrons, ε_0 the dielectric constant of vacuum (for cgs units multiply the expression under the squareroot by $4\pi\varepsilon_0$).

Since for nonferromagnetic materials the magnetic permeability is very close to unity, the refraction index is given by $\sqrt{\varepsilon}$ and the body will be transparent to light above ω_p and opaque with a metallic shine below it since the refraction index is then purely imaginary. No absorption of electromagnetic radiation will take place if the imaginary part of the dielectric function is zero as in the case of the free-electron gas described by (18.2), but the waves will not be able to propagate inside it and be reflected back. In the case of alkali metals, ω_p falls in the near ultraviolet explaining the ultraviolet transparency of these materials.

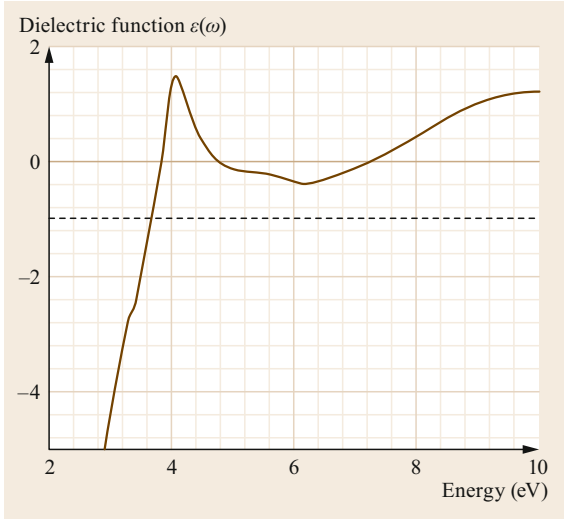

Fig. 18.7 Dielectric function for Ag. The interband transitions from the d bands to the Fermi level give an important contribution $> 3.8\,\text{eV}$ thus causing the shift of ω_p and ω_{sp} to lower energies. (Reprinted from [18.48], with permission from Elsevier) ►

As mentioned above the plasma resonance corresponds to a longitudinal excitation of the electron gas. Bulk plasmons, therefore, cannot be excited by photons since there is no matching in the polarization of the two waves. They are, conversely, excited by the swift electrons used in transmission electron microscopes (TEMs; Fig. 18.2a) and in ion-scattering experiments as long as electrons and ions are inside the material. Since ω_p depends quadratically on the three-dimensional wavevector $\boldsymbol{q}$, the transparency threshold scales with the inverse of the particle diameter since the wavelength of the excitations is limited by the size of the particles hosting it.

The $\varepsilon(\omega)$ is a bulk quantity and so is also its crossing of the -1 level, determining the value of the SP frequency, which is thus determined by bulk properties. For simple metals, (18.2) implies that $\omega_{sp} = \omega_p/\sqrt{2}$. In the presence of bound electrons contributing with ε_b to the dielectric function, the resonance is shifted to $\omega_{sp} = \omega_p/\sqrt{(2+\varepsilon_b)}$. The ratio ω_{sp}/ω_p will then be determined by the steepness of the $\varepsilon(\omega)$ curve in the region where this function changes from 0 to -1. The Ag case is shown in Fig. 18.7. For this metal the d-electron contribution shifts the surface plasma frequency from its free-electron value of 6.35 to 3.70 eV.

18.2 Surface Plasmon Dispersion

At variance with the frequency, the wavevector dependence of ω_{sp} is dictated by surface properties. Indeed, it depends on the position of the centroid of the polarization charge with respect to the geometric surface plane corresponding to halfway between the center of the atoms in the outermost layer and the center of the atoms of the first atomic layer which has been removed to form the surface.

Following *Feibelman* [18.20], the charge associated with the SP must be located above the geometric surface plane since there the electronic charge density is small and it costs less energy to add additional charge to the thinner, and therefore softer, electron gas. The model is schematized in Fig. 18.8a. The d parameters correspond to the centroid of the induced charge, located at $d_\perp$, and to the geometric surface coinciding with the jellium edge at $d_\parallel$.

Energy-dissipation mechanisms can be introduced by allowing for an imaginary part $d_\perp$. The dependence on frequency of real (distance) and imaginary (dissipation) parts of $d_\perp$ are reported in Fig. 18.8b as calculated by *Liebsch* [18.21] for simple metals with different density (expressed as usual by r_s, the radius of the sphere with a volume equivalent to the one available for each free electron in the unit cell (expressed in multiple of the Bohr radius a_0, $1\,a_0 \approx 0.5$ Å). In accord with Feibelman, $d_\perp$ is still outside of the jellium edge at the SP frequency and drops abruptly only at $\omega_m \approx 0.8\omega_p$ where the dissipation is largest especially for low-density materials ($r_s = 5$).

The additional charge associated with the SP generates a potential, which at any given location depends on its spatial distribution at the surface, i.e., on the wavelength of the SP. As mentioned above, at large wavelengths (small wavevectors) the surface plasmon potential penetrates deeply into the bulk, while at short wavelengths (large wavevectors) it will be confined to the near-surface region. Since the electronic charge density decreases exponentially with the distance from the surface, the SP will *see* a wavevector-dependent effective charge density n_{eff} largest at small wavevectors and smallest at short wavelengths. The surface plasma frequency will therefore decrease with SP wavevector. Given the $\sqrt{n}$ dependence of ω_p, for small wavevectors such dependence will be linear and correspond to a negative slope. This result has been confirmed experimentally for simple metals by HREELS [18.11, 18].

In Fig. 18.9, HREEL spectra are shown for a thick amorphous K film [18.11]. They were recorded by varying the angle of incidence of the incoming beam while keeping the scattering angle fixed and sweeping over

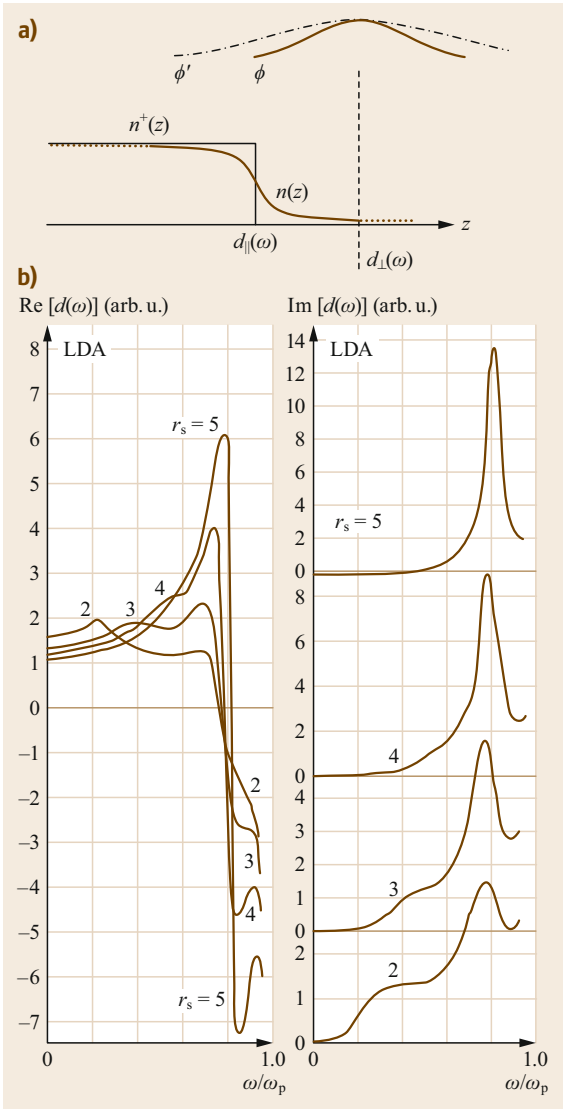

Fig. 18.8 **(a)** Position of the centroid of the oscillating charge associated with the SP, $d_\perp$, with respect to the geometric surface plane. The latter, coincides with the jellium edge and is indicated by $d_\parallel$ since it corresponds to the position where charge would be induced by an electric field oriented parallel to the surface. The electric potential associated with the additional charge is reported for two values of $q_\parallel$; ϕ' corresponds to a smaller $q_\parallel$ value than ϕ and is therefore restricted to a narrower region at the surface where the charge density is smaller, resulting in a wavevector dependence of n_{eff}. **(b)** Real (*left*) and imaginary (*right*) part of $d_\perp$ versus frequency parametric in the density of the material modelled by the parameter r_s (radius of the sphere at disposition of each electron, expressed in multiple of the Bohr radius). Fig. 18.9 HREEL spectra recorded for thick K films versus impinging angle of the electron beam, θ_i, for fixed scattering angle θ_s. The lowest frequency loss corresponds to the surface plasmon. Above $\theta_i = 50°$ also the multipole and the bulk plasmon losses are observed. (Reprinted with permission from [18.13]. Copyright (1990) by the American Physical Society)

the energy loss. Since the energy loss is comparable with the energy of the impinging electrons, scanning over energy implies sweeping also over exchanged parallel momentum.

As demonstrated by the Ewald construction reported in Fig. 18.10, the vanishing parallel momentum transfer condition at the SP energy of 2.6 eV occurs off specular. The SP loss peak moves then to a higher energy-loss value than for in-specular scattering. Plotting the position of the maximum of the energy loss versus exchanged momentum, calculated from the energy and parallel momentum conservation equations

$$\frac{\hbar^2 k_f^2}{2m} = \frac{\hbar^2 k_i^2}{2m} - \hbar\omega_{sp} \,, \tag{18.4}$$

$$k_{\parallel f} = k_{\parallel i} - q_\parallel \,, \tag{18.5}$$

with $\boldsymbol{k}_i$ and $\boldsymbol{k}_f$ wavevectors of the incident and scattered electrons, yields the data points reported in Fig. 18.11

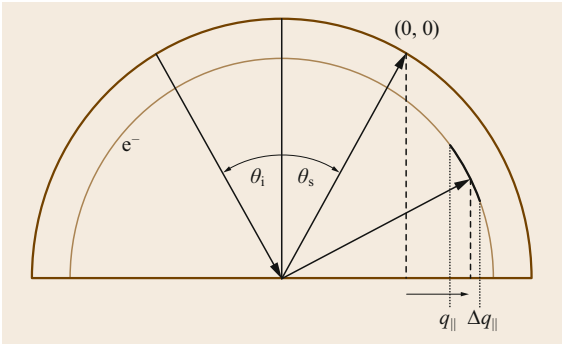

Fig. 18.10 Ewald construction showing the scattering geometry of the HREELS experiment; θ_i and θ_s correspond to incident and scattering angles, the *circle* to *on the energy shell*, i.e., to elastic scattering events for which $|k_f| = |k_i|$. Vanishing parallel momentum transfer is indicated by the *dashed vertical line* and corresponds to off-specular scattering for any nonzero energy-loss value (crossing point between *dashed line* and *light brown sphere* corresponding to a smaller final energy). The arc indicates the angular integration due to the acceptance of the spectrometer which translates into an integration over reciprocal space $\Delta q_\parallel$. The latter determines the quality of the HREEL spectra since achieving a good enough energy resolution is not problematic for the investigation of electronic excitations

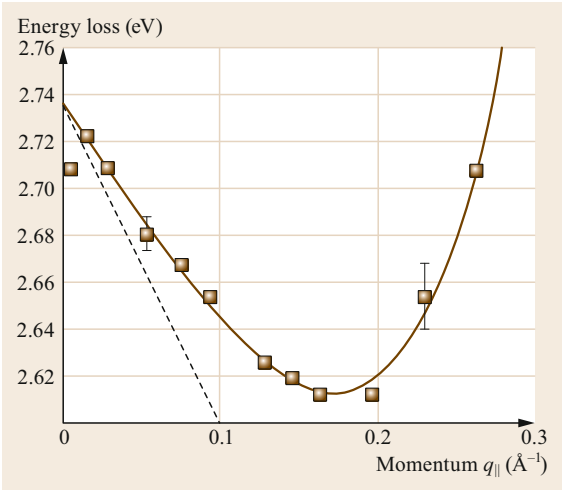

Fig. 18.11 Surface plasmon energy versus exchanged momentum for a thick K film. The dispersion is initially linear and negative. A quadratic term becomes important above 0.2 Å^{-1}. (Reprinted with permission from [18.11]. Copyright (1989) by the American Physical Society)

which nicely witness the negative dispersion up to some 0.1 Å^{-1} beyond which quadratic terms of bulk origin become important.

Back to Fig. 18.9, off-specular additional losses are apparent. They correspond to the multipole plasmon and to the bulk plasmon, respectively. The multipole corresponds to an excitation with an additional node in the normal direction. Excitation of multipole and bulk modes is more efficient for scattering conditions closer to normal incidence since the electrons penetrate then deeper inside the K film. Contrary to the excitation of the surface plasmon which is dipolar in nature, the one of the multipole mode is due to a different mechanism. Its cross section could be reproduced only recently by theory [18.49–52] and is treated thoroughly in Chap. 17.

The experimentally determined ratio of surface-to-volume plasmon energy for simple metals is reported in Table 18.1. As one can see the $1/\sqrt{2}$ ratio appropriate for a free-electron gas is respected quite accurately in experiment. The only important deviation is for Li for which band structure effects cannot be neglected.

The SP dispersion is well described by a polynomial fit. The values of the coefficients up to the fourth degree (A to D) are reported in Table 18.2 for the different simple metals. The quadratic term can be ascribed to the polarizability of the electron gas, an effect determining the dispersion also for the bulk plasmon, while no evident interpretations are possible for cubic and quartic terms. The order of magnitude of the quadratic term is in reasonable agreement with the quadratic coefficient of $\approx 2.2\,\text{eV}\text{Å}^2$ reported, e.g., for the bulk plasmon of Al [18.53]. The error bar on such terms is, however, quite large since the plasmon loss is heavily damped at large wavevector transfers. Indeed, the cubic term for K is associated to a very small quadratic term and the outcome could be flawed by a compensation effect in the curve fitting procedure.

According to Feibelman's theory the linear term of the dispersion is related to the position of the centroid of the induced charge $d_\perp(\omega)$ by

$$\omega_{sp}(q_\parallel) = \omega_{sp}(0)\left\{1 - \frac{1}{2}\left[d_\perp(\omega_{sp}) - d_\parallel(\omega_{sp})\right] q_\parallel + O\left(q_\parallel^2\right)\right\}. \quad (18.6)$$

The values extracted for the different simple metals are compared with theory in Table 18.3 and nicely confirm the calculated values quantitatively. The centroid of the induced charge lies accordingly on the average at some 0.7 Å above the geometric surface.

If a similar procedure is applied to the multiplasmon loss a linear positive dispersion with $q_\parallel$ is obtained. The multiplasmon frequency ω_{mp} is compared in Table 18.4 for the different simple metals. The ratio of

Table 18.1 Surface and bulk plasmon energies and line widths for simple metals. The $1/\sqrt{2} = 0.707$ condition on the frequency ratio of surface versus volume plasmon, expected for a free-electron gas is very well respected for all alkali and for Al except for Li

ω_{mp} to ω_p is always close to 0.84, the value expected for a free-electron gas. At ω_{mp} the PY is enhanced since the multiplasmon implies strong electric fields across the geometric surface plane. The dispersion of the multipole mode with transferred momentum is always positive.

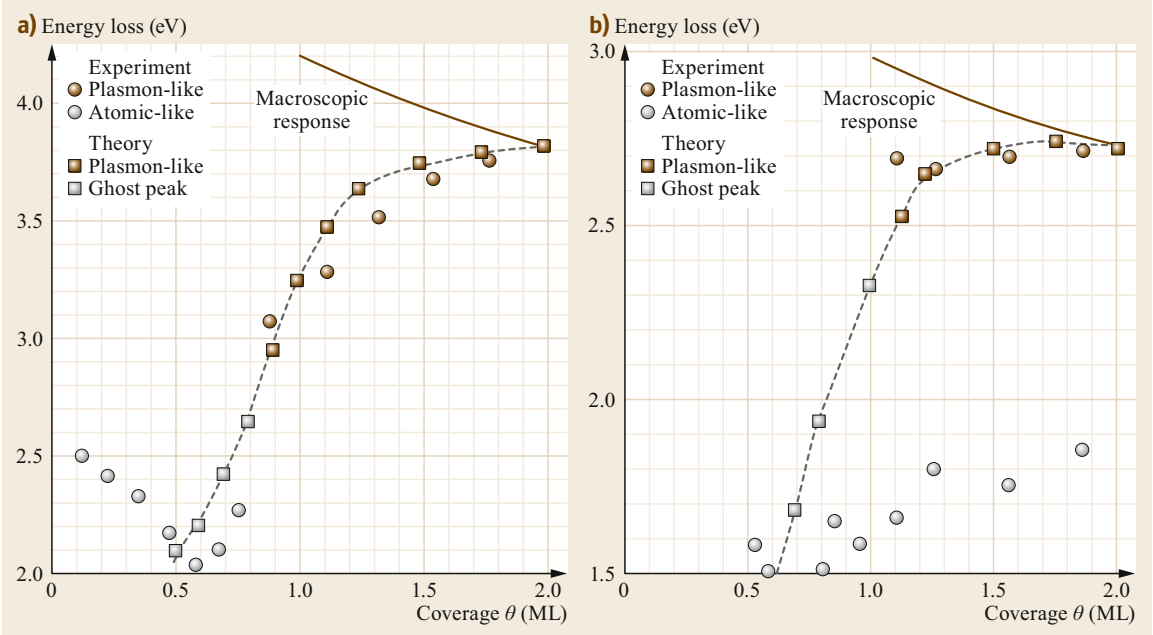

Fig. 18.12a,b Position of the losses in the surface plasmon region versus alkali film thickness: **(a)** Na/Al, **(b)** K/Al. The surface plasmon loss appears only after the completion of the first monolayer. At lower coverage the excitation is confined inside nanosized islands and is better described as a Mie resonance (see later the discussion for Ag clusters on Si(111)) or corresponds to an atomic-like excitation. The ghost peak corresponds to spectra in which because of inhomogeneity, both SP- and atomic-like modes are excited. (Reprinted with permission from [18.14]. Copyright (1991) by the American Physical Society)

The surface-loss spectra have been investigated also as a function of the thickness of the alkali film [18.14]. As shown in Fig. 18.12, the SP is excited only above one monolayer film thickness. At lower coverage the observed loss corresponds to a localized atomic-like excitation.

18.3 Lattice Effects on the Surface Plasmon Dispersion

Lattice effects on the surface plasmon frequency and dispersion, already evident for Li, become even more important for solid Hg. The experimental data are shown in Fig. 18.13 [18.57]. The data show a quite large scattering of the maximum of the energy-loss peaks due to the intrinsic broadness of the loss (1 eV). The initial slope of the dispersion is, however, clearly negative and can be reproduced by the stabilized jellium model which provides a better electronic density profile at the surface than normal jellium.

18.4 Effect of the Band Structure on Surface Plasmon Energy and Dispersion: The Case of Noble Metals

The situation is radically different for noble metals. In this case at the SP frequency important additional contributions to the surface response function come in due to the strongly bonded d-electrons localized around the ion cores. Their effect is to shift the plasma frequency (from the free-electron density value 9.6 eV to 3.78 eV

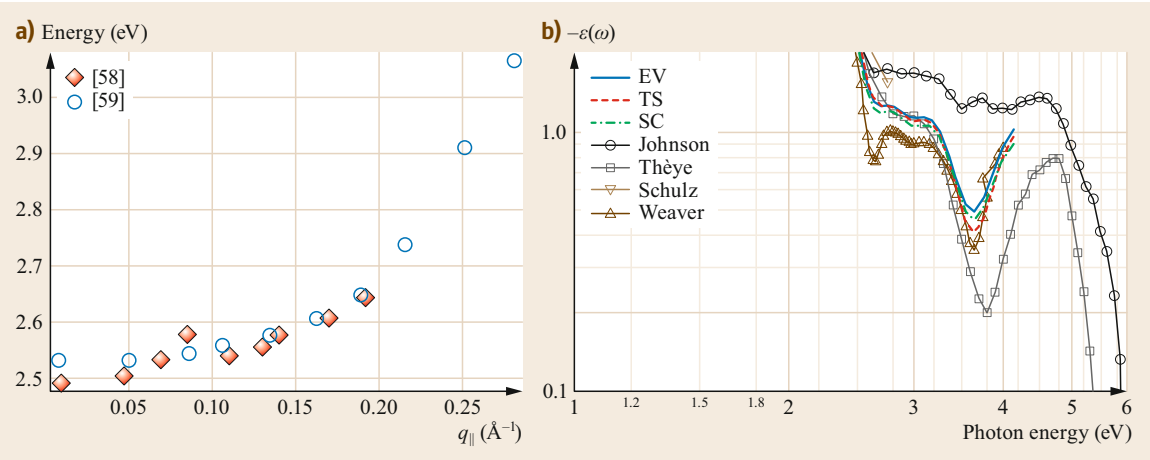

Fig. 18.14 **(a)** SP dispersion for Au(111) as published by *Park* and *Palmer* [18.58] and *Politano* et al. [18.59]. The data show a positive initial dispersion and a strong quadratic term. **(b)** Negative of the real part of the dielectric function in the relevant region according to different reports [18.60]. The *green curve* labeled SC corresponds to an Au(111) single crystal and crosses the $\varepsilon = -1$ value at around 3.2 eV, rather than at 2.5 eV shedding doubts on the assignment of the HREELS loss which corresponds rather to ε values close to -1.2. (Reprinted with permission from [18.60]. Copyright (1995) by the American Physical Society)

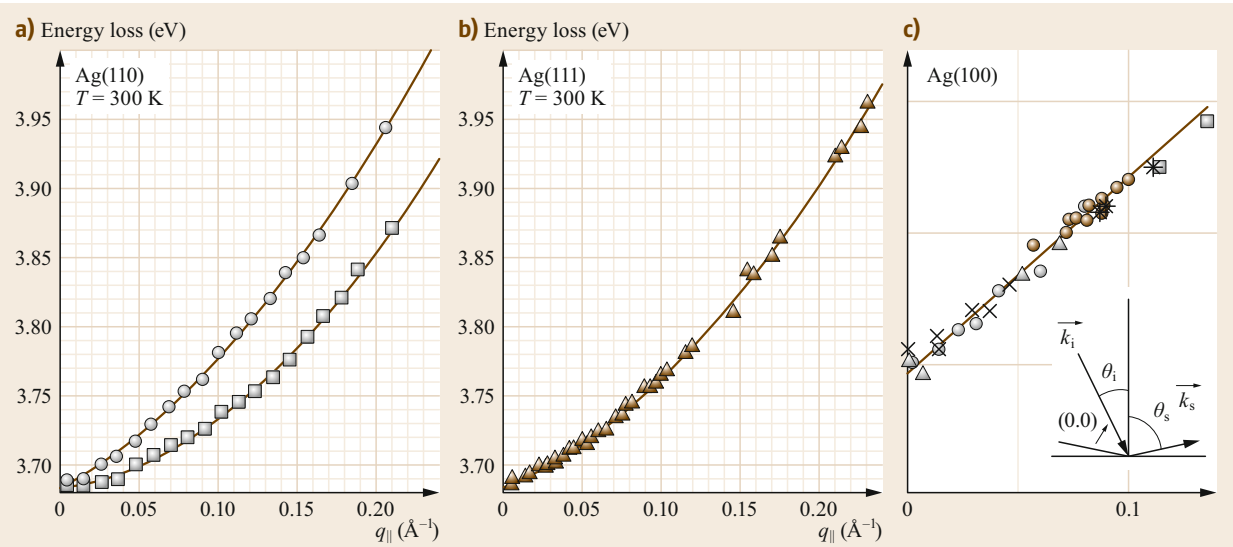

Fig. 18.15a–c Surface plasmon dispersion for **(a)** Ag(110), along the two high-symmetry directions of the strongly anisotropic surface (squares [110], circles [001]), **(b)** Ag(111), and **(c)** Ag(100). The data were recorded by HREELS for Ag(100) and by ELS-LEED for the other two surfaces. Notice the initial positive slope which is different for the different surfaces and anisotropic for Ag(110). The quadratic term is important for the (110) and (111) cases only. The different symbols for the dispersion of Ag(100) refer to data recorded for different impact energies ranging from 10 to 116 eV. Au(111)					2.46	0.12	10.75

in the case of Ag and from a similar value to 2.4 eV for Au). The dispersion with exchanged momentum is therefore determined not only by the effective charge density seen by the potential associated with the SP charge but also by the wavevector-dependent efficiency of the screening of d-electrons. *Seeing* the d-electrons less, implies a shift of the surface plasmon energy back to the unscreened value, i.e., towards higher energies. Globally, the effect on the surface plasmon dispersion becomes thus opposite to the one observed for simple metals and the dispersion slope is then positive. The centroid of the induced charge lies, however, still outside of the geometrical surface plane [18.21]. These effects were investigated experimentally for Au [18.58, 59] and Ag [18.15, 16, 61] surfaces.

The HREELS investigation of Au(111) is shown in Fig. 18.14a. The data show a fairly narrow peak at 2.5 eV which shows a positive dispersion and, at hand of the data for the dielectric function available at that time, was assigned to the SP excitation. According to more recent and more accurate optical investigations [18.60], however, such frequency does not correspond to $\varepsilon = -1$. The real part of ε remains indeed quite small from 2.5 to 6 eV (Fig. 18.14b) while the imaginary part of ε is large (around 6, not shown). The $\varepsilon = -1$ line is crossed thereby only at 3.2 eV. Further investigation is therefore needed to clarify the nature of the observed energy loss. Theoretical work in that direction is currently being performed [18.62].

The data for the SP dispersion of Ag are easier to interpret since in that case a very well-defined EEL peak is present at the frequency for which $\varepsilon(\omega) = -1$. The sharpness of the loss (full-width-at-half-maximum of only 50 meV for the Ag(111) surface, corresponding to a $\Delta E_{loss}/E_{loss}$ ratio close to 2%) allowed fine effects such as the face and the crystallographic direction dependence of the SP dispersion to be investigated.

The different Ag surfaces were investigated both by HREELS and by electron energy-loss-low-energy electron diffraction (ELS-LEED) [18.63], the latter being a technique performed with a spectrometer in which incident and scattering angles are set electronically rather than mechanically thus guaranteeing a higher reproducibility. The ELS-LEED spectrometer has also a better angular resolution which however translates into a momentum resolution comparable to the one of conventional HREELS since the incident and scattering beam directions are restricted to near-normal values. The results are reported in Fig. 18.15 while the coefficients resulting from the polynomial fit are collected in Table 18.5.

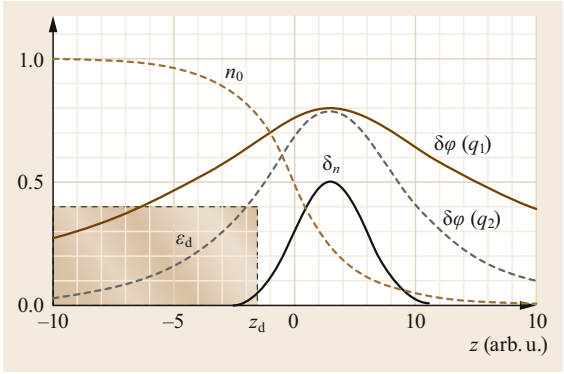

Fig. 18.16 Effective medium model for the plasmon dispersion on noble metal surfaces. The electric potential associated with the SP penetrates approximately one wavelength inside the surface. The effective charge density at large wavevectors is therefore less influenced by the effective medium describing the d-electrons than at small wavevectors. Since the effect of the effective medium is to shift the plasmon resonance to lower frequencies, ω_{sp} will increase with $q_\parallel$ giving a positive slope to the SP dispersion. (Reprinted by permission from [18.21], © Springer 1997)

Liebsch [18.21] modeled the effect of the localized d-electrons introducing an effective polarizable medium

mimicking their density and noticing that such medium is spatially localized closer to the nuclei than the sp-electrons (Fig. 18.16). He was then able to obtain a positive dispersion slope by placing the effective polarizable medium inside the jellium edge by some 0.8 Å. The different slope of the dispersion for the different crystal faces would then result from different positions of the polarizable medium with respect to the geometric surface. While this model gives a rational for the positive dispersion, it cannot reproduce the experimentally observed dependence of plasmon dispersion on crystal face even qualitatively since the position of the polarizable medium should be shallower for Ag(111) than for Ag(001) while the lattice spacing in the direction normal to the surface plane scales in the opposite way.

A merit of this model is, however, to explain the strong negative dispersion reported for Pd(110) [18.64] which is in accord with the fact that the SP frequency for this metal is at 7.8 eV with a marginal displacement with respect to the value expected for a free-electron gas with the density of Pd.

A more refined theoretical model was proposed by *Yan* et al. [18.65] who obtained the surface plasmon dispersion for Ag(111) as well as H/Ag(111) from first principles by calculating the q-dependent dielectric function.

18.5 Surface Plasmon Damping

The SP linewidth is determined by the damping mechanisms active at the surface, i.e., mainly by the possibility to decay into electron–hole pairs. A linear increase with $q_{\parallel}$ is therefore expected due to the increased phase space for transitions. This mechanism will, however, be largely ineffective as long as it is limited to intraband transitions. As soon as $\hbar\omega_{sp}(q_{\parallel})$ allows for the decay also via interband transitions, a sharp increase of the damping is therefore expected. This effect is shown in Fig. 18.17 for the Ag(001) surface [18.17]. The onset of interband transitions is clearly evident from the kink in the width versus wavevector curve at 0.1 $Å^{-1}$ or 3.82 eV. Interestingly, a smaller (and even negative) initial slope is observed for Ag(111) [18.61]. This indicates that the decay channels determining the plasmon line width at vanishing momentum become less effective with $q_{\parallel}$. The effect has not been investigated further.

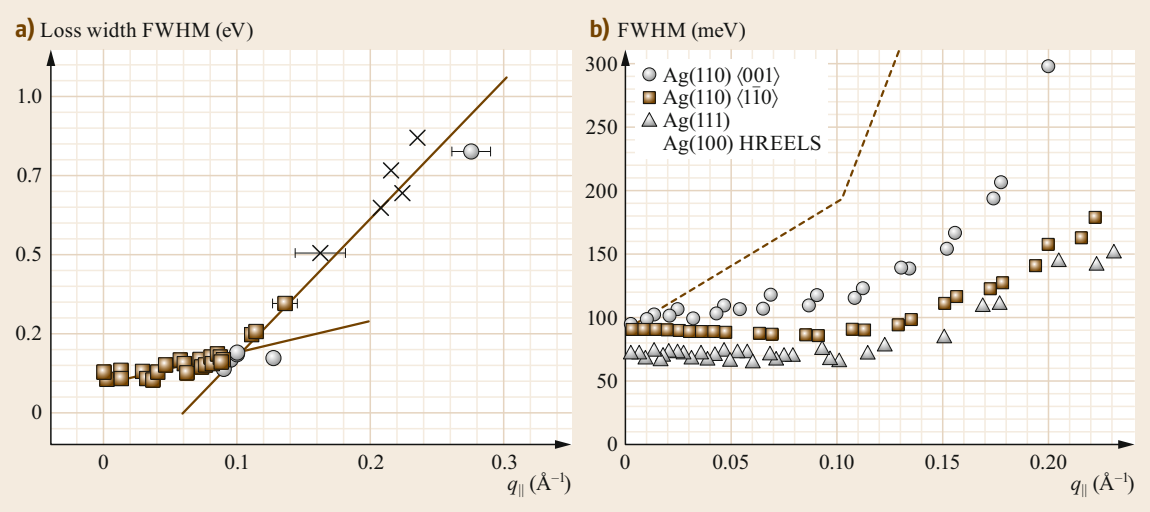

Fig. 18.17a,b Surface plasmon linewidth versus exchanged momentum for Ag(001) ((**a**) HREELS) and Ag(110) and Ag(111) ((**b**) ELS-LEED). The change in the slope is due to the onset of interband transitions involving the d-bands of Ag. ((**a**) Reprinted with permission from [18.17]. Copyright 1990 by the American Physical Society. (**b**) Reprinted from [18.61], with permission from Elsevier)

18.6 Multipole Plasmon Mode at Noble Metal Surfaces

Similar to the case of simple metals a multiplasmon mode is expected to be present also for the noble metals. By definition it corresponds to the frequency at which the real part of $d_\perp(\omega)$ crosses zero and one would therefore expect it to be in-between ω_s and ω_{sp} but no clear cut indications are drawn from theory. Resolving the multipole as a well-separated energy-loss peak is not possible for Ag due to the natural broadness of the SP. However, from the investigation of alkali metals it is evident that the multipole loss is excited most efficiently off specular (so its intensity is not expected to scale proportionally to the elastic reflectivity) and the intensity is largest at small $q_\parallel$ values.

As shown in Fig. 18.18, *Moresco* et al. [18.66] noticed small energy shifts at small $q_\parallel$ for experiments performed at different impact energy. The effect could not be ascribed to a more or less efficient excitation of the bulk plasmon since the latter is excited only when the electrons are below the surface and the penetration depth of the electron beam is a smooth function of energy. The shift must therefore be associated with the presence of contributions caused by different excitation mechanisms as is the case for the SP (excited by dipolar scattering) and the multipole (excited by a different mechanism).

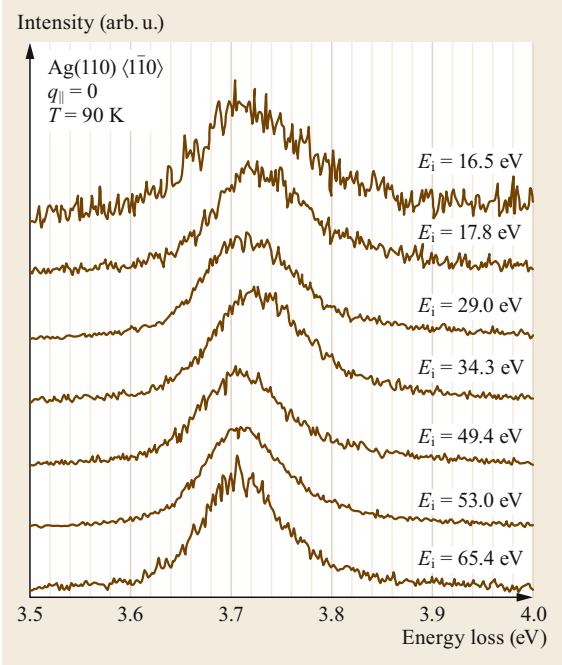

Fig. 18.18 HREEL spectra recorded with ELS-LEED for different impact energies. The position of the maximum was found to depend on the impact energy indicating a complex nature of the loss which must consist of two contributions excited by different excitation mechanisms. (Reprinted with permission from [18.66]. Copyright (1996) by the American Physical Society)

The evidence for an additional contribution is even stronger when looking at the apparent dispersion curves recorded at different impact energy. In some experimental conditions the curve flattens out at small wavevector (Fig. 18.19a for Ag(110) and Fig. 18.19b for Ag(111)). The loss is then definitively higher in frequency and broader than for conditions in which the maximum appears at the lowest energy. Similar observations had been made with HREELS (crosses in Fig. 18.19b).

Deconvoluting the energy-loss spectra with respect to SP and multipole contributions is not trivial since:

1. The width of the SP is not known (at $q_\parallel = 0$ it should be zero according to theory).
2. The width of the multipole is not known.
3. A background of electron–hole pairs is present whose exact shape is also not known.
4. The achievable signal-to-noise ratio does not allow accurate deconvolutions as for XPS data recorded with synchrotron radiation to be performed.

The authors proceeded therefore in a different way: They assumed that the sharpest peaks correspond to excitation of the SP only and determined the additional loss intensity by subtracting losses recorded at other impact energies. The result is shown in Fig. 18.20. It clearly shows a peak centered for $q_\parallel = 0$ at 3.74 eV at all impact energies and for both investigated Ag faces, (110) and (111). Such energy is too low to be due to the excitation of the volume plasmon as well as to the onset of interband transitions. A safe conclusion could therefore be drawn about the existence of a multipole mode for Ag.

This result was confirmed later by PY and angle-resolved photoemission measurements with low-energy photons performed by *Barman* et al. [18.67], who reported a multipole mode for Ag(111) at 3.7 eV for Ag(111) and Ag(100).

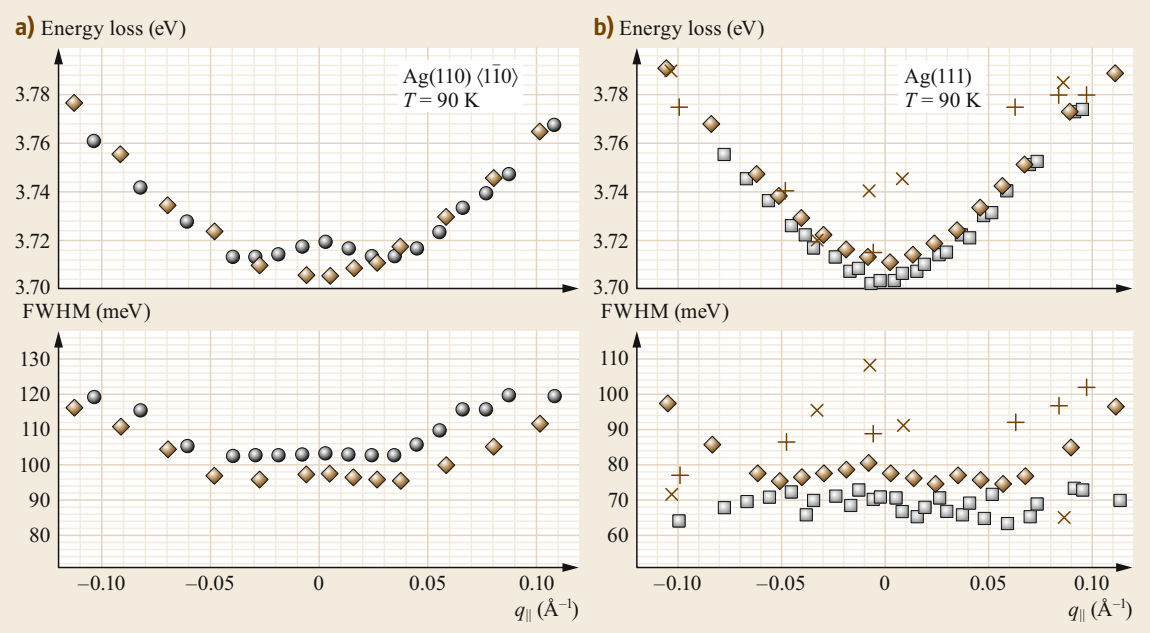

Fig. 18.19 **(a)** Collection of the energy losses and of the full-width-at-half maximum of the losses recorded with ELS-LEED for Ag(110) at 64.5 eV incident energy (*diamonds*) and 16.5 eV (*circles*). *Top*: SP energy; *bottom*: SP loss width versus $q_\parallel$. **(b)** Same as **(a)** but for Ag(111). The experiments have been performed both with ELS-LEED (*squares* $E_i = 20.1$ eV, *diamonds* $E_i = 51.5$ eV) as well as HREELS ($+$ $E_i = 10.7$ eV, $\times$ $E_i = 15.0$ eV). 18.7 Temperature Dependence of the SP

Little work exists on the crystal temperature dependence of SPs, since only small effects are expected for electronic excitations. However, the SP loss on Ag is so sharp that it allows for very precise measurements of its energy. A small but non-negligible decrease with crystal temperature was indeed reported for both Ag(110) and Ag(111) (Fig. 18.21). Such an effect is compatible with the decrease of the electron gas density following thermal expansion.

18.8 Effect of Adsorption and of Surface Nanostructuring on Surface Plasmon Energy and Dispersion

Alkali metals induce an extended surface reconstruction on Ag(110) already at low coverage. 3% of K is sufficient to induce an extended (1×3) missing row reconstruction whereby one Ag row out of three is removed. With increasing K dose a (1×2) structure forms corresponding to 50% missing Ag atoms and finally the low-energy diffraction pattern evolves into a (1×3) structure at 30% K coverage corresponding to the removal of two out of three Ag rows. Models of these reconstructions are reported in Fig. 18.22c,d [18.69–71].

18.8.1 Alkali Metal Adsorption on Ag Surfaces

As shown in Fig. 18.22a,b the SP dispersion is differently affected for different K coverage and the effect is anisotropic with respect to crystal azimuth. The result of a polynomial fit of the dispersion curves is shown in Table 18.6.

At the lowest coverage, a change is visible only along ⟨001⟩, the direction along which the substrate atomic density decrease is dramatic since every third Ag row is removed. The linear term is thereby unaffected, while the quadratic term drops from 3.4 to 2 eV Å^2. The anisotropy of the surface becomes therefore larger.

The linear dispersion term is eventually affected with increasing K coverage. Indeed it doubles along the ⟨1$\bar{1}$0⟩ direction. The effect becomes dramatic as soon as the high coverage (1×3)-phase forms.

A slight drop occurs also for the frequency at $q_\parallel = 0$, the effect being systematic but within experimental error. Conversely, for larger K coverage ω_{sp} shifts remarkably from the bare surface value of 3.70 eV to 3.82 eV for 1.5 ML of K. The SP loss associated with K becomes apparent above half a monolayer coverage [18.69].

The effect on the ⟨1$\bar{1}$0⟩ direction becomes evident only for the largest K coverage. K adsorption, therefore, initially increases the azimuthal anisotropy. The most corrugated surface, however, is remarkably the least anisotropic at least with respect to the SP dispersion.

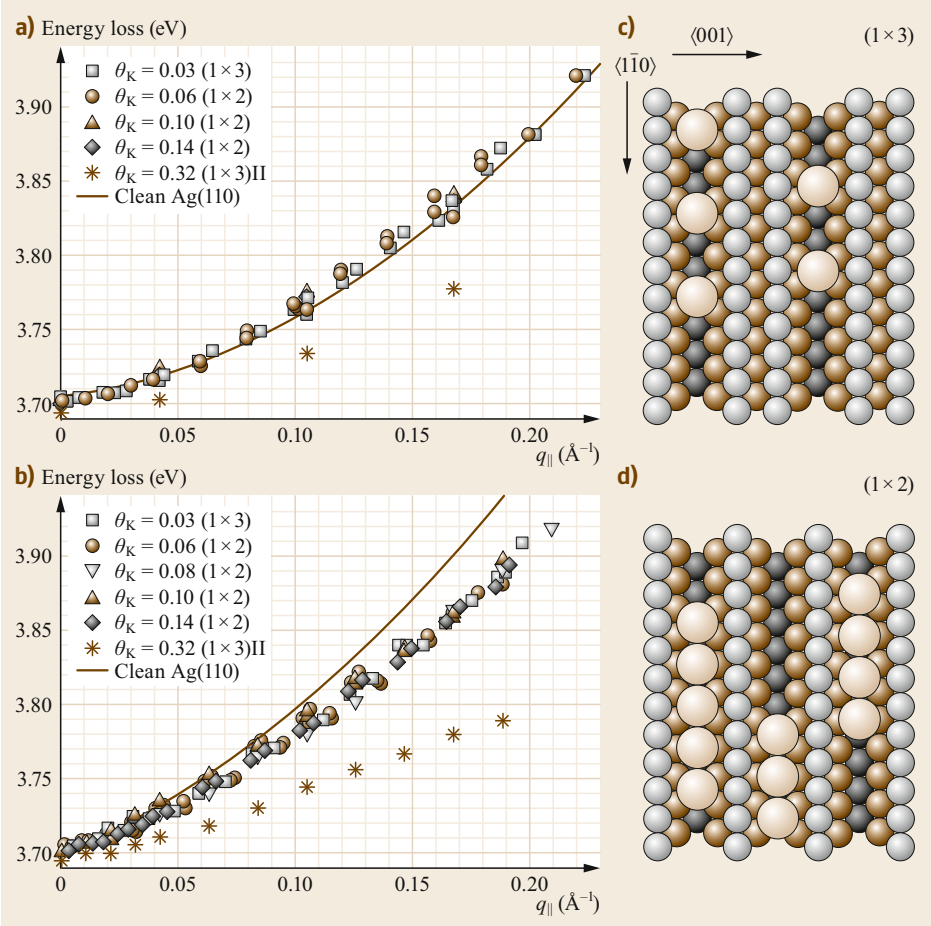

Fig. 18.22a–d Ag(110) SP dispersion for different K-induced reconstructions measured with ELS-LEED at 65.4-eV kinetic energy along the two high-symmetry directions: **(a)** ⟨1$\bar{1}$0⟩, **(b)** ⟨001⟩. With increasing K coverage the SP dispersion becomes markedly flatter especially along ⟨001⟩. Corresponding models are shown for the (1 × 3) **(c)** and (1 × 2) reconstruction **(d)**. (Reprinted from [18.70], with permission from Elsevier)

The effect of K adsorption on SP damping is shown in Fig. 18.23 for Ag(110) along both high-symmetry directions. Again at low coverage the effect is marginal along ⟨1$\bar{1}$0⟩ and larger along ⟨001⟩. At the highest coverage the surface becomes isotropic with respect to SP damping. Notably also the effect of the onset of interband transitions on SP damping is smoothed out.

18.8.2 Effect of Surface Defectivity on Surface Plasmon Dispersion

SP dispersion has been investigated also with respect to the defectivity induced by sputtering at different crystal temperatures. The result for Ag(001) is shown in Fig. 18.24. The bare surface result corresponds to a purely linear dispersion which is at odds with the result of the other two low Miller index faces for which the linear coefficient of the dispersion is smaller and the quadratic one more important. Sputtering makes the curve more quadratic, as expected from the fact that atomic arrangements different from (001) are formed by the damaging action of the sputtering beam. The effect is, however, more marked at room than at low temperature since partial healing of the defects occurs. The difference could be only apparent since surface disorder implies also a worse resolution in reciprocal space which could shift up the SP at small $q_{\parallel}$ values.

In a different experiment the Ag(001) surface has been modified by oxygen adsorption. As shown in Fig. 18.25a, only a drop in the dispersion slope takes place when:

1. The surface is dosed at low temperature so that oxygen adsorption occurs molecularly on a non reconstructed substrate or
2. When adsorption occurs at room temperature where O adsorbs dissociatively and the O adatoms end up at fourfold hollow sites of a nonreconstructed substrate.

However, when the surface is dosed with oxygen at an intermediate temperature at which O_2 dissociates and

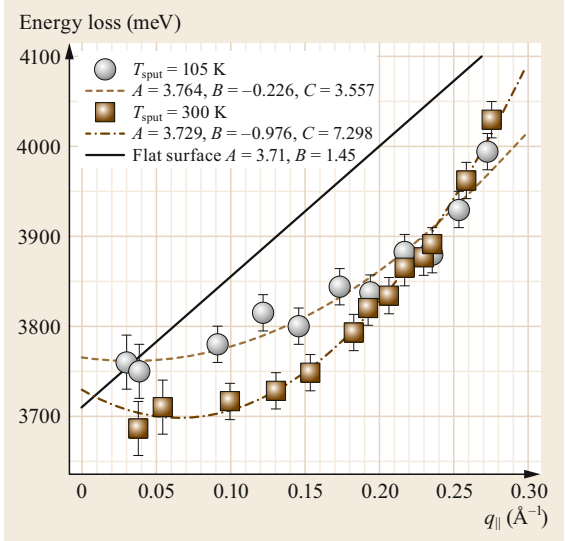

Fig. 18.24 SP dispersion for sputtered Ag(001) performed at 105 and 300 K. We note the drop in the linear dispersion term and the corresponding increase in the quadratic one. (Reprinted with permission from [18.72]. Copyright (2003) by the American Physical Society)

the surface reconstructs forming missing rows [18.74], then the dispersion becomes parabolic, see Fig. 18.25b.

Sputtering and oxygen adsorption indicate therefore that a qualitative change in the dispersion occurs upon surface reconstruction only. One possibility is that the reconstruction as well as sputtering kill a surface state at the X bar point of the 2-D Brillouin zone.

The outcome of the polynomial fits are reported in Table 18.7.

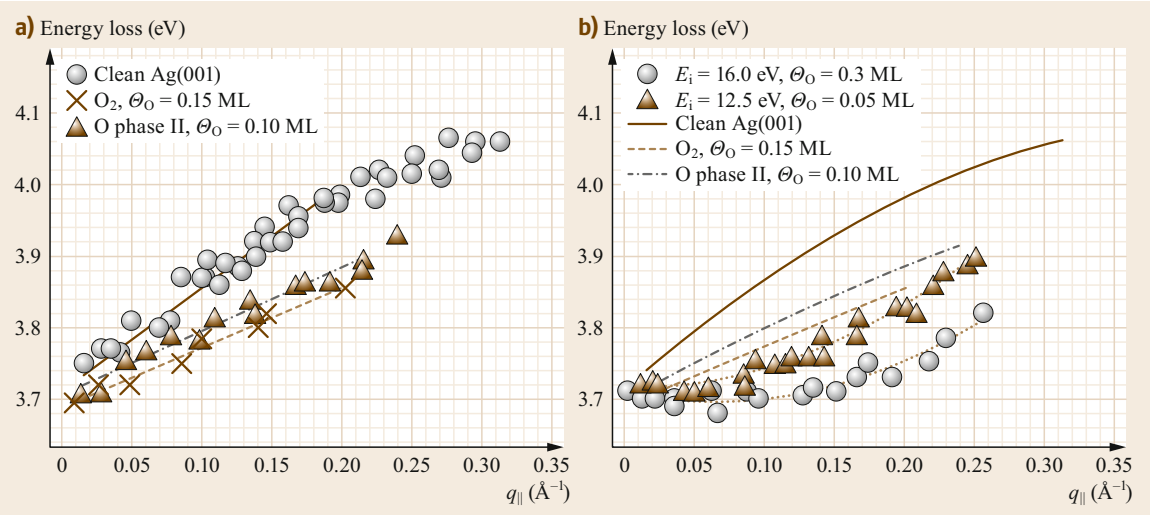

Fig. 18.25a,b SP dispersion of Ag(100) for different oxygen coverage. **(a)** O_2 and O in phase II correspond to a non reconstructed substrate. **(b)** O in phase I induces a missing row reconstruction of the surface. (Reprinted with permission from [18.73]. Copyright (2000) by the American Physical Society)

Table 18.7 SP dispersion coefficients for Ag(001) bare and following the adsorption of oxygen in different phases. Phase I corresponds to a reconstructed surface, while in phase II the O adatoms are adsorbed on a nonreconstructed substrate

Phase	Coverage (ML)	$\hbar\omega(0)$ (eV)	A (eV Å)	B (eV Å^2)
Bare Ag(001)		3.71	1.73 ± 0.13	-1.9 ± 0.4
O_2	0.15	3.69	0.86 ± 0.20	-0.1 ± 1.0
O phase II	0.10	3.70	1.1 ± 0.2	-0.9 ± 0.5
O phase I	0.05	3.71	0.0 ± 0.1	3.1 ± 0.5
O phase I	0.3	3.71	-0.4 ± 0.1	3.1 ± 0.5

The conclusion of these experiments is that, at least for Ag, both the linear and the quadratic terms of the dispersion are determined by surface properties (the only ones which may be affected by adsorbates or by surface disorder).

18.8.3 Other Reports on Adsorption-Induced Modifications of the Surface Plasmon Dispersion

An important modification of the SP dispersion was reported for Ag(111) by the group of *Kesmodel* [18.75] following dosing with Cl_2. The initial dispersion of the SP changes thereby from positive to negative. The data are reported in Fig. 18.26. Notably also the frequency at $q_{\parallel} = 0$ decreases, an effect which is not expected for an ultrathin film. The change of sign of the linear dispersion coefficient is ascribed to charge transfer between the Ag substrate and the molecular layer, although contributions due to plasmon screening via the Cl overlayer and surface chloride formation are mentioned as important factors as well.

Feng et al. [18.76] reported a similar effect upon adsorption of 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4-TCNQ) on the same surface. In this case no change occurs for the SP frequency at $q_{\parallel} = 0$, but the SP frequency was then abnormally high already for the bare surface, an effect not explained by the authors which sheds doubt on the reliability of the experiment.

A change in dispersion and in SP frequency has been reported also for Au(111) following 4-ethylbenzenethiol and dodecanethiol adsorption [18.58]. This data should be considered with due care since, as discussed before, in this case the energy-loss maximum does not satisfy the $\varepsilon = -1$ condition.

18.9 Mie Resonance Shift and Surface Plasmon Dispersion

The Mie resonance [18.78] corresponds to a maximum of the optical cross section for metallic nanoparticles resulting from the excitation of the SP at their surface. The resonance condition is determined by the largest possible wavelength over a closed path on the surface of the cluster. In the limit of spherical particles only one

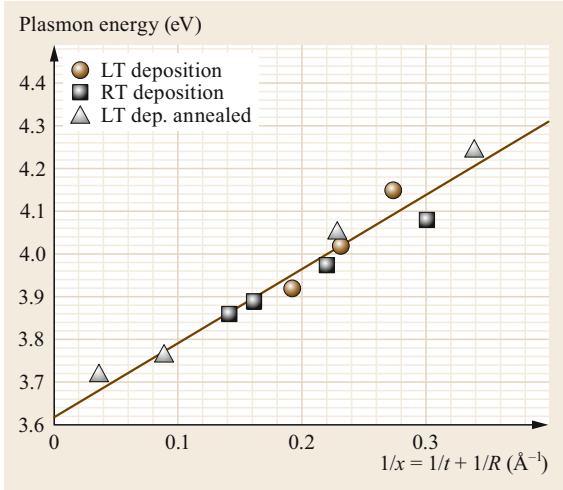

Fig. 18.30 Collection of the data of the SP energy recorded for Ag films grown on Si(111) 7×7 versus film thickness t and island size. Such a plot is equivalent to mapping the dependence of the SP energy versus surface-to-volume ratio of the islands. (Reprinted with permission from [18.77]. Copyright (1999) by the American Physical Society)

mode exists and the resonance corresponds to $2\pi R =$ wavelength $= 2\pi/q_{\parallel}$ with R radius of the nanoparticle. The $1/R$ dependence for the Mie resonance is thus equivalent to the $q_{\parallel}$ dependence of the SP frequency. As shown in Fig. 18.27, the effect has indeed opposite sign for bare K [18.23] and Ag [18.25] nanoparticles in perfect accord with the reasoning about simple and noble metals. Note that the asymptotic value of the frequency differs from the surface plasmon frequency since the limit is not a flat surface but the surface of a sphere.

The concept of the size dependence of Mie resonances was demonstrated to be useful also for the interpretation of SP excitations on ultrathin films deposited at surfaces if they consist of an ensemble of clusters. This is the case for silver deposited on Si(111) 7×7, which grows in flat cylinders of the size of half the 7×7-unit cell of the substrate and are terminated by a flat Ag(111) face. The data were apparently inconclusive since, as shown in Fig. 18.30, at vanishing $q_{\parallel}$ the SP energy took all possible values from 4.4 eV down to 3.7 eV. Plotting the data versus inverse film thickness, as suggested by [18.79], helped only partially. The reasoning is thereby that the film cannot support propagation of SP exceeding its thickness. The SP frequency is therefore determined by the largest supported wavelength. Depending on the sign of the SP dispersion the $1/t$ dependence arises naturally.

This analysis is reported in Fig. 18.28. As is evident the data points obtained after low-temperature

deposition followed by annealing are at odds with any reasonable dependence on film thickness.

More information could be gained from the inspection of data recorded versus wavevector transfer, see Fig. 18.29. They show an evident threshold beyond which dispersion is present while below it the SP behaves like an Einstein oscillator. For small $q_{\parallel}$ values the electron gas in the single clusters oscillates therefore in an uncorrelated way. The threshold value of $q_{\parallel}$ therefore permits the average lateral size of the clusters to be determined as $d = 2\pi/q_{\parallel}$.

When the data are plotted versus inverse thickness and inverse radius of the islands they finally fall on a straight line. Little reasoning will convince the reader that the $1/x$ in the abscissae is equivalent to the area versus volume ratio of the clusters. The dependence of the SP frequency is thus the same as the Mie resonance shift in anisotropic clusters.

18.10 Surface Plasmons and Surface Plasmon Polaritons

Since SP are transverse waves they may mix with light which gives rise to surface plasmon polaritons (SPP) in the long wavelength limit [18.5]. Such excitations are very interesting since they have larger wavevectors with respect to light at the corresponding frequency and allow therefore for its confinement especially at energies close to the one of the SP.

18.10.1 Dispersion of the Surface Plasmon Polariton

A typical dispersion curve of the SPP is reported in Fig. 18.31a for the Au/air interface. The slope of the dispersion depends on the dielectric with which gold is in contact. The SPP can thus have speeds up to 5 times lower than light and a correspondingly shorter wavelength. Confinement is, however, even stronger for frequencies closer to the SP frequency since the SPP dispersion curve bends then to the right. The phase and group velocities for the Ag and Au interfaces with air are shown in Fig. 18.31b. As one can see a further reduction by 30% occurs for Au at 2.25 eV [18.80].

18.10.2 Anisotropy of the Surface Plasmon Polariton Dispersion

As mentioned above the SP dispersion is anisotropic with respect to surface azimuth for Ag(110). Such anisotropy is present also for the SPP but with a reversed sign [18.7, 8]. The effect is pictorially summarized in Fig. 18.32. The apparent contradiction is due to the different origins of the anisotropy in the two ranges of exchanged momentum. At large wavevectors what matters is the microscopic position of the centroid of the induced charge and of the d-electrons with respect to the geometric surface plane. At short wavelengths the SPP anisotropy has a macroscopic origin being linked to the one of the interband transitions between surface states. A similar, but less clear cut result has been reported also for Au(110) [18.82].

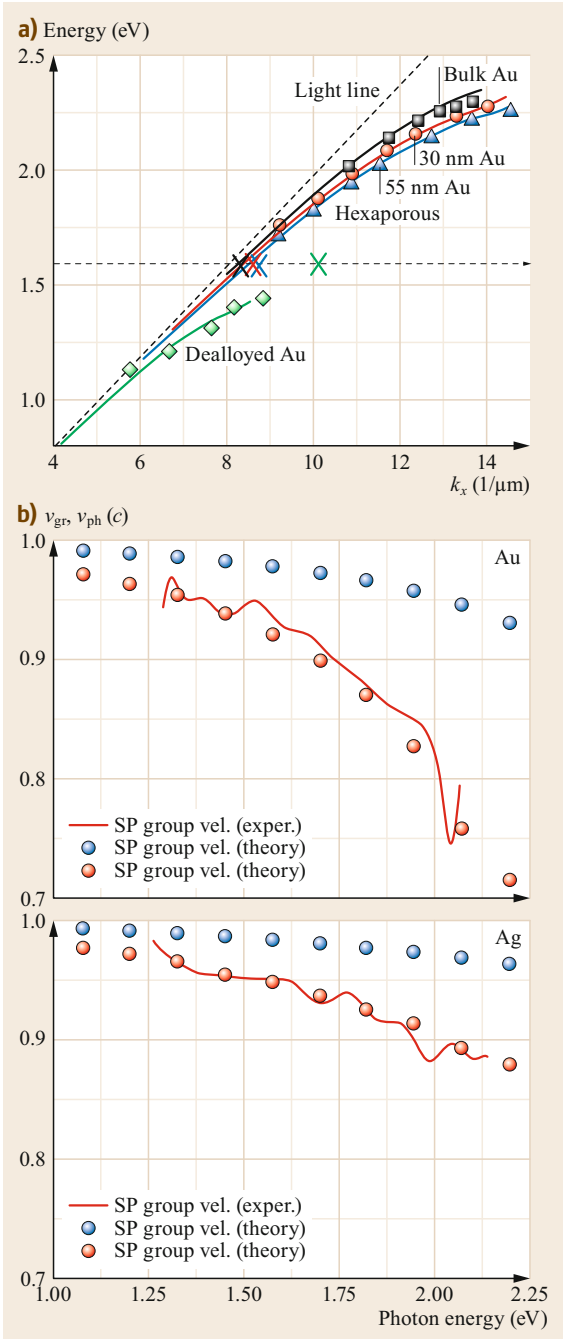

Fig. 18.31a,b SPP dispersion for Au and group **(a)** and phase velocities (expressed in terms of the velocity of light, c) for Au and Ag **(b)**. (Adapted with permission from [18.80] © IOP Publishing. Reproduced with permission. All rights reserved. And adapted with permission [18.81], The Optical Society (OSA))

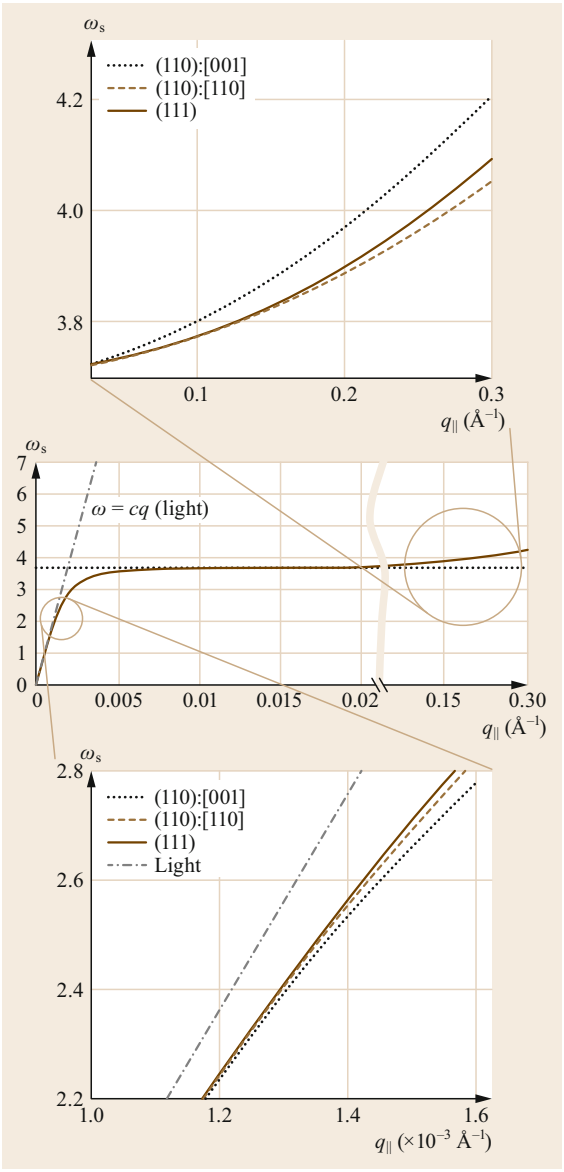

Fig. 18.32 The anisotropy of the Ag(110) surface is reflected both in the SP and in the SPP momentum range. The sign of the anisotropy is, however reversed, the frequency in $\langle 1\bar{1}0 \rangle$ direction being larger than along $\langle 100 \rangle$ for the SPP and smaller for the SP. (Reprinted from [18.19], with permission from Elsevier)

18.11 Conclusions and Perspectives

The surface science of conventional surface plasmons is by now a mature and well-understood topic. More recent papers by *Politano* et al. [18.83–86] analyzed the SP dispersion for Ag layers grown on Cu(111) and Ni(111). The perspectives of future work and discoveries are however in the applications of surface plasmons and surface plasmon polaritons mentioned in the introduction and in the new field of acoustic surface plasmons firstly reported for Be [18.87] and then for the noble metal surfaces [18.88–91] as well as for the 2-D monolayers [18.92] and naturally layered materials [18.93, 94] which are reviewed in Chap. 19.

rocca@fisica.unige.it

Mario Rocca received his PhD in Physics at the University of Aachen (Germany) and is currently full professor of condensed matter physics at the University of Genova (Italy), where he leads a joint research group on Surface Science with CNR-IMEM. His major scientific achievements are on gas-surface interaction, ultrathin film growth, surface phonons and acoustic surface plasmons.

19. Plasmons in One and Two Dimensions

Herbert Pfnür, Christoph Tegenkamp, Luca Vattuone

This chapter will provide an overview of the properties of low-dimensional plasmons, discussing particularly characteristic examples. We will start with two-dimensional sheet plasmons (Sect. 19.1), concentrating on the plasmonic properties of the system most widely investigated in the recent past, graphene. Further emphasis will be given to low-dimensional plasmons coupled to other electron gases, which leads to linearization in the form of acoustic surface plasmons, but also to crossover of dimensionality, depending on plasmonic wavelengths. Finally we turn to quasi-one-dimensional systems and their corresponding plasmons, and try at the end to solve the puzzle of broad loss peaks but still fairly large plasmonic lifetimes.

Plasmons in low-dimensional systems represent an important tool for coupling energy into nanostructures and the localization of energy on the scale of only a few nanometers. Contrary to ordinary surface plasmons of metallic bulk materials, the dispersion of low-dimensional plasmons goes to zero in the long wavelength limit, thus covering a broad range of energies from terahertz to near-infrared, and from mesoscopic wavelengths down to those of just a few nanometers. Using specific, characteristic examples, we first review the properties of plasmons in two-dimensional (2-D) metallic layers from an experimental point of view. As demonstrated, tuning of their dispersion is possible by changes in charge carrier concentration in the partially filled 2-D conduction bands, but for a relativistic electron gas such as in graphene, only in the long wavelength limit. For short wavelengths, on the other hand, the dispersion turns out to be independent of the position of the Fermi level with respect to the Dirac point. A linear dispersion, seen under the latter conditions in graphene, can also be obtained in nonrelativistic electron gases by coupling between 2-D and 3-D (three-dimensional) electronic systems. As a well-investigated example, we discuss the acoustic surface plasmons in Shockley surface states, coupled with the bulk electronic system. Also, the introduction of anisotropy, e.g., by regular arrays of steps, seems to result in linearization (and to partial localization of the plasmons normal to the steps, depending on wavelengths). In quasi-one-dimensional (1-D) systems, such as arrays of gold chains on regularly stepped Si surfaces, only the dispersion is 1-D, whereas the shape and slope of the dispersion curves are dependent on the 2-D distribution of charge within each terrace and on coupling between wires on different terraces. In other words, the form of the confining quasi-1-D potential enters directly into the 1-D plasmon dispersion and offers new opportunities for tuning.

The long-range Coulomb interaction between valence electrons in metals results in collective plasma oscillations, as noted by *Pines* and *Bohm* [19.1, 2] as early as 1952. Plasmons exist in all dimensions [19.3]. The surface as the typical truncation of a bulk material imposes a new boundary condition on these collective plasma oscillations, resulting in localized states at the surface, called surface plasmons [19.4, 5]. In other words, the surface plasmon is the edge plasmon of a three-dimensional metal. Surface plasmons have a finite frequency in the long wavelength limit, which for a nearly free electron gas is located at $\omega_p/\sqrt{2}$, with

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-46906-1_19

ω_p the bulk plasmon frequency, and a small dispersion with either positive or negative slope depending on the screening properties of the participating electronic orbitals [19.6, 7]. These properties of the surface plasmon also allow direct crossing of the surface plasmon dispersion with the light line and thus the direct interaction with light. The combined excitation of a surface plasmon in the presence of electromagnetic radiation is called a surface plasmon polariton (SPP), which represents the basis for the rapidly growing field of nanoplasmonics, opening the route for surface plasmon subwavelength optics [19.8], surface plasmon enhanced spectroscopy [19.9], near-field optics [19.10] and chemical applications [19.11, 12].

In this chapter, however, we will deal primarily with a different kind of collective low-energy excitations, generated in low-dimensional electron gases in one (1-D) and two dimensions (2-D). The most prominent examples are the 2-D sheet plasmons of a metallic monolayer that have been observed, e.g., in Ag or Dy monolayers on Si(111) [19.13, 14] and in monolayers of graphene on SiC or metal surfaces [19.15], but also the 2-D plasmons of partially filled surface states found on the clean surfaces of Be(0001) [19.16, 17], Cu(111) [19.18, 19] and Au(111) [19.20, 21], which result in so-called acoustic surface plasmons (ASP). Their relevance has two aspects: It is worthwhile to study the specifics of plasmonic excitations in low-dimensional systems in greater detail, since both partial localization and correlations are important [19.7]. Therefore, a quantitative theory for plasmonic excitations going beyond the nearly free electron gas model (NFEG) [19.22] is highly desirable. Secondly, much higher in-plane confinements of excitations can be achieved with plasmons associated with a 2-D electron gas, since their dispersion is much flatter than that of SPP, which allows for extraordinary confinement of energy from subterahertz to mid-infrared frequencies through the use of appropriate nanostructures providing the necessary momentum transfer. The $\sqrt{q}$-dependence of dispersion, however, makes a distortionless propagation of nonmonochromatic signals inherently impossible, since the different frequency components propagate at different velocities. This drawback can be overcome by the use of systems that have a linear rather than a square root dispersion. As we will illustrate later, a linear dependence of dispersion is always expected for low-D plasmons that are coupled and shielded by other 2-D or 3-D electron gases [19.23, 24]. This is particularly the case for metal surfaces supporting an electronic Shockley surface state (SS) with band dispersion crossing the Fermi level [19.25], which leads to the formation of the ASP.

The physics of experimentally accessible systems that exhibit quasi-1-D properties is still largely unexplored. The most obvious reason is their inherent instability, which allows their existence as isolated systems only at $T = 0\,\mathrm{K}$. 1-D properties can, however, be stabilized if embedded into a 2-D or 3-D environment. The interaction with these environments not only stabilizes these systems, but their feedback on 1-D properties opens a wide range of variability and enables them to be manipulated. Thus a variety of exotic phenomena such as charge and spin density waves becomes accessible and make them quite interesting objects to be studied [19.26, 27]. In this context, the arrays of atomic wires generated by self-assembly on semiconducting surfaces [19.28–32] are particularly attractive: they are geometrically strongly anisotropic [19.29, 33, 34], and they also exhibit quasi-1-D Fermi surfaces and/or even 1-D electronic transport properties under certain conditions. Depending on their chemical interaction with the substrate, but also on the details of the coupling of these wires mediated by the substrate, these ensembles reveal in part fundamentally different characteristics. As an example, bundles of In wires on Si(111) forming a (4×1) reconstruction are metallic at room temperature, but undergo a metal–insulator transition to form charge density waves below 130 K. In contrast, chains of Au on Ge(100), under special conditions, seem to reveal the spectroscopic signatures of a Luttinger liquid without any instabilities at low temperature [19.32, 35], although this behavior is still under discussion. Not only are quasi-1-D metal-insulator transitions observed [19.31, 36], but surface instabilities result in electronic stabilization of new facets. This stabilization is intimately coupled with changes in the electronic band structure leading, in some cases, to coupled spin and charge order [19.37, 38].

The 1-D properties are both visible by a combined view at geometry and occupied electronic states, and also manifest themselves in electronic excitations, which in the limit of pure 1-D behavior with its strong electronic correlations cannot be discriminated from collective plasmonic excitations [19.39]. As we will show later, although the identification of purely 1-D dispersion is easily possible [19.3, 40–43], the quantitative properties are explicitly dependent on the coupling to the environment. If the wires in arrays are essentially decoupled from each other, the strong confinement perpendicular to the chains leads to the generation of electronic subbands. As a consequence, the simultaneous excitation of subband plasmons and intersubband plasmon are observed [19.3, 41, 44]. In fact, various forms of interwire coupling [19.42, 45] lead partly to two-dimensional crossover in the quantitative dispersion properties that are also reflected in modifications of the band structure.

19.1 Sheet Plasmons

Historically, sheet plasmons were first observed as standing waves for a dilute 2-D electron system (2-DES) on a liquid He surface [19.46] at extremely low electron densities (few $10^6/\mathrm{cm}^2$). The square root dependence of the 2-D plasmon frequency was already seen in inversion layers of Si-MOS field effect transistors and in GaAlAs quantum well structures [19.47, 48]. These artificially tailored systems allowed only large electron spacing or long Fermi wavelengths ($\geq 1000\,\text{Å}$). Their energy dispersions were studied in a tiny wave-number region $q_\parallel \leq 0.01\,\text{Å}^{-1}$ where they can be described by classical local response theory and are also free from the lifetime broadening caused by Landau damping. Plasmons of Shockley surface states are other examples apart from 2-D metallic layers or stacks. Common to all these systems is that they are not freestanding, but are either on top of or embedded in a carrier material. Depending on its conductive properties, this material is responsible for shielding and modification of the electric field caused by the plasmons. Therefore, before we discuss specific examples, let us briefly summarize the theoretical ideas explained in more detail in Chap. 17.

19.1.1 Plasmon Dispersion for the 2-D Electron Gas

For a purely 2-D nearly free electron gas (NFEG), i.e., when no bulk electrons are present, theory predicts the existence of a surface plasmon exhibiting in the limit $q_\parallel \to 0$ a square root dependence of dispersion on $q_\parallel$; $q_\parallel$ is the component of the wave vector of the excitation parallel to the surface that is created in a scattering event. At least the next order, however, will be important in some cases (see later). Following *Stern* [19.22], the energy of the corresponding plasmon is given by

$$\omega_{2\text{-D}}^2 = e^2 \frac{E_\mathrm{F}}{2\epsilon' \pi \hbar^2} q_\parallel + \frac{3}{4} v_\mathrm{F}^2 q_\parallel^2 + \ldots \qquad (19.1)$$

with the Fermi energy E_F. For a freestanding 2-D system, ϵ' is just equal to the vacuum dielectric constant ϵ_0, whereas it becomes $\epsilon' = \epsilon_0 \epsilon$ when the 2-D electron gas is embedded in an insulating environment with dielectric function ϵ.

The first term in (19.1) is identical to the result for a thin metallic film obtained by the classical response theory [19.4], whereas the second term (and higher-order terms) results from the correlations in a 2-D Fermi gas and corresponding changes in the excitation spectrum. For the free electron gas, the 2-D electron density of occupied electronic states is related to E_F and to the effective mass $m^\star$ by

$$n_{2\text{-D}} = \frac{E_\mathrm{F} m^\star}{\pi \hbar^2} \,. \qquad (19.2)$$

On the contrary, for a relativistic electron gas with linear dispersion ($E = \hbar v_\mathrm{F} q_\parallel$), $n_{2\text{-D}}$ depends quadratically on E_F

$$n_{2\text{-D}} = \frac{E_\mathrm{F}^2}{\pi \hbar^2 v_\mathrm{F}^2} \qquad (19.3)$$

so that the leading term in (19.1) of the plasmon frequency at small $q_\parallel$ depends on electron density as $n_{2\text{-D}}^{1/4}$. Interestingly, the second term of (19.1) does not depend on the electron density in this case, since v_F is constant. As we shall show later, experiments confirm this prediction.

Screening by the environment due to embedding in or adsorption of a 2-D layer on a carrier material, or due to the presence of a bulk in the case of a surface state, will lead to modifications of (19.1). In the simplest case of adsorption of the 2-D layer on an insulating material, the resonances are far from the plasmon frequencies, and screening effects can be described by a dielectric constant, which is taken as the average of the dielectric constants of this material and of vacuum, so that ϵ' now reads $\epsilon' = \epsilon_0(\epsilon + 1)/2$.

In the case of a metallic surface state screened by the presence of 3-D electrons, theory predicts in the long wavelength limit the existence of two plasmons [19.7]: One corresponds to the high-frequency oscillation ω_h, in which 2-D and 3-D electrons oscillate in phase with each other. The other corresponds to a low-frequency oscillation in which both 2-D and 3-D electrons oscillate out of phase, characterized by a linear dispersion

$$\omega_\mathrm{l} = \alpha v_\mathrm{F}^{2\text{-D}} q_\parallel \,, \qquad (19.4)$$

where α is a constant with a value close to 1, and v_F is the 2-D Fermi velocity. Because of its linear dispersion, it is called acoustic surface plasmon (ASP).

As we shall later show, in the most common case, i.e., for Be(0001) [19.16], the 2-D Fermi velocity will be lower than that of the 3-D system, so that α is slightly larger than 1. However, there are cases, e.g., Au(111) [19.20] and Cu(111) [19.49], for which the 2-D Fermi velocity is higher than in 3-D, so that α is slightly lower than 1.

In order to understand the basic mechanism behind the ASP, let us compare the behavior of a conventional 2-D electron gas having a parabolic dispersion

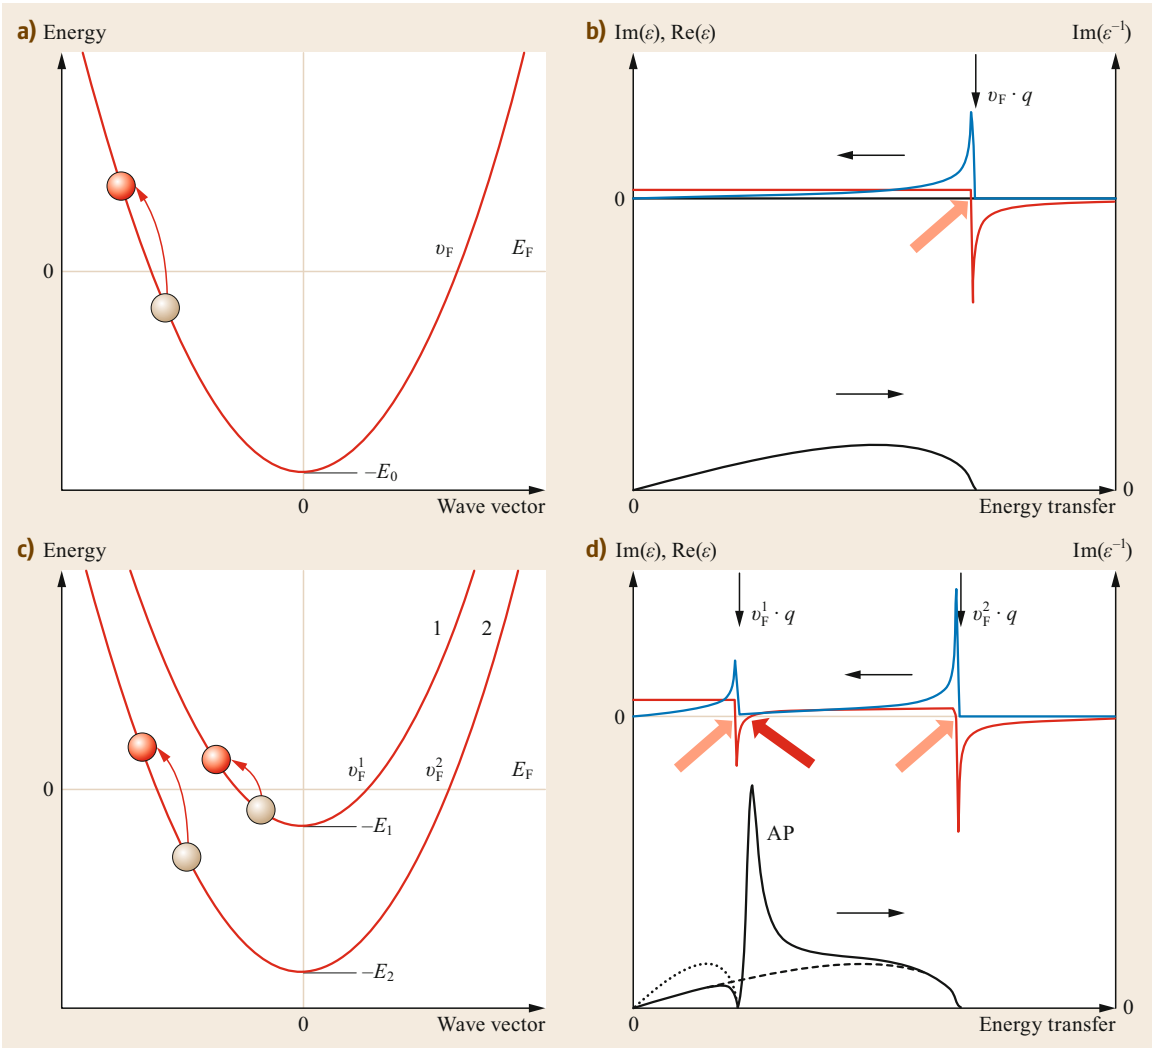

Fig. 19.1a–d Schematic of electronic excitations and decay in single- **(a,b)** and double-component **(c,d)** 2-D electron gases: Energy dispersion as a function of wave vector **(a,c)** with single-electron intraband transitions (*red arrows*). In **(b)** and **(d)**, the dielectric function ϵ with real (*red lines*) and imaginary parts (*blue lines*), and the loss function $\mathrm{Im}(1/\epsilon)$ (*black lines*) are plotted for an arbitrary but given small momentum transfer. Unobservable low-energy resonances are indicated by *light red arrows*. The observable feature, characterized by $\mathrm{Re}(\epsilon) = 0$ and a maximum in the loss function (and hence a small value in $\mathrm{Im}(\epsilon)$), is indicated by a *dark red arrow*. (Adapted with permission from [19.20]. © 2013 by the American Physical Society)

(Fig. 19.1a) with an electron gas consisting of two components with different Fermi velocities (Fig.19.1c). The corresponding dielectric function $\epsilon(\omega, \boldsymbol{k})$ for a given wave vector $\boldsymbol{k}$ (in the long wavelength limit) and the loss function $\mathrm{Im}(1/\epsilon)$ are shown Fig 19.1b,d. For the 2-D electron gas with only one component, the low-energy zero-crossing of $\mathrm{Re}[\epsilon(\omega, \boldsymbol{k})]$ is not associated with a peak in the loss function, and thus corresponds to the excitation of incoherent intraband electron–hole pairs. For a two-component electron gas, there exist three zero-crossings of $\mathrm{Re}[\epsilon(\omega, \boldsymbol{k})]$ at low energy. One is associated with a peak marked in the loss function $\mathrm{Im}(1/\epsilon)$. Since it lies just above the edge of single-particle transitions within the band with the lower Fermi velocity, it corresponds to a collective mode screened by the electrons located in the other band. In the long wavelength limit, i.e., for $q_\parallel \to 0$, the energies of both peaks in $\mathrm{Im}(\epsilon)$ disperse linearly with $q_\parallel$. The peak in the loss function, being limited by such linearly dispersing peaks, also exhibits a linear dispersion and thus satis-

fies (19.4). In the case of a Shockley surface state at a metal surface, the model still captures the essential physics, provided that one of the two components of the electron gas is associated to the 3-D electron system and that the coexistence of 3-D and 2-D electron gases in the same volume is properly considered.

It is worth mentioning here that this scenario of interacting electron gases is not limited to the specific case just discussed. For example, stacking of identical layers, separated by insulating spacers, considered theoretically in [19.23] also leads to coupling between electron gases and to linearization of plasmon dispersion. Even the anisotropy within the same 2-D band, e.g., in freestanding graphene at the K- and K′-points of the Brillouin zone, is predicted to lead to the formation of an ASP in addition to the standard sheet plasmon [19.50].

The plasmon dispersion can be measured experimentally by using (highly resolved) electron energy loss spectroscopy (HREELS). An instrument with simultaneous high energy and high momentum resolution is called ELS-LEED [19.51]. Electrons with energy E_i impinge at an angle θ_i with respect to the surface normal. Electrons can scatter elastically or inelastically. The energy spectrum of the electrons scattered at an angle θ_s from the surface normal may contain peaks at energy E_s. The energy lost (or gained) corresponds to the creation (or annihilation) of a collective excitation of energy E such that

$$E_\mathrm{i} = E + E_\mathrm{s} \,. \tag{19.5}$$

Note that E is positive when the excitation is created and negative if it is destroyed in the scattering event. The conservation of momentum in the direction parallel to the surface reads

$$k_{\mathrm{i},\parallel} = k_{\mathrm{s},\parallel} + q_\parallel + g_\parallel \,, \tag{19.6}$$

where $g_\parallel$ is any reciprocal lattice vector of the surface unit cell. Since before and after scattering the electron is a free particle (the same relationship holding also for any free particle with nonvanishing mass in the nonrelativistic limit), the modulus $k_{\mathrm{i},\parallel}$ of the parallel component $\boldsymbol{q}_\parallel$ of the wave vector is given by

$$k_{\mathrm{i},\parallel} = \frac{\sqrt{2mE_\mathrm{i}}}{\hbar} \cos\theta_\mathrm{i} \,. \tag{19.7}$$

The modulus $k_{\mathrm{s},\parallel}$ is given by a similar relationship. It is thus possible to obtain $q_\parallel$ and E, i.e., the dispersion relation of the collective excitation (or the energy and the momentum of the particle) created in the scattering event. Experiments performed for Ag on Si [19.13] and for $DySi_2$ [19.14] confirmed the prediction. At very long wavelengths, 2-D plasmons have low energy. However, they are unable to affect electron–phonon interaction and phonon dynamics close to the Fermi energy because of the square root dispersion.

19.1.2 Sheet Plasmons in 2-D

Metallic Layers

Here we discuss the prototype system Ag/Si(111) [19.13]. Similar results have been obtained for Dy/Si(111) [19.14]. The flat Ag/Si(111) system has been a prototype for the investigation of surface conductance on a low-doped Si substrate [19.52], in which metallic conductance has been shown to be associated with the formation of a $\sqrt{3}\times\sqrt{3}$R30° structure. Conductance can be changed by adding additional Ag atoms. In fact, such $\sqrt{3}$-structure was found to be a semi-metal [19.30], and metallicity is attained only by adding surplus Ag atoms to this structure [19.52]. The most natural explanation for this self-doping phenomenon seems to be the formation of a lattice gas in the second layer, as also suggested by a HREELS study as a function of Ag concentration [19.53]. The investigations on stepped Si(557) yield, however, are a somewhat different picture (see later).

In any case, 2-D metallicity can be generated in this system. Direct proof is found in the existence of a plasmonic excitation whose energy goes to zero at long wavelengths, i.e., no further excitation is necessary to create this plasmon. The first test for such a purely 2-D system has indeed been carried out in Ag/Si(111) at monolayer concentration [19.13]. The main results are shown in Fig. 19.2.

As shown in Fig. 19.2b, the dispersion can be well described by a 2-D nonrelativistic NFEG using the two terms given explicitly in (19.1). Within errors there was no angular dependence of the dispersion, but the slope of the dispersion changed when further Ag was added to the (already self-doped) $\sqrt{3}\times\sqrt{3}$R30°-Ag structure. From their fits, the authors determined electron concentrations of between 1.9 and $8\times10^{13}\,\mathrm{cm}^{-2}$ and an effective electron mass of around $0.3m_\mathrm{e}$. This result is in good agreement with data from angle-resolved photoemission (ARPES) for the same system [19.30]. From these numbers, an effective electron transfer of about one-third of an electron per surplus Ag atom was deduced. For the present case, the screening by the substrate can thus be accurately described by an effective dielectric constant of the interface.

Plasmons in the 2-D Relativistic Electron Gas

Since its ultimate discovery in 2004 [19.54], graphene has become one of the most studied materials in

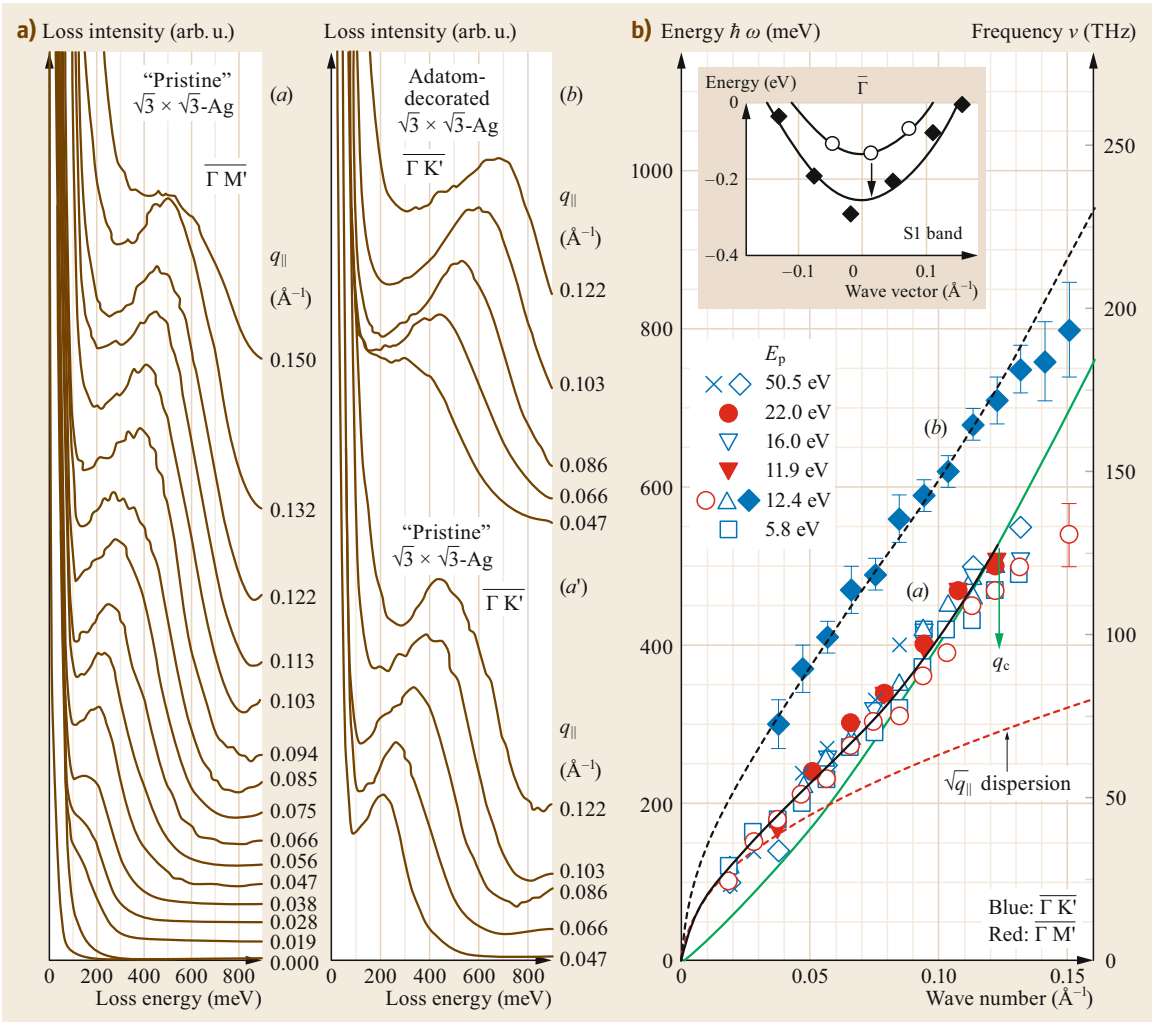

Fig. 19.2 **(a)** EELS spectra taken at an incident electron energy of $E_p = 12.4$ eV. For better visibility, the curves were shifted; the momentum transfer is given as parameter. (a) Scans along the $\overline{\Gamma M}$ direction (a′) and (b): Blueshift of losses due to the additional adatom decoration. **(b)** Plasmon dispersions of (a) a $\sqrt{3} \times \sqrt{3}$R30° ordered surface at a coverage slightly above 1 ML (monolayer) and (b) after further decoration with 0.15 ML of additional Ag. nanoscience. The coupling of light into flat and nanostructured graphene in the terahertz and far-infrared frequency regime using the plasmonic properties of graphene in order to form surface plasmon polaritons (SPP) has been a widely covered subject [19.55–57], and many potential applications have been suggested [19.58–61]. We refer the reader to these excellent reviews and will not elaborate on these topics here, since although in this range of frequencies subwavelength phenomena (compared with optical and infrared wavelengths) can be observed, the typical wavelengths of several micrometers do not allow entry into the nanoscale of 10 nm and below.

However, there is a unique property of 2-D plasmons that has become obvious by studying 2-D plasmons in graphene. Here we concentrate again on the low-energy plasmons. Other plasmons in graphene, in particular the standard π plasmon excitations, have been reviewed previously [19.15], and we refer the reader to this literature. At low $q_\parallel$ (typically in the range of μm^{-1}), i.e., at plasmon frequencies in the terahertz range, a series of studies have exploited the fact that

the plasmon frequencies of plasmon polaritons, i.e., the combined excitation of a plasmon in an external electromagnetic field, can be tuned by changing the carrier concentration in the graphene layer. This can be done most conveniently by using a gate voltage [19.62, 63]. Thus plasmon polaritons at a wavelength of a few hundred nanometers can be excited with light in the far- to mid-infrared range. This result is attractive because of its relatively low damping: decay lengths reaching 1 μm indeed allow us to foresee many potential applications including tunable infrared lasers [19.64], plasmonic quasicrystals [19.58], ultrasensitive detection down to the single-molecule level [19.65], improved photovoltaics [19.66] or nonlinear optics [19.67]. This tunability, however, is subject to physical limitations that we will further describe later.

Surprisingly, this tunability seems to completely disappear when $q_\parallel$ is in the range of $1\,\mathrm{nm}^{-1}$. An example is shown for graphene on Si-terminated 6H-SiC(0001) in Fig. 19.3. Figure 19.3a shows the plasmon dispersion, recorded with electron energy loss spectroscopy with simultaneous high momentum and high energy resolution [19.68]. These results agree well with those of [19.69]. The first layer of graphene on SiC grows on a carbon buffer layer. It turns out to be n-doped with a doping concentration of $1\times10^{13}\,\mathrm{cm}^{-2}$, and the Fermi level under these conditions to be about 400 meV above the Dirac point [19.68].

At very low $q_\parallel$, the dispersion is compatible with a $\sqrt{q_\parallel}$ dispersion, as predicted by the first term of (19.1). Deviation from this function is already evident at $q_\parallel < 0.03\,\text{Å}^{-1}$, similar to the Ag/Si(111) case discussed above. For $q_\parallel > 0.1\,\text{Å}^{-1}$, on the other hand, there is a linear slope of $1.35\pm0.1\times10^6\,\mathrm{m/s}$, very close to the Fermi velocity in graphene on SiC [19.70]. Between these two regimes there is a characteristic cusp that was ascribed to resonant damping, since the plasmon dispersion enters the continuum of single-particle interband transitions.

Qualitatively, the experimental dispersion curve follows the theoretical forecast for a 2-D Fermi gas of relativistic electrons within the random phase approximation (RPA) [19.71]. The resonant damping has not been considered in theory. Nevertheless, a cusp can be seen in theory (Fig. 19.4), which is therefore a characteristic property of the relativistic electron gas. It is much less pronounced than in experiment because damping is neglected in the theoretical calculation. Therefore, quantitative agreement between theory and experiment cannot be expected.

The main qualitative difference between the non-relativistic and the relativistic 2-D electron gas comes

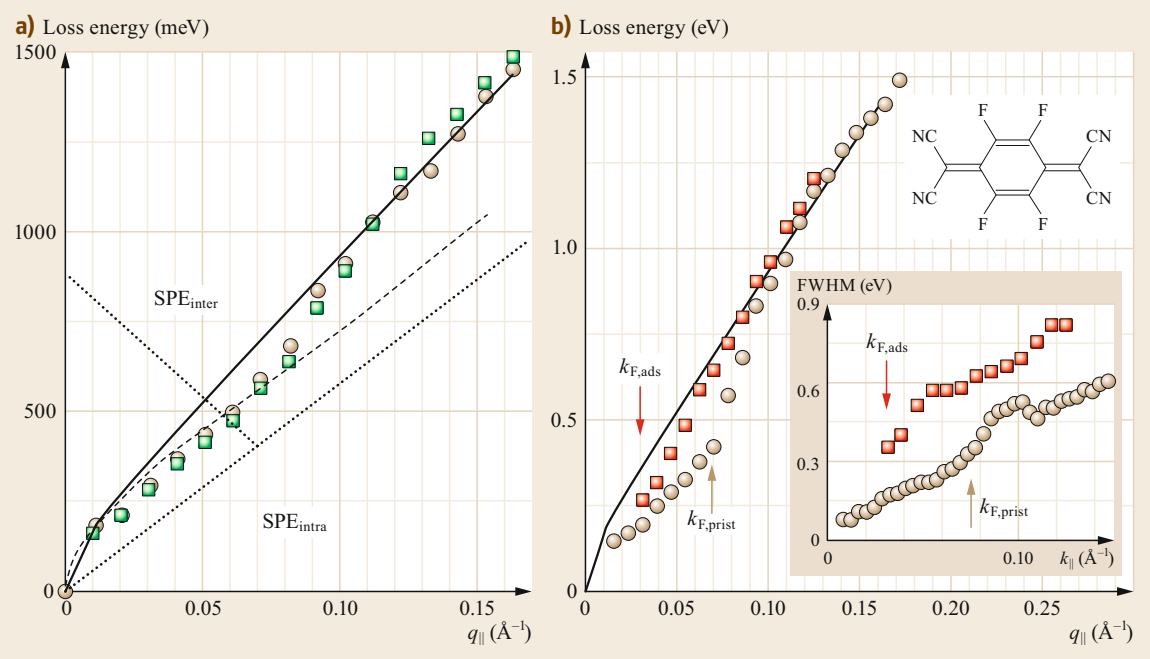

Fig. 19.3 **(a)** Plasmon dispersion for 1 ML graphene layer grown on H-etched SiC samples, measured at 300 K (*squares*) and at 80 K (*circles*). **(b)** Graphene plasmon dispersion before (*circles*) and after (*squares*) F4-TCNQ doping. *Lower inset*: changes in *k*-dependent half widths (same symbols as in main figure). *Upper inset*: stereographic model of F4-TCNQ. from the second term in the expansion of plasmon dispersion, which becomes dominant for large $q_\parallel$. This term disperses linearly with a slope $\propto v_\mathrm{F}$, as already outlined above (19.1). For the relativistic electron gas of graphene, this limit is reached for $q_\parallel/k_\mathrm{F} > 1$ [19.71]. If this second term dominates, its slope, according to (19.1), does not depend on the embedding environment. Even more importantly, for the relativistic electron gas with a constant Fermi velocity, this term is independent of the doping level. Thus the slope of the dispersion in this limit should be usable as a calibration standard. This prediction can easily be tested.

One test is shown in Fig. 19.3b. Here, the plasmon dispersion curves are compared before and after covering the graphene layer with about one percent of a monolayer of 4F-TCNQ molecules at 300 K. F4-TCNQ is known to reduce the carrier density of graphene and hence to shift E_F downward [19.72]. As expected, the dip shifts to lower $q_\parallel$ values (to $\approx 0.03\,\mathrm{Å}^{-1}$). This shift is also seen in the resonance of the FWHM. Since the molecules added act as scattering centers, the loss structure is further broadened. This reduction of the doping concentration to $\approx 3 \times 10^{12}\,\mathrm{cm}^{-2}$ also reduces both E_F and k_F correspondingly. Therefore, the transition to the linear part of the dispersion happens at smaller $q_\parallel$, as expected from the considerations mentioned above, and the linear range is extended. The average slope of the linear part, however, remains unchanged, in accordance with a constant Fermi velocity and (19.1). Very similar behavior has been found for a quasi-freestanding graphene layer on SiC(0001), generated with a graphene buffer layer by intercalation with hydrogen, by gradual desorption of the hydrogen [19.73], which mainly shifts the Fermi level and thus the doping concentration.

A second example of this finding is shown by comparing these results with those obtained for graphene on Ir(111) [19.74, 75]. The growth of graphene on Ir is self-limited to a single layer by decomposition of hydrocarbons (ethylene) at temperatures around 1320 K, at a pressure of 2×10^{-7} Pa. It is characterized by a Fermi level very close to the Dirac point [19.76, 77], i.e., a doping concentration of less than $1 \times 10^{11}\,\mathrm{cm}^{-2}$. Therefore, and in accordance with the results just presented, only a linear slope can be observed within the $q_\parallel$ range resolvable with ELS-LEED. This result is shown in Fig. 19.5 together with the results obtained after doping the layer by intercalation with half a monolayer of Na and in comparison with those from SiC. Here we concentrate first on the lower dispersion branch. When the slope of the quasi-linear dispersion for graphene on Ir(111) is compared with that on SiC(0001) (Fig. 19.5b), they are virtually identical. While the more effective shielding of the metallic surface compared with SiC should lower the slope of dispersion [19.70], this shielding is not static and leads to a more complicated interaction between the 2-D electron gas of graphene and the 3-D electron gas in the conduction bands of Ir, which may compensate the expected redshift. However, this effect has not been studied quantitatively in this system. Completely linear dispersion has also been found for graphene on Pt(111) [19.15, 78]. The slope, however, is about 15% smaller than in the examples just shown, possibly due to different interaction and shielding compared with the Ir(111) substrate.

Intercalation of graphene on Ir(111) by half a monolayer of Na has the effect of strong n-doping of graphene due to a shift of the Fermi level of graphene by nearly 1 eV. As a consequence, the linearity of plasmon dispersion is seen over a reduced $q_\parallel$ range up to $0.1\,\mathrm{Å}^{-1}$, whereas for higher $q_\parallel$ values there is a tendency for leveling off. The slope measured in the linear $q_\parallel$ range is about 10% larger than with graphene on clean Ir(111). This is a remarkably small effect considering the change in doping level by about four orders of magnitude. On the other hand, both findings indicate

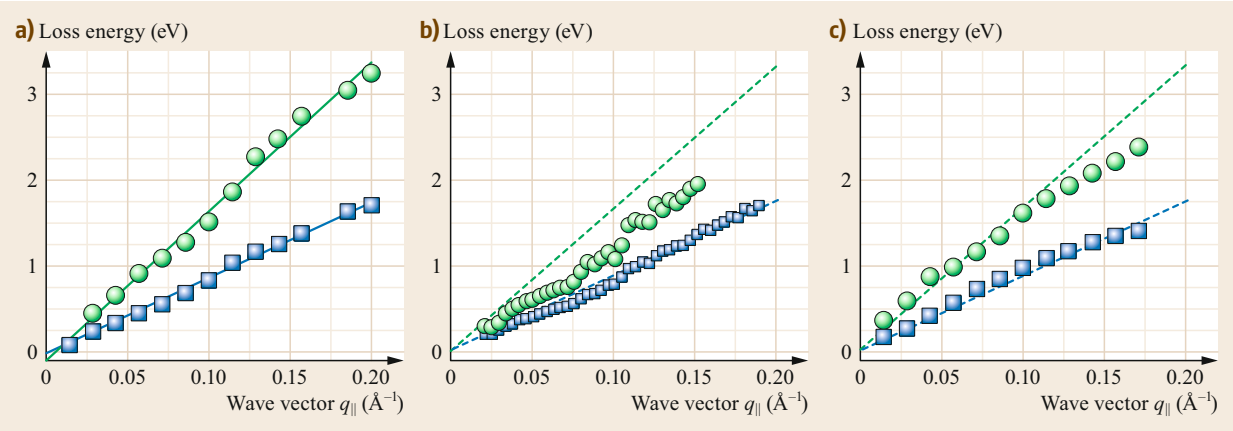

Fig. 19.5 **(a)** Plasmon dispersion of the two plasmonic branches of graphene on Ir(111). **(b)** Same type of data evaluation for graphene on SiC(0001) (n-doped layer $n \approx 10^{13}$ cm^{-2}). **(c)** Results for Na-intercalated graphene on Ir(111). The average linear slopes of **(a)** are drawn as *dashed lines* in the other graphs. (Reprinted by permission from [19.74])

that Na intercalation not only results in a rigid shift of the graphene bands, but also causes Na to interact more strongly with both graphene and Ir, resulting in the deviations measured. The increase in measured half widths of plasmon losses also points in this direction [19.74].

In view of (19.1), these results are not expected, since the doping level increases the first term of this equation considerably, so that it should dominate over a larger range of $q_{\|}$. A clear dependence of the plasmon dispersion has indeed been seen on SiC(0001) by varying the amounts of intercalated potassium [19.79]. In fact, due to the high doping level studied there, this first term of (19.1) dominates most of those results, and there is semi-quantitative agreement with the predictions of (19.1) with this assumption. At this point, we want to stress, however, that the findings of [19.79] are not in contradiction to the results found on Ir and the others discussed above. On the contrary, they fully agree with the predictions of (19.1). Since on a metal the screening is much more effective, the dielectric function is up to two orders of magnitude larger than for SiC, so that the first term of (19.1) is smaller by the same factor on metals like Ir or Pt as on SiC: the linear term in $q_{\|}$ thus already dominates at small $q_{\|}$. Moreover, the interaction with the shielding metal electrons leads to further linearization of the dispersion curves [19.23, 24], a mechanism not present on a semiconductor like SiC.

From these results we conclude that the tunability of the plasmon frequencies in the relativistic 2-D electron gas is possible only if the term $\propto \sqrt{q_{\|}}$ dominates the dispersion. The strong sensitivity of this term to the environment via its dielectric function ϵ influences both the accessible frequencies and the range of tunability. This range can easily be exceeded particularly on metals, where the term linear in $q_{\|}$ is responsible for the insensitivity of plasmon dispersion to the doping level and to the environment. This robustness has not yet been exploited, but is quite important for many potential applications.

Two-dimensional plasmons were also shown to couple to other excitations, in particular to phonons and single-electron excitations. The enhanced coupling of plasmons to single-particle excitations is quite well known: similar to the situation described above [19.68], due to opening of new decay channels, it causes resonantly enhanced damping. Similar phenomena have been observed in photoemission, but here the linear dispersion of (ideally) noninteracting single quasi-electrons and quasi-holes is modified close to the Dirac point by the interaction with the plasmon due to excitations of so-called plasmarons [19.80, 81]. For coupling between sheet plasmons and phonons, a prominent example is the coupling in graphene to the surface optical phonon of the underlying SiC on the Si-terminated surface [19.82, 83]. The coupling of this phonon was found to be remarkably robust. It cannot be quenched by intercalation or modifications of the intercalation. Instead, new coupled modes appear that are due to the coupling between the sheet plasmon with phonons of the intercalated material. Coupling of the plasmon with the internal LO phonon was found to be detectable only for bilayer graphene. This coupling may give a further handle to tailoring plasmonic properties.

Finally, we turn to the observation of multipole modes, which were identified for graphene on Ir(111)

and on SiC(0001) [19.74]. As evident from Fig. 19.5, these modes closely follow the dispersion of the basic mode, but with a different slope depending on the substrate material. On the metal, the ratio between slopes is roughly 2, while on SiC it is reduced to 1.4. The half widths of the multipole losses were found to be essentially the same as for the basic mode. Both modes appear at the same $q_{\parallel}$, so it seems that both modes are excited by the same mechanism. It is indeed only a matter of scattering cross section which one dominates. The different ratios of slope found on the metal and on the semiconductor, on the other hand, may be due again to different screening efficiency. These multipole modes in low-dimensional systems have not yet been explicitly considered theoretically, even if this improvement is highly desirable in order to gain deeper insight.

The Acoustic Surface Plasmon (ASP) for Be(0001), Cu(111) and Au(111)

As mentioned at the beginning of the chapter, a new mechanism governing linearization of plasmon dispersion comes into play when excitations of different electron gases are coupled. An important example is the 2-D electron gas of a Shockley surface state, which exists, e.g., on the close-packed surfaces of the noble metals (Ag(111), Au(111) and Cu(111)), but also on Be(0001). The 2-D sheet plasmon will inevitably be screened by the underlying 3-D electron gas of the metal. The ASP was first observed experimentally on Be(0001) with HREELS. Experimental data are shown in Fig. 19.6 along the $\overline{\Gamma M}$ direction for two different kinetic energies (7.26 and 10.74 eV, respectively) while keeping the scattering angle θ_s fixed (63.3° and 59.2°,

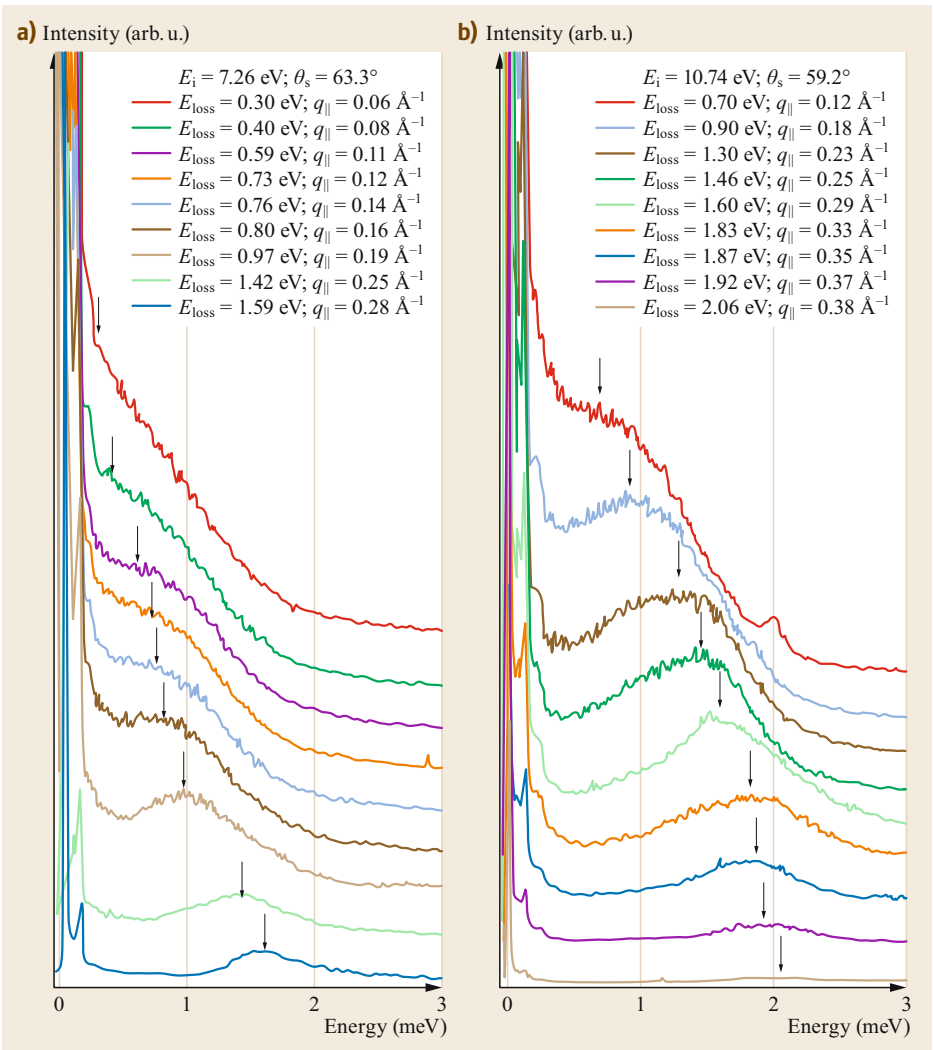

Fig. 19.6a,b HREEL spectra recorded for different scattering conditions starting from the specular direction (*uppermost spectra*) and moving out of specular for Be(0001). The *arrow* indicates the position of the energy loss feature. (After [19.16])

respectively) and changing the angle of incidence $\theta_i y$. The parallel momentum is obtained using (19.6).

It is apparent that a relatively broad energy loss feature is present and that it shifts to higher energy with increasing parallel wave vector. The position of the loss feature for several scattering conditions is shown in Fig. 19.7. The slope of the dispersion curve was found to be 5.5 eV Å (for comparison: 1 eV Å $\cong 1.52 \times 10^5$ m/s), slightly lower than predicted by a simplified 1-D model and in very good agreement with the prediction of a more accurate ab initio model. Measurements along ΓK were performed by another group [19.17]. The slope (group velocity) was found to be slightly higher (6.4 eV Å) than for the $\overline{\Gamma M}$ direction. Moreover, along the $\overline{\Gamma K}$ high-symmetry direction, the ASP has a greater width than along $\overline{\Gamma M}$, because the ASP dispersion is closer to the electron–hole pair continuum along $\overline{\Gamma K}$ [19.84].

The discovery of the ASP on Be(0001) triggered further measurements on other surfaces such as Cu(111) [19.18] and Au(111) [19.21], for which theory had already predicted its existence. For Au(111), actually two linearly dispersing losses were found [19.20], with group velocities of 3.95 and 8.1 eV Å, respectively. Only the latter loss was excited in [19.21]. A selection of spectra for different scattering conditions and the dispersion curves are shown in Fig. 19.8. According to time-dependent density functional theory (DFT) calculations [19.20], however, only the first with the lower slope corresponds to the ASP, whereas the second, higher-energy branch was assigned to an interband transition between a band edge of the bulk and the Shockley surface state. A further contribution to this loss from a multipole ASP cannot be excluded.

Interestingly, as seen from Fig. 19.8, the slope of the low-energy branch corresponds to a value of $\alpha < 1$ in (19.4), i.e., to a loss running slightly below the edge of the electron–hole pair continuum. As demonstrated theoretically [19.20], this is a particular screening effect of the surface state excitation by the bulk electrons. For Au(111), the electrons in the Shockley surface state close to the Fermi level have velocities higher than the corresponding majority of bulk electrons, thus leading to a value of α slightly lower than 1. The complication with two losses also appeared for the Cu(111) case, as a recent investigation with very high-energy resolution showed, i.e., the loss feature assigned to the ASP by *Pohl* et al. [19.18] actually consists of two losses. The component with the lowest slope among them was then assigned to the ASP for Cu(111), suggesting a scenario similar to Au(111) [19.49]. Thanks to the higher energy resolution, the width of the ASP is now lower than estimated before: using the time-energy principle of indeterminacy, it is thus possible to estimate the lifetime and the propagation length of the ASP, a parameter relevant for assessing the feasibility of ASP-based de-

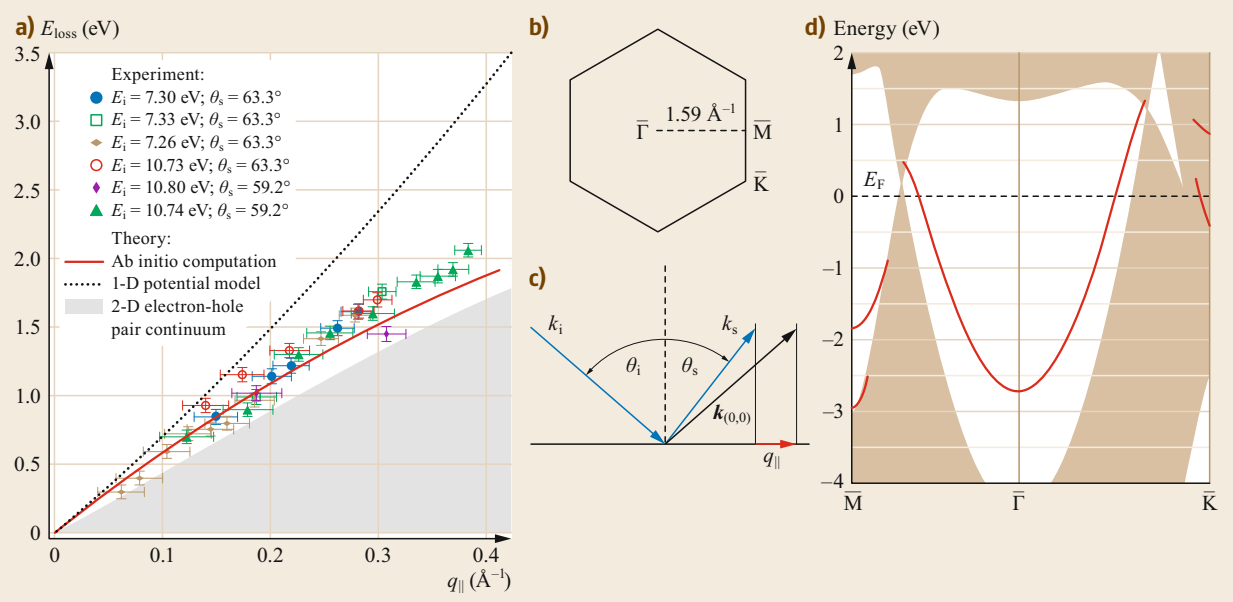

Fig. 19.7a–d Experimentally measured dispersion curve showing the energy of the ASP versus parallel wave vector. vices. For a wavelength of 0.05 Å^{-1}, an FWHM (full width at half maximum) of the order of 20 meV has been estimated on Cu(111), corresponding to a propagation length of the order of 4 nm, a relatively low value. We shall discuss this important point again in the last section of the chapter.

ASP for Nanostructured and Regularly Stepped Surfaces

After having shown that the ASP exists for most of the surfaces for which it had been predicted, a quite natural question arises: How robust is this excitation? Is it affected by surface nanostructuring? In order to address such issues, experiments for both ion-bombarded Cu(111) and stepped Au surfaces were performed. In the former case, domes and pits of different sizes form upon ion bombardment, the morphology of which is determined by the interplay between thermal diffusion and removal of atoms by collision with the incoming ions. In the latter case, an ordered array of terraces separated by monatomic steps is present. The ASP turns out to be a relatively robust excitation: it is not destroyed by surface nanostructuring at either room temperature or 393 K, at least for moderate ion doses [19.19]. The linear best fit to the dispersion data yields a slope of (3.7 ± 0.5) eV Å. This value has to be compared with that found for the pristine surface ((4.33 ± 0.33) eV Å, [19.18]). As demonstrated by *Theilmann* et al. [19.85], the Shockley surface state (SSS) shifts from −0.4 to about −0.3 eV when the roughness of the Cu(111) surface is increased. This causes a decrease in the Fermi velocity and thus a decrease in the slope of the plasmon dispersion, in qualitative agreement with experiment. For large enough ion doses and when sputtering at 393 K, a non-dispersing loss was observed and tentatively assigned to a nonvertical inter-band transition from the bottom of the SSS to the Fermi level, the required momentum being provided by surface disorder [19.19].

With decreasing wavelength, plasmons also become more and more susceptible to scattering at atomic defects. This effect has clearly been seen for plasmons scattered at substrate steps in graphene on SiC(0001) [19.86]. On a metallic surface, scattering at steps is expected to be smaller due to the less directed bonds, but as was demonstrated for the regularly stepped Au(788) surface, it leads to subband formation and partial localization of plasmons. The (788) surface

consists of (111) terraces that are ≈ 40 Å wide, separated by monatomic steps. The choice of this particular terrace size is motivated by the fact that the distance between steps exceeds the critical value (around 20 Å for Au) beyond which the short-range interaction between steps becomes negligible, so that opening of an energy gap in the surface band structure can occur [19.87]. The choice of Au surfaces is motivated by their chemical inertness: the existence of the ASP is indeed closely related to the existence of a partly unoccupied Shockley surface state, which can in turn be destroyed by surface oxidation. The dispersion of the ASP for Au(788) was measured using an ELS-LEED setup [19.88].

The data are summarized in Fig. 19.9. Two losses with sound-like dispersion are present, denoted by I and II. The branch with the steeper slope originates from the ASP associated to the SSS of the (111) terraces, and has indeed a very similar slope as the ASP on flat Au(111). The branch with lower slope has no analogue on Au(111). Although full ab initio calculations are not feasible because the unit cell is too large, it was possible with the help of theoretical calculations to assign all the features observed experimentally [19.88].

In particular, we underline that:

1. Along the steps, two ASP modes exist. They have different group velocities determined by the Fermi velocities of two partly occupied SSS subbands.
2. The anisotropy introduced by the steps on Au(788) does not automatically lead to plasmon localization normal to the terraces.
3. The QW1 and QW2 subbands are still able to generate propagating plasmonic modes across the steps at wavelengths longer than the terrace width. The slightly different slopes of the modes parallel and normal to the steps reflect the anisotropy of the system.
4. Across the steps, plasmon localization becomes visible when $q_{\parallel}$ exceeds the reciprocal lattice vector of the periodic step array.

The interest in the effect of the presence of a regular array of steps on ASP existence and dispersion is not purely academic: It has been suggested indeed that vicinal surfaces might naturally provide a diffraction grating of nanometer size needed to couple the ASP with light [19.7]. Due to the large difference between the speed of light and the Fermi velocity in the Shockley surface state (almost three orders of magnitude!), an (infrared) photon with an energy of ≈ 0.5 eV could excite on Au(111) an ASP with a wavelength of ≈50 Å, provided that a diffraction grating is able to bridge the momentum gap. A hypothetical device effectively converting photons into ASP should therefore have a characteristic spacing of that order, i.e., about two/three orders of magnitude smaller than a traditional optoelectronic system operating at the same frequency.

Although some theoretical estimates for nanoparticles predict a low efficiency for the conversion of photons into ASPs [19.90], no experiments have yet been reported. In Table 19.1, experimental and theoretical values obtained for the slope of the ASP dispersion are summarized.

Table 19.1 Fermi velocity, experimentally determined slope of the dispersion, and experimental and theoretical α for different systems. The last row shows the theoretically predicted slope of the dispersion as estimated by the authors from Fig. 2c of [19.89]

System	Fermi velocity ($e^2/\hbar$)	Experimental slope (eV Å)	α_{exp}	α_{teo} (non ab initio: [19.24])
Be(0001)	0.41	5.5 [19.16]	1.08	–
Cu(111)	0.28	4.33 [19.18]	1.13	1.053
Cu(111)	0.28	3.11 [19.49]	0.81	–
Au(111)	0.35	3.95	0.83	1.032
Ag(111)	0.11	–	–	–
Ag(111)	–	–	–	≈ 7 [19.89]

Summarizing the ASP observations, it is apparent that the interaction between two electron gases provides a mechanism of mutual screening that leads to linearization of the dispersion, particularly also for small $q_\parallel$. Therefore, it is not described by (19.1), which at small $q_\parallel$ predicts a $\sqrt{q_\parallel}$ dependence.

The fact that α can be < 1, as observed for Au(111), so that the ASP runs below the electron–hole pair continuum, does not directly lead to overdamping of the ASP, as erroneously assumed before experimental evidence. Possible reasons are small overlap between SSS and bulk states, but also phase mismatch of wave functions, expressed by the different Fermi velocities of bulk and surface states.

The reliable calculation of these phenomena is still a challenge for simulations, as seen by two conflicting predictions for the Ag(111) surface: according to [19.89] this system should exhibit a slope even higher than for Au(111), while the non ab initio theory predicts a slope even lower than on Cu(111), in agreement with a third, independent calculation [19.91]. No experiments have measured the ASP dispersion for Ag(111), so this controversy remains open. On the other hand, the experiments carried out so far for ASP by HREELS measurements demonstrate that ambiguities due to the appearance of several losses can only be resolved by reliable quantitative theoretical descriptions.

19.2 Quasi-One-Dimensional Plasmons

As already demonstrated above for the case of Au(788), the introduction of extended defects such as steps on highly symmetric surfaces reduces the symmetry of surface states so significantly that subbands are formed, which are also visible by two separate subband plasmons for the two occupied subbands in the ground state. These plasmons, however, propagate across the steps for long wavelengths and are localized to single terraces only for wavelengths of the order of the terrace width. Therefore, they cannot be considered as quasi-one-dimensional.

On the other hand, the experimental observation of a purely 1-D dispersion of a plasmonic signal is clearly a necessary condition for quasi-1-D behavior, but is it sufficient? In the ideal case, a Tomonaga–Luttinger liquid may appear, in which, due to spin and charge separation of the lowest excitations, the plasmon should appear as a holon with a linear dispersion [19.92–94]. While there is no final answer to this question yet, in the following we will discuss systems in which the requirement of 1-D dispersion is clearly fulfilled: the formation of metallic chains of single atomic height on regularly stepped Si surfaces. Regular arrays of these chains are formed by self-organization, and the widths of the wires vary from single atomic chains to metallic strips that fill a whole (111) terrace, depending on the metal, but also on the step orientation. The main question is, of course, how strongly the potential 1-D properties of these wires are modified by their environment and the coupling to neighboring wires. As it turns out, there is again a wide variation in the strength of interaction, which still has to be understood.

A possible approach to 1-D plasmonic properties starts from a 2-D quasi-free electron gas that is confined to a wire of finite width by an appropriate potential. Within this model, following [19.95], the plasmon dispersion for a single isolated wire can be expressed as a function of the upper and lower boundaries of the electron–hole continuum of excitation, $\omega_\pm = q_\parallel^2/2 \pm q_\parallel k_F/m^\star$, as

$$\omega_p(q_\parallel) = \sqrt{\frac{\omega_-^2 - \omega_+^2 e^{A(q_\parallel)}}{1 - e^{A(q_\parallel)}}}\,, \tag{19.8}$$

with $A(q) = 2\pi q/\{m^\star g_s V(q)[1 - G(q)]\}$. $V(q)$ is the Fourier transform of the confining potential, $G(q)$ the local field correction factor due to electronic correlations, and g_s the spin degeneracy (1 or 2). Already this model yields to lowest order a dispersion linear in $q_\parallel$, contrary

to a 2-D electron gas. As one sees from (19.8), the dispersion depends not only on electron density (via k_F) and effective masses, but also explicitly on the form of the confining potential, and electronic correlations. For the coupling between wires, no such analytic expression can be given, but an approximate description of coupling, valid in the limit of small $q_\parallel$ [19.96–98], exists and will be discussed later for Au wires on Si surfaces.

19.2.1 Arrays of Quasi-1-D Wires with Small Coupling

From the few investigations of low-dimensional plasmons carried out on quasi-1-D systems so far, Ag/Si(557) [19.43, 99, 100] and $DySi_2$/Si(100)vic. [19.41] are those systems in which the properties of individual wires seem to be dominant, i.e., the coupling between wires is weak. Since the plasmonic properties of $DySi_2$/Si(100)vic. resemble those in the Ag/Si(557) system in many aspects, we concentrate here on the latter system.

As mentioned above, the Ag/Si(111) system is a prototype system for the investigation of 2-D plasmons, since carrier concentration in the Ag-modified Si surface state can be tuned by Ag surplus concentration. Similar properties have been found in the Ag/Si(557) system by investigation of the concentration-dependent plasmonic properties. Although the doping mechanism on the flat and stepped surfaces need not be exactly the same, these studies allow us to gain some surprising insights, not only into the doping mechanism, but also into general plasmonic properties in 1-D [19.43, 99, 100]. A possible reason for the decoupling of wires on different (111)-oriented mini-terraces in this system may be the separation of these terraces by (112)-oriented mini-facets, which contain three atomic double steps.

The atomic Ag wires formed in this system at coverages below 0.3 ML were found to be semiconducting. Therefore, low-energy plasmons do not exist below 0.3 ML. The formation of metallic wires is coupled to the appearance of $(\sqrt{3}\times\sqrt{3})$R30°-order on the (111)-

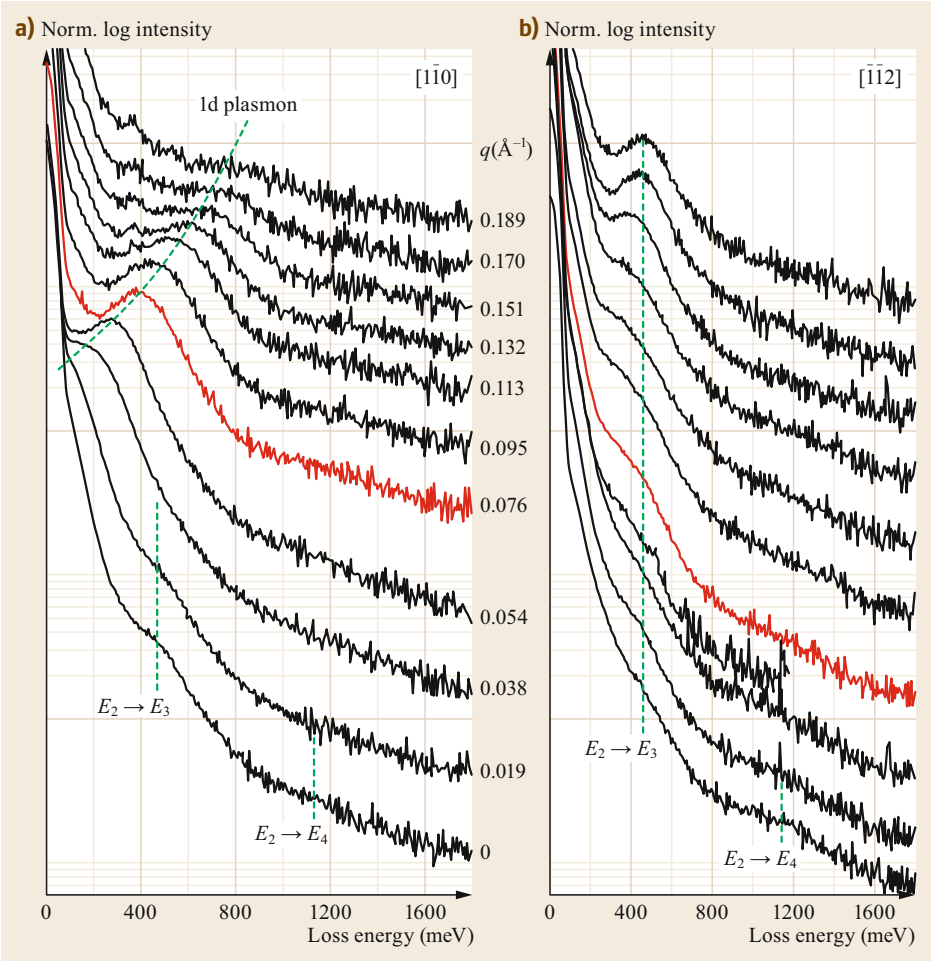

Fig. 19.10a,b EEL-spectra of 1 ML Ag/Si(557) along the [1$\bar{1}$0] **(a)** and [$\bar{1}\bar{1}$2] **(b)** directions taken at 300 K. Apart from the dispersing 1-D plasmon loss in **(a)**, two non-dispersing quantum well transitions $E_2 \rightarrow E_3$ and $E_2 \rightarrow E_4$ at 470 and 1160 meV are seen. Spectra are shifted for better visibility. (Reproduced by permission from [19.43], © IOP publishing 2013)

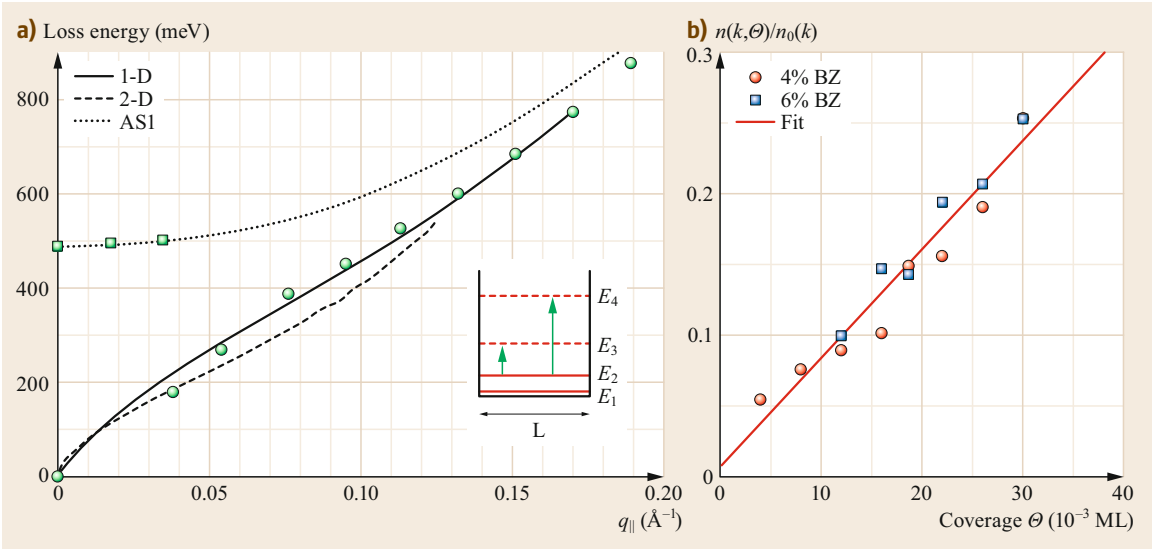

Fig. 19.11 **(a)** Dispersion along the [1$\bar{1}$0] direction. For comparison, the 2-D plasmon dispersion in Ag/Si(111) [19.13] is shown. The *dotted line* is a guide to the eye for AS1-mode. The AS2-branch is not shown. oriented mini-terraces, which have a local coverage of 1 ML.

As shown in Fig. 19.10, a clear 1-D dispersion was measured by EELS-LEED, which means that the triple steps between the (111) terraces act as insulating separators between the conducting strips. Indeed, the measured dispersion for the lowest plasmon mode, shown in Fig. 19.11b, agrees quantitatively with calculations [19.41] which assume a single strip of a 2-D electron gas that is confined by parabolic barriers to a width of 3.6 nm. Not only is the 1-D dispersion reproduced, but also the appearance of intersubband plasmons along the wires, which are expected to behave as coupled (and simultaneous) excitations of quantum well states and plasmons in these wires of finite width [19.44]. In the limit of long wavelengths they merge into the non-dispersing losses measured in the direction perpendicular to the wires (see Fig. 19.10b). They correspond to quantum well states normal to the wires. Their positions can be quantitatively fitted assuming a simple particle-in-a-box model with the measured wire width of 3.6 nm.

The metallic properties of the wires are not intrinsic, and instead are induced by extrinsic self-doping caused by Ag atoms adsorbed at the adjacent step edges, i.e., the bare Ag-wires with $\sqrt{3}\times\sqrt{3}$-order are semi-metallic. The doping atoms can be desorbed thermally without destroying the majority of Ag wires on the (111) terraces, but can be made metallic again by the tiniest amounts of post-adsorbed Ag atoms. Thus this system enables us to precisely determine the dependence of plasmon excitation energy on doping concentration in the range between 0.003 and 0.03 ML. Assuming that all parameters except the electron density remain constant, and that each surplus Ag atom contributes the same amount of charge to the system at low concentrations, we found that $E_{\mathrm{plasmon}} \propto \sqrt{n_{\mathrm{e}}}$, in agreement with theory (Fig. 19.11b). Remarkably, this dependence turns out to be universal, independent of dimension, and to be valid even for a Luttinger liquid. To the best of our knowledge, this is the first direct experimental verification of the $\sqrt{n_{\mathrm{e}}}$ dependence for plasmons in a quasi-1-D system.

This lateral doping mechanism on the atomic scale is most likely caused by the different binding strength of Ag atoms on terraces and at step edges. It leads to preferential trapping of Ag surplus atoms at the step edges and results in lateral band bending, as sketched in Fig. 19.12. As a consequence, the effective wire width is reduced with increasing doping concentration, since the doping chains of atoms are partially charged. Depending on the chemical differences between terrace and step, this charging also limits the maximum doping concentration. Impurity atoms of different sorts can change this situation drastically, but this has not yet been tested in any detail. These experiments also clearly ruled out the long-debated doping process by a lattice gas in the second Ag layer, which was found to be inactive with respect to the formation of a low-energy plasmon.

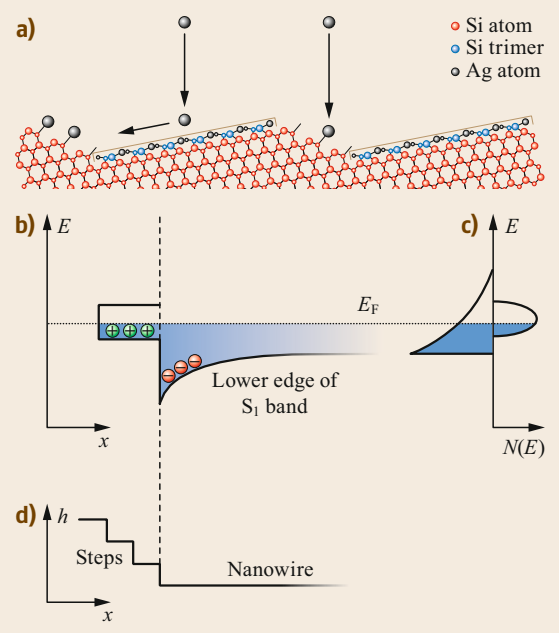

Fig. 19.12 **(a)** Sketch of doping mechanism by adsorption of surplus Ag atoms (*gray balls*) on both the uncovered steps and the Ag monolayer on flat terraces, where they diffuse and are trapped at step edges. **(b)** Lateral band bending resulting from different adsorption energies (and corresponding level filling **(c)** at terraces) and step edges, schematically shown in **(d)**. (Reproduced by permission from [19.100])

The final proof for this model came from the fact that, similar to the Pb/Si(557) system (Sect. 19.2.2), Ag/Si(557) also modifies surface and step energies, so that at high temperature (here 600 °C), the surface becomes unstable in the presence of a monolayer of Ag and tends to form larger (111) terraces and step bunches. Extended heating of the Ag-covered surface to 600 °C roughly doubled the average terrace size. This provided unique proof of the extrinsic doping mechanism, since the line doping concentration remains essentially constant at saturation, but the overall concentration is reduced with increasing terrace size, as the amount of electrons donated by the dopant atoms is distributed over the larger (111) terraces [19.100].

19.2.2 Between 1-D and 2-D: Pb/Si(557)

The situation is much less clear in the Pb/Si(557) system, although at first glance it looks quite similar to Ag/Si(557). For a critical coverage of 1.31 ML and at low temperature (below 78 K) the system clearly has 1-D properties in electrical conductance due to Fermi nesting and 1-D band filling induced by facet formation. Faceting locally transforms the surface into a (local)

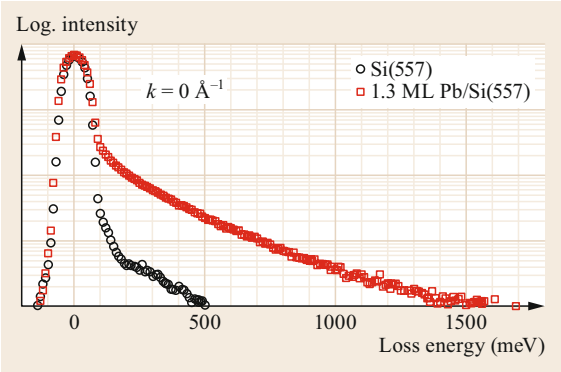

Fig. 19.13 Comparison of the electron loss spectra on clean Si(557) (*circles*) and that with 1.31 ML of Pb adsorbed at $q_{\parallel} = 0$. Due to the metallic property of the Pb layer, an exponentially decaying continuum of losses is seen (Drude tail). Primary energy $E_0 = 20$ eV. (Reproduced by permission from [19.42], © APS 2011)

(223) orientation [19.31, 36] that causes the opening of a small 1-D gap of 25 meV around the critical coverage. On the other hand, this high Pb concentration exhibits relatively strong electronic coupling between the terraces, so that the general appearance of the band structure is 2-D-like, but with 1-D properties close to the Fermi energy. This leads to the following intriguing question: are such 1-D properties still visible in collective electronic excitations with energies far higher than the bandgap of 25 meV? There may even be a transition between 1-D and 2-D behavior depending on the available decay processes into single-particle excitations.

The metallicity of the layer at 1.31 ML Pb coverage can be easily identified even qualitatively by comparing the electron energy loss spectra for the clean and Pb-covered Si(557) surface. Whereas for Si(557), only phonons can be created at small excitation energies, the continuum of low-energy electronic excitations in a metallic system results in a broad structureless background with exponentially decaying intensity as a function of loss energy. This is a clear signature of metallicity for the monolayer Pb/Si(557) system.

For the critical Pb concentration of 1.31 ML the HREELS spectra as a function of q both parallel and perpendicular to the terraces were measured at room temperature and with liquid-He cooling (Fig. 19.13). No clear temperature dependence was found. While a clearly dispersing loss peak was observed in the direction along the wires, no such loss was detected in the perpendicular direction. In other words, plasmonic excitations have a clear a 1-D dispersion at this Pb coverage. As seen from Fig. 19.14, the measured data points can be naturally extrapolated to zero momentum and zero energy. The dispersion can be quantitatively described by a model of a confined 2-D electron gas

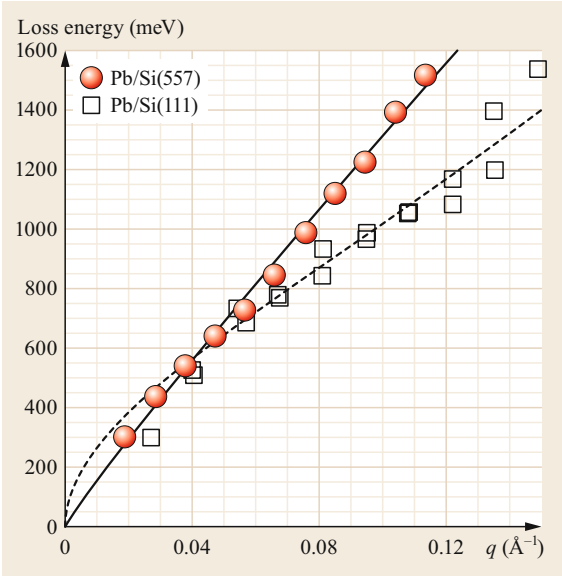

Fig. 19.14 Dispersion for 1.31 ML Pb on Si(557) parallel to the steps (*red balls*), compared with that obtained for the same coverage of Pb on Si(111). The *solid curve* is a quasi-1-D fit with $m^* = 0.4m_e$ and $N_{1\text{-D}} = 3.6 \times 10^7$ cm^{-1} (see text), whereas the *dashed curve* is a 2-D fit with the nearly free electron gas (NFEG) model with an effective mass of $0.4m_e$ and an electron density of $N_{2\text{-D}} = 2.4 \times 10^{14}$ cm^{-2}. (Reproduced by permission from [19.42], © APS 2011)

with local field corrections and correlations [19.44, 101] using a *single* four-atoms-wide metallic strip that is confined in a parabolic potential with the effective mass, m^*, and the 1-D electron density, N_D, given in the caption of Fig.19.14. Further details can be found in [19.42]. As also seen by the comparison with an analogous measurement for the isotropic Pb/Si(111) layer (see Fig. 19.14), there is a clear qualitative difference between a 1-D and a 2-D system (note that both dispersions must go through zero). Unlike the Ag/Si(557) system [19.43], however, no indications for quantum well confinement were detected.

The missing temperature dependence of the 1-D plasmonic dispersion can be taken as an indication that the physical mechanism for decoupling the plasmonic excitation on the various terraces cannot be related solely to Fermi nesting and opening of the 1-D bandgap. The absence of quantum well states means that the simple picture of a confining potential must be questioned. The key to this seemingly contradictory behavior may be hidden in the spin structure and the preferentially antiferromagnetic spin orientation on adjacent terraces, which leads to orthogonal electronic states. While there are no measurements, part of this spin correlation may still exist even at room temperature and consequently reduce the coupling. In the direction normal to the steps, the high resistance of steps [19.102], which at this Pb concentration turned out not to be covered by Pb [19.103], is already sufficient to prevent the formation of plasmon waves in this direction. This situation, however, is modified by the gradual filling of step edges with Pb at higher Pb concentrations.

Interestingly, the quasi-linear dispersion remains when the steps are decorated by Pb, as shown now by increasing Pb coverage to 1.4 ML. At this Pb concentration, about half of the Si step edges are decorated [19.104]. While these added chains increase the coupling between different terraces, the effective bandgap is also reduced [19.105]. Both changes in coupling parameters between terraces now lead to the behavior documented in Fig. 19.15. While there was no detectable signal for long wavelengths, losses and their dispersion were found both parallel and perpendicular to the steps for wavelengths shorter than 15 nm, and with quite small anisotropy of about 10%. This means that when switching on the coupling between terraces, dispersing plasmonic excitations appear with wavelengths that are more than ten times the terrace width.

It should be noted that a quasi-linear dispersion is still detected in both directions, similar to the Au(788) system discussed above. Anisotropy seems to be sufficient for the linearization of the plasmon dispersion. This finding may be obvious from (19.8) for the direction parallel to the wires, but not along the perpendicular direction. Unlike the Au(788) surface, we find here that propagating and dispersing plasmons normal to the wire direction are found only at wavelengths considerably shorter than the undistorted periodicity of (223) facets. This lack of periodicity for distances larger than 20 nm, of course, also makes it impossible to form long-wavelength plasmons here.

Thus there is a clear crossover behavior from 1-D to 2-D induced by a very small change in the surface concentration of Pb. At this moment there is neither a clear understanding of the underlying physical mechanism for the crossover nor a quantitative theory for the plasmonic excitations in these anisotropic low-D systems.

Interestingly, the metal-insulator transition of In/Si(111), historically the first well-investigated quasi-1-D system [19.28], was not only seen in DC conductance, but could also be detected by the disappearance of the plasmonic loss [19.3, 40], in contrast to the Pb/Si(557) system.

At first glance, these findings seem to be contradictory: the phase transitions in both systems are obviously of first order, though with opposite sign of temperature, the main difference lying in the structural changes in-

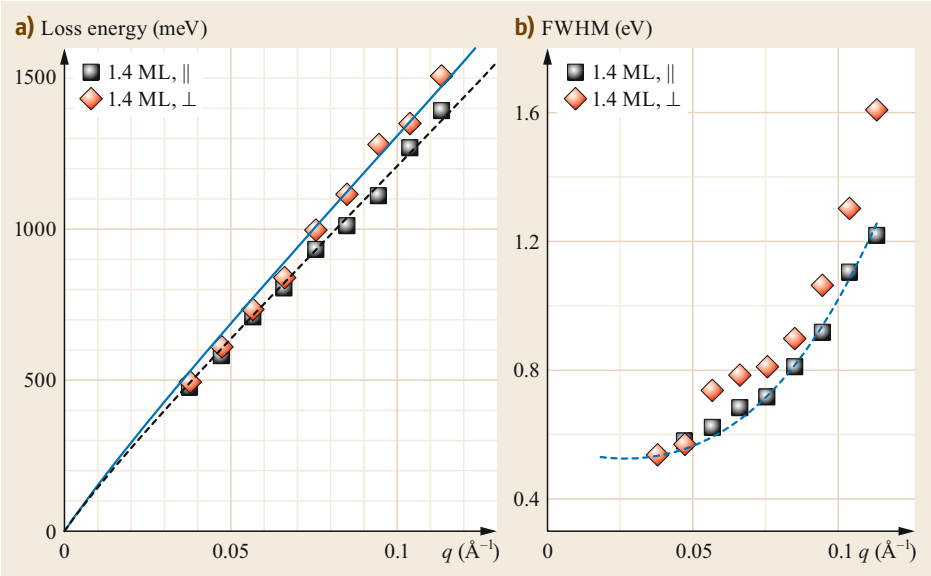

Fig. 19.15 **(a)** Dispersion parallel and perpendicular to the Si(557) steps. **(b)** Corresponding half widths (FWHM) of the measured losses. The *dashed curves* correspond to the results of 1.31 ML. (Reproduced by permission from [19.42])

volved. In Pb/Si(557) the Pb structure on each terrace essentially remains the same when going through the phase transition [19.106]. Only the average step distance is changed, by just 3.5% [19.103], which turns out to be sufficient to destroy the nesting condition at the critical coverage of 1.31 ML, and to form a sequence of charge density waves with varying periodicity and decreasing bandgap normal to the steps as a function of increasing Pb concentration [19.104]. The electronic changes in the band structure of this system associated with the metal–insulator transition also seem to be small. The plasmon excitation seems to be quite insensitive to these small electronic changes. This scenario contrasts very much with the strong structural and electronic changes in the In/Si(111) system when going from the (4×1) to the low-temperature (8×2) phase [19.33, 107], which involves melting and disappearance of the whole CDW system.

19.2.3 Coupling in Atomic Wires: Si(*hhk*)–Au

Au chains on regularly stepped Si(111) surfaces, tilted at various angles toward the $[\bar{1}\bar{1}2]$ direction, provide the narrowest possible arrays of chains consisting of either one or two atoms, depending on the type of step. Here, only double steps of Si separate the (111)-oriented terraces. Although purely 1-D dispersion along the chain direction is found, the lateral extension of the charge distribution, determined by both the structural motif and the terrace width, is found to explicitly influence the slope of the measured plasmon dispersion curves. In other words, the crossover into the second dimension is crucial for the quantitative interpretation of this quasi-1-D phenomenon, but is not completely described by existing theories.

Depending on coverage and step density, the widths of the Au-chains and their interwire spacing can be tuned, while their electronic band structures are still very similar. For example, 0.2 ML of Au on Si(557) results in growth of single-atom Au-chains and a row of Si-adatoms on each mini-terrace, with an interwire spacing of 19.2 Å [19.3, 108]. In contrast, Si(553) and Si(775)-Au host double Au chains in the center of the terrace [19.34, 109]. The interwire spacing is 14.8 for Si(553) and 21.3 Å for Si(775) [19.108, 110, 111]. For double Au chains, a nominal coverage of 0.48 ML on Si(553) and 0.32 ML on Si(775) results. Common to all these structures is a graphitic Si-honeycomb chain located at the step edges [19.108, 110, 111]. Each of these systems is characterized by metallic bands that are well known from angle-resolved photoemission (ARPES) measurements [19.108]. They only disperse along the chain direction $q_{\|}$, and have their minima at the zone boundary. Thus, the (equilibrium) electron density available for plasmonic excitations is also well known.

Here we compare the collective excitations in Si(553)-Au and Si(775)-Au, which have the same structural motif of the double gold chain. Furthermore, the Si(553)-Au system allows the coupling between wires to be varied, because it forms two phases. In the high-coverage (HCW) phase at Au coverage of 0.48 ML, all terraces are covered with a double strand of Au, whereas in the low-coverage (LCW) phase, at 0.21 ML, only every second terrace hosts the double gold chain [19.45, 112]. We will also make reference to the Si(557)-Au system with only a single gold chain.

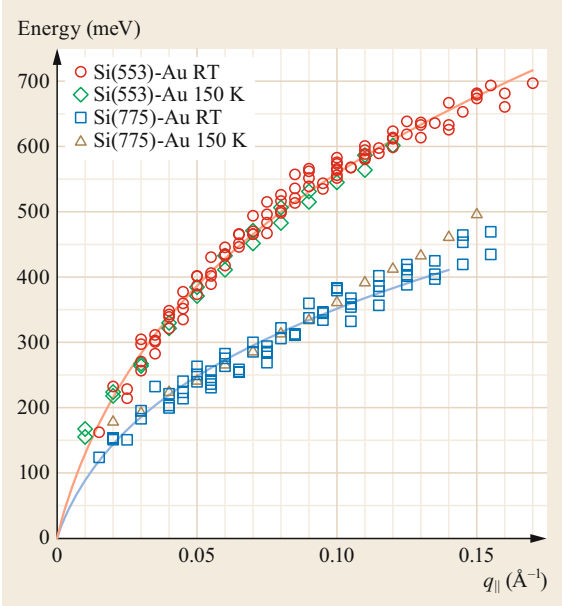

Fig. 19.16 Plasmon dispersion for Au quantum wires grown on Si(553) (HCW phase) and on Si(775). *Lines* are fits according to (19.9). For further details, see text. (Adapted with permission from [19.114]. © 2002 by the American Physical Society)

Interestingly, the step structure seems to have a significant influence on the coupling between wires on different terraces. While the Au wires on Si(553) and Si(775) seem to be strongly coupled, as shown later, this coupling was found to be weak for Au/Si(557) [19.95]. The plasmonic coupling between the wires in the ordered arrays, which is another aspect of dimensional crossover, is quantitatively modeled by existing mesoscopic theories [19.97, 98].

Contrary to the EELS spectra for Ag/Si(557) shown above, the spectra for all Au systems close to $q_\parallel = 0$ are structureless, apart from a small non-dispersing feature that dies out quickly with increasing $q_\parallel$. Metallicity is demonstrated by the exponentially decaying background intensity as a function of loss energy, known as the Drude tail [19.100], in agreement with findings from ARPES for the Si(553)-Au [19.108], scanning tunneling microscopy (STM) [19.113], and theory [19.111]. However, this result is at variance with the ARPES data for the Si(775)-Au [19.108] for reasons still to be explored. In the direction along the wires, clear loss features are observed, which shift to higher loss energies with increasing scattering angles, i.e., with increasing $q_\parallel$. In the $k_\perp$ direction, however, and similar to Ag/Si(557), no dispersing mode is seen.

The dispersion curves along the wires, derived from the loss maxima, are shown for Si(775)-Au and for the HCW phase of Si(553)-Au in Fig. 19.16. From the ARPES data cited above, the ratio of electron densities and effective masses is found to be virtually identical in the two systems for all surface bands. Therefore (19.9), and in spite of two existing bands, only one plasmon loss is expected, in agreement with our findings. Thus, for a true 1-D system, no dependence on terrace width, d, is expected to first order. This is obviously not the case, since a $1/d$ dependence is found. Using existing theories for a nearly free electron gas confined in quasi-1-D wires [19.40, 96, 97, 115], it was found that a quantitative fit was possible with a modified model of coupled wires sitting in a periodic array of square potentials at distance d [19.97, 98]. At small $q_\parallel$, the dispersion is given by

$$E = \hbar \sqrt{\frac{4ne^2}{(1+\epsilon)\epsilon_0 m^* a^2} q_\parallel a_0} \times \sqrt{K_0\left(\frac{q_\parallel a}{2\sqrt{2}}\right) + 2\sum_{l=1}^{L} K_0(q_\parallel l d)\cos(k_\perp l d)}\,, \tag{19.9}$$

where the first term of the product contains the electronic and structural properties of a single wire, the second the intrawire (first term under square root) and the interwire interaction; n is the electron density per unit length, e the elementary charge, m^* the effective mass. ϵ is the dielectric function of Si as partially embedding medium. K_0 are modified Bessel functions of zeroth order and second kind, $k_\perp$ is the momentum normal to the wires. If a (the effective wire width) is set equal to a_0 (a constant for normalization), (19.9) corresponds to the original formula given in [19.97, 98], which, however, turns out not to describe our findings. The ratio a_0/a accounts for both differences in structural motifs and effective wire widths of a single wire, and is the only free parameter in (19.9). In the array of square potentials, the first term under the second square root accounts for the self-interaction of a single wire, whereas the second term describes the interaction between different wires at multiple distances of d.

A further test of the sensitivity of the dispersion to the structural motif was carried out by fitting the published data of [19.3] for Si(557)-Au to (19.9). The Si(775) and Si(557) surfaces have almost the same terrace widths (21.2 versus 19.8 Å, respectively). However, for the best fit, the first term of (19.9) has to be a factor of 1.6 *larger* for Si(557)-Au than for Si(775)-Au. Taking the differences in n and the d-dependence from above for the two systems, the effective width a, as suggested in (19.9), is reduced by roughly a factor of 2 for Si(557)-Au compared with Si(775)-Au. These

results demonstrate that the dispersion is directly influenced not only by the periodicity, given by the wire distances d, but also by the *internal 2-D distribution* of the (excited) electron density within each wire. This result for Au/Si(557) is very much in agreement with the findings of [19.95]. Subband excitations, as in the Si(557)-Ag system, can be ruled out here as a possible source of the observed differences, since for these narrow structures and the given k_F, only the lowest subband of a quantum well is occupied. These results show that even in the case of purely 1-D plasmonic dispersion, there is a crossover to 2-D, and both the width of a wire on the atomic scale and the internal electronic distribution within the wire itself enter directly into the slope of plasmonic dispersion. Additional details, e.g., the choice of a_0, can be found in [19.45].

As it turns out, the LCW phase of Si(553)-Au can be described by the same formalism as (19.9) [19.114]. In fact, according to the analysis of *Song* et al. [19.112], the Au-covered terraces should have the same terrace width as in the HCW phase, whereas the empty terrace acts as separator between the Au wires.

This same effective wire width, however, does not reproduce the measured dispersion for the LCW phase, if we only assume a reduced coupling between wires due to their increased interwire distance from 14.8 to 32.7 Å. By actually fitting the data with a as a free parameter, we obtain an effective wire width of 8.8 Å, compared with 7.5 Å for the HCW phase. This effective spreading of the plasmon excitation on the terrace is in fact quite plausible. In the LCW phase, terraces not covered by gold are under tension [19.112], with the consequence of atomically rough edges. This gives the plasmon mode the ability to spill out more into the uncovered neighboring terrace by approximately $0.5a_\perp = 1.66$ Å. Assuming the same proportionality factor between terrace width and effective wire width as for the HCW phase [19.45], a corrected value of 8.5 Å is obtained that is very close to the value obtained here. Therefore, this result fits the general picture for the stepped Au-covered Si surfaces that the electron density spills out as far as possible, limited by the structure of the step edges, and expresses the crossover of two-dimensional properties on the one-dimensional plasmon dispersion. The effect of spill-out of electrons in the LCW phase compared with HCW may also be taken as indication of softening of the confining potential. A softer potential than the square would in fact have a qualitatively similar effect at constant effective wire width.

Summing up this section, we demonstrated that the Si(hhk)-Au systems offer the unique possibility to study both the spreading of the chain-induced electron density on the mini-terraces and the influence of wire coupling in plasmonic excitations of quasi-one-dimensional arrays of gold chains. As it turns out, there is an intriguing interplay between geometric terrace width and structural motif that influences the effective wire width, as is obvious from a comparison of, e.g., Si(775)-Au and Si(557)-Au. Coupling between wires, on the other hand, varies both with terrace size and with the step structure. These phenomena of course have a direct influence on the band structure in these systems. The relationship between plasmon dispersion and band structure is the subject of future investigations. Coming back to the Ag/Si(557) system, it is mainly the large average separation between terraces in the Si(557)-Ag system that makes them appear as essentially isolated wires. Weak coupling across Si(557) steps, which was found to be much weaker for Si(557)-Au than for Si(775)-Au, acts in the same direction.

19.3 Measured Peak Width of Plasmon Losses

So far, we have used only the information about peak positions, and have not discussed the line widths of the plasmon losses. These loss peaks were found to be fairly broad and not limited by the instrumental energetic resolution of the measurements. We discuss this problem using the recent example of Au/Si(553).

From a quick look at the measured width of the loss peaks, as shown in Fig. 19.17 for both Au phases on Si(553), particularly in the limit of $q_\parallel \to 0$, it is already obvious that these widths cannot be attributed to a lifetime, since in this limit the plasmonic excitation energies also go to zero. Consequently, the lifetimes have to go to infinity. Taking the measured width as lifetime would mean that the plasmonic excitation is highly overdamped, and plasmonic excitations would not exist. This is in sharp contrast to plasmons (at 125 meV) in comparable systems, where mean free paths exceeding 200 nm were observed [19.116]. Therefore, the FWHM at $k = 0$ must be the convolution of instrumental resolution in reciprocal space and in energy of the spectrometer, possibly also with a contribution caused by the short interaction time of the electron scattering process. The energy resolution of the instrument, however, cannot be the main source of the measured half widths—it accounts for only up to 10% of the measured FWHM. Geometric imperfections, as seen by the finite width in k for the elastic peak, is another source, since it will cause corresponding averaging over the disper-

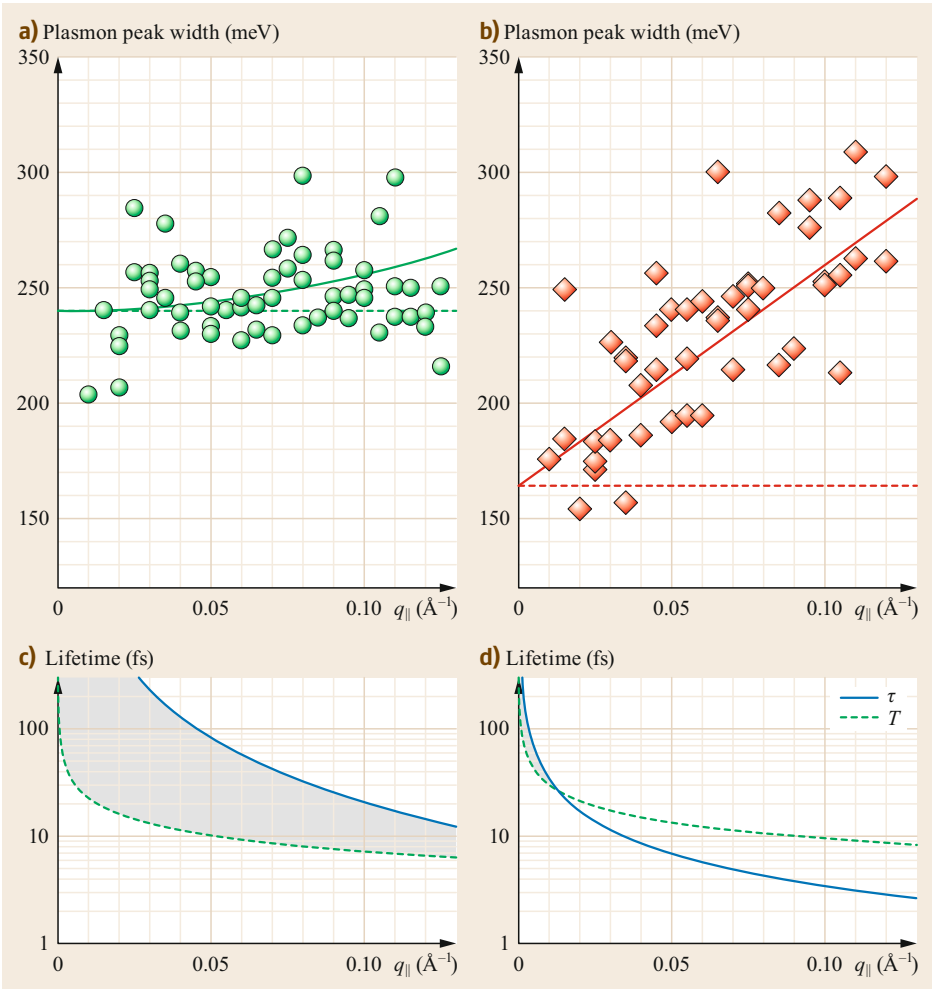

Fig. 19.17 **(a,b)** Plasmon peak widths for varying $q_\parallel$ as a measure of the change in plasmon lifetime for the HCW **(a)** and LCW phase **(b)**. **(c,d)** Estimated lifetimes τ from the data above after the subtraction of the *dashed* offset in comparison with the oscillation period T derived from the dispersion relations (see text). sion and thus energetic broadening. From systematic studies of LEED profile analysis, it can also be safely ruled out here as a main source of broadening. The finite k-space resolution of ± 0.01 Å^{-1}, however, can be the main source of broadening, as seen by a comparison with the slope of dispersion of the HCW phase from Fig. 19.16. Since this slope is generally lower by about 30% for the LCW phase than the HCW phase, the broadening in the limit of $q_\parallel \to 0$ is correspondingly reduced, as indeed seen in Fig. 19.17. Therefore, the short interaction time of the inelastically scattering electrons as the possible reason for broadening seems to play a minor role. It may, however, not be negligible in the present case, since only near-field multipole scattering can be effective here—dipole scattering cannot transfer the momentum necessary for excitation—the scattering process being closer to impact scattering [19.117].

Starting from the FWHM at $q = 0$ as an *instrumental* baseline, there is a tendency for a slight increase in FWHM by about 30 meV at $q_\parallel = 0.13$ Å for the HCW phase. This increase is much higher for the LCW phase and amounts to about 120 meV for the same range of $q_\parallel$. Two interpretations seem possible: broadening due to reduced lifetime with increasing energy of excitation, or inhomogeneous broadening caused by the existence of two plasmons.

For the HCW phase, lifetime broadening alone seems to be a possible explanation for the observed increase in FWHM as a function of $q_\parallel$, depicted in Fig. 19.17c. Using the procedures as just described, we approximated the increase in the peak widths by polynomial functions of second order (solid curves), subtracted the offset (dashed lines), and estimated the lifetime with Heisenberg's uncertainty principle of $\Delta E \Delta t \geq \hbar/2$, which yields the blue curve in Fig. 19.17c. This curve still represents a lower limit, since no broadening due to slight energetic differences in the two plasmon modes, especially at higher $q_\parallel$, was

assumed to exist. In any case, it is compatible with other data [19.116].

For the LCW phase, on the other hand, lifetime broadening as the main source of the increase in FWHM can be ruled out right away. Assuming that we can simply subtract the half widths of the baseline from the measured ones, the determined *lifetime* τ as a function of $q_\parallel$ quickly falls below the time T necessary for a single plasmon oscillation, as shown in Fig. 19.17d. Of course, this overdamped situation is unphysical. Therefore, it seems more realistic that a large part of the broadening seen is due to the existence of two plasmons.

From the large line widths of the plasmonic losses observed for both phases and their weak dependence on $q_\parallel$, we conclude that the main contribution is not due to short lifetimes, but even with the high momentum resolution of the present instrument is still mainly caused by the finite instrumental q-resolution, i.e., there is still a need for further experimental improvement. While the two plasmons originating from the two Au-induced electronic surface bands cannot be resolved in either HCW or LCW phases, their larger difference in excitation energy in the LCW phase leads to an additional contribution to the measured half widths.

19.4 Conclusions

Considerable knowledge has been gathered over the past 20 years on the dispersion of 2-D sheet plasmons. Plasmon dispersion in these systems—a few characteristic examples have been shown above—can be described surprisingly well by a nearly free electron gas, even with the modifications of massless fermions in a relativistic electron gas. The inclusion of correlation effects beyond RPA seems to have mainly a quantitative effect on the general slope of dispersion. At long wavelengths, the dependence on electron density of plasmons in a nonrelativistic electron gas, on the other hand, seems to follow the $\sqrt{n_e}$ dependence in all dimensions. Only in the relativistic case is it reduced to $\propto n^{1/4}$.

Furthermore, two main possibilities for linearization of plasmon dispersion have been identified that are quite important for potential signal transmission via plasmonic coupling. The first is due to the general form of plasmon dispersion (see 19.1), if the second term of this equation dominates. This condition depends on k_F, and it can be easily achieved at low electron concentrations and large $q_\parallel$. In the special case of a relativistic electron gas such as in graphene, it leads to the observed insensitivity of plasmon dispersion with respect to the doping level at large $q_\parallel$. In other words, the tunability of plasmons in graphene by changes of the doping level only exists at long wavelengths (terahertz to far-infrared range). The short wavelengths can still be used, but the strategy must be the selection of certain wavelengths, which are then quite robust against distortion. On metal surfaces in particular, this range is even more limited due to the large value of the real part of the dielectric function of metals at terahertz frequencies.

Linearization of plasmon dispersion already in the long wavelength limit can be achieved by coupling a 2-D electron gas to other 2-D or 3-D electron gases, leading to the acoustic surface plasmon (ASP). This property has been demonstrated for the Shockley surface states on Be(0001) and on the (111) surfaces of noble metals, but the concept is fairly general. For example, it might also be applicable for stacks of 2-D metallic sheets separated by insulating material, or for stacks of graphene sheets, thereby combining linear dispersion with tunability.

In the anisotropic 2-D case, which as a limit includes the quasi-1-D wires, the situation is less clear. While it is obvious that restriction of an electron gas to 1-D leads to linearization of the plasmon dispersion already to lowest order in $q_\parallel$, there is an explicit dependence of dispersion on the form of the confining potential. Furthermore, the crossover into the second dimension by explicit consideration of the wire width and the role of coupling of plasmonic excitations with the environment is a general problem whose description is still incomplete. Also, the role of correlations exceeding NFEG properties is still an open question. This sensitivity to the embedding environment, on the other hand, opens many still largely unexplored possibilities for tuning and manipulation on both the experimental and the theoretical side.

The present experimental setups, mainly electron loss spectroscopy (HREELS, EELS-LEED), still enable only limited studies of the dynamics of 2-D and 1-D plasmons. The main limit is k-space resolution. It is obvious that there is sensitivity to atomic-size defects such as steps, which increases as a function of $q_\parallel$ [19.86], i.e., there is high sensitivity to the quality of long-range order and its imperfection on the atomic scale.

The questions related to electronic effects in plasmon dynamics, on the other hand, are an urgent problem that has been touched upon qualitatively at best, as our examples show. Since the low-D plasmons are more strongly damped than, e.g., surface plasmons due to the conductive properties of the metallic sheets and wires, but also of their environment, it is clear that solving these questions will be a key issue for any application of these plasmons.

Acknowledgments. It is a pleasure to acknowledge the experimental contributions of the groups in Hannover and in Genova to several parts of this work, in particular by T. Block, U. Krieg, T. Lichtenstein, L. Savio, M. Smerieri and M. Rocca. We also strongly benefited from collaborations and discussions with the theory group at DIPC, San Sebastian, Spain, in particular by the collaboration with V.M. Silkin. Financial support for this work by the Deutsche Forschungsgemeinschaft, mainly through FOR1700 and project Pf238/28, is gratefully acknowledged.

Genova, Italy
vattuone@fisica.unige.it

Luca Vattuone received his PhD from the University of Genoa in 1994, worked as postdoc at Cambridge University (1995) and at Genoa University (1996–1999). In 1999 he became Staff Researcher and in 2012 Associate Professor of Condensed Matter Physics at Genoa University. His research activity focuses on the experimental investigation of gas–surface interactions and surface plasmons.

20. Ab Initio Theory of Interband Transitions

Conor Hogan, Maurizia Palummo, Olivia Pulci, Carlo Maria Bertoni

This chapter reviews the principles behind the theory and computation of interband transitions at surfaces. Particular emphasis is given to state-of-the-art ab-initio methodologies, and their application is illustrated through numerous practical examples in realistic surface systems. Following a simple introduction, we outline a general theoretical framework of surface spectroscopy, obtaining an expression for the surface response function that is appropriate for computation with ab-initio methods and for simulating various experimental spectroscopic techniques. We then revise the key ab-initio approaches, namely, density functional theory, Green's function-based many-body theory, and time-dependent density functional theory. The rest of the chapter presents examples of calculations at different levels of theory for various clean and modified surfaces of current interest, illustrating in each case the interplay between the surface geometry, electronic band structure, and interband excitations. Advanced concepts such as local field and excitonic effects at surfaces are highlighted. The chapter concludes with an outlook on challenges in the field and perspectives for future development.

While direct access to surface electronic bands and their dispersions in semiconductor and insulator surfaces is provided by standard experimental techniques such as electron photoemission, inverse photoemission, and scanning tunneling spectroscopies, optical spectroscopies were the first experimental tools—since surface studies really took off about 50 years ago—to yield insight into surface states by means of interband transitions. Nowadays, surface optical spectroscopies, especially when carried out in combination with first-principles simulations, constitute a truly powerful method for characterizing the geometrical and electronic properties of surfaces and interfaces [20.1].

20.1 General Theoretical Framework

According to standard band theory, interband transitions occur when an external perturbation—typically an incoming electromagnetic wave—excites an electron from an occupied electronic state into an unoccupied state by absorption of a photon. At a surface, the states taking part in these transitions can be of different character, such as: *true* surface states, i.e., those that lie within the bulk electronic gap and are usually localized within the topmost surface layers; surface *resonances*, which have energies overlapping with the (projected) bulk band structure and are more delocalized than true surface states; and *bulk* states that terminate at the surface and are modified by the change in potential. (See Chap. 16 for a thorough discussion of electronic states at surfaces.)

Figure 20.1 illustrates the connection between the surface band structure and the optical absorption spectrum for a few such possible interband transitions. The transitions indicated in a plot where the electronic bands are a function of the $\boldsymbol{k}$ wavevector in the surface Brillouin zone are almost vertical when the frequency of the light is in the optical range (from IR to UV) and there is no coupling with vibrational excitations. In this simplest picture of direct transitions of noninteracting particles, the absorption probability is

$$\text{Absorption} \propto \sum_{i,j} |\langle i|\boldsymbol{D}|j\rangle|^2 \delta(E_j - E_i - \hbar\omega) \,. \quad (20.1)$$

The sum spans occupied and unoccupied states i and j, $\boldsymbol{D}$ is the dipole operator related to the perturbation, and the delta ensures that a peak will occur when the incoming photon energy $\hbar\omega$ resonates with the energy difference $E_j - E_i$. If the matrix elements $\langle i|\boldsymbol{D}|j\rangle$ are assumed to be constant, it is clear that the optical spectrum is proportional to the joint density of states. Equation (20.1) is, of course, general to all systems. In the case of surfaces, however, the optical absorption can show peaks or shoulders arising from transitions between (Fig. 20.1) (a) true surface states, (b) bulk states, (c) surface resonances, or, indeed, combinations of these, with the peak intensity being determined by the appropriate matrix element. As surface states can lie inside the bulk gap, it is clear that the onset of optical transitions can occur at a lower energy than for the bulk material.

One major problem with using optical probes to study surfaces, however, is sensitivity. Indeed, the penetration depth of light is quite large—about 10 nm for photon energies between 2 and 4 eV in GaAs. Hence, whereas electron spectroscopies are naturally surface sensitive, optical methods are much more sensitive to the bulk. In order to circumvent this issue, techniques have been developed that allow information about the surface optical response to be extracted. Two such techniques are reflectance anisotropy spectroscopy (RAS), developed independently by *Aspnes* [20.2] and *Berkovits* et al. [20.3] in 1985, and surface differential reflectance spectroscopy (SDRS), used by *Chiarotti* et al. [20.4] for the first time in 1968 to study the Ge(111) surface—the first evidence of optical transitions involving surface states.

In RAS experiments, the difference in reflectivity for light polarized along two perpendicular directions

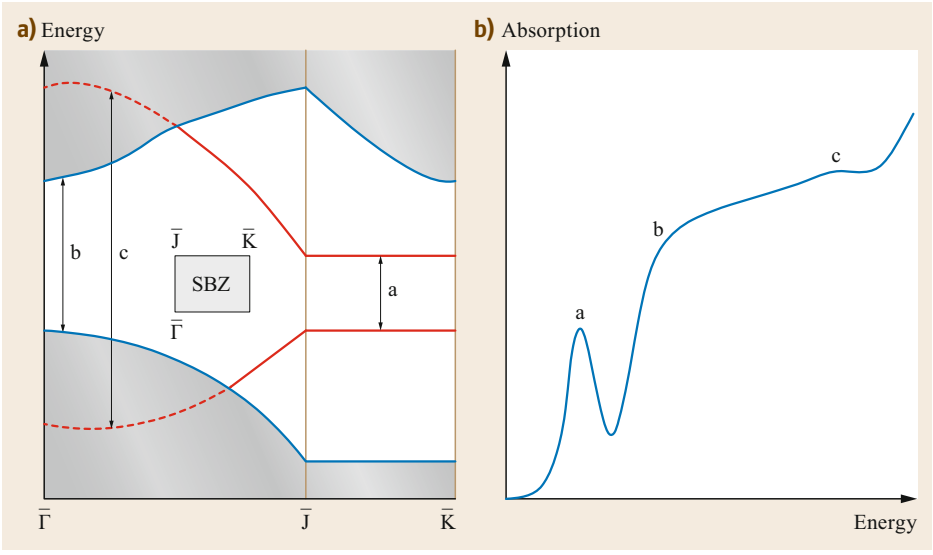

Fig. 20.1a,b Relationship between **(a)** the surface electronic band structure and **(b)** optical absorption due to typical interband transitions. Illustrated are transitions between true surface states a, projected bulk states b, and surface resonances c, respectively. SBZ denotes the surface Brillouin zone

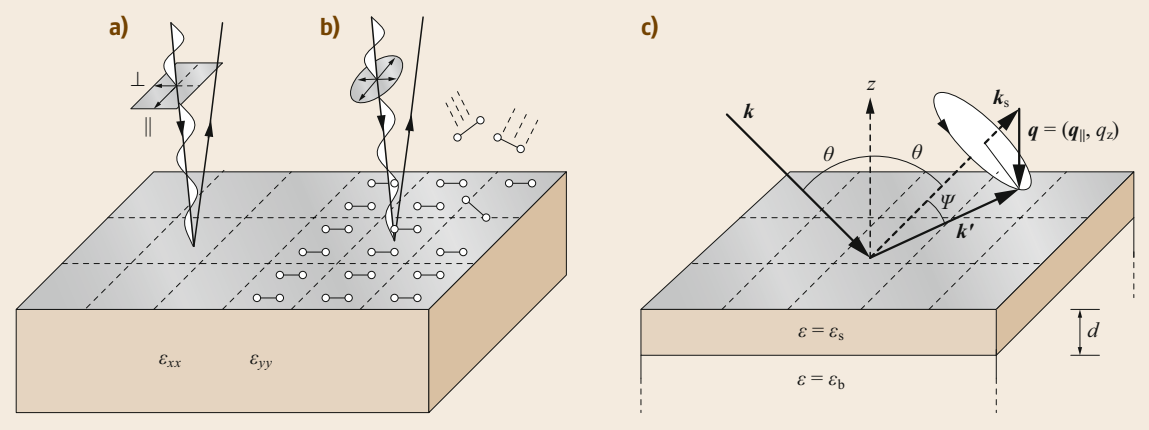

Fig. 20.2a–c Surface-sensitive optical and electronic spectroscopies. **(a)** Reflectance anisotropy spectroscopy (RAS). **(b)** Surface differential reflectance spectroscopy (SDRS). **(c)** Reflection/high-resolution electron energy-loss spectroscopy (REELS/HREELS). The surface response is represented by an anisotropic dielectric function **(a,b)** or an isotropic, three-layer model **(c)**

in the surface plane (x and y, usually parallel and perpendicular to the principal surface axes (Fig. 20.2a)) is measured. If the volume (bulk) is optically isotropic (e.g., in cubic materials), any observed signal must be due to the surface. As we will show later, such anisotropic signals are due to interband transitions involving states localized at, or modified by, the surface geometry. In the standard setup, RAS probes interband transitions in the 1.5−5.0 eV range, although this can be extended to the mid-IR and UV, and is thus sensitive to the full range of surface-derived transitions in semiconductors and insulators. For a recent review see [20.5, 6].

SDRS instead is based on measuring the change in reflectance due to chemical modification or deliberate contamination of the surface layer, typically via chemisorption of oxygen or hydrogen (Fig. 20.2b). Adsorption passivates (removes) the surface electronic states, thus modifying the optical response from the surface. Instead, the bulk response is unchanged and can thus be eliminated by measuring the reflectance change. SDRS is sensitive to *all* surface interband transitions, not only the anisotropic ones. It can easily measure transitions at low energies (≈ 0.5 eV). See [20.7] for a classic review and [20.8] for a modern application.

First-principles computation of interband transitions probed by these two spectroscopies are the main focus of this chapter. On the theoretical side (for some reviews, see [20.9–12]), simulation of RAS and SDRS has progressed beyond early dipole models and tight binding calculations and is nowadays capable of truly predictive analysis of experimental spectra based on first-principles atomistic simulations. Although other optical techniques exist that also probe interband transitions such as spectroscopic ellipsometry (SE) and nonlinear techniques such as surface second harmonic generation (SSHG) [20.1], we do not discuss them here, as they have been less studied at the ab-initio level (although progress is being made [20.13]). Interband transitions can also be probed by electron spectroscopies; the electric field associated with an electron beam impinging on a surface can induce interband excitations in a region well localized at the surface, with the resulting energy-loss function linked to the same response functions involved in the optical processes. In particular, reflection/high-resolution electron energy-loss spectroscopy (REELS/HREELS, Fig. 20.2c) can yield information that is complementary to that obtained with RAS or SDRS, and will also be considered here.

The chapter is organized as follows. Section 20.2 will introduce the theoretical framework for describing the response of a surface to photonic and electronic probes, respectively. The semi-infinite crystal surface itself will be modeled using a slab approximation, which allows the structure of the outer surface planes to differ from the geometry of the bulk planes. The microscopic slab polarizability α_s, together with the dielectric function of the underlying bulk material ε_b, will then be connected to the macroscopic (observable) RAS and SDRS signals in Sect. 20.2.1, and to the HREELS signal in Sect. 20.2.5.

Section 20.3 will discuss state-of-the-art ab-initio theoretical methods that allow the main microscopic ingredients, α_s and ε_b, to be calculated using quantum mechanical simulations. The basic framework for all atomistic simulations will be density functional theory (DFT), which is frequently used to compute the interband optical response in an independent particle (IP)

approximation. The effects of electron–electron interaction in the study of pair and collective excitations are addressed through many-body Green's function techniques and adequately approximated descriptions beyond the one-particle scheme. This is summarized in terms of single-particle excitations in Sect. 20.3.2 and two-particle excitations in Sect. 20.3.3. These methods constitute the state-of-the-art approach to calculate in an ab-initio framework the electronic and optical properties of materials beyond the mean-field DFT but including the so-called many-body effects (such as self-energy, local-field, and excitonic effects), allowing to improve the comparison with the experimental data and the predictive value of the simulations [20.11]. Section 20.3.4 shines a brief spotlight on an alternative way to include these effects by extending the capabilities of the DFT average-field approach to the description of excited states in the presence of a time-dependent perturbation: the time-dependent density functional theory (TDDFT).

Sections 20.4 and 20.5 will present examples of RAS, SDRS, and HREELS calculations performed mostly at the independent-particle level and applied to a range of clean and modified surfaces, respectively. In each case, we will show how atomistic simulations allow the surface spectra measured to be interpreted in terms of specific interband transitions linked to the surface geometry and the related electronic states. We will consider only semiconductor surfaces. Here, large rearrangements of the bonding geometry in the outermost layers occur, which allow the surfaces to stabilize energetically. In particular, the formation of dimers and their involvement in the interband transitions will be considered in Sects. 20.4.1 and 20.4.2. The influence of steps and defects, i.e., typical features of real surfaces, are briefly discussed in Sects. 20.4.3 and 20.4.4. Changes in the optical properties due to adsorption of atoms and molecules, and adlayer formation, will be discussed in Sect. 20.5. Although metal surfaces also show distinct interband peaks in their optical spectra, the major features are due to bulk dispersive effects, plasmons, and intraband transitions, which lie outside the scope of this chapter (see, instead, Chaps. 17 and 18). Nonetheless, theoretical studies of RAS/SDRS can be found for systems based on metal surfaces and ordered adsorbates such as Ag(111):Si [20.14], Ag(110) [20.15, 16], Cu(110) [20.16, 17], and Cu(110):CO [20.18].

Section 20.6 will discuss cases where it is strictly necessary to include correlation, excitonic, and local field effects well beyond a simple description in terms of a joint local density of states picture. Calculations of RAS and SDRS based on many-body Green's functions (Sect. 20.6.1) and TDDFT (Sect. 20.6.2) will show how the simple picture of electronic interband transitions begins to break down, especially where strongly bound excitons are present as on the C(100) surface (Sect. 20.6.3).

Finally, in Sect. 20.7 we will provide a glimpse of present and future challenges in the field and present some cases that are still open.

20.2 Theory of Surface Spectroscopy

In this section we establish the general phenomenological description of RAS, SDRS, and HREELS in terms of the surface and bulk dielectric functions. The recipe for the actual microscopic computation procedure that provides the link with surface interband transitions will be given in Sect. 20.3. We will not attempt to give an exhaustive account of the theory: for this, we refer the reader to the classic overview by *Del Sole* [20.19].

20.2.1 Surface Response Function

The reflected light from a surface carries information both on the surface and on the bulk, as the light wavelength in the infrared (IR), visible and near-UV regions is much larger than the surface reconstruction characteristic length usually involving only few atomic layers. Thus, the atomic reconstruction and electronic properties of surfaces by light reflectance can be investigated, depending on the ability to identify and to separate surface and bulk contributions. To this aim the surface sensitivity is achieved by measuring differences between signals, to enhance the surface contribution with respect to the bulk.

Classical electrodynamics provides the description of reflection and refraction laws at the abrupt interface between vacuum and a continuous dispersive medium of dielectric function $\epsilon(\omega)$, through the matching of the parallel component of the electric field $\boldsymbol{E}$ and of the perpendicular component of the electric displacement field $\boldsymbol{D}$. Neglecting spatial dispersion, $\boldsymbol{D}(\omega) = \epsilon(\omega)\boldsymbol{E}(\omega)$. The Fresnel equations give the reflectivities when the electric field vector is parallel to the plane of incidence (p-polarization),

$$R_{\mathrm{p}} = \frac{\epsilon(\omega)q_z - q'_z}{\epsilon(\omega)q_z + q'_z} \qquad (20.2)$$

and perpendicular (s-polarization)

$$R_s = \frac{q_z - q_z'}{q_z + q_z'} , \tag{20.3}$$

where q_z and q_z' are the components perpendicular to the surface of the light wavevector in vacuum and in the bulk, respectively.

A fully microscopic model must take into account the local dependence of $\boldsymbol{D}(\boldsymbol{r}, \omega)$, and $\boldsymbol{E}(\boldsymbol{r}, \omega)$,

$$\boldsymbol{D}_\alpha(\boldsymbol{r}, \omega) = \sum_\beta \int \mathrm{d}^3\boldsymbol{r}' \epsilon_{\alpha\beta}(\boldsymbol{r}, \boldsymbol{r}'; \omega) \boldsymbol{E}_\beta(\boldsymbol{r}', \omega) . \tag{20.4}$$

where α and β label the cartesian coordinates and $\epsilon_{\alpha\beta}(\boldsymbol{r}, \boldsymbol{r}'; \omega)$ is the microscopic dielectric matrix of the whole vacuum–surface system and interface. In the case of homogeneous systems, $\epsilon_{\alpha\beta}(\boldsymbol{r}, \boldsymbol{r}'; \omega) \approx \epsilon_{\alpha\beta}(|\boldsymbol{r} - \boldsymbol{r}'|; \omega)$ and (20.4) simplifies if the wavelength of the electric field $\boldsymbol{E}_\beta(\boldsymbol{r}', \omega)$ is large in the region where the microscopic dielectric function is nonvanishing, because $|\boldsymbol{r}' - \boldsymbol{r}|$ is of the order of some Å. Then the relation becomes local

$$\boldsymbol{D}_\alpha(\boldsymbol{r}, \omega) = \sum_\beta \epsilon_{\alpha\beta}(\omega) \boldsymbol{E}_\beta(\boldsymbol{r}, \omega) \tag{20.5}$$

and the dielectric tensor components

$$\epsilon_{\alpha\beta}(\omega) = \int \mathrm{d}^3\boldsymbol{r}' \epsilon_{\alpha\beta}(|\boldsymbol{r} - \boldsymbol{r}'|; \omega) \tag{20.6}$$

do not depend on position $\boldsymbol{r}$ because of the overall translational invariance of the crystal at long wavelengths. However, in real crystals, the atomic structure introduces a spatial inhomogeneity in the electron density at a microscopic level. This means that an external spatially constant perturbing field can induce fluctuations on the scale of the interatomic distances in the material, giving rise to additional internal microscopic fields. These are known as *local field effects*, that we can neglect only at a first approximation. It has been shown that local-field effects are important in some cases [20.20, 21]. In crystals with cubic symmetry, the dielectric tensor is diagonal and can be written as $\epsilon_{\alpha\beta}(\omega) = \epsilon(\omega)\delta_{\alpha\beta}$, where the *isotropic dielectric function* $\epsilon(\omega)$ appears.

Even neglecting the local-field effects, the dielectric function at the crystal–vacuum interface is intrinsically nonlocal and inhomogeneous. The dependence of the dielectric response on the coordinate perpendicular to the surface plane (z) should be considered. In the case of a system composed by vacuum for $z < 0$ and a semi-infinite solid for $z \geq 0$, (20.4) can be written for fields with a plane-wave dependence on coordinates and a phase of the form $\exp[\mathrm{i}(q_x x + q_z z - \omega t)]$ (the wavevector lies in the incidence plane xz). The resulting expression is given by

$$D_\alpha(q_x, z; \omega) = \sum_\beta \int \mathrm{d}z' \epsilon_{\alpha\beta}(q_x, z, z'; \omega) \times E_\beta(q_x, z'; \omega) , \tag{20.7}$$

which is valid in the long-wavelength limit $q_x \to 0$. In this case, the q_x-dependence can be omitted, and $\epsilon_{\alpha\beta}(z, z'; \omega)$ in this limit is a *macroscopic* nonlocal dielectric tensor (with the dimension of the inverse of a length) that describes the dielectric response of a medium nonuniform in the z-direction and, in principle, includes all nonlocal corrections in the normal plane in the long-wavelength limit.

The first attempt to solve Maxwell's equations for a realistic macroscopic model of a surface was done by *McIntyre* and *Aspnes* [20.22], where a surface layer of thickness d of a few Å, with a dielectric constant ϵ_s, was put in between the vacuum and a bulk region, with $\epsilon_v = 1$ and $\epsilon_b(\omega)$, respectively, and neglecting the surface anisotropy and nonlocality. The inhomogeneity was approximated by an abrupt step in both boundaries. The corrections to the Fresnel expressions at first order in $(\omega/c)d$, for $\Delta R_s(\omega)/R_s(\omega)$ and $\Delta R_p(\omega)/R_p(\omega)$ were found. They reduce to a simple expression that is the same for both cases when the incident angle is $\theta = 0°$ (normal incidence)

$$\frac{\Delta R_{s,p}(\omega)}{R_{s,p}(\omega)} = \frac{4\omega d}{c} \operatorname{Im}\left\{\frac{\epsilon_s(\omega) - \epsilon_b(\omega)}{\epsilon_b(\omega) - 1}\right\} . \tag{20.8}$$

The general formulae at $\theta \neq 0$ are not reported here, but this *three-layer model* was widely used at that time to interpret spectra and appeared to fail for high θ values, especially at grazing incidence.

In 1979, *Bagchi* et al. [20.23] developed a perturbation procedure to consider the variations in the vicinity of the surface. In their model, the bulk was assumed to be local, while the surface response was anisotropic with respect to the zz-component of the dielectric tensor. Employing a jellium model for the half-space $z > 0$, the field components are not continuous at the interface except for E_x, E_y and D_z, which are continuous functions and can be perturbatively calculated. The Fresnel formulae for the reflectivity for both s- and p-polarized light were given for the thickness of the surface $d \ll \lambda$.

Later on, *Del Sole* [20.24] found two general expressions of the corrections to Fresnel formulae for large anisotropies allowing in-plane anisotropy. They

can describe real crystals. In the case of s-polarized light, Del Sole obtained

$$\frac{\Delta R_{\mathrm{s}}(\omega)}{R_{\mathrm{s}}(\omega)} = \frac{4\omega}{c}\cos\theta\ \mathrm{Im}\left\{\frac{\Lambda_{yy}(\omega)}{\epsilon_{\mathrm{b}}(\omega)-1}\right\}, \tag{20.9}$$

while for p-polarization

$$\frac{\Delta R_{\mathrm{p}}(\omega)}{R_{\mathrm{p}}(\omega)} = \frac{4\omega}{c}\cos\theta \times \mathrm{Im}\left\{\frac{\left[\epsilon_{\mathrm{b}}(\omega)-\sin^2\theta\right]}{\left[\epsilon_{\mathrm{b}}(\omega)-1\right]}\frac{\Lambda_{xx}(\omega)+\epsilon_{\mathrm{b}}^2(\omega)\sin^2\theta\Lambda_{zz}(\omega)}{\left[\epsilon_{\mathrm{b}}(\omega)\cos^2\theta-\sin^2\theta\right]}\right\}; \tag{20.10}$$

$\Lambda_{ij}(\omega)$ (where i and j can be the Cartesian indices x, y), and $\Lambda_{zz}(\omega)$ are averaged response functions that account for nonlocal surface contributions and are given by [20.24]

$$\Lambda_{ij}(\omega) = \int \mathrm{d}z \int \mathrm{d}z' \left[\epsilon_{ij}(z,z';\omega) - \delta_{ij}\delta(z-z')\epsilon_0(z;\omega)\right] - \int \mathrm{d}z \int \mathrm{d}z' \int \mathrm{d}z'' \int \mathrm{d}z''' \epsilon_{iz}(z,z';\omega) \times \epsilon_{zz}^{-1}(z',z'';\omega)\epsilon_{zi}(z'',z''';\omega) \tag{20.11}$$

and

$$\Lambda_{zz}(\omega) = \int \mathrm{d}z \int \mathrm{d}z' \left[\epsilon_{zz}^{-1}(z,z';\omega) - \delta(z-z')\epsilon_0^{-1}(z;\omega)\right], \tag{20.12}$$

where

$$\epsilon_0(z;\omega) = \theta(z)\epsilon_{\mathrm{b}}(\omega) + \theta(-z) \tag{20.13}$$

is the *abrupt* interface dielectric function of the bulk plus the vacuum. The inverse kernel $\epsilon_{zz}^{-1}(z,z';\omega)$ is defined by

$$\int \mathrm{d}z''\epsilon_{zz}(z,z'';\omega)\epsilon_{zz}^{-1}(z'',z';\omega) = \delta(z-z')\,. \tag{20.14}$$

All these surface response functions $\Lambda_{\alpha\beta}(\omega)$ have the dimensions of length as they are multiple integrals of the dielectric tensor $\epsilon_{\alpha\beta}(z,z'';\omega)$. We remark that only longitudinal (diagonal) components appear in (20.9) and (20.10), as the quantities Λ_{xy} and Λ_{yx} will be present only in the second-order mixing terms of s and p light.

In principle, (20.11) and (20.12) can include all many-body and local-field effects [20.25].

20.2.2 Connection with Experiment

As mentioned in the introduction, the surface response functions can be probed experimentally by a variety of experimental techniques. Surface differential reflectance spectroscopy (SDRS), also abbreviated to SDR and DRS, is based on measuring the change in reflectance after a chemical modification of the surface (typically the deposition of a layer of oxygen or hydrogen) quenches the specific features coming from surface bands and the clean surface reconstructions: $\mathrm{SDRS} = (R_{\mathrm{oxidized}} - R_{\mathrm{clean}})/R_{\mathrm{clean}}$. In terms of the modified Fresnel reflectivities, this is written as

$$\frac{\Delta R_{\mu}(\omega)}{R_{\mu}(\omega)} = \left(\frac{\Delta R_{\mu}(\omega)}{R_{\mu}(\omega)}\right)_{\mathrm{clean}} - \left(\frac{\Delta R_{\mu}(\omega)}{R_{\mu}(\omega)}\right)_{\mathrm{modified}}. \tag{20.15}$$

Here, μ denotes s or p light polarization. By taking the reflectance difference, the unmodified bulk contribution cancels out, and any observed signal should be related to the surface modification. The percentage difference of the spectra is related to the surface structure of the clean surface and to the surface electronic state sensitivity upon adsorption.

Reflectance anisotropy spectroscopy (RAS), also known as reflectance difference spectroscopy (RDS), measures the difference in reflectance by a change of the linear polarization of light between two principal axes (x and y) along the surface. For cubic crystals, the bulk optical response is isotropic, and any observed reflectance anisotropy should be related to the break of symmetry of the surface region or from nonlinear effects. The latter are usually small, although measurable, and can be neglected in a typical RAS measurement. For crystals with uniaxial symmetry, like wurtzite, RAS can be applied when the surface normal is parallel to the c-axis. The RAS technique has some advantages over SDRS, since it does not need a reference system where the structural surface features are assumed to be canceled in a uniform and isotropical way. It has been used to follow in situ the epitaxial growth to verify the layer by layer deposition [20.26–28]. Interpretation of the RAS signal is also simpler, since only the knowledge of the atomic structure of the clean surface is necessary. RAS experimental setups measure the polarization state of the reflected light,

$$\frac{\Delta\tilde{r}}{\tilde{r}} = \frac{\tilde{r}_x - \tilde{r}_y}{(\tilde{r}_x + \tilde{r}_y)/2}\,, \tag{20.16}$$

where $\tilde{r}_\alpha = [\Delta R_\alpha(\omega)/R_\alpha(\omega)]_{\mathrm{clean}}$, for light polarized along the α axis. The RAS signal is commonly given in terms of the reflectance $\Delta R/R$ or of the complex

Fresnel reflectivities $\Delta\tilde{r}/\tilde{r}$. The latter is usually used for setups where both real and imaginary parts can be measured. The two quantities are related, and for small amplitudes the relation is $\Delta R/R = 2\,\mathrm{Re}\,\Delta\tilde{r}/\tilde{r}$.

The previous description is based on a general dielectric model that accounts for all possible effects of nonlocal field corrections and anisotropy through the explicit dependence of the function $\Lambda_{\alpha\beta}(\omega)$ on $\epsilon_{\alpha\beta}(z,z',\omega)$ and its inverse. From an explicit form of these ingredients we could calculate directly, for instance, the difference between (20.9) and (20.10). Conversely, we could fit the functions $\Lambda_{\alpha\beta}(\omega)$ from the experimental RAS and SDRS signals themselves [20.29, 30]. For instance, in the case of normal incidence, we can write the RAS signal as

$$\frac{\Delta R}{R} = \frac{4\omega}{c}\,\mathrm{Im}\left\{\frac{\Lambda_{yy}(\omega)-\Lambda_{xx}(\omega)}{\epsilon_\mathrm{b}(\omega)-1}\right\}. \tag{20.17}$$

Since $\Lambda_{yy}(\omega)-\Lambda_{xx}(\omega)$ can be written as a length d multiplied by the difference of two effective complex dielectric susceptibilities at surfaces, $\Delta\epsilon_{\mathrm{s,eff}}(\omega) = \Delta\epsilon'_{\mathrm{s,eff}}(\omega) + \mathrm{i}\Delta\epsilon''_{\mathrm{s,eff}}(\omega)$, and $\epsilon_\mathrm{b}(\omega)$ is also complex, we can write

$$\frac{\Delta R}{R} = \frac{4\omega d}{c}\left[A(\omega)\Delta\epsilon''_{\mathrm{s,eff}}(\omega) - B(\omega)\Delta\epsilon'_{\mathrm{s,eff}}(\omega)\right], \tag{20.18}$$

where

$$A(\omega) = \frac{\epsilon'_\mathrm{b}-1}{(1-\epsilon'_\mathrm{b})^2+(\epsilon''_\mathrm{b})^2},$$
$$B(\omega) = \frac{\epsilon''_\mathrm{b}}{(1-\epsilon'_\mathrm{b})^2+(\epsilon''_\mathrm{b})^2} \tag{20.19}$$

are functions that depend only on the bulk substrate. Thus, the surface and the bulk contribution can be identified in particular conditions [20.29].

20.2.3 Slab Approximation

If we possess a microscopic quantum description of the electronic structure of the semi-infinite crystal, we can obtain, in principle, its response functions and make a comparison with the experimental results. However, identification of the proper ingredients at the level of the phenomenological description developed above (at an appropriate level of approximation) is a heavy task to perform. The electronic properties of a semi-infinite crystal, occupying a half-space $z>0$, are difficult to treat in practice [20.31], and it is simpler to describe the surface and bulk with a stack of a finite but sufficient number of atomic planes embedded in a vacuum region. The slab of atomic planes has a surface periodicity that is determined by the surface reconstruction, if present. A vacuum region with a thickness comparable to that of the atomic slab is added. This structure can be periodically repeated to obtain a 3-D (three-dimensional) periodic structure thereby accessible to the software tools designed for 3-D crystal band structures (even if large unit cells are necessary). The unit cell (supercell) has the 2-D (two-dimensional) surface cell of the surface with area A as its basis and a height L equal to the slab thickness plus the width of the vacuum region. Many phenomena in surfaces are relatively short range in nature, so that the surface region d_s where the system differs with respect to the bulk is restricted to a few atomic planes and is, indeed, much less than L. The number of atomic layers that are used in a slab calculation can vary from 10 to 30, depending on the surface, its reconstruction, and the phenomena to be described. Nonetheless, any calculation has to be tested for convergence with respect to the number of atomic planes and the total thickness of the unit cell.

The quantities Λ_{yy} and Λ_{xx} that appear in (20.9) and (20.10) are the only ingredients required at $\theta = 0$, and they can be interpreted in terms of the polarizability that can be obtained from a slab calculation. To do this, we consider the first term in (20.11), as in most cases, the second term with four integrations does not give relevant contributions. For an interface between semi-infinite vacuum and bulk, we have

$$\Lambda_{ij}(\omega) = \int_{-\infty}^{\infty}\mathrm{d}z\int_{-\infty}^{\infty}\mathrm{d}z'[\epsilon_{ij}(z,z';\omega) - \delta_{ij}\delta(z-z')\epsilon_0(z;\omega)]\,. \tag{20.20}$$

We can put $i=j=(x,y)$ and observe that the upper limit in the first integration can be limited to a value d, with $d>0$ and also $d>d_\mathrm{s}$

$$\Lambda_{ii}(\omega) = \int_{-\infty}^{d}\mathrm{d}z\int_{-\infty}^{\infty}\mathrm{d}z'[\epsilon_{ii}(z,z';\omega)-\delta(z-z')] - [\epsilon_\mathrm{b}(\omega)-1]d\,. \tag{20.21}$$

Figure 20.3 describes the matching of the semi-infinite model with the microscopic slab calculation. If d is sufficiently larger than the thickness of the surface region d_s, where some difference between the electronic structures of the semi-infinite crystal and the bulk are present, the difference does not depend on the value of d, and it converges rapidly to a fixed value. We notice, however, that the second term has some uncertainty in

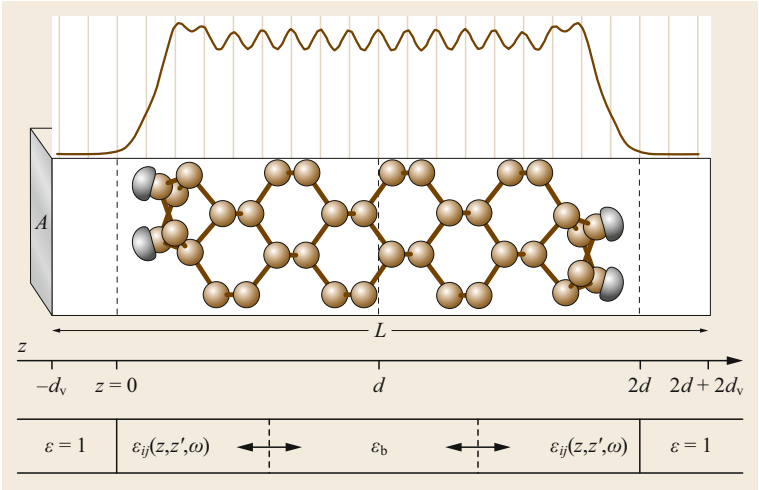

Fig. 20.3 Schematic of the bulk–surface–vacuum interfaces and the corresponding atomic slab. In the *upper part* of the figure, a slab of 16 atomic planes presenting surface reconstruction at the two sides is shown with atomic positions and sketches of the surface states of dangling bond type. The slab is confined by vacuum regions, and the whole is inside a repeated cell of thickness L, to recover 3-D periodicity. The electron charge density obtained from the valence states, laterally integrated, as a function of z, is also shown, and we can see the partial spilling of charge into the vacuum at the two surfaces. In the *lower part* of the figure, the ingredients of the phenomenological model are shown. The boundaries between the regions where the surface response functions match the bulk ones are mobile, as indicated by the *arrows*

the phenomenological model because the semi-infinite bulk has a cut plane located at some arbitrary $z=0$, not well defined with respect to the last atomic positions at the surface (Fig. 20.3).

Using a repeated slab calculation, we can identify the lower integration limit $(-\infty)$ with $z=-d_v$, the *midpoint* of the vacuum region; $z=0$ is the coordinate of the ideal surface plane in the abrupt interface plane (rather arbitrary); and $z=d$ is the middle of the slab. Thus, the supercell has $L=2d+2d_v$, and we can evaluate (20.21) as

$$\Lambda_{ii}^{hs}(\omega)=4\pi\alpha_{ii}^{hs}(\omega)-(\epsilon_b-1)d\,, \qquad (20.22)$$

where $i=x,y$ and α_{ii}^{hs} is the half-slab polarizability

$$4\pi\alpha_{ii}^{hs}(\omega)=\int_{-d_v}^{d}dz\int_{-d_v}^{2d+d_v}dz'[\epsilon_{ii}(z,z';\omega)-\delta(z-z')]\,. \qquad (20.23)$$

The half-slab polarizability can be directly calculated in an independent-particle scheme or including the electron–electron interaction from a many-body perturbative approach. For nonsymmetric slabs (where front and back surfaces are not equivalent), the half-slab polarizability for one surface can be extracted using a real-space cut function [20.32].

20.2.4 Independent Particle Response

In order to express $\alpha_{ii}^{hs}(\omega)$ in terms of independent particle or quasiparticle energies and wavefunctions, we have to use the RPA (random-phase approximation) without the local-field effects (Sect. 20.3.1) form of the imaginary part of the slab polarizability that is related by time-dependent perturbation theory to the transition probability induced by the radiation between the slab eigenstates [20.33]

$$\mathrm{Im}\left\{4\pi\alpha_{ii}^{hs}(\omega)\right\}=\frac{4\pi^2e^2}{m^2\omega^2A}\sum_{\boldsymbol{k}}\sum_{v,c}|p_{vc,k}^{i}|^2 \times\delta(E_c(\boldsymbol{k})-E_v(\boldsymbol{k})-\hbar\omega)\,. \qquad (20.24)$$

Here, $p_{vc,k}^{i}$ is the matrix element of the i-th Cartesian component of the momentum between valence and conduction states at a given $\boldsymbol{k}$; the sum over $\boldsymbol{k}$ is over the 2-D surface Brillouin zone; and $E_c(\boldsymbol{k})$ and $E_v(\boldsymbol{k})$ are the energies of the single/quasiparticle states involved in the transition between valence and conduction bands. A factor of 2 due to the spin degeneracy of the bands is compensated by the division by 2 of the half-slab evaluation of these diagonal (xx) and (yy) terms. The imaginary part can be used to obtain $\mathrm{Re}[4\pi\alpha_{ii}^{hs}(\omega)]$ through the Kramers–Kronig relations. To be consistent, the quantity $\epsilon_b(\omega)$ that appears in (20.22) and in (20.9) and (20.10) should be calculated at the same lev-

els of approximation from the long-wavelength limit of the RPA bulk dielectric function, computing the imaginary part and then deriving the real part. These are thus truly *microscopic* versions of the response functions, without including local-field effects.

In summary, therefore, the functions $4\pi\alpha_{ii}^{\mathrm{hs}}(\omega)$ for the half-slab are thus evaluated at a first-level approximation in the RPA-independent particle (IP) scheme, using a Kohn–Sham picture (as particles seeing the same effective field), or in an independent quasiparticle (IQP) picture (as quasiparticles moving in a nonlocal and state-dependent potential). Having obtained $4\pi\alpha_{ii}^{\mathrm{hs}}(\omega)$, one can then use (20.22) and finally use the appropriate explicit expressions of relative reflectances.

Note that the use in (20.24) of self-consistent energy eigenvalues and eigenvalues coming from the Kohn–Sham equations of DFT or from a self-energy equation, coupled with the RPA approximation for the polarizability, is a particular choice. In practical studies, surface dielectric properties are often computed in this way. The framework can be extended to include local-field corrections and other many-body corrections with respect to the self-energy, as we will show in Sect. 20.3; however, this comes with a high computational cost. Nevertheless, the IP approach can very often offer a reasonably good interpretation of the experimental data in terms of surface interband transitions, as Sects. 20.4 and 20.5 will show.

20.2.5 Electron Energy-Loss Spectroscopy

Electron energy-loss spectroscopy (EELS) is a powerful and versatile technique for characterizing materials across a wide range of excitations. When used in a reflection geometry, with incident electrons in the 1−10 eV range, the technique is known as reflection or high-resolution electron energy-loss spectroscopy (REELS/HREELS) and is sensitive to surface excitations, including interband transitions [20.34]. In fact, HREELS can be used to probe the surface anisotropic response in the visible–UV range in a manner complementary to RAS but with a much higher sensitivity (by two orders of magnitude) [20.35, 36].

According to standard dipole scattering theory, the electron scattering probability is given by the product of a kinematic term and the surface loss term [20.37],

$$P(\boldsymbol{q}_\parallel,\omega) = 2\left(\frac{me}{\hbar^2\pi}\right)^2 \frac{1}{\cos\varphi_\mathrm{i}}\frac{k'}{k}\frac{q_\parallel}{|q_\parallel^2+q_\perp^2|^2} \times \mathrm{Im}\, g(\boldsymbol{q}_\parallel,\omega)\,, \tag{20.25}$$

where $\boldsymbol{k}$ and $\boldsymbol{k}'$ are the wavevectors of the incident and scattered electrons, such that $\boldsymbol{q}_\parallel = \boldsymbol{k}_\parallel - \boldsymbol{k}'_\parallel$ and $q_\perp = k_\perp - k'_\perp$ are the transferred momenta parallel and perpendicular to the surface. The energy transfer is $\hbar\omega = \hbar^2[k^2 - k'^2]/2m$. The surface loss function itself can be expressed in terms of an *effective* dielectric function $\epsilon_{\mathrm{eff}}(q_\parallel,\omega)$, which takes into account all surface and bulk excitations

$$\mathrm{Im}\{g(\omega)\} = \mathrm{Im}\left\{\frac{-2}{1+\epsilon_{\mathrm{eff}}(q_\parallel,\omega)}\right\}. \tag{20.26}$$

Within a simple picture of a semi-infinite bulk crystal, this expression, inverted, reduces to a simple average of the bulk ($\epsilon_{\mathrm{eff}} = \epsilon_\mathrm{b}$) and vacuum ($\epsilon_\mathrm{v} = 1$) response function.

Assuming the more realistic picture of an anisotropic surface layer of the dielectric tensor $\epsilon_\mathrm{s} = \mathrm{diag}(\epsilon_{\mathrm{sx}}, \epsilon_{\mathrm{sy}}, \epsilon_{\mathrm{sz}})$, lying atop an anisotropic (cubic) bulk (three-layer model), the effective dielectric function can be written as [20.38, 39]

$$\epsilon_{\mathrm{eff}}(q_\parallel,\omega) = \epsilon_\mathrm{s}\frac{\epsilon_\mathrm{s}+\epsilon_\mathrm{b}+(\epsilon_\mathrm{b}-\epsilon_\mathrm{s})\mathrm{e}^{-2q_\parallel d\sqrt{\epsilon_{\mathrm{sx}}/\epsilon_{\mathrm{sz}}}}}{\epsilon_\mathrm{s}+\epsilon_\mathrm{b}-(\epsilon_\mathrm{b}-\epsilon_\mathrm{s})\mathrm{e}^{-2q_\parallel d\sqrt{\epsilon_{\mathrm{sx}}/\epsilon_{\mathrm{sz}}}}}\,, \tag{20.27}$$

where $\epsilon_\mathrm{s} = \sqrt{\epsilon_{\mathrm{sx}}\epsilon_{\mathrm{sz}}}$ is the geometric mean and ϵ_b the dielectric function of the bulk. The appropriate expressions for an anisotropic bulk response (e.g., for II-VI wurtzite surfaces) have been derived by *Esquivel-Sirvent and Noguez* [20.40].

The connection to the surface interband transitions can be more clearly seen by considering the well-known limit of (20.27) when $q_\parallel d \ll 1$[20.37, 38]

$$\epsilon_{\mathrm{eff}}(q_\parallel,\omega) \simeq \epsilon_\mathrm{b} + q_\parallel d\left(\epsilon_{\mathrm{sx}} - \frac{\epsilon_\mathrm{b}^2}{\epsilon_{\mathrm{sz}}}\right). \tag{20.28}$$

Clearly for $q_\parallel \to 0$ or $d \to 0$, $\epsilon_{\mathrm{eff}}(q_\parallel,\omega)$ tends to ϵ_b; for very large $q_\parallel$, $\epsilon_{\mathrm{eff}}(q_\parallel,\omega)$ can be shown to tend to ϵ_s. Thus, the HREELS signal contains terms ultimately proportional to $\mathrm{Im}\{\epsilon_{\mathrm{sx}}\}$ and/or $\mathrm{Im}\{\epsilon_\mathrm{b}\}$, which can be resolved experimentally under the appropriate kinematic conditions or computed using a three-layer model.

In practical calculations, the optical dielectric functions ($q \to 0$) are often used where the experimental momentum transfer is small [20.39]. A theoretical scheme for computing HREELS spectra beyond the three-layer model, including nonlocality and full q-dependence, is given in [20.41].

20.3 Ab-initio Approach

The theoretical framework developed in the previous section is quite general and can be applied to phenomenological or (semi-)empirical descriptions of the surface dielectric response. In this section, we focus on state-of-the-art ab-initio approaches that allow parameter-free and quantitatively correct calculations of surface interband excitations. Although the simple band picture of interband transitions depicted in Fig. 20.1 offers a clear and intuitive explanation of the connection between surface electronic states and optical or energy-loss spectra, the reality is more complicated. Electrons and holes are, after all, *interacting* particles and feel the effects of long and short-range screening by themselves and by other particles in the system.

In the following, we will outline the three-step procedure that will allow us to compute, in an ab-initio framework, the electronic and optical properties of materials beyond mean-field density functional theory and including so-called many-body effects (such as self-energy and excitonic effects). This will allow us to improve the comparison with the experimental data and add truly predictive value to the simulations [20.11]. The steps are:

1. Density functional theory calculation of surface geometry and electronic structure
2. Many-body perturbation theory (Green's function method) to obtain quasiparticle energy bands via the GW approximation
3. Solution of the Bethe–Salpeter equation to describe particle–hole interactions.

This theoretical scheme is quite general and nowadays is applied to systems of different chemical character and dimensionality, from bulk to surfaces, nanostructures, molecules, and organic or hybrid compounds. Figure 20.4 summarizes the various levels of approximation for computing interband excitations that will be considered.

In Sect. 20.6, we will show how the application of the full three-step procedure to several simple semiconducting and insulating surfaces has been of fundamental importance for understanding the exact nature of the optical interband features measured in the experiments. In discussing the calculation of the dielectric properties of a material we will remain quite general, speaking in terms of the macroscopic dielectric function $\epsilon_{\mathrm{M}}(\omega)$. For the case of surfaces, which are the main topic here, the half-slab polarizability $4\pi\alpha_{ii}^{\mathrm{hs}}$ introduced in Sect. 20.2.1 can be obtained by multiplying the macroscopic dielectric function by half the cell thickness. This section will end with an alternative method to the three-step procedure that has become popular in recent years: the time-dependent density functional theory (TDDFT) [20.42].

20.3.1 Density Functional Theory

Density functional theory (DFT) [20.43] in the Kohn–Sham (KS) formalism [20.44] is a very powerful computational approach to predict a wide range of chemical and physical properties of materials of different dimensionality, including surfaces. In their 1964 work [20.43], *Hohenberg* and *Kohn* demonstrated that the ground-state energy of a system of N interacting electrons in an external potential $V_{\mathrm{ext}}(\boldsymbol{r})$ is a functional of the electronic density which is minimized at the true ground state density of the system. In a following paper in 1965 [20.44], *Kohn* and *Sham* reformulated the variational problem of the functional energy minimization in terms of the solution of a set of one-particle self-consistent equations (Kohn–Sham equations)

$$\left[-\frac{1}{2}\nabla^2 + V_{\mathrm{eff}}^{\mathrm{KS}}(\boldsymbol{r})\right]\phi_i(\boldsymbol{r}) = \epsilon_i\phi_i(\boldsymbol{r})\,, \qquad (20.29)$$

where the electron density of the interacting system is reproduced by the sum of the densities of N independent particles described by the Kohn–Sham wavefunctions $n(\boldsymbol{r}) = \sum_i^N |\phi_i(\boldsymbol{r})|^2$, and the effective potential is the sum of the external potential, the Hartree potential,

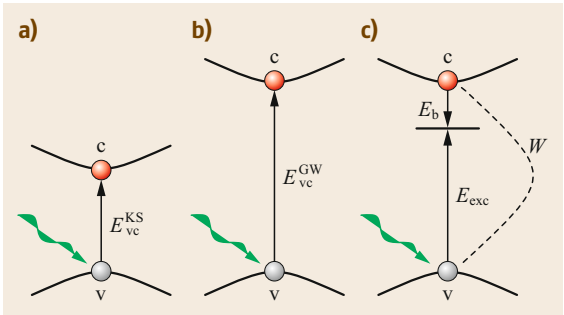

Fig. 20.4a–c Ab-initio approaches for computing interband excitations, in order of increasing difficulty. **(a)** Independent particle approximation (IP) using DFT (Kohn–Sham) energies and wavefunctions. **(b)** Independent quasiparticle approximation (IQP) using GW energies and wavefunctions, which typically opens the DFT band gap and yields higher excitation energies. **(c)** Interacting quasiparticle approximation within the Bethe–Salpeter equation (BSE) approach, allowing formation of bound excitons below the GW gap. Equivalent physical results can also be obtained with TDDFT

and the exchange-correlation (xc) potential: $V_{\rm eff}^{\rm KS}(\boldsymbol{r}) = V_{\rm ext}(\boldsymbol{r}) + V_{\rm H}(\boldsymbol{r}) + V_{\rm xc}(\boldsymbol{r})$. Here, $V_{\rm xc}$ is explicitly defined as the functional derivative with respect to the density of the exchange-correlation energy $E_{\rm xc}[n]$ that is a universal functional of the density and contains, in principle, all the many-body effects, but it is actually the unknown part since the theory does not provide an explicit analytical form of it. Hence, the approximations made to calculate this contribution are of crucial importance for the success of the approach. Most DFT calculations of periodic materials adopt local [20.44] or semilocal [20.45] forms for the exchange-correlation energy.

From the solution of the KS equations it is possible to obtain the ground-state electronic total energy as

$$E_{\rm tot} = \sum_i^N \epsilon_i - \frac{1}{2}\int {\rm d}\boldsymbol{r}'{\rm d}\boldsymbol{r}\frac{n(\boldsymbol{r})n(\boldsymbol{r}')}{|\boldsymbol{r}-\boldsymbol{r}'|} + E_{\rm xc}[n] - \int {\rm d}\boldsymbol{r} V_{\rm xc}(\boldsymbol{r})n(\boldsymbol{r})\,. \tag{20.30}$$

In the Born–Oppenheimer approximation, the ionic contribution can be added to the electronic total energy and, by means of the use of the Hellman–Feynman theorem, the electronic forces on the ions can be calculated. Within such a scheme (and thanks to efficient algorithms) DFT simulations are nowadays used to search for the equilibrium geometry of complex systems such as relaxed or reconstructed surfaces, clean and covered with adsorbates. The outcome of these calculations gives both the equilibrium geometry of the surface, as well as the band structure of the Kohn–Sham equations that can be considered as a first effective picture of the electron bands.

Within this approach, the Kohn–Sham eigenvalues are introduced as Lagrange multipliers, hence, their interpretation as excitation energies of the real system has no theoretical foundation. In fact, their interpretation as electron addition or removal energies leads to the well-known band gap problem of DFT: the electronic band gaps predicted by the theory are typically 30–50% (sometimes even more) smaller than the experimental ones. Nonetheless, KS eigenvalues and wavefunctions are often used as a first approximation in optical properties calculations and used directly in the simple interband picture depicted in Fig. 20.4a and represented by (20.24). As a result, computed spectra are generally redshifted with respect to the experiment. For systems with a gap, this can be corrected using a so-called *scissors* shift Δ that opens the gap, as long as an appropriate renormalization recipe is used [20.46]. The value of the shift can be estimated from GW calculations or used ad hoc. Due to fortuitous cancelations when differences are computed, this approximation (DFT-IP plus scissors) often works well for calculations of RAS and SDRS.

20.3.2 Green's Function Theory—GW

An appropriate theoretical framework for treating electronic excitations is the many-body perturbation theory based on a Green's function formalism. This allows us to improve the description of the electronic charged and neutral excited states and to give reliable predictive results, overcoming the DFT-KS single-particle scheme. In the second quantization formalism, the propagation of an electron added or extracted in an interacting N-electron system is described by the time-ordered single-particle Green's function [20.47]

$$G(1,2) = -{\rm i}\,\langle \Phi_N |\, T(\hat{\psi}_{\rm H}(1)\hat{\psi}_{\rm H}^{\dagger}(2))\,|\Phi_N\rangle\,. \tag{20.31}$$

Here $1 = (x_1, t_1)$ (where t_1 is a time coordinate, while $x_1 = (\sigma_1, \boldsymbol{r}_1)$ indicate the spin and spatial coordinate and a similar definition stands for 2, ...); $|\Phi_N\rangle$ is the ground state of the interacting N-particle system, $\hat{\psi}_{\rm H}, \hat{\psi}_{\rm H}^{\dagger}$ are the field operators in the Heisenberg representation, and T is Wick's time-ordering operator. We here assume that the system is in equilibrium and at zero temperature. For a more extended formulation, we refer to several textbooks [20.47, 48].

In principle, from the knowledge of Green's function, one can calculate the ground-state total energy and the expectation value of any single-particle operator. Moreover, using the so-called Lehman representation of G, it can be shown that its poles in the complex-frequency space correspond to the charged excitation energies of the many-body system [20.48]. Nevertheless, $|\Phi_N\rangle$ being an unknown quantity in an arbitrary interacting N-particle system, (20.31) does not provide a practical way to calculate G and all the related physical quantities. Starting from the equation of motion for G and using its spectral representation, it can be shown that the electronic excitations of the many-body interacting system correspond to the eigenvalues of the so-called quasiparticle (QP) equation, [20.48, 49]

$$\left(-\frac{1}{2}\nabla^2 + V_{\rm ext} + V_{\rm H}\right)\Phi_i^{\rm QP}(x) + \int \Sigma(x,x',\epsilon_i^{\rm QP})\Phi_i^{\rm QP}(x'){\rm d}x' = \epsilon_i^{\rm QP}\Phi_i^{\rm QP}(x)\,, \tag{20.32}$$

where a nonlocal, time-dependent, non-Hermitian operator, the *self-energy* Σ, appears. The self-energy can be thought of as the effective potential that the electron

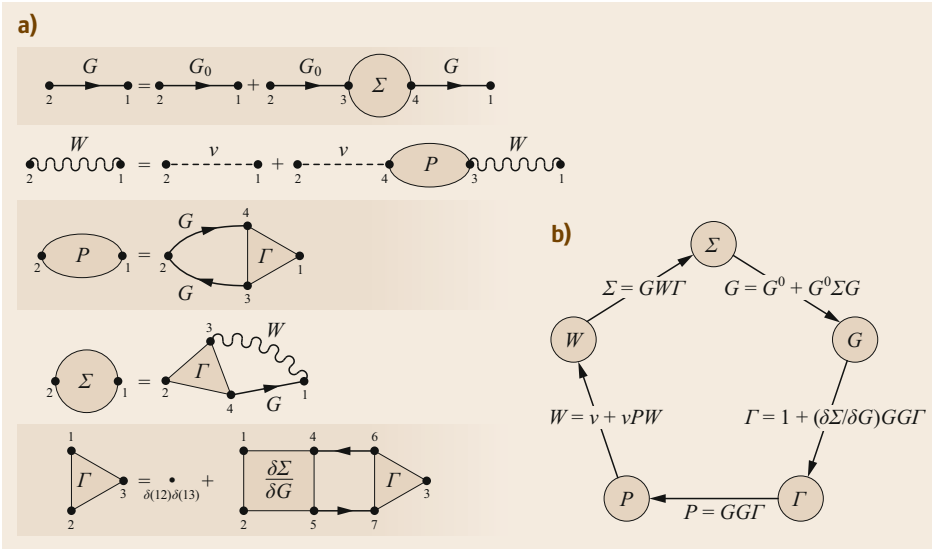

Fig. 20.5 **(a)** The five Hedin equations are written in terms of Feynman diagrams. **(b)** The same equations are represented in the so-called *Hedin's Pentagon*, which illustrates the idea of solving the set of five Hedin equations through an iterative procedure

or the hole added to the system feels due to the change in the charge distribution induced by its own presence. With respect to KS electrons which are completely independent particles, the quasiparticles can be seen as weakly interacting dressed electrons characterized by finite lifetimes which are related to the imaginary part of the complex eigenvalues ϵ_i^{QP} [20.49–51].

Suitable approximation for the self-energy can be found using the so-called *Hedin equations* [20.52], a closed set of equations (Fig. 20.5) that connects the self-energy Σ and the Green's function G to other fundamental functions characterizing the system such as the vertex function Γ, the polarization P, and the screened Coulomb interaction W

$$\Sigma(1,2) = \mathrm{i}\int G(1,3)\Gamma(3,2,4)W(4,1)\mathrm{d}(34)\,, \tag{20.33}$$

$$W(1,2) = v(12) + \int v(13)P(3,4)W(4,2)\mathrm{d}(34)\,, \tag{20.34}$$

$$P(1,2) = -\mathrm{i}\int G(1,3)G(4,1)\Gamma(3,4,2)\mathrm{d}(34)\,, \tag{20.35}$$

$$\Gamma(1,2,3) = \delta(12)\delta(13) + \int \frac{\delta\Sigma(1,2)}{\delta G(4,5)} G(4,6)G(7,5)\Gamma(6,7,3)\mathrm{d}(4567)\,, \tag{20.36}$$

where v is the bare Coulomb interaction. Here, the presence of commas indicates the separate dependence on the different variable sets, while the absence of commas indicates the dependence on the difference of spatial coordinates and times. The symbols d(34) and d(4567) indicate that multiple integrations must be performed on the space coordinates and time and a sum of spin variables must be done for every numerical label.

These equations cannot be solved exactly but are a good starting point for various approximations of Σ. Hedin proposed an iterative solution of these equations starting with $\Sigma = 0$ (this corresponds to the Hartree approximation). This way, at the first iteration step, the vertex function, the polarization, and the self-energy are

$$G = G_0; \quad \Gamma(1,2,3) = \delta(12)\delta(13)\,; \tag{20.37}$$

$$P(1,2) = -iG(1,2)G(2,1);$$
$$\Sigma(1,2) = iG(1,2)W(2,1)\,. \tag{20.38}$$

The Green's function G is computed using the noninteracting particle Green function G_0, and the screening is constructed within the random phase approximation (RPA). In practical calculations, the quasiparticle energies are generally computed in a first-order perturbative scheme, starting from the DFT Kohn–Sham eigenvalues and eigenfunctions. This is the so-called G_0W_0 perturbative approximation of the self-energy. The computation of quasiparticle energies within this approach nowadays represents a sufficiently refined method for band structure calculations of materials [20.53]. A few successful applications of this approach for the QP band structure of insulating and semiconducting surfaces will be discussed in Sect. 20.6, but other examples can be found in the literature. Optical excitations can also be considered at this level by replacing the KS eigenvalues with the GW ones in an appropriate manner [20.54]; such a scheme is depicted in Fig. 20.4b, and examples will appear later in the chapter. Several self-consistent GW schemes have been proposed in the

last years [20.55, 56] but have rarely been applied to surfaces [20.57]. Computationally less expensive, self-consistent GW_0, updating only energies in G, is instead a method often used to estimate the quasiparticle energies also for surfaces [20.58].

20.3.3 The Bethe–Salpeter Equation

The macroscopic dielectric function $\epsilon_{\mathrm{M}}(\omega)$ is the crucial physical quantity that is needed to describe the optical properties of surfaces (and materials in general). It can be obtained at different levels of accuracy in the theoretical ab-initio framework we are describing here, starting from the simplest independent particle (Sects. 20.2.1 and 20.3.1) or quasiparticle approximation (Sect. 20.3.2) up to the inclusion of local-field and excitonic effects by solving the Bethe–Salpeter equation (BSE). First of all, it is worth remembering that $\epsilon_{\mathrm{M}}(\omega)$ is not the simple average of the microscopic quantity but, following the *Adler* and *Wiser* formulation, it is [20.20, 21]

$$\epsilon_{\mathrm{M}}(\omega) = \lim_{\boldsymbol{q}\to\boldsymbol{0}} \frac{1}{\epsilon^{-1}_{\boldsymbol{G}=\boldsymbol{0},\boldsymbol{G}'=\boldsymbol{0}}(\boldsymbol{q},\omega)} \,, \tag{20.39}$$

where $\boldsymbol{G}$ are the reciprocal lattice vectors. This formula relies on the fact that, in an inhomogeneous material, while the macroscopic field varies with frequency ω and has the Fourier component of vanishing wavevector, the microscopic field varies with the same frequency but with a mix of wavevectors $\boldsymbol{q}+\boldsymbol{G}$. These microscopic fluctuations induced by the external perturbation are at the origin of the local-field effects and reflect the spatial inhomogeneity of the material.

At the microscopic level ϵ is related to the irreducible polarization function P by the following equation: $\epsilon(1,2) = \delta(12) - \int v(1,3)P(3,2)\mathrm{d}3$. As we discussed in the previous section, the simplest approximation is to consider the electron and hole propagators as independent and use $P = -\mathrm{i}GG$. We will refer to this approach as the random phase approximation without local fields (RPA-noLF)). It can be shown that it is exactly equivalent to using the so-called Fermi golden rule

$$\mathrm{Im}\{\epsilon(\omega)\} \propto \sum_{i,f} |\langle\phi_i| D \left|\phi_f\right\rangle|^2 \delta(\varepsilon_i - \varepsilon_f - \hbar\omega) \,, \tag{20.40}$$

where D is the dipole operator and the DFT-KS or the QP eigenfunctions and eigenvalues can be used.

For the case of surfaces in a repeated slab geometry, this equation multiplied by the half-thickness of the cell and the appropriate prefactor, gives the half-slab polarizability, which is then used to calculate RAS and SDRS at the independent (quasi) particle level of approximation (i.e., it reduces to (20.24)). While the local-field effects can be taken into account using (20.39), the solution of the Bethe–Salpeter equation, for coupled electron and hole propagators, allows us to describe local fields and the electron-hole interaction on the same footing.

More than two decades of applications of the BSE approach have shown that the optical spectra of materials calculated for different dimensionalities can result in much better agreement with experiments. Unfortunately, such calculations are very demanding from a computational point of view, especially for complex materials. In the case of surfaces, its application has, up to now, mainly remained limited to simple reconstructions of elemental semiconducting surfaces.

Starting from the GW approximation for the self-energy and multiplying the vertex function by $-\mathrm{i}GG$, it can be shown that a four-point integral equation for a generalized reducible polarization ${}^4\bar{P}(1,2;3,4)$ can be obtained at the second iterative step of the Hedin equations (see [20.49] for a full derivation) as

$$\begin{aligned} {}^4\bar{P}(1,1';2,2') = {}& {}^4P_{\mathrm{IQP}}(1,1';2,2') \\ & + \int \mathrm{d}(33'44')\, {}^4P_{\mathrm{IQP}}(1,1';3,3') \\ & \times K(3,3';4,4')\, {}^4\bar{P}(4,4';2,2') \end{aligned} \tag{20.41}$$

where the kernel K contains two contributions [20.59]

$$\begin{aligned} K(1,1',2,2') = {}& \delta(1,1')\delta(2,2')\bar{v}(1,2) \\ & - \delta(12)\delta(1'2')W(1,1') \,. \end{aligned} \tag{20.42}$$

The term $\bar{v}$ is the unscreened Coulomb potential where the long-range ($\boldsymbol{G}=0, \boldsymbol{q}\to 0$) Fourier transform component is set as zero. When spin is not explicitly treated, this term acquires a factor of 2 for singlet excitons. The second term, $-W$, is the screened Coulomb attraction between the electron and the hole. While this last term is obtained from the functional derivative of the self-energy, the first term (here using $\bar{v}$ to obtain the macroscopic dielectric function instead of the microscopic one) formally comes from the functional derivative of the Hartree potential [20.60], which enters in the equation for the reducible polarization function.

Rewriting this equation in transition space, using the basis of the KS wavefunctions ϕ_{n_k}, the Bethe–Salpeter equation becomes

$$\begin{aligned} \bar{P} &= [1 + P_{\mathrm{IQP}}K]^{-1}\bar{P}_{\mathrm{IQP}} \\ &= [H^{\mathrm{exc}} - I\omega]^{-1}_{(n_1,n_2),(n_3,n_4)}(f_{n_4} - f_{n_3}) \,, \end{aligned} \tag{20.43}$$

where an effective excitonic Hamiltonian is introduced, defined as

$$H^{\mathrm{exc}}_{(n_1,n_2),(n_3,n_4)} = (E_{n_2} - E_{n_1})\delta_{n_1,n_3}\delta_{n_2,n_4} + (f_{n_2} - f_{n_1}) \times \int \mathrm{d}\boldsymbol{r}_1\,\mathrm{d}\boldsymbol{r}'_1\,\mathrm{d}\boldsymbol{r}_2\,\mathrm{d}\boldsymbol{r}'_2\;\phi_{n_1}(\boldsymbol{r}_1)\,\phi^*_{n_2}(\boldsymbol{r}'_1) \times K(\boldsymbol{r}_1,\boldsymbol{r}'_1,\boldsymbol{r}_2,\boldsymbol{r}'_2)\,\phi^*_{n_3}(\boldsymbol{r}_2)\,\phi_{n_4}(\boldsymbol{r}'_2)\,. \tag{20.44}$$

Then, using the spectral representation [20.49] for the inverse of a matrix, the interacting polarization can be obtained by solving an effective eigenvalue problem

$$\sum_{(n_3,n_4)} H^{\mathrm{exc}}_{(n_1,n_2),(n_3,n_4)} A^{(n_3,n_4)}_{\lambda} = E_{\lambda} A^{(n_1,n_2)}_{\lambda}\,. \tag{20.45}$$

In particular, it can be shown that for the calculation of the optical properties of extended systems such as surfaces (at least in one of the three spatial directions): (i) one needs to include only transitions with positive frequency [20.49] (i.e., (n_1, n_2) and (n_3, n_4) are pairs made of one valence and one conduction band, respectively); (ii) only transitions with the same $\boldsymbol{k}$ for the initial and final states can be included. Then, the macroscopic dielectric function reads as

$$\epsilon_{\mathrm{M}}(\omega) = 1 + \lim_{\boldsymbol{q}\to 0} v(\boldsymbol{q}) \sum_{\lambda} \frac{\left|\sum_{v,c;\boldsymbol{k}} \langle v,\boldsymbol{k}-\boldsymbol{q}|\mathrm{e}^{-\mathrm{i}\boldsymbol{q}\boldsymbol{r}}|c,\boldsymbol{k}\rangle A^{(\mathrm{v,c};\boldsymbol{k})}_{\lambda}\right|^2}{E_{\lambda}-\omega}\,. \tag{20.46}$$

The meaning of this equation is clear; instead of a simple sum of independent-particle optical matrix elements (interband transitions), the latter are weighted by the excitonic eigenstates A_λ. This occurs because the electron–hole Hamiltonian (20.45) is not diagonal due to the presence of the nondiagonal excitonic kernel.

This formulation allows us to interpret optical spectra (like absorption, reflectivity, transmission, EELS, etc.) in terms of mixing of single-particle interband transitions. Moreover, the excitation energies in the denominator of (20.46) are related to the excitonic eigenvalues E_λ which, in the case of reduced-dimensionality systems or low-dielectric screening, can be smaller with respect to the difference between the quasiparticle energy of occupied and unoccupied states. This difference quantifies the exciton binding energy. With reference to the schematic shown in Fig. 20.4c, E_λ is the excitonic eigenvalue E_{exc}, and E_{b} the exciton binding energy.

In summary, a three step procedure (DFT, GW, and BSE) of increasing computational cost is required if excitonic effects have to be included. It is clear that this approach cannot be applied to very complex systems, and indeed, full GW and Bethe–Salpeter calculations are generally done only for systems composed of few tens of atoms.

20.3.4 TDDFT

An alternative approach to calculate the optical properties of materials is the time-dependent density functional theory (TDDFT) [20.61], which is formally a powerful tool for the description of *neutral* excited states. In fact, TDDFT is, in principle, exact for neutral excited-state properties, and its simplicity relies on the fact that a two-point response function, instead of the four-point response function of the Bethe–Salpeter approach, is needed. The rigorous generalization of DFT to time-dependent external fields was proposed in [20.61, 62], where a theory similar to the Hohenberg–Kohn–Sham one was developed, albeit for time-dependent potentials.

Several reviews of the foundation of TDDFT and its applications can be found elsewhere [20.42, 63, 64]. In contrast to DFT, no energy minimum principle is available, and the evolution of the system is described by the quantum-mechanical action. The true time-dependent density is that which makes the action stationary. Minimizing the action, it is possible to obtain a set of time-dependent Kohn–Sham equations. Since all observables are unique functionals of the density, in principle, any property can be exactly obtained by the Kohn–Sham time-dependent formalism. TDDFT casts all many-body effects into the dynamical exchange-correlation kernel $f_{\mathrm{xc}}(r,t;r',t') = \delta v_{\mathrm{xc}}(r,t)/\delta n(r't')$, where $v_{\mathrm{xc}}(r,t)$ is the time-dependent exchange-correlation potential. A reliable calculation of absorption spectra relies on a good approximation to $f_{\mathrm{xc}}(r,t;r',t')$. The simplest approximation, the adiabatic extension of the static LDA (ALDA), fails to yield good absorption spectra in extended systems, although it is surprisingly good in some molecules and small clusters [20.65].

This failure is due to the lack, in the ALDA, of the long-range tail of the kernel, which is essential for the calculation of absorption spectra in extended systems, while the same term has little effect in small systems. Two derivations of approximate xc kernels with a long-range tail, based on the comparison with BSE results, have appeared. In the former approach, due to *Reining* and others [20.66], the basic assumption is the equivalence of the four-point polarizability of the BSE with the two-point polarizability of TDDFT (this equivalence is, in fact, rigorous only for the two-point contraction of the BSE polarizability), while the latter approach [20.67, 68] expands the xc correlation kernel to first order in the screened e–h interaction W. Quite

surprisingly, in spite of the different assumptions, both derivations yield the same formula for $f_{xc}(r,t;r',t')$, and spectra calculated for some bulk semiconductors and insulators [20.66, 67] result in very good agreement with experiment. Even the occurrence of strongly bound excitons [20.68] is equally well described within BSE and the TDDFT approach.

According to [20.67], the xc kernel is expanded to first order in the screened Coulomb potential, W, yielding

$$f_{xc} = P_0^{-1} P^{(1)} P_0^{-1} \,, \tag{20.47}$$

where $P^{(1)}$ is the first-order (in W) contribution to the irreducible polarizability P of many-body theory. Then, the irreducible polarizability is calculated according to the TDDFT formulation

$$P = P_0 + P_0 f_{xc} P \,. \tag{20.48}$$

Since P, f_{xc} etc. are all two-point quantities, TDDFT is, in principle, computationally less demanding than the BSE, and it could be employed in the case of more complex systems, like surfaces, nanostructures, biological molecules, and so on, where the BSE is hardly usable. Surfaces are especially difficult to study, since a large number of k-points and transitions have to be included in the excitonic Hamiltonian, rendering its diagonalization a bottleneck. Hence, it is of crucial importance to check the reliability of TDDFT optical spectra also in these cases. A practical illustration of the method will be given in Sect. 20.6.2 for Si(111)-(2×1).

20.4 Clean Semiconductor Surfaces

In the following three sections, we demonstrate how ab-initio simulations of the surface interband excitations yield a direct understanding of the surface geometry and electronic structure, and in many cases, help to interpret the experimental data. In this section, a few typical clean surfaces will be discussed. In particular, we will focus on different aspects of the (001) and (111) surfaces in elemental group IV and III-V compounds. For the most part, calculations will be discussed at the level of the independent particle approximation. In fact, it will become clear that surface spectra calculations at this level (based simply upon interband excitations between Kohn–Sham eigenstates, i.e., (20.24)) often yield a qualitatively correct description of the surface response due to fortuitous cancelation of terms in the RAS (20.16) and SDRS (20.15). This gives the advantage of allowing a straightforward interpretation of surface optical spectra in terms of interband transitions between well-defined electronic surface states.

For systems with a gap within DFT, the application of a simple *scissors* operator to open the KS gap (either chosen ad hoc or based on knowledge of GW/GW-BSE calculations) can even lead to quantitatively good agreement with experiments. This feature has allowed RAS and SDRS calculations to be applied to large and complicated systems that otherwise would not be tractable with a full MBPT or TDDFT approach. Section 20.6 will illustrate where higher order-effects, such as those from strongly bound excitons, are required.

20.4.1 Dimer Geometry

The main structural motif associated with (001) surfaces is the *dimer*. The spectral signature of dimer-induced states on the surface optical properties has been studied across many group-V and III-V(001) surfaces, including InP(001) [20.69, 70], GaP(001) [20.71, 72] and GaAs(001) [20.73–75]. However, the Si(100) surface is perhaps the most deeply studied of them all and is thus a good candidate to examine in detail. It has a simple structure based on rows of buckled dimers with well-defined surface states and a small reconstruction area; this has allowed it to be studied at various levels of theory, from tight binding, through DFT-IP, to GW-BSE. It is also an important template for simulating atomic and molecular adsorption, as will become clear in Sect. 20.5.

The first DFT-IP calculations on Si(100) established the connection between the surface dimers and the optical signal [20.76] and demonstrated that the correct geometry contains rows of alternating buckled Si dimers, most likely in a $c(4\times2)$ reconstruction [20.77]. A layer-by-layer spatial decomposition of the RAS signal [20.32] yielded a more complete picture of the various spectral features. A key fingerprint of the Si dimer is a sharp negative peak S_1 around 1.6 eV in the RAS, as shown in Fig. 20.6a. Analysis of the surface dielectric function (Fig. 20.6b) reveals that the S_1 peak arises from transitions between π and π^* orbitals running *parallel* to the dimer rows that are localized within the first few surface layers (Fig. 20.6c). Intra-dimer contributions are also present, but are much weaker. Both SDRS [20.77] and HREELS [20.39] (Fig. 20.6b) resolve a further surface-related feature S_0 below 1 eV, which appears to be due to transitions near the Γ points between bulk states and the π^* surface states, as shown.

Interpretation of experimental spectra at higher energy is more complicated, since much of the response

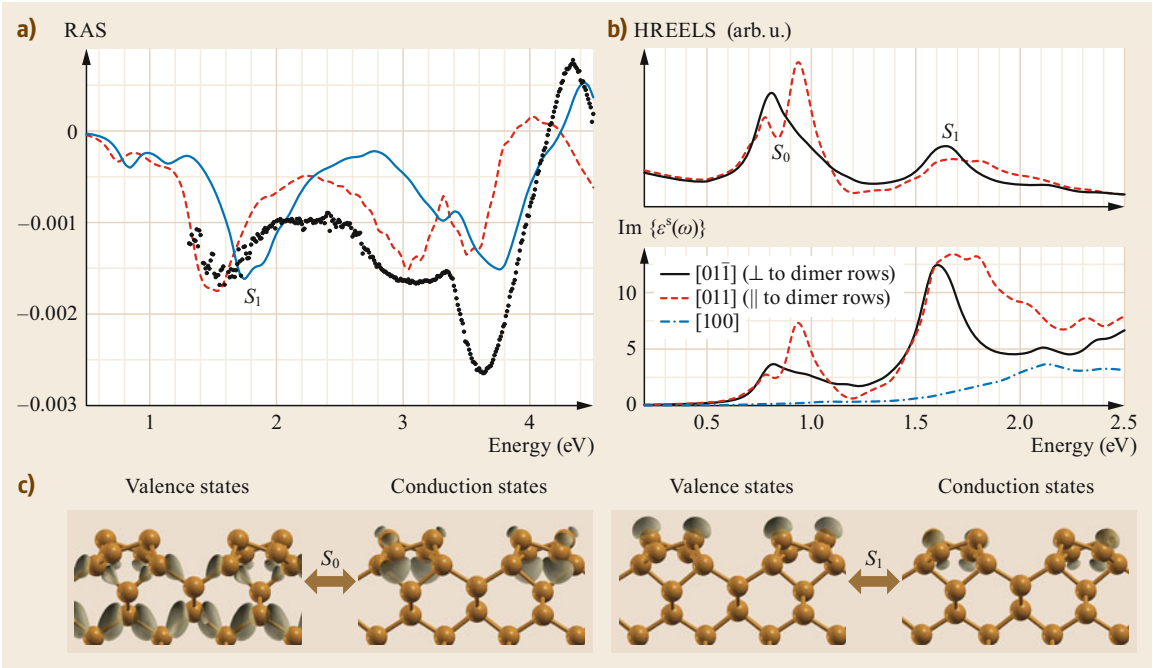

Fig. 20.6a–c Optical properties of the Si(100) surface. **(a)** RAS computed within DFT-IP plus scissors (*solid blue line*) and GW-BSE (*dashed red line*), compared with experimental data (adapted by permission from [20.78]). **(b)** HREELS and imaginary part of surface dielectric function. **(c)** Isosurfaces of wavefunctions contributing to the main optical peaks (Reprinted with permission from [20.39]. Copyright (2009) by the American Physical Society)

comes from bulk layers deep below the surface; indeed, the oscillation around 4 eV is characteristic of interband transitions between surface perturbed bulk states near E_2. The broad structure around 3 eV is of particular interest. Experimental evidence, coupled with the lack of a clear peak in the DFT-IP spectra, indicated that it arises from *steps* (this is discussed in more detail in Sect. 20.4.3). However, more advanced calculations of the ideal clean surface performed at the GW-BSE level [20.78] (see the red dashed curve in Fig. 20.6a) also produce a peak at this energy, suggesting that it can actually be a feature of the clean surface—due, in this case, to the presence of weakly bound excitons. Nonetheless, it is clear that the simpler DFT-IP scheme in this case succeeds in explaining most of the experimental data; surfaces exhibiting stronger excitonic effects are discussed in Sect. 20.6.

20.4.2 Dimer Composition

The GaAs(001)-c(4 × 4) surface offers a nice example of the sensitivity of interband transitions to small changes in the surface structure and chemistry. For many years, the c(4 × 4) surface was thought to be composed of a symmetric (or possibly asymmetric) triplet of As–As dimers (homodimers), as illustrated in Fig. 20.7. However, *Ohtake* et al. [20.79, 80] proposed that a new mixed dimer (heterodimer) structure, consisting of three Ga–As dimers, would form instead of the more As-rich surface if the preparation conditions were modified (specifically, if As_4 fluxes are used instead of As_2 during molecular beam epitaxial growth). The formation of two distinct structural phases α and β is clear from the RAS spectra measured.

Ab-initio calculations [20.81] of the RAS performed at the DFT-IP+scissors level provide strong confirmation of the proposals of *Ohtake* et al. [20.80]: the symmetric dimer calculations yield a relatively weak, single-peaked feature at 1.6 eV in agreement with the β-phase measurements, while the mixed dimer model yields a broader, stronger peak around 2.0 eV, as in the observed α phase data. The origin of the former feature was shown [20.36] to be derived from interband transitions between filled dangling bonds on the threefold coordinated As atoms backbonded to the dimers and empty π^* orbitals of the As–As dimers. Additional empty states at the Ga atoms are available on the mixed dimer surface, explaining the two-peaked RAS signal. A thorough decomposition of the various peaks in the GaAs(001)-c(4 × 4) RAS, by means of (20.19) is given in [20.29].

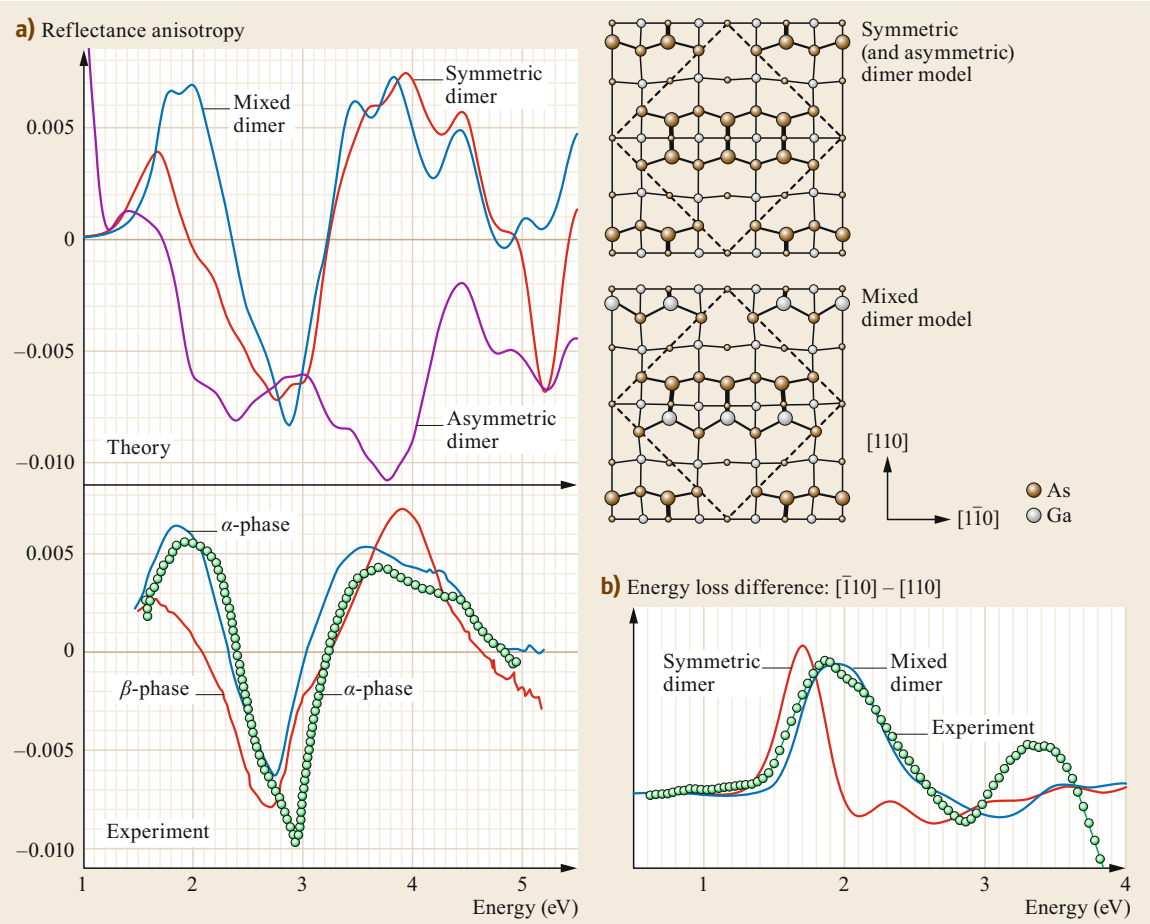

Fig. 20.7a,b Interband transitions at the GaAs(001)-c(4 × 4) surface probed by **(a)** optical (RAS) and **(b)** electronic (HREELS) spectroscopies. **(a)** Calculations from [20.81], measurements from [20.80] (*lines*) and [20.36] (*dots*). **(b)** Calculations from [20.41] and measurements from [20.36]. See text for details

These calculations highlight the remarkable sensitivity of surface optical spectra to the chemical composition of single surface bonds. The difference between the two surface models becomes even more apparent in HREELS spectra, which also probe interband transitions in ϵ_2, as explained in Sect. 20.2.5, but offer a higher surface sensitivity. Figure 20.7 reports calculations [20.41] using a simple three-layer model for the same surface models and experimental data from [20.36] for the β-phase. In this case, the difference is even more striking than before and stresses the one-to-one correspondence between RAS and HREELS where surface interband transitions are involved. Better agreement with experiments above 3 eV can be obtained by properly accounting for the nonlocality of $\epsilon(z, z', \omega)$, as discussed in [20.41].

20.4.3 Stepped Surfaces

The supercell framework allows perfectly aligned surface terraces to be constructed and studied. Real surfaces, however, exhibit a wealth of features that are difficult to account for in first-principles studies, such as defects, steps, adatoms, contaminants, strain, multiple domains, and so on. Although experimentalists strive to prepare model surfaces, these additional features are generally unavoidable, and in some cases even desired. In many cases, these deviations from the ideal surface lead to important features in the surface dielectric response and need to be accounted for or mitigated in calculations. Their influence on the surface interband spectra will be discussed in the following.

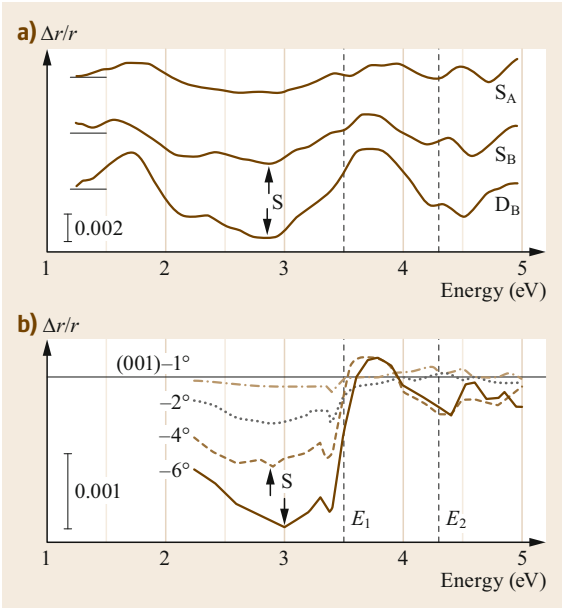

Fig. 20.8a,b Optical anisotropy signal arising from steps on Si(100). **(a)** DFT-IP calculations for single (S_A, S_B) and double (D_B) type steps. **(b)** Experimental data for different miscut angles (Reprinted with permission from [20.82]. Copyright (2001) by the American Physical Society)

Steps on Si(001)

The first ab-initio study of the influence of steps on the surface optical anisotropy was carried out by *Schmidt* et al. [20.82] and focused on the Si(001) surface. Nominally prepared Si(100) typically phase separates into a balanced mixture of (1×2) and (2×1)-oriented domains separated by single height steps. As RAS measures a macroscopic average, the generated signal is close to zero. In order to generate a nonzero RAS signal, a 4° offcut is often used, which forces the surface to form double-height steps and thus favor a single phase. The ab-initio calculations, shown in Fig. 20.8, demonstrated that single and double-height steps both generate broad negative signals above the gap in the 2.0–3.5 eV range, in agreement with experimental observations [20.83]. The signals are largely caused by perturbations of bulk wavefunctions by the anisotropic surface potential generated by the steps [20.82].

Steps on C(100):H

Hydrogenation of diamond surfaces brings three main effects. First, it enhances the semiconducting character of the surface. Secondly, new empty states, hydrogen-related, appear in the forbidden gap, near the Γ point, with nearly free electron character. Third, the electron affinity becomes negative, making hydrogenated diamond an appealing candidate as a cold cathode emitter.

The electronic properties of the ideal C(100)2×1:H surface have been studied by *Marsili* and *Pulci* [20.84] at the DFT and GW level. Its optical properties, for the nominally flat and for vicinal C(001):H surfaces, have been investigated experimentally and computed theoretically at the DFT level, in [20.85]. The experimental RAS shows an almost zero response for the 0° nominally flat surface, a negative broad signal for the 2° surface, and a broad positive signal, becoming negative above 3.5 eV, for the 4° surface.

Calculations performed simulating the presence of single and double steps of the *Chadi* [20.86] and of the *Tsai* and *Yeh* type [20.87] give indications that the single steps appearing in the C(001):H vicinal surface are more compatible with the Chadi geometrical model S_B (that is, with C dimers parallel to the single-step edges). In the case of double steps, instead, the comparison of the experimental and calculated RAS [20.85] gives hints towards the D_A Chadi geometrical model, that is with C dimers of the upper terrace perpendicular to the double-step edges.

Si(110)-(16 × 2)

Si(110) surfaces can be obtained with different high-temperature treatment in various reconstructions with different unit cell sizes. The most stable one is a long-range reconstruction that consists of alternately raised and lowered terraces in a huge (16×2) cell. From the results of STM topography a realistic model of the system was proposed by *Stekolnikov* et al. [20.88], which contains chains of pentamers on both terraces and single-layer height rebonded steps. The SDRS signal has been computed [20.30] ab initio, including TDDFT methods, and compared with experiments. A main SDRS peak at 1.8 eV was assigned to interband transitions involving states localized on the pentamers. However, the overall agreement is weak, suggesting that the structural model is not complete.

Vicinal Surfaces

Vicinal surfaces are currently a hot topic in surface and material science (Chap. 12), as the formation of regular step and terrace arrays offers a natural template for surface functionalization by atoms, molecules, or nanostructures, as well as a gateway to studying and harnessing novel physical phenomena. Changing the vicinal angle changes the step structure and terrace width, and thus also the density of nanostructures and the coupling between them. Although clean vicinal surfaces have been studied experimentally, theoretical work has focused on adsorbate-stabilized reconstructions, as they offer more regular step/terrace combinations and smaller unit cells. In particular, the Si(*hhl*)-Au surfaces have been studied intensively with

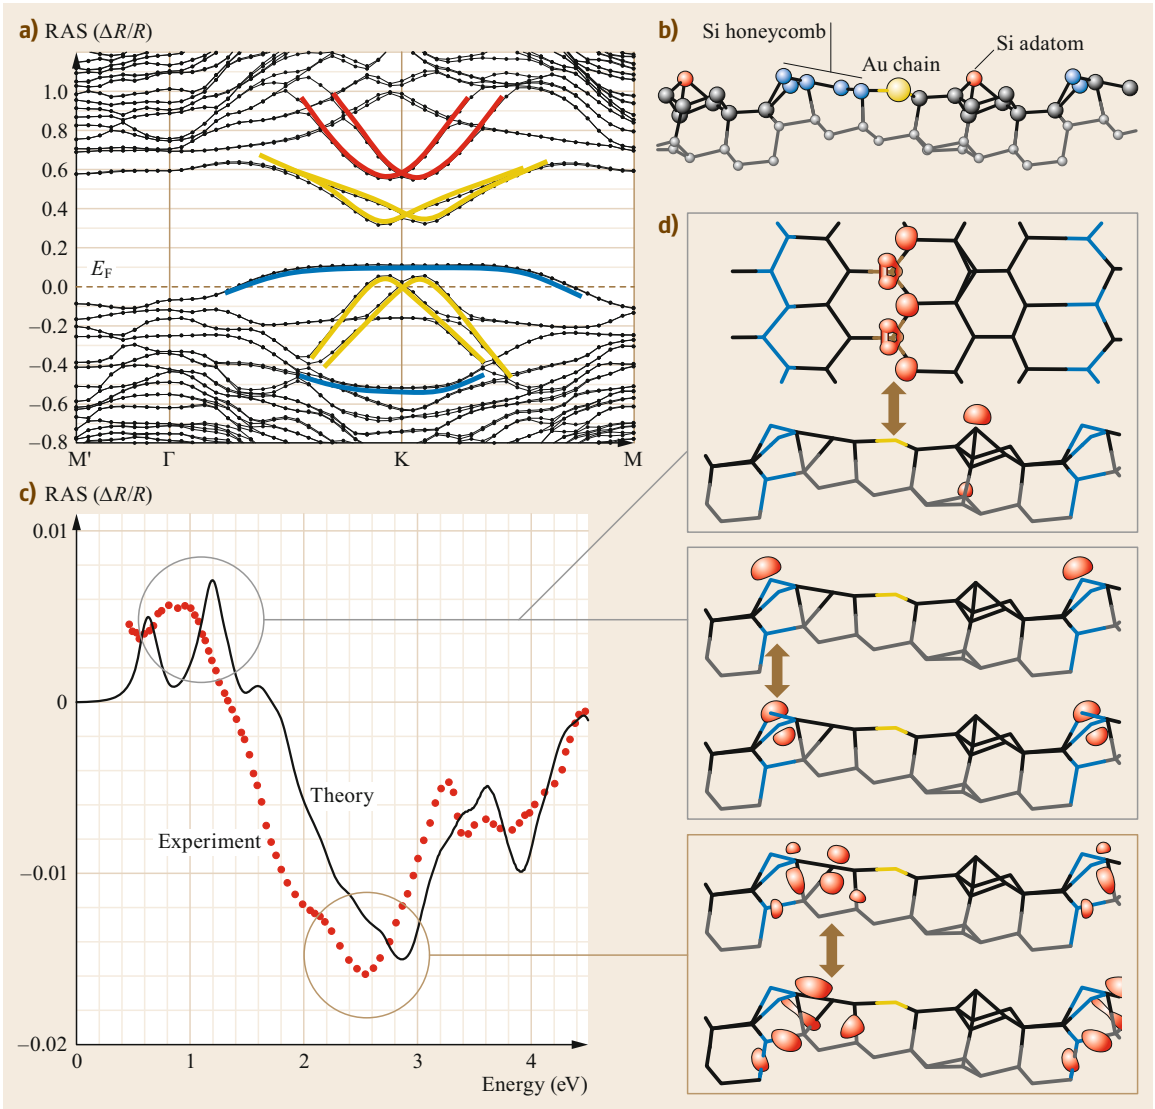

Fig. 20.9a–d Optical and electronic properties of the vicinal Si(557)-Au surface. **(a)** DFT-LDA band structure, with surface states at step-edge dangling bonds (*blue lines*), at the Au−Si chain (*gold*), and at Si adatoms (*red lines*), relative to the Fermi level. **(b)** Atomic structure (side view, topmost layers). **(c)** Computed RAS spectrum (DFT-IP plus scissors) compared with experimental data from [20.89]. **(d)** Filled (*bottom*) and empty (*top*) electronic states involved in the main interband transitions contributing to the peaks indicated in **(c)**

optical probes. There are several reasons for this. First, the Au-stabilized surfaces form regular single-height steps along [110] that border narrow terraces containing atomic chains of Au that can stretch for hundreds of Å. The array of quasi-1-D (quasi-one-dimensional) nanostructures are strongly anisotropic and, therefore, perfect for studying by using RAS, as it should be easy to decouple optical excitations along and perpendicular to the step edges and Au chains. Secondly, the unreconstructed Si(111) surface is naturally isotropic within the surface plane, and thus any observed anisotropy is strongly related to the formation of reconstructions that lower the symmetry. Thirdly, the RAS signal is rich with features in the 1–5 eV range and has similar, but not identical, spectra across the range of different vicinal angles and Au coverages. RAS spectra have been reported on Si(557)-Au, Si(553)-Au, and Si(775)-Au [20.90, 91].

As an example, we consider the Si(557)-Au surface (carefully analyzed by *Hogan* et al. [20.92]) and focus on the role of the step geometry on the surface interband transitions. Figure 20.9b shows a side view of the surface geometry. Besides the Au-chain embedded in the terrace and the presence of adatoms, the step edge is made of a characteristic Si honeycomb structure with dangling bonds lying right at the edge itself. (This honeycomb motif actually appears to be a feature common to all Si(*hhl*)-Au surfaces.) The Au chains, adatoms and Si dangling bonds all give rise to distinct surface states in the computed band structure (Fig. 20.9a); the latter states are partially filled. Calculations of the surface optical anisotropy (Fig. 20.9c) at the DFT-IP+scissors level appear in excellent agreement with the experimental data, thus allowing the experimental peaks to be interpreted in terms of the surface geometry. Most of the signal, i.e., 0.5–4.0 eV, in fact derives from transitions involving either the step edge Si orbitals lying close to the Fermi level or deeper-lying π/π^*-like orbitals of the honeycombs themselves (Si=Si bonds). Contributions from the Au chains are restricted to low energy and have a smaller overall contribution. The fact that most of the RAS signal derives from the step atoms explains the almost universally similar nature of the RAS signals observed across the Si(*hhl*)-Au family of vicinal surfaces [20.89].

20.4.4 Defects

Defects are the bugbear of surface preparation, and their presence can make interpretation of experimental data difficult. In some cases, however, some may actually drive formation of the lowest energy reconstruction, an example being subsurface Ga antisite defects on Sb-rich GaSb(001) [20.93]. On this surface, second-layer As atoms are substituted by Ga atoms in order to reduce or eliminate the metallicity of long dimer-chain reconstructions (effectively by doping the system with holes). The optical anisotropy of GaSb(001) shows features typical of (001) surfaces, with peaks and troughs deriving from interband transitions from occupied dangling bonds to dimer antibonding orbitals. Subsurface Ga substitution only weakly perturbs the geometry, which can nonetheless be detected in low energy (1 eV) peaks involving extended dimer chain orbitals. More importantly, however, the change in level occupation associated with the loss of metallicity is reflected in stronger changes in the spectrum at 2.5 eV, bringing the computed spectra more in line with the measured data [20.94].

20.5 Adsorbate-induced Effects

Adsorbates and adlayers have a marked effect on the surface optical properties. They can modify the interband transitions of the clean surface in various ways: by quenching such transitions (e.g., by destroying one or all of the optically active electronic states); by perturbing existing states (e.g., by changing the potential felt by states terminating at the surface); by introducing new optically active states; by stabilizing new surface reconstructions (as discussed for Au on vicinal Si(111) in Sect. 20.4.3); and so on.

It is important for the surface scientist to understand the extent of these changes. Undetected contaminants can lead to incorrect conclusions regarding the surface electronic structure. An interesting case is that of the InP(001)-(2×1) surface, which was understood (via STM) to consist of rows of buckled phosphorus dimers. However, such a structure should yield a metal in apparent violation of electron counting rules and in contradiction with the measured surface band gap of over 1.0 eV. The mystery was resolved with the help of DFT calculations of the RAS [20.95], which proved that the surface, which was prepared using metalorganic vapor phase epitaxy, was actually hydrogen stabilized. On the other hand, the induced change in the surface optical spectra due to passivants can be used to interpret the signal of the *clean* surface, at least in terms of surface or bulk-related transitions (the former being more sensitive to surface contaminants). This idea, in fact, encapsulates the technique of surface differential reflectance spectroscopy (SDRS), described in Sect. 20.2.1 and encapsulated by (20.15).

In the following, we outline how these effects can manifest in surface interband spectra through atomic, molecular, and layer adsorption.

20.5.1 Atomic Adsorption

Hydrogen

Being the most accessible passivant and contaminant, hydrogen and oxygen have been by far the most commonly used adsorbates in semiconductor surface optical and HREELS studies. Hydrogen adsorption is relatively easy to model within ab-initio calculations, as it tends to adsorb dissociatively at well-defined sites such as dangling bonds. Generally speaking, the main effect of H adsorption is to passivate the surface dangling bonds and, thereby, quench surface optical transitions occurring below the onset of bulk-like transitions near the E_1 peak energy. In the case of Si(100), this yields a quenched signal in RAS [20.78] and HREELS [20.97]

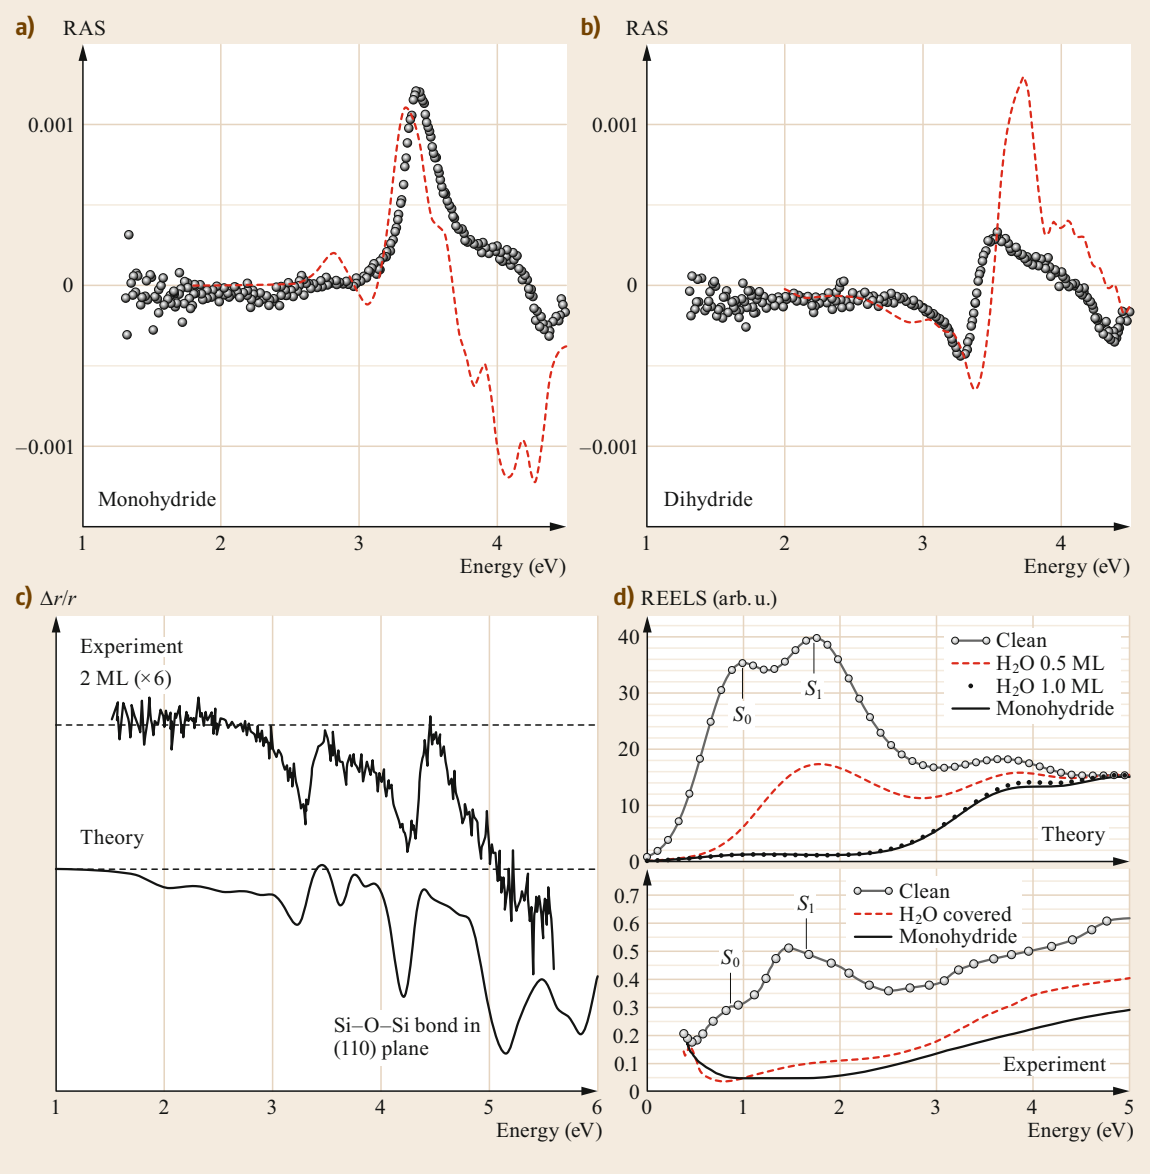

Fig. 20.10a–d Optical and energy-loss spectra of Si(100) with adsorbates. **(a)** RAS of monohydride and **(b)** dihydride passivated Si(100), computed using BSE and compared with experiments. **(c)** RAS of oxidized Si(100) using DFT-IP. **(d)** REELS of monohydride and water-contaminated surface ((**a**,**b**) reprinted with permission from [20.78]. below 3 eV, and pronounced peaks in SDRS [20.78] at 1.5 (at least in the calculations) and 3 eV. However, H adsorption can also change the surface structure, as shown in Fig. 20.10. Monohydride formation (Fig. 20.10a) on Si(100) leaves dimers intact, while (Fig. 20.10b) dihydride formation induces dimer breaking. The latter manifests as a characteristic SDRS peak at 3.8 eV, while the reduced strain also leads to a quite different surface-induced bulk anisotropy, as seen in RAS.

Similar quenching of π–π^* transitions has been noted on C(100):H terraces, leaving a zero RAS signal below 4.5 eV [20.84, 85, 98]. On GaAs(110):H, a similar mechanism results in a zero RAS below 3 eV, while the SDRS shows contributions across the

2.0–4.0 eV range from surface and perturbed bulk contributions [20.99]. The mechanism is slightly different on P-rich GaP(001)-$(2\times1)/(2\times2)$ [20.100] and InP(001)-(2×1) [20.95] surfaces. Here, H has a fundamental role in stabilizing the systems by passivating half of the dangling bond states on (buckled) P dimers. Strong optical anisotropies persist around 2.6 eV due to interband transitions between filled states on the remaining P dangling bonds and empty dimer antibonding orbitals.

Oxygen

The influence of oxygen adsorption on semiconductor surface interband transitions is complicated by the fact that the adsorption mechanisms are not thoroughly understood, and the preferred sites not uniquely defined [20.101, 102]. On Si(100), which is by far the mostly widely investigated using ab-initio schemes, theoretical simulations of the optical response reveal that the initial states of oxidation at room temperature are marked by oxygen insertion into dimers and (primarily) their backbonds [20.101, 103–105], i.e., forming Si–O–Si bonds. This causes strong perturbations on the dimer–dimer interactions, changing the dispersion of the surface localized bands and eventually pushing them outside the gap. In the RAS, this is reflected by a general quenching of the clean surface signals and a uniformly broad signal in SDRS [20.105]. During thermal oxidation, on the other hand, layer-by-layer growth of the oxide layer occurs and is reflected by oscillations in the optical anisotropy [20.106]. This was explained by *Fuchs* et al. [20.96] as deriving from strain perturbations on the Si bulk wavefunctions by oxygen being incorporated into Si–Si bonds below the interface (Fig. 20.10c); the disordered oxide layers above the interface only have a minor impact on the optical anisotropy. Complicated mechanisms also accompany oxygen adsorption on GaAs(001) surfaces [20.107], although the breaking of, and substitution into, As dimers (leaving Ga–O–Ga bonds) has been suggested using HREELS simulations (Fig. 20.10d) [20.108].

Alkali Metals

While oxygen and hydrogen are representative of the electronegative end of the periodic table of elements ($\chi = 3.5$ and 2.0, respectively), it is interesting to consider the effect that adsorption of more *electropositive* species such as alkali atoms can have on the surface interband spectra. Low coverages of Cs ($\chi = 0.8$) in particular have been investigated on As-rich GaAs(001) surfaces using RAS [20.109]. The observed effect on the surface optical response is the addition of a strong broad negative signal across the 3.0–5.0 eV range; similar studies using K ($\chi = 0.9$) and Na ($\chi = 1.0$) adsorption, or on Ga-rich surfaces, exhibit very similar changes in the experimental signal [20.110], hinting that the underlying mechanism is universal.

DFT calculations [20.109, 111] on GaAs(001) revealed that Cs adsorption only weakly perturbs the clean surface geometry. Instead, strong surface dipoles are created due to electronic charge transfer from the alkali to the surface, and furthermore, new surface resonance states are induced. The calculations attribute the induced optical signal both to perturbations of surface-terminating bulk states (through the change in the surface potential) and to bulk-like transitions involving Cs-induced resonance states. Although small site-dependent signals at low energy (2.0 eV) can directly arise from interband transitions involving Cs-substrate bonds, the primary influence of electropositive elements on the RAS remains, therefore, somewhat *indirect*, in strong contrast to more electronegative elements.

20.5.2 Adsorbate-stabilized Reconstructions

Besides atomic adsorbates that mainly perturb or passivate the surface structure, there is a huge number of adsorbate-stabilized surface reconstructions, many of which have been investigated using RAS or SDRS simulations. These include Si(001)-(1×1):Sb [20.112], GaAs(110):Sb/As [20.113], and the aforementioned H-stabilized P-rich (001) surfaces of GaP [20.100] and InP [20.95]. However, there are also many cases in which adsorbates generate highly anisotropic surface nanostructures that are ideal for studying using RAS. In particular, Si(111) offers a natural template for growth of quasi-1-D nanowires. Within the typical experimental convention, positive RAS signals correspond to excitations parallel to the wires. Indium adsorption induces metallic (4×1) and semiconducting (8×2) phases containing fairly broad In *ribbons*, which can be distinguished and interpreted using RAS [20.114–116]. Although the RAS signals of the two phases (Fig. 20.11a) are dominated by broad negative signals across 1.2–3.0 eV, sharp positive peaks are present in the mid-infrared. Both phases feature a peak at 0.50 eV due to transitions between bonding and nonbonding In chain states, as expected. However, only the hexagon model features a peak at 0.72 eV (0.53 eV in the calculation), related to the additional In–In bonds between the two zigzag rows, which allows the two models to be distinguished [20.115].

Li and Ag induce the so-called (3×1) honeycomb chain-channel reconstruction, wherein the metal atoms form single-atom wires between Si honeycomb chains (the same honeycomb motifs noted in Sect. 20.4.3). Also in this case, the optical spectrum (Fig. 20.11b)

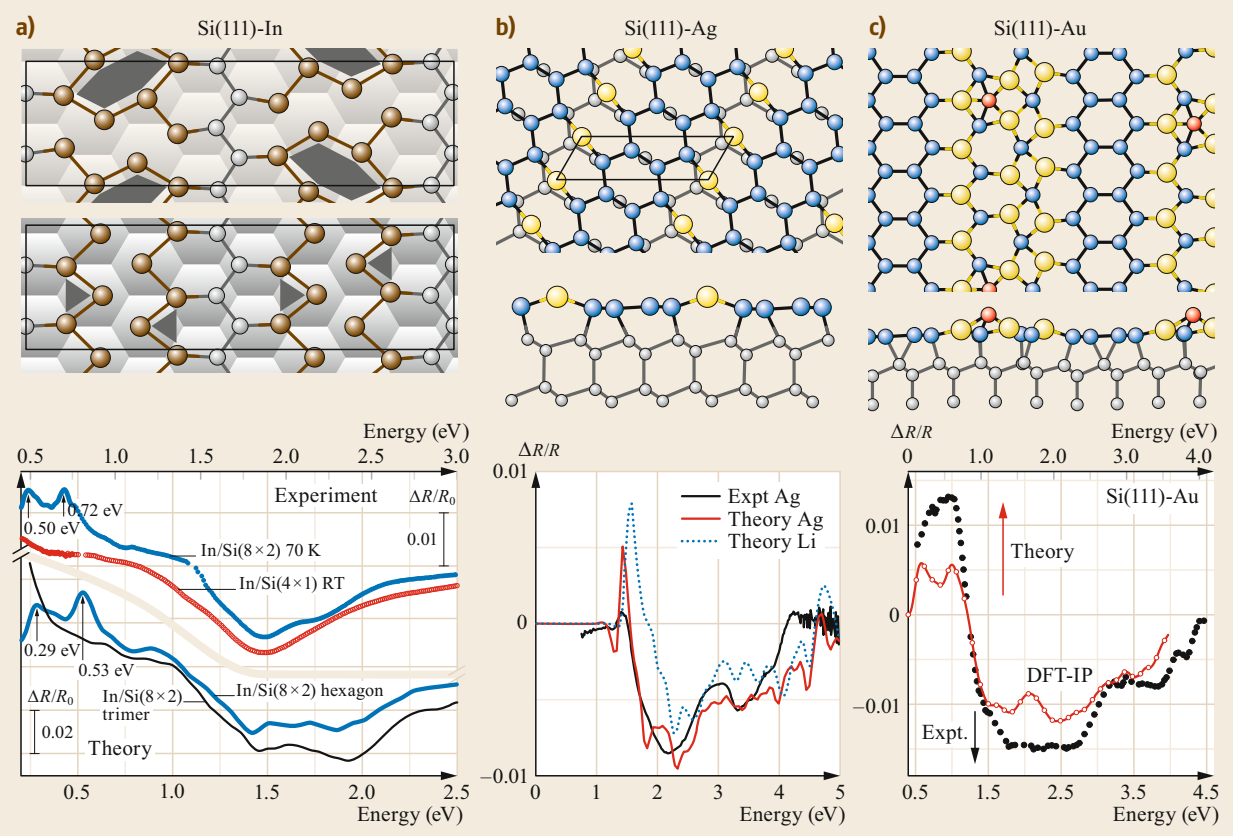

Fig. 20.11a–c Structural models and RAS of adsorbate stabilized Si(111) reconstructions (theory and experiment). **(a)** Hexagon and trimer models of the Si(111)-In nanowire array. **(b)** Ag and Li honeycomb chain-channel reconstructions, computed using a hybrid-DFT approach [20.117]. **(c)** Triple atomic Au nanowires on Si(111). is negative across the 1.8–4.5 eV range, being dominated by interband transitions involving π^*-like surface states localized on the Si honeycomb atoms [20.117], although a small positive structure appears at 1.5 eV due to transitions involving occupied states at the honeycomb edge. The same Si honeycombs also dominate in the case of the Si(111)-(5×2):Au surface [20.118, 119]. Although the precise Au coverage is still a matter of discussion, computed RAS spectra using a 0.6 monolayer (ML) coverage model of triple Au chains, and Si adatoms are in good agreement [20.118] with experimental data (Fig. 20.11c). Again, in this case, the spectra are dominated by Si honeycomb and localized Si-Au states. However, a fairly sharp positive feature, corresponding to *intrachain* optical transitions, is found around 1 eV.

Thus, in contrast to expectations, the optical spectra of adsorbates forming quasi-1-D atomic chains are not dominated by electronic transitions along the chain direction; instead, their presence is reflected indirectly in the optical signals of the adsorbate-stabilized substrate geometry. Weaker positive signals related to extended states along the atomic chains appear below 1.5 eV; experiments report that they are sensitive to surface quality.

20.5.3 Molecular Adsorption

As in the atomic case, the influence of molecular adsorption on surface interband excitations largely occurs through modification or quenching of signals from the clean surface (i.e., the molecule–substrate bonding), at least within the typical experimental range of $\approx$ 1.5–5.0 eV. Simulations have, up to now, focused primarily on the Si(100) surface.

H_2O adsorption on Si(001) has been explored theoretically using RAS [20.120] and HREELS [20.97] (Fig. 20.10d). In both cases, partial coverage of the

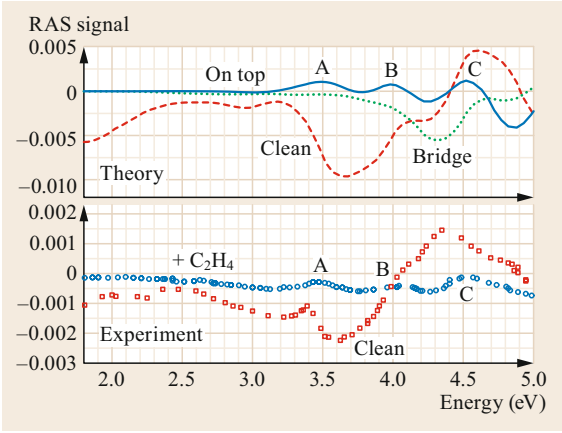

Fig. 20.12 RAS of ethylene adsorption on Si(001). Theory (*top*), for clean, on-top and bridge sites, respectively; and experiment (*bottom*), for clean and 1 ML coverage of C_2H_4. The contribution of steps has been subtracted from the measured clean surface signal

surface results simply in attenuation of the RAS or HREELS spectra. At full coverage, dissociation of the H_2O molecule across the Si dimers passivates all surface dangling bonds and removes the dimer-related (π, π^*) surface states (Sect. 20.4.1), thus killing the prominent peak(s) arising from interband transitions below 1.8 eV. At higher energy, both RAS and HREELS show bulk-related features (around E_1 and E_2) that persist after adsorption.

Organic molecules offer more interesting possibilities. DFT-IP level studies have been performed for adsorption of a number of such molecules on Si(001). Neither acetylene [20.121] nor ethylene [20.122, 123] cause dimer cleavage. However, the induced optical signal remains sensitive to the adsorption geometry, i.e., parallel (on-top) or perpendicular (bridge site) to the dimer. Whereas on-top adsorption kills the inter-dimer (chain) peak at 1.7 eV by removing dimer empty states, the bridge site suppresses positive intradimer contributions and enhances the negative inter-dimer peak [20.122]. A comparison with experiments (Fig. 20.12) demonstrates that the on-top configuration is, in fact, favored. Both cyclopentene [20.124, 125] and uracil [20.126] may cause further perturbations on the surface response, e.g., through dimer breaking or oxygen insertion, and various adsorption geometries are possible, along with a general attenuation of the clean surface signals around E_1 and E_2.

A notable example of where the molecular adsorbate was thought to have a more direct influence on the surface optical anisotropy is the case of 9,10-phenanthrenequinone on Si(100) [20.125, 127], which introduces a characteristic new peak at 5.2 eV in the experimental data. Intra-molecular π–π^* excitations were proposed to explain this peak based on gas-phase spectra [20.128]. However, the ab-initio calculations [20.127] showed that, while π–π^* transitions do contribute to the optical anisotropy of the molecular layer, the adsorption-modified Si bulk states are dominant across the full spectral range.

Last, we note that differential reflectance spectroscopy can be used to probe the molecular adsorbate layer itself if nonreactive surfaces are used. This idea was widely applied in [20.8, 129] to the study of organic epitaxial films using molecules whose chromophores generate the dominant optical signal. However, the need to use GW-BSE to study the optical response of such organic layers has limited their appearance in theoretical studies [20.130].

20.5.4 Adlayers

Since visible light can penetrate several hundred nm into a crystal, it is a useful probe of buried interfaces [20.131], capping layers [20.90], and adlayers [20.132]. An interesting example of the latter that has been investigated using RAS and DFT-IP calculations is the Si(105)-Ge surface. Its geometry has long been established as the *rebonded step* (RS) model [20.133], which consists of a smooth, highly reconstructed Ge layer (about 5 Å thick) atop a Si(105) substrate. The main reconstruction motif is a curious 6-atom *horseshoe* structure composed of three dimers and stabilized by the in-plane strain due to the Si-Ge lattice parameter mismatch.

Fazi et al. [20.134] measured the RAS of this surface and compared it with ab-initio calculations assuming the RS model and obtained excellent agreement

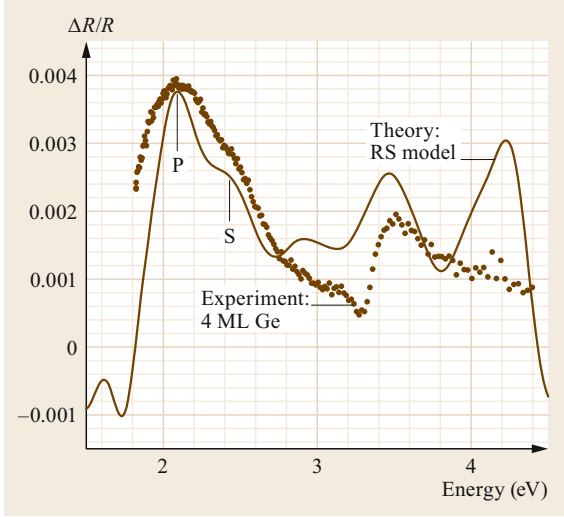

Fig. 20.13 Measured and computed RAS of the Si(105)-Ge rebonded step (RS) surface reconstruction

between them (Fig. 20.13). The main features P and S in the spectrum derive from interband transitions from occupied bulk-like states lying ≈ 1 eV below the valence band maximum to empty surface states lying inside the bulk gap. In the case of the main peak P, these surface states are, in fact, physically localized well *below* the horseshoe structure on the surface—a curious fact considering the density of surface dimers—near the location of the Si-Ge interface itself. Fazi and colleagues used this unique character to cast light on the microscopic structure of the Si-Ge interface. By monitoring the RAS signal during growth and comparing it with calculations for different Ge coverages and interface models (sharp/gradient/disordered), they confirmed that a sharp interface is present and demonstrated the connection between the surface optical spectra and the interface chemistry. This highlights the sensitivity of interband transitions to the bond stoichiometry of subsurface layers, in a similar fashion to the dimer composition on GaAs(001) discussed in Sect. 20.4.2.

20.6 Excitonic and Local-Field Effects

The importance of excitonic effects on the dielectric response of materials has been known for quite a long time [20.135]. The presence of the interaction between the electron and the hole pairs in the optical excitation process in spectroscopical measurements like light absorption or reflectivity, or electron energy loss, has an effect on the spectral line shapes above the gap and the formation of bound exciton states below it. Due to the low screening, the latter phenomenon is particularly evident in insulators or in low-dimensional systems, where binding energies of the order of 1 eV are observed. The relevance of these effects at several surface terminations of simple elemental semiconductors is now well established. This knowledge has been reached thanks to a systematic comparison of experimental RAS/SDRS and photoemission data with theoretical results obtained by DFT and MBPT calculations. In particular, strongly bound surface-state excitons have been found at the (111)-(2×1) surface of Si [20.136, 137], in Ge, [20.138] and C(111) [20.57], and at the (100)-(2×1) termination of diamond [20.139, 140].

As we will show in this section, the exciton dynamics has a one-dimensional character due to the peculiar atomic reconstruction of these surfaces (along the dimer rows in C(100) and along the Pandey chains [20.141] in Si and Ge(111)). For this reason, it is more difficult for electrons and holes not to feel their mutual interaction, which leads to bound excitons with binding energies (BE) ranging from a few tens of eV in Si and Ge, to 1 eV or slightly less in diamond. The large exciton binding energy observed at the C(100) surface—about four times larger with respect to that found in Si and Ge (111)—has been explained in terms of its reduced static screening with respect to Si (111), and will be the focus of Sect. 20.6.3.

20.6.1 BSE Approach to Group IV (111) Surfaces

The (111) termination is the natural cleavage surface of the most important group-IV semiconductors like silicon, germanium, and diamond, and for this reason, it is the most widely and deeply studied. It shows different geometric structures depending on preparation and actual temperature of the sample, but upon cleavage in ultra-high vacuum (UHV) and at low temperature the low energy electron diffraction (LEED) pattern is compatible with a (2×1) reconstruction. Angle-resolved photoemission measurements performed on the (111)-(2×1) termination of Si and Ge reveal the presence

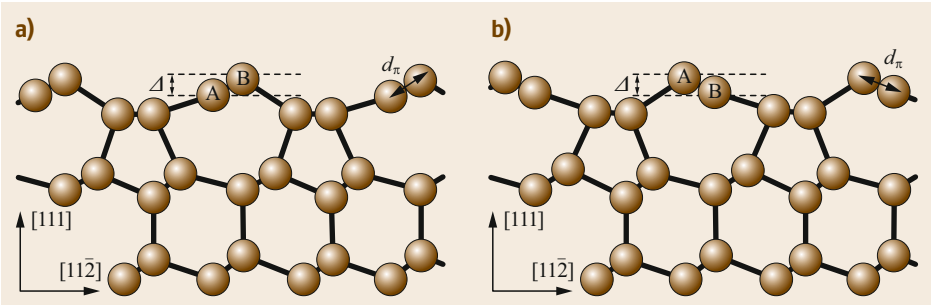

Fig. 20.14a,b Atomic structure of the negative (**a**) and positive (**b**) buckling chain model. The distance d_π between atom A and atom B is the bond length along the Pandey chain, while the difference in height Δ between atom A and atom B is the buckling amplitude

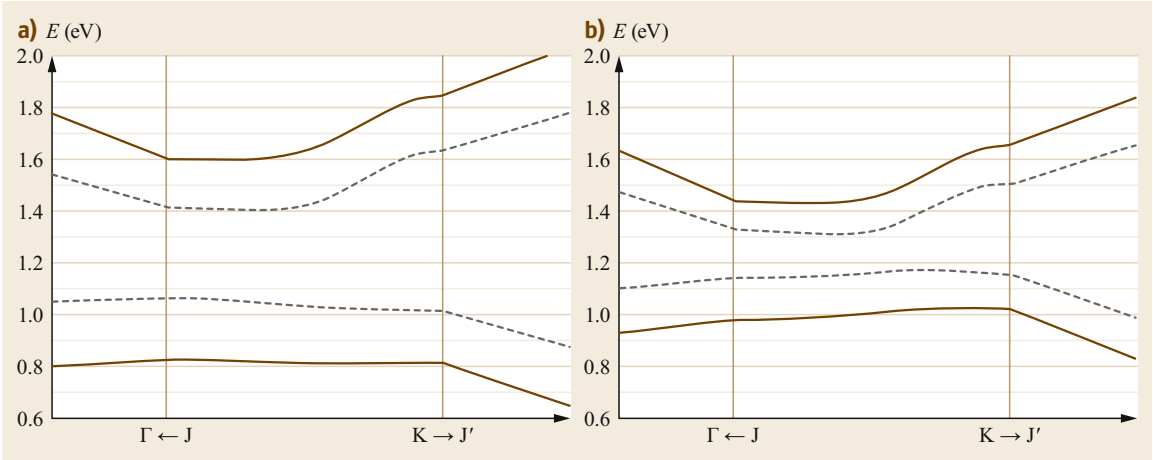

Fig. 20.15a,b DFT (*dashed line*) and GW (*solid line*) band structure around the Fermi energy of the Si(111)-(2 × 1) positive **(a)** and negative **(b)** buckling chain model

of an occupied and unoccupied surface band. SDRS data are, instead, characterized by a strong optical anisotropy with a peak for light polarized along the Pandey chains at 0.45 eV for Si, and at 0.49 eV for Ge. The Pandey model featuring five and seven-member rings of atoms in the surface bilayer can explain most of the experimental spectroscopic data of the (111)-(2 × 1) reconstruction of silicon and germanium.

Theoretical simulations have revealed the presence of two geometries, generally identified as positive and negative buckling (or right and left isomers, respectively), as shown in Fig. 20.14, which are almost degenerate in energy. For both Si and Ge, the energy difference between the two isomers is very small; in fact, one can assume that the two geometries are energetically degenerate within the accuracy of the DFT method. It should thus be expected that both isomers could coexist in nature. However, recent low-temperature angle-resolved ultraviolet photoemission spectroscopy and scanning tunneling microscopy and spectroscopy (STM and STS) measurements, together with state-of-the-art first-principles excited-state calculations demonstrated that for highly n-doped Si(111), both isomers coexist at the surface [20.145]. For undoped samples, the standard Pandey chain model [20.141] (right chain or positive buckling) yields a good comparison with SDRS data for Si(111)-(2 × 1), while for Ge(111)-(2 × 1) a better agreement between experiment and theory is obtained considering the negative buckling reconstruction (Fig. 20.14).

The reason of the dominance of one isomer over the other is not completely clear. A possibility is that the dominant structure is cleavage induced. For both isomers of Si and Ge surfaces, the band structure exhibits two surface bands, i.e., one is mainly composed of an occupied dangling-bond state (D_{up}) on the externally shifted atom and the other is an empty dangling-bond state (D_{down}). Figure 20.15 reports the theoretical GW band structures obtained for both isomers by *Violante* et al. [20.137]. The band structure of the right isomer is consistent with previously published data calculated within the same theoretical approach [20.136]. The quasi-particle band structures of positive and negative buckling show a small band dispersion along the JK direction while a larger dispersion is observed along the perpendicular direction corresponding in real space to the Pandey chain direction. This is due to the fact that the coupling between the orbitals is very strong along the chain, while the interaction among the chains is weak. In Fig. 20.16 the corresponding GW band structures [20.138] of the two isomers for Ge(111)-(2 × 1) are reported, showing qualitatively similar behavior to that described for Si. More specifically, the surface state bands along the JK direction have a larger dispersion in Ge with respect to the Si case, suggesting a larger interaction among the Pandey chains in Ge. In both cases the surface gap calculated for the negative isomer results smaller with respect to the positive isomer indicating the differences due to the underlying bulk geometry. In Si(111)-(2 × 1) with negative buckling the occupied and empty surface bands result flatter and more parallel with respect to those of the positive Pandey chain model. A minimum gap of 0.44 eV near JK/2 occurs for negative buckling, while for the positive buckling a minimum gap of 0.77 eV is observed near J. For Ge(111)-(2 × 1) the dispersion of the empty D_{down} band between J and K is different from the positively buckled chain. For the positive isomer the minimum direct gap results to be 0.88 eV and is located along the JK direction. For the negatively buckled isomer the minimum direct surface gap is significantly smaller, amounting to 0.66 eV.

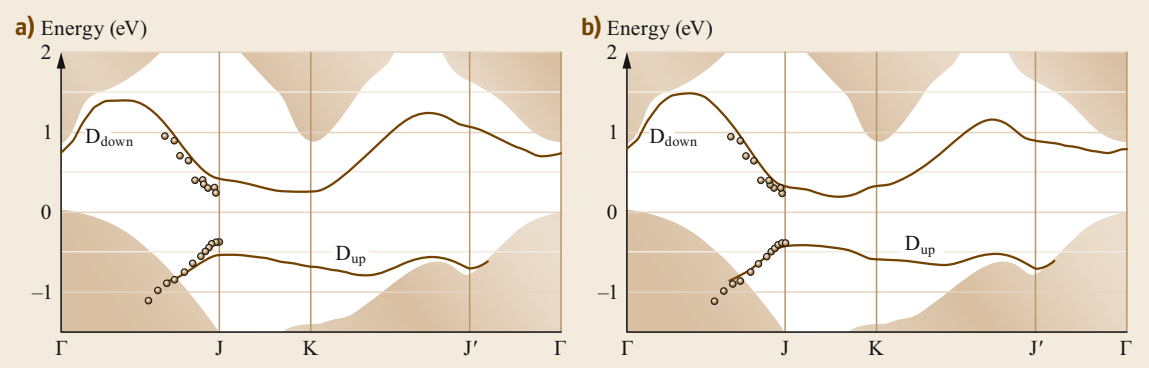

Fig. 20.16a,b GW band structure of the Ge(111)-(2 × 1) surface. **(a)** Positive buckling chain model. **(b)** Negative buckling chain model. The *brown area* represents the bulk state region. Experimental data (*dots*) from [20.142–144]

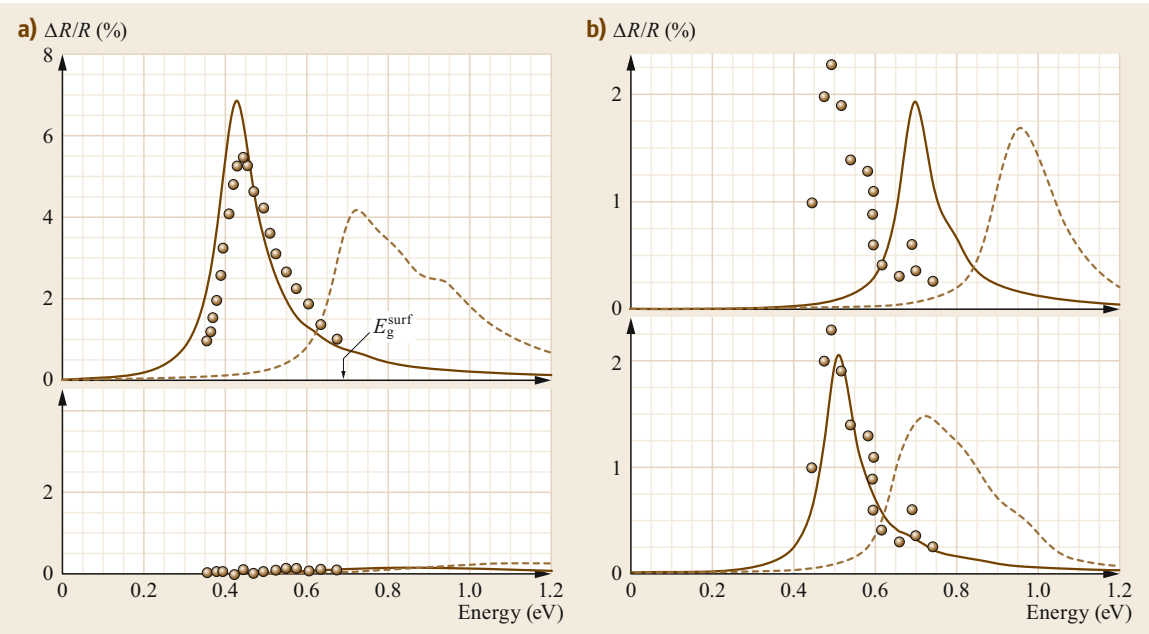

Fig. 20.17 **(a)** SDRS spectra at normal incidence of the positively buckled Si(111)-(2 × 1) surface, compared with experiments [20.146] (*dots*). The *solid* (*dashed*) *curves* include (neglect) electron–hole interaction. The electric field is parallel (*top*) and perpendicular (*bottom*) to the Pandey chains. **(b)** SDRS of the Ge(111)-(2 × 1) surface for positive (*top*) and negative (*bottom*) buckling chain models, compared with experimental data from [20.147] (*dots*)

The presence of the Pandey chains gives rise to a large anisotropy in the optical properties, as demonstrated by various experimental SDRS and RAS spectra measured at these surfaces since 1980 [20.146, 148, 149]. A large optical peak for light polarized along the Pandey chain direction is visible in the experimental spectra at 0.45 eV for Si and 0.49 eV for Ge. The comparison of the SDRS data with the corresponding BSE theoretically computed spectra clearly reveals the excitonic nature of this optical feature and the dominance of the negative isomer at the Ge surface and of the positive buckling in Si. In both surfaces, the excitonic effects are quite strong, drastically modifying the optical spectra calculated at the independent quasiparticle (IQP) level. *Rohlfing* and *Louie* [20.136] performed the first ab-initio BSE calculation of the SDRS of Si(111)-(2 × 1). Using the positive buckling Pandey chain model, they obtained a very good agreement with the experimental optical SDRS spectrum, proving the presence of a bound surface exciton and of the dominance of the right isomer in normally doped samples (Fig. 20.17a). RAS spectra recently computed

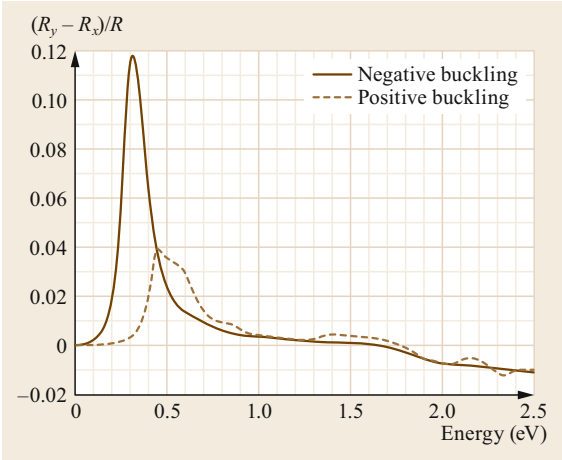

Fig. 20.18 RAS spectra of Si(111)-2 × 1 for positive and negative buckling structures, calculated within BSE; y is the [110] direction, parallel to the Pandey chains, and x is the [112] direction, perpendicular to the chains. An artificial broadening of 0.05 eV has been included

by *Violante* et al. [20.137] confirm this result. In this work, the authors extended the analysis to the negative bucking model, and Fig. 20.18 reports their RAS spectra calculated at the BSE level for both isomers.

Figure 20.17b shows the comparison of the SDRS experimental spectra with theoretical curves obtained at the IQP and BSE level of approximation, both for the negative and positive isomer of Ge(111)-(2 × 1) [20.138]. From Fig. 20.17 it is clear that the good agreement with experiment is, in this case, obtained by considering the negative chain model as the dominant reconstruction.

From the electronic and the optical experimental and theoretical data, the excitonic binding energy results to be 0.32 eV (0.13 eV) for the positive (negative) isomer in Si [20.137], while the corresponding values for Ge are 0.18 eV for the positive and 0.15 eV for the negative isomer [20.138]. The smaller binding energy for negative buckling isomers is consistent with the narrower electronic gaps and is a consequence of a more effective screening. The exciton is localized at the surface, along the chain for both isomers, and it is almost one-dimensional along the [110] direction, as a direct consequence of the weak interaction between the chains. The amplitude of probability of the electron is very large on the same chain where the hole is located, and it is already much weaker on the neighboring chains. The spatial distribution of the lowest excitonic wavefunction along this direction is different for the two isomers, as demonstrated for Si, where the probability to find the excited electron, keeping the hole position fixed along a Pandey chain, ranges over a larger

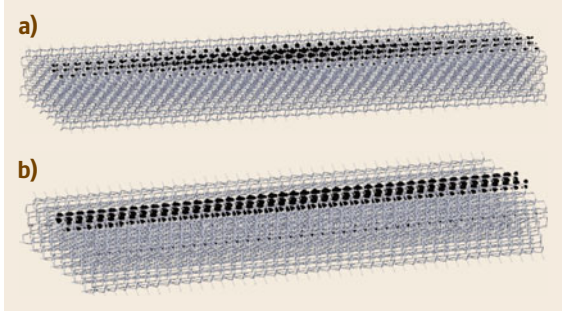

Fig. 20.19a,b Spatial distribution of the surface exciton at the Si(111)-(2 × 1) positive and negative buckling chain models. **(a)** Positive buckling, **(b)** negative buckling

distance along the [110] direction and decays to nearly zero in 80 Å for the positive buckling model, but still remains large for the negative buckling, with an estimated excitonic *length* larger than 80 Å (Fig. 20.19). As a consequence, the excitonic peak calculated is sharper in the case of negative buckling.

To conclude we can state that the accurate comparison of the results of ab-initio DFT plus MBPT simulations including the electron–hole interaction in the BSE approach, with the available experimental data have revealed that: i) in both Si and Ge(111)-(2 × 1) surfaces, the optical spectrum is dominated by the presence of bound surface excitons, with binding energy of the order of 0.25 eV; ii) the excitonic spatial distribution is highly anisotropic at the surface with the amplitude of the electron very large in the same Pandey chain where the hole is created. This analysis is obviously not accessible within the simpler one-particle picture of independent optical interband transitions.

20.6.2 Si(111)-(2 × 1) from TDDFT

As mentioned before, TDDFT is, in principle, exact for describing neutral excitations, and its advantage lies in the fact that the two-point response function $\chi(r, r', \omega)$ is needed instead of the four-point function of the Bethe–Salpeter approach. However, the exact form of the key ingredient of this approach, which is the exchange-correlation xc kernel f_{xc}, is unknown and needs to be approximated. The simplest and most used scheme for molecular systems, the adiabatic local density approximation (ALDA), is known to fail in extended systems such as surfaces. Other refined kernels have been derived in the last years but never tested on surfaces [20.67, 68, 150], while a nonlocal, static kernel with the correct long-range behavior, known as the RORO kernel [20.150] has been successfully applied only to three-dimensional systems. Moreover, several authors have derived another more elaborate nonlo-

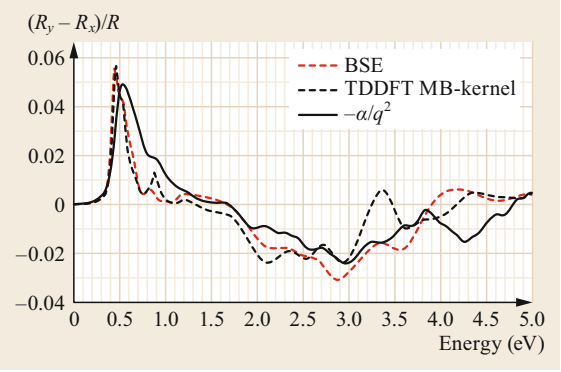

Fig. 20.20 Calculated RAS for Si(111)-(2 × 1) (positive buckling model) using different approaches: the Bethe–Salpeter equation; the TDDFT many-body kernel; and the TDDFT RORO [20.150] kernel with $\alpha = +0.2$

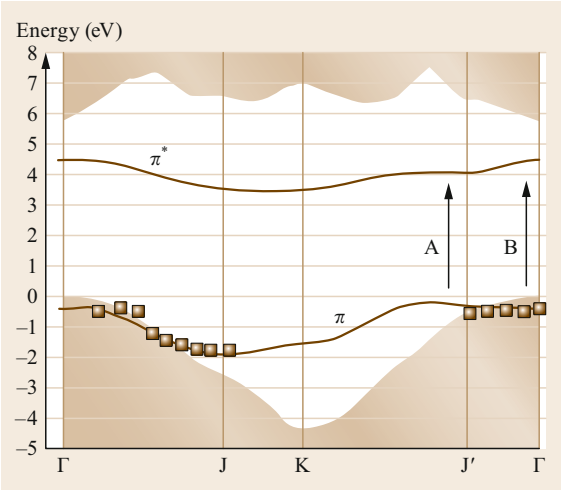

Fig. 20.21 Quasiparticle band structure of C(100)-(2 × 1) along high-symmetry lines of the surface Brillouin zone. *Brown regions* indicate the projected bulk band structure; *solid lines* are the dimer surface states. The *vertical arrows* indicate the two one-particle vertical transitions associated to the main optical peaks called A and B. Experimental data from [20.152]

cal and energy-dependent exchange-correlation kernel starting from the parallelism of the response function in TDDFT and many-body schemes. Also in this case, bulk and one-dimensional materials were studied, yielding a very good agreement with the BSE and experimental spectra.

Pulci et al. [20.151] selected Si(111)-(2 × 1) as a prototype surface for testing the performance of these different exchange-correlation kernels in TDDFT calculations to describe the surface optical properties. They showed how ALDA clearly fails to reproduce the excitonic optical peak of this surface, while the many-body derived TDDFT kernel reproduced a spectrum in very good agreement with the BSE one, both for transitions across surface states, where strong excitonic effects occur, and for bulk-like transitions (Fig. 20.20). Interestingly, using the static α/q^2 RORO kernel [20.150] the agreement with BSE results worsens slightly, but it is still very satisfactory.

20.6.3 Strongly-Bound Excitons on C(100)

At variance with Si(100), the lowest energy configuration of C(100) is the (2 × 1) unbuckled dimer reconstruction. While the tilting of dimer atoms at Si(100) breaks the surface symmetry and opens the gap between surface bands, the C(100)-(2 × 1) surface with symmetric dimers is already semiconducting, and a Jahn–Teller-like transition does not occur. Moreover, the localized nature of the C-2p orbital leads to a strong tendency to form a π bond within each dimer, giving a smaller interaction with neighboring dimers with respect to the case of silicon. The electronic band structure, obtained including the GW corrections, is shown in Fig. 20.21 together with direct photoemission data [20.152]. The agreement between theory and experiment is very good. The QP corrections do not affect the dispersion much but increase the LDA gaps between occupied and empty surface states by 1.8−2.1 eV. The minimum surface gap is indirect (along J′–K), and the surface bands are almost parallel near J′. This feature, together with the low dielectric screening of diamond, is the main reason for the formation of a strongly-bound exciton. The different behavior at the Si and diamond (100) surfaces is related to the different surface band structure of the two surfaces; while in the case of C(100) both surface LDA bands are within the gap (as in the case of the Si(111)-(2 × 1) and Ge(111)-(2 × 1) surfaces), with the empty one just in the middle of the gap; in the case of Si(100), both surface bands are energetically close to bulk bands.

Regarding the optical properties of this surface, several theoretical works, performed at different stages of approximation (DFT, GW, BSE), reported a strong anisotropy of the surface dielectric function for light polarized along and perpendicular to the dimer rows [20.76, 98]. Figure 20.22 reports results obtained from DFT-IP, GW-IQP, and BSE simulations (see [20.140] for more details). In the top panel (DFT-IP level), we see that two peaks (A and B), at 2.4 and 3 eV, which are due to surface-state to surface-state transitions, are present only for light polarized along the dimers (full lines) while for light polarized perpendicular to the dimers (dashed lines) the absorption onset occurs at 3.8 eV. On the central panel (self-energy

An artificial broadening of 0.1 eV has been used

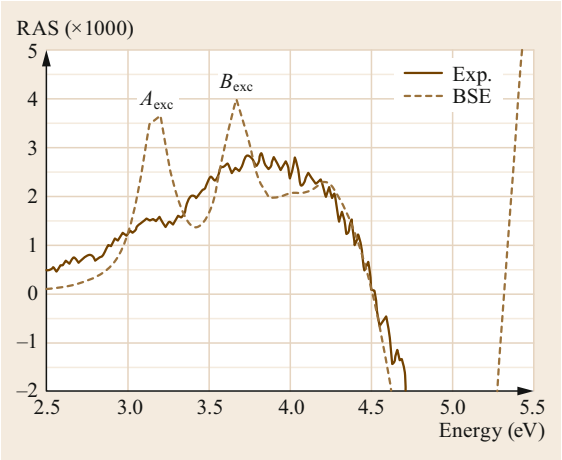

Fig. 20.23 RAS signal of the C(100) surface, calculated including excitonic, self-energy, and local-field effects (*dashed line*), compared with the experimental spectrum (*solid line*). A_{exc}, B_{exc} indicate the two bound excitons corresponding to the two one-particle transitions indicated with labels A and B in Fig. 20.21 (Reprinted with permission from [20.139]. Copyright (2005) by the American Physical Society)

effects included) we observe that the GW dielectric functions are essentially blue shifted by about 1.9 eV with respect to the DFT curves. Finally, on the third panel, when the e–h attractive interaction (W) and the local field effects ($\bar{v}$) are included through the solution of the Bethe–Salpeter equation, the surface dielectric function is redshifted by about 1 eV, and a significant shape and intensity modification is observed.

In Fig. 20.23, the RAS theoretical and experimental spectra are reported, the former at the BSE level of approximation, showing how the inclusion of local-field and excitonic effects provides a good agreement with experimental data. The inclusion of the electron–hole interaction in the calculation has dramatic effects: two strongly bound excitons (A_{exc} and B_{exc} in Fig. 20.23) develop from the corresponding one-particle transitions ([20.139, Fig. 3]). Good agreement with the experimental RAS curve behavior is also obtained in the region of interband transitions, with a deep negative contribution above 4.5 eV. This can be explained by the formation of bound excitons (with a binding energy of 0.9 eV), which induces a transfer of oscillator strength to lower energies for light polarized parallel to the dimers with a consequent depletion at higher frequencies.

The importance of excitonic and local-field effects in this surface is also clearly visible in the EELS spectrum [20.140]. Figure 20.24 reports the theoretical EEL spectra, obtained including many-body effects (Fig. 20.24b), are compared with the experimental data [20.153] (Fig. 20.24a). The experimental loss function is characterized by three main peaks located at 3.5, 4.7, and 5.9 eV. One can see that the agreement of the theoretical results with the experiment is reasonably good (Fig. 20.24b). The lowest energy double-peak (centered around 3.5 eV) is due to the excitation of the surface-state excitons, appearing at 3.1 and 3.8 eV in the surface dielectric functions; the calculated double peak corresponds well to the asymmetric experimental structure around 3.4 eV. The calculated structure at about 5 eV is due to surface state to surface state transitions, and the higher structures are mixed surface state to bulk state transitions.

In the interpretation of semiconductor surface optical data there has been a persistent discussion about the role of local-field effects. In fact, it is generally supposed that they are more important at the surface than in the bulk due to an increased inhomogeneity of the charge density, but due to the complexity of the problem, frequently these effects were studied by modeling the surface by a lattice of polarizable point atoms. In fact, the C(100) surface is an example where the optical anisotropy observed can be mainly attributed to the importance of local-field effects. Keeping in mind the atomic geometry of the surface reconstruction, it is clear that along the [011] direction, parallel

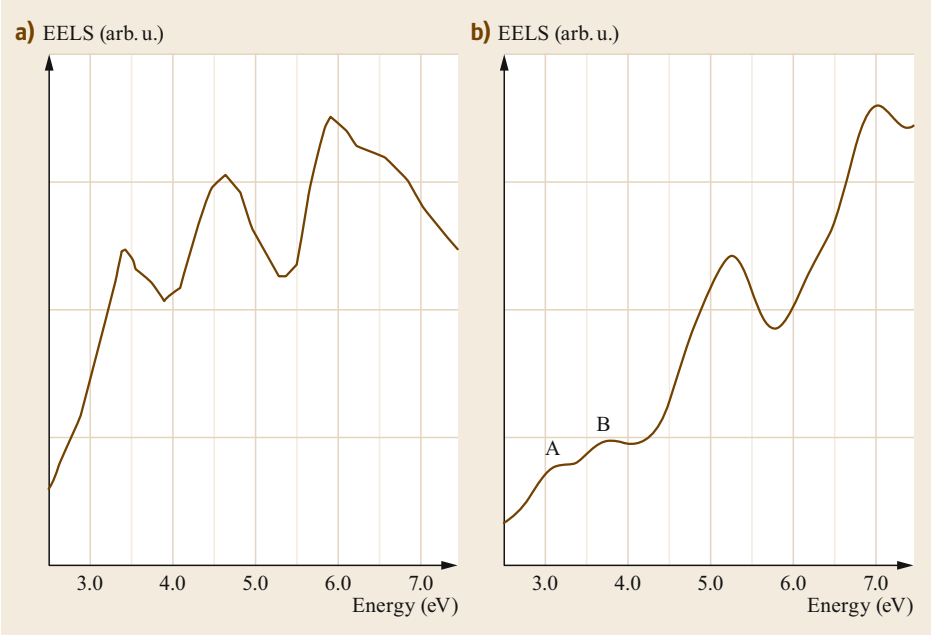

Fig. 20.24a,b Electron energy-loss spectrum of C(100)-(2 × 1). **(a)** Experimental data [20.153]. **(b)** Theoretical spectrum including excitonic effects

to the dimers (and perpendicular to the dimer rows), wide vacuum regions between the surface atoms are present, while in the $[0\bar{1}1]$ direction (which is the direction of the dimer rows) the atomic distances are similar to the bulk ones. In other words, the electric field for light polarized along [011] undergoes a surface distortion, such as to keep, according to Maxwell's boundary conditions, its electric displacement constant within the dimer rows and in between them. This can induce a strong reduction of the electric field within the dimer rows, and hence of the dielectric response for light polarized along the dimers ([011] direction). A similar anisotropic behavior of local-field effects (the so-called *depolarization effect*) has been observed in other strongly anisotropic systems like nanowires and nanotubes [20.154].

20.7 Concluding Remarks

We conclude this chapter with some comments on the practical challenges that face researchers in the field of surface interband excitations and mention some open questions.

First of all, we note that most of the systems discussed in this chapter correspond to relatively simple surfaces with small unit cells. Real surfaces can be much more complex, however. Even low-index surfaces can have huge unit cell reconstructions (e.g., Si(110)-(16 × 2) and Si(111)-(7 × 7)), vicinal surfaces like Si(557), adsorbate-stabilized nanostructured surfaces such as Ge(100):Au, and large systems containing d or f orbitals present an even tougher challenge. Other aspects of complexity derive from phenomena such as mixed domains, strain, surface charging, defects, and dislocations. Computation of optical properties in such systems can generally only be described using the simplest ab-initio approach, i.e., at the DFT-IP level, since self-energy calculations and the inclusion of excitonic and local-field effects become prohibitively heavy for slabs with hundreds of atoms inside large supercells. Other effects (strain, for instance, can penetrate hundreds of atomic layers) simply lie beyond any current ab-initio approach. However, we have seen that even in some of the simplest structures, the anisotropy of localized states make the DFT-IP approach unreliable. In these cases, the combined effects of quasiparticle, excitonic, and local-field corrections must be included in the description of the optical spectra. We expect that these phenomena may become even more important in highly nanostructured surfaces. Promising attempts have been made to avoid using GW and BSE using hybrid DFT functionals [20.117, 119], and fast and accurate TDDFT kernels (*bootstrap* kernels) may offer an alternative solution. The accuracy of these methods in surface systems, with respect to more

accurate GW-BSE approaches, needs to be carefully tested.

Another difficult task is the separation of the bulk and surface effects in the optical properties, due to the presence of *bulk-like* interband signals that are shifted or modified in shape by the presence of the surface. These effects can arise from interband transitions involving deep surface resonances or bulk states terminated at the surface, and often this identification remains a challenge. Although attempts have been made to understand the *derivative-like signals*, as in the spectra around E_1 and E_2 [20.155], respectively, at 2.6–3.0 and 4.5–4.7 eV in GaAs(110) [20.156], a microscopic understanding in terms of surface geometry is lacking. Another point is the effect of the use of finite slabs to model the surface-bulk systems. Although computation of optical spectra has a more critical dependence on the slab size thickness than, say, electron spectroscopy, there is no need to move beyond the slab model toward semi-infinite models in the computation of interband transitions if adequately thick slabs are used.

With regard to specific systems, a case that still seems unsolved is the (111) surface of diamond. After cleavage, the surface is not reconstructed, as the surface dangling bonds are mostly saturated by hydrogen atoms. After annealing at 700 K, hydrogen desorbs and the surface forms a (2×1) reconstruction. Total energy calculations indicate a Pandey chain geometry with no buckling and no dimerization as the most stable structure for the clean surface. In DFT-LDA calculations, this flat geometry gives origin to two surface bands nearly degenerate along the $\bar{J}$–$\bar{K}$ direction of the C(111)-(2×1) surface Brillouin zone. However, experimental RAS measurements show a peak extending from 1.1 to 2.8 eV with a maximum at 1.47 eV [20.157]. The experimental studies have been continued more recently [20.158], considering also the modifications of the RAS spectra induced by oxygen adsorption, comparing the shapes of surface spectra at the three (111)-(2×1) surfaces of C, Si and Ge, and their behavior upon adsorption, confirming for C the previous results and a shift similar to Si and reduction of the peak strength with oxygen uptake.

Calculation of GW corrections at the lowest level of approximation does not significantly open the gap along $\bar{J}$–$\bar{K}$ even if the effect is stronger elsewhere in the Brillouin zone. Inclusion of BSE corrections goes in the opposite direction and reduces the excitation energy. A detailed analysis [20.122] showed that the shape and location of the experimental peak can be obtained, if excitonic effects are included, only with an artificial opening of the gap by 1.8 eV. Further theoretical work [20.159] addressed this point, confirming the discrepancy between theory and experiments (always assuming this *ideal* flat surface reconstruction and the absence of defects in the theoretical computation). It has been suggested that the presence of low hydrogen contamination, defects, steps, and terraces could be responsible for the opening of the gap. A more accurate analysis is required, in both experiment and theory, to understand to what extent the interband excitations are due to the geometry of the clean surface, or to the presence of bonded hydrogen atoms and other surface steps or defects.

Thus, it is clear that even the simplest systems need further study. It is not surprising that another such surface presents aspects still to be clarified: the highly-studied Si(111)-(2×1) surface (now 40 years under investigation!). From a theoretical point of view, despite the very small difference in the total energy values of the two geometries, the energetically most stable reconstruction should be the *negative buckling* Pandey model, as obtained in the case of Ge. Experimentally, instead, the *positive buckling* isomer is seen, with the former occurring just in hyperdoped silicon samples. Again, the presence of defects, steps, and terraces could stabilize the positive buckling and be responsible for the observed preference. We have seen that the RAS spectra corresponding to the two geometries are significantly different, and this, in conjunction with other experimental local probes, can offer further tools of investigation.

To conclude, we note that 50 years of experimental study of surface optical properties, together with the development in the last four decades of theoretical methods well beyond the DFT-IP picture, have provided reliable tools for understanding surface interband excitations. Despite the technical difficulties present both in experiment and theory, it is now possible to describe the connection between surface interband transitions and the surface geometry to a high degree of sensitivity (including, as we have illustrated, details of the surface structure, stoichiometry, and composition). *Real* surfaces, featuring more complex geometries and morphology, will soon be accessible in the near future through combined experimental and theoretical studies, while simpler problematic cases still invite further investigation.

Acknowledgments. In this perspective, this chapter is dedicated to Wolfgang Richter and to Rodolfo Del Sole, as a tribute to their great contribution, through experiment and theory, to the understanding of surfaces.

Conor Hogan

Institute of Structure of Matter (ISM-CNR)
National Research Council of Italy
Rome, Italy
conor.hogan@ism.cnr.it

Dr Conor Hogan received his PhD in Physics from Trinity College Dublin (2001). He joined the Italian National Research Council (CNR) in 2005 and became a permanent Researcher in 2009 at the Institute of Structure of Matter (ISM) in Rome. His research interests include simulation of surface and interface spectroscopies from first principles, excitations in organic molecules and nanostructures, structural and electronic properties of 2D materials, and development of the Yambo code.

Maurizia Palummo

Dept. of Physics and INFN
University of Rome "Tor Vergata"
Rome, Italy
maurizia.palummo@roma2.infn.it

Professor Maurizia Palummo obtained her PhD in Physics in 1994. Following several postdoctorate and research positions, she has been Associate Professor at the Department of Physics of the University of Rome "Tor Vergata" since 2017. The main focus of her present research is on the ab-initio calculation of electronic and optical properties of surfaces, organic molecules, and derivatives and nanostructures, mainly nanowires and novel 2D materials.

Olivia Pulci

Dept. of Physics, and INFN
University of Rome "Tor Vergata"
Rome, Italy
olivia.pulci@roma2.infn.it

Professor Olivia Pulci obtained her PhD in Physics from the University of Rome "Tor Vergata" (1996). She was Researcher at Rome Tor Vergata until 2010, when she took up her present post as Associate Professor in Physics. Her research interests include ab-initio calculations of the electronic and optical properties of low-dimensional semiconductor structures (including surfaces, novel 2D systems, nanocrystals), but also of ice, water, and of cellulose for cultural heritage preservation.

Carlo M. Bertoni

Dept. of Physics, Informatics and Mathematics
University of Modena and Reggio Emilia
Modena, Italy
carlo.m.bertoni@gmail.com

Carlo Maria Bertoni graduated in physics (1970). He became Full Professor of Quantum Theory of Solids (University of Rome "Tor Vergata", 1987) and in Theoretical Physics (University of Modena, 1994). He served as Dean of the Faculty of Science (University of Modena, 2005-2012). His research fields include electronic, structural and vibrational properties of solids, low-dimensional systems, nanoscience, surfaces and interfaces, and theory of electron and X-ray spectroscopies using synchrotron radiation.

Part E Surface Magnetism

Part E Surface Magnetism

Part E is devoted to surface magnetism. Because translational invariance in the direction normal to the surface is broken at the surface itself, and due to the low dimensionality, broken bonds, and reduced coordination associated with surfaces, the magnetic properties of a surface or thin film may differ substantially from those of the same material in bulk form. On the other hand, a surface is also a template that can be used to grow magnetic nanostructures for magnetic memories. For the latter application, one has to keep in mind that the magnetic properties of the clusters depend on the magnetic coupling with the support. Decoupling from a metal substrate can be realized with ultrathin oxide films. A wide set of applications can be foreseen, covering information technology (data storage, processing, sensing), energy harvesting, power conversion (thermoelectric and spin-motive devices), and medicine (nanoparticles for drug targeting and hyperthermia).

Chapter 21 provides a pedagogic and broad introduction to surface magnetism starting from the fundamental concepts of the band structure model, which can be used to explain spin and orbital magnetic moments, exchange interactions, and magnetic anisotropy in low-dimensional structures. Solid surfaces, thin films, and noncollinear spin configurations including one-dimensional atomic chains and single-atom magnets are addressed. The latter represent magnetic structures at the ultimate size limit.

Chapter 22 focuses on the magnetic properties of transition metal oxide surfaces and thin films. After establishing a framework that distinguishes magnetic metal oxides from metallic magnetic materials, the chapter describes experimental methods that are used for sample preparation as well as to characterize the surface geometries and magnetic properties of these materials. Oxide/metal interface engineering through the use of buffer layers is covered as well. In the final section of the chapter, the interplay between magnetic and chemical properties is discussed.

21. Magnetic Surfaces, Thin Films and Nanostructures

Pietro Gambardella, Stefan Blügel

This chapter presents a pedagogical overview on fundamental aspects of surface and interface magnetism that have implications for the understanding of a broad variety of nanoscale magnetic and spintronic phenomena. We introduce general concepts derived from electronic band structure models to explain the evolution of the spin and orbital magnetic moments, exchange interaction, and magnetic anisotropy in low-dimensional structures. Trends due to the reduced symmetry and atomic coordination are emphasized, including the effects of spin–orbit coupling and the Dzyaloshinskii–Moriya interaction. We present spin Hamiltonian models that capture the collective behavior of a magnetic lattice and enable the description of the low-energy spin excitations as well as of the onset of magnetic order as a function of temperature in systems of arbitrary size and dimension. Finally, we illustrate the magnetic behavior of exemplary surface systems, such as the surfaces of bulk crystals, ultrathin films, non-collinear spin structures, and atomically engineered spin networks, including one-dimensional atomic chains and single-atom magnets.

Surface magnetism is a vast subject that has ramifications in several areas of condensed matter physics, materials science, and nanotechnology. Because the surface is what we can see and touch of a magnet, one could argue that the study of surface magnetism is as old as magnetism itself. However, the recognition that the surface properties of magnets are distinct from those of the bulk came relatively late, thanks to the work of Louis Néel, Francis Bitter, and others in the second half of the twentieth century. Starting in the 1970s, the development of increasingly sophisticated and reliable surface preparation methods, as well as of sensitive analysis techniques, revolutionized the field and brought surface magnetism to the forefront of fundamental and applied research. Today, the study of surfaces and interfaces overlaps with the fields of nanomagnetism and spintronics, forming one of the most lively areas of magnetism.

Surfaces have a dual nature. On the one hand, a surface represents the abrupt termination of a bulk crystal. As such, one may expect that the properties of a magnet will change in the proximity of the uppermost surface layers due to the reduced atomic coordination. On the other hand, a surface is a platform that can be used to fabricate and manipulate magnetic nanostructures. By using physical vapor deposition methods, such as molecular beam epitaxy or sputtering, and either top-down or bottom-up patterning techniques, structures of almost arbitrary shape and composition can be assembled. These structures present magnetic and electronic properties that do not exist in the bulk. Such a diversity of nano- and heterostructures underpins a wide spectrum of applications, ranging from information technology (data storage, processing, sensing) to energy harvesting, power conversion (thermoelectric and spin-motive devices), and medicine (nanoparticles for immunoassays, drug targeting, and hyperthermia).

The theoretical approaches used to predict and describe the magnetic properties of surfaces are based on either itinerant electronic band structure models extended from the bulk to low-dimensional systems or ligand field models extended from few atoms to structures of increasing size. As is typical in the description of correlated electron systems, the choice of one approach or another largely depends on the degree of electron localization as well as on the phenomena under investigation. In magnetic metals, for example, the unpaired electrons in the outer shells of the magnetic atoms are neither fully itinerant nor fully localized, which results in a rich variety of electronic and magnetic effects.

Despite this diversity, most of the peculiar features of surface magnetism can be attributed to a few basic facts, namely the change of the atomic coordination number and symmetry breaking. The purpose of this chapter is to present a pedagogical overview of these effects, focusing on ground-state properties such as the saturation magnetization, magnetic anisotropy, and critical temperature, as well as on the behavior of magnetic atoms in different coordination environments. The emphasis is on metal systems, but many of the concepts introduced here are general and can be extrapolated to insulators, semiconductors, and two-dimensional materials. Nonequilibrium effects, such as magnetization dynamics, magnetotransport properties, and voltage- or current-induced magnetization switching, are not treated explicitly. For a detailed description of these topics, we refer to more extensive reviews on ultrathin metal films [21.1–9], multiferroic heterostructures and oxide interfaces [21.10–12], magnetic clusters and nanoparticles [21.13–16], and single atoms [21.17–21]. Comprehensive reviews also exist on nonequilibrium effects such as spin dynamics in confined geometries [21.22–25], ultrafast magnetism [21.26], magnetotransport phenomena [21.27–32], as well as current-induced spin torques and magnetization switching [21.33–35].

21.1 Fundamentals

This section provides an overview of the theoretical concepts used to predict and analyze the magnetic ground state of surfaces and low-dimensional structures. The magnetic ground-state properties are determined by (i) the formation of local moments of different sizes, (ii) the interactions responsible for magnetic order as well as for the magnetic coupling at interfaces or across spacer layers, and (iii) the magnetic anisotropy energy, which couples the direction of the magnetization to the lattice and determines the easy and hard axes of magnetization. Table 21.1 compares the magnetic energies involved in (i)–(iii) with the structural and compositional ground-state energies of typical transition metals. From the relative importance of the different energies, it is evident that the formation of local magnetic moments has a considerable influence on the stability and structural arrangement of surfaces and interfaces. Since the local moments may change quite substantially in different coordination environments, materials with new and unknown phases [21.36], crystal structures, and magnetic structures [21.37] are to be expected. The anisotropy energy is a rather small quantity, being energetically nearly decoupled from the rest, but it has a strong influence on the stability and finite-temperature properties of thin films and nanoparticles. An important point related to (i) and (ii) is that the broken inversion symmetry of

Table 21.1 Typical ground-state energies for 3d metal films

Property	Energy (eV/atom)
Cohesive energy	5.5
Local moment formation	1.0
Alloy formation	0.5

Magnetic anisotropy	10^{-4}–10^{-2}

surfaces and interfaces, which is common to all nanostructures, gives rise not only to the well-known symmetric Heisenberg exchange interaction but also to antisymmetric exchange, viz. the so-called Dzyaloshinskii–Moriya interaction (DMI), which favors non-collinear spin alignment (Sect. 21.1.6). Depending on the strength of the DMI, chiral or vortex-like spin structures such as spirals and skyrmions can emerge in thin magnetic films deposited on nonmagnetic substrates. Predicting the magnetic ground state of a low-dimensional magnetic system is therefore a highly nontrivial problem.

Historically, itinerant models of magnetism based on ab initio band structure calculations have been used to predict the magnetic ground state of metallic ferromagnets and antiferromagnets at zero temperature. On the other hand, the magnetism of complex spin structures, stemming from either itinerant or localized spins, has been almost exclusively discussed within the framework of spin lattice Hamiltonians, such as the Heisenberg and Ising models. Due to necessity of taking spin fluctuations into account, the temperature dependence of the magnetization has also been treated using spin lattice models. More recent approaches map the results of ab initio calculations onto Heisenberg-type Hamiltonians to study the thermodynamical properties of bulk and low-dimensional magnets [21.38]. In the following, we give a basic introduction to both itinerant and localized models of magnetism with an emphasis on dimensionality effects relevant to understanding the behavior of surfaces and nanostructures.

21.1.1 Stoner Model

This subsection focuses on the dimensional aspect of itinerant magnetism, in particular of those systems including d electrons, as relevant for the magnetic ground-state properties of metallic surfaces, heterostructures, and nanoparticles. Considering the vast number of possible systems, which grows quickly with the types of constituent atoms, the surface and interface orientation, the chemical and structural roughness at interfaces, and the electronic nature of the substrate (metal, semiconductor, or insulator), an exhaustive review of such effects is impractical. Instead, we discuss chemical trends for transition metals to develop an intuition of the dimensional aspects that influence the magnetic behavior of metallic surfaces, interfaces, multilayers, ultrathin films, and magnetic clusters deposited on surfaces. The simplest low-dimensional systems are isolated atoms, whose spin moments as a function of the number of d electrons are well described by Hund's first rule: the spins of all electrons in an atom are aligned parallel to each other as long as no quantum state is occupied more than once. Thus, nearly all of the 30 transition-metal atoms have magnetic spin moments. The largest possible d moments occur at the center of each series, i.e., 5 μ_B for Cr and Mn in the 3d series. On the other hand, it is well known that only 5 of the 30 transition metals remain magnetic in their bulk crystalline phase: Co and Ni are ferromagnetic, Cr is antiferromagnetic, and Mn and Fe are ferromagnetic or antiferromagnetic depending on their crystal structure (Fig. 21.1). Low-dimensional transition metals should fall in between these two extremes. Also, systems that are nonmagnetic as bulk metals may be magnetic at the surface or as nanostructures.

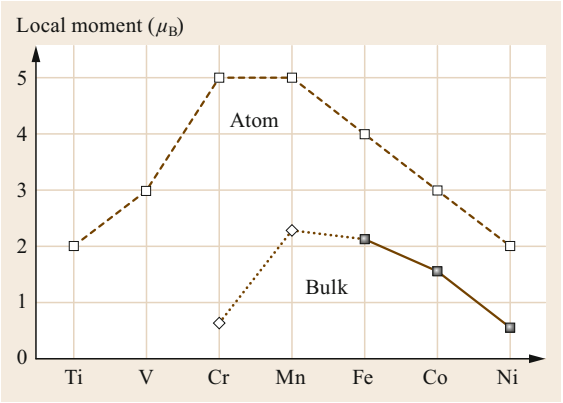

Fig. 21.1 Local magnetic moments of isolated 3d atoms (*empty squares* connected by *dashed line*), ferromagnetic (*solid squares* connected by *solid line*) and antiferromagnetic (*diamonds connected* by *dotted line*) 3d bulk metals. The magnetism of the atom includes only the moment due to the d electrons. For the bulk metals, the experimental spin moments are shown

Spontaneous magnetic moments in itinerant electron systems form due to the repulsive electron–electron interactions and Pauli exclusion principle, which favor either parallel or antiparallel alignment of the spin moments on neighboring lattice sites. Elements in the first half of the 3d series, if magnetic such as Cr and Mn, tend to develop antiferromagnetic exchange interactions. This is because the d-states at the bottom of the band have bonding character and singlet-like wavefunctions, with large amplitudes between atomic sites. As the electrons are more likely to be found close to each other, Pauli's exclusion principle forces their spins to be antiparallel. Elements in the second half of the 3d series, such as Fe, Co, and Ni, on the other hand, tend to develop ferromagnetic exchange interactions. This is because the wavefunctions in the upper half of the d-band have predominantly antibonding character, with a node between atomic sites. As a result, the d electrons are more localized, with a tendency to align their

spins parallel to each other. Exchange is usually introduced into band structure calculations by means of an exchange–correlation potential, which shifts the energy eigenvalues by a constant amount $\mp(1/2)Im_S$, where m_S is the local spin magnetic moment given by the integral of the magnetization density over the atomic unit cell and I is the exchange integral (the Stoner parameter). In the rigid band approximation, the energy eigenvalues for spin up ($\uparrow$) and spin down ($\downarrow$) electrons are thus given by

$$\varepsilon_\nu^{\uparrow,\downarrow}(\boldsymbol{k}) = \varepsilon_\nu^0(\boldsymbol{k}) \mp \frac{1}{2} I m_S \,, \tag{21.1}$$

where $\varepsilon_\nu^0(\boldsymbol{k})$ is the energy dispersion of the electron states in the absence of exchange, $\boldsymbol{k}$ is the electron's wavevector, and ν is a band index. The densities of states (DOS) $n^{\uparrow,\downarrow}(E)$ are also shifted compared with the DOS $n^0(E)$ of the nonmagnetic metal

$$n^{\uparrow,\downarrow}(E) = \sum_\nu \int_{\mathrm{BZ}} \delta\left(E - \varepsilon_\nu^{\uparrow,\downarrow}\right) \mathrm{d}\boldsymbol{k} = n^0\left(E \pm \frac{1}{2} I m_S\right) , \tag{21.2}$$

where the integral is over the Brillouin zone. From (21.2), one obtains the number N of electrons and m_S as the sum and difference, respectively, of the occupied spin-up and spin-down states integrated up to the Fermi energy E_F,

$$N = \int^{E_F} \left[n^0\left(E + \frac{1}{2} I m_S\right) + n^0\left(E - \frac{1}{2} I m_S\right) \right] \mathrm{d}E \,, \tag{21.3}$$

$$m_S = \int^{E_F} \left[n^0\left(E + \frac{1}{2} I m_S\right) - n^0\left(E - \frac{1}{2} I m_S\right) \right] \mathrm{d}E \,. \tag{21.4}$$

Equations (21.3) and (21.4) can be solved self-consistently with the condition of charge neutrality that determines N, thus E_F gives nonmagnetic solutions $m_S \neq 0$ only if the so-called Stoner criterion is satisfied, namely

$$I n^0(E_F) > 1 \,. \tag{21.5}$$

The Stoner criterion is thus an instability condition that expresses the competition between the exchange interaction that drives the system into ferromagnetism for large I and the kinetic energy of the electrons. The kinetic energy increases if the system becomes magnetic, as exchange splitting raises the energy of the spin-down (minority) states above E_F. However, if $n^0(E_F)$ is large, a large gain in exchange energy can be realized for relatively little cost in kinetic energy. The rigid band shift exemplified in (21.1) is a simplified model that works well for small values of the exchange splitting energy Im_S, as is the case for bulk ferromagnets. Although deviations can be found for thin films, as the magnetic moments and thus the exchange splitting are large, this model provides a good basis for discussing trends in magnetic moment formation across the Periodic Table as well as dimensionality effects. Moreover, the Stoner criterion can be generalized to antiferromagnetic as well as non-collinear spin structures by introducing a staggered susceptibility $\chi_{\boldsymbol{q}}$ that describes the tendency to form a frozen spin wave of wavevector $\boldsymbol{q}$ and is proportional to the local DOS, which favors the formation of stable moments for $I\chi_{\boldsymbol{q}}(E_F) > 1$ [21.6].

21.1.2 Role of the Coordination Number

The exchange integral I is an intra-atomic, element-specific quantity that, in the simplest approximation, is independent of the local environment, the structure, and the site of a given atom, e.g., in the surface or bulk. According to *Gunnarsson* [21.39] and *Janak* [21.40], the global trend

$$I_{3d} > I_{4d} > I_{5d} \tag{21.6}$$

is found for the exchange integrals of the 3d, 4d, and 5d transition-metal series. Focusing on the d electrons as those relevant for itinerant magnetism, the DOS depends on both the coordination number N_{nn} and the hopping matrix elements h_d between the d-states. This can be understood as follows: The integral of the d-DOS (corresponding to states with angular momentum quantum number $l = 2$) is $\int_W n_l(E)\mathrm{d}E = 2l + 1$, where W is the bandwidth of the d-states. Thus, in the simplest approximation possible (i.e., a rectangular-shaped DOS), one can assume that the local DOS scales inversely proportionally to the bandwidth W,

$$n(E_F) \propto \frac{1}{W} \,. \tag{21.7}$$

In the atomic limit, the bandwidth converges to zero, the Stoner criterion is always fulfilled, and moments in accordance with Hund's first rule will be found. In general, the DOS consists of contributions from electrons in s, p, d, and f states. For transition metals, by far the largest contribution comes from the d electrons, and the d–d hybridization determines the shape of the DOS. Therefore, in the following discussion, we restrict our-

selves to d electrons and write

$$n(E_F) \approx n_d(E_F) \approx \frac{1}{W_d} . \tag{21.8}$$

The average local bandwidth $\overline{W}_d(\boldsymbol{R}_i)$ for atom i at position $\boldsymbol{R}_i$ can be estimated in a nearest-neighbor tight-binding model, applicable for the itinerant but tightly bound d electrons of transition-metal atoms, as

$$W_d \approx \overline{W}_d(\boldsymbol{R}_i) = 2\sqrt{N_{nn}(\boldsymbol{R}_i)}\, h_d(R_{nn}) . \tag{21.9}$$

According to (21.9), the bandwidth depends on two quantities: (a) the hopping matrix element h_d of the d electrons and (b) the number of nearest-neighbor atoms N_{nn} (the coordination number). The influence of these parameters is discussed below.

(a) h_d depends on the overlap of the d wavefunctions, decreasing with increasing distance R_{nn} to the nearest-neighbor atoms. For a given lattice constant, h_d increases with the extension of the wavefunction or, equivalently, the number of nodes. Figure 21.2 shows a schematic of the bandwidths of 3d, 4d, and 5d bulk transition metals, together with the bandwidths of rare earths and actinides. In line with the arguments of increasing number of nodes from 3d to 5d wavefunctions, a clear *macrotrend* emerges in the transition-metal series, which can be summarized as follows

$$\begin{aligned} h_{3d} < h_{4d} < h_{5d} &\Longrightarrow W_{3d} < W_{4d} < W_{5d} \\ &\Longrightarrow n_{3d} > n_{4d} > n_{5d} . \end{aligned} \tag{21.10}$$

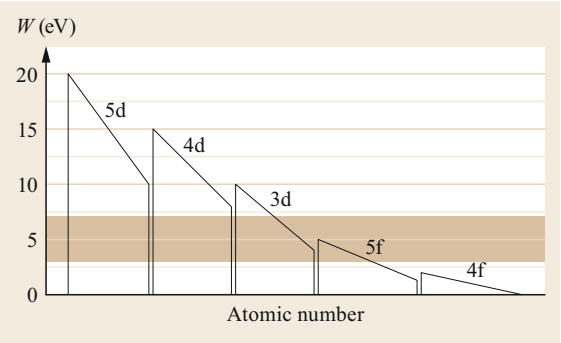

Fig. 21.2 Schematic illustration of bandwidth W of transition metals together with rare earths (4f) and actinides (5f) in the bulk phase. The 5f electrons of the early actinides and the 3d electrons of transition metals from the middle to the end of the 3d series (Cr to Ni) show itinerant magnetism, whereas the late actinides and the rare earths are best described by a localized electron picture with magnetic properties determined, to a good approximation, by Hund's rules. The *shaded rectangle* indicates the region favorable for band magnetism. Above the rectangle magnetism is suppressed, while below the rectangle localized (atomic) magnetism is preferred

Within each transition-metal series, there exists in addition a microtrend: due to the incomplete screening of the Coulomb potential of the nucleus by the d electrons, the d wavefunctions are more extended at the beginning than at the end of the series, thus the hopping matrix element is larger at the beginning than at the end of the series, which has consequences for the bandwidth W and DOS $n(E_F)$.

(b) The smaller the value of N_{nn}, the smaller the d–d hybridization and the width of the d-bands. Consider, for example, an atom in the environment of a face-centered cubic (fcc) crystal ($N_{fcc} = 12$), in the (001) surface ($N_{(001)} = 8$), in a two-dimensional (001) monolayer (ML) film ($N_{ML} = 4$), and in a monatomic chain ($N_{chain} = 2$), keeping the nearest-neighbor distance fixed ($R_{nn} = \text{const}$) and the bond strength fixed ($h_d = \text{const}$). Under these circumstances, one obtains for the ratio of the bandwidths

$$W_d^{chain} : W_d^{ML} : W_d^{(001)} : W_d^{fcc} = 0.41 : 0.58 : 0.82 : 1 , \tag{21.11}$$

or the local DOS

$$n_d^{chain} : n_d^{ML} : n_d^{(001)} : n_d^{fcc} = 2.45 : 1.73 : 1.22 : 1 . \tag{21.12}$$

The important message of (21.11) and (21.12) is that the reduction of the coordination number leads to less d–d hybridization and thus band narrowing, and the tendency towards magnetism is considerably increased. The reduction of the coordination number is hence responsible for the fact that the magnetism is enhanced at surfaces as compared with bulk, and the magnetism of ultrathin films should be larger than at surfaces. A nice manifestation of these arguments is shown in Fig. 21.3a, where the spin-resolved DOS of single-monolayer Fe and of a single Fe atom adsorbed on the Au(111) surface are calculated from first principles [21.41]. Clearly, the width of the 3d-band of the single Fe atom is smaller than that of the Fe monolayer and much smaller compared with the Au 5d-band, whereas $n(E_F)$ is largest for the single Fe atom. Accordingly, the spin and magnetic moments of the single Fe atoms are larger than those of the Fe monolayer, and both are enhanced relative to the bulk Fe moments. The arguments put forward here for the increased ferromagnetism in reduced dimension can be carried over directly to antiferromagnetism. Additionally, one can expect that transition metals, which are nonmagnetic as bulk metals, will become magnetic at surfaces or as ultrathin films.

The magnetic properties are expected to depend also on the surface or film orientation, because along with

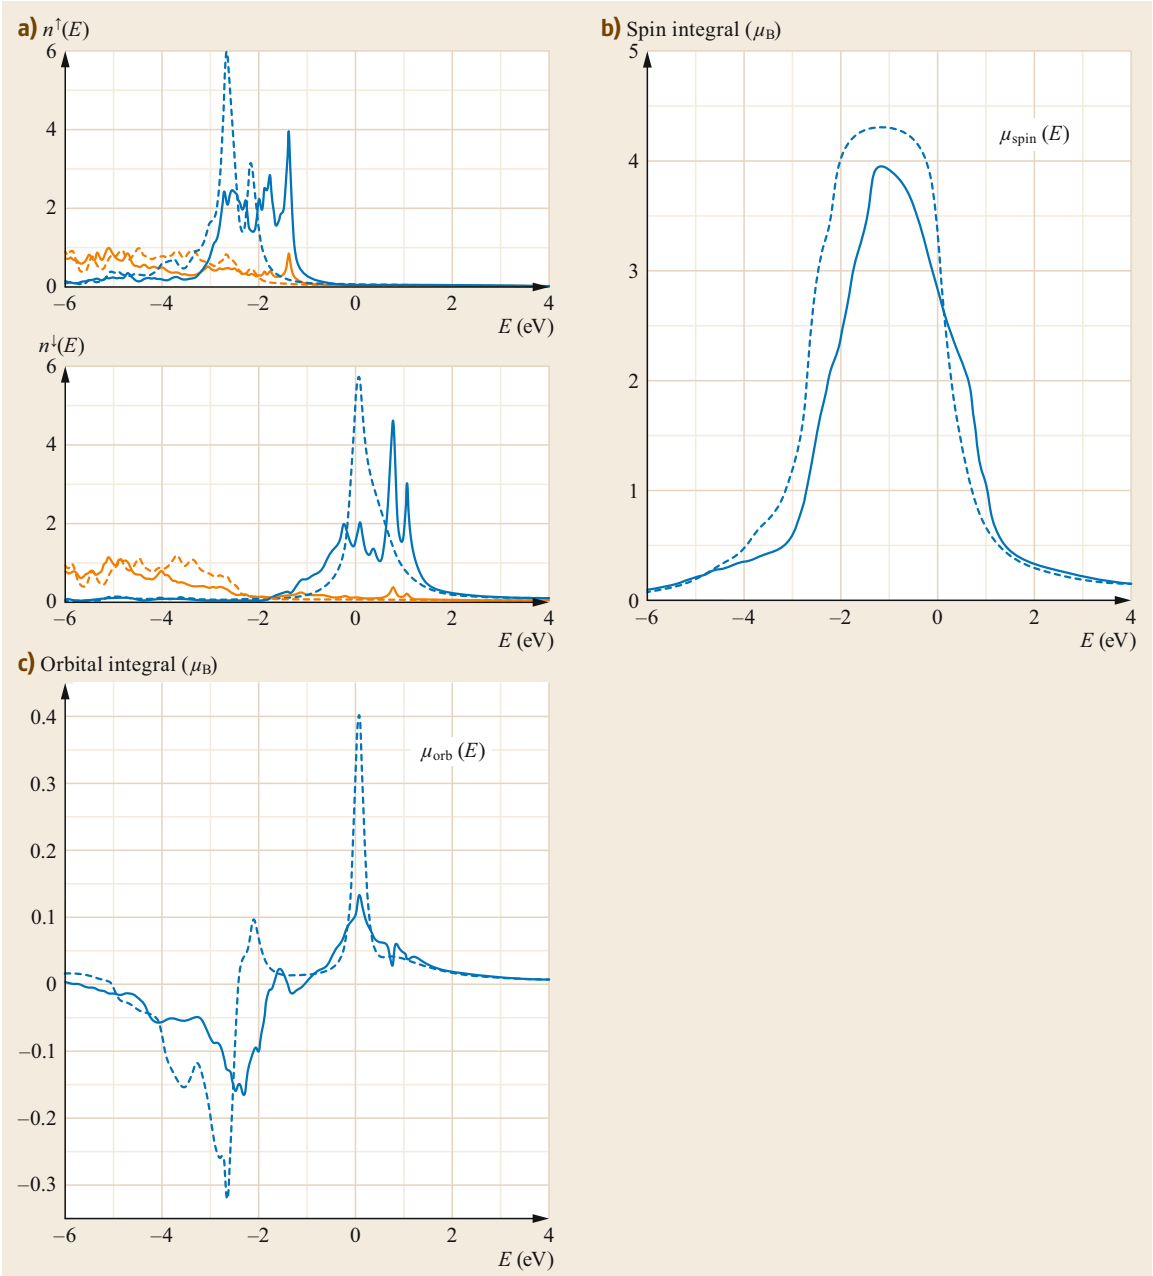

Fig. 21.3 **(a)** Spin-resolved DOS of 1 ML of Fe/Au(111) (*solid lines*) and a single Fe atom on Au(111) (*dashed lines*) calculated ab initio using density functional theory. *Blue* and *yellow lines* represent the DOS projected on Fe and Au orbitals, respectively. Supported atoms are treated as a perturbation on the clean surface using a relativistic impurity Green function formalism [21.42]. **(b,c)** Spin and orbital magnetic moment per Fe atom as a function of energy relative to the Fermi level. Note that the spin moment is maximum and the orbital moment is minimum at $E \approx -1$ eV, corresponding to a half-filled d-band, in agreement with the first and second Hund rules. Figure courtesy of *Šipr* and *Minár*, based on calculations reported in [21.41, 43]

Table 21.2 Coordination number N_{nn}, interlayer distance t, point symmetry S, and packing density ρ (fraction of area of surface unit cell covered by atoms represented by touching spheres) for an fcc lattice. Only the three low-index surfaces, (001), (011), and (111), are considered. a is the lattice parameter of the simple cubic unit cell

Surface	N_{nn}	S	t/a	ρ
(111)	9	C_{3v}	0.5774	0.9068
(001)	8	C_{4v}	0.5000	0.7854
(011)	7	C_{2v}	0.3536	0.5554

a change of the surface orientation goes a change of the coordination number N_{nn} (Table 21.2) as well as a change of the nearest-neighbor distance $R_{\parallel}$ between the surface atoms and the distance $R_{\perp}$ between the surface atoms and the atoms in the next layer. For an fcc lattice, the (111) surface is the most densely packed one, leading to the smallest enhancement of the magnetic moments. Among the three low-index surfaces with orientation (001), (011), and (111), the (011) surface is the most open. For the latter, we expect the largest magnetic moments. At surfaces or ultrathin films with body-centered cubic (bcc) lattice structure, the trend should be exactly the opposite. The most densely packed surface is the (011) surface, for which we expect the smallest enhancement of the magnetic moments. The (111) surface is the most open. This surface is already close to a stepped one.

The coordination number discussed so far is an important aspect in interface magnetism but not the whole story. Further important aspects have to be taken into account to provide a qualitatively correct description of magnetism at surfaces and interfaces, as described below.

Point Symmetry

The disruption of the translational symmetry perpendicular to a surface or interface reduces the point symmetry. Degeneracies typical for cubic bulk metals may be lifted. One example is the threefold-degenerate t_{2g} orbital, which is split into a twofold-degenerate state and a nondegenerate state at a (001) surface. This symmetry breaking induces a splitting or broadening of the DOS and makes magnetism unfavorable. A famous victim of this scenario is Pd. Bulk Pd has a large DOS at the Fermi level, which contributes to a large exchange-enhanced susceptibility. Thus, bulk Pd is nearly ferromagnetic. The band narrowing experienced at the surface due to the reduction of the coordination number should drive the surface of Pd into a ferromagnetic state, but this is not the case. Instead, the change of the surface symmetry splits the states at the Fermi energy, broadens the DOS, and counteracts the band narrowing. The surface of Pd(001) thus remains nonmagnetic.

Shift of the d-Band Relative to the sp-Band

Compared with an isolated atom, the d electrons in a solid are in a state of compression. Therefore, their energy levels are positioned at a much higher energy than in an atom. At the surface, the charge density of the d electrons can relax and their energy levels move downwards, closer to the bottom of the sp-band, leading to an increase of the number of d electrons. This downward shift is often facilitated by a significant hybridization of the d electrons with sp electrons or holes in the case of a transition-metal film deposited on a nonmagnetic metal substrate. As depicted in Fig. 21.4a, this effects leads to a Lorentzian tail of the DOS. If this tail is positioned close to the Fermi energy, magnetism can be drastically reduced due to the decrease of the Fermi-level DOS. An example of this effect is a single Ni monolayer on Cu(100), for which the local Ni moment amounts to 0.33 μ_B, which is smaller than the magnetic moment of Ni atoms at the Ni(100) surface (0.72 μ_B). For the same reason, a monolayer of Pd on Ag(100) is nonmagnetic, whereas small Pd clusters support the formation of 4d magnetic moments [21.44, 45]. In both cases, we would expect an increase of the moment due to the reduction of the coordination number by a factor two when compared with the respective (100) surfaces. On the other hand, elements at the beginning of the transition-metal series such as V profit from this effect, and magnetism can appear more likely.

sp–d Dehybridization

The main carriers of itinerant magnetism are the d electrons. In free atoms, the number of d electrons is an integer. In metallic systems, the number of d electrons is noninteger and depends on, besides the dominating d–d hybridization, the hybridization with the s and p electrons. Due to sp–d hybridization, the d-states below the Fermi energy are mixed into unoccupied sp hybrids, which reduces the number of d electrons in bulk systems compared with free atoms. If the coordination number decreases or the nearest-neighbor distance increases, the d-states become more localized, leading to sp–d dehybridization and a consequent increase in the occupation of the d-states, as illustrated in Fig. 21.4b. Surfaces and monolayers, with their smaller coordination numbers, therefore have a higher number of d electrons favorable for magnetism.

Charge Neutrality

Local charge neutrality has to be fulfilled to avoid the appearance of strong Coulomb forces. Band narrowing (at interfaces) automatically means that the number

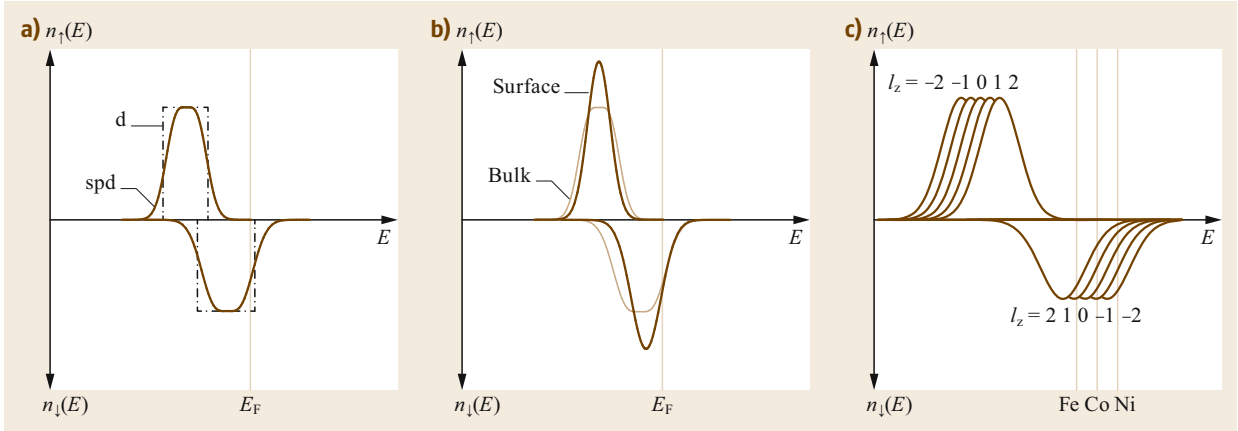

Fig. 21.4 **(a)** Schematic illustration of hybridization of d electrons of a magnetic layer with sp electrons, e.g., of the substrate. The *dot-dashed* (*solid*) line shows the d-projected DOS in the absence (presence) of sp–d hybridization. **(b)** Schematic illustration of the role of sp–d dehybridization on the DOS of the d electrons. The integrated density of d-states for the surface is larger than for the bulk. Note also that the exchange splitting between majority and minority states is larger for the surface because of the upward shift of the minority DOS. **(c)** Schematic DOS of a 3d bulk metal, showing the hybridization of states with different orbital angular momentum quantum number l_z. The spin–orbit coupling partially removes the degeneracy between the $+l_z$ and $-l_z$ states, inducing a net orbital moment. The *dashed line* indicates the approximate position of the Fermi level for Fe, Co, and Ni. (Adapted by permission from [21.46] © APS 1990)

of electrons must change. To avoid charged interfaces, a realignment of the center of gravity of the bands occurs (Fig. 21.4b). The d band, which moved to lower energy in order to relax the compression, now moves upwards again. Due to this upward shift in energy, the minority and majority electrons depopulate by different amounts. Together with the change of the number of majority electrons due to the sp–d dehybridization, this effect leads to an increase of the magnetic moment. All together, we find a complex alignment of each band, which depends on the symmetry of the Bloch wavefunctions.

Strong and Weak Ferromagnets

Strong ferromagnets (magnets with filled majority band) are less sensitive to changes of the coordination number and the lattice parameter relative to weak ferromagnets (magnets with partly occupied majority bands). Neglecting these interwoven effects has been a source of confusion in the past. They are readily included by performing self-consistent first-principles calculations.

21.1.3 Spin and Orbital Moments

The magnetic moment discussed in the previous section, given by (21.4), is clearly a consequence of the imbalance of spin-up and spin-down electrons caused by intraatomic exchange–correlation effects and is, therefore, a pure spin magnetic moment. The narrowing of the d-projected DOS as well as the shifts of the center of gravity of the majority and minority d bands with reduced coordination number generally result in an increase of m_S at surfaces and low-dimensional structures, as seen in Fig. 21.3 for the case of Fe monolayers and adatoms on Au(111). From atomic physics, moreover, we know that the total magnetic moment is the sum of the spin and orbital contributions, $\boldsymbol{m} = \boldsymbol{m}_S + \boldsymbol{m}_L$. In a classical picture, the orbital moment results from the orbital motion of the electron revolving around the nucleus. To obtain a finite orbital moment, the symmetry in the number of electrons revolving clock- or counterclockwise must be broken, which we refer to as broken orbital degeneracy. Generally, three mechanisms can enable such symmetry breaking: (i) Coulomb correlation effects, as known for single atoms, which lead to Hund's second rule, (ii) the spin–orbit interaction, and (iii) the scalar spin chirality $\kappa = \boldsymbol{S}_i \cdot (\boldsymbol{S}_j \times \boldsymbol{S}_k)$, involving at least three atoms with a non-coplanar spin texture. The first two mechanisms are ubiquitous and well characterized [21.47–50]. Mechanism (iii), on the other hand, is rather new and restrained to non-collinear spin systems [21.51]. The scalar spin chirality κ originates from the non-coplanarity between three neighboring spins, and replaces the spin–orbit interaction in giving rise to an emergent effective magnetic field, which is the source of *topological orbital magnetization*. Such an effect is present, e.g., in skyrmions, where the topological orbital magnetization is proportional to the topological charge of the skyrmion [21.52] and can

Table 21.3 Local spin (m_S) and orbital (m_L) magnetic moments in units of μ_B calculated using the generalized gradient approximation to density functional theory for Fe, Co, and Ni atoms in bulk crystals (D = 3), unsupported (111) monolayers (D = 2), atomic chains (D = 1), and free atoms (D = 0). For the bulk crystals the variation of the orbital moment with the direction is small, but for films and chains the orbital moments parallel (∥) and perpendicular (⊥) to the film plane or chain axis are given. The lattice spacing is chosen as if the film or chain had been grown epitaxially on a Pt(111) substrate

0	4	2		3	3		2	3	

be comparable in magnitude to the orbital moments due to the spin–orbit interaction [21.53, 54].

Table 21.3 reports representative values of m_S and m_L calculated by density functional theory for structures of various dimensions (D). In line with the arguments presented in Sect. 21.1.2, we observe that the spin moment increases in going from 3-D to 0-D structures as a result of the decrease in coordination number of the magnetic atoms. The calculations yield very small bulk orbital moments: $m_L = 0.05\,\mu_B$, $0.08\,\mu_B$ and $0.05\,\mu_B$ for bcc Fe, hexagonal close-packed (hcp) Co, and fcc Ni. It is well known that the orbital moments are quenched in the bulk due to crystal-fields effects. In metals, moreover, the broadening of the 3d levels due to sp–d hybridization contributes to the simultaneous occupation of electronic states with orbital quantum numbers $l_z = \pm 1$ and $l_z = \pm 2$ [21.46, 55], as shown in Fig. 21.4c. Larger orbital moments are obtained for crystal structures with noncubic crystal-field symmetry, such as hcp Co, and, more prominently, in 2-D and 1-D structures due to the reduced hybridization (Fig. 21.3). However, it is important to realize that these enhanced orbital moments are still significantly smaller than the corresponding free atom values, as given by Hund's second rule (last row in Table 21.3). Note that first-principles calculations based on local spin density approximation or the generalized gradient approximation typically underestimate orbital moments. In literature, several methods have been discussed to overcome this problem [21.56–58]; for example, the orbital moments of bulk magnets increase by about a factor of 2 if Brooks' orbital polarization is applied [21.59, 60] and even more in low dimensions [21.61]. A systematic comparison of density functional theory (DFT) results for free-standing and Pt-supported Fe and Co magnets in various dimensions using the local spin density approximation can be found in the works of *Komelj* et al. [21.62] and *Ederer* et al. [21.63].

Despite being smaller than the spin moment, the orbital moment plays a major role in determining the preferred orientation of the magnetization in crystalline as well as low-dimensional structures. At the atomic level, the coupling between m_L and m_S is established by the spin–orbit interaction

$$\mathcal{H}_{so} = \frac{1}{r}\frac{dV(r)}{dr}(\boldsymbol{s}\cdot\boldsymbol{l}) = \xi(r)\boldsymbol{s}\cdot\boldsymbol{l}\,, \tag{21.13}$$

where $V(r)$ is the radially symmetric Coulomb potential, and $\boldsymbol{s}$ and $\boldsymbol{l}$ are the one-electron spin and orbital angular momentum operators, respectively. Since the radial derivative of the potential in a crystal is largest in the vicinity of a nucleus, we can expect that the major contribution to the spin–orbit interaction will come from this region. Furthermore, since for small r the potential will be Coulomb like ($V = -(Z/r)$), the radial expectation value of $\xi(r)$ leads to a material-dependent spin–orbit coupling constant ξ that is roughly proportional to the square of the atomic number, $\xi \propto Z^2$ [21.64]. The spin–orbit interaction additionally provides a mechanism to promote the formation of finite orbital moments in systems in which crystal-field and hybridization effects would otherwise completely quench m_L [21.46, 48, 49, 55]. In a solid where the symmetry of the electronic states ψ_i is such that the zeroth-order orbital moment $m_L = -\mu_B \sum_i \langle\psi_i|\boldsymbol{l}|\psi_i\rangle = 0$, the spin–orbit interaction admixes states that carry no orbital momentum, e.g., the d_{xy} and $d_{x^2-y^2}$ orbitals, such that their combination forms an orbital moment in the z direction. In perturbation theory using the first-order correction for the wavefunctions, the expectation value of the orbital moment can be written as

$$\begin{aligned} m_L &= -\mu_B\langle\boldsymbol{l}\rangle \\ &= -\mu_B \sum_{i,j} \frac{\langle\psi_i|\boldsymbol{l}|\psi_j\rangle\langle\psi_j|\mathcal{H}_{so}|\psi_i\rangle}{\varepsilon_i - \varepsilon_j} \\ &\qquad \times f(\varepsilon_i)[1 - f(\varepsilon_j)]\,, \end{aligned} \tag{21.14}$$

where f is the Fermi function ensuring that the state ψ_i is occupied and ψ_j is unoccupied. In a metal where sev-

eral bands cross the Fermi level E_F, it is basically the sum of all contributions from the bands near E_F that determines the orbital moment.

Anisotropy of the Orbital Moment

The dependence of m_L on atomic coordination in systems of reduced dimensionality and interfaces is best understood in terms of a schematic model that includes the effects of crystal field, hybridization, and spin–orbit interaction for the exemplary case of a free-standing and supported d-metal monolayer [21.49, 50, 65, 66]. Figure 21.5 shows the schematic DOS and crystal-field splitting of a free-standing Co monolayer and of a supported Co monolayer on a strongly interacting substrate such as Pd, Pt, or Au. Following *Stöhr* [21.66], we assume that the d-band is substantially exchange split and more than half-filled, so that the majority band does not contribute to m_L and we only have to consider the partially filled minority band. The d orbitals at each lattice site experience a crystal field V that leads to a splitting of these levels. If the surface normal is assumed to be in the z-direction, the d_{xy} and $d_{x^2-y^2}$ orbitals will experience a crystal-field splitting $2V_\parallel$ that is different from the splitting $2V_\perp$ of the out-of-plane d_{zx}, d_{yz}, and d_{z^2} orbitals. In a band picture, these splittings can be translated into bandwidths $W_\parallel \propto V_\parallel$ and $W_\perp \propto V_\perp$. Assuming that the minority band is half-filled, which is approximately correct for Co, the energy splittings appearing in the denominator of (21.14) are $\varepsilon_{d_{xy}} - \varepsilon_{d_{x^2-y^2}} = 2V_\parallel$ and $\varepsilon_{d_{yz,xz}} - \varepsilon_{d_{z^2}} = 2V_\perp$. Calculating the matrix elements of the orbital moment operator between the different d orbitals and using the ratio $R = V_\perp/V_\parallel$, (21.14) allows us to calculate the in-plane and out-of-plane orbital moments [21.65, 66]

$$m_L^\parallel = \frac{\xi\mu_B}{2V_\parallel}\left(\frac{3}{R} + \frac{2}{R+1}\right) \quad \text{and} \quad m_L^\perp = 4\frac{\xi\mu_B}{2V_\parallel} \,. \tag{21.15}$$

Equation (21.15) shows that $m_L^\parallel$ and $m_L^\perp$ are inversely proportional to the bandwidths of the out-of-plane and in-plane oriented states, respectively. This result is intuitively clear, since, e.g., $m_L^\perp$ originates from the in-plane motion of the electrons that is favored by the hopping between the d_{xy} and $d_{x^2-y^2}$ states, separated by $V_\parallel$. The more these two levels are split in energy, the more difficult it will be for the electron to *circle* around the atom and, therefore, to form an orbital moment.

In the case of a free-standing monolayer (Fig. 21.5a), the strongest electronic interactions are in-plane, which leads to $R < 1$ and $m_L^\parallel > m_L^\perp$. This is also the case of Co monolayers on weakly interacting substrates such as Cu. On the other hand, substrates made of heavy elements with rather delocalized 4d and 5d states favor strong hybridization with the 3d out-of-plane orbitals of Co, leading to $R > 1$ and $m_L^\perp > m_L^\parallel$ (Fig. 21.5b). Taking typical values for 3d-metal monolayers, viz. a spin–orbit coupling strength of $\xi \approx 75\,\text{meV}$ and bandwidths of $W^\parallel \approx 3\,\text{eV}$ and $W^\perp \approx 2\,\text{eV}$, one estimates orbital moments of $m_L^\parallel = 0.28\,\mu_B$ and $m_L^\perp = 0.20\,\mu_B$ for a free standing system, in agreement with the ab initio results

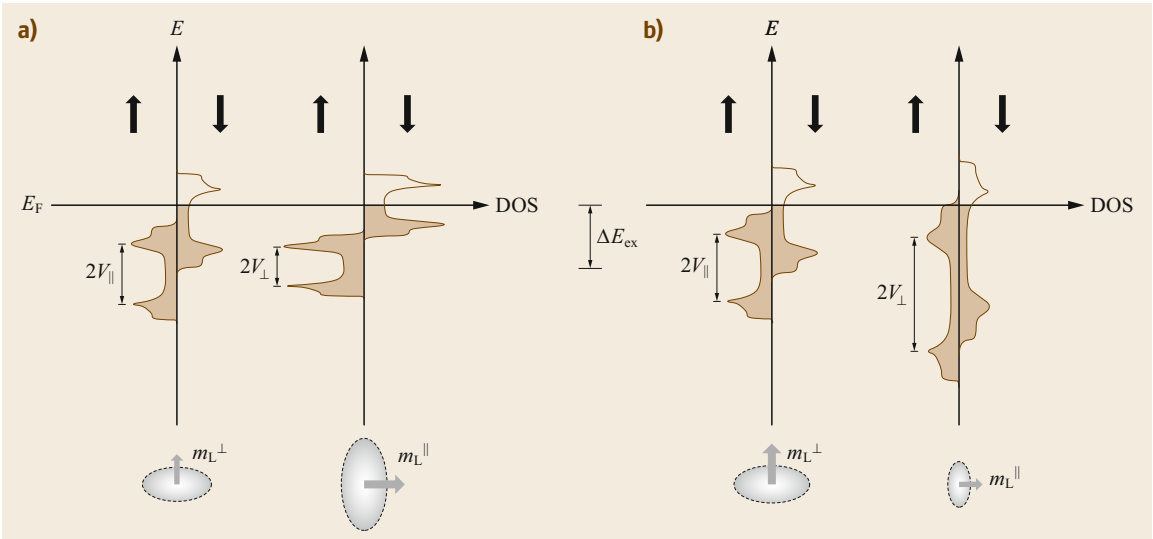

Fig. 21.5a,b Schematic spin-resolved DOS and crystal-field splitting of **(a)** a free-standing Co monolayer and **(b)** a Co monolayer supported on Pt or Au. The different crystal-field splitting for in-plane and out-of-plane orbitals leads to different in-plane and out-of-plane bandwidths. The splittings shown here are representative of electronic states with $\boldsymbol{k}$ wavevector close to the center of the Brillouin zone. (Adapted from [21.66], © Elsevier 1999)

reported in Table 21.3. This simple model thus captures the main mechanisms leading to the enhancement and anisotropy of the orbital moment, which, as we shall see later, plays a fundamental role in determining the magnitude of the magnetocrystalline anisotropy.

21.1.4 Magnetic Anisotropy

The behavior of a magnetic material in an applied field is typically anisotropic. This means that, besides the isotropic exchange interaction, there are additional interactions that make the total energy depend on the orientation of the magnetization with respect to a reference frame tied to the crystal or the geometrical axes of the sample. This orientation-dependent energy contribution is called the magnetic anisotropy energy, E_{MAE}. Without magnetic anisotropy, magnetism would have been hard to discover and exploit. In some way or another, most applications of magnetic materials hinge on the fact that it is easier to magnetize a magnet in one direction than another. Among other things, the magnetic anisotropy is responsible for the occurrence of easy and hard axes, stabilizes magnetic order against thermal fluctuations in low-dimensional systems where the exchange interaction alone would not suffice, and limits the width of a magnetic domain wall. Magnetic anisotropy, for example, is responsible for the bistability of magnetic domains with uniaxial symmetry, which allows the two possible magnetization directions in space to be interpreted in terms of bits 0 or 1 and makes magnetic materials valuable as storage media.

Phenomenological expressions for the magnetic anisotropy energy can be obtained by expanding the free magnetic energy in powers of the direction cosines of the magnetization along the three coordinate axes and retaining only those terms compatible with the symmetry of the crystal. The magnetic anisotropy energy of cubic and hexagonal surfaces is usually given as a function of the azimuthal and polar angles ϕ and θ of the magnetization direction relative to the crystal axes x, y, and z:

1. *Tetragonal symmetry:* (001) surface of cubic crystals

$$E_{\mathrm{MAE}} = K_1 \sin^2\theta + K_2 \sin^4\theta + K_3 \sin^4\theta \cos 4\phi + \ldots \qquad (21.16)$$

2. *Orthorhombic symmetry:* (011) surface of cubic crystals

$$E_{\mathrm{MAE}} = K_1 \sin^2\theta + K_1' \sin^2\theta \cos 2\phi + K_2 \sin^4\theta + K_2' \sin^4\theta (10\sin^2\phi - 3\sin^4\phi) + \ldots \qquad (21.17)$$

3. *Hexagonal symmetry:* (111) surface of cubic crystals or (0001) surface of hexagonal crystals

$$E_{\mathrm{MAE}} = K_1 \sin^2\theta + K_2 \sin^4\theta + K_3 \sin^6\theta + K_3' \sin^6\theta \cos 6\phi + \ldots \qquad (21.18)$$

General expressions for E_{MAE} for different crystal symmetries are given, e.g., in [21.67, 68]. The anisotropy constants $K_{1,2,3,\ldots}$ depend sensitively on the chemical composition and dimensionality of the system, which ultimately determine the electronic band structure. The microscopic origins of the magnetic anisotropy are the spin–orbit interaction (21.13) and the magnetic dipolar interaction, which give rise to the magnetocrystalline anisotropy and shape anisotropy, respectively. Both interactions contribute to the total anisotropy energy

$$E_{\mathrm{MAE}} = E_{\mathrm{MCA}} + E_{\mathrm{shape}} \,. \qquad (21.19)$$

Magnetocrystalline Anisotropy

The magnetocrystalline anisotropy (MCA) can be explained by the interplay of crystal-field effects and spin–orbit coupling. The latter couples the (isotropic) spin moment to the (anisotropic) orbital moment, which is determined by the symmetry and type of the partially filled orbital states at the magnetic ion's site (21.15). The relationship between the MCA energy and m_{L} can thus be exemplified by means of the perturbation model presented in Sect. 21.1.3 [21.49, 50, 65, 66]. In the absence of spin-flip terms (i.e., when the majority and minority band are well separated by the exchange interaction), the spin–orbit coupling changes the total energy in second-order perturbation theory as [21.50]

$$\langle \mathcal{H}_{\mathrm{so}} \rangle = \sum_{i,j} \frac{|\langle \psi_j | \mathcal{H}_{\mathrm{so}} | \psi_i \rangle|^2}{\varepsilon_i - \varepsilon_j} \mathrm{f}(\varepsilon_i)[1 - \mathrm{f}(\varepsilon_j)] \propto -\frac{\xi}{4\,\mu_{\mathrm{B}}} \widehat{\boldsymbol{s}} \cdot \left(\boldsymbol{m}_{\mathrm{L}}^{\downarrow} - \boldsymbol{m}_{\mathrm{L}}^{\uparrow} \right) \,, \qquad (21.20)$$

where $\widehat{\boldsymbol{s}}$ is the direction of the spin moment, and $\boldsymbol{m}_{\mathrm{L}}^{\downarrow}$ and $\boldsymbol{m}_{\mathrm{L}}^{\uparrow}$ are the orbital moment vectors of the spin-down and spin-up bands, respectively. If the spin-up band is completely filled, the energy $\langle \mathcal{H}_{\mathrm{so}} \rangle$ is proportional to the size of the orbital moment. E_{MCA} is the difference of $\langle \mathcal{H}_{\mathrm{so}} \rangle$ for two different magnetization directions and is therefore proportional to the anisotropy of the orbital moment,

$$E_{\mathrm{MCA}} = \langle \mathcal{H}_{\mathrm{so}}(\widehat{\boldsymbol{s}}^{\parallel}) \rangle - \langle \mathcal{H}_{\mathrm{so}}(\widehat{\boldsymbol{s}}^{\perp}) \rangle \propto -\frac{\xi}{4\,\mu_{\mathrm{B}}} \left(m_{\mathrm{L}}^{\parallel} - m_{\mathrm{L}}^{\perp} \right) \,. \qquad (21.21)$$

This relationship between orbital moment anisotropy and MCA was first derived by *Bruno* [21.49] and has

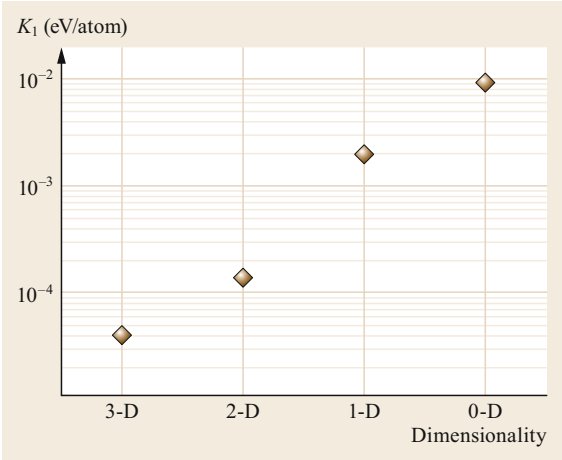

Fig. 21.6 Values of magnetocrystalline anisotropy energy per Co atom in a 3-D hcp crystal, 2-D monolayer film on Pt(111), and 1-D monatomic chain on Pt(997), and as 0-D single atoms on Pt(111). (Adapted by permission from [21.72, 73], © SpringerNature 2003)

been experimentally verified in 2-D thin films [21.69–71] as well as in 1-D and 0-D systems [21.72–74]. According to (21.21), the easy axis of magnetization is the direction with the largest m_L. The magnetic anisotropy energy is thus the energy cost required to rotate the magnetization away from the easy axis, which can be visualized as the torque exerted by the orbital moment on the spin moment during the rotation of the magnetization [21.75].

In 3-D cubic crystals, m_L is very small and nearly isotropic since all the d orbitals have balanced $\pm l_z$ contributions. The MCA energy is consequently small: on the order of 0.005 meV/atom in bulk fcc metals such as Fe and Ni, and about 0.05 meV/atom in crystals with uniaxial symmetry such as hcp Co. Low-dimensional systems, however, present strongly enhanced orbital moments due to the broken symmetry and reduced atomic coordination [21.69, 72–74, 76–78]. The MCA thus increases quite spectacularly in these systems, with typical values of 0.1−1 meV/atom in 2-D layers, and 1−10 meV/atom in 1-D and 0-D nanostructures (Fig. 21.6). The anisotropy of the orbital moment also explains the emergence of perpendicular magnetic anisotropy in thin films, as obtained from (21.15) and (21.21) in the limit of strong substrate hybridization ($R > 1$, see Fig. 21.5b).

Shape Anisotropy

In contrast to the MCA, the shape anisotropy is a non-relativistic effect that originates from magnetostatic dipolar interactions. This anisotropy is closely related to the demagnetizing field $\boldsymbol{B}_{\rm dem}$ produced by the spatial distribution of the magnetization in materials of finite shape. In uniformly magnetized samples of ellipsoidal shape, the demagnetizing field can be written as

$$\boldsymbol{B}_{\rm dem} = -\mathfrak{N}\mu_0\boldsymbol{M}\,, \quad \text{with} \quad B_{{\rm dem},i} = -\mathfrak{N}_{ij}\mu_0 M_j\,, \tag{21.22}$$

where $\boldsymbol{M}$ is the magnetization, μ_0 is the magnetic permeability of vacuum, $\mathfrak{N}$ is the demagnetization tensor, and $i, j = x, y, z$. As is well known from classical electromagnetism, $\boldsymbol{B}_{\rm dem}$ opposes the magnetization inside a magnet due to the tendency of the dipolar field to oppose the field produced by neighboring dipoles. If x, y, z are the principal axes of a sample with ellipsoidal shape, $\mathfrak{N}$ is a diagonal 3×3 matrix with unit trace. The demagnetizing factors $\mathfrak{N}_{xx}$, $\mathfrak{N}_{yy}$, and $\mathfrak{N}_{zz}$ have very simple expressions in a 2-D thin film ($\mathfrak{N}_{xx} = \mathfrak{N}_{yy} = 0$, and $\mathfrak{N}_{zz} = 1$ if the surface normal is along z) and a 1-D wire ($\mathfrak{N}_{xx} = 0$, $\mathfrak{N}_{yy} = \mathfrak{N}_{zz} = 1/2$ if the wire axis is along x). The magnetostatic self-energy associated with the demagnetizing field is

$$E_{\rm dem} = -\frac{1}{2}\int_V \boldsymbol{M}\cdot\boldsymbol{B}_{\rm dem}{\rm d}V = +\frac{1}{2}\mu_0\int_V \boldsymbol{M}\cdot\mathcal{R}\cdot\boldsymbol{M}{\rm d}V\,, \tag{21.23}$$

where the integration is performed over the magnet's volume V. The magnetization tends to adopt a configuration that minimizes this energy, and the shape anisotropy is essentially the difference of $E_{\rm dem}$ for a magnetic body magnetized along two different directions, e.g., x and z

$$\begin{aligned} E_{\rm shape} &= E_{\rm dem}(\boldsymbol{M} \parallel \boldsymbol{x}) - E_{\rm dem}(\boldsymbol{M} \parallel \boldsymbol{z}) \\ &= \frac{1}{2}\mu_0(\mathfrak{N}_{zz} - \mathfrak{N}_{xx})M^2 V\,. \end{aligned} \tag{21.24}$$

It is easy to see that the minimization of $E_{\rm shape}$ in a 2-D magnetic thin film requires $\boldsymbol{M}$ to lie in the film's plane, and that the larger the volume (i.e., the thickness) of the film, the more this tendency will be accentuated. For bcc Fe, for instance, with a bulk magnetic moment of 2.215 μ_B/atom ($M = 1.71 \times 10^6$ A/m) and a lattice constant of 5.42 arb.u., the effective shape anisotropy constant $K_{\rm shape} = (1/2)\mu_0 M^2$ is equal to -0.140 meV/atom (1.8 MJ/m^3). In bulk samples, thick films, or polycrystalline layers without a preferred grain orientation, and patterned nanostructures, the shape anisotropy is frequently the dominant form of anisotropy. The minimization of the demagnetizing energy (21.23) is also the driving force for the spontaneous formation of magnetic domains. The structure of the domains and domain walls, however, is ultimately

determined by the competition between diverse factors, including exchange, MCA, and DMI, for which we refer the reader to specialized monographs [21.79–81].

Equations (21.22)–(21.24) assume that the magnetization arises from a continuous magnetic medium; therefore, K_{shape} is the same for all atoms irrespective of their position. For thin films and wires of a few atomic layers, however, this assumption is no longer valid. In such a case, the magnetic dipole–dipole energy has to be evaluated explicitly instead of E_{dem}. In transition metals, the magnetization distribution around the atom is almost spherical and can thus be treated to a good approximation as a collection of discrete magnetic dipoles arranged regularly on a crystalline lattice. The dipolar energy E_{dip} per atom experienced by a dipole at site i due to the presence of ferromagnetically aligned dipoles on all other sites j can then be expressed as

$$E_{\text{dip}}^{(i)}(\theta) = K_{\text{dip}}^{(i)} \cos^2\theta = \frac{1}{2}\frac{\mu_0}{4\pi}\sum_{j(j\neq i)}\frac{m_i m_j}{R_{i,j}^3}\left(1-3\cos^2\theta_{ij}\right) , \quad (21.25)$$

where θ_{ij} is the angle between the direction of the magnetic moment m of the dipoles at sites i or j given in units of the Bohr magneton μ_{B} and the vector $\boldsymbol{R}_{i,j}$ connects atoms i and j. The θ dependence expresses explicitly the fact that the dipole–dipole interaction contributes to the magnetic anisotropy. Obviously, in thin films and wires, the anisotropy energy depends on the position of the atom i relative to the surface or wire axis, respectively (in contrast to E_{shape}). For crystalline thin wires and films, the sum in (21.25) can be evaluated straightforwardly using fast-converging summation techniques [21.82, 83]. *Draaisma* and *de Jonge* [21.84] have worked out in detail the layer-dependent dipolar anisotropy $K_{\text{dip}}^{(i)}$. In general, the outer atoms experience values of K_{dip} that are appreciably smaller than those of the inner layers, which finally approach K_{shape}. The inner atoms reach 95% of K_{shape} at ≈ 15 Å below the surface. The exact details depend on the crystal structure and surface orientation; e.g., a reduction between 25 and 45% of K_{shape} was reported for a (100)-oriented fcc or bcc monolayer, respectively. The dipolar interaction is also sensitive to the interface or surface roughness, which is always present on real films. According to *Bruno* [21.85], the roughness gives rise to an effective perpendicular contribution to the shape anisotropy whose order of magnitude depends on the parameters characterizing the roughness.

Effective Anisotropy Field

The different sources of magnetic anisotropy add up and compete to determine the preferential orientation of the magnetization in a given sample. Consider, for example, the case of a thin film with uniaxial MCA given by $K_1 \sin^2\theta$, where θ is the angle between the surface normal and the magnetization. If $K_1 > 0$, the MCA will favor the perpendicular direction. This term, however, will compete with the shape anisotropy $E_{\text{shape}} = -(1/2)\mu_0 M^2 \sin^2\theta$ that favors the in-plane direction. The total anisotropy energy per unit volume is therefore

$$E_{\text{MAE}} = \left(K_1 - \frac{1}{2}\mu_0 M^2\right)\sin^2\theta = K_{\text{eff}}\sin^2\theta , \quad (21.26)$$

where K_{eff} is the effective anisotropy constant of the film that determines the in-plane ($K_{\text{eff}} < 0$) or out-of-plane ($K_{\text{eff}} > 0$) orientation of the magnetization. Note that, for practical purposes, it is often customary to define a fictitious *magnetic anisotropy field* $\boldsymbol{B}_{\text{K}}$ to represent the strength of the magnetic anisotropy on an equal footing with an applied magnetic field. Such a field is defined by setting $E_{\text{MAE}} = -(1/2)V\boldsymbol{M}\cdot\boldsymbol{B}_{\text{K}}$, which, for a thin film with uniaxial anisotropy along z, gives $\boldsymbol{B}_{\text{K}} = -\Re\mu_0\boldsymbol{M} + (2K_1/M)(\boldsymbol{M}\cdot z/M)z$.

Temperature Dependence of the Magnetic Anisotropy

In general, both types of magnetic anisotropy are temperature-dependent quantities. Whereas the shape anisotropy simply scales as $M(T)^2$, the MCA has a more complex temperature dependence (see also Sect. 21.3.2). Intuitively, a reduction of the MCA is expected with increasing temperature not only because the saturation magnetization decreases, but also because thermal vibrations smear out the effects of the crystal field. Thus, one expects that the MCA will vanish much faster than the magnetization as a function of temperature. Theoretical models of single-ion anisotropies yield a power law [21.86, 87]

$$\frac{K_l(T)}{K_l(0)} = \left[\frac{M(T)}{M(0)}\right]^{l(l+1)/2} , \quad (21.27)$$

where l is the order of each term in a spherical harmonic expansion of the MCA energy. In cubic systems, K contains terms of order $l = 4$ and the exponent is 10; in uniaxial systems, K is formed by terms with $l = 2$, leading to an exponent of 3. It must be noted, however, that the MCA of itinerant magnetic systems often deviates from this power law; in hcp Co, for example, K_1

($l = 2$) changes sign at ≈ 500 K, leading to a transition from uniaxial to easy-plane anisotropy. Furthermore, (21.27) implies that MCA vanishes at the Curie temperature, which is hard to understand given that the local magnetic moments survive the ferromagnetic–paramagnetic transition and the spin–orbit coupling is independent of temperature. Alternative approaches to calculate the temperature dependence of the MCA from first principles are described, e.g., in [21.88–90]. In thin films, the temperature-dependent effective anisotropy scales with the film thickness and surface magnetization [21.90].

21.1.5 Spin Hamiltonians

Effective spin models have been developed to capture the microscopic exchange mechanisms among magnetic atoms and reduce the problem of modeling arbitrary magnetic configurations to the spin degree of freedom, whereby the details of the electronic structure are included into effective exchange parameters. In general, the Hamiltonian of such a system may contain contributions from the isotropic and anisotropic exchange interactions, DMI, magnetocrystalline anisotropy, dipolar interactions, as well as the coupling of the spin and orbital moments to an external magnetic field (Zeeman interaction). The spins localized on lattice sites i, j are considered as either classical vectors or quantum operators $\boldsymbol{S}$, with equal magnitude $|\boldsymbol{S}|^2 = S^2$ or $|\boldsymbol{S}|^2 = S(S+1)$ on all sites, respectively. Working with a spin Hamiltonian offers various advantages, as it permits (i) an efficient search for the magnetic ground state, (ii) the calculation of dynamical properties such as the magnon dispersion or magnetic excitations, and (iii) the calculation of thermal properties such as the critical temperature. One of the most familiar spin lattice models is the Heisenberg Hamiltonian

$$\mathcal{H} = -\sum_{i,j} J_{ij} \boldsymbol{S}_i \cdot \boldsymbol{S}_j \,, \tag{21.28}$$

where the exchange interaction between the spins is isotropic and described by the pair interaction J_{ij}. In model spin systems, J_{ij} can be safely approximated by the ferromagnetic ($J_1 > 0$) or antiferromagnetic ($J_1 < 0$) nearest-neighbor (nn) interaction, i.e., $J_{ij} = 0$ for all i, j, except for $J_{\mathrm{nn}} = J_1$. Although in magnetic insulators J_1 often dominates over the rest of the more distant pairs, an attempt to reproduce the magnetic complexity or T_c solely from J_1 produces results of limited validity. In itinerant transition-metal magnets, depending on the Fermi surface, J_{ij} between distant pairs are required to model the properties reliably even though J_1 is usually the largest interaction.

The Heisenberg model allows one to construct a zero-temperature phase diagram of relevant spin states as a function of the exchange parameters J_{ij}, including non-collinear spin states. For example, a spin spiral state with a propagation vector $\boldsymbol{q}$ in the first Brillouin zone is a fundamental solution of the Heisenberg model of classical spins for a Bravais lattice. For such structures, it is convenient to write the spin on lattice sites in terms of their discrete Fourier-transformed equivalents

$$\boldsymbol{S}(\boldsymbol{q}) = \frac{1}{N} \sum_n \boldsymbol{S}_n \mathrm{e}^{-\mathrm{i}\boldsymbol{q}\boldsymbol{R}_n} \quad \text{and} \quad J(\boldsymbol{q}) = \sum_n J_{0n} \mathrm{e}^{-\mathrm{i}\boldsymbol{q}\boldsymbol{R}_n} \,. \tag{21.29}$$

Exploiting the translational invariance of the lattice, we can then rewrite (21.28) as

$$\mathcal{H} = -N \sum_{\boldsymbol{q}} J(\boldsymbol{q}) \boldsymbol{S}(\boldsymbol{q}) \cdot \boldsymbol{S}(-\boldsymbol{q}) \,, \tag{21.30}$$

where we have to ensure that the length of all spins $\boldsymbol{S}_n^2 = S^2$ is conserved on all sites n. This condition is fulfilled by solutions of the type [21.91]

$$\boldsymbol{S}_n = S[\hat{\boldsymbol{e}}_x \cos(\boldsymbol{q} \cdot \boldsymbol{R}_n) + \hat{\boldsymbol{e}}_y \sin(\boldsymbol{q} \cdot \boldsymbol{R}_n)] \,, \tag{21.31}$$

where the unit vectors $\hat{\boldsymbol{e}}_x$ and $\hat{\boldsymbol{e}}_y$ are orthogonal to each other and have otherwise arbitrary directions. Equation (21.31) describes a spiral spin density wave as shown in the lower half of Fig. 21.7. A more general form of spiral spin density waves can be obtained for a magnetization precessing around a cone with an opening angle ϑ, which can be understood as a superposition of a flat spin spiral and a ferromagnetic state

$$\begin{aligned} \boldsymbol{S}_n = S[&\hat{\boldsymbol{e}}_x \cos(\boldsymbol{q} \cdot \boldsymbol{R}_n) \sin\vartheta \\ &+ \hat{\boldsymbol{e}}_y \sin(\boldsymbol{q} \cdot \boldsymbol{R}_n) \sin\vartheta + \hat{\boldsymbol{e}}_z \cos\vartheta] \,, \end{aligned} \tag{21.32}$$

as shown in the upper half of Fig. 21.7. From (21.30), one can conclude that the spiral spin density wave with

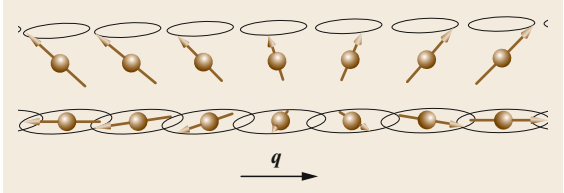

Fig. 21.7 Spiral spin density wave or spin spiral propagating along the wavevector $\boldsymbol{q}$. The upper spiral represents a coned spiral with a cone angle of 45°; the bottom spiral represents a flat spiral, with a cone angle of 90°. Both spirals exhibit a counterclockwise rotational sense expressed by a chirality vector parallel to the z-axis

the lowest total energy will be the one with the propagation vector $\boldsymbol{Q}$ that maximizes $J(\boldsymbol{q})$. These will be preferably the high-symmetry points in the Brillouin zone of $\boldsymbol{q}$-vectors, and then high-symmetry lines. For example, if $\boldsymbol{Q}=0$ maximizes $J(\boldsymbol{q})$, the solution corresponds to the ferromagnetic state; if $\boldsymbol{Q}=\hat{\boldsymbol{e}}_z(\pi/a_z)$ and a_z is the lattice constant in the z-direction, then the structure is layered antiferromagnetic in the z-direction.

Exchange interactions beyond the classical Heisenberg model, such as biquadratic, four-spin three-site and four-spin four-site interactions, can be derived from a perturbation expansion of the Hubbard model [21.92, 93]. Note also that, in recent years, there has been an effort to develop multiscale approaches to calculate the material-specific exchange parameters and magnetic properties from first principles and map them onto spin lattice Hamiltonians, thus enabling the modeling of realistic systems over mesoscopic dimensions [21.6].

21.1.6 Dzyaloshinskii–Moriya Interaction

In 1957, *Dzyaloshinskii* [21.94] predicted on the basis of symmetry arguments the presence of a chiral magnetic interaction of the form

$$\mathcal{H}_{\mathrm{DM}}=\sum_{i,j}\boldsymbol{D}_{ij}\cdot(\boldsymbol{S}_i\times\boldsymbol{S}_j)\,, \tag{21.33}$$

where the Dzyaloshinskii vector $\boldsymbol{D}$ depends on the symmetry of the system and on the direction of the vector connecting the two sites i and j in real space. This interaction is now referred to as the DMI or antisymmetric exchange interaction [21.95]. Necessary conditions for the occurrence of the DMI are a structural assymmetry and a spin–orbit interaction. The strength of $\boldsymbol{D}$ depends also on details of the electronic structure. The DMI can be understood as the spin–orbit contribution to the total energy due to a rotating or winding magnetic structure. The existence of the DMI has far-reaching consequences. Depending on the sign, the symmetry properties, and the value of $\boldsymbol{D}_{ij}$, collinear ferro- or antiferromagnetic structures become unstable and are replaced by a non-collinear magnetic structure with one specific chirality, $\boldsymbol{c}=\boldsymbol{S}_i\times\boldsymbol{S}_{i+1}$, either right-handed ($c>0$) or left-handed ($c<0$). The DMI is fundamentally different from the direct, kinetic, or metallic exchange interactions, which are caused exclusively by the Coulomb interaction. These interactions are symmetric; i.e., two magnetic configurations with right-handed ($\uparrow\rightarrow$) or left-handed ($\uparrow\leftarrow$) alignment of the magnetic moments have the same energy. The nature of the DMI favors non-collinear magnetic structures and is responsible for weak ferromagnetism, i.e., the occurrence of small net magnetic moments in otherwise antiferromagnetic materials. In the context of bulk magnetic materials, one may think of hematite (Fe_2O_3), a mineral with an antiferromagnet exchange ($J<0$), as an example. The canting angle between neighboring spins can be estimated from a simple two-site model

$$\mathcal{H}_{\mathrm{DMI}}=-J\boldsymbol{S}_1\cdot\boldsymbol{S}_2+\boldsymbol{D}\cdot(\boldsymbol{S}_1\times\boldsymbol{S}_2)\,. \tag{21.34}$$

Assuming that the spins $\boldsymbol{S}_1$ and $\boldsymbol{S}_2$ are located in the same plane, then the energy depends only on the angle θ between the antiferromagnetically aligned spins,

$$E=-JS^2\cos(\pi-\theta)+DS^2\sin(\pi-\theta)\,. \tag{21.35}$$

Minimization of this expression yields the equilibrium canting angle $\tan(\pi-\theta)=-D/J$. For atoms in a periodic lattice, if D is large, spin–orbit energy is gained by a strong winding (large θ) of the magnetic texture. For small D the period of the winding magnetic texture becomes large (small θ), and may be much larger than the period of the crystal lattice. In this case one works with the micromagnetic formulation of the DMI, which can be found in [21.56].

Since the Dzyaloshinskii vector $\boldsymbol{D}$ is an axial vector, $\mathcal{H}_{\mathrm{DMI}}$ has the most general form of an antisymmetric tensor of second rank that is second order in spin $\boldsymbol{S}$. Typically, the combination of hopping of spin-polarized electrons and the presence of the spin–orbit interaction can produce such a term. The microscopic details depend on the specific material system and are described using different microscopic models. In 1960, *Moriya* identified the spin–orbit interaction as the microscopic origin of the DMI in magnetic insulators by treating the spin–orbit interaction on top of the superexchange mechanism [21.96]. Moriya also derived a set of symmetry rules that determine under which circumstances the DMI will occur. These rules are general and apply also to metallic systems. Considering two magnetic ions located at sites A and B, respectively, and the point C bisecting the straight line AB, the following five Moriya rules are obtained:

(i) When a center of inversion is located at C: $\boldsymbol{D}=0$
(ii) When a mirror plane perpendicular to AB passes through C: $\begin{cases}\boldsymbol{D}\parallel\text{mirror plane}\\ \text{or}\quad \boldsymbol{D}\perp\text{AB.}\end{cases}$
(iii) When there is a mirror plane including A and B: $\boldsymbol{D}\perp$ mirror plane.
(iv) When a twofold rotation axis perpendicular to AB passes through C: $\boldsymbol{D}\perp$ twofold axis.
(v) When there is an n-fold ($n\geq 2$) axis along AB: $\boldsymbol{D}\parallel$ AB.

The strength of the DMI can be estimated as $D\propto|(\xi/\Delta E)|J$, where ΔE is roughly the energy difference

between the ground states and the first excited states of the two magnetic ions. The DMI is thus first order in the spin–orbit interaction, here expressed in terms of the spin–orbit coupling constant ξ (Sect. 21.1.3), in contrast to the magnetocrystalline anisotropy (Sect. 21.1.4) that is at least second order. It is thus clear that $D = 0$ in the case of a mirror symmetry or point of inversion between the two ions. In other words, the DMI exists only between two *different* atoms. However, *different* need not mean different ion species; it can just mean different chemical environments, such as in a bipartite lattice, where the symmetry of the electronic orbitals changes between the two types of lattice site.

Today we understand that the DMI (21.33) is the lowest order chiral interaction in a sequence of higher-order interactions that are systematically derivable [21.97, 98]. An example are the chiral four-spin interactions of the type $(\boldsymbol{S}_i \cdot \boldsymbol{S}_j)(\boldsymbol{S}_k \times \boldsymbol{S}_l)$ [21.99], which are necessary to describe the chiral magnetism of Fe chains on Re(0001). Novel types of interactions are the topological chiral interactions [21.97], which do not depend on the vector spin chirality $\boldsymbol{c}_{ij} = \boldsymbol{S}_i \times \boldsymbol{S}_j$ but on the scalar spin chirality $\kappa_{ijk} = \boldsymbol{S}_i \cdot (\boldsymbol{S}_j \times \boldsymbol{S}_k)$, that breaks the time inversion symmetry and causes a topological orbital moment (Sect. 21.1.3). The interaction of the topological orbital moments brings about terms of the type κ_{ijk}^2 and the triple index suggests energy gain not through the formation of a rotating magnetic structure but a curved one.

The DMI in metals has been discussed in relationship to different hopping mechanisms using different microscopic models that go back to *Smith* [21.100], *Fert* and *Levy* [21.28, 101], and *Kanamori* and coworkers [21.102]. *Fert* and *Levy* [21.101] derived an expression for the antisymmetric exchange interaction mediated by the Ruderman–Kittel–Kasuya–Yosida (RKKY) coupling for two magnetic atoms in spin glasses doped with heavy impurity atoms, i.e., impurity atoms with a large atomic number and thus a large spin–orbit interaction. This model is also applicable to magnetic adatoms on surfaces, for which the DMI can be interpreted as an equilibrium manifestation of the Byshkov–Rashba interaction [21.103–105]. Consider, for example, a thin magnetic film on a substrate with the vacuum potential on one side and the potential of the substrate on the other side. This inversion asymmetry leads to a gradient of the potential that can be interpreted to a first approximation as an electric field normal to the film surface. In the rest frame of moving electrons, the electric field $\boldsymbol{E}$ appears via the Lorentz transformation as an intrinsic $\boldsymbol{k}$ dependent magnetic field $\boldsymbol{B} \propto \boldsymbol{k} \times \boldsymbol{E}$ oriented parallel to the film plane, which then interacts with the spin $\boldsymbol{s}$ of the conduction electron, giving rise to an additional term in the Hamiltonian, similar to (21.13) in the context of spin–orbit coupling. Here, instead of an orbital motion, a linear motion of an electron with momentum $\boldsymbol{k}$ in an electric field oriented along $\boldsymbol{e}_z$ is considered. This so-called Rashba effect [21.106] is described by an Hamiltonian $\mathcal{H}_\mathrm{R} = \alpha_\mathrm{R} \boldsymbol{s} \cdot (\boldsymbol{k} \times \boldsymbol{e}_z)$, where the strength of the Rashba parameter, α_R, is determined, e.g., by the asymmetry of the wavefunction due to the asymmetry of the potential or the electric field, respectively, and the spin–orbit coupling strength ξ of the electrons involved. The magnetic interaction between the localized spins $\boldsymbol{S}_i$ at lattice site i and $\boldsymbol{S}_j$ at lattice site j is caused by conduction electrons which hop from site i to site j and back. Electrons in a magnetic film propagate in an exchange field $\pm 1/2 I m_\mathrm{S}$ (21.1), the bands are exchange split, and the time-inversion symmetry is lost. Due to the spin–orbit interaction caused by the Bychkov–Rashba term, electrons experience a kinetic energy with an additional weak spin-dependent potential which depends on the propagation direction $\boldsymbol{k}$ of the electrons. Thus, the motion from site i to j and the back motion from j to i is slightly different. The same is true for the time-reversed process, i.e., the electron hopping first from site j to i and then back. At first sight, both processes look identical, and indeed both contribute equally to the isotropic Heisenberg exchange in (21.28). However, the presence of the spin–orbit interaction in conjunction with the broken inversion symmetry introduces a complex phase factor into the conventional hopping between the sites i and j [21.107, 108]. This factor provides an antisymmetric component to the hopping, such that the two processes do not cancel out identically [21.109]. Instead, it gives rise to a DMI term equivalent to (21.33), which is proportional to α_R and falls off almost linearly with the distance between magnetic and nonmagnetic atoms. Extending the concept of an electric field originating from broken inversion symmetry beyond the simple Bychkov–Rashba model, it has been found that the DMI in multilayer systems can be related to the differences in the workfunctions [21.110] or electronegativities [21.111] of the interface layers. In an atomic picture, the minimal model that exemplifies such an antisymmetric exchange interaction is shown in Fig. 21.8 and consists of three atoms, at least two of which are magnetic, representing the magnetic film, while one has a strong spin–orbit interaction, representing the substrate. Typical values of D for 3d/5d metal interfaces are in the range of $0.5{-}2\,\mathrm{mJ/m^2}$ for magnetic layers that are about $t = 2$–6 atoms thick, which corresponds to $\approx (0.25 - 1)t\,\mathrm{meV}$ per interface atom. The sign of D changes between 5d elements in the first and second half of the transition-metal layer, reflecting the sign of the spin–orbit coupling. Interfaces between 3d metals and oxides, such as Co/MgO and Co/AlO_x,

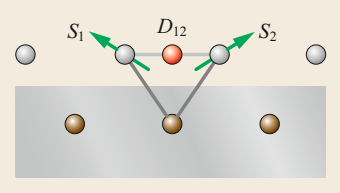

Fig. 21.8 Schematic diagram of DMI interaction at the interface between a magnetic layer (*top*) and a heavy metal (*bottom*), inducing a canting of spins S_1 and S_2 on adjacent lattice sites

also present significant DMI [21.112, 113]. Methods used to measure the strength of the DMI include field- and current-driven domain wall displacement measurements [21.114, 115] as well as Brillouin light scattering, which measures the nonreciprocal propagation of spin waves [21.116, 117].

Surprisingly, the effects of the DMI on the magnetism of surface systems were discovered only recently [21.118]. One reason for this late discovery is probably that the DMI has traditionally been neglected in the study of metal systems, since most metals crystallize in structures with centrosymmetric symmetry. However, recent studies have shown that the DMI plays an important role in defining the spin configuration of low-dimensional magnets, such as spin spirals in 2-D [21.118–120] or 1-D systems [21.121–123], as well as non-collinear magnetism in 0-D structures [21.124–126]. This type of interaction is decisive also in defining the chirality of magnetic domain walls [21.127–129], in the formation of magnetic skyrmions (Sect. 21.4) [21.130–137], as well as in the coupling of nanomagnets at surfaces [21.138].

21.1.7 Critical Phenomena

It is well known that magnetic excitations in itinerant ferromagnets are basically of two different types, namely Stoner excitations associated with longitudinal fluctuations of the magnetization, and spin-waves or magnons, which correspond to collective transverse fluctuations of the magnetization direction. Near the bottom of the excitation spectrum, the density of states of magnons is considerably greater than that of Stoner excitations, so that the thermodynamics in the low-temperature regime is completely dominated by magnons, while Stoner excitations can be safely ignored. Thus, it seems reasonable to extend this approximation up to the critical temperature, to neglect the Stoner excitation systematically, and to describe the transversal fluctuations using the Heisenberg model expressed in (21.28). More advanced theoretical models adopt this approach by mapping first-principles exchange parameters onto Heisenberg-type Hamiltonians to study the thermodynamical properties of bulk and low-dimensional magnets [21.139]. Below the critical temperature, the so-called Curie temperature T_C for ferromagnets or the Néel temperature, T_N, for magnets with more complex magnetic phases, including antiferromagnets, the spontaneous magnetization remains finite, while it is zero above T_C. The phase transition is second order; i.e., the spontaneous magnetization M_s, which is the order parameter characterizing the phase transition, vanishes continuously at T_C. A second-order phase transition is governed by the principle of universality, according to which the behavior of the system close to a phase transition does not depend on the details of the system itself, such as its material parameters or geometry, but rather on the symmetry group of the order parameter and the dimensionality of both the lattice and spin vector [21.140, 141].

Critical Temperature

Within the assumptions of the Heisenberg model, the magnetic moment at each lattice site is given by $\boldsymbol{m}_i = -g\mu_B \boldsymbol{S}_i$, where g is the Landé g-factor and μ_B is the Bohr magneton, and the magnetization is

$$\boldsymbol{M} = -\frac{g\mu_B}{NL^D}\sum_{i=1}^{N}\boldsymbol{S}_i\,, \tag{21.36}$$

where N is the total number of sites in the lattice and L^D ($D = 3, 2, 1, 0$) is the *volume* of the lattice. By solving (21.36) self-consistently in the mean-field approximation (MFA), one obtains the well-known result

$$k_B T_C^{MFA} = \frac{2}{3} N_{nn} J_1 S^2\,, \tag{21.37}$$

where k_B is the Boltzmann constant, N_{nn} is the coordination number of nearest-neighbor atoms, and J_1 is the interaction strength introduced in Sect. 21.1.5. For more complex structures, such as a 3-D system exhibiting a helical spin spiral ground state with wavevector $\boldsymbol{Q}$, the critical temperature is given by

$$k_B T_N^{MFA} = \frac{2}{3} S^2 J(\boldsymbol{Q}) \tag{21.38a}$$

and

$$k_B T_C^{MFA}(\mathrm{nn}) = \frac{2}{3} S^2 N_{nn} J_1\,. \tag{21.38b}$$

The MFA gives the right proportionality of T_C with respect to the number of neighbors, but it has also a few deficiencies. Besides overestimating T_C for 3-D systems by about 20%, T_C^{MFA} does not depend on the lattice structure or the dimensionality of the system.

These shortcomings can be remedied by treating the Heisenberg model in the random-phase approximation (RPA) [21.38, 142], which gives

$$\frac{1}{k_B T_N^{RPA}} = \frac{3}{4}\frac{1}{NS^2}\sum_{\boldsymbol{q}}\left(\frac{1}{J(\boldsymbol{Q})-J(\boldsymbol{q})} + \frac{1}{J(\boldsymbol{Q})-\frac{1}{2}J(\boldsymbol{q}+\boldsymbol{Q})-\frac{1}{2}J(\boldsymbol{q}-\boldsymbol{Q})}\right) \quad (21.39a)$$

and

$$k_B T_C^{RPA}(\mathrm{nn}) = \frac{2}{3}S^2 N_{\mathrm{nn}} J_1 \begin{cases} 0.660 & \mathrm{sc} \\ 0.718 & \mathrm{bcc} \\ 0.744 & \mathrm{fcc} \end{cases} . \quad (21.39b)$$

The RPA gives weight to the low-energy magnon excitations $E(q) \propto J(\boldsymbol{Q}) - J(\boldsymbol{q})$ in the summation over all modes. This provides estimates of T_C that are in close vicinity to those obtained by numerical analysis using classical Monte Carlo simulations [21.143, 144].

Both approximations show that T_C and T_N depend on the number of nearest neighbors; one therefore expects these critical temperatures to decrease if the dimensionality of the system is reduced. However, both approximations show a qualitatively different behavior for low-dimensional magnets. The mean-field approximation overestimates the tendency for long-range order and always predicts a phase transition to ferromagnetic order in the Heisenberg model, no matter whether we have a 1-D, 2-D, or 3-D system, whereas $T_C^{RPA} = 0$ already for 2-D systems. This is consistent with the theorem of *Mermin* and *Wagner* [21.145], which states that, in two dimensions, there is no spontaneous long-range ferromagnetic order for isotropic Heisenberg models with a short-range interaction

$$\sum_j J_{ij} r_{ij}^2 < \infty$$

at finite temperature. In thin films, however, long-range order at finite temperature is stabilized by the magnetic anisotropy, which is practically always present, either due to MCA or dipolar interactions [21.146]. The magnetic anisotropy opens a gap Δ in the excitation spectrum of the spin waves, $E(q) \propto \Delta + J(\boldsymbol{Q}) - J(\boldsymbol{q})$, and suppresses low-energy long-wavelength fluctuations which occur at low temperatures. According to the renormalization group analysis of *Erickson* and *Mills* [21.147, 148], the critical temperature in two dimensions, $T_C^{(2\text{-D})}$, scales as

$$T_C^{(2\text{-D})} = T_C^{(3\text{-D})} \frac{2}{\ln\left(\frac{3\pi}{4}\frac{k_B T_C^{(3\text{-D})}}{K}\right)} , \quad (21.40)$$

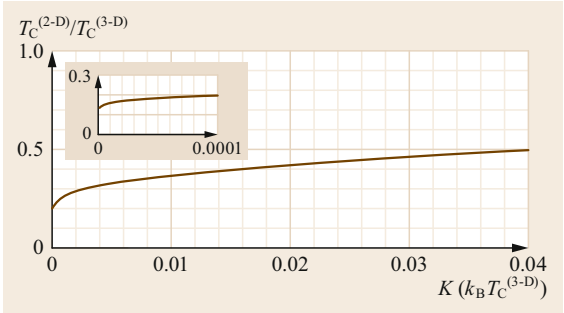

Fig. 21.9 Critical temperature of a two-dimensional magnet as function of the uniaxial anisotropy following (21.40). The function starts at zero for $K = 0$. Note its rapid growth in the vicinity of the origin, as shown in the inset at magnified scale

where the critical temperature of the three-dimensional Heisenberg model is renormalized by a logarithmic factor which depends on the strength of the uniaxial magnetic anisotropy K (Sect. 21.1.4). This result is displayed in Fig. 21.9. T_C vanishes in the isotropic limit ($K \to 0$) in accordance with the Mermin–Wagner theorem. Interestingly, for finite K, there is a rapid increase of T_C, reaching reasonable values, of, e.g., 20% of the critical temperature in 3-D systems, for anisotropy values of less than a percent of the ferromagnetic coupling constant. Consider, for example, Fe, with a shape anisotropy of 0.140 meV, which corresponds to 1.63 K on the temperature scale. This is only 0.14% of the Curie temperature of Fe, $T_C^{(3\text{-D})}(\mathrm{Fe}) = 1183\,\mathrm{K}$, but already causes a Curie temperature for a Fe film of $T_C^{(2\text{-D})}(\mathrm{Fe}) = 0.27 T_C^{(3\text{-D})}(\mathrm{Fe}) = 320\,\mathrm{K}$. A detailed treatment of T_C for 2-D monolayers with either out-of-plane or in-plane anisotropy is presented in [21.146, 149].

Thus, for any finite anisotropy, there is a critical temperature at which the spin degree of freedom is frozen, i.e., the dimensionality of the spin is reduced from three for the Heisenberg model to one, viz. spin up and spin down. In terms of universality, the Heisenberg model with any finite anisotropy value belongs to the universality class of the Ising model, and the Ising model shows a phase transition in 2-D.

In 1-D, even the Ising model does not show long-range order at finite temperature. However, in quasi-1-D magnetic chains (i.e., chains of finite size), there is a so-called blocking temperature below which a finite chain has a spontaneous and remanent magnetization, with long-range metastable order in the chain (Sect. 21.5). In reality, this magnetic order is accompanied by a slow relaxation [21.151]. The relaxation time depends on the magnetic anisotropy and can be long relative to the observation time, such that a quasi-1-D chain appears as a ferromagnet, as verified experimentally [21.72].

Table 21.4 Critical exponents for the 3-D mean-field approximation, 3-D Heisenberg model ($n = 3$), 3-D planar (or xy) model ($n = 2$), and 3-D and 2-D Ising models ($n = 1$), where n is the dimensionality of the spin vector. The values are taken from Rushbrooke et al. [21.150]

	MFA	3-D Heisenberg	3-D planar	3-D Ising	2-D Ising
β	1/2	0.35–0.385	1/3	5/16	1/8
γ	1	7/5	4/3	5/4	7/4
δ	3	5	5	5	15
ν	1/2	0.735	0.67	0.64	1

Scaling Laws

Beyond the MFA, the temperature-dependent behavior of systems described by spin lattice Hamiltonians is usually derived by means of high-temperature ($T \propto T_C$) and low-temperature ($T \ll T_C$) power series expansions of the relevant thermodynamic properties [21.152].

High-Temperature Limit. In the vicinity of the critical point T_C, the functions $f(T)$ of interest are assumed to have power-law singularities of the form

$$f(T) \approx A \left(1 - \frac{T}{T_C}\right)^{-\lambda} , \qquad (21.41)$$

where λ is the critical exponent and A is called the amplitude of the singularity. For the saturation magnetization, one thus expects

$$M_s(T) \propto \left(1 - \frac{T}{T_C}\right)^{\beta} , \quad \text{for} \quad T \to T_C^- , \qquad (21.42)$$

and $M_s(T) = 0$ for $T > T_C$. Moreover, as T approaches T_C, the response of the system to an external field is very large, so that the isothermal magnetic susceptibility diverges at T_C

$$\chi(T) \propto \left(\frac{T}{T_C} - 1\right)^{-\gamma} , \quad \text{for} \quad T \to T_C^+ . \qquad (21.43)$$

Related to the diverging susceptibility is the correlation length ξ, one of the most fundamental features of a critical point, which also diverges at T_C. ξ defines the range r over which the magnetic correlations decay, typically following an exponential function at large r and $T > T_C$: $\langle M(r)M(r=0)\rangle \propto \exp(-r/\xi)$. It is found that ξ varies as

$$\xi \propto \left(\frac{T}{T_C} - 1\right)^{-\nu} , \quad \text{for} \quad T \to T_C^+ . \qquad (21.44)$$

Finally, the application of a magnetic field H induces a finite magnetization at $T = T_C$ and above. The relation between H and M_s, called a magnetic isotherm, shows the following critical behavior

$$M_s(H, T_C) \propto H^{1/\delta} , \quad \text{for} \quad H \to 0^+ . \qquad (21.45)$$

Although there is no proof that such expressions are generally correct, (21.42)–(21.45) agree with exact solutions, when available, as well as experimental data [21.153]. Values of the critical exponents β, γ, ν, and δ are reported in Table 21.4 for different lattice models. In contrast to the MFA, the critical exponents are independent of the number N_{nn} of nearest neighbors because they describe the magnet's behavior at macroscopic length scales, which is dominated by long-range fluctuations and does not depend on the atomic environment. Another notable result of universal critical behavior is that fluctuations become increasingly important as the dimensionality of a system is reduced, as illustrated by the critical exponents of the 3-D and 2-D Ising model, and by the absence of spontaneous magnetic order for the isotropic 2-D Heisenberg model and 1-D Ising model.

Low-Temperature Limit. At low temperature, the free energy of a magnetic system can be expanded in ascending powers of the temperature. The expansion parameter is the dimensionless ratio $k_B T/J_1$ or, equivalently (21.39), T/T_C. Once the free energy is known, most of the other thermodynamic quantities of interest can be easily calculated. For a 3-D cubic lattice of identical spins with isotropic exchange coupling between nearest neighbors described by the Hamiltonian in (21.28), *Dyson* showed that the saturation magnetization in zero external field is approximated by

$$M_s(T) = M_s(0) + a_1 \left(\frac{T}{T_C}\right)^{3/2} + a_2 \left(\frac{T}{T_C}\right)^{5/2} + a_3 \left(\frac{T}{T_C}\right)^{7/2} + a_4 \left(\frac{T}{T_C}\right)^{4} + \mathcal{O}\left(\frac{T}{T_C}\right)^{9/2} , \qquad (21.46)$$

where the coefficients a_i depend on the type of cubic lattice as well as on the spin value S [21.154]. Such a power-series development is limited to low temperature ($T \lesssim (1/4)T_C$). The behavior of the ferromagnet in the critical region cannot be determined even if all terms in the expansion are supposed to be accu-

rately known, because effects of order $\exp[-J_1/(k_BT)]$, which play a decisive role at temperatures around the order–disorder transition where $k_BT \propto J_1$, are neglected. Equation (21.46) is derived by a detailed analysis of the spin wave excitations in a ferromagnet, considering deviations of the energy spectrum from the quadratic dispersion law as well as the mutual interactions between spin waves.

The concept of a spin wave (or magnon, the associated quantized excitation analog to a phonon) is fundamental to understand the low-temperature behavior of any magnetic system. In such collective excitations of the spin lattice, spins on adjacent sites have nearly parallel magnetic moments and the energy cost of a spin flip $\propto J_1$ is spread over one wavelength $2\pi/q$, where $\boldsymbol{q}$ is the wavevector of the spin wave. In the limit of infinite wavelength, a spin wave corresponds to a constant rotation of all spins that does not change their orientation relative to each other. As a result, such an excitation costs no energy. For this reason, spin wave energies can be very small, on the order of μeV per atom, which makes them accessible by thermal fluctuations on an energy scale of k_BT down to the lowest temperature.

Spin waves are eigenstates of the Heisenberg Hamiltonian in (21.28)–(21.30) with eigenvalues

$$\hbar\omega(\boldsymbol{q}) = S\hbar^2[J(0) - J(\boldsymbol{q})] \approx \mathcal{A}q^2 + \dots , \qquad (21.47)$$

where $\mathcal{A}$ is the so-called exchange stiffness parameter, which is a scalar for materials with cubic crystal structure but may be a tensor otherwise. The above approximation is valid at small wavevectors and is responsible for the leading term of order $T^{3/2}$ in the low-temperature expansion in (21.46). This term was first derived by Bloch by assuming that the density of reversed spins is so small that the interaction between two or more spin waves can be neglected. Corrections to the quadratic dispersion relationship in (21.47) are responsible for higher-order terms in the expansion, whereas spin-wave interactions in the spontaneous magnetization start manifesting themselves only at order T^4 [21.154]. This result can be explained by considering that spin waves excited at low temperature have long wavelengths and are basically coherent small-amplitude movements of a great number of atomic spins, such that mutual disturbances due to the overlapping of spin waves at the same atomic site are very small.

At finite temperature, all thermodynamic quantities, including the magnetization, must be calculated from a statistical average of the ground state and excited states. As each spin wave corresponds to the inversion of a single spin, i.e., carries $\hbar/2$ angular momentum, the saturation magnetization at finite temperature is equal to the saturation magnetization at zero temperature minus the average number of excited spin waves, namely

$$M_s(T) = M_s(0) - \frac{g\mu_B}{NL^D}\sum_{\boldsymbol{q}} \frac{1}{e^{\hbar\omega(\boldsymbol{q})/(k_BT)} - 1} , \qquad (21.48)$$

where the term in the sum is the expectation value of the magnon number operator at thermodynamic equilibrium, which obeys Bose–Einstein statistics. By changing the wavevector summation into an integral over the first Brillouin zone, assuming $\hbar\omega(q) = \mathcal{A}q^2$, and keeping track of the dimensionality D of the system, we obtain

$$M_s(T) = M_s(0) - g\mu_B \frac{\Omega_D}{(2\pi)^D} \times \int_0^\infty \frac{1}{e^{\mathcal{A}q^2/(k_BT)} - 1} q^{D-1} dq , \qquad (21.49)$$

where $\Omega_{3\text{-D}} = 4\pi$, $\Omega_{2\text{-D}} = 2\pi$, and $\Omega_{1\text{-D}} = 1$. Since the integrand is proportional to q^{D-3} at small wavevectors, the integral diverges in 1-D and 2-D. This results, which coincides with the Mermin–Wagner theorem [21.145], is a consequence of the diverging number of low-energy magnons at any finite temperature in isotropic 1-D and 2-D systems. However, as stated in Sect. 21.1.7 on the *critical temperature*, any interaction that breaks spherical symmetry, such as a magnetic field H or anisotropy energy K, is sufficient to stabilize magnetic order in 2-D. In such a case, the magnon dispersion relation writes $\hbar\omega(q) = \mathcal{A}q^2 + g\mu_BH + K$ and, assuming $k_BT \gg g\mu_BH + K$, (21.49) becomes

$$M_s(T) = M_s(0) - g\mu_B \frac{k_BT}{4\pi\mathcal{A}t} \ln \frac{k_BT}{g\mu_BH + K} , \qquad (21.50)$$

where t is the thickness of the 2-D layer [21.155, 156]. Thus, since the magnon number is approximately independent of t, and the logarithmic factor is almost constant except near $T = 0\,\mathrm{K}$, the magnetization decreases approximately proportional to T/t rather than $T^{3/2}$ as in Bloch's theory. On the high-energy side, the range of validity of (21.50) is determined by the energy interval over which the spin wave modes with wavevector q_z in the direction perpendicular to the film plane can be safely ignored. For a film of thickness t, $q_z = n_z(\pi/t)$, where $n_z = 0, \pm1, \dots$ Therefore, no mode with $q_z \neq 0$ can be excited if $k_BT < \mathcal{A}(\pi^2/t^2)$. On the low-energy side, (21.50) assumes that the thermal energy is large enough to overcome the gap in the magnon spectrum induced by either the field or anisotropy energy, such that $k_BT > g\mu_BH + K$. The overall tendency expected in thin films is a faster decrease of $M_s(T)$ compared with bulk 3-D magnets at low temperature.

21.1.8 Superparamagnetism

In the absence of magnetic anisotropy, the magnetization of any ferromagnetic system (as well as the Néel vector of an antiferromagnet) would oscillate randomly in time due to thermal fluctuations. In most bulk magnets and antiferromagnets, however, the presence of magnetic anisotropy of either crystalline or dipolar origin stabilizes the magnetization along one of the easy axes of the system, either globally or at the level of individual domains. As the total magnetic anisotropy energy scales with the volume, structures with a reduced number of atoms such as nanoparticles, nanowires, and small surface clusters present a transition from a paramagnetic-like behavior at high temperature to a ferromagnetic-like state below the so-called blocking temperature T_b. This transition occurs as the total anisotropy energy NK, given by the product of the number of atoms N and the anisotropy energy per atom K, becomes larger than the thermal energy $k_B T$. Unlike the Curie temperature, however, T_b does not correspond to a thermodynamic phase transition but to the kinetics of the relaxation process over the NK energy barrier. Therefore, the value of T_b depends on the timescale of the experimental observations and not only on the material properties of the system. Because the atomic spins are still strongly coupled by exchange in small structures, systems that present this type of behavior are called *superparamagnetic* in order to distinguish them from ordinary paramagnetic systems.

Here, following [21.157, 158], we present an analytical model describing the transition from blocking to superparamagnetism of an ensemble of monodisperse noninteracting particles. We assume that the magnetic particles have uniaxial out-of-plane anisotropy NK and are thus characterized by two local minima of the magnetic energy as a function of the angle θ between the surface normal and the magnetization $\boldsymbol{M}$ (see inset of Fig. 21.10). The anisotropy energy at zero field is the energy associated with the barrier that has to be overcome as a transition state during magnetization reversal. The rate of barrier crossing for an ensemble of monodisperse particles, all having identical values of K and M, or the time average of this rate for a single particle, is described for small fields by an Arrhenius expression

$$\nu = \nu_0 \mathrm{e}^{-(K+\boldsymbol{M}\cdot\boldsymbol{B})/(k_B T)} , \qquad (21.51)$$

where typically $\nu_0 = 10^9 - 10^{10}\,\mathrm{s}^{-1}$ [21.159]. At zero field, the relaxation time τ is given by $\tau = 1/2\nu = \tau_0 \exp[NK/(k_B T)]$, with $\tau_0 = 1/2\nu_0$. The barrier is readily overcome if $T > T_b = NK/\{k_B \ln[1/(\omega\tau_0)]\}$, where ω is related to the observation time $t = 2\pi/\omega$, given, e.g., by the sweep frequency of the external magnetic field used to measure χ. T_b is the temperature at which the ensemble reaches half of its thermodynamic equilibrium susceptibility χ_{eq}. For $T > T_b$ the particles are superparamagnetic, and $\chi(T) = \chi_{eq}(T)$. For $T < T_b$ the particles are blocked in a fixed magnetization state (up or down), hence $\chi(T) = 0$. In the vicinity of T_b, the state of the system is determined by the kinetics of barrier crossing. The zero-field susceptibility of the ensemble of monodisperse particles can be calculated numerically by solving the master equations for the occupation of the two energy minima and allowing for thermal fluctuations around these minima (see red dots in Fig. 21.10) [21.157]. Alternatively, in the limit of small fields, the real part of the complex zero-field susceptibility can be derived analytically by linearization

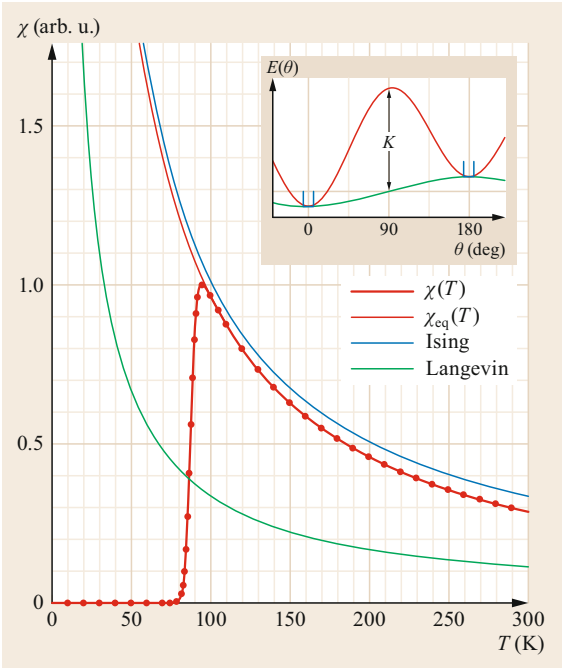

Fig. 21.10 Zero-field magnetic susceptibility $\chi(T)$ for an ensemble of monodisperse, uniaxial particles ($NK = 200\,\mathrm{meV}$, $M = 1500\,\mathrm{atoms} \times 2.1\,\mu_B = 182\,\mathrm{meV/T}$, field sweep with $\omega/(2\pi) = 0.3\,\mathrm{Hz}$). The analytical model (*thick red curve*) describes well the blocking-to-superparamagnetic transition, as evidenced by comparison with the numerical calculation (*red dots*). The equilibrium zero-field susceptibility, χ_{eq}, is shown as *thin red curve*. $\chi(T)$ derived from the Ising model (two states: up and down) and Langevin model (continuum of states, no anisotropy, only the Zeeman energy $-\boldsymbol{M}\cdot\boldsymbol{B}$ is present) are shown for comparison. *Inset*: Energy of a uniaxial monodomain particle as a function of the orientation of $\boldsymbol{M}$ with respect to an out-of-plane external field $\boldsymbol{B}$ in the Ising model, Langevin model, and the full model incorporating the anisotropy energy NK. (Reprinted by permission from [21.157], © SpringerNature 2003)

of the master equations, which gives [21.157, 160, 161]

$$\chi(T) = \frac{1}{1+\omega^2\tau^2}\chi_{\mathrm{eq}}(T)\,, \quad \text{where}$$

$$\chi_{\mathrm{eq}}(T) = M^2\left\{\frac{\mathrm{e}^{NK/(k_\mathrm{B}T)}}{\sqrt{\pi NKk_\mathrm{B}T\,\mathrm{erf}\left[\sqrt{NK/(k_\mathrm{B}T)}\right]}} - \frac{1}{(NK)^2}\right\}. \tag{21.52}$$

Figure 21.10 shows that the analytical solution for $\chi(T)$ (full red line) perfectly reproduces the numerical one, even though the former includes only the maximum energy NK via the relaxation time, whereas the latter takes into account the full energy curve. Note that, despite the fact that the particles are monodisperse, the transition from blocked to superparamagnetic behavior occurs over a finite temperature range $\Delta T = 2k_\mathrm{B}T_\mathrm{b}^2/(NK)$. The maximum of χ is located just above T_b and approximately given by $M^2/(k_\mathrm{B}T_\mathrm{b}) \propto M^2/K$. The figure also shows the infinite anisotropy limit (Ising model, blue curve) and the vanishing anisotropy limit (Langevin model, green curve). Ensembles of polydisperse magnetic particles can be modeled by calculating a weighted average of (21.52) while taking into account the finite size distribution of the particles and the dispersion of the parameters N, M, and K.

21.2 Surfaces of Bulk Crystals

Owing to the relation between the magnetic moment and coordination number, the surface magnetization of bulk ferromagnets is typically enhanced relative to the interior of the material. Theoretical studies of the magnetism of transition-metal surfaces can be summarized as follows: Magnetic moments have been found for all investigated surfaces of Cr, Fe, fcc and hcp Co, and Ni [21.162]. The surface of Mn has not been investigated in depth, due to the many possible bulk ground states of Mn. The enhancement of the calculated moments at the Co and Ni surfaces is relatively small. Co and Ni are strong ferromagnets, so that the enhancement is basically due to the sp–d dehybridization. On the other hand, Cr is a weak antiferromagnet and Fe is a weak ferromagnet (or antiferromagnet, depending on the lattice spacing), so that additional majority d-states can be occupied at the expense of minority d-states at the surface, leading to a greater enhancement of the magnetic moment. Because of the reduced coordination of open surfaces, the magnetic moment of a Ni atom at the Ni(110) surface is larger than that of a Ni atom at the Ni(100) surface. The smallest moment is found for the close-packed Ni(111) surface. For bcc Fe, the situation is slightly different: Here also the smallest moment is found for the close-packed (110) surface, but the largest moment is not found for the most open Fe(111) surface but for the (100) surface. Both the (100) and (111) surfaces have four atoms with nearest-neighbor bulk distance, but they differ in the number of next-nearest neighbor atoms and their distribution in the surface and subsurface layers. In general, the screening of the surface due to the d electrons is rather efficient. The surface-induced perturbation of the magnetic moments does not penetrate deep into the bulk. The moments at the fcc Co(100) and hcp Co(0001) surface already reach the bulk value in the first or at most second layer below the surface. For bcc (100) surfaces such as those of Fe or Cr, the perturbation penetrates slightly deeper into the bulk because the change of the surface moments is greater. Additionally, for bcc metals with half d-band filling, the bcc pseudogap in the density of states provides worse screening of the surface perturbation and the surface states can penetrate deeper into the bulk. Figure 21.11 shows a comparison of the layer-resolved magnetic moments calculated for Fe(100) and Fe(110).

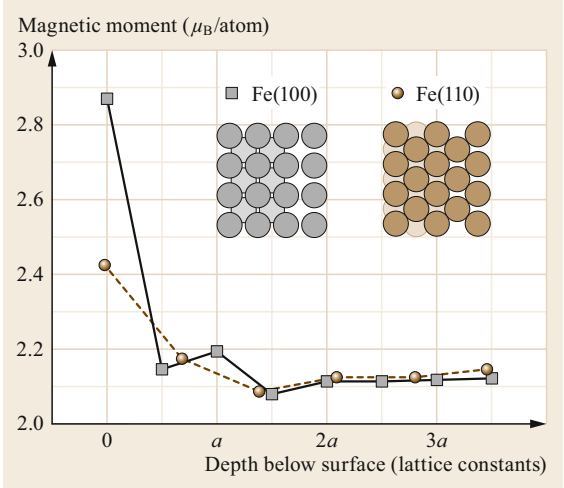

Fig. 21.11 Layer-resolved local magnetic Fe moment from the surface to bulk for Fe(100) and Fe(110). (Adapted by permission from [21.163], © Handschuh 1997)

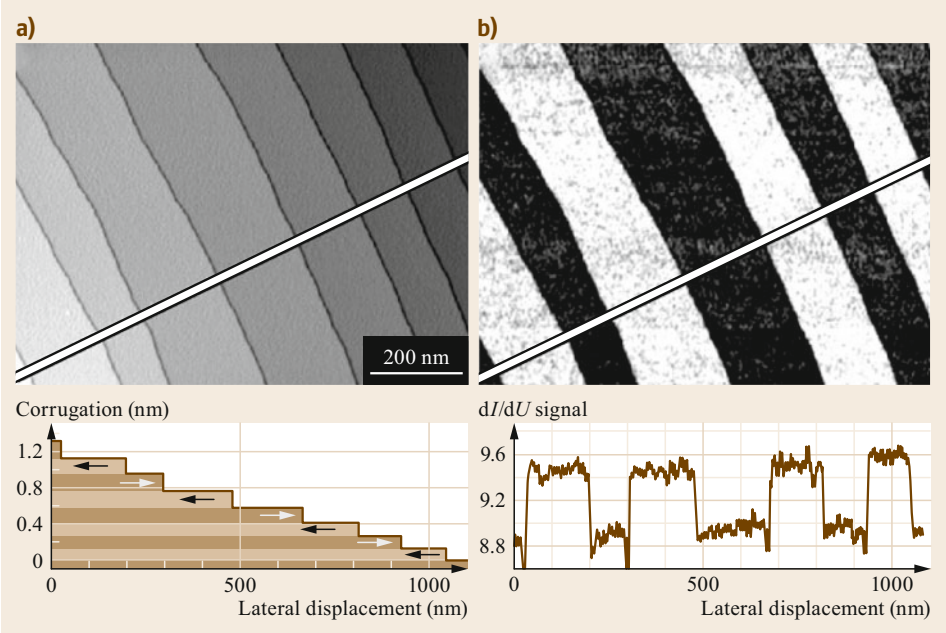

Fig. 21.12 **(a)** STM image of Cr(001) surface. Nine terraces separated by monatomic steps are visible. **(b)** Simultaneously acquired spin-resolved dI/dU map at $U = -290\,\mathrm{mV}$ sample bias. The signal changes at every step between low and high due to antiparallel magnetization of adjacent terraces. (Reprinted by permission from [21.164], © Am. Phys. Soc. 2002)

Due to symmetry breaking, materials that have antiferromagnetic or non-collinear spin structures in the bulk may present different types of magnetic order at the surface. A famous example is bcc Cr, which has a layered antiferromagnetic structure along the (001) direction modulated by an incommensurate spin density wave with wavevector $\boldsymbol{Q} = (2\pi/a)(0, 0, Q)$, where a is the lattice parameter of Cr and $Q = 0.952 \approx 19/20$. The spin density wave in bulk Cr can be ascribed to the so-called nesting between parallel sheets of the paramagnetic Fermi surface, which gives rise to a peak in the $\boldsymbol{q}$-dependent spin susceptibility $\chi_{\boldsymbol{q}}$ at the nesting wavevector $\boldsymbol{q} = \boldsymbol{Q}$. At the surface, one may envisage that the Fermi surface topology alters and that no spin density wave appears. This problem has been investigated both theoretically and experimentally [21.165–167]. Spin-polarized scanning tunneling microscopy (STM) and neutron scattering studies have confirmed that the Cr(001) surface consists of ferromagnetically ordered planes with an in-plane magnetization that inverts between adjacent terraces separated by monatomic step edges (Fig. 21.12). As the magnetization direction alternates over a large number of terraces without any change in the spin-polarized contrast, the surface magnetic structure cannot be described appropriately by a simple continuation of the bulk spin density wave. Rather, the surface pins the maximum of the spin density wave as well as the direction of the spins such that the Cr magnetic moments align along the easy (100) direction, likely due to strong in-plane surface anisotropy [21.167].

Another interesting consequence of the reduced surface coordination is that elements that are nonmagnetic in the bulk may present magnetic surfaces, such as V(100), Rh(100), and Pd(001). For both V(100) and Rh(100), the situation is controversial, as there are experimental and theoretical investigations suggesting surface magnetism, while others argue for the opposite [21.168–171]. Probably, Rh(100) is at the edge of becoming magnetic. For the (100) surface of Pd, which exhibits a strong Stoner-enhanced susceptibility in the bulk, no surface magnetism was found. However, although both the bulk and (001) surface of V, Ru, Rh, and Pd metals are nonmagnetic, theoretical calculations predict that the M_xV_{1-x} alloys with M = Ru, Rh, Pd are magnetic due to the shift of the d_{z^2} surface state, common to all bcc (100) surfaces, towards the Fermi energy, which increases $n(E_F)$ [21.172].

From the investigation of the layer dependence of the local moments from the surface to the bulk, we draw the important conclusion that the changes of the local moment due to the reduced coordination environment are limited approximately to the first and second topmost layers. In the context of thin metal films, this observation means that the effect of surfaces and interfaces will extend over a very limited thickness range.

21.3 Ultrathin Films

Much of the progress in the field of magnetism and spintronics over the last 50 years has been due to the development of refined techniques to grow high-quality thin films and complex multilayers with controlled thickness, stoichiometry, and crystal structure. The methods of choice for the growth of magnetic thin films are based on physical vapor deposition and include thermal and electron-beam evaporation as well as direct-current (DC) and radiofrequency (RF) sputtering. Whereas sputtering is used extensively at high throughput for producing polycrystalline films and coatings for the magnetic recording industry, molecular beam epitaxy (MBE) is used to deposit single-crystal layers with controlled lattice structure and orientation, mostly for fundamental investigations. The extreme sensitivity of the magnetic properties to the film structure and interfaces makes it impractical to present a detailed overview of the relevant growth processes here, which are necessarily specific to each system. For more details on the growth of magnetic metal films by MBE on metal and semiconducting substrates we refer to [21.1, 173, 174], respectively; the growth of magnetic oxide films has been reviewed in [21.175, 176]. Another factor that contributed enormously to the understanding of magnetic thin films is the emergence of surface science techniques capable of probing the magnetization with atomic-scale detail, sub-nanosecond temporal resolution, and element sensitivity. A synopsis of some of the main techniques employed in the study of surface magnetism is presented in Table 21.5. Finally, the development of ab initio and micromagnetic computational approaches has provided unprecedented insight into the electronic structure and magnetic configuration of finite-size systems, including equilibrium as well as nonequilibrium properties. In the following, we describe some of the most peculiar properties of magnetic thin films.

21.3.1 Magnetic Moments

The magnetic moments of thin films vary as a function of thickness. There are two factors that are responsible for this behavior. First, because of the reduced coordination of the magnetic atoms in a few-layer-thick film, the width of the d-band is typically smaller than in bulk systems. As a consequence (Sect. 21.1.2), the exchange splitting as well as the Fermi-energy DOS increase relative to the bulk (Fig. 21.4), driving up the magnetic moments and favoring the formation of stable magnetic states (21.5) for a much wider variety of transition-metal elements than just the bulk 3d ferromagnets and antiferromagnets. Second, the electronic hybridization between film and substrate also affects the d-bandwidth; For instance, substrates that are wide-bandgap insulators, such as MgO(100), allow for the formation of two-dimensional electron bands within the bandgap of the substrate material. In this case, the impact on the magnetization of the film due to the substrate is expected to be small. The same is true for noble-metal substrates, which have d-bands well below the Fermi energy. Even in the monolayer limit, the width of the d-band is not significantly broadened by the d–d interaction with the substrate, and magnetism is restricted to the monolayer. Increasing the d–d hybridization by choosing appropriate nonmagnetic transition-metal substrates, such as Pd, Pt, or W, however, leads to a considerable broadening of the monolayer bands and also introduces a significant spin polarization of the substrate. Broadening of the d-band can also be caused by d–sp hybridization, particularly in the case of metallic substrates with a large free-electron density such as Al, which generally leads to a reduction of the d magnetic moments [21.183, 195].

As transition-metal monolayers on noble-metal substrates are the classical systems exhibiting 2-D magnetism, we present in Fig. 21.13a systematic theoretical

Table 21.5 Synopsis of experimental techniques that are widely used in the investigation of magnetic thin films and nanostructures. Typical sensitivity values are given for measurement times ranging from a few seconds to a few hours. Units of μ_B/cm^2 can be converted into surface coverage by recalling, e.g., that 1 ML $\approx 1.5\times10^{15}$ atoms/cm^2 for the (111) surface of Pt or (100) surface of Cu. Additional microscopy techniques are described in [21.187]

Technique	Measured quantity	Sensitivity	Probing depth	Lateral resolution	References
SQUID	Magnetic flux	$5\times10^{13}\ \mu_B$	–	–	[21.177]
MOKE	Kerr rotation	10^{10}–$10^{14}\ \mu_B/cm^2$	10–20 nm	$\geq 0.5\,\mu m$	[21.178–180]
FMR	Resonant magnetic field	10^{10}–$10^{14}\ \mu_B/cm^2$	$\approx 1\,\mu m$	–	[21.68, 181]
XMCD	Element-specific m_S and m_L	10^{12}–$10^{14}\ \mu_B/cm^2$	≤ 5 nm	–	[21.182, 183]
XPEEM	Element-specific m_S and m_L	$10^{14}\ \mu_B/cm^2$	≤ 5 nm	20–50 nm	[21.182, 184]
MFM	Magnetic field gradient	10 μT	Near surface	10–50 nm	[21.185–188]
NVM	Magnetic field	1 μT	Near surface	20–50 nm	[21.189–191]
SP-STM	Tunneling resistance	$\leq 1\ \mu_B$	≤ 1 nm	≤ 1 Å	[21.192–194]

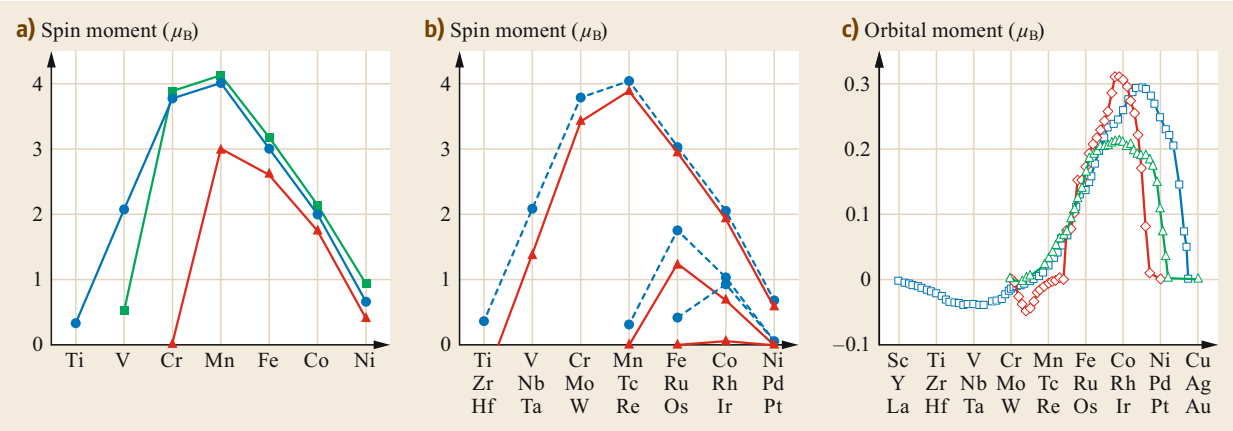

Fig. 21.13 **(a)** Local spin magnetic moments as calculated for ferromagnetic 3d metal monolayers on Ag(100) [21.196] (*dots*), Pd(100) [21.197] (*squares*), and Cu(001) [21.36] (*triangles*), and **(b)** 3d, 4d [21.198], and 5d monolayers on Ag(001) [21.199] (*dots*) and Ag(111) [21.200] (*triangles*). **(c)** Local orbital magnetic moments calculated for free-standing ferromagnetic 3d (*squares*), 4d (*triangles*), and 5d (*diamonds*) monolayers. The lateral lattice constant corresponds to that of Ag(100), although, in contrast to **(a,b)**, the layers are unsupported. The calculations are carried out for films with noninteger atomic number Z. The data are averages of the in-plane and out-of-plane moments

calculations of the magnetic moments of all possible 3d, 4d, and 5d transition-metal monolayers on Ag(001). In the ideal case of a pseudomorphic (001) monolayer, all the 3d metals (Ti, V, Cr, Mn, Fe, Co, and Ni) have a ferromagnetic ground state, whereas Tc, Ru, and Rh are ferromagnetic among the 4d metals, and Os and Ir are ferromagnetic among the 5d metals. The local magnetic moments are very large, not only for the 3d monolayers, but surprisingly also for the 4d and 5d ones. In the 3d series, the overall trend of the local moments follows Hund's first rule. The largest local moment of about $4\,\mu_B$ is found for Mn, whereas from Mn to Ni the magnetic moment decreases in steps of $1\,\mu_B$. The latter is a consequence of the strong ferromagnetism in these monolayers. The magnetic moments of Ti, V, and Cr monolayers show a pronounced dependence on the substrate: Ti is magnetic on Ag(100) but nonmagnetic on Pd(100), the magnetic moment of V is reduced by more than $1.5\,\mu_B$ when changing the substrate from Ag to Pd, whereas for Cr the magnetic moment changes from $3.8\,\mu_B$ on Ag(100) or Pd(100) to zero on Cu(100). Although not as dramatic, such a reduction is also visible for Mn. The drastic reduction of the monolayer moments is caused by the decrease of the lattice constants in the sequence Ag to Pd to Cu as well as by the increase of d–sp hybridization on Cu. When comparing the results of the local moments between 3d, 4d, and 5d monolayers on Ag(001), an interesting trend is observed: The element with the largest magnetic moment among each transition-metal series shifts from Mn to Ru (isoelectronic to Fe) and finally to Ir (isoelectronic to Co), respectively. Experimental investigations of Rh and Ru layers on Ag(100), however, have failed to provide evidence for finite 4d magnetic moments, even at low temperature [21.201]. Calculations have further shown that including the spin–orbit interactions significantly reduces the magnetic spin moment of the 5d metal monolayers, and depending on the interlayer relaxation, the spin moment might be suppressed [21.202].

On the (111) surface of an fcc crystal or the (0001) surface of an hcp crystal, the coordination number changes from 4 to 6 relative to the (100) surface, and the symmetry changes from fourfold to threefold or sixfold, respectively. Figure 21.13b exemplifies the general trend that the magnetic moments of the sixfold-coordinated monolayers on Ag(111) are smaller in magnitude than those of the fourfold-coordinated ones on Ag(001). The greater reduction of the magnetic moments is found at the beginning of the 3d series, where the wavefunctions are more extended than at the end of the series. Changing the coordination number from 4 to 6 does not change the local moments of Mn, Fe, Co, and Ni significantly. One consequence of this result is that no dramatic difference in the formation of large local moments is expected for monolayers that do not grow pseudomorphically on any substrate, but keep an average distance between atoms similar to the pseudomorphic films. The heavier metals are more affected by the change in coordination, however, because of the increasing degree of delocalization of the d wavefunction when going from the 3d to the 4d and 5d series.

Experimental investigations of the magnetic moments of ultrathin films, and of low-dimensional magnets in general, are complicated by the fact that the

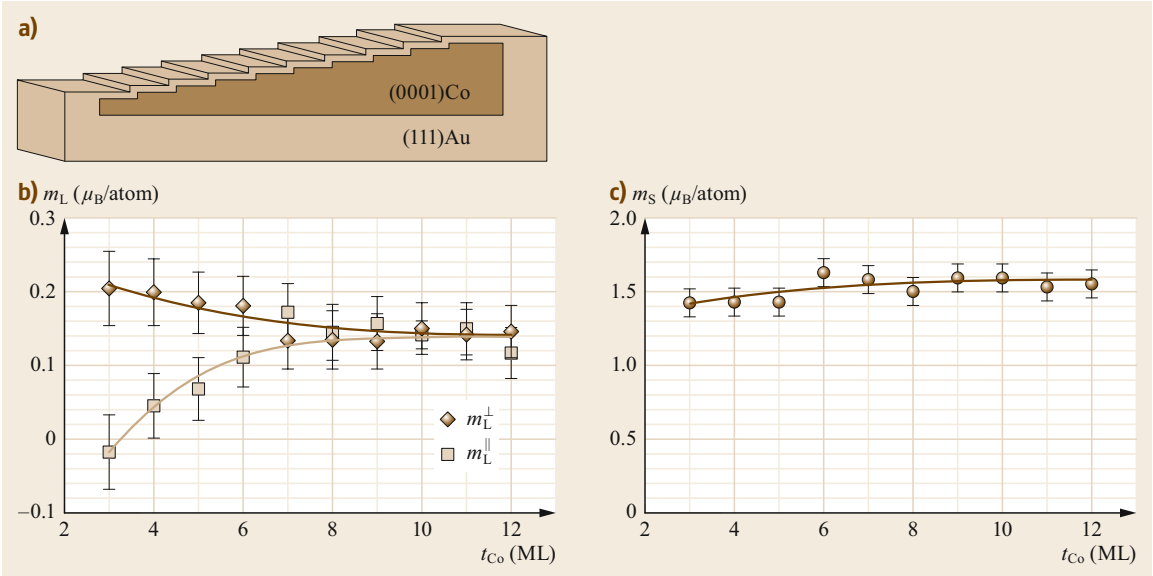

Fig. 21.14 **(a)** Schematic of Au/Co(3–12 ML)/Au wedge sample grown by molecular epitaxy on a float-glass substrate. The film has (111) texture after annealing and has a perpendicular easy axis at small Co thickness but in-plane easy axis for Co layers ≥ 11 ML. **(b)** In-plane ($m_L^\parallel$) and out-of-plane ($m_L^\perp$) orbital moments determined by XMCD as a function of Co thickness. **(c)** Angle-averaged spin moment. The measurements were performed at room temperature; the spin moment decreases with decreasing Co thickness, due to a drop in T_C. (Adapted by permission from [21.182], © SpringerNature 2007)

saturation magnetization is strongly temperature dependent (Sects. 21.1.7 and 21.3.3), which makes it hard to compare m_S and m_L between different systems, unless low temperatures and/or high magnetic fields are applied. Nonetheless, one generally finds that the magnetic moments of 3d films that form sharp interfaces with weakly interacting substrates tend to increase with reduced thickness [21.1, 203]. The presence of surface steps, which introduce lower-coordination sites relative to a smooth 2-D film, also has measurable effects on the magnetization [21.204]. Importantly, the different coordination environment inside the films relative to the bottom and top interfaces leads to a thickness-dependent distribution of the local magnetization [21.205, 206]. However, the magnetic moment measured by most experimental techniques is an average quantity over the film thickness. By artificially separating the bulk and surface magnetic moments, m^b and m^s, respectively, one may expect such an average moment to vary as $m = m^b + (m^s - m^b)t_s/t$, where t is the total thickness of the film and t_s is the effective thickness of the surface or interface region over which the effects of the reduced coordination are significant (typically 1 or 2 ML). This formula also accounts for the formation of magnetic dead layers ($m^s = 0$), which occur due to strong electronic hybridization with the substrate or, more often, intermixing between magnetic and nonmagnetic species at diffuse interfaces. One should be careful, however, because structural effects, e.g., due to strain relaxation, may also lead to substantial changes of the magnetic moment [21.207, 208] or even of the magnetic phase as a function of thickness [21.3]. Fcc Fe films grown on Cu(100) constitute a famous example of a system for which the magnetic order depends sensitively on the lattice parameter and growth mode [21.1, 209, 210].

The orbital magnetic moment can be deduced from x-ray magnetic circular dichroism (XMCD) measurements, in which dipolar selection rules allow for the separation of m_S and m_L [21.213–215] as well as from the g-factor shifts detected in angular-dependent ferromagnetic resonance spectra of thin films [21.68, 216]. Figure 21.14 shows m_S and m_L measured at room temperature on a thin Co wedge sandwiched between two Au layers. Whereas m_S does not change significantly, as the expected increase of the spin moment is masked by the decrease of T_C, m_L changes strongly with decreasing Co thickness. Moreover, the anisotropy of the orbital moment $m_L^\perp - m_L^\parallel$ increases from nearly zero to $\approx 0.24\,\mu_B$ in the 3-ML-thick film. In the model outlined in Sect. 21.1.3, this trend shows that the contribution to the Co orbital moment from the in-plane orbitals (d_{xy} and $d_{x^2-y^2}$) becomes larger than that from the out-of-plane orbitals (d_{xz}, d_{yz}, and d_{z^2}), indicating that the d–d hybridization at the Co/Au interface is

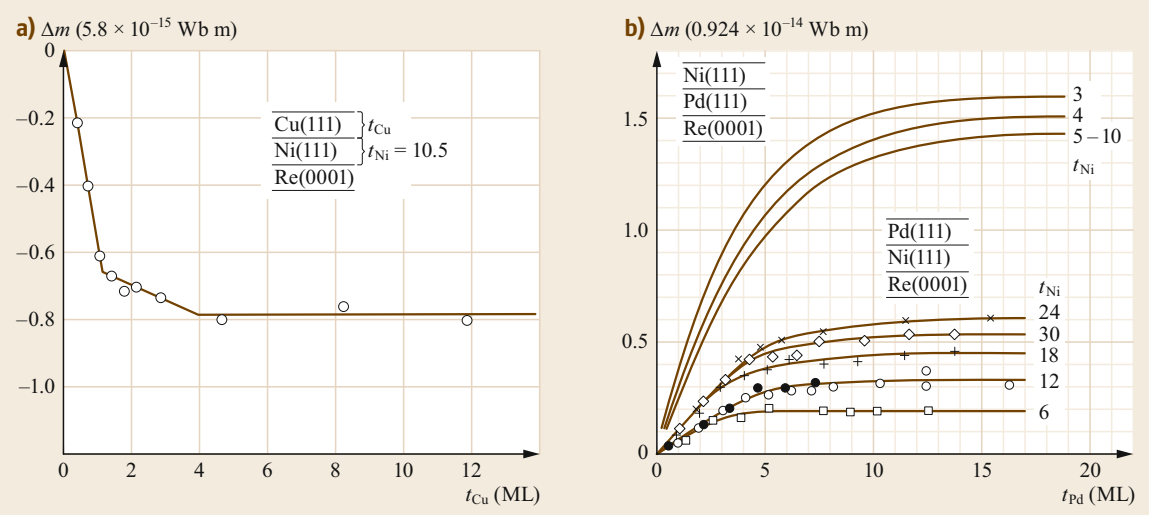

Fig. 21.15 **(a)** Decrease of magnetic moment in a 10.5-ML-thick Ni(111) film induced by Cu coating. The decrease Δm is given in units of the bulk monolayer moment of 5.8×10^{-15} Wb m, versus the number of coating Cu layers, t_{Cu}. stronger than the in-plane hybridization (Fig. 21.5b). The stronger out-of-plane orbital moment also explains the perpendicular magnetic anisotropy observed in this system for Co films ≤ 11 ML [21.69]. In general, an increase of m_L of up to 50% is detected in thin films and monolayer structures [21.76, 216–218]. A similar increase is reported for the ratio m_L/m_S, which signifies that m_L is more sensitive than m_S to changes of the atomic coordination environment and band filling (Fig. 21.13c), in line with the hierarchy of the Hund's rules.

Induced Magnetic Moments at Interfaces

If the substrate and the capping layer affect the interfacial moments of a magnetic film, the reciprocal effect also occurs. Magnetic films (and adsorbates in general) can induce sizable moments in otherwise nonmagnetic materials via the so-called *magnetic proximity effect*, which is due to the exchange splitting of hybridized wavefunctions at interfaces. These effects were recognized very early on by *Gradmann* and collaborators, who studied the magnetization of Fe, Co, and Ni layers capped by Cu, Ag, and Pd [21.1, 212, 219]. Figure 21.15a shows the decrease of the moment of Cu/Ni/Re(0001) layers as a function of the Cu coverage due to the hybridization of the Ni d bands with the Cu sp bands, and the increase of the total moment of Ni/Pd/Re(0001) and Pd/Ni/Re(0001) layers due to the formation of induced moments in Pd. Proximity effects are prominent in nonmagnetic metals that are close to a magnetic Stoner instability such as Pd and Pt (Sect. 21.1.1).

Recent investigations have exploited the element sensitivity of XMCD to separately measure the magnetic moments of the ferromagnetic films and the induced magnetic moments in the nonmagnetic layers [21.218, 220, 221]. Figure 21.16a shows the XMCD spectra of polycrystalline W, Ir, and Pt in Fe/W, Fe/W, and Co/Pt multilayers. The finite XMCD signal shows that all the 5d elements have acquired sizable induced moments, with m_S and m_L extracted from the XMCD sum rules indicated next to the spectra [21.221]. The different sign of the XMCD spectra shows that W is coupled antiparallel with respect to the ferromagnetic layer, in contrast to Ir and Pt, which are coupled parallel to it. This behavior originates from a general trend in the transition-metal series with d band filling, whereby elements with less than a half-filled d shell have a negative interatomic exchange integral J, whereas elements with more than a half-filled d shell have a positive J. Figure 21.16b shows the layer-dependent magnetic moment profile reconstructed for a Ni_6/Pt_5 multilayer using data from layers with different Ni and Pt thicknesses [21.218]. The data evidence how the changes in magnetic moment (reduction of the Ni moment and induction of the Pt moment) are layer specific and confined to the atoms next to the interface.

Importantly, proximity effects at the interface between nonmagnetic metals, e.g., Pt, and magnetic oxides such as garnets [21.222] or ferrites [21.223, 224],

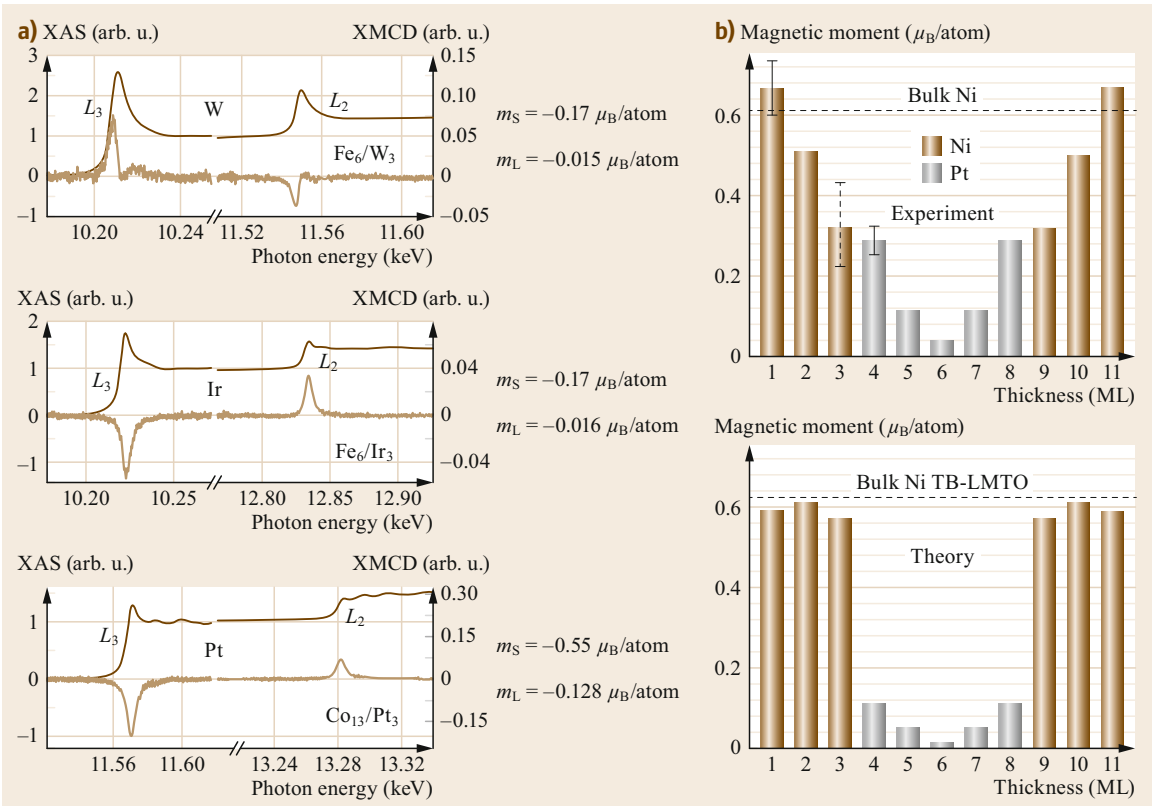

Fig. 21.16 **(a)** x-Ray absorption (*top*) and XMCD (*bottom*) spectra measured at the $L_{3,2}$ edges of W, Ir, and Pt in Fe/W, Fe/Ir, and Co/Pt multilayers measured at 10 K in a magnetic field of 5 T applied normal to the film plane. are typically much smaller than for 3d metal films due to the localization of the 3d wavefunctions in the oxide compounds. Such effects, which depend strongly on the quality of the oxide interface [21.222, 225], are currently under intense investigation to understand the magnetotransport properties of nonmagnetic metal films deposited on ferrimagnetic insulators [21.226].

21.3.2 Magnetic Anisotropy

There are three important sources of magnetic anisotropy in thin films, which are related to the reduced symmetry as well as to the crystalline structure of 2-D layers: (i) the shape anisotropy discussed in Sect. 21.1.4, (ii) the reduced or modified coordination of atoms at surfaces, interfaces, or step edges [21.1, 227–231], and (iii) the distortion of the lattice due to strain between the magnetic layers and the substrate, resulting in a magnetoelastic energy contribution [21.1, 232–234]. (ii) and (iii) are related to the anisotropy of the orbital moment in a noncubic environment, which produces a strong enhancement of the MCA.

First-principles calculations reveal that the MCA energy of free-standing (100) transition-metal monolayers is a strong function of band filling [21.229–231]. Calculations by Blügel et al. show that the uniaxial anisotropy constant K_{MCA} is negative between Fe and Cu, peaks at -4.75 meV between Co and Ni, is positive for Fe, and oscillates between positive and negative values from Fe to Ti with amplitude $|K_{MCA}| < 0.2$ meV. Thus, among the 3d metal elements, only the Fe(100) monolayer has an out-of-plane magnetization direction. The strong dependence of K_{MCA} on the occupation of the d-band explains why the MCA is extremely sensitive to electrical gating and oxidation, which has important consequences for the realization of voltage-controlled memory devices [21.9, 235–237]. The calculations also show that K_{MCA} reaches values of 12.32 meV for Os and -13.50 meV for Ir, reflecting the strong increase of the MCA in 5d monolayers due

to their large spin–orbit coupling. Although the magnetism of 5d monolayers is purely theoretical, such an increase shows that the MCA of the induced 5d moments at interfaces can be very strong and even surpass that of the magnetic 3d layers.

Any discussion of the magnetic anisotropy of thin films, however, should include the influence of the substrate and capping layers on (i) and (ii) described above. In the spirit of the model introduced in Sect. 21.1.4, the electronic interaction with the substrate tends to decrease the in-plane orbital moment. This effect alone may not be sufficient to force a change of sign of K_{MCA}, e.g., from negative (favoring in-plane magnetization) to positive (favoring out-of-plane magnetization). For example, K_{MCA} calculated for a Co monolayer on a weakly interacting substrate such as Ag(100) is $-1.33\,\mathrm{meV}$, which adds to the negative in-plane shape anisotropy. However, heavy-metal substrates with strong spin–orbit interactions, which have in addition a large Stoner-enhanced susceptibility, such as W or Pt, can modify the MCA of the interface atoms and also develop strongly anisotropic induced moments, thus determining the overall magnetic anisotropy of the film. This situation is typical for Co films on Pt(111), Pd(111), and Au(111), and multilayers containing the same combination of Co and nonmagnetic elements [21.228, 238, 239]. Interfacial bonding to electronegative atoms, such as oxygen, provides another means to strongly influence the MCA of metal films, even in the absence of heavy metals [21.9, 240]. The axial bonds that develop between O and 3d atoms when, e.g., or MgO or AlO_x are deposited on Fe or Co, or vice versa, induce a crystal-field splitting that favors a very strong out-of-plane orbital moment and the consequent out-of-plane anisotropy [21.74, 241, 242]. This effect is exploited to stabilize the perpendicular magnetization of magnetic tunnel junction devices that utilize CoFeB and MgO as the magnetic electrode and insulating barrier, respectively [21.243].

Extensive reviews have been published on experimental measurements concerning the magnetic anisotropy of transition-metal films on metal substrates [21.1, 68, 232, 244], multilayers [21.245], semiconductors [21.174, 246, 247], and oxide interfaces [21.9]. Rather than presenting an exhaustive overview of different systems, we focus here on general trends, highlighting two cases that are representative of thin-film behavior. To facilitate the discussion, it is common practice to separate the volume-like contributions to the effective anisotropy constants, K^{V} (energy per unit volume), from the interface term K^{I} (energy unit per area). This separation is justified qualitatively by observing that, if more than one or two layers of magnetic material are deposited as a thin film, the layers that are not forming an interface (with the vacuum or the substrate) are expected to exhibit more bulk-like properties. The effective magnetic anisotropy constant K^{eff} of a magnetic layer of thickness t is thus

$$K^{\mathrm{eff}} = K^{\mathrm{V}} + \frac{K^{\mathrm{I}}}{t} \,. \tag{21.53}$$

The two anisotropy constants in (21.53) contain contributions of the dipolar and the spin–orbit-derived anisotropy. Thus, we can write for the volume term $K^{\mathrm{V}} = K^{\mathrm{V}}_{\mathrm{shape}} + K^{\mathrm{V}}_{\mathrm{MCA}}$, and for the interface term $K^{\mathrm{I}} = K^{\mathrm{I}}_{\mathrm{shape}} + K^{\mathrm{I}}_{\mathrm{MCA}}$. In such a model, $K^{\mathrm{V}}_{\mathrm{MCA}}$ includes the thickness-independent crystalline and magnetoelastic contributions, whereas K^{I} includes all the thickness-dependent effects. $K^{\mathrm{V}}_{\mathrm{shape}}$ is the shape anisotropy due to the average dipolar energy as obtained by the continuum theory (21.24), while $K^{\mathrm{I}}_{\mathrm{shape}}$ is the contribution due to the reduction of the dipole anisotropy field experienced by the atoms in the surface or interface region calculated using (21.25). Because the negative shape anisotropy has a constant value per atom and thus increases with thickness, the magnetization of thick films is usually in-plane, with a few exceptions due, e.g., to tetragonally distorted crystal structures. For thicknesses smaller than 1–2 nm, however, $K^{\mathrm{I}}_{\mathrm{MCA}}$ can dominate K^{V} and determine the easy axis. If these terms have different signs, a reorientation transition of the easy axis can occur.

Co layers deposited on Pt(111), by either molecular beam epitaxy or sputtering, represent a prototype system in which such a spin reorientation transition occurs due to a positive K^{I} and negative $K^{\mathrm{V}}_{\mathrm{shape}}$. Figure 21.17 shows that the product $K^{\mathrm{eff}} t_{\mathrm{Co}}$ of a (111)-textured $AlO_x/\mathrm{Co}(t_{\mathrm{Co}})/\mathrm{Pt}$ layer changes from positive to negative as a function of thickness, leading to an out-of-plane to in-plane spin transition for $t_{\mathrm{Co}} > 1\,\mathrm{nm}$ [21.249], as expected based on (21.53). The measurements additionally show that the threshold thickness shifts from 1.35 nm in the as-deposited layers to more than 3 nm after annealing at 598 K for 30 min. This effect is attributed to the migration of oxygen through the Al capping layer to the Co interface, leading to the homogeneous formation of Co–O–Al bonds over the interface and a consequent increase of the perpendicular anisotropy of the top Co surface. The increase of the perpendicular anisotropy due to oxidation is also confirmed by exposing as-grown Al/Co/Pt trilayers to an rf oxygen plasma, as shown in Fig. 21.18a. Whereas the pristine Al/Co/Pt structure has in-plane anisotropy, progressive oxidation leads to an out-of-plane easy axis and square magnetization loops (Fig. 21.18b). The perpendicular anisotropy, reflected by the coercivity in Fig. 21.18c, has a maximum coinciding with full oxidation of the top Co interface

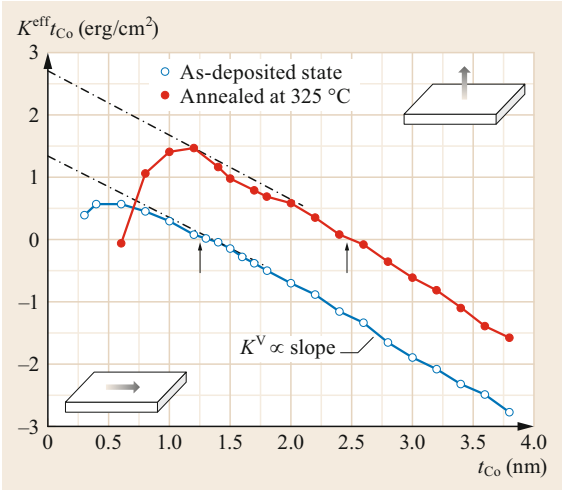

Fig. 21.17 Variation of product of effective anisotropy energy K^{eff} and Co thickness t_{Co} as a function of Co thickness for as-deposited and annealed polycrystalline films of Pt(2)/Cu(2)/AlO_x(0.5)/Co(t_{Co})/Pt(20)/Ta(2) grown by sputtering on a SiO_2 wafer. The thickness of each layer is given in nanometers in the parentheses. The oxide layer is obtained by natural oxidation of Al in an oxygen pressure. The sum of the interface terms, K^{I}, is given by the intersection with the ordinate axis, whereas the volume-like contribution, K^{V}, is deduced from the slope of the curve. The *thin arrows* indicate the thickness at which the spin reorientation transition occurs. (Reprinted by permission from [21.9], © Am. Phys. Soc. 2017)

and declines afterwards due to overoxidation of the Co layer [21.248]. From the slope of $K^{\text{eff}}t_{\text{Co}}$ in Fig. 21.17, one deduces that the effective bulk anisotropy is essentially the demagnetizing energy of the Co layer ($-\mu_0 M^2/2$) and does not change with oxidation. The sum of the interfacial anisotropy at the Co/Pt and AlO_x/Co interfaces, given by the y-axis intercept of $K^{\text{eff}}t_{\text{Co}}$, however, increases sharply after annealing, giving $K^{\text{I}} = 2.8\,\text{mJ/m}^2$ ($1\,\text{mJ/m}^2 = 1\,\text{erg/cm}^2$). Note that $1\,\text{mJ/m}^2 \approx 0.5\,\text{meV/atom}$ for a *single* Co layer, assuming the same atomic density as for a Pt(111) monolayer. Since the anisotropy of the Co/Pt interface is in the range of $0.6-1.4\,\text{mJ/m}^2$ [21.250, 251], this result implies that K^{I} at the AlO_x/Co interface is in the range of $1.4-2.2\,\text{mJ/m}^2$, i.e., comparable to that of the Co/Pt interface. Similar enhancements of the perpendicular anisotropy are obtained at the MgO/CoFe interface [21.252], which is quite remarkable considering the weak spin–orbit coupling of Co, AlO_x, and MgO [21.9].

A different case is that of epitaxial Ni layers grown on Cu(100) [21.232, 233, 253]. Here the interface anisotropy is negative, which leads to an in-plane easy axis of the thinner Ni films. However, Ni grows pseudomorphically on Cu(001) with an in-plane lattice constant that is 1.6% larger compared with fcc Ni. To compensate this strain, the vertical spacing between the Ni layers contracts, leading to a crystalline structure with face-centered tetragonal (fct) symmetry. According to the arguments presented in Sect. 21.1.4, we would now expect that $V_\perp > V_\parallel$, therefore $R > 1$ and a crystalline volume term $K^{\text{V}}_{\text{MCA}}$ that favors perpendicular magnetization. Indeed, a plot of K^{eff} as a function of $1/t_{\text{Ni}}$ (Fig. 21.19a) shows that K^{I} is negative, $\approx -85\,\mu\text{eV/atom}$ at room temperature, whereas $K^{\text{V}}_{\text{MCA}}$ is positive, $\approx 30\,\mu\text{eV/atom}$, which is more than an order of magnitude larger compared with fcc Ni. By estimating the compensation point at which $K^{\text{eff}} = 0$, we would expect an in-plane to out-of-plane spin reorientation transition at around $t_{\text{Ni}} = 5-6\,\text{ML}$. However, as the shape anisotropy contributes another $-10\,\mu\text{eV/atom}$ to K^{V}, the transition actually sets in at $\approx 7\,\text{ML}$. In very thick films, the structure of Ni relaxes back to fcc and K^{V} decreases until the influence of the shape anisotropy brings the easy axis back in-plane.

The two examples presented above show how the nature of the interfaces as well as of the *bulk* crystalline structure of the film concur in determining the orientation of the magnetization, together with the shape anisotropy. Surfaces with reduced in-plane symmetry, due to either the presence of steps [21.204, 254–256] or inequivalent bonding geometries [21.246, 257], further show preferential in-plane directions, captured by higher-order anisotropy constants in (21.17); for example, symmetry breaking at atomic steps of ultrathin Fe films grown on stepped Ag(001) induces a uniaxial magnetic anisotropy with the easy axis parallel to the step edges, which scales quadratically with the step density [21.255]. In such a case, the origin of the step-induced magnetic anisotropy is almost independent of the Fe film thickness, which has been attributed to a long-range distortion of the cubic symmetry of Fe [21.258]. In other cases, however, local effects due to the reduced coordination of the step atoms dominate the anisotropy behavior, as shown, e.g., by the abrupt 90° switching of the in-plane easy axis for 20-ML-thick Co films grown on stepped Cu(001) upon step decoration by only 0.03 ML of Cu [21.259]. Such local step-edge effects are also responsible for oscillations of the MCA during layer-by-layer growth of Co on Cu(001), as the film morphology alternates between filled and incompletely filled atomic layers [21.260]. Other morphology-related effects are due to electron confinement, which, in crystalline films, has been

shown to lead to oscillations of the MCA due to the formation of quantum well states in either a nonmagnetic metal cap layer [21.261] or the ferromagnetic layer itself [21.262].

Finally, magnetic anisotropies are temperature-dependent quantities, as mentioned in Sect. 21.1.4 and illustrated in Fig. 21.19b for the second- and fourth-order anisotropy constants of Ni/Cu(001) [21.253]. The different temperature dependence of the surface, volume, and shape anisotropies may give rise to spin reorientation transitions as a function of temperature [21.244]. Such transitions have been observed, e.g., in Fe films on Cu(001) and Ag(001) [21.263–265], which evolve from out-of-plane at low temperature to in-plane at high temperature, as well as in Ni/Cu(001), which shows the opposite behavior [21.253].

21.3.3 Temperature Dependence of Magnetic Order

The temperature dependence of magnetic order is different in thin films relative to bulk materials (Sect. 21.1.7). Magnetic films grown pseudomorphically on nonmagnetic substrates with appropriate lattice spacing allow for the investigation of the order–disorder phase transition in a layerwise fashion, provided that the films are thermodynamically stable, i.e., that their microstructure does not change with temperature.

Curie Temperature

The first extensive studies of magnetic order in ferromagnetic films were carried out by Gradmann and coworkers for epitaxial NiFe and Co layers grown on

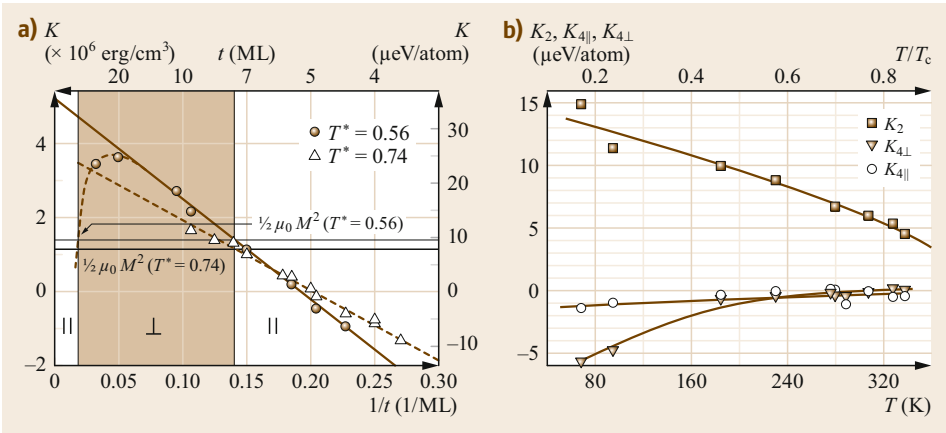

Fig. 21.19 **(a)** Effective anisotropy energy K of epitaxial Ni layers grown on Cu(100) as a function of Ni thickness for two reduced temperatures $T^* = T/T_C$. The *shaded area* is the perpendicularly magnetized phase where the crystalline anisotropy exceeds the shape anisotropy, indicated by the *solid* and *dashed horizontal lines* for the two temperatures. Note that $K_{4\parallel} \neq K_{4\perp}$ as a result of the tetragonally distorted structure of the Ni film, and that the convention used to number the K_i indexes here is different from that used in (21.17) (Reprinted by permission from [21.253], © Am. Phys. Soc. 1997)

Cu(111) as well as for Ni on Re(0001) and Fe on W(110) [21.1, 266, 267]. The results evidenced a drastic decrease of the Curie temperature T_C when the film thickness approached the monolayer limit, as shown in Fig. 21.20. The decrease of T_C is related to the reduced coordination of the magnetic atoms, as discussed in Sect. 21.1.7 for the Heisenberg model. Qualitatively, the decrease of the average coordination number $\overline{N}$, schematized in Fig. 21.20b, leads to a $1/t$ decrease of T_C. The data in Fig. 21.20c agree with the reduction of

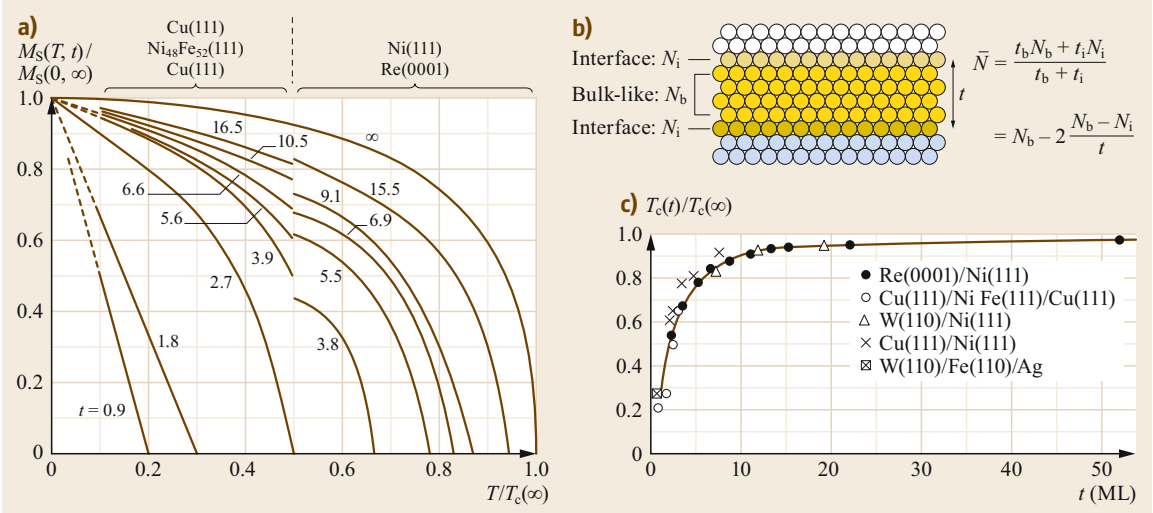

Fig. 21.20a–c Dependence of spontaneous magnetization $M_s(T, t)$ on temperature T (normalized to the Curie temperature $T_C(\infty)$ of the bulk material) and the number t of atomic layers, given as parameters for $Ni_{48}Fe_{52}(111)$ films on Cu(111) ($T < 0.5T_C(\infty)$) and Ni(111) films on Re(0001) ($T > 0.5T_C(\infty)$). Data for bulk Ni are shown for comparison. **(b)** Schematic diagram of the change of the average coordination number $\overline{N}$ for a thin film. **(c)** Normalized Curie temperature versus number of atomic layers t for different densely packed cubic transition-metal films. T_C relative to the bulk Curie temperature $T_C(\infty)$ predicted by finite-size scaling models [21.268–270],

$$\frac{T_C(\infty) - T_C(t)}{T_C(\infty)} = \left(\frac{t_0}{t}\right)^{1/\nu} , \qquad (21.54)$$

where t_0 is a constant and ν is the critical exponent of the spin–spin correlation length introduced in Sect. 21.1.7. The values of $1/\nu$ vary from 1 in the mean-field case to 2 depending on the boundary conditions assumed for the magnetic film and the geometry of the lattice. The curves in Fig. 21.20c are well reproduced by $1/\nu = 1.27 \pm 0.2$, although (21.54) is strictly valid only for a 3-D layered system ($t > 4$ ML) with thickness-independent magnetic anisotropy. For thinner films, higher ordering temperatures than predicted by (21.54) are actually observed, consistent with the fact that T_C increases with surface anisotropy (21.40). Studies of Ni layers grown on Cu(110), Cu(100), and Cu(111) also reveal that T_C depends on the symmetry of the lattice and interlayer spacing [21.271].

The morphology and, thereby, the magnetic properties of ultrathin films depend strongly on the preparation conditions. Although it is possible to grow smooth 2-D monolayers with sharp interfaces, care must be taken to adjust the deposition conditions in order to achieve wetting and layer-by-layer growth while minimizing interdiffusion [21.272, 273]. A well-known example is that of bcc Fe films grown on W(110), which have been characterized by low-energy electron diffraction (LEED), Auger, and STM, and studied by conversion electron Mössbauer spectroscopy [21.1, 272, 274], torsion oscillation magnetometry [21.203, 275], spin-polarized LEED [21.276, 277], the magnetooptic Kerr effect [21.278, 279], as well as spin-polarized STM [21.192, 280–283]. The relative contributions of the first, second, and bulk-like Fe layers can be distinguished by their different magnetic hyperfine fields as measured by Mössbauer spectroscopy [21.274, 284]. For thickness $t < 0.2$ ML, the films are pseudomorphic, as observed by LEED and STM, and the monolayer component alone is present in the Mössbauer spectra, independent of the preparation temperature ($T_{prep} =$ 300 or 475 K) and despite the large misfit of 9.4% between the lattice constants of W and Fe. Wetting in this case is favored by the large difference between the surface energy of the substrate and overlayer. For $t > 0.8$ ML, the growth mode depends sensitively on T_{prep}. For films deposited at $T_{prep} = 300$ K, second-layer Fe islands form on top of a closed and thermodynamically stable pseudomorphic monolayer, whereas for films grown at $T_{prep} \geq 475$ K, step-flow growth leads to the formation of continuous double-layer stripes on top of the first layer, accompanied by the appearance of nonperiodic dislocation lines along the [001] direction to relax the accumulated tensile strain in the Fe lattice [21.192, 272, 285], as shown in Fig. 21.21.

The surfaces of thicker films are atomically smooth. The changes of the Curie temperature as a function of T_{prep} reported in Fig. 21.22 for Fe/W(110) capped by Ag reflect the fact that the morphology of films prepared at 475 K is stable for 0.35 ML $< t <$ 1.2 ML, and $T_C = (282 \pm 3)$ K is an intrinsic property of the Ag-covered monolayer (uncapped Fe films have $T_C \propto$ 210 K [21.274]). As T_C does not depend on the Fe coverage in the sub-monolayer regime, one concludes also that the lateral size of the monolayer patches is sufficiently large that finite-size effects of the 2-D lattice can be ignored. In contrast, the strong increase of T_C with t for films grown at $T_{prep} = 300$ K indicates that the morphology of the Fe films is not stable and that Fe islands of increasing size form or coalesce with increasing T_{prep} [21.272]. Note also that the first and second Fe layer have in-plane and out-of-plane anisotropy, respectively, and that on vicinal substrates with a terrace width of less than 10 nm, Fe stripes grown on adjacent terraces couple antiparallel, both effects having an influence on T_C [21.275–280].

Low-Temperature Behavior

The low-temperature behavior of the saturation magnetization is determined, as in bulk systems, by the excitation of spin waves (Sect. 21.1.7, *Scaling Laws*). According to (21.46) and (21.50), the reduced magnetization $M_s(T)/M_s(0)$ should scale as $1 - T \ln T \approx 1 - T$ for $T < T_C/2$. In experiments, however, deviations from this trend have been reported depending on the temperature range and anisotropy barriers specific to each system as well as extrinsic factors (e.g., overlapping magnetic signals resulting from magnetic layers with different interfaces or a superparamagnetic phase). The low-temperature magnetization can nonetheless be approximated by a dependence of the type

$$\frac{M_s(T)}{M_s(0)} = 1 - bT^{\alpha} , \qquad (21.55)$$

where b is an effective spin wave parameter and α varies from 1 in the case of an ideal 2-D layer with finite magnetic anisotropy to 3/2 for sufficiently thick ferromagnetic layers, as expected according to Bloch's law. A detailed description of low-temperature magnetization measurements of thin films is reported in [21.1, 2].

21.4 Non-collinear Spin Configurations

For a long time, one of two possible magnetic orders, either ferromagnetic or antiferromagnetic, with collinear spin orientation in single domain regions was considered as the ground state of surfaces and ultrathin films. Progress in theoretical and experimental methods led to the realization that non-collinear spin structures can have a lower energy compared with collinear ones, thanks to either antiferromagnetic interactions frustrated by geometric contraints imposed by the crystal, Heisenberg-type interactions competing between different pairs of atoms or Heisenberg exchange competing with the antisymmetric exchange. In the following, we discuss how such effects can give rise to periodic frustrated spin lattices, 1-D periodic chiral textures (spin spirals), 1-D localized chiral textures (chiral domain walls), and 2-D localized or periodic chiral textures (skyrmions and skyrmion lattices, respectively).

21.4.1 Frustrated Systems

In general, magnetic frustration is a phenomenon where the geometry of the crystal lattice or the competition of different interactions imposes constraints on the energy minimization of the global spin texture, thus preventing pairs of neighboring spins from adopting a configuration with minimal bond energy.

The first case is exemplified by materials with antiferromagnetic nearest-neighbor interactions deposited on a triangular lattice, such as the (111) and (0001) surfaces of an fcc and hcp crystal, respectively, on which the antiferromagnetic alignment of neighboring spins is frustrated by geometry. The epitaxial growth of such ultrathin films has been studied intensively using various experimental techniques. In particular, pseudohexagonal c(8 × 2)Mn films on Cu(100) [21.286], Mn films on the (111) surfaces of fcc Pd [21.287],

Ir [21.288], Cu [21.289–291], and MgO [21.292], and on the (0001) surface of Ru [21.293] and Co [21.294] have been prepared and analyzed. However, other ultrathin hexagonal films, e.g., Cr and V on Pt(111) and Ru(0001) [21.295–297], have also been investigated. Detailed investigations of the magnetic structure have been carried out in selected cases by means of spin-polarized STM [21.298]. From a theoretical point of view, even when neglecting the effects of spin–orbit coupling, a large variety of spin ground states are possible, depending on the relative magnitude and sign of the nearest- and next-nearest-neighbor exchange coupling constants, J_1 and J_2, respectively. If J_2 is zero or positive (ferromagnetic), then there are only two possible magnetic ground states, determined by the sign of J_1, the ferromagnetic and the antiferromagnetic 120° Néel state. But small negative values of J_2 are already sufficient to allow for an infinite number of magnetic states, namely commensurate or incommensurate spin spiral states with wavevector $\boldsymbol{Q}$ along any high-symmetry line of the surface (Sect. 21.1.5). Examples are shown in Fig. 21.23 for three particular cases of spin spirals: the rowwise antiferromagnetic state ($\boldsymbol{Q} = \overline{\mathrm{M}}$), the 120° Néel state ($\boldsymbol{Q} = \overline{\mathrm{K}}$), and the so-called 3Q-state, a 3-D non-collinear spin structure on a 2-D lattice with four chemically identical atoms per surface unit cell, where the relative angle between all nearest-neighbor spins is given by the tetrahedron angle of 109.47°. The 3Q-state is formed as a linear combination of the three rowwise antiferromagnetic structures orthogonal in spin space, each having one of the three $\boldsymbol{Q}$-vectors corresponding to a different $\overline{\mathrm{M}}$-point of the surface Brillouin zone. From the viewpoint of the Heisenberg model (21.28), the single- and triple-Q state have the same energy, but both are discriminated by higher-order spin-interaction such as the biquadratic or four-spin interactions. Ab initio calculations of 3d monolayers with or without a Cu(111) substrate show that the energy differences between different magnetic states change due to the presence of the substrate, but the magnetic ground state remains unaltered: Cr/Cu(111) exhibits the 120° Néel state and Mn/Cu(111) the 3Q-structure, which is 17 meV lower in energy than the 1Q-state, while Fe/Cu(111) is ferromagnetic ($\boldsymbol{Q} = \overline{\Gamma}$). Experimental investigations have identified the 120° Néel state for monolayer Mn/Ag(111) [21.299] and Fe/Re(0001) [21.300] and the 3Q-state for monolayer Mn/Re(0001) [21.301].

The second case of frustration refers to competing exchange interactions. Suppose a chain of 3 identical atoms of spin $S = 1$ at equidistant lattice sites subject to a nearest neighbor exchange interaction J_1 between atom 1 and 2 as well as atom 2 and 3 and a next-nearest neighbor interaction J_2 between atom 1 and 3. Referring to the Heisenberg model (21.28) and assuming between neighboring atoms the same canting angle θ of the lo-

Note that, due to the neglect of the spin–orbit interaction, only the relative orientation of the moments is specified

cal moments, the magnetic energy of the system is given by $E(\theta) = -2J_1\cos(\theta) - J_2\cos(2\theta)$. The energy minimization leads to the solutions $\sin(\theta) = 0$, which refers to the ferromagnetic state ($\theta = 0°$) with the energy $E_{\mathrm{FM}} = -2J_1 - J_2$ if all atoms couple ferromagnetically ($J_1, J_2 > 0$), or to the antiferromagnetic state $\theta = 180°$) with equal energy $E_{\mathrm{AFM}} = -2|J_1| - J_2$, if the nearest neighbor interaction is antiferromagnetic and the next-nearest neighbor ferromagnetic ($J_1 < 0, J_2 > 0$). However, if the nearest neighbor interaction is ferromagnetic and the next-nearest interaction is antiferromagnetic ($J_1 > 0, J_2 < 0$) or all interactions are antiferromagnetic ($J_1 < 0, J_2 < 0$), then neither the ferro- nor the antiferromagnetic chain satisfies the interactions between all pairs of atoms. Subsequently, the energy of the collinear state will be higher than $-2|J_1| - |J_2|$ and rises depending on J_1 and J_2 until a non-collinear solution with a non-trivial canting angle of $\cos(\theta_{\mathrm{NC}}) = -J_1/(2J_2)$ becomes lower in energy. This happens if $-3/4|J_1| < J_2 < 0$ and the energy amounts to $E(\theta_{\mathrm{NC}}) = 3/2J_1^2/J_2 - J_2$. The canting angle follows from a ratio of exchange interactions. It is interesting to compare this canting angle with the one discussed in (21.35), which followed from a competion between Heisenberg exchange and DMI. Since the DMI is a spin–orbit phenomenon, its energy scale is typically one order of magnitude smaller than the exchange interaction. Translating this simple model to periodic structures such as films and chains shows that exchange frustration leads to magnetic structures with short pitches, often on the atomic scale, whereas the DMI-stabilized noncollinear structures can be of a different scale. A nice example is Mn/W(110) [21.118] in comparison to Mn/W(100) [21.119]. Both have the same chemical composition, in both Mn is grown on lattices that give no cause for geometric frustration, both exhibit spin-spiral ground states, but the periods of the magnetic spirals are 12 nm versus 2.2 nm, clearly indicating that the latter is due to exchange competition and the former to the DMI. We conclude that exchange frustration offers a path of producing small localized magnetic textures.

21.4.2 Chiral Spin Spirals

Magnetic films or clusters on surfaces, including multilayer structures, present broken inversion symmetry along the surface normal, which, together with spin–orbit coupling, gives rise to antisymmetric exchange or DMI (Sect. 21.1.6). The DMI competes with the symmetric exchange and the anisotropy energy: whereas the latter terms favor collinear spin alignment, the DMI favors a spatially spiraling magnetic structure with a specific rotational direction. In this context, a completely new class of chiral magnets has been recently established, being made of monolayers and ultrathin films or heterostructures of 3d metals, where the DMI interaction and magnetic chirality are introduced due to the presence of heavy-metal surfaces and interfaces. In some instances, the DMI introduces chiral ground states, e.g., in Mn/W(110) [21.118], Mn/W(100) [21.119], Fe/Ir(111) [21.134, 302, 303], Pd/Fe/Ir(111) [21.135], and biatomic Fe chains on the (5×1)-Ir(001) reconstruction [21.123]. If the magnetic structure changes on a mesoscopic length scale, the non-collinear magnetization can be described by a continuous vector field $\boldsymbol{m}(\boldsymbol{r})$ with $|\boldsymbol{m}| = 1$. In the simplest case, $\boldsymbol{m}$ varies only along one spatial coordinate x and the energy of a magnetic configuration can be described

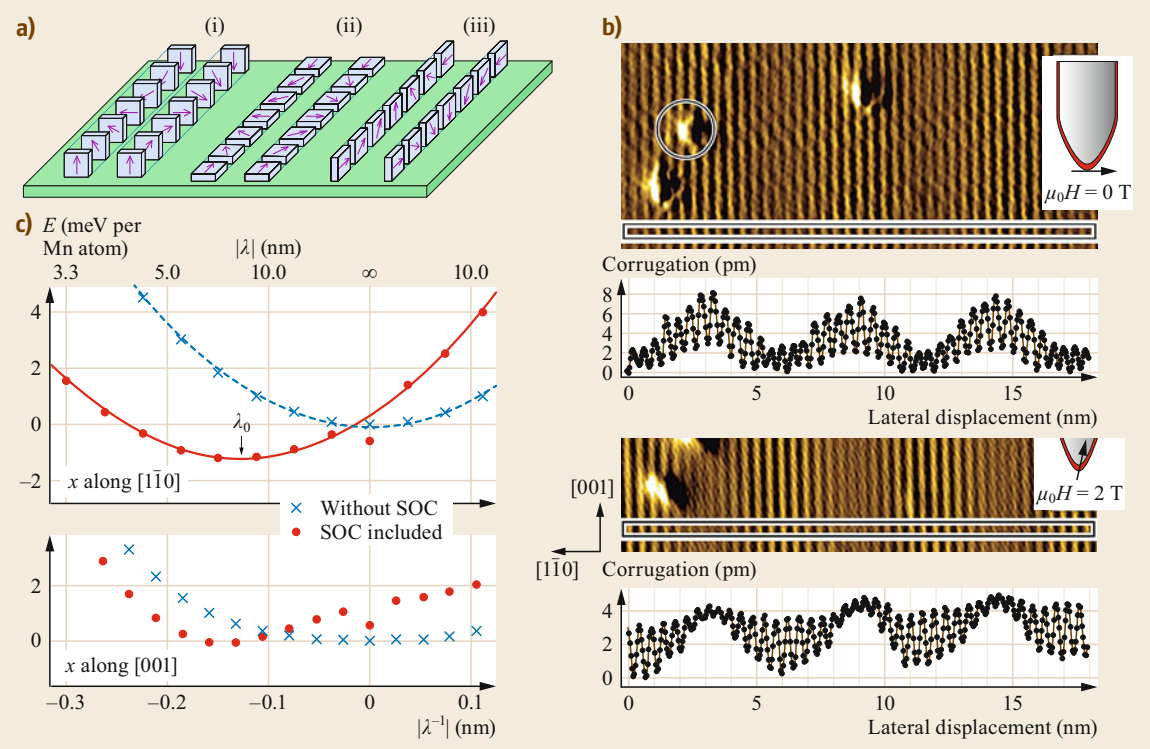

Fig. 21.24 **(a)** Schematics of right- and left-handed spin spirals with different rotation axes on a symmetric surface. For (i) and (ii), the right- and left-handed spirals are mirror images of each other. In (iii), the surface breaks the mirror symmetry. Therefore, the two spirals in (iii) are not equivalent to each other and may differ in energy. The left-rotating cycloidal spiral shown in (iii) corresponds to the one found for 1 ML Mn on W(110), a system with local antiferromagnetic order. **(b)** Spin-polarized STM images of the Mn monolayer on W(110) and corresponding line sections taken with a ferromagnetic Fe-coated tip at external fields of 0 T (*top*) and 2 T (*bottom*). As sketched in the *insets*, the external field rotates the tip magnetization from in-plane to out-of-plane, shifting the position of maximum spin contrast. The stripes on the nanometer scale represent the local antiferromagnetic structure. On a larger length scale, however, the image shows a spiral structure that is driven by the DMI, as seen in the line profiles at the bottom of each image. **(c)** Electronic energy of a homogeneous spin spiral depending on the period length $|\lambda|$. The sign of λ depends on the rotational direction. The *data points* show the results obtained from electronic structure calculations, and the *lines* indicate the fits with the terms of (21.57). by a simple micromagnetic energy functional of the form

$$E(\boldsymbol{m}) = \int \mathrm{d}x \left[\frac{A}{4\pi^2} \left(\frac{\mathrm{d}\boldsymbol{m}(x)}{\mathrm{d}x} \right)^2 + \boldsymbol{m}(x)^{\mathsf{T}} \cdot \overleftrightarrow{\mathcal{K}} \cdot \boldsymbol{m}(x) + \frac{\boldsymbol{D}}{2\pi} \cdot \left(\boldsymbol{m}(x) \times \frac{\mathrm{d}\boldsymbol{m}(x)}{\mathrm{d}x} \right) \right], \tag{21.56}$$

where the spin stiffness A represents the exchange interactions that favor collinear spin alignment, the symmetric anisotropy tensor $\overleftrightarrow{\mathcal{K}}$ accounts for the preferred orientation of the magnetization with respect to the crystal lattice, and the micromagnetic Dzyaloshinskii vector $\boldsymbol{D}$, also called spiralization vector, is nonzero only if the underlying crystal structure does not possess inversion symmetry. The DMI breaks the degeneracy of right- and left-handed spin rotations, thus favoring either a right- or left-handed spiral magnetic structures (Fig. 21.24a; note that only cycloidal spin spirals of type (iii) have nondegenerate right- and left-handed states).

Monolayer Mn/W(110) is an exemplary system where DMI-induced cycloidal spin spirals are observed, characterized by a fixed rotation axis and $(\mathrm{d}\boldsymbol{m}/\mathrm{d}x)^2 = \text{const}$ [21.118]. Figure 21.24b shows a constant-current spin-polarized STM image measured on an atomically flat Mn layer on W(110) using a Fe-coated probe tip sensitive to the in-plane magnetization. The spin-polarized STM data reveal periodic stripes running

along the [001] direction, with an interstripe distance of 0.47 nm matching the surface lattice constant along the $[1\bar{1}0]$ direction. This contrast stems from the local c(2 × 2)-antiferromagnetic structure [21.304]. The line profile further reveals that the magnetic amplitude is not constant but modulated with a period of about 6 nm along this direction. Imaging the surface using an Fe-coated tip with out-of-plane magnetization shows that the maximum contrast of the long-wave modulation is achieved where the in-plane spin signal exhibits a minimum (Fig. 21.24c), consistent with the contrast expected of a spin spiral propagating along the $[1\bar{1}0]$ direction with magnetic moments rotating from in-plane to out-of-plane. For such a homogeneous spiral, (21.56) simplifies to

$$E = A\lambda_0^{-2} + D\lambda_0^{-1} + \overline{K}\,, \tag{21.57}$$

where the integration is performed over one period length $|\lambda_0|$, the sign of λ_0 distinguishes between right- and left-handed spirals, and $\overline{K}$ is the anisotropy energy averaged over the spiral. The energy given by (21.57) is lower for the spiral than for the antiferromagnetic state if the DMI overcomes the average energy penalty per atom for spins spiraling in a plane rather than pointing along a preferred easy axis of magnetization, that is, if $D^2 > 4A\overline{K}$. The period of the optimal homogeneous spiral is thus given by $\lambda_0 = -2A/D$. Density functional theory calculations, reported in Fig. 21.24c, show how the energy of the Mn/W(110) monolayer depends on the direction and period of the spin spiral. The calculated parameters are $A = 94\,\mathrm{meV\,nm^2}$, $D = 24\,\mathrm{meV\,nm}$, and $\overline{K} = 0.6\,\mathrm{meV}$ per Mn atom [21.118]. Notably, considering only isotropic exchange (no spin–orbit interaction), the total energy minimum occurs for the antiferromagnetic state. Introducing spin–orbit coupling has two effects: first, it shifts the energy of the antiferromagnetic state by $\overline{K}$; second, it breaks the inversion symmetry between right- and left-handed spin rotation, leading to a DMI that contributes a term linear in λ^{-1} to the total energy. As a result, the minimum energy now appears for a left-handed (cycloidal) spin spiral along the $[1\bar{1}0]$ direction (a spin spiral along the [001] direction is energetically unfavorable because of the greater anisotropy energy cost for spins pointing along [001]).

In general, the energy minimization of (21.56) leads to an inhomogeneous spin spiral [21.305], whereby the degree of inhomogeneity is controlled by a positive dimensionless parameter $\kappa = (4/\pi)^2 A\overline{K}/D^2$, into which all three micromagnetic parameters A, D and $\overline{K}$ in (21.56) enter. For the parameter set $\kappa \in [0, 1[$ a periodic spin spiral takes the lowest energy. The spiral is homogeneous for infinitesimally small positive κ and becomes maximally inhomogeneous if κ approaches 1. For example, for Mn/W(110), $\kappa = 0.3$ [21.306]. For a double-layer of Fe/W(110) (see also discussion in Sect. 21.3.3), κ is close to 1 or larger than 1 depending on the strain induced into the system in response of cutting angle or step width, respectively, of the W(110) crystal. At $\kappa = 1$ a phase transition occurs from a spin-spiral state ground state to a ferromagnetic state with chiral domain walls.

21.4.3 Chiral Domain Walls

When the exchange interaction is much stronger than the DMI, the preferred ground state is the collinear one, but the DMI can still force the formation of chiral domain walls, as, e.g., in Fe/W(110) [21.128, 282], Co/Pt(111) [21.307], $[\mathrm{Co/Ni}]_n$/Pt(111) and Ir(111) [21.80], and Ni/Fe/Cu(001) [21.308, 309], as shown in Fig. 21.25, as well as canting of the magnetization at the edge of laterally confined magnetic structures [21.310]. The effects of the DMI on domain walls are readily observed in ultrathin films with perpendicular anisotropy, where the DMI induces a transition from achiral Bloch (helical-like) walls, favored by dipolar interactions, to homochiral Néel (cycloidal-like) walls for sufficiently large values of D [21.128, 129, 309]. Figure 21.25a–c shows schematic diagrams of the different domain wall types typically observed in ultrathin films with perpendicular anisotropy. As seen for $[\mathrm{Co/Ni}]_n$ multilayers grown on Pt(111) and Ir(111), shown in Fig. 21.25d–f, the domain wall chirality depends on the substrate as well as on the thickness of the magnetic film [21.80]. The opposite chirality observed at the Ni/Pt(111) and Ni/Ir(111) interfaces is due to the opposite sign of the DMI in these systems. Achiral walls can be obtained either by depositing a thin Ir layer on Pt in order to compensate the DMI or by increasing the magnetic film thickness in order to favor Bloch walls. Experimental and simulated phase diagrams of the domain wall chirality and its dependence on the DMI and magnetic anisotropy parameters are shown in Fig. 21.25g–j. The chirality of the domain walls plays a fundamental role in determining the domain wall motion [21.81, 129, 311–313] and the polarity of current-induced switching by spin–orbit torques in thin films and nanostructures [21.35, 314]. Similar to Fig. 21.25a, the chirality reported for 3d layers grown on Pt, such as the AlO_x/Co/Pt films typically used for investigating switching and domain wall motion, is left handed [21.307, 314–316]. In simple one-dimensional domain wall models, the effects of the DMI in such systems can be included by considering an effective in-plane chiral field $B_{\mathrm{DMI}} = D/M\delta$, where $\delta = \pi\sqrt{A/\overline{K}}$ is the domain wall width. The DMI

further alters the dynamical properties of collinear ferromagnetic films, as found for the magnon dispersion in Fe/W(110) [21.317] as well as in Co, Co/Ni, and $Ni_{80}Fe_{20}$ films sputtered on Pt [21.116, 117, 318].

21.4.4 Skyrmions

Besides inducing 1-D spiral spin states and chiral domain wall configurations, the DMI also stabilizes 2-D spin textures known as chiral magnetic *skyrmions*. Skyrmions are vortex-like axially symmetric structures in which the magnetic moments rotate coherently across the center, as shown in Fig. 21.26. However, in contrast to a magnetic vortex, the magnetic moments in a skyrmion point into a unique three-dimensional direction and consequently have a topology that cannot be *unwound* in a continuous way to form, e.g., a collinear magnetic state. In mathematical terms, a skyrmion is a smooth, localized, and topologically stable field configuration which maps from real space to an order parameter space with a nontrivial topology and has particle-like properties [21.319] and has particle-like properties. The topological index of the field is called the 2-D winding number or the topological charge of the skyrmion, which, for a 2-D magnetic texture, is given by

$$\mathcal{W} = \frac{1}{4\pi} \int \boldsymbol{m} \cdot \left(\frac{\partial \boldsymbol{m}}{\partial x} \times \frac{\partial \boldsymbol{m}}{\partial y} \right) \mathrm{d}x\mathrm{d}y \,. \qquad (21.58)$$

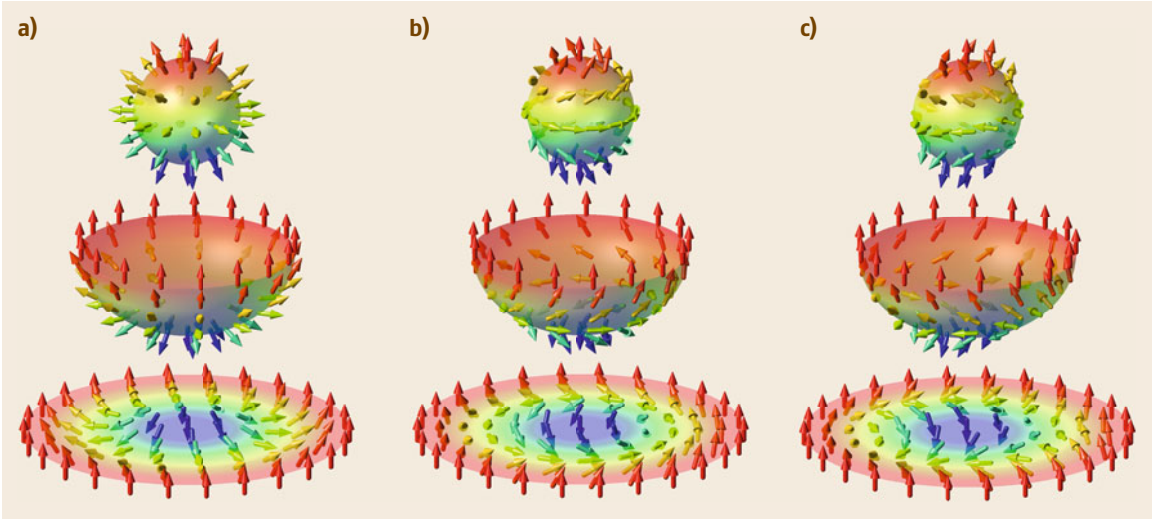

Fig. 21.26 **(a)** Schematic picture of a Néel skyrmion and its mapping onto a sphere (hedgehog configuration), **(b)** of a Bloch skyrmion (*combed* hedgehog configuration) and **(c)** antiskyrmion or multichiral skyrmion, for which the winding sense of the magnetic moments changes between clock- and counterclockwise in orthogonal spatial directions. The color code describes the value of the z-component of the magnetisation with *red* (*blue*) representing $m_z = +1$ (-1). (Figures courtesy of K. Everschor-Sitte, from [21.319])

The sign of $\mathcal{W}$ is defined by the orientation of the magnetization in the ferromagnetic background, which is taken along the positive z-direction of an external magnetic field. Each topological class characterized by an integer $\mathcal{W}$ corresponds to a spatial distribution of magnetic moments wound $\mathcal{W}$ times around a sphere, as shown in Fig. 21.26, where the boundary of the skyrmion (*infinity*) is mapped onto the north pole. For example, a magnetic film with uniform magnetization has $\mathcal{W} = 0$, a vortex has $\mathcal{W} = \pm 1/2$, whereas both Néel- and Bloch-type skyrmions have $\mathcal{W} = -1$ and antiskyrmions $\mathcal{W} = +1$. From the skyrmion core to the ferromagnetic rim, skyrmions have a unique winding sense of the magnetization, clockwise or counterclockwise depending on the sign of the DMI. Antiskyrmions or multichiral skyrmions have both winding senses, but along orthogonal directions. Following the magnetization density 360° around the antiskyrmion core, Bloch and Néel-type magnetization textures with different windings alternate. The type of skyrmion or the choice of an antiskyrmion depends on the lattice symmetry. For example, Bloch-type skyrmions are a consequence of a cubic lattice, Néel-type skyrmions are a consequence of interface geometry in particular with (100) and (111) surface orientation. An exception are interfaces with C_{2v} symmetry or lower symmetry, like the bcc or fcc (110) surfaces. On these surfaces, skyrmions and antiskyrmions can become stable simultaneously [21.320]. Néel and Bloch skyrmions differ in that the former are mapped to spins pointing outwards or inwards of the unit sphere, as in a hedgehog structure, whereas the latter are mapped to spins that rotate clockwise or counterclockwise around the sphere (Fig. 21.26). Although the real-space spin configurations appear different for Néel and Bloch skyrmions, both have the same topological charge, thus live in the same topological subsector, and the two structures are topologically equivalent. Consequently, a Bloch skyrmion can be continuously deformed into a Néel skyrmion by 90° rotation of the spins, and vice versa. Note that skyrmions differ quite substantially in the dynamical and excitation properties from bubble-like spin textures that have been extensively studied in the past in perpendicularly magnetized systems such as hexagonal ferrites [21.321], uniaxial garnets [21.322, 323], and single-crystalline Co(0001) films [21.324]. Magnetic bubbles in these materials are stabilized by dipole interactions rather than by the DMI, which gives rise to a rich variety of spin textures with nonuniform chirality and topologies, and therefore arbitrary topological winding numbers [21.323].

Whether a system supports the formation of skyrmions and skyrmion lattices, as opposed to uniform magnetic domains or spiral spin states, depends on the interplay of the parameters appearing in (21.34) and (21.56) with the addition of the Zeeman interaction due to an external magnetic field. A skyrmion lattice can either be the ground state of the system, if high-order exchange interactions [21.134] or dipolar interactions [21.137] are present, or emerge out of a spin spiral phase by the application of an ex-

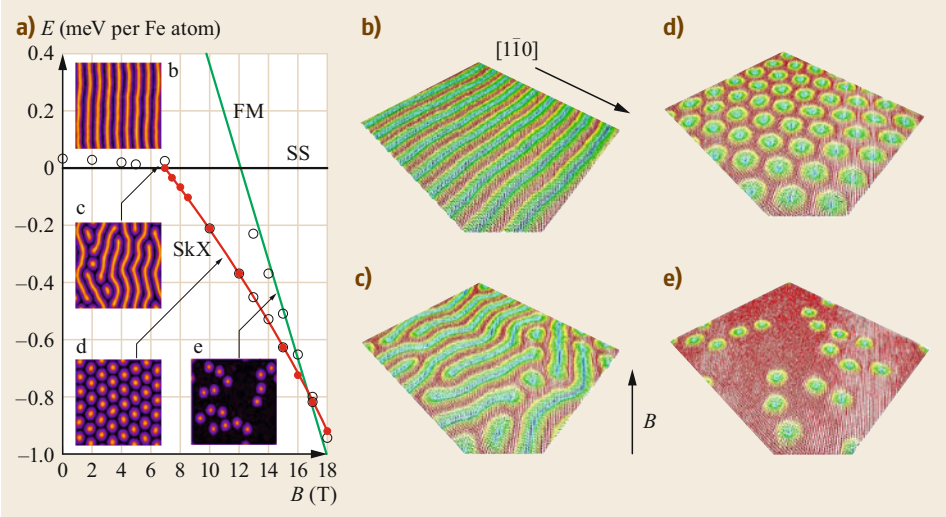

Fig. 21.27 **(a)** Low-temperature phase diagram calculated for fcc-Pd/1 ML Fe/Ir(111) as a function of a magnetic field applied perpendicular to the film. ternal magnetic field as metastable state [21.131, 132, 135]. Magnetic skyrmions of the Bloch type were first experimentally observed in non-centrosymmetric bulk MnSi single crystals [21.131] and in other compounds that have the same cubic B20 crystal structure, such as $Fe_{1-x}Co_xSi$ [21.132] and FeGe [21.133]. Symmetry breaking due to interfaces and strong spin–orbit coupling facilitate the formation of Néel-type skyrmions in ultrathin magnetic layers deposited on heavy metals such as Pt, Ir, and W. Low-temperature spin-polarized STM studies evidenced the formation of a skyrmion-like lattice with periodicity of about 1 nm for a pseudomorphic Fe monolayer on Ir(111) [21.134]. For this system, the competition between the magnetic exchange interaction and DMI determines the periodicity, and the DMI imposes a unique rotational sense, whereas the two-dimensional lattice is stabilized by a four-spin interaction. Adding a single nonmagnetic layer of Pd on Fe/Ir(111) changes the magnetic properties such that the ground state is a spin spiral with a period about seven times longer than the skyrmion lattice of the uncovered Fe/Ir(111) surface, and a skyrmion lattice appears only in an applied magnetic field of the order of 1 T. In contrast to the spin spiral state, which is magnetically compensated, the hexagonal skyrmion lattice exhibits a net magnetization and is, therefore, favored by the Zeeman energy. For the same reason, at even larger fields, the system evolves into a saturated ferromagnetic state [21.135]. This behavior, schematized in Fig. 21.27, is typical for field-induced skyrmion lattices. For this particular system, ab initio electronic structure calculations [21.325] show that the change of ground state from Fe/Ir(111) to Pd/Fe/Ir(111) is not due to a decrease of the DMI, which is mainly determined by the Ir interface and does not depend significantly on the 4d transition-metal overlayer. Rather, the addition of Pd increases the exchange interaction among the Fe atoms relative to Fe/Ir(111), as the nearest-neighbor exchange interaction in a hexagonal Fe monolayer depends on the d-band filling of the substrate and can be tuned from ferro- to antiferromagnetic [21.326]. Thus, in Pd/Fe/Ir(111), the energy barrier separating the skyrmion phase from the uniform ferromagnetic phase is lower relative to Fe/Ir(111), and comparable to k_BT at measurement temperatures of ≈ 10 K. In these conditions, thermally activated switching between topologically distinct states occurs. Moreover, skyrmions can be imprinted or annihilated one by one into the ferromagnetic phase, e.g., by voltage sweeps with the STM tip, as the switching rate and direction can be controlled by the spin-polarized current as well as by the presence of atomic defects that act as preferred nucleation and pinning sites for the skyrmions [21.135].

Skyrmions are also found in ultrathin ferromagnetic/heavy-metal layers deposited by sputtering, such as

$[Ir/Co/Pt]_n$ and $[Ta/Co/Pt]_n$ multilayers [21.136, 327], $TaO_x/CoFeB/Ta$, $AlO_x/Co/Pt$, and $MgO/CoFeB/W$ trilayers [21.137, 328, 329]. In these materials, the magnetic anisotropy, DMI, and exchange parameters that control the skyrmion stability and size can be easily tuned by adjusting the nature and thickness of the films that comprise the multilayers. Such systems are also of interest to create and manipulate skyrmions in racetrack-type devices [21.330], which has raised hopes of fabricating skyrmion-based magnetic memories and logic devices based on the same technology as that developed for magnetoresistance devices. It shall be noted, however, that despite their topological protection, skyrmions are neither indestructible nor insensitive to the pinning potential of the medium in which they form, and do not move faster than domain walls at comparable current densities. Their potential for spintronic applications therefore remains to be established. On the other hand, skyrmions represent an interesting system for studying the interaction of nontrivial topological magnetic textures with externally applied magnetic and electric fields. For further information on this topic, we refer to recent monographs [21.331–334].

21.4.5 Synthetic Spin Structures

The non-collinear spin structures described in Sects. 21.4.2–21.4.4 form spontaneously whenever the DMI is strong enough to offset the interactions that favor collinear spin states, namely the exchange interaction and magnetic anisotropy, in (21.56). It is possible, however, to tune the balance of such interactions in order to induce the formation of artificial spin structures that have a predetermined size, shape, and topology. Spatial modulation of the magnetic anisotropy can be achieved using ion irradiation [21.335–339], oxidation [21.9, 138, 340], and electric gating [21.235, 236, 341]. Likewise, it is possible to tune the DMI [21.112], e.g., by electric gating [21.342]. Local reduction of the perpendicular magnetic anisotropy induced by ion irradiation was used to introduce low-field domain nucleation sites in Pt/Co multilayer strips [21.335, 339], which allows one to modulate the formation and flow of chiral domain walls [21.339, 343]. Alternatively, selective oxidation can be used to pattern regions with in-plane and out-of-plane magnetic anisotropy next to each other [21.138]. In the presence of the DMI, the magnetization in two adjacent regions with orthogonal magnetization experiences a chiral coupling (21.33), favoring spin configurations with a specific handedness. For example, in $Pt/Co/AlO_x$ trilayers with adjacent out-of-plane regions pointing either *up* (↑) or *down* (↓) and in-plane regions pointing either *left* (←) or *right* (→), the DMI favors the left-handed →↑ and ↓→ configurations over the right-handed ones ←↑ and ↓←. It can be shown that, below a critical size, the magnetic behavior of the coupled regions is predominantly determined by the lateral chiral coupling induced by the DMI [21.138]. Indeed, if the energy associated with the chiral coupling is larger than the energy barrier to switch one or both magnetic regions, the direction of the magnetization in one region effectively controls the magnetization in the adjacent region, leading to a lateral exchange bias. Therefore, this coupling, mediated by chiral domain walls between out-of-plane and in-plane magnetic regions, provides a powerful means to engineer the lateral interactions between nanomagnets, which is an alternative to long-range dipolar fields. As the dipolar interaction is nonlocal and scales inversely with the volume of the magnets, the chiral coupling induced by the DMI is significantly stronger than the dipolar coupling in nanometer-sized structures and thin films. Coupled out-of-plane/in-plane building blocks can be used to fabricate synthetic antiferromagnets with linear or curved geometry, artificial spin lattices with checkerboard or frustrated antiferromagnetic interactions, and even synthetic skyrmions with an arbitrary number of windings [21.138]. Examples of such structures are shown in Fig. 21.28. The DMI thus provides a tool to design arrays of non-collinear nanomagnets with tunable couplings, which can be used, e.g., to realize nanomagnet logic gates [21.344], reconfigurable magnonic crystals, as well as current-induced switching between multistate magnetic configurations [21.138].

21.5 One-Dimensional Atomic Chains

Owing to the reduced number of neighbors contributing to the exchange interaction, thermal fluctuations become more disruptive with decreasing dimensionality. As a result, magnetism in 1-D structures is more sensitive to temperature effects compared with 2-D systems. In fact, whereas in 2-D the introduction of dipolar coupling or an arbitrarily small anisotropy of spin–orbit origin is sufficient to establish long-range magnetic order [21.345], in 1-D low-energy spin wave excitations, i.e., fluctuations in the relative alignment of adjacent spins, are more effective in breaking long-range order for obvious topological reasons [21.346, 347]. Even in the 1-D Ising model, i.e., the extreme anisotropic limit of the Heisenberg model in (21.28), magnetic order is forbidden in the absence of an external field for any $T > 0$. A simple thermodynamic argument, due to Lan-

dau, exemplifies this point very clearly as a function of the system size [21.348]. Consider a chain consisting of N magnetic moments described by the Ising Hamiltonian $H = -J\sum_{i=1}^{N-1} S_{zi}S_{zi+1}$, with nearest-neighbor exchange coupling energy $J > 0$ (ferromagnetic interaction). The ground-state energy of the system is $E_0 = -J(N-1)$ and corresponds to the situation where all the moments are aligned, as shown in Fig. 21.29a. The lowest-lying excitations are those in which a single break occurs at any one of the N sites. There are $N-1$ equivalent such excited states, all with the same energy $E = E_0 + 2J$, shown in Fig. 21.29b. At a given temperature T, the change in free energy due to these excitations is $\Delta G = 2J - k_\mathrm{B}T\ln(N-1)$. For $N \to \infty$, the entropy term prevails and we have $\Delta G < 0$ at any finite temperature. The ferromagnetic state becomes unstable to thermal fluctuations. For chains of finite length, however, if $(N-1) < \mathrm{e}^{2J/(k_\mathrm{B}T)}$, ferromagnetic order is energetically stable. Assuming $2J = 10\,(20)$ meV, we get an upper limit of $N \approx 10\,(100)$ atoms at $T = 50$ K. Such conclusions apply to an ideal 1-D lattice of spin point vectors in both the ferromagnetic and antiferromagnetic case. An antiferromagnetic system, however, presents additional complications. If the spins in the Heisenberg Hamiltonian are considered as classical vectors, then the ground state of a 1-D chain is easily found to be the alternate up–down configuration shown in Fig. 21.29c, viz. the so-called Néel state. Note that, depending on whether N is odd or even, the chain may or may not have a net magnetization. When the quantum nature of the spins is considered, the situation is radically different. The eigenstates of the quantum antiferromagnetic Heisenberg Hamiltonian are then given by a superposition of states, each representing a classical spin configuration (Fig. 21.29d). As a consequence, contrary to the ferromagnetic case, we cannot assign a well-defined orientation to individual atomic spins in the ground state of an antiferromagnetic quantum system; the spins are entangled, inseparable from each other. Such an effect, which is well known for the wavefunctions describing the triplet singlet pair $1/\sqrt{2}(|\uparrow\downarrow\rangle \pm |\downarrow\uparrow\rangle)$ of a two-electron molecular bond, is generally present in antiferromagnetic 2-D and 1-D low-dimensional magnetic systems and is discussed more at length in [21.349, 350].

Historically, experimental investigations on 1-D magnetic systems have concentrated on bulk insulating crystals consisting of arrays of linear chains

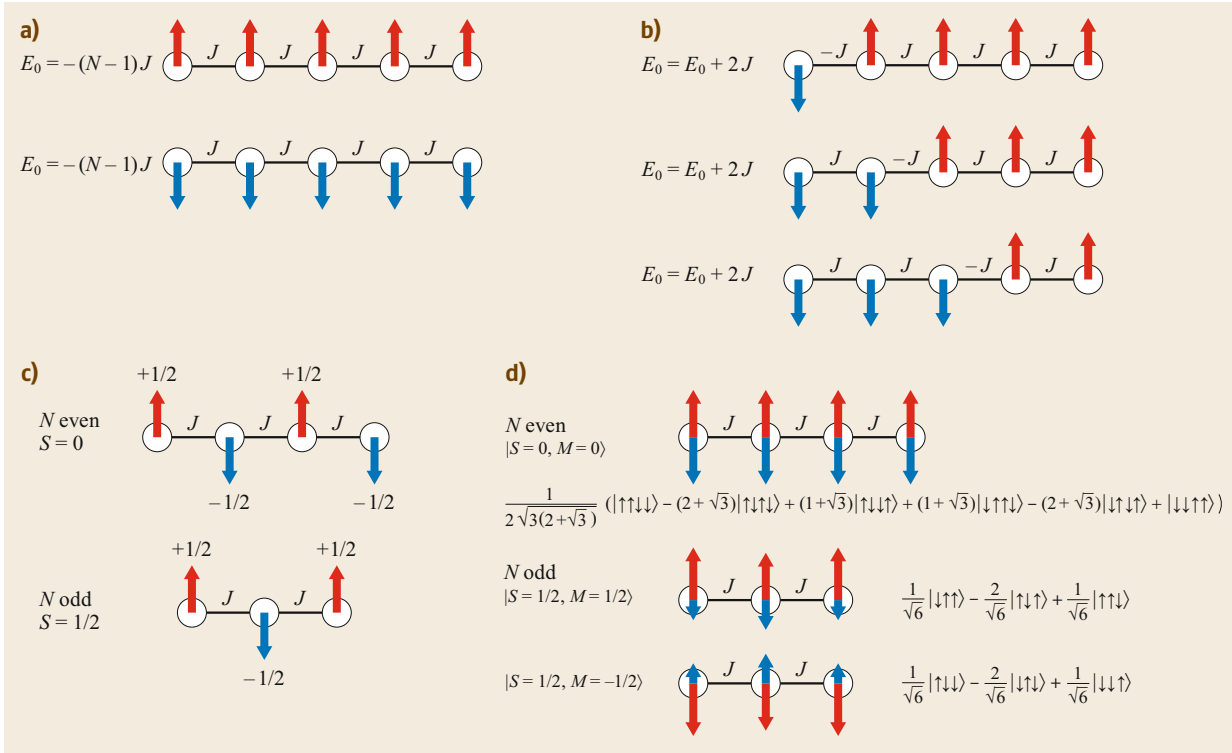

Fig. 21.29 **(a)** Equivalent ground-state configurations of a ferromagnetic Ising spin chain in zero applied magnetic field. **(b)** Lowest-energy excited states. **(c)** Néel ground state of antiferromagnetic Ising classical spin chains with $N = 3$, 4 atoms. **(d)** Ground state of antiferromagnetic quantum chains with spin 1/2. The length of the *arrows* represents the relative probability for each spin to point up or down. The corresponding wavefunctions are also given

of exchange-coupled transition-metal ions separated by nonmagnetic atom spacers and characterized by weak interchain interactions [21.349, 353, 354]. One example is tetramethylammonium manganese chloride, which typically exhibits antiferromagnetic coupling and 1-D paramagnetic behavior down to $T \approx 1$ K [21.355]. Molecular ferri- and ferromagnetic chain-like compounds containing magnetically anisotropic ions also allow the realization of 1-D Ising model systems, so called *single-chain magnets*, which display slow relaxation of the magnetization on a macroscopic time scale [21.356], as predicted by *Glauber* in the 1960s [21.151]. Surface science studies of 1-D magnetism are based on two approaches, namely the deposition of magnetic atoms on templated nonmagnetic surfaces [21.72, 357] and the atom-by-atom fabrication of single-atomic chains using scanning probe manipulation [21.358, 359]. In the first approach, the atomic steps of a nonmagnetic vicinal surface are used as a deposition template for the magnetic atoms, thus producing a large number of nanowires in a parallel process. The average thickness and spatial separation of the wires can be controlled independently using the coverage and surface miscut angle, respectively. The high wire density and overall uniformity of these systems allow for their investigation using powerful spatially integrating spectroscopic techniques, such as angle-resolved photoemission and XMCD. In the second approach, chains with a well-defined number of atoms and lattice spacing can be assembled one atom at a time and investigated locally using spin-polarized STM and inelastic tunneling spectroscopy. In both cases, the transition from 1-D to 2-D magnetic behavior can be studied in the same material system by simply varying the coverage of the magnetic atoms, which makes surface studies of magnetism very appealing.

21.5.1 Self-Assembly of 1-D Chains on Template Surfaces

Arrays of continuous, quasi-1-D monolayer-thick stripes of a magnetic metal on top of a nonmagnetic substrate are obtained by exploiting self-assembly on vicinal surfaces [21.360], for which the control of the stripe width can be pushed down to the monatomic limit [21.351, 352, 361–364]. Depending on the sur-

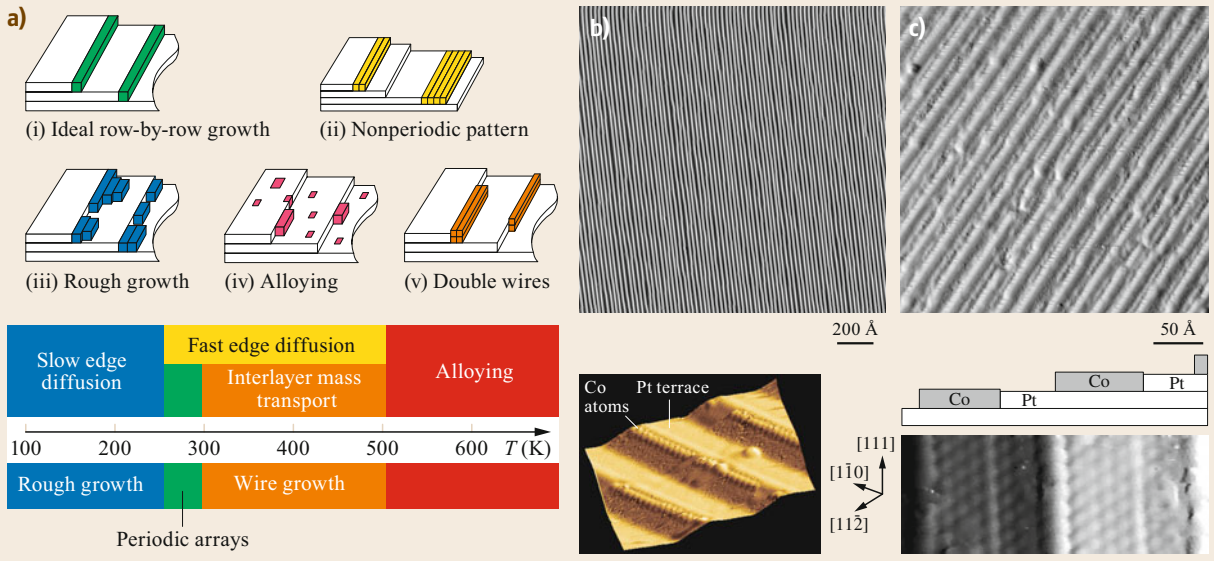

Fig. 21.30 **(a)** Schematic representation of the growth modes of Co on a stepped Pt(997) surface as a function of the substrate temperature. **(b)** STM topograph of the periodic step structure of Pt(997) (*top*) and of monatomic Co chains adjacent to the Pt steps (*bottom*). **(c)** STM image of 0.6 ML Co deposited at $T = 250$ K on Pt(997); the step-down direction is from *right* to *left*. Row-by-row growth conserves the original step pattern, forming regular stripes that run parallel to the Pt steps. The *bottom image* shows a detail of two adjacent steps with atomically resolved Co chains and Pt terraces. (Adapted by permission from [21.73, 351, 352], © Am. Phys. Soc. 2000, Elsevier 2003)

face temperature, adatoms on vicinal surfaces tend to self-assemble into chain-like structures at the lower side of the step edges, where the binding energy is largest [21.362, 365]. Growth proceeds either as a smooth step-wetting process [21.351, 352, 366, 367] or as nucleation of two-dimensional (2-D) islands at the step edges [21.368], provided that the adatom displacement prior to nucleation is larger than the terrace width of the substrate. Figure 21.30a shows different scenarios of heteroepitaxy on a stepped substrate, as derived from the growth of Co on the vicinal Pt(997) surface. We distinguish:

(i) The ideal case of row-by-row growth
(ii) Chains of different widths due to interlayer crossing of the adatoms
(iii) Formation of irregular 2-D islands at the step edges
(iv) Alloying
(v) Formation of double-layer-thick stripes.

In preparing arrays of 1-D chains for spectroscopic investigation with spatially integrating probes, one must focus on the conditions that favor the ideal case (i). As a general trend, 1-D chain formation is limited at low temperature by slow edge-diffusion processes and at high temperature by interlayer diffusion and, eventually, by alloying between the metal adspecies and the substrate.

Figure 21.30b shows an STM image of the Pt(997) surface, which has an average terrace width of 20.2 ± 2.9 Å [21.369], corresponding to a step density of $5 \times 10^6\,\mathrm{cm}^1$. Periodic arrays of Co chains grow only between 250 and 290 K [21.351]. A monatomic chain array is obtained as the coverage equals the inverse of the number of atomic rows in the substrate terraces, i.e., 0.125 ML ($1\,\mathrm{ML} = 1.5 \times 10^{15}\,\mathrm{atoms/cm}^2$) for Pt(997). The average length of a continuous Co chain is estimated to be ≈ 80 atoms from the average kink density per Pt step obtained by STM. As the coverage increases to more than a monatomic chain per terrace, Co grows in a row-by-row mode (Fig. 21.30c). This approach was first explored by *Elmers* et al. [21.276] in a study of wide Fe stripes (> 10 nm) on vicinal W(110), which show in-plane anisotropy and a relaxation-free ferromagnetic phase transition due to dipolar-induced coupling across adjacent stripes [21.278, 280, 281]. Deposition on stepped substrates has also been used to investigate the magnetic behavior of quasi-1-D Fe stripes on stepped Cu(111) [21.370, 371] and Au(778) [21.372], as well as of Fe and Co stripes on Pd(110) [21.373–375]. Recent investigations have shown that step decoration can be used also to produce bimetallic 1-D alloys [21.361, 376, 377] as well as transition-metal

oxide chains [21.378, 379], which may have either ferromagnetic or antiferromagnetic couplings [21.380].

21.5.2 Magnetic Properties and Magnetic Order in 1-D Chains

In the limit of atomically thin metal chains, tight-binding [21.381–383] as well as ab initio electronic calculations predict large exchange splittings and strongly increased m_S and m_L relative to those of the bulk and 2-D monolayers [21.62, 63, 384–388] as well as MCA energies exceeding 1 meV per atom [21.384, 385, 389–392], which are attributed to the reduced d-bandwidth in 1-D structures as well as interactions with the substrate. Angle-resolved photoemission measurements of Co monatomic chains grown along the step edges of Pt(997) corroborate the prediction of large exchange splitting of the Co 3d-states (2.1 eV) [21.393] compared with thin films (1.4−1.9 eV) or bulk Co (1.4 eV) [21.394, 395], suggesting that m_S is on the order of $2\,\mu_B$/atom [21.360], i.e., $\approx 0.4\,\mu_B$/atom larger compared to bulk Co. Extensive XMCD investigations performed on the Co/Pt(997) system have allowed the measurement of the Co magnetic moment as a function of chain width [21.72, 73, 396]. Most strikingly, the m_L of the monatomic Co chains reaches up to $0.68\,\mu_B$/atom, representing an almost fivefold enhancement relative to bulk hcp Co and being more than twice the value found for a Co monolayer on Pt(997). The lateral thickness of the chains has a strong influence on m_L, which drops already to $0.37\,\mu_B$/atom in biatomic chains [21.396].

Figure 21.31 shows the magnetization of Co chains with different atomic thicknesses deposited on Pt(997), measured along the easy (filled symbols) and hard (open symbols) axes at 45 and 10 K. The significant dependence of the magnetization on the direction of the applied field indicates a very strong magnetic anisotropy, which increases from $K = 0.17$ meV/atom in the 2-D monolayer limit up to $K = 2.0$ meV/atom in the monatomic chains. Further, both K and the easy axis direction oscillate as a function of the chain thickness (top diagrams in Fig. 21.31 and [21.396]). This behavior is specific of 1-D metal systems and was predicted by tight-binding calculations for both free-standing [21.381] and supported [21.383] 1-D Co chains. The canting of the easy axis in the plane perpendicular to the chains is due to symmetry breaking at the Pt step edges [21.385, 391, 392]. The DMI at the step edge does not change the magnetic order in the Co chain but selects homochiral Néel-walls over Bloch-walls [21.121].

The magnetic response of the Co chains as a function of field at $T = 45$ K shows reversible behavior with zero remanent magnetization, thus indicating the absence of long-range ferromagnetic order. However, the shape of the magnetization curve reveals the presence of short-range order, i.e., of significant interatomic exchange coupling in the chains. For noninteracting paramagnetic moments, in fact, the magnetization would be significantly smaller and nearly linear up to 6 T. By lowering the sample temperature to 10 K, the magnetization of the monatomic chains becomes hysteretic, indicating a transition to a long-range ferromagnetic ordered state with finite remanence extended over the whole sample. The observation of long-range ferromagnetic order might appear in contrast to the predicted absence of magnetism in 1-D systems. However, similar to the single-chain molecular magnets, the ferromagnetic state in the chains is a metastable state stabilized by the large MCA barriers, which allow ferromagnetic order to persist over timescales equal to or longer than the measurement time. The observed behavior is therefore that of a 1-D superparamagnetic system, i.e., a system composed by segments, or spin blocks, each containing N_c exchange-coupled Co atoms, whose resultant magnetization orientation is not stable due to thermal fluctuations. Fits of the magnetization of the monatomic chains above the blocking temperature performed using a classical spin block model [21.351] yield $N_c = 15$ atoms and $K = 2{-}0$ meV/atom, as well as a total magnetic moment per Co atom of $\approx 3.8\,\mu_B$/atom, including the spin and orbital Co moments as well as the induced moment on Pt. The same curves can be fit using a finite-size transfer matrix algorithm using the Heisenberg Hamiltonian [21.346]

$$\mathcal{H} = -\sum_{i=1}^{N_c-1} J\boldsymbol{S}_i \cdot \boldsymbol{S}_{i+1} - \sum_{i=1}^{N_c} [K(S_i^z)^2 + g_{\text{Co–Pt}}\mu_B \boldsymbol{B} \cdot \boldsymbol{S}_i] \,, \qquad (21.59)$$

where $J = 20$ meV, $K = 3.3$ meV, $|\boldsymbol{S}_i|^2 = 1$, $g_{\text{Co–Pt}} = 3.8$, and $N_c = 80$. The two approaches yield consistent results, apart from the *magnetic length* of the chains. This is not so surprising given that the spin block model does not include the possibility of spin excitations inside each block. Although the structural analysis of the Pt(997) surface yields atomically straight step edges with a length of ≈ 80 lattice sites, the actual magnetic length of the chains can be also influenced by dislocations, substitutional impurities, and contaminants that can never be completely eliminated in experiments. Inhomogeneities of the chain length and thickness are likely also responsible for the reduced remanence relative to the saturation magnetization observed at 10 K.

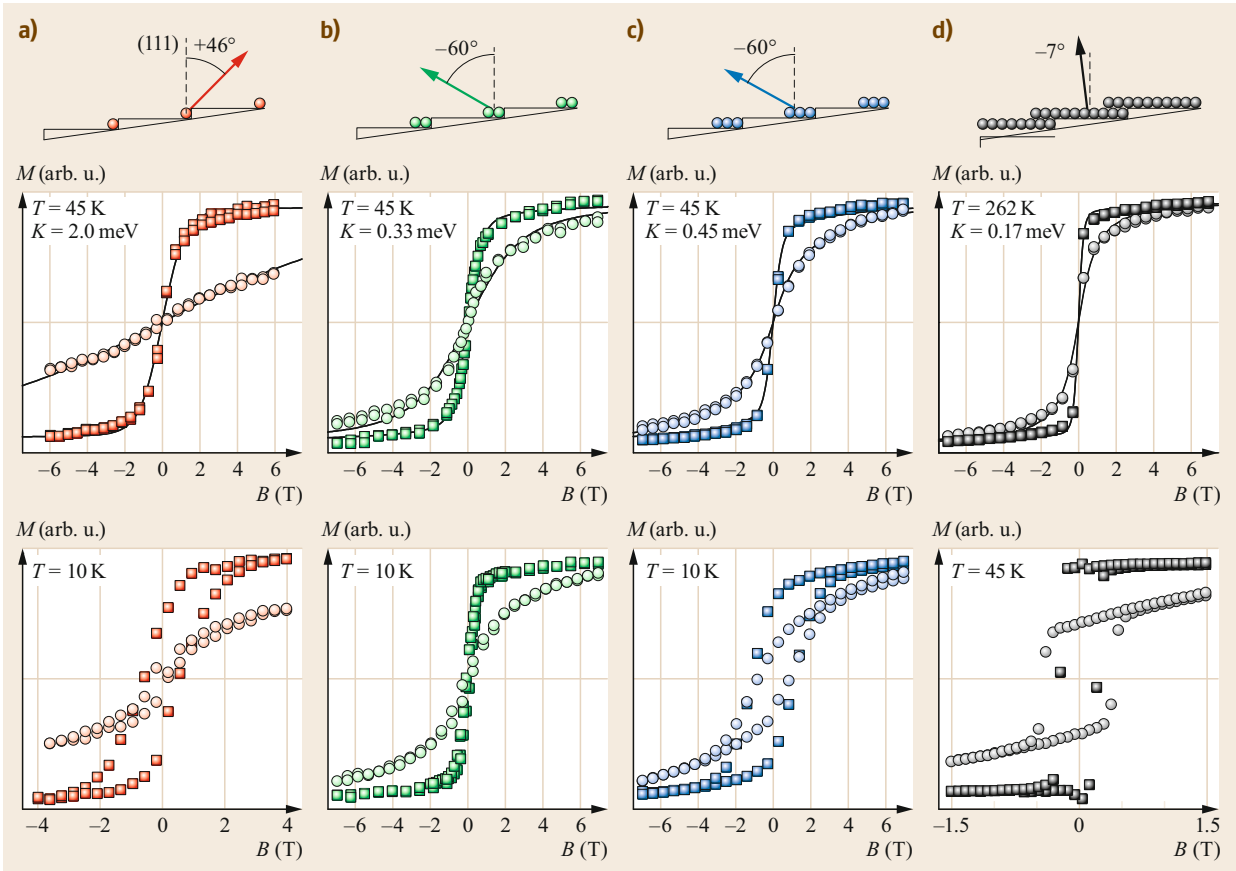

Fig. 21.31a–d Magnetization of **(a)** monatomic, **(b)** biatomic, and **(c)** triatomic chains and **(d)** 1.3 ML Co on Pt(997) along the easy and hard directions (*filled* and *open symbols*, respectively), measured above and below the blocking temperature. The easy axis is indicated by the *arrows* in the top diagrams. The data points represent the XMCD at the L_3 Co edge (779 eV) normalized by the L_3 absorption edge jump. *Solid lines* are fits to the data according to a classical spin block model. As the system evolves towards a 2-D film and the number of exchange-coupled Co atoms in the chains increases (Fig. 21.31b–d), a stronger tendency towards magnetic order is expected. Contrary to expectations, however, the two-atom chains do not exhibit long-range magnetic order, even at low temperature (Fig. 21.31b, bottom panel). In this case, the tendency towards order is counteracted by the drastic reduction of K, consistent with the reduction of m_L. Paradoxically, therefore, the 1-D character of the monatomic chains favors magnetic bistability rather than disrupting it, owing to the enhanced magnetic anisotropy energy of the low-coordinated Co atoms. Eventually, a fully coalesced magnetic layer forms (Fig. 21.31b–d), showing properties typical of a 2-D film (Sect. 21.3).

Equation (21.59) further allows modeling of size- and site-dependent spin correlation effects along the monatomic chains. Because the spins at the two ends of a chain lack one magnetic neighbor, the first and last spins along the chains can fluctuate more freely than those in the middle, leading to the confinement of entropy close to the end spins. Figure 21.32 shows the site dependence of the average easy-axis spin projection $\langle S_i^z \rangle$ in the presence of an applied field $B_z = 2\,\mathrm{T}$ at $T = 45\,\mathrm{K}$. The profiles obtained for segments of different lengths N are compared with the expectation value for the infinite chain [21.397]. Translational invariance is broken for any segment but for the infinite chain, and $\langle S_i^z \rangle$ decreases symmetrically with respect to the middle of the segment while moving towards the end spins. Note that the asymptotic value for the infinite chain is never reached for segments smaller than $N = 50$. From the above discussion, it is evident that, depending on temperature, finite-size effects play a central role in determining the magnetization of 1-D systems.

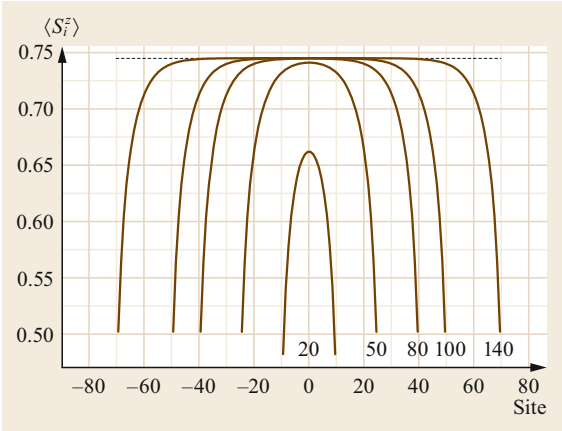

Fig. 21.32 Site dependence of $\langle S_i^z \rangle$ of monatomic Co chains shown for different lengths of the segments at $T = 45\,\mathrm{K}$ in zero applied field. The site index is enumerated starting from the middle of each segment. The *dashed line* corresponds to the infinite chain expectation value. (Reprinted by permission from [21.346], © Springer 2006)

21.5.3 Local Couplings and Excitations in 1-D Chains

Atom manipulation by low-temperature STM has opened up the possibility of assembling and probing magnetic chains of well-defined length and couplings on flat substrates. STM also provides a means to locally probe the ground state and spin excitation spectrum of the assembled structures using spin-polarized tunneling [21.192, 193] and inelastic tunneling spectroscopy [21.398, 399]. Adatom chains assembled on insulating substrates such as Cu_2N typically display localized electron behavior characterized by antiferromagnetically or ferromagnetically coupled integer or half-integer spins, providing a nice example of finite-size 1-D spin lattices [21.358, 359, 400]. Adatom chains assembled on metal surfaces, on the other hand, allow the study of the formation of delocalized quantum states and Kondo correlation effects in 1-D structures that incorporate *defects*, i.e., magnetic and nonmagnetic species, such as $CoCu_nCo$ chains on Cu(111) [21.401, 402]. Recently, ferromagnetic chains assembled on s-wave superconducting substrates with strong spin–orbit coupling have been proposed as a simple realization of a topological superconductor [21.403, 404]. Such 1-D chains with nearest-neighbor hopping, large exchange splitting of the d bands, and proximity-induced pairing carry zero-energy excitations at the chain ends, which are regarded as a solid-state equivalent to Majorana fermions in particle physics. Examples of these systems are Fe and Co chains on Pb(110), as described in [21.405, 406]. In the following, we describe two examples of ferromagnetic [21.358] and antiferromagnetic [21.359] chains assembled on insulating substrates in order to illustrate the rich physics accessible by STM spectroscopy.

Figure 21.33a shows a schematic diagram and STM image of a single-atomic layer of Cu_2N formed by N implantation on Cu(001). This layer has insulating properties, which prevents direct hybridization between the d electrons of magnetic adatoms with the Cu(001) sp-bands. Transition-metal adatoms deposited at cryogenic temperature on Cu_2N/Cu(001) adsorb on top of the Cu sites and can be manipulated by the STM tip using pick-up and release voltage pulses of opposite polarity. Figure 21.33b shows the atom-by-atom construction of a chain of nine Mn atoms positioned on neighboring Cu sites along the [100] direction, at a distance of 0.36 nm from each other. Inelastic electron tunneling spectroscopy performed by positioning the tip of the STM on top of the Mn atoms was used to determine the ground state and spin excitation spectrum of chains of different length, as shown in Fig. 21.33c. This technique is based on the increase of the conductance of a tunnel junction when the energy of the tunneling electrons matches that of a vibrational or magnetic excitation of the sample, thus opening an inelastic conduction channel that adds to the elastic conductance [21.398, 407]. In the case of magnetic atoms, $\mathrm{d}I/\mathrm{d}V$ conductance steps correspond to spin-flip excitations that change the spin projection S_z but leave the total spin S unchanged. The energy of these excitations, given by $-eV$, where V is the STM bias voltage, generally depends on the applied magnetic field, magnetic anisotropy, and exchange coupling to neighbor atoms. The $\mathrm{d}I/\mathrm{d}V$ spectra of Mn chains consisting of one to ten atoms at zero field display a striking dependence on the parity of the chain. At $V < 1\,\mathrm{mV}$, the spectra of odd-length chains, including a single Mn atom, exhibit a narrow dip in conductance centered at 0 V, typical of spin-flip excitations of a ground state with $S > 0$. None of the even-length chains, however, exhibit a spin-flip excitation: the spectra are flat near $V = 0$, at both zero and high magnetic field. The absence of spin-flip excitations in even-length chains is attributed to a ground state with $S = 0$. The alternation of the ground-state spin between zero and nonzero values is consistent with the compensation and uncompensation of the total Mn spin for even- and odd-length chains, respectively, indicating that the Mn spins are antiferromagnetically coupled. At larger bias voltages, both odd and even chains, with the exception of a single Mn atom, present large $\mathrm{d}I/\mathrm{d}V$ steps in conductance at voltages that are symmetric with respect to $V = 0$. These features can be analyzed by calculating the spin excitation spectrum starting from the Heisenberg Hamiltonian (21.28).

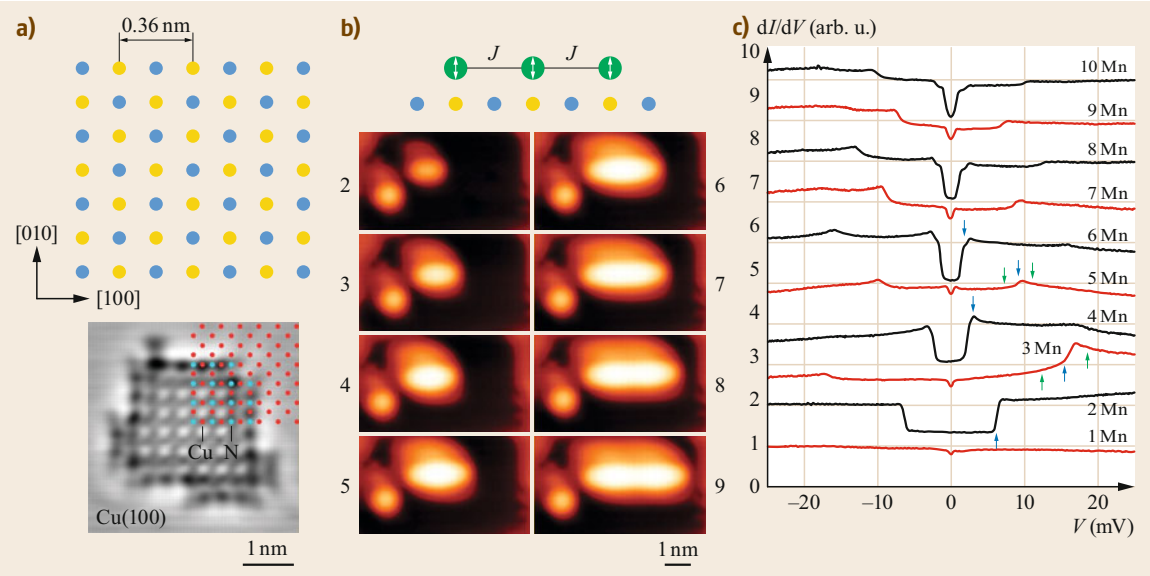

Fig. 21.33 **(a)** *Top*: Lattice model of a Cu_2N island on Cu(001). Cu atoms are shown as *yellow dots*, N atoms as *blue dots*. *Bottom*: constant-current STM topograph of a Cu_2N island on Cu(001). **(b)** STM images of the building of a Mn chain two to nine atoms long on Cu_2N. The top diagram shows the coupling between adjacent Mn spins, likely mediated by superexchange through the intervening N atom. **(c)** Conductance spectra of Mn chains on Cu_2N. Spectra were taken with the tip positioned above the center of chains of Mn atoms of length one to ten at $T = 0.6$ K and $B = 0$ T. Spectra on chains containing an odd (even) number of atoms are shown in *red* (*black*) to emphasize the parity dependence. *Blue arrows* indicate the lowest energy spin-changing excitation obtained from the isotropic Heisenberg model with $J = 6.2$ meV and $S = 5/2$. For comparison, *green arrows* indicate the same excitation with $S = 2$ (lower voltage) and $S = 3$ (higher voltage) on the trimer and pentamer; the same excitation with $S = 2$ and $S = 3$ is not distinguishable from $S = 5/2$ on the dimer, tetramer, and hexamer chains. (Adapted by permission from [21.358], © Am. Assoc. Adv. Sci. 2006)

Overall, the excitation energies of the chains can be well reproduced by assuming an antiferromagnetic exchange coupling constant $J = -6.2 \pm 0.3$ meV and a local spin $S_{Mn} = 5/2$ [21.358]. The magnetic anisotropy (i.e., the zero-field splitting parameter) is small in such a case, consistent with the orbital singlet state of Mn atoms with spin 5/2. An important point of this study is that the energy of the conductance steps turned out to be the same irrespective of the position of the STM tip along the chains, which suggests that the excited states are collective entangled states rather than single-atom spin flips, consistently with the picture drawn in Fig. 21.29d. Such states have also been reported for odd-length Mn chains assembled on Ni(110) [21.408].

In the Mn chains, the formation of entangled quantum spin states is favored by the large value of J relative to the on-site magnetic anisotropy energy K. By decreasing the ratio J/K, however, the classical Néel states with alternate spin orientation on each atom (Fig. 21.29c) can be stabilized. This situation is realized for Fe atoms aligned along the [010] rows of Cu_2N/Cu(001) with interatomic distance equal to 0.72 nm [21.359]. In these chains, the Fe spins couple antiferromagnetically with strength $J = 1.2$ meV and have an out-of-plane magnetic anisotropy of $K \approx 1.5$ meV [21.409]. Spin-polarized STM images of a linear eight-atom chain clearly distinguish the two Néel ground states, as shown in Fig. 21.34a,b. By applying a voltage > 7 meV between the chains and a magnetic tip, the spin configuration can be switched between the two Néel states with a probability that depends on the magnetic orientation of the tip, as expected for spin transfer torque, as well as on the position of the tip, due to the larger susceptibility of the spins at the two ends of a magnetic chain (Fig. 21.32 and [21.346]). The switching rate increased rapidly when either the bias voltage or tunneling current increased. Below the threshold for current-induced switching, the switching between opposite Néel states is either thermally activated or induced by quantum tunneling. The thermal switching rates of linear chains of Fe atoms with varying length $(1 \times n)$ and arrays of two coupled chains $(2 \times n)$ are shown in Fig. 21.34c. All structures containing eight or more atoms are stable at 0.5 K, whereas spontaneous fluctuations between the two Néel states set in with increasing temperature. Structures with more

The *line* profile on the *right-hand side* shows the alternate alignment of the Fe spins in the Néel state '0'. **(a)** Same as **(b)** for the Néel state '1'. **(c)** Arrhenius plot of the switching rates for different Fe arrays as determined by two-state noise of the tunneling current ($< 10^3\ s^{-1}$) and a pump–probe voltage scheme ($> 10^3\ s^{-1}$). **(d)** Thermal stability of antiferromagnetic arrays. *From left to right*: STM images of (2×6) and (2×4) arrays of Fe atoms at 1.2, 3.0, and 5.0 K. Both arrays have stable Néel states at 1.2 K, but the smaller array switched rapidly during the imaging at 3.0 K. At 5.0 K, both arrays switched rapidly. Image size 7.7×7.7 nm. A schematic of the atomic positions of Fe and Cu_2N substrate atoms is also shown (Cu atoms, *yellow*; N atoms, *light blue*). *Ball colors* depict the spin alignment of one Néel state, with *red* being parallel and *blue* antiparallel to the tip's spin. (Adapted by permission from [21.359], © Am. Assoc. Adv. Sci. 2012)

atoms remain stable to higher temperatures owing to the increase of the total anisotropy energy (Fig. 21.34d). Above 5 K, the switching rates of the (1×6), (1×8), and (2×6) arrays follow an Arrhenius law like (21.51) with exponential prefactors on the order of $10^8\ s^{-1}$ and reversal barriers of 7–12 meV, which are comparable to the threshold for voltage-induced switching and the energy $2S^2J = 9.6$ meV (assuming $S = 2$ for Fe) required to create a single Ising domain wall within one of the chains (Sect. 21.5). Below 5 K, the switching rates of the (1×6) and (1×8) chains become independent of temperature due to quantum tunneling of the magnetization between the two degenerate ground states, similar to molecular magnets [21.410] and magnetic nanoparticles [21.159]. Quantum tunneling rates can be decreased by increasing the chain length as well as by coupling two chains, e.g., from (1×6) to (2×6). Even a weak interchain coupling $J' = 0.03$ meV markedly suppresses quantum tunneling, as shown in Fig. 21.34c. These measurements also evidence the anisotropy of the exchange coupling ($J \gg J'$) due to the anisotropy of the superexchange interaction mediated by the Cu_2N substrate. Note that the sign of J depends on the alignment of the Fe atoms relative to the crystal axes, which allows for studying ferromagnetically coupled chains on the same surface [21.400, 411].

Overall, the examples presented in this section evidence the rich magnetic behavior and diverse properties of ferromagnetic and antiferromagnetic spin chains on different surfaces. Besides the possibility of preparing such systems by self-assembly or atom manipulation techniques, surfaces allow for in-depth investigations of the chain properties using photon and electron spectroscopy techniques, which provide unprecedented insight into the magnetism of 1-D systems.

21.6 Single-Atom Magnets

Magnetic atoms on surfaces represent the ultimate limit of monodisperse magnets. Although individual atoms generally present paramagnetic behavior, their investigation provides clues to fundamental and practical issues in magnetism, such as the dependence of the magnetization on system size, atomic coordination, and composition [21.17–21]. The spin and orbital magnetic moments, exchange coupling, and magnetic ordering of such systems can be tuned by tiny changes of dimensions and coupling to the environment [21.73, 124, 158, 183, 194, 412]. The magnetic anisotropy energy per atom can be increased by up to three orders of magnitude with respect to bulk materials, leading to metastable (blocked) magnetic states at low temperature [21.72, 359, 413, 414]. Depending on the system size and interaction with the host medium, the magnetization can behave as a classical vector or be quantized, leading to effects such as magnetic hysteresis, the typical macroscale property of a magnet, as well as quantum tunneling and phase interference effects, which are characteristic of microscopic systems [21.415–417]. Moreover, magnets made of one or a few atoms organized into regular patterns allow for the investigation of the ultimate limits of magnetic storage and quantum computation in novel materials [21.418–420].

Progress in the manipulation and probing of single atoms has allowed the study of the influence of the binding sites on the magnetic moments, anisotropy, and relaxation time with unprecedented spatial and temporal resolution. Inelastic electron tunneling spectroscopy gives direct access to the atomic spin excitations of both individual magnetic atoms and nanostructures (Sect. 21.5.3), providing information on the quantum properties of engineered spin structures at surfaces, albeit mostly on thin insulating layers [21.359, 398, 400, 409, 421, 422]. The development of pump–probe techniques based on spin-polarized STM [21.74, 359, 423] has made it possible to measure the spin relaxation time of individual atoms [21.44, 59], while the recent introduction of electron spin resonance (ESR) STM [21.242, 424, 425] allows for the exploration of the coherent dynamics of individual magnetic atoms of surfaces [21.419, 420] as well as sensitive measurements of the relatively weak, long-range dipolar interactions among adatoms [21.418, 426].

From a different perspective, controlling the bonding, diffusion, and nucleation processes of adatoms at surfaces offers many opportunities to tune the adatom–substrate interaction as well as to construct multiatom magnetic clusters with tailored shape and dimensions [21.427]. Adatoms and clusters may further be considered as the precursors of thin films, as the growth of magnetic mono- and multilayers is typically initiated by the deposition of transition-metal atoms from the vapor phase onto a nonmagnetic substrate. Investigating substrate–impurity hybridization and coordination effects thus provides basic understanding and useful guidelines to tailor the magnetization and magnetic anisotropy of nanomagnets and optimize sensitive interface properties that govern the performance of magnetic storage media and spintronic devices.

Although most transition-metal and rare-earth atoms possess a magnetic moment in the gas phase, the survival of this moment when an atom is placed on a nonmagnetic metal surface is not granted. For transition metals, the competition between the intraatomic Coulomb interactions and the kinetic energy associated with electron delocalization caused by hybridization of the adatom and the electronic states of the substrate may result in either magnetic or nonmagnetic ground states [21.195]. For moderate hybridization between the adatom and host electron states, the Anderson model [21.428] describes well the formation of a magnetic moment. Many-body spin-flip processes may also lead to the Kondo effect, the screening of the local moment by conduction electron spins [21.429], which can be directly visualized by scanning tunneling spectroscopy [21.19, 430, 431]. In the following, we describe the conditions that favor the emergence of strong local moments and magnetic anisotropy in single atoms at surfaces. Depending on the coupling of the magnetic degrees of freedom of the adatoms with the electronic and phononic baths of the substrate, single atoms may display fast spin relaxation, bistable magnetic states, or coherent quantum behavior.

21.6.1 Transition-Metal Atoms

In most cases, a transition-metal atom deposited on a metallic substrate presents reduced m_S and m_L compared with the gas phase (Fig. 21.1). The adatoms still follow Hund's first rule, with maximal moments at the center of each series; however, their magnetic moment assumes smaller, noninteger values relative to the free atoms. For example, a gas-phase Co atom with seven electrons in the d-shell has $m_S = 3$ and $m_L = 3\,\mu_B$, which reduce to about $m_S = 2$ and $m_L = 1\,\mu_B$ on Pt(111) owing to charge transfer from the substrate and hybridization of the Co 3d states [21.73]. The larger relative decrease of m_L compared with m_S is related to the hierarchy of Hund's rules, as electron delocalization reduces the Coulomb repulsion effects within the d-states. Note that the local moments tend to decrease further with increased coordination, as shown by experiments

and calculations performed for clusters and monolayer films. On the other hand, owing to the reduced atomic coordination, elements that are nonmagnetic in the bulk may display sizable magnetic moments as adatoms, including 4d and 5d elements (Sect. 21.1.2). This allows for a much broader choice of elements in the construction of atomic-scale magnets.

XMCD [21.17, 183] and photoemission [21.195] studies show that the electronic valence of single Co atoms typically changes from d^7 in the gas phase to d^8 upon deposition on a metal surface. Experiments on alkali-metal films, for which the electron density increases from Cs to Li, indicate that the delocalization of the 3d-states increases with the electron density of the substrate, being maximum on Li [21.183]. The delocalization of the 3d-states causes a progressive decrease of m_S and m_L, which eventually leads to a nonmagnetic ground state due to Kondo screening of the local moments by the substrate conduction electrons [21.195]. On transition-metal substrates, on the other hand, the admixture of adatom and substrate d-states leads to unequal filling of orbitals with different symmetry and hence to strong anisotropy of m_L (Sect. 21.1.3, *Anisotropy of the Orbital Moment*). As the spin–orbit interaction couples m_L and m_S, a strong magnetic anisotropy is also expected, as schematized in Fig. 21.35 for $Co_1/Pt(111)$.

XMCD experiments and ab initio calculations also show that m_L and the MCA energy K of small Co_N clusters are correlated and dramatically sensitive to unitary changes of the atomic coordination [21.73, 432], as shown in Fig. 21.36. This tendency, governed by lateral adatom–adatom interactions as well as substrate–adatom interactions, continues from adatoms to clusters and thin films until, eventually, values of m_L and m_S close to bulk are reached (Fig. 21.36). The decreasing trend of K with atomic coordination must be taken into account if more atoms are assembled together with the aim of obtaining clusters with total magnetic anisotropy strong enough to stabilize ferromagnetic behavior against thermal fluctuations. Structures where the shape and composition are tuned so as to control the coordination of the magnetic atoms and maximize m_L and K, such as core–shell 2-D particles [21.157], 1-D atomic wires (Sect. 21.5), 2-D metalorganic networks, and single molecules [21.433–436], offer several opportunities to prevent a drastic decrease of K.

The high magnetic anisotropy of 3d adatoms on heavy-metal surfaces such as Pt, Pd, Ir, and W suggests that the magnetic moment of a single atom may become stable below a certain temperature, as the spin relaxation time τ increases exponentially with the ratio $K/(k_BT)$ (Sect. 21.1.8). Whereas this would certainly occur for a classical spin, spin-flip scattering with the conduction electrons of the substrate [21.422] and spin–phonon coupling [21.48] severely limit the stability of the magnetic moment in realistic situations. In addition, zero-point quantum spin fluctuations, which are a direct consequence of Heisenberg's uncertainty principle, can alter the magnetic ground state by effectively reducing the magnetic anisotropy energy barrier, which in turn reduces the magnetic stability [21.437, 438]. Indeed, no indication of magnetic remanence was observed for $Co_1/Pt(111)$ [21.73], even down to 0.3 K [21.439], while the longest τ reported for $Fe_1/Pt(111)$ is 3 ns at 0.3 K [21.440].

Electron scattering from a conductive surface can be effectively suppressed by introducing a thin insulating layer between the substrate and the magnetic adatoms. Such a layer additionally allows for tuning the phonon density of states of the surface as well as the symmetry and strength of the ligand field experienced by the adatoms, with the aim of reducing the spin–phonon relaxation and quantum tunneling rates, respectively. A first experiment performed on $Co_1/MgO/Ag(001)$ showed that the insertion of a few-monolayer-thick MgO spacer led to a drastic increase of τ, up to $232 \pm 17\,\mu s$ at 0.6 K in a magnetic field of 1 T. In this case, spin-flip transitions involving ground and excited states prevent even larger τ values from being reached [21.74].

The preferred binding site of Co on MgO(001) is on top of oxygen with four Mg atoms as neighbors, resulting in C_{4v} symmetry (Fig. 21.37). The dominant bond is between the out-of-plane d-orbitals of Co and p-orbitals of O, resulting in a nearly uniaxial ligand field (Fig. 21.37). This axial coordination plays a major role in determining the magnetic ground state of the adatoms as well as the energy separation of the lowest excited states, in particular the *zero-field splitting* between the two lowest spin doublets. The effects of the axial ligand field are shown in Fig. 21.37 by adopting a simplified one-electron picture of the Co d-orbitals (Fig. 21.37c) and a many-electron multiplet scheme including electronic interactions and spin–orbit coupling (Fig. 21.37e) derived from analysis of x-ray absorption spectra [21.74]. As seen in Fig. 21.37c, the axial field splits the 3d orbitals into three groups with different magnetic quantum numbers (0, 1, and 2) without breaking the degeneracy between the $d_{x^2-y^2}$, d_{xy} and d_{xz}, d_{yz} orbitals. This splitting preserves the orbital moment of the free atom along the vertical axis, leading to a ground state with $m_L \approx 3\,\mu_B$. A more detailed analysis carried out using multiplet ligand field theory [21.441, 442] reveals that the Co ground state is a mixed d^7 and $d^8\underline{1}$ configuration, where $\underline{1}$ describes a ligand hole on the O site, which arises due to charge transfer between the Co d-states and O 2p-states via the

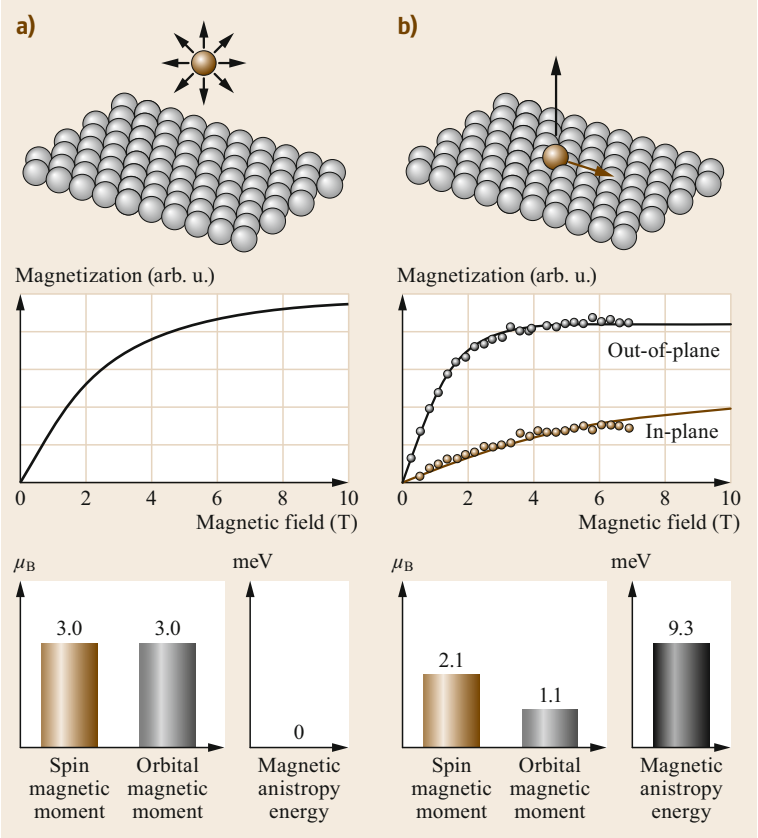

Fig. 21.35a,b Schematic representation of the symmetric and asymmetric environment of a magnetic atom in the gas phase **(a)** and on a close-packed metal surface **(b)**, respectively. The spin and orbital magnetic moment of a gas-phase Co atom are given by Hund's rules for a d^7 electronic configuration and compared with that of an individual Co atom deposited on the Pt(111) surface. The field-dependent magnetization is represented in **(a)** by a Brillouin function in the absence of magnetic anisotropy. In **(b)**, symmetry breaking and Co–Pt hybridization induce strong anisotropy of the magnetization measured out-of-plane (*black*) and close to in-plane (*brown*). d_{z^2} orbital. The evolution of the calculated Co states as a function of ligand field splitting and spin–orbit interaction (Fig. 21.37e) shows that the lowest energy level is a doublet with $L_z = \pm 2.91 \otimes S_z = \pm 1.27$, where L_z and S_z are the projections of the total orbital and spin moments on the axial direction. The spin moment is slightly less than the free atom value of $S = 3/2$ because of mixing of the ground-state terms ^{4}F and ^{2}F of the d^7 and d^8 configurations, respectively. Since both terms have $L = 3$, however, configuration mixing does not reduce the total orbital moment. The first excited level, with $L_z = \pm 2.54 \otimes S_z = \pm 0.39$, lies 58 meV above the ground state. This zero-field splitting, which can also be measured by inelastic tunneling spectroscopy [21.74], is the largest ever found for a 3d transition-metal element and represents an upper limit

of K for single atoms. The key to such a large splitting is the nearly unquenched orbital moment of the lowest energy levels, which allows the $S_z = \pm 3/2$ states to be maximally split from the $S_z = \pm 1/2$ states by the spin–orbit interaction. In such a case, the zero-field splitting is equal to $\lambda L_z \Delta S_z = \lambda L_z \approx 60$ meV, where $\lambda \approx -20$ meV is the atomic spin–orbit coupling constant of Co. This value reaches the full magnitude of the spin–orbit coupling energy available to a Co atom, in contrast to most molecular and solid-state systems, where the orbital moment is quenched by the ligand field and the zero-field splitting has a second-order dependence on λ^2 [21.49, 443].

Achieving a large magnetic anisotropy requires breaking the spatial symmetry of the atomic wavefunctions without quenching the orbital magnetization. The most promising strategy to preserve the large orbital moment of a free atom and induce uniaxial anisotropy is to use low-coordination geometries, as shown for atoms bound to oxygen sites on MgO(001) or on the threefold-coordinated sites of a (111) surface [21.73, 444], as well as for molecular complexes with axially coordinated metal species [21.445–449]. This strategy can also be adapted to extended thin films, where perpendicular magnetic anisotropy is induced by depositing thin oxide layers, such as MgO and AlO_x, on 3d ferromagnetic layers, such as Co, Fe, or CoFe (Sect. 21.3.2).

21.6.2 Rare-Earth Atoms

The gas-phase electronic configuration of the rare-earth atoms is $[Xe]6s^25d^04f^n$. Because the partially filled 4f shell is shielded from the environment by the outer filled $5s^2$ and $5p^6$ shells, the spin and orbital magnetic moments of the 4f electrons retain large, atomic-like values even in a bulk environment. In free atoms, the total angular momentum J, which is the vector sum of the momenta S and L of the 4f shell, and its projection J_z are good quantum numbers. The electronic levels of a given configuration split according to J, with energy determined by the intraatomic Coulomb interaction and spin–orbit coupling. Each level is a $(2J + 1)$-degenerate multiplet. When the ions are incorporated into a crystal or deposited onto a surface, the ligand field partially lifts the degeneracy of the J-manifolds, splitting states with different $|J_z|$ over several tens of meV according to the strength and symmetry of the crystal potential. This splitting determines the magnitude of the total magnetic moment as well as the magnetic anisotropy of the rare-earth ions. Magnetic and electric hyperfine interactions provide additional structure to the energy levels, which is relevant for understanding spin coherence and relaxation processes.

Isolated rare-earth impurities in bulk dielectric crystals are currently being investigated for quantum mem-

ory and optical signal processing applications [21.450]. These systems combine long optical and spin state coherence times with the possibility of controlling light–matter interactions using external electric and magnetic fields. In the context of surface magnetism, rare-earth ions provide an alternative to transition metals to explore magnetic bistability and quantum coherence in single atoms, taking advantage of the quantized nature of J and J_z as well as of the multiplicity of the electronic levels. The angular symmetry of the ligand field provided by the surface determines the symmetry of the quantum states and thereby their coupling via tunneling matrix elements. Therefore, depending on the symmetry of the ligand field, the magnetic moment may be protected from direct quantum tunneling between the two $\pm J_z$ ground states as well as from reversal induced by single-electron spin flips [21.444, 451].

In principle, rare-earth atoms can have either a divalent $(6s6p5d)^2 4f^n$ or trivalent $(6s6p5d)^3 4f^{n-1}$ electronic configuration, where divalent and trivalent refer to the occupancy of the (6s6p5d)-derived valence band. Most rare earths are divalent as free ions and trivalent in the bulk [21.452–454], although mixed valencies have been reported for several of the early lanthanides [21.455–458] and Tm [21.459]. Bulk lattice–ion interactions are well understood in the framework of spin Hamiltonians including ligand field effects [21.460–462]. For rare-earth atoms in low-coordination environments, such as for surfaces [21.463–466], thin films [21.467], small clusters [21.468, 469], and adatoms, the 4f occupancy may be different with respect to the bulk. Tm atoms on W(110) are trivalent [21.470]. Dy, Ho, Er, and Tm atoms adsorbed on Pt(111), Cu(111), Ag(100), and Ag(111) assume a trivalent (divalent) configuration when the sum of the $4f \rightarrow 5d$ promotion energy and intershell coupling energy is low (high) and the substrate density of states at the Fermi level is large (low) [21.454]. On oxide surfaces such as MgO, the prevalent configuration is trivalent, whereas Dy atoms on graphene/Ir(111) are divalent [21.471]. The MCA of trivalent rare-earth atoms is on the order of a few meV/atom and typically larger than that of divalent atoms.

Similar to the transition metals, rare-earth atoms adsorbed on metallic surfaces behave as paramagnets [21.454, 472, 473]. Ho atoms deposited on MgO(100) thin films grown on Ag(100), on the other hand, display long-lived remanent magnetization, with a relaxation time that depends on the MgO thickness [21.414]. Not only do the Ho atoms show magnetic bistability, they also have an exceptionally large coercive field and present magnetic hysteresis up to 40 K, a temperature substantially higher than the blocking temperature of most single-molecule magnets on comparable time scales. The adsorption site, XMCD spectra, and magnetic hysteresis of an ensemble of Ho atoms on 7 ML of MgO/Ag(001) measured at 6.5 K are shown in Fig. 21.38a–c. The spin relaxation time of this system measured at 10 K by XMCD is $\tau \approx 1600 \pm 100$ s at low field (0.01 T) and $\approx 1200 \pm 100$ s at high field (6.8 T). Thus, the Ho atoms on MgO retain a long relaxation time even at very high field, in contrast with single-molecule magnets, which typically exhibit faster relaxation at high field because of phonon scattering and level crossing [21.446, 474–477]. Comparable magnetic lifetimes are reported down to 2.5 K, implying that, < 10 K, relaxation is essentially driven by non-thermal processes. Moreover, measurements taken at different photon fluxes show that τ is mostly limited by the secondary-electron cascade generated by the absorbed x-rays. The scattering with these hot electrons reduces the magnetic lifetime [21.478]. The relaxation times measured by XMCD hence represent a lower bound on the intrinsic τ. Indeed, spin-polarized STM measurements demonstrate that τ exceeds several hours at temperatures < 4 K [21.418].

These exceptional properties originate from a combination of factors. XMCD [21.414] and inelastic tunneling spectroscopy measurements [21.479] show that the Ho atoms on top of oxygen sites have a $4f^{10}$ electronic configuration with $J = 8$. The C_{4v} symmetry of the oxygen adsorption site determines a ligand field with strong (weak) axial (fourfold) components, resulting in a ground-state doublet with either $J_z = \pm 7$ or $J_z = \pm 8$ character, depending on the interpretation of the available experimental data. The $J_z = \pm 7$ ground state is protected from quantum tunneling and first-order electron spin excitations ($\Delta m = 0, \pm 1$) at any external magnetic field [21.451], which prevents magnetization reversal by electron scattering. However, theoretical calculations indicate that spin–phonon coupling is the most relevant mechanism allowing for spin relaxation of Ho/MgO, for both $J_z = \pm 7$ and $J_z = \pm 8$ ground states. The very low density of vibrational modes in the MgO layer at low energy strongly suppresses first-order scattering with phonons ($\Delta m = \pm 1, \pm 2$). The absence of Ho–MgO vibrational modes in the region of hyperfine level crossing can further slow down relaxation at low fields, as observed for $TbPc_2$ molecules grafted onto suspended nanotubes [21.480].

The reversal processes that are triggered by the scattering with conduction electrons and with the soft phonon modes of the metal substrate are expected to depend strongly on the thickness of the MgO layer. Indeed, the hysteresis loops of Ho atoms become narrower when the thickness of the MgO film is reduced below 4 ML, and they almost close for a thickness of 2 ML [21.414]. Hence, symmetry protection against first-order reversal is not a sufficient condition to pre-

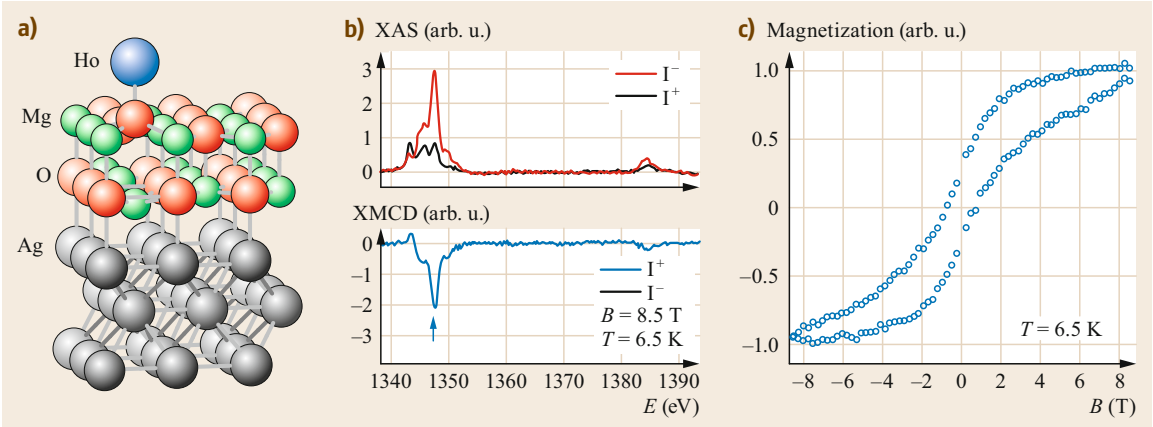

Fig. 21.38 **(a)** Adsorption geometry of a Ho atom on top of oxygen on 2 ML of MgO on Ag(100) calculated by DFT. **(b)** x-Ray absorption and XMCD spectra taken at the Ho $M_{4,5}$ edges (3d → 4f transitions) for an ensemble of individual Ho adatoms deposited on seven monolayers of MgO on Ag(100) at 6.5 K in a field of 8.5 T applied perpendicular to the sample's surface. The Ho coverage corresponds to 0.01 ML referred to the Ag(100) lattice. **(c)** Magnetization as a function of applied field recorded at the maximum of the XMCD signal (see *arrow* in **(b)**). vent magnetization reversal. To obtain long magnetic lifetimes in single atoms, efficient decoupling from the electron and phonon bath of the substrate is required. Notably, the magnetic lifetime of the Ho atoms on MgO is much longer than for Ho ions in $HoPc_2$ [21.481] and Ho-doped dielectric crystals [21.482], likely because of the larger level splitting and the smaller number of vibration modes allowed for atoms adsorbed on surfaces.

Reading and Writing the Magnetic States of Single Atoms

Recent experiments have demonstrated that it is possible to read and write the magnetic state of individual Ho atoms on MgO using spin-polarized STM [21.418, 479]. The Ho states can be sensed by measuring either the tunnel magnetoresistance [21.193] or the shift of the electron spin resonance (ESR) spectrum measured on a nearby Fe atom [21.242] and written by spin-polarized current pulses, as shown in Fig. 21.39. At bias voltages $V < 73$ mV, i.e., below the first spin excitation threshold accessible by STM, the tunneling magnetoresistance is stable for hours at low temperature. At larger bias, discrete changes in conductance are observed, separated by plateaus of long residence times in the high- and low-conductance states (Fig. 21.39b). The switching rate increases linearly with the tunnel current, indicating that it is limited by a single-electron process with a switching probability on the order of 10^{-9} per tunneling electron (Fig. 21.39c). The rate depends in a nonlinear way on the bias voltage (Fig. 21.39d), reflecting transition energies between different magnetic states of Ho on MgO. To write the Ho state, repeated current pulses at $V > 150$ mV are applied to an Ho atom, until a change in magnetoresistance measured at $V = 50$ mV indicates that the magnetic moment has switched. The magnetic origin of the long-lived states is confirmed by single-atom ESR on a nearby Fe atom, which shows that the resonance peak of Fe shifts by almost 1 GHz as the dipolar field produced by the Ho magnetic moment changes sign upon switching (Fig. 21.39e).

ESR-STM measurements also allow for estimating the magnetic moment of Ho by measuring the resonance shift as a function of the Fe–Ho distance [21.418]. The out-of-plane magnetic moment estimated by ESR-STM is $10.1 \pm 0.1\ \mu_B$, which is compatible with the 4f magnetic moment expected of a pure $J_z = 8$ state, but about $1\ \mu_B$ larger than that of a pure $J_z = 7$ state, as well as significantly larger than the magnetic moment estimated by XMCD [21.414]. Whereas the latter discrepancy may be due to the incomplete magnetic saturation of Ho atom ensembles measured by XMCD at high field, owing to their extremely long relaxation times, it remains to be established whether part of the total magnetic moment measured by ESR-STM arises from the polarization of the d and 6s-electrons or of the nearest-neighbor oxygen 2p-states [21.479].

STM measurements further show that the magnetic bistability of Ho extends to relatively high temperature. The first spontaneous magnetization reversal events are measured at 45 K with a relaxation time of ≈ 66 s. The high temperature required to activate thermally induced switching confirms the weak interaction between the magnetic quantum states and lattice vibrations. Strikingly, this temperature is close to the onset of Ho

At these tunneling conditions, switching is induced by tunneling electrons. **(c)** Switching rate measured as a function of current at constant $V = 150$ mV. **(d)** Bias dependence of the switching rate at constant current ($I = 1.5$ nA) showing three rate-increasing thresholds at 73, 104, and 119 mV. **(e)** ESR spectra of an Fe atom located at a distance of 1.4 nm from a Ho atom in the high-conductance (*top*, *red*) and low-conductance (*bottom*, *blue*) state. The ESR measurements were performed by adding a radiofrequency voltage of ≈ 15 mV at 10–30 GHz to the dc bias voltage in the presence of an external magnetic field providing 100 mT out-of-plane, which induces a Zeeman splitting of ≈ 20.8 GHz for Fe [21.242]. The *inset schematics* show the dipolar field of the Ho atom in the up and down states. All data were recorded at a temperature of 1.2 K. (Adapted by permission from [21.418], © SpringerNature 2017)

diffusion from the oxygen to the bridge site of the MgO lattice [21.479], providing further confirmation of the extremely weak spin–phonon coupling in this system. Stiff insulating spacer layers such as MgO therefore effectively decouple the electronic and phononic degrees of freedom of the adatoms from the substrate bath, opening novel possibilities to probe and manipulate atomic spins and their environment in a controlled way.

21.7 Outlook and Perspectives

The experiments on single atoms presented in the last section exemplify the extraordinary series of theoretical and experimental breakthroughs in surface and interface magnetism that have occurred over the past three decades. The ability to build and probe magnetic structures with tunable interactions one atom at a time, in controlled environments, and on timescales that extend from thousands of seconds to the sub-ns regime, provides direct experimental access to emergent phenomena at surfaces as well as a stringent test of equilibrium and nonequilibrium models of magnetic systems relevant for condensed-matter and statistical physics. This level of control has been instrumental in enabling large scale commercial applications of surface and interface magnetic systems, such as magnetic sensors, data storage media for hard drives, and magnetic random access memories. Beyond these achievements lie several possibilities for future research and technological developments.

21.7.1 Merging Functionalities

Worldwide demand for data storage, processing, and communication rates is expanding at a rapid pace. At the same time, the exponential increase in capability, and corresponding decrease in size and cost, of electronic devices captured by Moore's Law is coming to an end as the smallest device features approach the atomic scale. One way out of this conundrum is to develop a new generation of materials and devices that integrate more functions in a seamless manner, such as memory and logic or signal transduction and data transfer. Magnetic systems that couple the electronic charge with the orbital and spin de-

grees of freedom can serve this purpose, e.g., by allowing for on-chip low-power information transfer at GHz to THz frequency, beyond-complementary metal–oxide–semiconductor (CMOS) logic-in-memory architectures, as well as novel biosensing and quantum sensing techniques. Many of these applications rely on the fine engineering of the magnetic and electrical response of thin films and nanostructures. The great variety of magnetic parameters (magnetization, anisotropy, damping, domain structure), couplings (exchange bias, RKKY, DMI, dipolar) and transport properties (several types of magnetoresistance and Hall effects, spin torques) that can be tuned in these systems provides a tell-tale demonstration of the versatile functions of magnetic surfaces and interfaces.

21.7.2 Novel 2-D Materials

Originally restricted to metallic thin films, investigations of surface and interface magnetism now encompass all classes of materials: metals, semimetals, topological insulators, semiconductors, and insulators. A recent subject of research are atomically thin crystals produced by either exfoliation or chemical vapor deposition of van der Waals materials, so-called 2-D materials. Examples include ferromagnetic insulators, such as single-layer chromium trihalides, itinerant ferromagnets such as iron germanium tellurides, as well as antiferromagnets. Whereas most of the theoretical concepts and experimental techniques used for the investigation of 2-D magnetic materials are common to those developed for magnetic thin films, these materials open novel perspectives due to the broad range of couplings and electron correlation phenomena that can be obtained in van der Waals heterostructures. Besides their fundamental interest, future studies shall address the potential for technological impact of such materials, which hinges on achieving robust magnetic order above room temperature and on finding efficient ways for large-scale fabrication of 2-D heterostructures.

21.7.3 Neuromorphic Computing

Taking into consideration the Hopfield relation between early neural networks, spin-glass transitions, and spin models, localized topological spin textures open new opportunities to include neuromorphic computing functionalities in magnetic films. In this context, skyrmions and antiskyrmions have been proposed to realize reservoir computing networks, which exploit the complex dynamics of nonlinear systems for sequential data processing [21.483]. This suggestion is based on the fact that pinned skyrmions deform under the action of a current, which modifies their transport properties and leads to nonlinear current–voltage characteristics. The degree of nonlinearity has been suggested to depend strongly on the character of the chiral states constituting the magnetic texture [21.484]. Correspondingly, the interaction of skyrmions with currents and magnons can result in a manifold of internal degrees of freedom that can be utilized for achieving neural networks functionalities.

21.7.4 Quantum Computing

Quantum computing promises unprecedented capabilities for certain computational tasks such as prime factorization, decryption, and quantum many-body problems. The basic building block of a quantum computer is the quantum mechanical bit (qubit), which can represent arbitrary quantum superpositions of two basis states. Magnetic atoms at surfaces with a magnetic doublet ground state well-separated from other states can serve as model systems for spin qubits. By changing the substrate, adsorption site, and proximity to other magnetic species, the coupling and decoherence of quantum spins can be studied with atomic-scale precision in different environments. The development of scanning probe techniques that can probe and manipulate quantum coherence in single atoms is very promising in this respect (Sect. 21.6). Furthermore, helical spin chains and ferromagnetic chains of transition-metal atoms on superconducting substrates offer the possibility to realize topological qubits based on the formation of so-called Majorana bound states [21.21]. These states are nonlocal zero-energy quasiparticle excitations that emerge in superconductors in the presence of spin–orbit coupling and broken time reversal symmetry. Majorana qubits are topologically protected against perturbations and obey non-Abelian exchange statistics, two properties that make them very appealing for fault-tolerant topological quantum computation [21.485].

Pietro Gambardella

Laboratory for Magnetism and Interface Physics, Department of Materials
ETH Zurich
Zurich, Switzerland
pietro.gambardella@mat.ethz.ch

Pietro Gambardella graduated in physics from the University of Genova and obtained his PhD from EPFL, Switzerland. He was a postdoc at Max Planck Institut for Solid State Physics and research assistant at EPFL. In 2006, he was appointed ICREA Research Professor at the Catalan Institute of Nanotechnology before joining ETH Zurich as Full Professor in 2013. His research interests include magnetism, spintronics, surfaces, and interfaces, as well as x-ray and scanning probe techniques.

Stefan Blügel

Peter Grünberg Institute and Institute for Advanced Simulation
Forschungszentrum Jülich
Jülich, Germany
s.bluegel@fz-juelich.de

Stefan Blügel received his PhD in physics from RWTH-Aachen University. Since 2002, he has been the director of the Quantum Theory of Materials Institute at Peter Grünberg Institute, and in 2003 he joined RWTH-Aachen as Full Professor. He is one of the founding directors of the Institute of Advanced Simulation. His research interests include materials-specific theory and supercomputing of electronic properties, focusing on quantum materials and topology, spintronics, magnetism, and materials for nanoelectronics.

22. Magnetic Properties of Oxide Surfaces and Films

Alberto Brambilla, Andrea Picone, Marco Finazzi, Lamberto Duò, Franco Ciccacci

This chapter discusses the interesting magnetic properties of low-dimensional oxides, especially transition metal (TM) oxides (Sect. 22.1), which have long been the focus of scientific investigations. In recent years, researchers have taken a particular interest in low-dimensional TM oxide systems, especially ultrathin films (in the nanometer thickness range) that typically develop at surfaces and interfaces. In this respect, interfaces are at the heart of the magnetic phenomena associated with low-dimensional systems containing magnetic oxides. Understanding and mastering the physics of interfaces is therefore crucial if we are to manipulate the magnetic properties of such small-scale systems. Thus, several experimental techniques that allow the chemical compositions and magnetic properties of surfaces and interfaces to be probed have been developed over the last century, some of which are described in Sect. 22.2.

We also discuss various physical aspects of interfaces between magnetic transition metal oxides (TMO) and other magnetic layers (usually magnetic TMs). Since the ferromagnetic (FM) elemental metals (Fe, Co, and Ni) react strongly with oxygen, chemical interactions at those O/M interfaces can influence their magnetic properties. In Sect. 22.3, we consider the use of buffer layers—ultrathin layers of a different oxide or metal incorporated at the O/M interface—as a strategy for controlling such reactions. Finally, Sect. 22.4 provides an overview of the influence of interface chemistry on the magnetic coupling at O/M interfaces.

22.1 Overview

Oxides are compounds that are naturally abundant and have long been widely exploited for technological applications ranging from electronics to catalysis. In their natural forms, oxides possess important magnetic properties. For example, the first permanent magnets to be discovered were lodestones—rocks containing spontaneously magnetized iron oxide Fe_3O_4 (magnetite, which is ferrimagnetic (FI)).

Magnetic oxides have been widely studied and are extensively employed in their bulk forms and in low-dimensional systems (down to the nanometer scale). There are already a large number of books and reviews that discuss the general properties of oxides, so in this chapter we only briefly mention their general solid-state properties (i.e., their structural, electronic, and chemical features).

22.1.1 Crystalline and Electronic Properties

Oxides are typically ionic compounds containing metal cations and oxygen anions. The bonds in oxides can range from strongly ionic to notably covalent, depending largely on the electronegativity of the cations. This range of bonding leads to a great variety of crystal structures and electronic properties. Many oxides are good insulators, while a number of them (such as cuprates [22.1]) exhibit conducting or even superconducting behavior.

Crystal Structure

The crystal structure of an oxide is determined by its stoichiometry and the coordination number(s) of the cationic species in the oxide. In metal oxides, the crystal structure is typically based on an oxygen sublattice with either face-centered cubic (fcc) or hexagonal close packed (hcp) symmetry, with the metal cations occupying octahedral and tetrahedral interstitial sites. Variations in stoichiometry and the sites that are occupied by cations lead to a myriad of possible crystal structures of oxides, some of which are listed in Table 22.1.

This range of possible crystal structures is even greater for ultrathin oxides grown epitaxially on metallic substrates, as the interaction of the oxide with the substrate can induce the development of new phases that are not found in the corresponding bulk materials. As an example, ultrathin (monolayer (ML)) TiO_2 and reduced (TiO_x) films with various peculiar structures have been obtained through pseudo-epitaxial growth on different substrates: rutile TiO_2(110) crystals, hexagonal reconstructions, and ordered arrays of titanium oxide nanodots have been prepared on Ni(110) [22.2]; rectangular and hexagonal phases are also seen when ultrathin TiO_x films are stabilized on Pt(111) [22.3]; and exotic structures such as those with a pinwheel shape appear when TiO_2 is grown on herringbone-reconstructed Au(111) surfaces [22.4].

Low-dimensional oxides with exotic mesoscopic morphologies can also be obtained by exploiting structural features of the substrates, such as those associated with growth on vicinal surfaces. In addition, such an approach permits the stabilization of one-dimensional (1-D) and two-dimensional (2-D) nanostructures, i.e., nanowires and nanostripes. One example is CoO on Pd(1 1 23), which is vicinal to Pd(100). In this case, quasi-1-D CoO nanostripes grow in a pseudomorphically strained hexagonal phase. The driving mechanism for this process is step decoration [22.5]. The same mechanism is responsible for the stabilization of 2-D Mn oxide nanostripes grown on the stepped Pd(1 1 21) surface, which is also vicinal to Pd(100) [22.6]. Note that the mismatch between the MnO and the Pd lattices, about 14%, is relatively large. Interactions with the edges of the steps offer the oxide a path to strain relaxation, thus permitting the formation of well-ordered structures, as displayed in Fig. 22.1.

Besides its interaction with the substrate, another aspect that strongly influences the structure of an ultrathin oxide is the employed growth procedure. A significant example of this is the growth of ultrathin MgO films on Fe(001); it was shown that the optimal growth conditions depend on a delicate balance between the oxygen partial pressure during the reactive deposition of Mg and the growth rate maintained by the Mg evaporator [22.7]. For instance, an excessively high oxygen pressure leads to unwanted substrate oxidation; on the other hand, low growth rates give oxygen-deficient MgO films. There is typically a narrow window of growth parameters that are suitable for generating ultrathin oxide films with the desired quality, as exemplified by Fig. 22.2.

Electronic Structure

Oxides are commonly considered to be insulating materials. However, their electronic properties vary significantly depending on the cations in and the stoichiometry of the oxide. A wide range of bandgaps are seen for oxides, meaning that many oxides are very good insulators (e.g., MgO), some have semiconductor-like properties (e.g., TiO_2), while others are conductors (e.g., V_2O_3) or even superconductors (e.g., cuprates, such as $YBa_2Cu_3O_7$). Indeed, metal–insulator transitions occur for some oxides (e.g., V_2O_3, Ti_2O_3) at particular temperatures.

Table 22.1 List of common oxide crystal structures with examples

Structure	Magnetic examples	Nonmagnetic examples
Halite (rock salt)	NiO, CoO, FeO	MgO
Wurtzite	–	ZnO
Spinel	Fe_3O_4	Al_2MgO_4
Perovskite	$La_{0.67}Sr_{0.33}MnO_3$ (LSMO)	$SrTiO_3$
Corundum (sapphire)	Fe_2O_3, Cr_2O_3	Al_2O_3
Rutile	CrO_2	TiO_2
Pyrochlore	$Gd_2Ti_2O_7$	$Y_2Ti_2O_7$
Garnet	$Y_3Fe_5O_{12}$ (YIG)	$Y_3Al_5O_{12}$ (YAG)

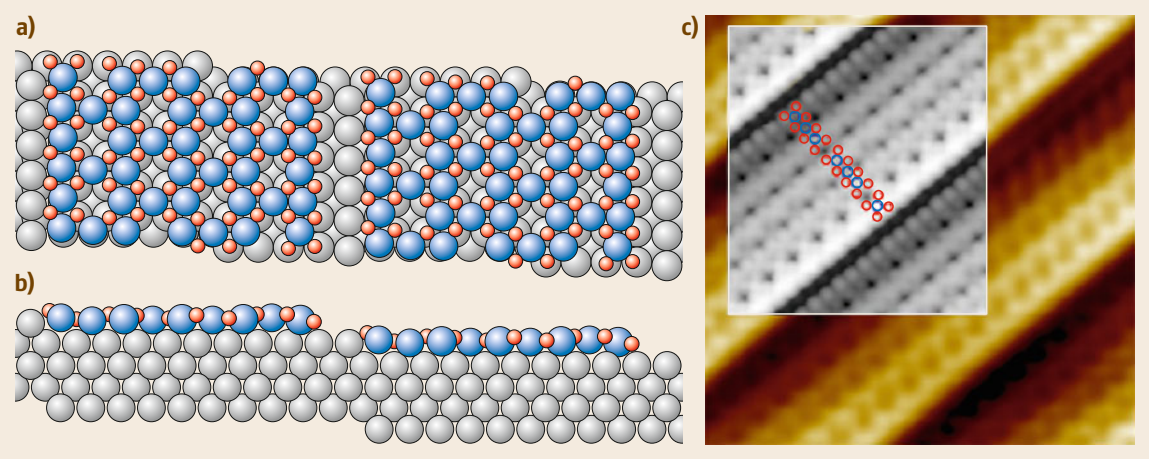

Fig. 22.1a–c Panels **(a)** and **(b)** display top and side views of the c(4×2)-$Mn_{14}O_{20}$/Pd(1 1 21) structural model. *Large* (*blue*) and *small* (*red*) adatoms indicate manganese and oxygen atoms, respectively, adsorbed on a Pd(1 1 21) substrate represented by *light gray spheres*. Fig. 22.2 Low-energy electron diffraction (LEED) patterns of 8 ML MgO films grown on Fe(001) at room temperature under different O_2 partial pressures and at various Mg deposition rates (Reprinted from [22.7], with permission from Elsevier)

Given the different characteristics exhibited by different oxides, they are often categorized into non-TM oxides and TM oxides. Magnetic oxides typically belong to the latter category, as also indicated by Table 22.1.

A common feature of non-TM oxides is that the valence and conduction states of the M atoms exhibit either s or p symmetry. This situation leads to far fewer possibilities than for TM oxides: either a wide-bandgap insulating oxide containing an element from the first two groups of the periodic table, such as MgO ($E_g = 7.8\,\text{eV}$), or a smaller bandgap insulating oxide that is based on elements in groups that occur after the TMs in the periodic table, such as ZnO ($E_g = 3.3\,\text{eV}$). Note that the bandgap of ZnO is substantially altered in the presence of defects or doping, which can yield semiconducting oxides (ZnO is an example, as is SnO_2).

TM oxides are instead characterized by the role played by d atomic orbitals, leading to a huge variety of possible cation oxidation states and to issues linked to the symmetry of the crystal field. The first aspect stems from the fact that the energy associated with a d^n configuration barely changes when n changes by ± 1, resulting in several stable oxides with different stoichiometries. The different electronic configurations of the different oxidation states of the cation also correspond to different crystallographic structures, as shown for several TMs in Table 22.2. A crucial feature of TM oxides is that the band resulting from d orbital overlap is typically narrower than that resulting from the overlap of s and p orbitals. For this reason, band formation competes with other effects such as electron–electron and electron–phonon interactions, giving rise to effects such as the well-known Mott transition [22.8]. The relative strength of the interaction between cations in TM oxides also provides the potential for long-range magnetic ordering, such as that seen in NiO and other magnetic insulators.

22.1.2 Origin of Magnetism in Transition Metal Oxides

The long-range magnetism exhibited by ferromagnets is generated by the exchange interaction. This quantum-mechanical effect occurs when wavefunctions of ions that are nearest neighbors in the lattice overlap. However, magnetic ions are not usually adjacent to each other in oxides. The occurrence of long-range magnetic order in oxides may be interpreted as arising through the indirect coupling of magnetic ions; in other words, the wavefunctions of two magnetic ions overlap with that of a nonmagnetic ion adjacent to both of the magnetic ones. The most important indirect exchange mechanisms are called superexchange and double exchange.

Superexchange typically occurs in ionic solids such as TM oxides, and involves the states that participate in the bonding between the metal and the oxygen atoms, namely 3d TM atoms and 2p valence states of oxygen. In particular, superexchange generates long-range antiferromagnetic (AF) order in several TM monoxides such as NiO, CoO, FeO, and MnO. This mechanism is often described schematically, as shown in Fig. 22.3 [22.9]. In this figure, the hypothetical ground-state (GS) distribution of electrons in the magnetically active (i.e., not completely filled) subshells is depicted

Table 22.2 Electronic configuration of the 3d shell and corresponding crystal structures for some 3d transition metal oxides

	Bixbyite	Rutile	Corundum	Rock salt	Spinel	Other

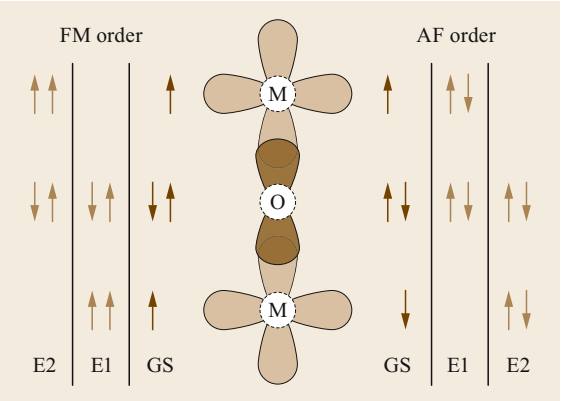

Fig. 22.3 Schematic of the superexchange mechanism. GS indicates the ground-state configuration; E1 and E2 are two possible excited configurations (see text)

with black arrows in the case of FM or AF order, where the direction of the arrow indicates the electron spin direction in the metal ion. Possible excited states are shown as gray arrows. It is found that the indicated excited states are allowed by the exclusion principle for the AF case but are forbidden for the FM case. This implies that, in the former case, electrons can be delocalized over the whole ionic structure, thus lowering the total energy of the system, leading to an AF ground state.

Double exchange refers in particular to cases with a mixed-valence magnetic cation; e.g., Fe_3O_4 (Fig. 22.4) contains both Fe^{2+} and Fe^{3+} ions. This mechanism, which was originally proposed to explain the magnetoconductivity of some oxides (e.g., doped perovskites), involves electrons hopping from one magnetic cation to another through a common O^{2-} ion. The 2p shell of the latter is full, so the process occurs in two steps (hence the term *double exchange*): an electron is transferred from the occupied oxygen state to one of the cations (e.g., Fe^{3+}), leaving an unoccupied level that receives a second electron from the other cation (in this case Fe^{2+}). Both processes occur without spin flipping, which is unfavorable according to Hund's rules,

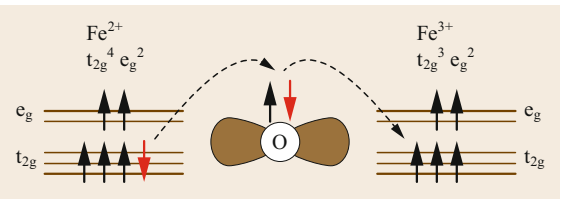

Fig. 22.4 Schematic of the double exchange mechanism for Fe_3O_4. *Arrows* indicate the direction of electron spin. The schematic assumes that hopping is permitted due to FM alignment between the ions (see text)

so hopping is only allowed when the two cations have the same magnetic structure, i.e., when their spins are parallel. The double exchange process, just like the superexchange process, results in the delocalization of the electron over the entire M-O-M system (which is then said to be of mixed valence), thus lowering its total energy. Another important example of a compound in which the double exchange mechanism is active is lanthanum strontium manganite $La_{1-x}Sr_xMnO_3$ (LSMO), which is known to possess a rich electronic phase diagram that depends on the doping level x and includes a FM phase.

22.1.3 Surfaces and Interfaces

Magnetic oxide thin films and surfaces are commonly prepared on FM surfaces, as discussed in the following sections. Elemental ferromagnetic TMs (Fe, Co, and Ni) react strongly with oxygen. Therefore, when they form interfaces with oxides, relevant oxidation/reduction (redox) processes would be expected to occur. This often results in the formation of defective oxides and/or oxidized metallic surfaces.

The various magnetic TMOs that can form when TMs are oxidized or at the interface between the TMO and TM can be inferred by calculating the standard enthalpy (heat) of formation $\Delta_f H^0$ of each oxide considered. This is the enthalpy change during the reaction in which the oxide is formed from its constituent elements in their standard states (the redox process in particular), which is normally calculated assuming the initial presence of 1 mol of oxygen. The lower the value of $\Delta_f H^0$, the more thermodynamically favorable the oxide formation. Table 22.3 provides a list of $\Delta_f H^0$ values in kJ/mol for the formation of a number of magnetically relevant oxides at 298.15 K. These enthalpies are taken from [22.10, 11], and the compounds are listed in order of increasing magnitude of $\Delta_f H^0$. The table also reports the magnetic order exhibited by each oxide, and its magnetic ordering temperature (the Curie temperature for FM oxides and the Néel temperature for AF oxides). $\Delta_f H^0$ values for the nonmagnetic (NM; i.e., materials with no long-range magnetic order) oxides MgO and Al_2O_3, which are frequently used as substrates for the growth of metallic thin films, are also shown for reference.

Redox reactions at oxide interfaces directly influence the magnetic properties of the sample. If we consider, for instance, the interfaces between AF TMOs such as NiO and CoO and FM TMs such as Fe, Co, and Ni, a comprehensive study by *Regan* et al. [22.12] utilizing x-ray absorption spectroscopy (XAS) showed how reactions at the interface between oxygen and metal layers always resulted in the reduction of the

Table 22.3 Standard enthalpy (heat) of formation values $\Delta_f H^0$ (at 298.15 K), types of magnetic order, and magnetic ordering temperatures for some magnetic oxides

Molecular formula	Name	$\Delta_f H^0$ (kJ/mol)	Magnetic order	Ordering temperature (K)
CoO	Cobalt(II) oxide	−237.9	AF	292
NiO	Nickel(II) oxide	−240.6	AF	523
FeO	Iron(II) oxide	−272.0	AF	198
MnO	Manganese(II) oxide	−385.2	AF	116
CrO_2	Chromium(IV) oxide	−598.0	FM	390
MgO	Magnesium oxide	−601.6	NM	–
Fe_2O_3	Iron(III) oxide	−824.2	AF	950
Co_3O_4	Cobalt(II,III) oxide	−891.0	AF	40
Fe_3O_4	Iron(II,III) oxide	−1118.4	FI	858
Cr_2O_3	Chromium(III) oxide	−1139.7	AF	307
$FeWO_4$	Iron(II) tungstate	−1155.0	AF	76
Mn_3O_4	Manganese(II,III) oxide	−1387.8	FI	43
Al_2O_3	Aluminum oxide (corundum)	−1675.7	NM	–
$CoFe_2O_4$	Cobalt ferrite	−20 000.0	FI	793
$NiFe_2O_4$	Nickel ferrite	−20 000.0	FI	858

former and/or the oxidation of all of the latter for all combinations of the above materials. Both the redox reaction products and the thickness of the reduced/oxidized region (typically a few atomic layers at room temperature (RT)) can typically be predicted based on the $\Delta_f H^0$ values of the oxides involved. For instance, a NiO or CoO layer is reduced more strongly when it is next to a metallic Fe layer than when it is next to a cobalt or nickel metal layer, since Fe oxides have lower enthalpies of formation than Co or Ni oxides. The magnetic properties of the Fe oxides formed at the interface depend on their magnetic environment; e.g., when NiO thin films are grown on Fe(001) by reactive deposition, the FI oxide Fe_3O_4 has been reported to form at the interface, as demonstrated by the x-ray absorption spectrum presented in the left panel of Fig. 22.5. The magnetization vector of the Fe_3O_4 layer was observed to be parallel to that of the Fe(001) substrate, which was parallel to the surface and aligned along one of the [100] in-plane directions [22.13]. On the other hand, when a thin layer of Fe_3O_4 was realized by oxidizing an Fe(110) substrate, antiparallel magnetic coupling of the overlayer with the substrate was observed [22.14], as displayed in Fig. 22.6.

In other cases, particularly when a thin metallic Fe overlayer is grown on a NiO(100) substrate (i.e., in reverse order with respect to the example provided above), the growth conditions lead to the formation of a different Fe oxide at the interface: FeO [22.15]. As reported in Table 22.3, the latter is characterized by AF order, leading to a completely different magnetic environment for an otherwise analogous interface. More examples of the interplay between interface chemistry and magnetic properties are provided in Sect. 22.4.

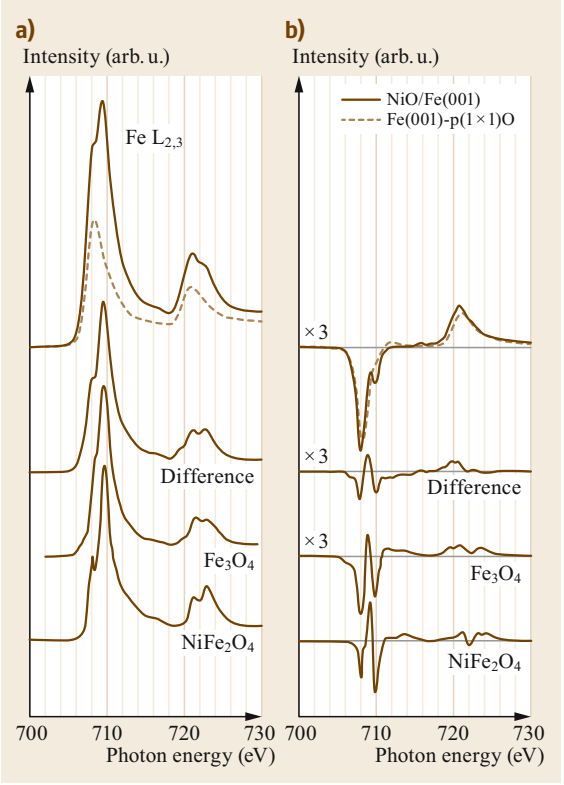

Fig. 22.5a,b Comparison of the Fe $L_{2,3}$ XAS **(a)** and x-ray magnetic circular dichroism (XMCD) spectra **(b)** of 20 ML NiO/Fe(001) and Fe(001)-p(1×1)O. After normalization, the spectra obtained for Fe(001)-p(1×1)O were multiplied by a factor of 0.5. The difference spectra are compared to the XAS and XMCD spectra of Fe_3O_4 and $NiFe_2O_4$ (Reprinted from [22.13], with permission from Elsevier)

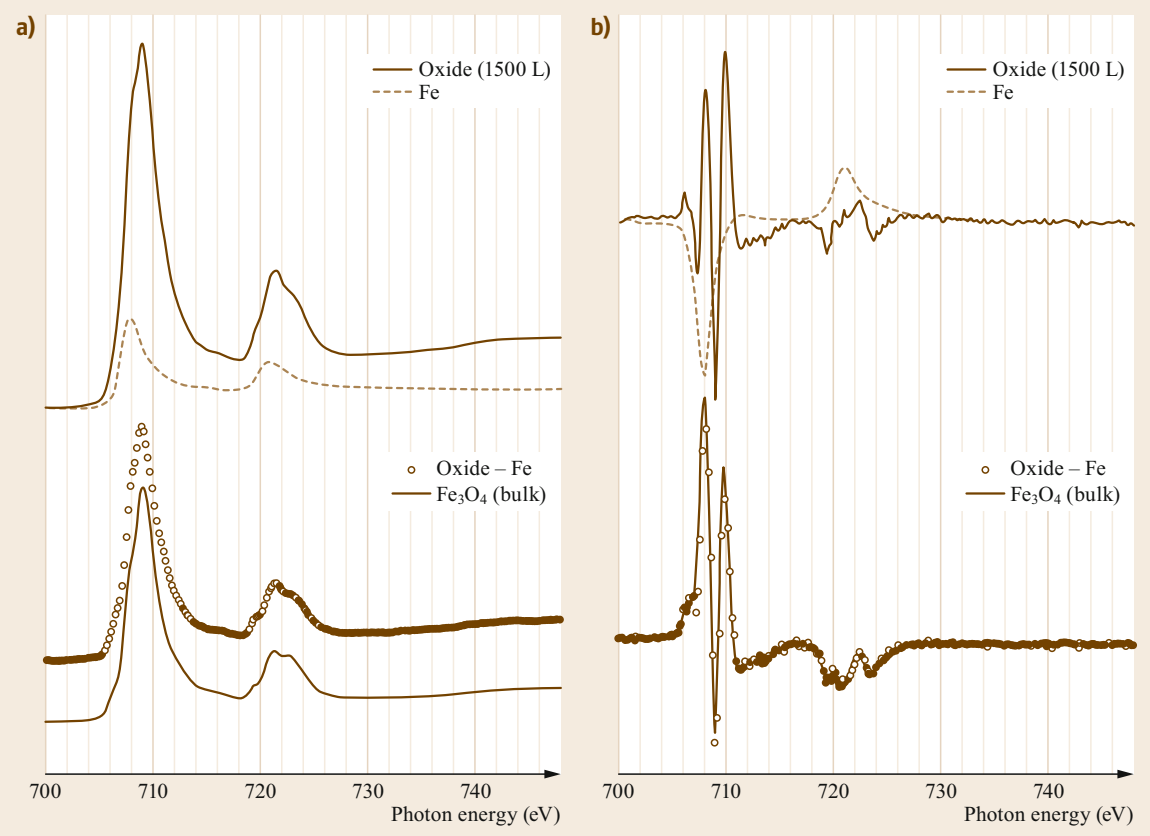

Fig. 22.6 **(a)** Fe $L_{2,3}$ XAS spectra acquired for an Fe film exposed to 1500 L oxygen (*top, solid line*) and for metallic Fe (*top, dotted line*). The Fe-subtracted spectrum (*bottom, open circles*) is compared to the bulk Fe_3O_4 spectrum (*bottom, solid line*). **(b)** Same as **(a)**, but for magnetic circular dichroism (MCD) curves. To aid comparison, the sign of the MCD for the bulk Fe_3O_4 has been reversed (Reprinted from [22.14], with permission from Elsevier)

22.2 Experimental Methods

Since oxides are used in many scientific and technological fields, a large number of experimental methods are employed for their preparation and characterization. The methods applied often depend on the approach used. Here, we limit ourselves to a survey of the most important experimental methods associated with thin and ultrathin films of magnetic oxides.

The formation of thin and ultrathin MOs usually involves chemical reactions that may modify the chemical and physical properties (including the magnetic properties) of the substrate, resulting in various possible interfaces. This is a particularly important consideration for TM substrates, as discussed in Sect. 22.1, and one that necessitates tight control over the growth procedure, particularly during the early stages of MO oxide growth. This in turn implies that a controlled environment is required, along with (typically) ultrahigh vacuum (UHV) conditions (base pressures on the order of 10^{-10} mbar) and the ability to monitor sample properties even when the thickness of the growing MO is in the sub-ML range. The sample preparation approaches and experimental characterization methods that are best suited to such goals are those typical of surface science studies. The most relevant methods for studying MO are briefly described in the following section.

22.2.1 Sample Preparation and Growth

The growth of thin and ultrathin films under controlled conditions is usually achieved via physical vapor methods. The most widely used of these is molecular beam epitaxy (MBE), which is well known as a technique for

growing semiconductors and involves the use of molecular beams of the deposited elements. These beams are produced by heating solid state sources and travel a short distance to the crystalline substrate in UHV or a controlled atmosphere. The latter case is particularly common in oxide thin film growth, where the molecular beam of the cationic element is evaporated in an oxygen atmosphere (this oxygen atmosphere can either be molecular, achieved by simply connecting a pure O_2 bottle to a leak valve, or atomic, which requires more complicated tools such as plasma sources). Such an approach is often called reactive deposition.

The word *epitaxy* refers to the development of a thin film on a crystalline substrate where the crystal structure of the thin film is dictated by that of the substrate. This influence of the substrate on the structure of the thin film can be exploited to produce crystalline thin films of very high quality as well as metastable structures that have no stable equivalents in the bulk, as discussed earlier.

MBE sources can be either very simple evaporation cells or more sophisticated effusion cells (such as Knudsen cells). The simplest cell consists of a hot filament that either directly heats a solid piece of the source material or a crucible containing the material if the latter is in powder form or has a low melting temperature (for example). In some cases, electron bombardment is employed to heat up the source (particularly when higher temperatures are needed), which can be achieved by simply establishing an appropriate voltage difference between the filament and source. More sophisticated cells often include shutters that are employed to isolate the sample from the molecular beam during preheating and calibration phases, as well as temperature monitoring systems such as thermocouples.

MBE is particularly well suited for growing ultrathin films (down to the sub-ML range) as it permits very small evaporation rates (on the order of 1 ML/min) and is performed in UHV. For the same reasons, MBE is not practical for realizing relatively thick films (on the order of hundreds of nm or more) or for industrial applications.

Other physical deposition techniques can provide higher rates and require less demanding environments. Sputtering is a very common method of growing thin films that involves accelerating a beam of (typically Ar^+) ions towards a target containing the source material, causing the ejection of target atoms (or small clusters) which are then directed onto a substrate surface. This technique is very versatile and robust in terms of the quality, uniformity, and purity of the grown film. Both simple and ternary oxides, as well as other compounds and alloys, can be produced by sputtering deposition starting from a target of the material to be grown or by (for instance) mixing oxygen with the argon in the ion source. The high speed of this process makes it particularly applicable for the preparation of samples comprising several different thin film layers (such as multilayer stacks used in spin valves).

Another versatile physical method employed in research laboratories is pulsed laser deposition (PLD). In this technique, high-power laser pulses are directed onto a target in a dedicated vacuum chamber, causing the ablation of the target material. This ablated material ionizes and forms a plasma plume that is directed toward a substrate, where the material is deposited. The stoichiometric composition of the target is generally preserved on the substrate. This method is used to grow complex magnetic oxides such as manganites for instance.

A further method of preparing ultrathin oxide films is through the oxidation of a metallic substrate by direct exposure to oxygen. This approach is clearly limited to the formation of native MO films. The thermodynamics (in particular the enthalpies of formation reported in Table 22.3) and kinetics of the oxidation process determine the compound that forms during the process. Another relevant aspect of direct oxidation is the fact that the crystal structure of the MO often does not correspond to that of the parent metallic crystal. For instance, bulk Co has a hexagonal close-packed (hcp) structure, while bulk CoO possesses a face-centered cubic (fcc) structure. Ultrathin MO films of high crystalline quality are therefore only rarely prepared by direct oxidation; one such example is alumina Al_2O_3 ultrathin film (a few ML in thickness) prepared on the alloy NiAl(110), where the film is stabilized by oxidation and subsequent annealing [22.16].

22.2.2 Chemical and Structural Characterization

In the following sections, the main spectroscopic and microscopic experimental techniques used in structural and chemical analyses of oxide surfaces are described.

Spectroscopic Techniques

The spectroscopic methods that are used to characterize surfaces and ultrathin films are those typically employed in experimental surface science. Such methods feature high surface sensitivity, meaning that they allow the experimenter to explore properties associated with the topmost layers of a sample, with probing depths on the order of a nanometer or less. Electrons are suitable probes for achieving such sensitivity, since the inelastic mean free path (IMFP) of an electron with an energy of a few tens of eV is typically less than 1 nm, even in oxides. The energy dependence of the IMFP of

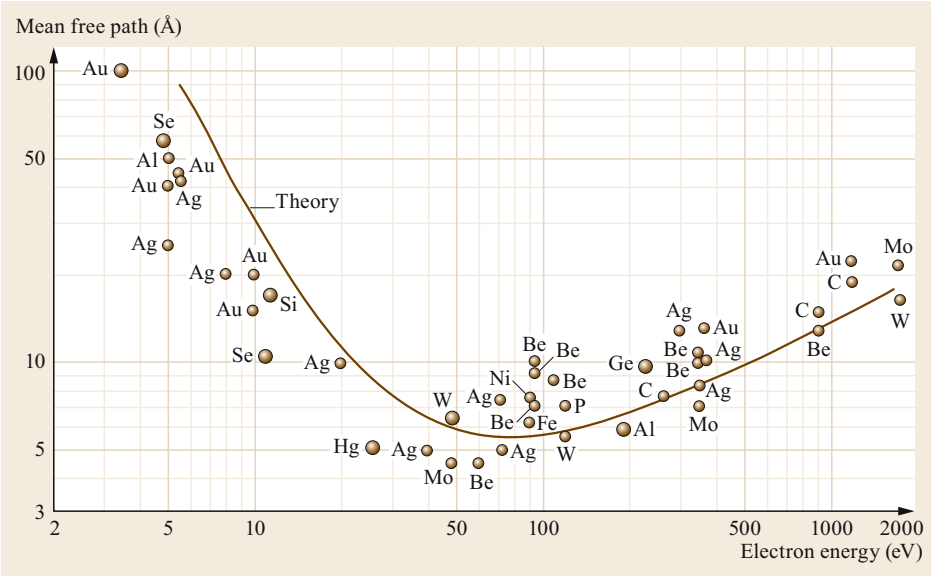

Fig. 22.7 Quasi-universal curve of the inelastic mean free path of an electron in a solid. *Points* are experimental data and the *continuous line* is the theoretical curve. Experimental data from [22.17, 18]; theoretical data from [22.19] (Reprinted by permission from [22.20], © Cambridge Univ. Press 1988)

an electron in a solid exhibits a quasi-universal curve, an example of which is reported in Fig. 22.7. The reference work of *Seah* and *Dench* [22.21] proposes the following heuristic equation for evaluating the IMFP λ_{IMFP} in an inorganic compound (such as an oxide): $\lambda_{\mathrm{IMFP}} = 143/E^2 + 0.054\sqrt{E}$, where the electron kinetic energy E is in eV and the resulting IMFP is in nanometers. The IMFP is related to the length d that electrons travel into the solid by the attenuation of the electron beam intensity with respect to the initial intensity I_0 as follows: $I(d) = I_0 \mathrm{e}^{-d/\lambda_{\mathrm{IMFP}}}$.

Photoemission spectroscopy (PES) is one of the tools most commonly used to investigate the electronic and chemical properties of surfaces. This technique allows the binding energy of an electron photoemitted from the sample following the absorption of a photon of energy $h\nu$ to be calculated via the energy balance $E_{\mathrm{K}} = h\nu - E_{\mathrm{B}} - \phi_{\mathrm{a}}$, where E_{K} is the electron kinetic energy as measured by an energy analyzer, E_{B} is the electron binding energy, and ϕ_{a} is the analyzer work function. Photon energies in the ultraviolet (UV; up to a few tens of eV) or the soft x-ray region (on the order of 1 keV) allow the binding energies of electrons from the valence band and from core levels to be probed, respectively. The same technique is therefore usually denoted UPS (ultraviolet photoemission spectroscopy) or XPS (x-ray photoemission spectroscopy), depending on the energy range of the photons employed. XPS is also known as ESCA (electron spectroscopy for chemical analysis), as the electron binding energy is specific to each element. Thus, identifying the energies of the most intense peaks in an XPS/ESCA spectrum allows the elements present to be discerned.

When analyzing compounds, one of the most useful features of XPS is the chemical shift effect, which is the shift in energy of core-level peaks that occurs when the chemical environment of the element is changed. Although the core levels are not directly involved in chemical bonding, such bonding changes the electrostatic potential generated by the valence electrons, which in turn influences the binding energies of the core electrons. In oxides, the chemical shift depends on the oxidation state, the lattice sites, and the ionic environment. In general, larger binding energies are measured for the core levels in oxides than for the core levels in the cationic element in the metallic state. The example shown in Fig. 22.8 relates to TiO_2, the 2p core-level peaks of which show a relatively large chemical shift (almost 5 eV) when compared to those of metallic Ti. Other less evident features, such as different symmetries of the XPS line shapes of the metallic and oxide materials, are not discussed here.

Other effects are responsible for variations in the core-level line shapes in XPS, among which we will briefly mention the final-states effect known as *shake up*. This effect arises because the creation of a positively charged core hole during the photoemission process induces a decrease in the electron density near to that core hole, which in turn reduces the kinetic energy of the outgoing electron such that a peak appears at higher binding energy. This effect is observed in particular in magnetic TM monooxides such as CoO and NiO, as demonstrated by the spectra reported in Fig. 22.9. In the latter, shake-up peaks relating to the Ni $2p_{3/2}$ and Ni $2p_{1/2}$ core levels of a NiO sample are indicated. Multiplet splitting is also apparent; this occurs

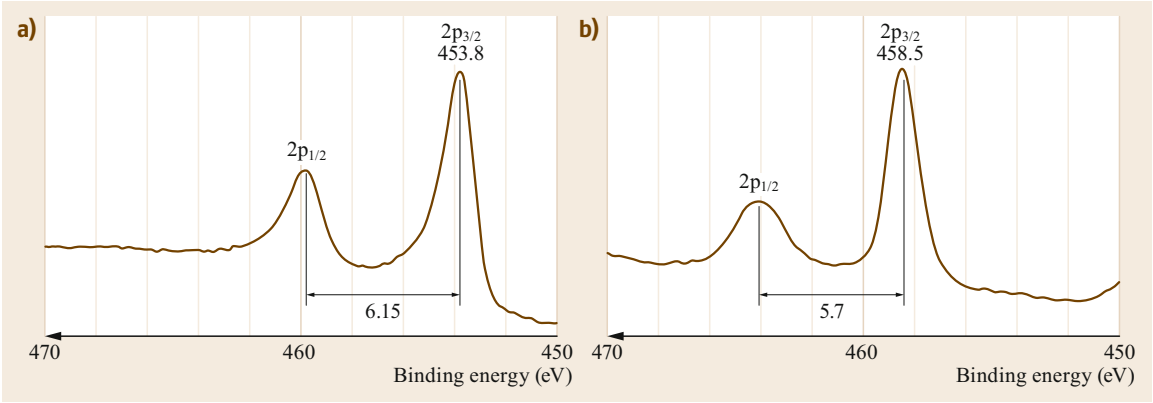

Fig. 22.8a,b XPS spectra of the 2p core levels of **(a)** Ti and **(b)** TiO_2 (Reprinted by permission from [22.22], © PerkinElmer 1979)

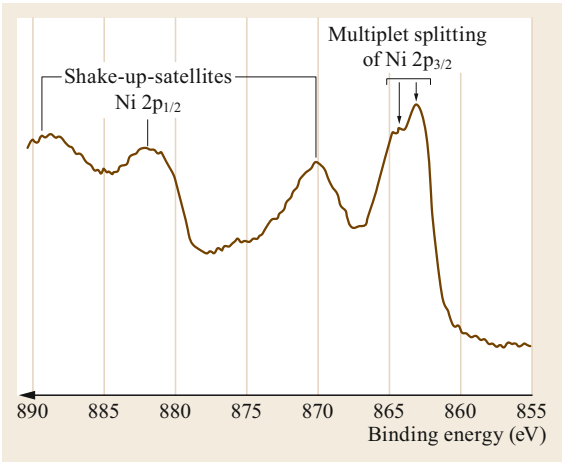

Fig. 22.9 Ni 2p shake-up and multiplet splitting features in the 2p core-level region of the XPS spectrum of a NiO sample (Reprinted from [22.23], with permission from Elsevier)

due to the presence of unpaired electrons in the valence band [22.23].

We should also mention charging effects, which are common in insulating samples such as sufficiently thick nondefective oxides. Electron emission generates a positive charge at the sample surface that cannot be neutralized by a negative charge from the ground reservoir. The outgoing electron is attracted by this positive charge, which decreases the measured kinetic energy (or artificially increases the binding energy). It is sometimes possible for the correct energy values to be retrieved by utilizing a well-known core level peak as a reference, thus permitting the energy scale to be calibrated. Another way of avoiding charging effects is to employ a charge neutralizer, i.e., an electron gun that directs negative charge to the sample surface. However, this approach must also be thoroughly calibrated, since there is a risk of negatively charging the surface if the neutralizing electron beam is too intense.

Another widely used electron-based spectroscopic technique is Auger electron spectroscopy (AES), which makes use of the well-known Auger effect, a nonradiative route for an ion with a core hole (created by exciting the sample with either electrons or photons) to relax to a lower-energy state. This relaxation results in the emission of a so-called Auger electron, and the kinetic energy of this electron depends on the set of core levels of the involved atom, which gives AES the element specificity that makes it a valuable method of identifying the chemical species at the surface of a sample, similar to XPS. Another similarity to the latter technique is its surface sensitivity, as typical kinetic energies of Auger electrons as measured with laboratory instruments are on the order of tens to hundreds of eV. As a matter of fact, Auger electrons can also be observed in XPS spectra, thus allowing the chemical composition of the sample to be cross-checked. Peak positions in AES spectra are also influenced by the chemical environment and exhibit chemical shifts comparable to those of XPS peaks. However, this behavior is often overlooked in AES because AES peaks are usually larger and have more complicated line shapes.

At this point, it is worth mentioning the use of synchrotron radiation as a source for spectroscopy experiments on low-dimensional materials. The high intensities, energies, and spatial resolutions of such sources as well as their tunability over a wide energy range make them ideal for spectroscopic and microscopic investigations of nanostructures.

X-ray absorption spectroscopy (XAS) in the soft x-ray range (about 100–1000 eV) is often used as a reference spectroscopic technique. This is a core-level

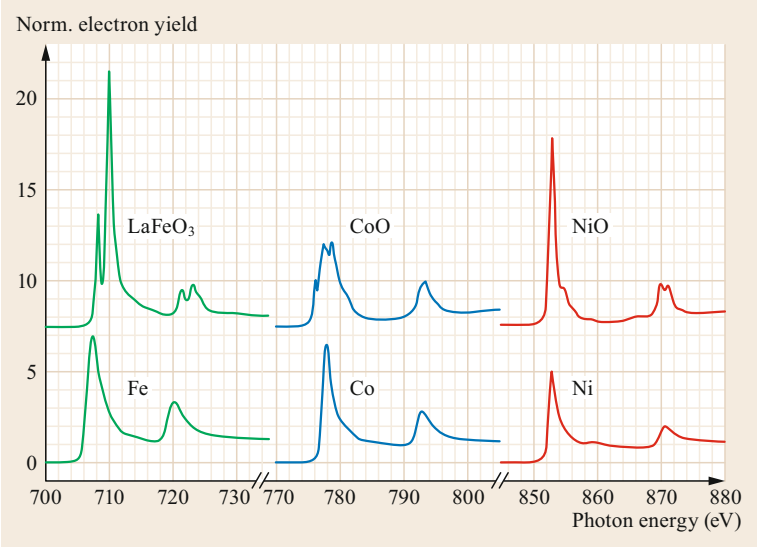

Fig. 22.10 XAS spectra obtained at the $L_{2,3}$ edges of elemental Fe, Co, and Ni (*lower row*) and cationic Fe, Co, and Ni in oxide compounds (*upper row*) (Adapted from [22.24])

spectroscopic method, implying that it is sensitive to the chemical environment and thus also useful for studying compounds. The associated physical mechanism is the absorption of a photon by a core-level electron (at specific absorption edges) that is promoted to an unoccupied state just above the Fermi level. The core hole then relaxes through both radiative and nonradiative processes, and the resulting secondary electrons are collected and measured as the signal. Here, we focus on a region on the order of 10 eV above the absorption edge (sometimes called x-ray absorption near-edge structure, XANES), whereas larger energy windows may include other information too (e.g., structural order), and the XAS in such cases is generally termed extended x-ray absorption fine structure (EXAFS) [22.25].

XAS spectra of TMs are typically taken at the so-called L-edge, which corresponds to $2p \rightarrow 3d$ electronic transitions that occur following the absorption of photons in the soft x-ray range, i.e., between about 700 and 900 eV for Fe, Co and Ni, as shown in Fig. 22.10 [22.24]. More precisely, these spectra contain two broad peaks that relate to L_2 (originating from $2p_{1/2}$ states) and L_3 (originating from $2p_{3/2}$ states) absorption edges, which are split by the spin–orbit interaction. Such transitions are regulated by dipole selection rules and are therefore linked to the 3d valence states, which are responsible for the magnetic properties of TMs. When TMs are included as cations in oxides, their XAS spectra develop a complicated fine structure called multiplet structure, which is influenced by crystal field and multiplet effects. The latter reflect various interactions between valence holes and electrons that are not discussed here.

Microscopy Techniques

Spatially resolved investigations of a sample surface can be realized at several length scales by exploiting various probes. Here, we limit our discussion to just a few examples involving probes that are suited for investigating matter (in particular oxides) at the nanometer scale. These probes are again electrons with low kinetic energies, photons in the soft x-ray range, and small tips in scanning probe approaches. Furthermore, we focus on techniques that are also implemented as magnetic imaging tools.

Photoemission electron microscopy (PEEM) is a microscopy counterpart to PES, where an UV/x-ray photon beam is directed onto a sample, leading to the emission of photoelectrons, which are then scattered by the surrounding atoms. The resulting secondary electrons that leave the sample are transferred by means of an electron optical column to a dedicated imaging system. Just as in PES, the sample depth probed by PEEM is very thin (in the nm range), making it a surface-sensitive technique. Electron collection is achieved using several electron optical elements, as described in [22.26]. A high lateral resolution of less than 20 nm can be obtained using state-of-the-art instruments by limiting the energy range and angular dispersion of the electron beam (at the expense of intensity).

Of particular interest to us in the context of this chapter is the version of PEEM that uses x-ray beams to excite photoelectrons, which is known as x-ray photoelectron emission microscopy (X-PEEM). Synchrotron radiation sources are frequently exploited to excite photoemitted electrons in X-PEEM, particularly for

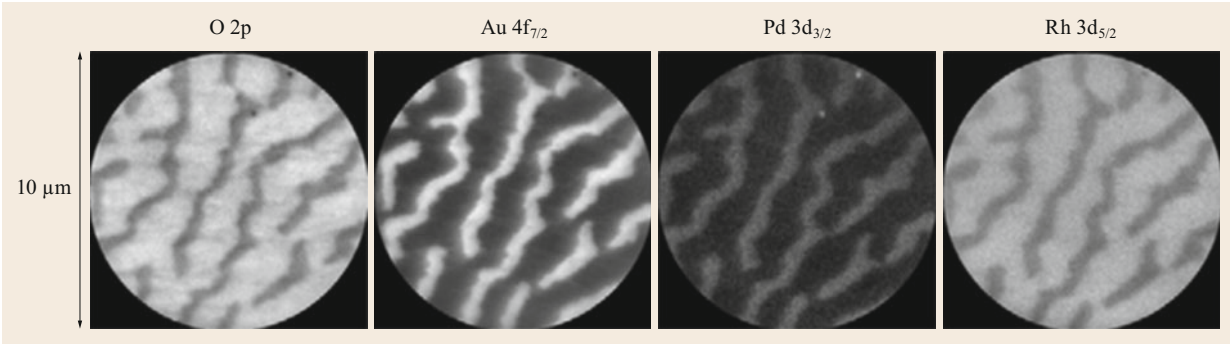

Fig. 22.11 X-PEEM images illustrating the formation of stationary patterns of Au and Pd on Rh(110) along with phase separation of Au and Pd from O (Reprinted from [22.27]. © IOP Publishing. Reproduced with permission. All rights reserved)

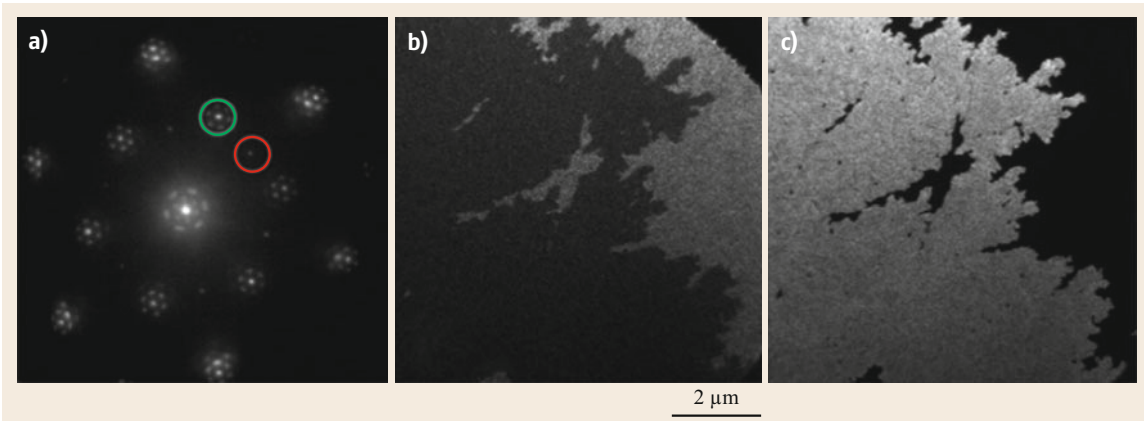

Fig. 22.12a–c Steps involved in phase identification for iron oxide films using **(a)** LEED and **(b,c)** LEEM structures. Images **(b)** and **(c)** focus on the *green*- and *red-labeled* LEED spots in **(a)**, which correspond to bright areas with corundum and spinel structures, respectively. The electron energy in all measurements was 38 eV (Reprinted from [22.28], with permission from Elsevier)

low-dimensional systems. For such systems, X-PEEM also facilitates chemical contrast, which is obtained by tuning the incident photon energy at the absorption edges of the various elements. Furthermore, the abovementioned problem with low counting rates when attempting to achieve high-resolution performance is mitigated by the high flux of synchrotron sources.

As an example of the ability of X-PEEM to resolve chemical species, Fig. 22.11 shows four images of the same sample surface obtained with photoemission energies corresponding to the indicated core levels. The sample is Rh(110) modified with Au and Pd of sub-ML coverage, and this material has been used as a catalyst for water formation. This leads to reorganization and phase separation within Au and Pd adlayers, which are spectator species (they do not actively participate in the reaction but they do block some active sites on the surface). The phase separation is clearly visible in the energy-resolved X-PEEM images [22.27].

Among the various electron microscopy techniques available, one particular method exploits low-energy (on the order of 1–100 eV) electrons and is therefore known as low-energy electron microscopy (LEEM) [22.29]. In this method, the probe is an electron beam that impinges on the sample and is backscattered towards a screen through an electron optical column. The typical spatial resolution of this approach is high (about 10 nm laterally). An important feature of the technique is the ability to image surface structures in situ and in real time, even at relatively high temperatures, which makes LEEM a very powerful tool for studying surface phase transformations, mainly by aiding the identification of the different phases. The example presented in Fig. 22.12 is phase identification for an iron oxide film containing mixed phases. LEEM also allows for the acquisition of low-energy electron diffraction (LEED) patterns. Figure 22.12a shows that these patterns are related to the presence of differ-

ent crystal structures, namely corundum (green circle) and spinel (red circle). By selecting the momentum of the emitted electrons, different LEEM images can be acquired, as shown in Fig. 22.12b,c. Further chemically sensitive measurements (not shown) revealed the presence of both Fe_3O_4 and Fe_2O_3 (the latter also in different phases) [22.28].

Finally, scanning probe techniques are widely exploited in the study of low-dimensional systems. The most well known are atomic force microscopy (AFM) [22.30] and scanning tunneling microscopy (STM) [22.31], both of which utilize sharp tips that are placed in close proximity (subnanometer range) to a sample surface and scanned laterally by piezoelectric actuators, allowing the surface morphology to be measured.

AFM is based on the detection of attractive and repulsive interactions between the apex atoms in the probe tip and atoms on the surface of the sample. The tip is typically mounted on a cantilever that bends to a degree that depends on its hardness and the strength of the interactions, which have different effective ranges; for instance, chemical interactions are short-range interactions whereas van der Waals and electrostatic interactions are longer-range interactions. The strengths of the different types of interactions depend on the system that is probed. Measurements can either be static (the bending of the cantilever is measured directly) or dynamic (the cantilever is oscillated close to resonance and the interaction forces influence the frequency, amplitude, or phase of the oscillations).

In STM, a metallic tip is brought in close proximity to (a few angstroms from) the surface of a conducting sample, leading to an overlap of the wavefunction of the apex atom in the probe tip with surface electronic states. If an electrostatic potential is applied between the probe tip and the surface, the quantum tunneling of electrons is facilitated. A tunneling current can therefore be measured that depends strongly on the tip–sample distance, which is the reason for the extremely high spatial resolution (atomic level) of STM.

AFM is a straightforward choice when examining insulating materials because, unlike STM, the sample and tip do not need to be conductors. This is particularly useful for thick oxides that, in principle, cannot be investigated using STM (although they can be made sufficiently conductive for STM using specific strategies, e.g., by producing defects [22.32]).

Figure 22.13 shows, as an example, an AFM topographic image of the surface of a thin (8 ML) MgO film on Fe(001). MgO is a wide-gap insulator and is therefore difficult to study with STM unless it is present as ultrathin layers on conducting substrates (see later in this chapter). Figure 22.13 reveals, in particular, the development of directional step edges that form due to the presence of misfit dislocations [22.7].

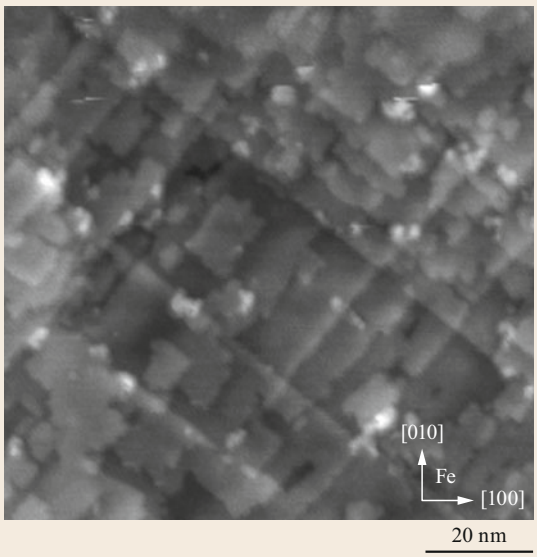

Fig. 22.13 AFM image of an 8 ML thick MgO film on Fe(001) (Reprinted from [22.7], with permission from Elsevier)

On the other hand, STM is widely used for ultrathin oxide films because it is often performed in UHV conditions, and these are the conditions that are usually applied when samples of this nature are investigated. An example of the use of STM in this context was shown earlier in the chapter: see Fig. 22.1. Very high quality STM images of ultrathin oxides with atomic resolution have also been obtained in many other cases. Figure 22.14 shows two examples relating to a 2 ML thick MgO film deposited on Ag(001) and a FeO monolayer grown on Pt(111). In their bulk forms, both oxides have a rock salt crystal structure (Table 22.1) that develops along different crystallographic planes in the images due to the epitaxial relationships of the oxides with their respective substrates (see also Sect. 22.2.1).

22.2.3 Magnetic Measurements

For thin and ultrathin magnetic oxide films, it is also necessary to experimentally characterize the magnetic properties of the samples. All of the methods discussed in earlier sections can be implemented as a magnetic variant, as described below.

Magnetic Spectroscopic Techniques

In magnetized FM samples, the internal magnetic field acts as a quantization direction for electron spin, mean-

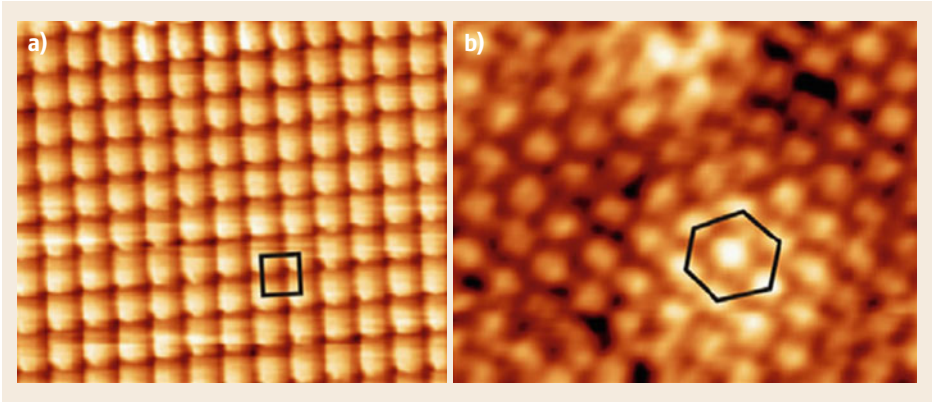

Fig. 22.14a,b STM images of **(a)** 2 ML MgO/Ag(001) and **(b)** 1 ML FeO/Pt(111) (both images show regions $3.5 \times 2.9\,\mathrm{nm}^2$ in size). Both oxides have a rock salt structure, but they expose different crystallographic planes due to differences in substrate symmetry (Reprinted from [22.33], with permission from Elsevier)

ing that the electrons emitted in photoemission experiments have a spin quantum number. This allows the spin polarization P of the photoelectrons to be defined as follows:

$$P = \frac{N_\uparrow - N_\downarrow}{N_\uparrow + N_\downarrow} , \qquad (22.1)$$

where the up and down arrows refer to the spin direction with respect to the quantization axis. The measurement of P in PES experiments is achieved by adding spin detectors (polarimeters) to the standard equipment, leading to a method known as spin-polarized PES (SPPES) or spin-resolved PES (SRPES). Polarimeters are commonly used to measure spin scattering asymmetries, although they have the drawback of dramatically reducing the signal intensity. State-of-the-art instruments and synchrotron radiation measurements can largely bypass this limitation, making SPPES an important method for deriving information on the spin-resolved electronic structures of magnetic materials.

As an example, Fig. 22.15 presents PES and SPPES spectra for a $CrO_2(100)$ epitaxial film on TiO_2. As also mentioned in Table 22.3, CrO_2 is a FM oxide with an ordering temperature that is above RT in its bulk form. *Fujiwara* et al. [22.34] report SPPES measurements obtained at both RT and 40 K that are consistent with this characterization. The difference in the spin-polarized density of states is also related to the half-metallicity of CrO_2.

A different approach can be employed to measure spin-polarized electronic states in XAS experiments. In such experiments, dipole transitions do not allow spin flips, so, in principle, it is possible to measure the number of d holes with up and down spin provided that either spin-up or spin-down electrons can be selectively excited by the x-ray beam. This is achieved by using circularly polarized photons, which are available in dedicated beamlines of synchrotron radiation facilities. In x-ray magnetic circular dichroism (XMCD), XAS spectra with oppositely (either right or left) circularly polarized x-ray photons are acquired and then subtracted from each other. The XMCD signal is therefore proportional to the difference in spin-up and spin-down holes in the d shell, and its sign provides information on the direction of the sample magnetization. The strongest signal is obtained when the magnetization is parallel to the propagation direction of the photon beam. As it is based on XAS, XMCD also provides elemental and shell specificity, thus permitting the identification of magnetized species in multicomponent (e.g., multilayer) samples. Furthermore, it has been demonstrated that simple sum rules can be used to quantitatively determine spin and orbital angular momenta from XMCD spectra.

As an example, Fig. 22.16 reports one of the first XMCD measurements, which was performed on a Ni(111) crystal [22.35]. The opposite signs of the XMCD peaks at the two absorption edges are typical of XMCD spectra of all FM TMs.

Just as for XMCD, it is possible to acquire XAS spectra with linearly polarized x-ray photons where the polarization direction is either in or out of the synchrotron plane. Subtracting such spectra from each other leads to an x-ray magnetic linear dichroism (XMLD) spectrum. The XMLD signal is not related to the magnetization vector $\boldsymbol{M}$ (unlike in XMCD), which is zero in an AF material, but to the direction of the local magnetic moments. This implies that XMLD is a very special method: a magnetic spectroscopy that is sensitive to the AF order of a sample. On the other hand, an XMLD signal can be also produced by nonmagnetic properties, such as asymmetry of the crystal field of the

sample. Thus, care must be taken when analyzing the experimental data.

In the example shown in Fig. 22.17, XMLD spectra were acquired for an ultrathin (7 ML) NiO film on Fe(001). The spectra were obtained at the Ni L_2 edge for different measurement geometries, i.e., either normal ($\theta = 90°$) or grazing ($\theta = 30°$) incidence and with the substrate magnetization $\boldsymbol{M}$ in either the horizontal or the vertical plane (i.e., parallel or perpendicular to the x-ray linear polarization direction, respectively). Since the crystal field shows fourfold symmetry about the NiO(001) surface normal, it provides a constant contribution as a function of the azimuth, so the difference between the spectra acquired at normal incidence with crossed polarizations is due to the presence of long-range AF order in the measured film [22.36].

Magnetic Microscopic Techniques

The different responses of magnetic samples upon the absorption of differently polarized x-rays can also be exploited to obtain a magnetic contrast in images acquired with an X-PEEM microscope. This involves implementing the XMCD and XMLD techniques to realize XMCD-PEEM and XMLD-PEEM measurements. Such measurements are performed by acquiring images at photon energies corresponding to peaks in the XMCD and XMLD spectra of a magnetic element present in the sample with different circular or linear polarizations. The acquired images are then subtracted from each other and normalized in order to obtain the magnetic contrast image. Since the resolution of state-of-the-art X-PEEM microscopes can be as low as 10 nm, the images can reveal details of the magnetic domain and domain wall microstructure in both FM and in AF materials using XMCD and XMLD, respectively.

As an example, Fig. 22.18 shows XMCD-PEEM images of Fe domains in an Fe/NiO/Fe trilayer [22.37, 38]. Here, the incident direction of the x-ray beam was parallel to the horizontal axis of the image. The magnetization in the black domains differs from that in the white domains by 180°, as indicated by the red and yellow arrows, while domains differing in magnetization by 90° with respect to the white domains are not resolved (gray areas).

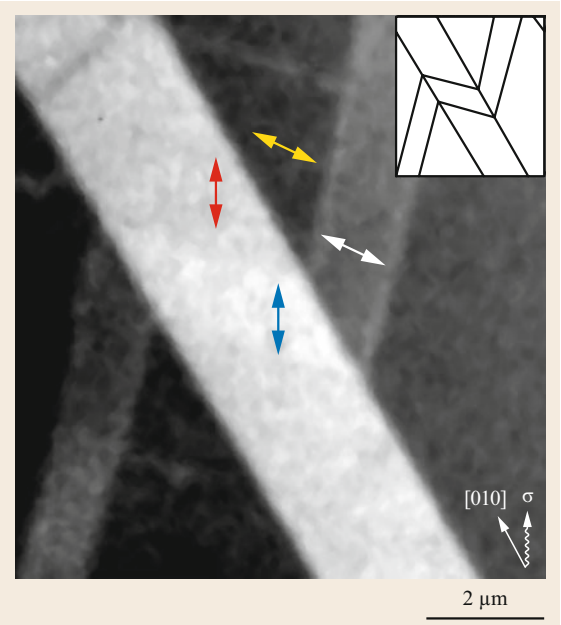

Fig. 22.19 XMLD-PEEM image of the surface of a NiO(001) crystal. The different gray tones correspond to different AF domain orientations (Reprinted with permission from [22.39]. © 2001 by the American Physical Society) ◄

An example of XMLD-PEEM is shown in Fig. 22.19, which presents the AF domain configuration of a cleaved NiO(001) crystal. Here, the linear polarization was in the synchrotron plane and the beam direction was 30° from the [010] sample direction, as indicated in the inset. Four different gray tones are discernible, which relate to four different AF domains. Note that the direction of the local magnetic moments has both in-plane and out-of-plane components; see [22.39] for a full description.

There is also a spin-polarized version of LEEM (SPLEEM), in which spin-polarized electrons are directed onto the sample. The polarization $\boldsymbol{P}$ of the impinging electron beam can potentially be oriented in any direction; low-energy electrons are either backscattered or absorbed depending on their spin and on the sample magnetization $\boldsymbol{M}$, so the reflected electron beam permits the imaging of magnetic domains and domain walls in FM samples [22.41].

Figure 22.20 demonstrates the ability of SPLEEM to resolve FM domains with a lateral resolution of few tens of nm in different spatial directions. The figure compares the magnetic domain configuration in a thin (11 ML) Co film on Ir(111) with that in a thin Co film intercalated beneath graphene that had previously been grown on the same Ir(111) substrate. In the former case, the Co magnetization is in the plane of the film,

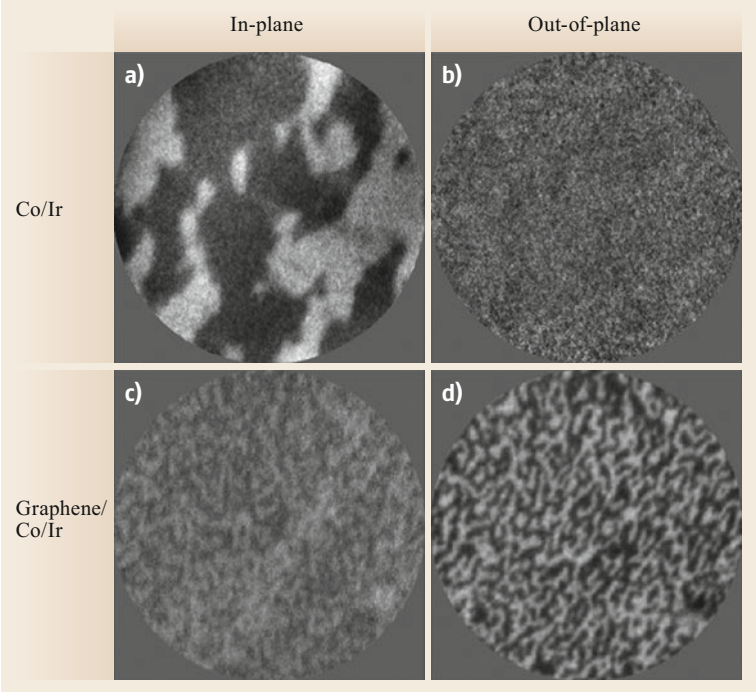

Fig. 22.20a–d SPLEEM images (field of view: 10 μm) of 11 ML of Co deposited on Ir(111) **(a,b)** and intercalated at the graphene/Ir(111) interface **(c,d)** (Reprinted from [22.40], with the permission of AIP Publishing)

whereas it is in the out-of-plane direction in the latter case [22.40].

There are also magnetic versions of both AFM and STM: magnetic force microscopy (MFM) [22.42] and spin-polarized scanning tunneling microscopy (SP-STM) [22.43], respectively.

In MFM, the FM sample produces a magnetic stray field that is detected by measuring the force it exerts on another small magnetic element, the tip. This approach is very similar to standard AFM, although the measured forces are usually considerably smaller. It is worth noting that a strong force would correspond to a strong magnetic interaction between the tip and the sample, which could potentially modify the magnetic configuration of the latter (clearly an unwanted effect). In a typical situation, the tip is tens of nm away from the surface, and bending of the order of a nm is measured [22.44]. MFM measurements are therefore usually performed in the dynamic mode (see above). So far, MFM has generally been employed in magnetic recording research, largely because it does not require specific sample preparation procedures, magnetic recording media have smooth surfaces and very high stray fields, and such media are not strongly influenced by external magnetic fields.

Figure 22.21 shows a typical FM domain configuration in a commercial hard disk; this configuration represents the recorded tracks [22.42].

In magnetic materials, the exchange interaction introduces a term that removes the spin degeneracy of the electronic bands. Provided that magnetized tips are employed, this implies that the tunneling probability in STM is dependent on the relative orientation of the magnetization vectors of the tip and sample, a scheme very similar to that used in magnetic tunneling junctions [22.45]. Since different tunneling probabilities reflect different apparent heights in the sample topography, this SPSTM approach permits the visualization of magnetic domains with the high spatial resolution typical of STM. In particular, it is possible to show that a magnetic contrast is obtained by mapping the differential conductance $\mathrm{d}I/\mathrm{d}V$, where I is the tunneling current and V is the applied bias [22.46].

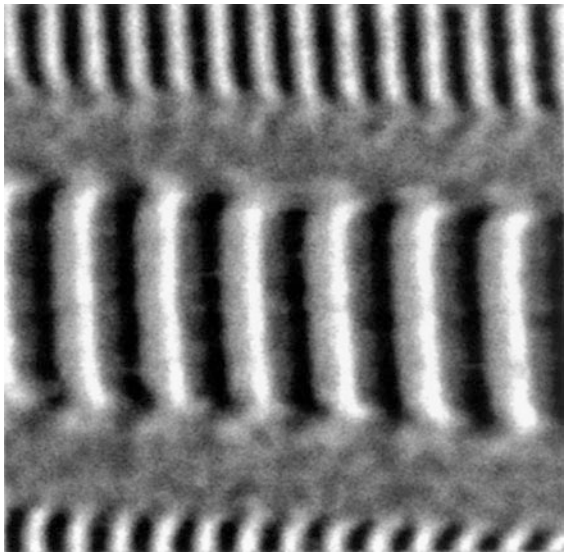

Fig. 22.21 Standard MFM image of recorded tracks on a hard disk. The image size is $12 \times 12\,\mu\mathrm{m}$ (Reprinted by permission from [22.42], © Ann. Revs. 1999)

One important aspect of SPSTM measurements is the preparation of suitable magnetized tips, which should be able to guarantee both high spatial resolution, high spin polarization, and very low stray fields to ensure that the magnetic configuration of the sample is not perturbed. One of the most successful methods of achieving this is to coat a standard W tip with an ultrathin layer of magnetic material such as Fe or Cr. In-plane or out-of-plane (with respect to the sample surface) magnetization of the tip can be realized by selecting an appropriate material and thickness for the coating [22.43].

An interesting example of the magnetic imaging capabilities of SPSTM is given by the measurement of Cr(001) crystal surfaces. Cr is termed a topological AF, as each (001) layer is FM and the magnetizations of the adjacent layers are opposite to each other, resulting in an AF structure overall. Therefore, when observing the Cr(001) surface, each terrace step separating an odd number of layers also separates oppositely magnetized FM domains. This is clearly apparent in Fig. 22.22, which compares the topography of a Cr(001) surface characterized by several single-layer steps (Fig. 22.22a) to a differential conductance map, which reveals oppositely magnetized FM domains (Fig. 22.22b) characterized by different gray tones [22.46].

Optical Methods: The Magneto–Optic Kerr Effect

The magneto-optic Kerr effect (MOKE) is the phenomenon where the properties of a linearly polarized laser beam change as it is reflected from the surface of a FM sample. The changes of interest are typically either a rotation of the direction of polarization or a shift in the ellipticity of the light, both of which are proportional to the magnetization of the sample. The depth sensitivity of MOKE is on the order of tens of nm, and it can be performed in different geometries by illuminating the sample at different angles of incidence. The application of a variable external magnetic field $\boldsymbol{H}$ per-

mits the acquisition of magnetic hysteresis loops. In the polar configuration (i), the beam hits the surface at normal incidence and the measured effect is related to the out-of-plane component of $\boldsymbol{M}$. In the longitudinal configuration (ii), the angle of incidence of the light is not zero and $\boldsymbol{H}$ is applied within the plane of incidence and parallel to the sample surface. Note that the polarization of the light can either be transverse magnetic or transverse electric and there is no longitudinal Kerr effect at normal incidence. In the transverse configuration (iii), $\boldsymbol{H}$ is perpendicular to the plane of incidence (which is, again, not normal to the surface). In this configuration, only a transverse magnetic polarized beam generates the Kerr effect.

This set of different measurement geometries permits vector magnetometry—the full spatial determination of the magnetization vector $\boldsymbol{M}$ during the hysteresis loop, as exemplified by Fig. 22.23, which relates to a 180 nm thick CoNiO film [22.47]. It is important to note that MOKE is a relative magnetometry technique, i.e., it is not able to measure the absolute value of $\boldsymbol{M}$.

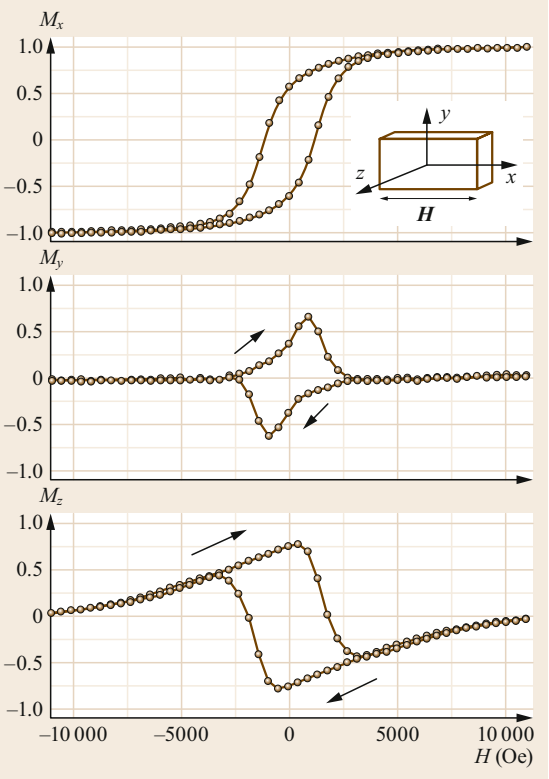

Fig. 22.23 Reduced components of the magnetization vector as a function of the applied magnetic field $\boldsymbol{H}$ of a 180 nm thick CoNiO film. The components are normalized to the saturation value of $\boldsymbol{M}$ (Reprinted from [22.47], with the permission of AIP Publishing)

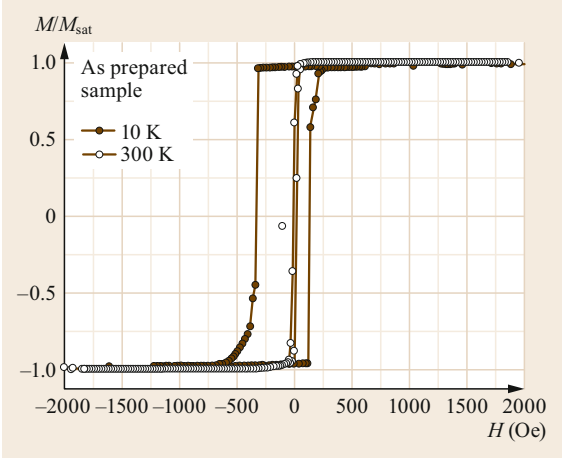

Fig. 22.24 Hysteresis loops of an Fe layer (21 nm thick) deposited on a CoO film (33 nm thick). *Open dots*: RT measurements obtained above the Néel temperature. *Filled dots*: magnetization reversal observed after field cooling to 10 K (Reprinted with permission from [22.48]. © 2007 by the American Physical Society)

The MOKE technique has been widely applied to the characterization of AF magnetic oxides included in layered FM/AF structures that exhibit the exchange bias (EB) effect [22.49]. This effect is seen when a system featuring a FM/AF interface undergoes a field cooling procedure starting from a temperature intermediate between the ordering (Curie) temperature of the FM material and the ordering (Néel) temperature of the AF material and finishing below the latter under the influence of an externally applied magnetic field. Due to the interaction between the magnetic moments at the interface, a unidirectional magnetic anisotropy is established in the sample. This can be observed as a rigid shift (EB field, H_E) of the hysteresis loop of the FM/AF system, which is usually accompanied by an increase in the coercive field H_C. AF oxides, especially NiO and CoO, have been widely studied as AF layers in EB systems [22.50].

Figure 22.24 shows the occurrence of both effects in an Fe/CoO bilayer. The MOKE loop at 300 K was obtained for an unbiased sample (open dots), whereas that at 10 K (filled dots) was attained subsequently to field cooling and clearly shows a large increase in H_C and a shift of the hysteresis loop of about 100 Oe [22.48].

22.3 Engineering Oxide–Metal Interfaces with Buffer Layers

The physical properties of layered metal–oxide heterostructures depend strongly on the atomistic details of the oxide–metal interface, so fine control of the boundary region is required to obtain specific functionalities [22.10, 50–53]. The structure and chemical composition of metal–oxide interfaces can be tailored by exploiting an appropriate buffer layer, i.e., a nanometer-thick film inserted between the substrate and the overlayer. The presence of oxide or metal buffer layers can assist the growth of oxide films on metallic substrates as well as the deposition of metallic films on oxide surfaces.

22.3.1 Buffer Layers

According to the recent literature, the presence of a buffer layer can affect the oxide–metal heterostructure in the following ways:

1. *It influences the chemical composition of the oxide–metal interface.* During the formation of an oxide–metal layered system, the metallic layer is often oxidized [22.12, 54, 55]. This oxidation occurs for two main reasons: (i) whenever an oxide film is grown via reactive deposition on highly oxidizable metallic substrates such as those composed of FM elements, the oxygen-rich atmosphere induces the development of a thin native oxide layer on the substrate [22.7, 56]; (ii) if the metallic layer can form an oxide compound that is more thermodynamically stable than the oxide it is interfaced with, migration of oxygen atoms triggers the reduction of the oxide and the oxidation of the metal [22.57, 58]. In case (i), the presence of the buffer layer can hinder substrate oxidation by preventing direct contact between its surface and gaseous oxygen, while in case (ii) it may inhibit interfacial redox reactions.
2. *It promotes the stabilization of high-quality interfaces between metals and their native oxides.* The crystal structure of a metal is often very different from that of its native oxide. For instance, Mg and Co crystallize with a hexagonal close-packed lattice, while the corresponding monoxides MgO and CoO adopt a cubic rock salt structure. Because of this symmetry mismatch, the oxidation of bulk metals results in poor-quality interfaces or even in the development of amorphous oxide layers. This drawback can be circumvented by growing metastable films, i.e., films that mimic the crystal structure of the substrate. By growing a suitable metastable phase, good epitaxy with the native oxide can be obtained [22.59–61].
3. *It can be used to tailor the morphology of metallic films grown on oxide substrates.* In epitaxial growth, the overlayer wets the substrate if the condition $\gamma_f + \gamma_{f/s} \leq \gamma_s$ is satisfied, where γ_f and γ_s are the surface free energies of the film and the substrate, respectively, while $\gamma_{f/s}$ quantifies the interaction between the substrate and the overlayer [22.62, 63].

Due to the low surface free energies of oxides, weakly interacting metals deposited on oxide surfaces generally nucleate 3-D islands. On the other hand, covering the oxide surface with a buffer layer of another oxide or metal prior to the deposition of a metal can provide a template for the growth of two-dimensional metallic films. Effective buffer layers are metals or oxides that interact strongly with their oxide or metal counterparts.

The following sections discuss some examples of the use of metallic or oxide buffer layers to tune the chemical compositions and/or the morphological structures of metal oxide heterostructures.

22.3.2 Metallic Buffer Layers

Ni and Co films on an Fe(001) surface are prototypical examples of magnetic metallic buffer layers used for the growth of epitaxial oxides on a FM metallic substrate. When NiO or CoO are grown directly on Fe(001) by reactive deposition, extensive oxidation of the substrate is observed [22.13, 64, 65]. This oxidation can be suppressed to some degree (but not prevented) by passivating the clean Fe(001) surface with 1 ML of oxygen, yielding an Fe(001)-p(1×1)O surface [22.66–70]. Figure 22.25a displays XAS spectra acquired after the deposition of NiO on an Fe(001)-p(1×1)O surface.

The XAS spectrum obtained at the Fe $L_{2,3}$ edges from Fe(001)-p(1×1)O is characterized by two peaks at about 708 and 722 eV. After the deposition of 20 ML of NiO, multiplet fine structure develops, as shown in Fig. 22.25a, indicating the chemical modification of the substrate. A comparison of the spectra of Fe oxides is provided in the top panel of Fig. 22.25a. It is apparent that a considerable amount of Fe oxide develops during NiO growth, and that the amount of Fe oxide increases as the system is annealed up to 350 °C. Finally, annealing at higher temperatures induces the dissolution of both NiO and Fe oxide, restoring the pristine metallic shape of the Fe peaks. Oxidation of the substrate also occurs with the deposition of CoO on the Fe(001)-p(1×1)O surface, as revealed by the XPS spectra shown in Fig. 22.25b. The Fe 2p peaks acquired on 1 ML CoO/Fe(001)-p(1×1)O can be obtained through the convolution of the Fe 2p transitions characteristic of Fe(001)-p(1×1)O (solid line), Fe_3O_4 (dotted line), and FeO (dashed line). Figure 22.25b also reveals that the thickness of the Fe oxide increases as the amount of CoO deposited increases.

The substrate oxidation observed at the interfaces NiO/Fe(001)-p(1×1)O and CoO/Fe(001)-p(1×1)O is mainly due to the gaseous oxygen used during the reactive deposition. As a matter of fact, assuming a typical deposition rate of 1 ML/min for Ni or Co and a background oxygen pressure of 10^{-6} mbar, the ratio of oxygen molecules that reach the surface to metal atoms

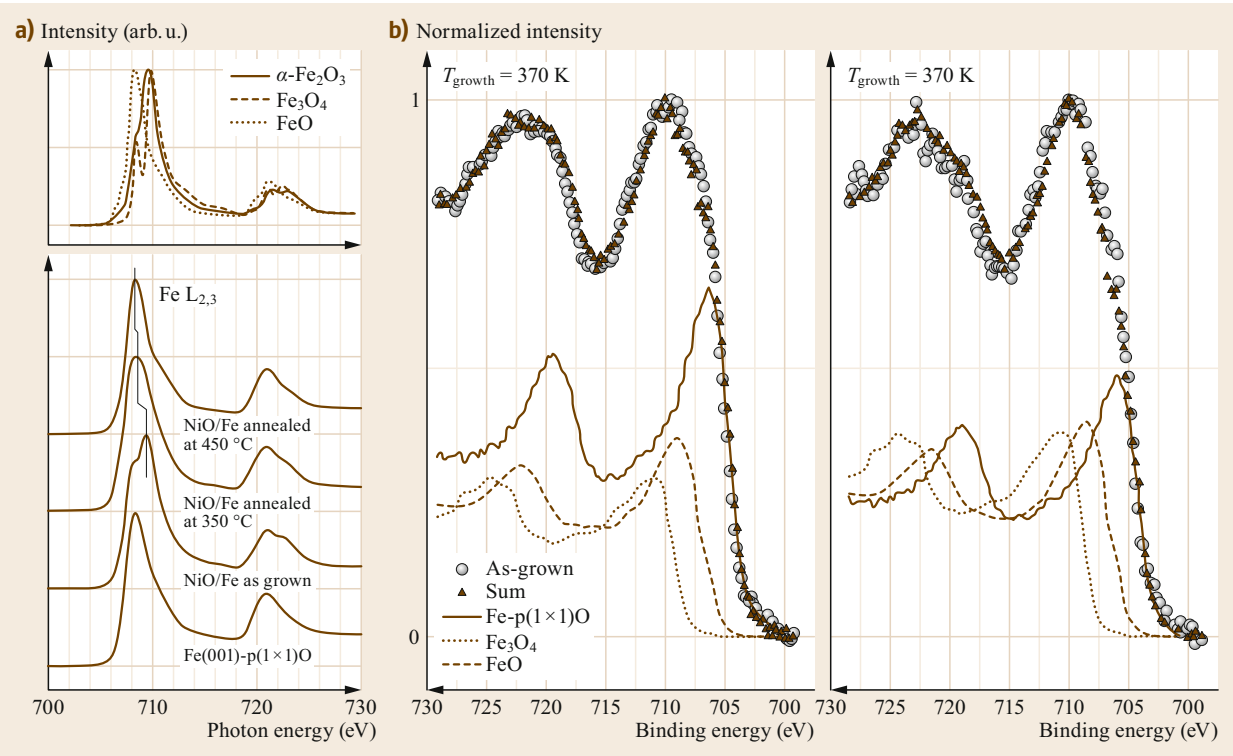

Fig. 22.25 **(a)** XAS spectra obtained at the Fe $L_{2,3}$ edges in the total electron yield mode from as-grown Fe(001)-p(1×1)O and 20 ML NiO/Fe(001) after annealing at 350 and 450 °C. Reference curves measured at the Fe $L_{2,3}$ edges from α-Fe_2O_3, Fe_3O_4, and FeO are shown at the *top* (Reprinted with permission from [22.13]. © 2004 by the American Physical Society). **(b)** *Open dots* Fe 2p XPS spectra from 1 ML CoO/Fe-p(1×1)O (*left*) and 5 ML CoO/Fe-p(1×1)O (*right*) bilayers. *Triangles* represent the sum of the Fe-p(1×1)O substrate spectrum (*solid*), the Fe_3O_4 spectrum (*dotted*), and the FeO (*dashed*) reference spectrum (Reprinted from [22.64], with permission from Elsevier)

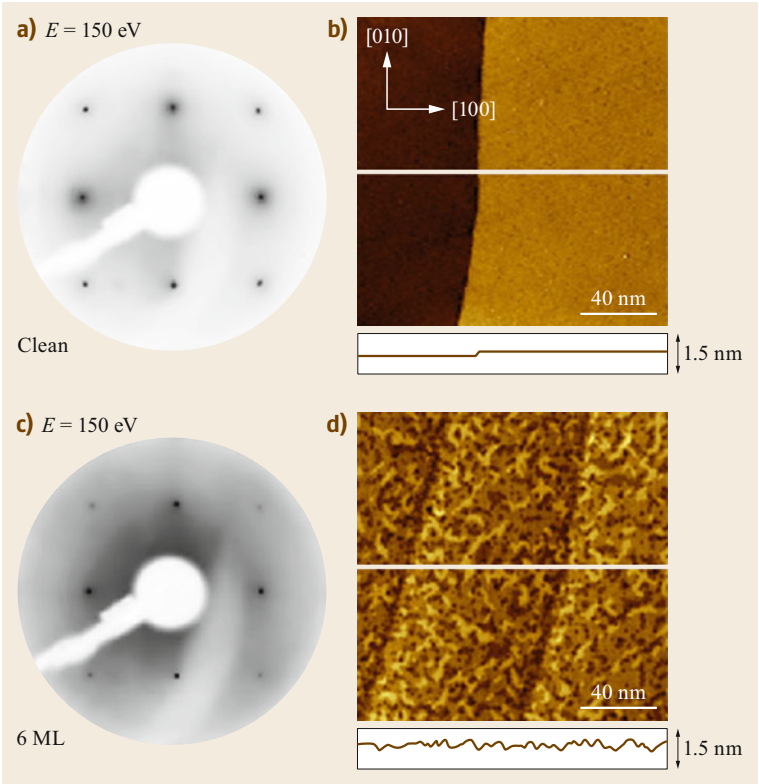

Fig. 22.26a–d LEED patterns and STM constant-current images acquired on the Fe(001) substrate **(a,b)** and after the deposition of a 6 ML thick Ni film **(c,d)** (Reprinted from [22.71]. © IOP Publishing. Reproduced with permission. All rights reserved)

that reach the surface is about 45, implying that the substrate is already covered with a native oxide layer when NiO or CoO starts to nucleate on Fe(001).

In order to avoid direct contact between the oxygen molecules and the Fe(001) surface, a Ni (Co) film can be deposited on the substrate before NiO (CoO) growth. In the following, we will see that it is important to choose an appropriate buffer layer to protect the substrate from oxidation. Bulk Ni crystallizes in a face-centered cubic (fcc) structure with a lattice constant of 352 pm, considerably smaller than that of fcc NiO (417 pm). However, ultrathin Ni films deposited on the Fe(001) surface adopt a body-centered cubic structure (bcc) with the same lattice constant as that of the Fe substrate [22.71, 73]. Figure 22.26a,c display LEED patterns measured on an Fe(001) substrate and a 5 ML thick Ni film, respectively. The diffraction patterns show the same unit cell, revealing that the Ni film grows pseudomorphically on the Fe(001) substrate. Figure 22.26b,d present STM images acquired on the surfaces of Fe(001) and 6 ML Ni/Fe(001), respectively. The bare surface displays atomically flat terraces separated by monoatomic steps, while the surface roughness increases slightly after Ni deposition.

In order to explore the possibility of using it as a protective coating against Fe oxidation, an ultrathin Ni film grown on Fe(001) was exposed to molecular oxygen [22.72, 75]. Figure 22.27a shows the evolution of AES curves acquired at normal (solid lines) and grazing (dotted lines) emission angles. The shape of the low kinetic energy peaks of AES is particularly sensitive to the chemical states of the surface elements, so it can be used to check their oxidation states [22.76]. The spectrum of the as-deposited sample (black curve) is characterized by two peaks at about 46 and 61 eV, corresponding to metallic Fe and Ni, respectively. Exposure to oxygen results in the appearance of a shoulder at lower kinetic energy than the metallic Fe peak. This feature indicates the presence of Fe oxide, as testified by the top spectrum (green curve), which was acquired for Fe(001) oxidized with 50 L of O_2. The Fe oxide peak becomes larger with increasing oxygen exposure (blue curve) and subsequent annealing in a vacuum (brown curve). Therefore, oxidation of the Ni/Fe(001) sample triggers the segregation of Fe from the bulk to the surface, where it is oxidized. Comparison of the STM images acquired before (Fig. 22.27d) and after (Fig. 22.27c) oxidation reveals that oxygen exposure causes surface roughening. Annealing in vacuum

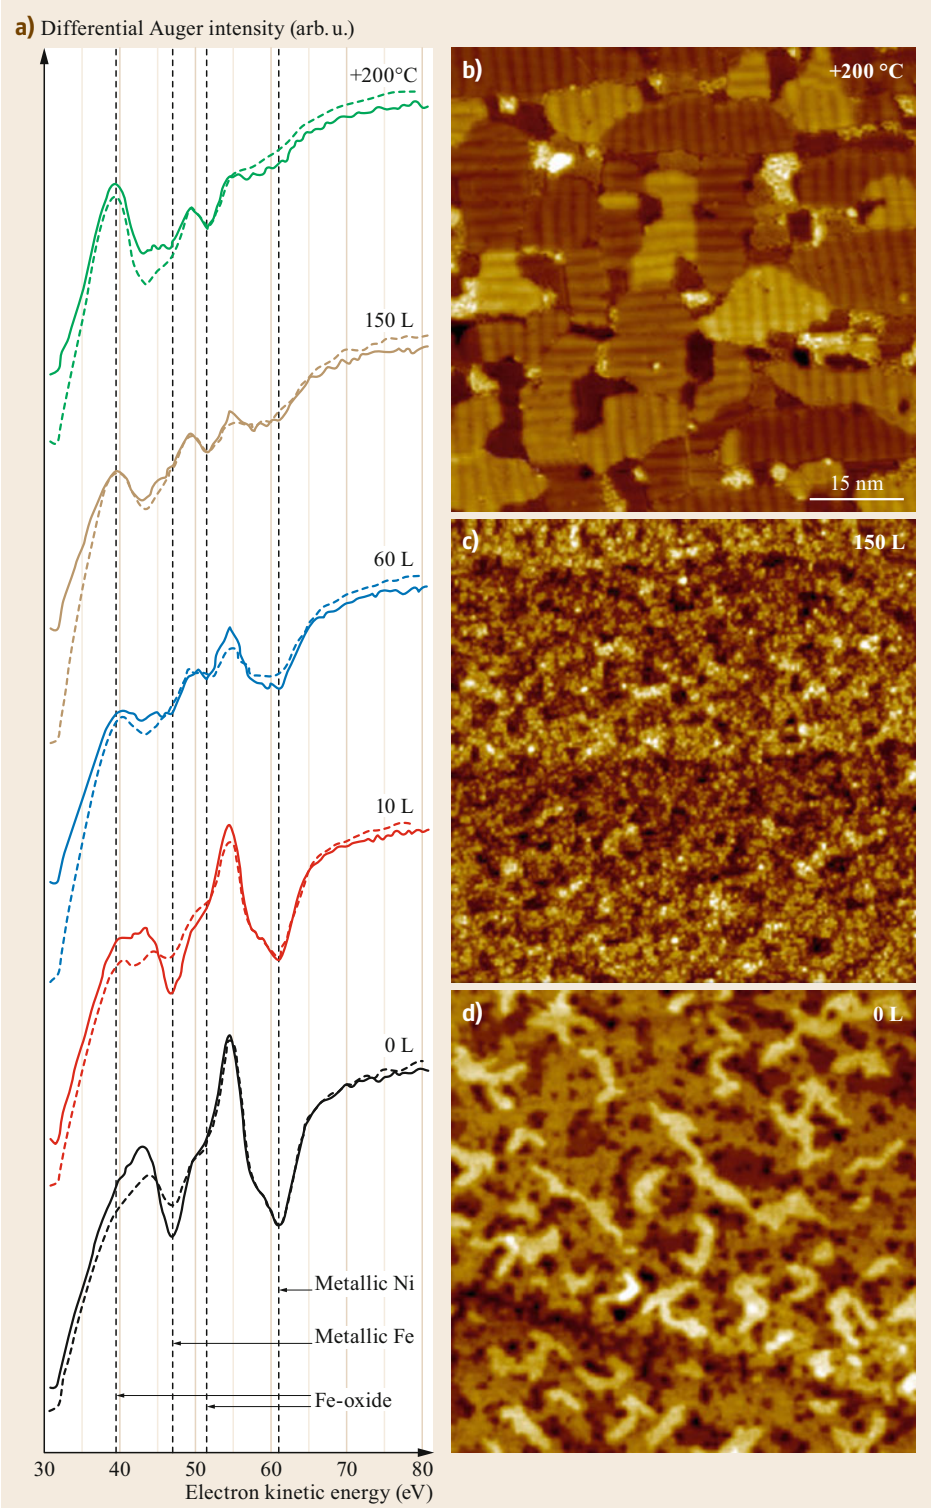

Fig. 22.27

(Fig. 22.27b) restores the atomically flat surface. This surface is characterized by a nanometric Moiré pattern arising from interference of the topmost hexagonal FeO(111) layer (not shown; see [22.72]) with the square Ni/Fe(001) substrate. In conclusion, the Ni buffer layer cannot prevent the oxidation of the Fe(001) substrate, indicating that the NiO/Fe(001) interface is highly unstable.

A completely different oxidation path is observed when a Co buffer layer is used to protect the Fe(001) substrate. As in the case of Ni, Co grows on Fe(001) as a tetragonally distorted body-centered cubic (bcc)

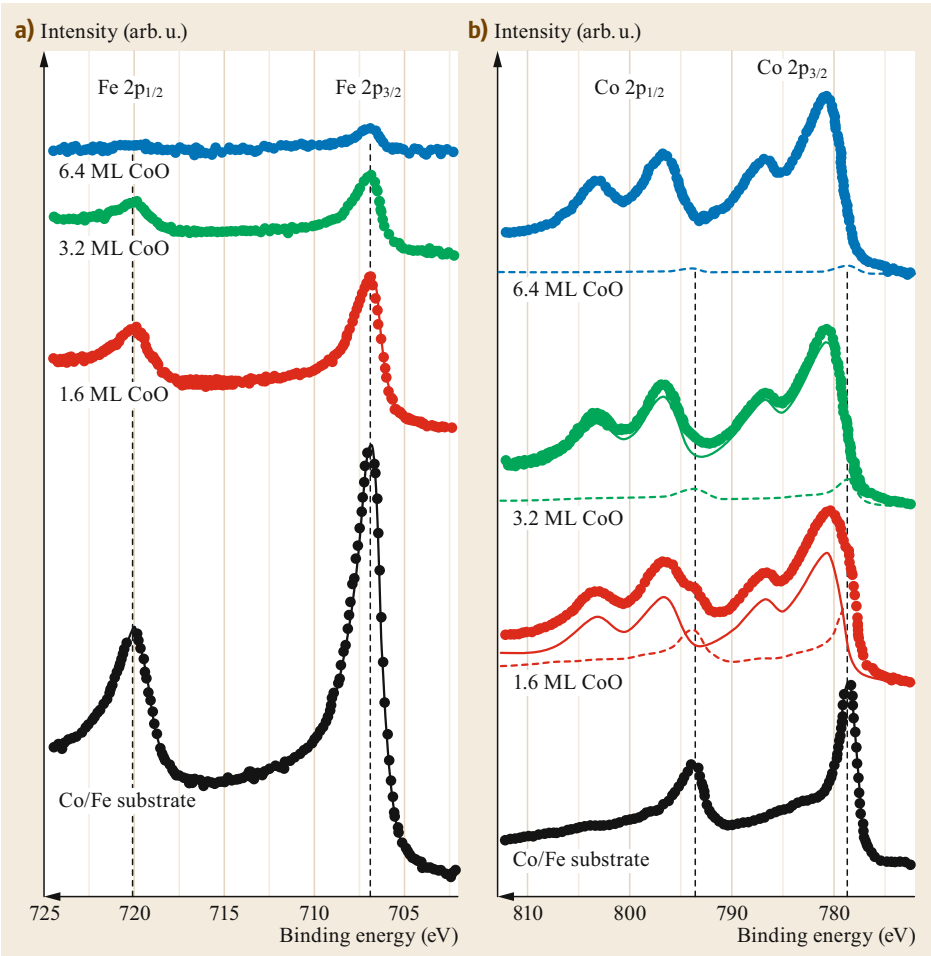

Fig. 22.29a,b XPS spectra obtained for various levels of CoO coverage. *Co/Fe substrate* refers to the surface of a 5 ML thick Co film grown on Fe-p(1×1)O. **(a)** Fe 2p peaks (*circles* are the raw data, *continuous lines* are fits to the data). **(b)** Co 2p energy region (*circles* are the raw data, *continuous lines* are fits to data for the oxidized components; *dashed lines* are fits to data for the metallic components) (Reprinted from [22.77], with permission from Elsevier)

metastable phase [22.78, 79]. The data presented in the following relate to a Co film grown on an Fe(001)-p(1×1)O surface [22.74], but similar results were observed when a Co buffer layer was stabilized on oxygen-free Fe(001). Figure 22.28a displays AES spectra measured for the Fe(001)-p(1×1)O (black curve), the 5 ML Co film (red curve), and after dosing with 20 L (green curve) and 480 L (blue curve) of oxygen. In contrast to the case in which Ni/Fe(001) is oxidized, no Fe oxide signature is observed in the spectra. However, if the sample is annealed to 300 °C in UHV, a small amount of Fe oxide can be discerned (brown curve). Figure 22.28b and c present STM images of the oxidized sample showing the nucleation of defective CoO_x islands. Due to the tunneling conditions used for the imaging, the islands appear as depressions with respect to the substrate, as indicated by the line profile drawn in Fig. 22.28d. Moreover, atomic-scale defects are visible inside the islands; these defects were assigned to oxygen vacancies [22.74].

Due its chemical stability, the Co/Fe(001) bilayer is a promising template for growing sharp CoO/Fe interfaces [22.77]. Figure 22.29 displays the XPS spectra acquired in the Fe 2p and Co 2p energy regions after the reactive deposition of increasing amounts of CoO. The Fe 2p peak position is that of metallic Fe at every step of CoO deposition, while the shape of the Co 2p doublet approaches that of oxidized Co, indicating the development of a stoichiometric oxide.

The absence of Fe oxidation also influences the morphology of the growing film. While CoO deposited directly on Fe(001)-p(1×1)O is characterized by a featureless mesoscopic morphology [22.65], the film grown on the Co buffer layer consists of a periodic array of islands (Fig. 22.30). The ordered nucleation of CoO is due to the presence of a network of misfit dislocations at the CoO/Fe(001) interface.

22.3.3 Oxide Buffer Layers

This section explores how oxide buffer layers have been successfully used to control both the interfacial chemical reactions and the morphologies of oxide–metal heterostructures.

Allegretti et al. used a CoO buffer layer inserted between NiO and Co to obtain a chemically sharp interface between an AF oxide and a FM metal [22.80]. Figure 22.31a shows the XPS Co and Ni $2p_{3/2}$ peaks acquired after the deposition of metallic Co on a NiO(001) surface. According to the upper curve, if the Co film is deposited at 100 K, its spectrum is characterized by the Co^0 component only. On the other hand, heating the Co/NiO sample at 550 K triggers the oxidation of Co, as revealed by the presence of a Co^{2+} component in the lower spectrum. The chemical instability of the Co/NiO(001) interface is also indicated by the evolution of the Ni $2p_{3/2}$ peak, as displayed in Fig. 22.31c. There are no discernible signatures of metallic N in the spectra acquired for the NiO surface (top) and the Co-covered sample at 100 K (middle), while a significant fraction of Ni^0 is present after heating.

The redox reaction can be prevented by depositing a 1–2 ML thick CoO buffer layer on the NiO before the growth of Co. Figure 22.31b displays the Co $2p_{3/2}$ peaks measured for the as-deposited CoO film (lower spectrum), those measured after the growth of metallic Co at 100 K (middle spectrum), and those measured after annealing the sample at 550 K (upper spectrum). These spectra imply that Co retains metallic character. Accordingly, after checking the Ni $2p_{3/2}$ spectra displayed in Fig. 22.32d, it is clear that there are no discernible signatures of Ni^0 at any step in the experiment.

Nozaki et al. recently used an ultrathin Fe_2O_3 layer to improve the crystalline quality of ultrathin Co films deposited on a MgO(001) surface [22.81]. Figure 22.32a displays reflection high-energy electron diffraction (RHEED) images acquired after the growth of 1 nm thick Co film on MgO. The faint diffraction spots indicate the development of 3-D Co islands that preferentially expose their hcp Co(1120) surfaces. On the other hand, if the MgO(001) surface is covered with a 0.2 nm thick Fe_2O_3 layer (Fig. 22.32b), the diffraction pattern becomes sharper, suggesting that a continuous and flat Co film develops. Interestingly, if the thickness of the Fe_2O_3 buffer layer is increased to 0.4 nm (Fig. 22.32c), a new diffraction pattern corresponding to a Co film with bcc structure develops.

22.4 Chemical and Magnetic Properties in Low-Dimensional Transition Metal Oxides

One of the main influences on the magnetic properties of a layered heterostructure is the chemical composition of its interfaces [22.82–88]. The magnetic order of a crystal depends on the chemical environment of the atoms that constitute the the crystal. For instance, Ni and Co are FM metals, but their native monoxides (NiO, CoO) are antiferromagnetically ordered. The situation is even more complex for elements that form several stable oxides, each characterized by a different stoichiometry and magnetic configuration. For example,

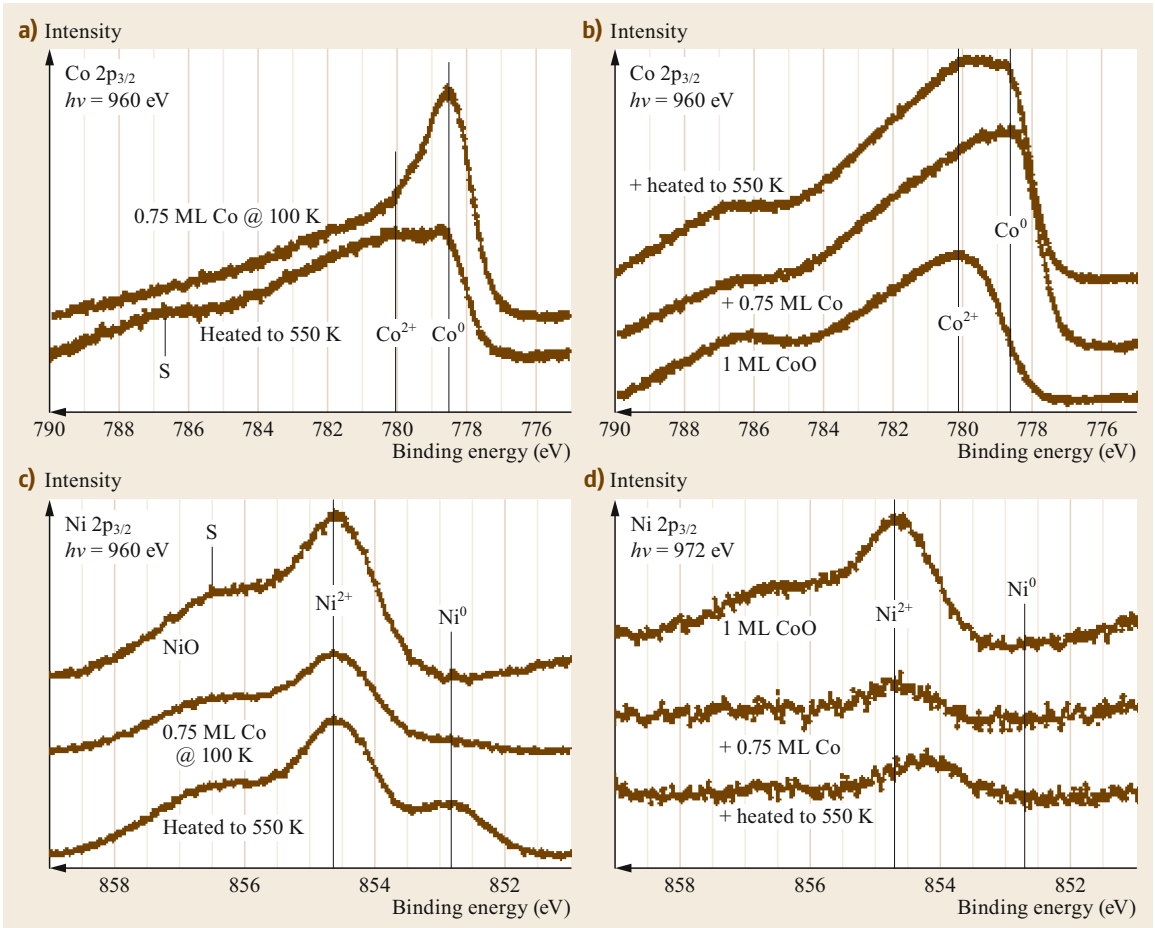

Fig. 22.31a–d Co $2p_{3/2}$ **(a)** and Ni $2p_{3/2}$ XPS spectra **(c)** acquired on the pristine 20 ML NiO(100) surface after the growth of 0.75 ML Co metal at 100 K and after annealing at 550 K, as well as Co $2p_{3/2}$ **(b)** and Ni $2p_{3/2}$ XPS spectra **(d)** of pristine 1 ML CoO(100) on NiO(100) after the deposition of 0.75 ML Co metal on the CoO(100) surface at 100 K and after increasing the temperature of this surface to 550 K (Reprinted from [22.80], with permission from Elsevier)

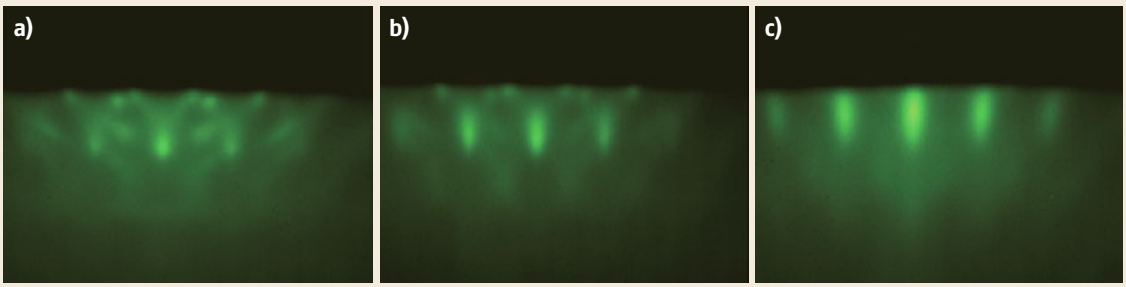

Fig. 22.32 **(a)** RHEED image of a 1 nm thick Co film deposited on pristine MgO. **(b,c)** RHEED images acquired after the deposition of 1 nm of Co on 0.2 and 0.4 nm thick Fe_2O_3 buffer layers, respectively (Reprinted from [22.81], with the permission of AIP Publishing)

FM Fe can form AF hematite (α-Fe_2O_3) and wüstite (FeO) as well as FI magnetite (Fe_3O_4) and maghemite (γ-Fe_2O_3). Heterostructures containing multivalent elements are often characterized by the presence of mixed phases, so a detailed knowledge of the interface composition is required to obtain the desired magnetic properties.

22.4.1 Influence of Interface Chemistry on Exchange Coupling

The influence of the chemical state at the interface on the magnetic properties of CoO/Fe(001) bilayers was recently investigated by *Młynczak* et al. [22.89]. Figure 22.33a presents hysteresis loops acquired in the Fe[110] direction for CoO/Fe samples containing different amounts of Fe oxide at the interface. The reference sample was obtained by growing CoO on Fe(001), the overoxidized sample by exposing the Fe(001) surface to 30 L of O_2 before CoO deposition, and the underoxidized sample by covering the Fe(001) surface with a thin Co buffer layer prior to reactive deposition. The hysteresis loops measured at 30 K for the three samples (displayed in Fig. 22.33a) demonstrate that the interface chemistry strongly influences the magnetization of the sample. Figure 22.33b displays both H_C and the exchange bias field (H_E) as functions of the temperature. These curves show that increasing the amount of iron oxide at the interface raises the temperature at which H_C starts to increase. Since the increase in H_C can be related to the establishment of AF order in the pinning layer, these data suggest that the presence of Fe_3O_4 increases the Néel temperature of CoO.

As discussed in Sect. 22.3.2, the oxidation of Fe in CoO/Fe(001) bilayers can be completely suppressed by inserting a sufficiently thick Co buffer layer into the interface. The magnetic properties of the CoO/Co/Fe(001) system have recently been investigated using MOKE [22.90]. The bare Fe(001) surface possesses two axes along which magnetization is easiest (known as *easy axes*): the [100] and [010] crystallographic directions. Due to the fourfold symmetry of the Fe(001) surface, the hysteresis loops measured in the [100] and [010] directions are identical (not shown). Figure 22.34 displays hysteresis loops acquired for a 25 ML CoO/5 ML Co/Fe(001) system. Due to the considerable thickness of the Fe substrate (more than 300 ML), EB is not observed in this system. However, the Co oxide layer strongly influences the magnetic properties of the Fe(001) substrate. The hysteresis curve acquired in the [100] direction is a square loop, i.e., the magnetization inverts in a single jump.

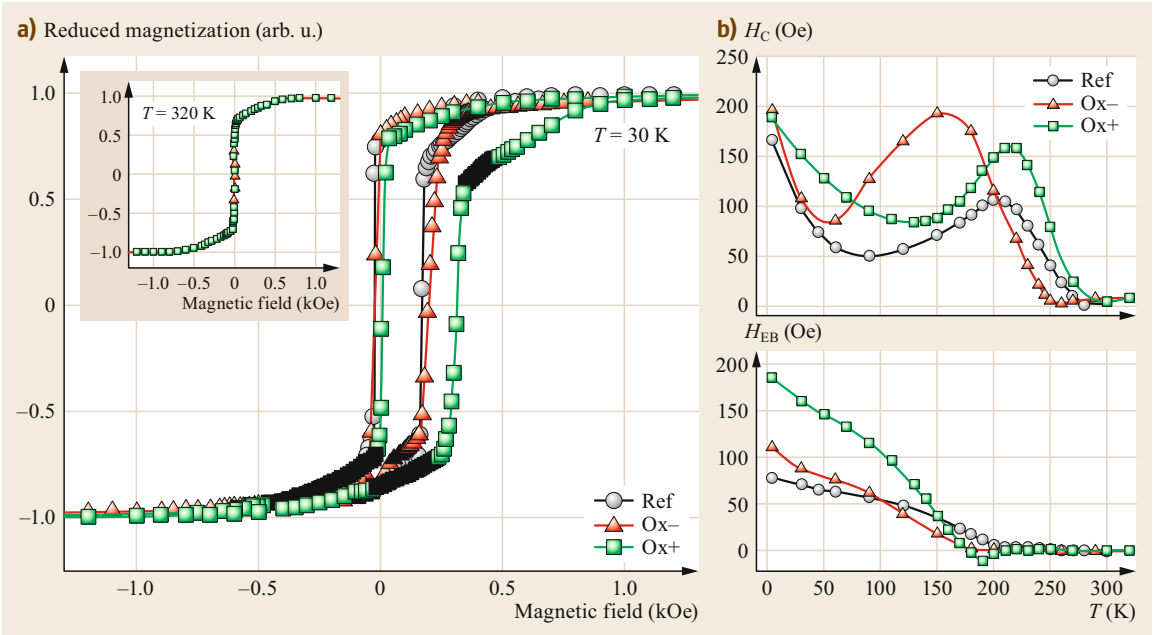

Fig. 22.33 **(a)** Magnetic hysteresis loops acquired at 30 K for the reference sample of CoO on Fe(001) (*empty circles*), an underoxidized sample (Ox−; *red triangles*), and an overoxidized sample (Ox+; *green squares*) with the magnetic field applied in the Fe[110] direction after field cooling (FC) at −20 kOe. The *inset* shows the loops measured at 320 K. **(b)** Temperature dependence of the coercive field (H_C) and that of the exchange bias field (H_{EB}). The *solid lines* are guides for the eye (Reprinted from [22.89], with permission from Elsevier)

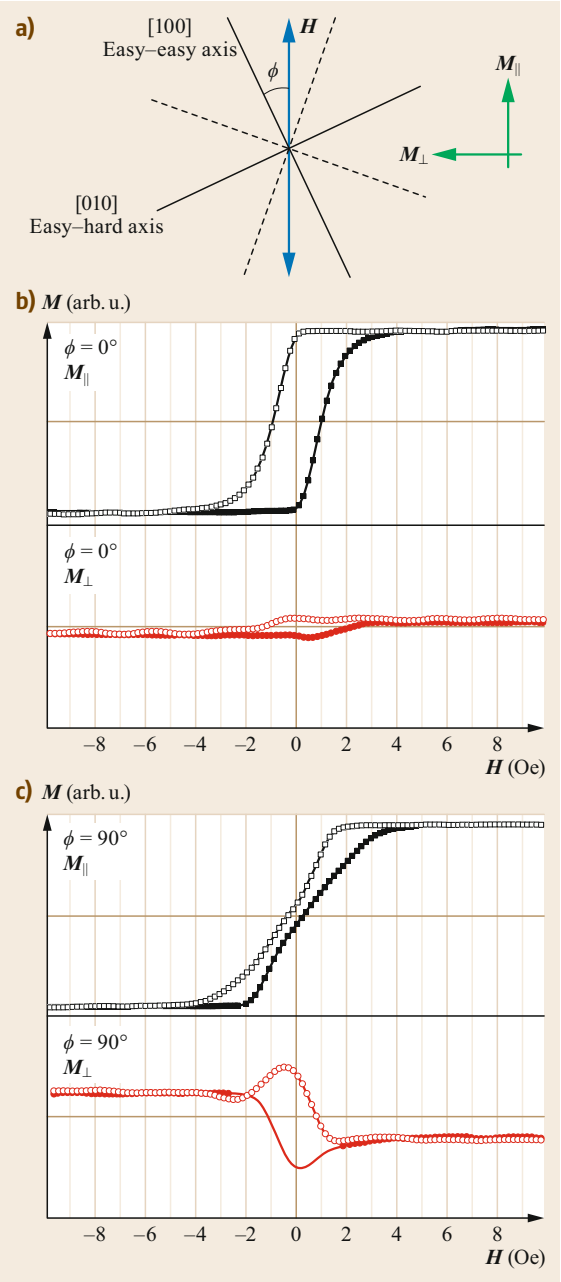

Fig. 22.34a–c MOKE hysteresis loops of the in-plane magnetization of a 25 ML CoO/5 ML Co/Fe(001) sample. The components parallel ($\boldsymbol{M}_{\parallel}$) and perpendicular ($\boldsymbol{M}_{\perp}$) to the applied field $\boldsymbol{H}$ are shown for different azimuthal angles. *Open* and *full symbols* correspond to decreasing and increasing loop branches, respectively. The experimental geometry is sketched in **(a)**, where the *continuous lines* represent the easy axes and the *dashed lines* show the axes along which magnetization is most difficult. **(b,c)** Hysteresis loops acquired in the [100] and [010] crystallographic directions, respectively (Reprinted from [22.90], with the permission of AIP Publishing) ◄

On the other hand, magnetization inversion in the [010] direction involves two jumps with two different H_C values, which are more visible in the magnetic vector component perpendicular to the applied field ($\boldsymbol{M}_{\perp}$). Such measurements suggest that during the hysteresis loop along the [010] axis, magnetic domains form with $\boldsymbol{M}$ parallel to the Fe [100] axis. The different magnetic inversions along the two nominally equivalent directions of Fe(001) can be explained by assuming that the CoO overlayer induces in-plane uniaxial magnetic anisotropy in the system, making magnetization along the [100] axis easier than that along the [010] axis [22.91, 92].

Chemical reactions at the metal–oxide interface can also induce EB in systems where the FM layer is coupled with a NM oxide. Using MOKE and magnetic second harmonic generation (MSHG), *Fan* et al. showed that the formation of a thin layer of AF FeO at the MgO/Fe(001) interface can pin the magnetization of the Fe atoms located at the interface with MgO [22.93]. Figure 22.35 shows hysteresis loops of Fe in the bulk (Fig. 22.35b–d) and at the interface (Fig. 22.35e–g) for different interfacial oxygen contents. While the bulk curves are all centered on $\boldsymbol{H} = 0$, the magnetization at the interface exhibits EB at sufficiently high interfacial oxygen concentrations.

22.4.2 Spin Transport

Magnetic tunnel junctions (MTJs) are devices consisting of two FM metals separated by a thin insulator. If the thickness of the insulator is small enough, electrons can tunnel across the junction when a voltage is applied. The electrical resistance (R) of the junction depends on the relative orientation of the magnetizations of the two electrodes, so different logic states can be obtained by writing the magnetic state of the MTJ. The parameter that quantifies the resistance asymmetry when the magnetizations of the electrodes are antiparallel (AP) or parallel (P) is the tunnel magnetoresistance (TMR), defined as $(R_{AP}–R_P)/R_P$. Large TMR values can be obtained using fully epitaxial Fe/MgO/Fe layers [22.95, 96]. These large values have been ascribed to Δ_1 majority spin electronic states of Fe(001), which decay slowly inside the MgO barrier [22.97]. For the P configuration, electrons tunnel efficiently across the barrier because the Δ_1 states that penetrate inside the MgO barrier match those present in the other Fe layer. On the other hand, for the AP configuration, the Δ_1 states are only present in one Fe electrode, so the electrons

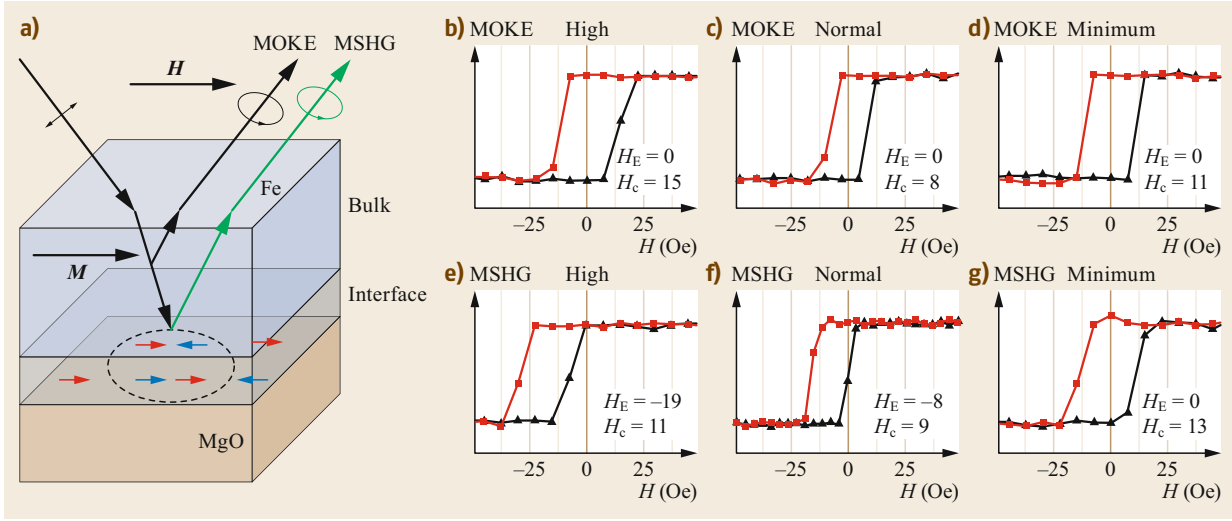

Fig. 22.35a–g Hysteresis loops acquired for MgO/Fe(001) in the bulk and at the interface with MOKE and magnetic second harmonic generation, respectively. **(a)** Experimental setup: the magnetic field H is applied in the plane along the easy axis [010] of Fe(001). The *top* and *bottom panels* show magnetization in the bulk and at the interface, respectively, for samples with high, normal, and low interfacial oxygen contents (From [22.93])

are reflected at the MgO/Fe interface. This scenario suggests that spin transport across a MTJ is strongly dependent on the interfaces between the FM metals and the oxide, so the chemical composition of the latter is expected to play a fundamental role. In the following, we discuss two examples in which chemical modifications influence MTJ performance: (i) the presence of an Fe oxide layer at the bottom MgO/Fe interface and (ii) the presence of oxygen vacancies in the MgO barrier.

In the former case, *Zhang* et al. studied the influence of an FeO layer on the electronic properties of the MgO/Fe interface via first-principles calculations [22.94]. Figure 22.36 compares the spatial dis-

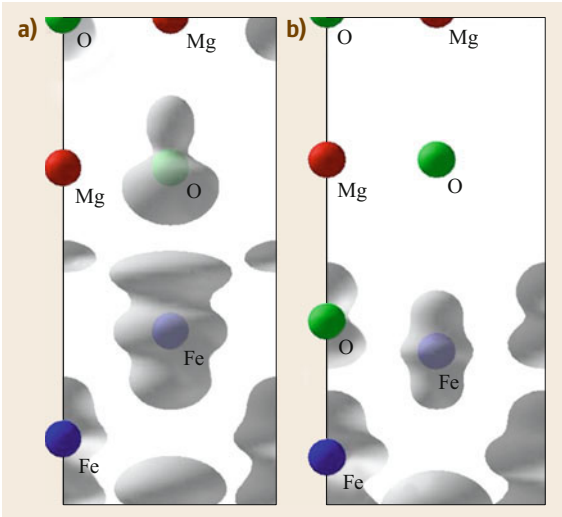

Fig. 22.36a,b The partial density of states at the Fermi energy due to the Δ_1 state in the majority spin channel near the interface region. **(a)** Without the FeO layer. **(b)** With the FeO layer (Reprinted with permission from [22.94]. © 2003 by the American Physical Society)

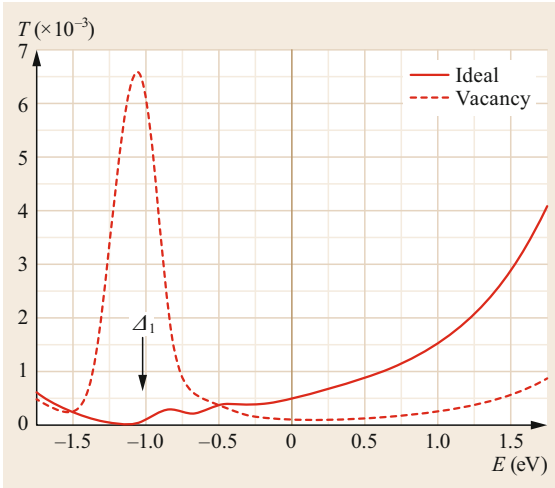

Fig. 22.37 Majority-spin transmission probability T as function of the energy E per cell in Fe/5 ML of MgO/Fe(001) for ideal MgO and for MgO with oxygen vacancies. The *arrow* indicates the bottom of the majority Δ_1 band (Reprinted from [22.98], with the permission of AIP Publishing)

tribution of the Δ_1 state for a MgO/Fe interface (Fig. 22.36a) to that for a MgO/FeO/Fe interface (Fig. 22.36b) and shows that the presence of the FeO layer strongly hinders the penetration of the electron wavefunction into the MgO barrier. The weaker coupling of the Δ_1 state to the MgO layer reduces the tunneling current of the majority spin channel and consequently the TMR. The postulated increase in R_p due to the oxidation of the Fe(001) bottom electrode was experimentally confirmed by *Bonell* et al. [22.99] and *Zermatten* et al. [22.100].

Modifying the MgO barrier can also influence the performance of the MTJ. *Velev* et al. studied the influence of O vacancies (F centers) on spin-dependent tunneling in Fe/MgO/Fe(001) magnetic tunnel junctions [22.98]. Figure 22.37 presents the transmission probability T as a function of the energy for perfect MgO (continuous line) and MgO with oxygen vacancies (dashed line). The transmission of the MTJ with vacancies drops markedly around E_F compared to that of a perfect MTJ. This reduction in majority-spin transmission can be explained by noting that tunneling electrons are scattered by the oxygen vacancies from slowly decaying states with $K = 0$ to electronic states with larger parallel K that are characterized by faster decay inside the MgO barrier.

22.5 Conclusions and Perspectives

In this chapter, we have focused on the magnetic properties of ultrathin oxide films grown epitaxially on metallic substrates. This topic was discussed from a surface science perspective, i.e., by considering model systems in UHV conditions. In the first part of the chapter, we analyzed the subtle interplay between the magnetic order of the oxide and its structural and electronic properties. The complexity of this problem requires a multifarious experimental approach involving both spin-resolved spectroscopic and microscopic techniques, as described in the second section of the chapter. The magnetic properties of metal–oxide multilayers are strongly related to the physicochemical coupling between the epitaxial film and the substrate. In this context, the third section of the chapter described how the structure and the chemical composition of the oxide–metal interface can be tailored by inserting an appropriate buffer layer. Finally, through the use of selected examples, we showed in the fourth section of the chapter how even a minor modification to the chemical composition of the interface can strongly influence the magnetic coupling between the ferromagnetic substrate and the oxide overlayer as well as the spin transport properties of a magnetic tunnel junction.

Turning our attention to future perspectives in this area of research, we can identify several lines of development. First, most of the literature in this area is focused on binary transition metal oxides; there have been relatively few studies of more complex systems such as ternary oxides. Multicomponent oxides with multiferroic order (such as rare earth manganites) are particularly interesting due to their application in magnetoelectronic devices. Another still largely unexplored field is heterostructures composed of an ultrathin oxide and two-dimensional materials (graphene, MoS_2, h-BN, etc.). It is expected that new layered van der Waals crystals of this nature will be synthesized through the epitaxial growth of monolayer oxides, expanding the library of two-dimensional materials that are available.

Alberto Brambilla

Dipartimento di Fisica
Politecnico di Milano
Milano, Italy

Alberto received his PhD in Physics at Politecnico di Milano (Italy) in 2005, with an experimental activity focused on the investigation of thin films and interfaces of magnetic materials, oxides, and semiconductors through ultrahigh vacuum spectroscopy and microscopy techniques. He was a researcher at CNISM and became Assistant Professor (2008) and then Associate Professor (2014) in the Physics Department of Politecnico di Milano.

Andrea Picone

Dipartimento di Fisica
Politecnico di Milano
Milano, Italy
andrea.picone@polimi.it

Andrea Picone received his PhD in Physics (2012) from the Politecnico di Milano. During his PhD he focused on the characterization of the structural and electronic properties of transition metal oxides. Currently, his scientific interest lies in the study of layered systems formed by ultrathin oxides and ferromagnetic metals, with emphasis on the interplay between interface chemistry and magnetic coupling. He is author of 27 scientific papers in international peer-reviewed journals.

Marco Finazzi

Dipartimento di Fisica
Politecnico di Milano
Milano, Italy

Marco Finazzi received his PhD in Physics in 1994 from the Politecnico di Milano. Since 2001 he has carried out his scientific activity in the Physics Department of Politecnico di Milano, where he became Full Professor in 2016. He teaches experimental physics and physics of low-dimensional systems. His main fields of interest span from the physics of the transport of spin in solid-state systems to nano-optics and plasmonics.

Lamberto Duò

Dipartimento di Fisica
Politecnico di Milano
Milano, Italy

Lamberto Duò received his PhD from Politecnico di Milano in 1987. He was then appointed as Staff Scientist in the Physics Department of Politecnico di Milano, where he subsequently became Full Professor. Professor Duò has worked on electron spectroscopies of highly correlated electron systems, spin-resolved electron spectroscopies of magnetic systems with low dimensionality and scanning near-field optical microscopy of magnetic nanostructures. He is author of over 150 publications.

Franco Ciccacci

Dipartimento di Fisica
Politecnico di Milano
Milano, Italy

Franco Ciccacci received his Doctor's degree in Physics at Università di Roma La Sapienza. He is currently Full Professor of Experimental Physics at Politecnico di Milano. His research activities include surface physics, production, and detection of spin-polarized electron beams, electron spectroscopy from solids, also with synchrotron radiation and spin resolution, thin film magnetism, deposition of nanostructured materials for spintronics. He is author of over 200 scientific papers in international journals.

Part F

Lattice Dy

Part F Lattice Dynamics

Part F is devoted to lattice dynamics. Atoms in solids vibrate around their equilibrium positions in a potential determined by interactions with their neighbors and by their electronic configuration, including the pronounced effect of their conduction electrons, if present. In the harmonic approximation, all terms in the Taylor expansion of the interaction potential beyond the quadratic are neglected, which is reasonable for small oscillations around the equilibrium positions. The solutions of the equation of motion are then noninteracting normal modes and their quanta are called phonons. When the solid is truncated, the translational invariance normal to the surface is lost and the phonon spectrum changes. The wavevector is two-dimensional at the surface, and the spectrum consists of the projection of the bulk states and of additional modes characterized by an amplitude that decreases away from the surface (surface phonons and resonances). Such modes arise due to the lack of inversion symmetry at the surface and play an essential role in determining phenomena such as energy dissipation in gas–surface interactions and surface diffusion. The surface phonon spectrum has been determined by two main methods: thermal energy He atom scattering and angle-resolved high-resolution electron energy loss spectroscopy (HREELS) performed with low-energy electrons. In addition, phonons at vanishing momenta can be excited by infrared light. Recent advances in HREELS allow the acquisition of the full phonon spectrum after just a few hours of work instead of weeks, opening the door to the study of more reactive systems.

Phonons are eigenstates of the harmonic Hamiltonian and thus have infinite lifetimes. However, the interaction potential is not exactly harmonic, causing phonon lines to have a finite energy width. Phonons are often computed within the Born–Oppenheimer approximation, which may break down under specific conditions. Such is the case for Kohn anomalies, which may be particularly strong at surfaces due to the reduced dimensionality, or for superconductivity, which can have a higher critical temperature at the surface.

Chapter 23 provides a detailed introduction to surface phonon spectra and the theoretical methods used to calculate them, including force constant models and ab initio methods. The results from theoretical predictions are compared to experimental results for several different kinds of solid surfaces. The final part of this chapter addresses problems that are still unresolved despite the advances made in this field over the past decades.

Chapter 24 is devoted to the theoretical description of the electron–phonon interaction, which determines many physical phenomena such as superconductivity, Kohn anomalies, photoemission, and the dynamics of excited electrons and holes. Current computational and experimental techniques are covered. A summary of the results obtained for elemental and adsorbate-covered metal surfaces, thin films, and metallic states on the surfaces of topological insulators is also provided.

Chapter 25 explores experimental results on surface vibrations obtained by STM-IETS (scanning tunneling microscopy–inelastic tunneling spectroscopy). This technique combines the atomic-scale spatial resolution of STM with the chemical sensitivity of vibrational spectroscopy. The chapter addresses the selection rules of STM-IETS, which are quite different from those pertinent to HREELS and infrared reflection spectroscopy. Vibrations at alkenethiol self-assembled monolayers are presented as an example.

Chapter 26 takes an unconventional approach to the topics of this session, showing how a detailed description of the chemical composition of a surface can be obtained through the combined use of multiple experimental techniques: infrared (IR) spectroscopy, low-energy ion scattering (LEIS), and x-ray photoemission spectroscopy (XPS). This information is required to understand several surface chemical and physical processes, such as thin-film growth, surface functionalization, catalysis, and near-surface diffusion.

23. Surface Phonons: Theoretical Methods and Results

Giorgio Benedek, Marco Bernasconi, Davide Campi, J. Peter Toennies, Matthieu J. Verstraete

The theoretical methods currently in use for the calculation of surface phonon dispersion curves and how they have evolved from the phenomenological force-constant models to the present day first principles theories are discussed. A selection of paradigmatic examples for the different classes of crystal surfaces is presented with comparisons to the experimental data obtained from helium atom scattering or electron energy-loss spectroscopy.

In Sect. 23.1, this chapter presents a general introduction to the concepts and methods in the theory of surface lattice dynamics. This is followed by a survey of theoretical developments, from the early theories, extending the original Born–von Kármán approach to the dynamics of crystal surfaces, to recent first-principles treatments based on the density functional theory. Since all theoretical methods, whether phenomenological or ab-initio, have their own domain of applicability, they will be illustrated in Sect. 23.2 according to the role that the electronic structure plays in lattice dynamics with a few paradigmatic examples of surface phonon calculations at the different levels of approximation. The final part on the density functional perturbation theory (DFPT) will only present examples that are particularly challenging today, requiring functionals including spin–orbit coupling and van der Waals contributions. These examples concern the surfaces of heavy 6sp elements and some topological insulator compounds. Some open problems concerning DFPT and expected future developments are briefly mentioned in the concluding Sect. 23.3.

Surfaces play a fundamental role in all branches of nanotechnology. In particular, a detailed knowledge of surface dynamics is essential for the structural and functional characterization of nanostructures. The study of quantized surface vibrations—surface phonons—enables us to learn about the forces at a solid surface, or between the surface and adsorbed molecules. This understanding makes it possible to elucidate and exploit a wide variety of transport and optical properties and functions involving phonons, either directly or via electron–phonon interaction.

Learning about the nature of things by studying their motion is an old concept: "Igitur impossibile est de aliqua re cognoscere, quòd fit natura, non cognoscendo motum" (It is therefore impossible to learn what nature makes about anything without knowing its motion) [23.1]. Most of what we know about the inner constitution of our planet comes from seismology, and it was in the realm of seismology that the study of solid surface dynamics started in the last two decades of the nineteenth century with the fundamental work of *Lord Rayleigh* [23.2, 3]. This work demonstrated for a semi-infinite elastic, homogeneous, and isotropic solid, the existence of acoustic waves propagating along the surface with a frequency proportional to the wavevector and decaying exponentially inside the solid. The decay length was shown to be proportional to the surface wavelength, as expected from a simple scale law: *a homogeneous semi-infinite continuum looks the same at any length scale*. Thus, surface waves, which originally explained the slow but most destructive long-wave component of earthquakes (Rayleigh waves (RWs)), exist at

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-46906-1_23

any scale, from the surface of planets to that of large nuclei, and, therefore, at the surface of crystal lattices. The intrinsic inhomogeneity of the solid at the atomic scale causes a deviation from the frequency-wavevector proportionality when wavelengths become comparable to the interatomic distances: the RW phase velocity is no longer constant but exhibits a dispersion. The detailed study of the dispersion relation $\omega(\boldsymbol{Q})$ of the frequency ω versus the wavevector $\boldsymbol{Q}$ is a rich source of information about the structure, the forces, and the interactions occurring at the surface of any solid material, much in the same way seismic RWs provide information about the constitution and inhomogeneities of the Earth's crust. Surface waves like RWs, which obey the fundamental scaling law illustrated above, are said to be *macroscopic*, otherwise they are called *microscopic*.

Rayleigh waves, however, do not come alone. Elastic-wave displacements are vectors with three possible components, so that two other acoustic surface waves may exist, possibly only at finite wavevectors, with polarization vectors orthogonal to those of Rayleigh waves. On the atomic scale, the solid is a periodic lattice with a unit cell that contains one or more atoms. In the latter case, the unit cell, besides its three degrees of freedom associated with the translations of its center of mass, has internal degrees of freedom. The vibrational modes of the lattice associated with these degrees of freedom have frequencies that do not vanish for $\boldsymbol{Q} \to 0$ and are known as optical vibrations, since they determine the infrared optical properties in ionic crystals. The creation of a free surface in a polyatomic crystal and the consequent break of translational symmetry in the direction normal to surface bring forth surface vibrations of optical nature. In general, they have as many dispersion curves as the crystal unit cell has internal degrees of freedom. Unlike Rayleigh waves, the frequencies of optical surface modes do not vanish at $\boldsymbol{Q} = 0$, and their penetration lengths remain very short, in general on the scale of the lattice distances. Thus, optical surface modes carry specific information on the surface geometry and local interactions, which makes their study of primary interest in the physics of nanostructures. The spectrum of surface vibrations is further enriched by the presence at the surface of adsorbed chemical species or by the deposition of ultrathin films, and much can be learnt about their properties from surface phonon spectroscopy.

For a more detailed discussion of the concepts and methods summarized in the following Sects. 23.1 and 23.2, the reader is referred to [23.4, Chaps. 3–5], which has recently appeared. Chapter 11 of this Springer Handbook also contains a comprehensive discussion and analysis of the important measurements of the surface phonon dispersion curves of insulators, semiconductors, and metals. Extended lists of measured surface phonon dispersion curves that have been analyzed with the different methods presented in this chapter can be found in the Landolt–Börnstein chapter [23.5] and in the appendices of the very recent monograph [23.4].

Although several early theoretical studies on surface phonons anticipated the advent of their spectroscopy, the great progress in the theoretical modeling and ab-initio methods for the surface dynamics of real surfaces would not have been possible without the parallel development of powerful experimental techniques, notably high-resolution electron energy loss (HREELS) spectroscopy, with the first evidence of a microscopic surface mode obtained by *Harald Ibach* in 1971 [23.6], and helium atom scattering (HAS), also in 1971, with the first observation of RWs from angular distributions by *Brian Williams* [23.7, 8]. HAS surface phonon spectroscopy moved from the detection of phonon signatures in angular distributions, with an essential contribution from the Genoa group [23.9–14], to time-of-flight (TOF) spectroscopy, by which the RW speed in LiF(001) was measured [23.15]. The real breakthrough was, however, the realization of nozzle-beam sources with a high speed ratio [23.16], which enabled high-resolution TOF spectroscopy and the measurement of surface phonon dispersion curves in ionic crystals [23.17–19] and metals [23.20, 21]. Good results for Cu(001) were also obtained as early as 1981 by measuring the energy loss with a LiF analyzer crystal [23.22], a method which was not adopted further. In the same year, intriguing results were reported for Ni(111) with Ne atom scattering [23.23], which are worth mentioning, not only for being the first observation of RWs in a metal surface with atom scattering but also for the possible assignment of an unexplained branch to acoustic surface plasmons [23.4]. A rich collection of review articles and books from the early 1990s on kept the pace of the progress in surface phonon HAS spectroscopy and related theory [23.24–51], including the realization of ^{3}He spin-echo spectroscopy, anticipated by *DeKieviet* et al. [23.52] and fully realized by the Cavendish group with an unprecedented resolution in the neV range [23.53, 54]. A full account of HAS spectroscopy from the origin to present can be found in the recent monograph and book mentioned above [23.4, 5].

In parallel with these developments, HREELS in the impact regime also acquired the necessary resolution for an accurate determination of the surface phonon dispersion curves, mostly on conducting materials [23.55–57]. Transition metal and noble metal surfaces have served as a benchmark for HREELS studies [23.58–70] and for early first-principles calculations of surface dynamics [23.66–68]. The important role of these surfaces in catalytical processes stimulated further extensive investigations on the vibrational spectra

of adsorbed phases and overlayers [23.65]. HAS and HREELS basically provide the same information of surface phonon dispersion curves, generally in excellent agreement. It was soon realized that on semiconductor and metals they rely on rather different mechanisms with respect to the energy and momentum transfer to surface phonons. While electrons in the impact regime are directly scattered by the ion cores, He atoms at thermal energy are scattered by the electron density at the surface and can only transfer energy and momentum to ion cores through electron–phonon coupling (Sect. 23.2). In other words, HAS and HREELS provide valuable complementary information on surface dynamics [23.32, 46]. This understanding was fostered by the continued feedback between experiment and theory.

23.1 Concepts and Methods of Surface Lattice Dynamics

In order to describe the vibrational dynamics of a crystalline solid [23.71–75], its potential energy U is Taylor-expanded in the time-dependent displacements $\boldsymbol{u}(l\kappa, t) \equiv \boldsymbol{u}(l\kappa)$ of the atoms with respect to their equilibrium positions $\boldsymbol{r}_{l\kappa}$, defined by the conditions $\partial U/\partial \boldsymbol{r}_{l\kappa} = 0$

$$U = U_0 + \frac{1}{2}\sum_{ll'\kappa\kappa'} \frac{\partial^2 U}{\partial \boldsymbol{r}_{l\kappa}\partial \boldsymbol{r}_{l'\kappa'}} \boldsymbol{u}(l\kappa)\boldsymbol{u}(l'\kappa') + \frac{1}{6}\sum_{ll'l''\kappa\kappa'\kappa''} \frac{\partial^3 U}{\partial \boldsymbol{r}_{l\kappa}\partial \boldsymbol{r}_{l'\kappa'}\partial \boldsymbol{r}_{l''\kappa''}} \boldsymbol{u}(l\kappa)\boldsymbol{u}(l'\kappa')\boldsymbol{u}(l''\kappa'') + \ldots \quad (23.1)$$

where U_0 is the static potential energy. Here, $\boldsymbol{r}_{l\kappa}$ stands for $\boldsymbol{r}_{l\kappa} \equiv l_1\boldsymbol{a}_1 + l_2\boldsymbol{a}_2 + l_3\boldsymbol{a}_3 + \boldsymbol{d}(\kappa)$, where $\boldsymbol{a}_m$ $(m = 1, 2, 3)$ are the basis vectors of the lattice, the integer indices l_m run from 0 to $N_m - 1$, with $N_1N_2N_3$ the number of unit cells of the crystal, and $\boldsymbol{d}(\kappa)$ $(\kappa = 1, 2, \ldots, s)$ define the relative positions of the s atoms inside each unit cell. The derivatives,

$$\frac{\partial^2 U}{\partial r_{l\kappa\alpha}\partial r_{l'\kappa'\beta}} \equiv R_{\alpha\beta}\left(l\kappa, l'\kappa'\right), \quad (23.2)$$

where α and β label the vector components, which define the harmonic atom–atom (two-body) *force constant matrix*. The cubic and further higher-order terms in the expansion of U determine a variety of important anharmonic effects in lattice dynamics, such as thermal expansion, thermal resistance, and phonon–phonon interaction. They are usually neglected (*harmonic approximation*) in the theory of surface dynamics and are treated perturbatively to obtain the above temperature-dependent properties. According to Born–von Kármán theory, the equations of motion in the harmonic approximation for the atomic vibrations of a crystal lattice are given by

$$-M_\kappa \ddot{u}_\alpha(l\kappa, t) = \Sigma_{l'\kappa'\beta} R_{\alpha\beta}(lk, l'\kappa') u_\beta(l'\kappa', t)\,, \quad (23.3)$$

where M_κ is the mass of the κ-th atom in the unit cell.

The theory of surface lattice dynamics in its classical Born–von Kármán formulation [23.76–81] considers two steps. In the first step, the bulk phonons, which are solutions of the dynamical equation for the crystal lattice with 3-D boundary conditions, are *projected* onto new coordinates appropriate to 2-D boundary conditions. In the second step, the effects of the surface perturbation arising from the removal of the periodic boundary condition in the direction normal to the surface are considered. The bulk phonons which are most affected by the surface perturbation transform into surface localized phonons, e.g., the Rayleigh waves (RWs), or in-band surface resonances, e.g., the anomalous longitudinal (AL) acoustic resonance in metal surfaces.

23.1.1 Surface-Projected Bulk Phonon Bands

In the first step, the 3-D lattice is viewed as generated by two-dimensional (2-D) translations in the $(\boldsymbol{a}_1, \boldsymbol{a}_2)$ plane of a large unit cell containing sN_3 atoms. Such a 2-D representation of a crystal is called the *slab representation* of a crystal. In this representation, the solutions of the atomic equations of motion are Bloch waves with 2-D wavevectors $\boldsymbol{Q}$ in the $(\boldsymbol{a}_1, \boldsymbol{a}_2)$ plane and angular frequencies $\omega_{\boldsymbol{Q}\nu}$

$$u_\alpha(l\kappa, t) \propto u_\alpha(l_3\kappa, \boldsymbol{Q}\nu) \times \exp[\mathrm{i}\boldsymbol{Q}\cdot(l_1\boldsymbol{a}_1 + l_2\boldsymbol{a}_2) - \mathrm{i}\omega_{\boldsymbol{Q}\nu}t]\,. \quad (23.4)$$

Here, the sets (l_1, l_2) and (l_3, κ) are used to label the slab cells in two dimensions and the atoms inside each slab cell, respectively, whereas the branch index ν labels the $3sN_3$ phonon solutions of (23.3) for each wavevector $\boldsymbol{Q}$. The latter are obtained by inserting (23.4) into (23.3) as a solution of the eigenvalue equation

$$M_\kappa\omega^2_{\boldsymbol{Q}\nu}u_\alpha\left(l_3\kappa, \boldsymbol{Q}\nu\right) = \sum_{\beta l'_3\kappa'} R_{\alpha\beta}\left(l_3\kappa, l'_3\kappa', \boldsymbol{Q}\right) u_\beta\left(l'_3\kappa', \boldsymbol{Q}\nu\right), \quad (23.5)$$

where

$$R_{\alpha\beta}\left(l_3\kappa, l_3'\kappa', \boldsymbol{Q}\right) = \sum_{l_1 l_2} R_{\alpha\beta}\left(l\kappa, l'\kappa'\right) \exp\left[\mathrm{i}\boldsymbol{Q}\cdot(l_1\mathrm{a}_1 + l_2\mathrm{a}_2)\right] \quad (23.6)$$

are the 2-D Fourier transform of the force constants given by (23.2). Equation (23.6) defines the set of $\boldsymbol{Q}$-*dependent interplanar force constants*. As in the 3-D case, the set of modes of given ν for all values of $\boldsymbol{Q}$ forms the ν-th phonon branch, and the function $\omega_{\boldsymbol{Q}\nu}$ is its dispersion relation (Fig. 23.1b). From the solution of (23.5), the eigenfrequencies $\omega_{\boldsymbol{Q}\nu}$ and the displacement vectors $u_\alpha(l_3\kappa, \boldsymbol{Q}\nu)$, known as the $\boldsymbol{Q}$-*dependent planar displacements*, are obtained. The quantized physical displacement of the (l,κ)-th atom, with $l = (l_1 l_2 l_3)$, for the $(\boldsymbol{Q},\nu)$-th phonon mode is then given by

$$u_\alpha(l\kappa, \boldsymbol{Q}\nu, t) = \left(\frac{\hbar}{2N_1 N_2 M_\kappa \omega_{\boldsymbol{Q}\nu}}\right)^{1/2} e_\alpha(l_3\kappa, \boldsymbol{Q}\nu) \times \exp\left[\mathrm{i}\boldsymbol{Q}\cdot(l_1\boldsymbol{a}_1 + l_2\boldsymbol{a}_2) - \mathrm{i}\omega_{\boldsymbol{Q}\nu}t\right], \quad (23.7)$$

where the *eigenvectors* $e_\alpha(l_3\kappa, \boldsymbol{Q}\nu)$ form an orthogonal complete set in their $3sN_3$ space and are normalized to unity. The eigenvectors determine the polarization of the displacement field amplitude and are, therefore, termed *polarization vectors*. The factor $(N_1N_2)^{-1/2}$ ensures the normalization to unity of the exponential plane waves, so that the eigenwaves $(N_1N_2)^{-1/2}\, e_\alpha(l_3\kappa, \boldsymbol{Q}\nu)\exp[\mathrm{i}\boldsymbol{Q}\cdot(l_1\boldsymbol{a}_1 + l_2\boldsymbol{a}_2)]$ form an orthonormal, complete set in the full crystal space (*normal modes*).

Since the periodic boundary condition is still maintained also for the third translation $N_3\boldsymbol{a}_3$, the above solutions are just those of the 3-D lattice, which have been relabeled to correspond to a 2-D representation. The eigenfrequencies $\omega_{\boldsymbol{Q}\nu}$, for each $\boldsymbol{Q}$ and for ν varying from 1 to $3sN_3$, now form $3s$ bands, each one containing N_3 modes. For an infinitely thick slab ($N_3 \to \infty$), the individual modes can no longer be resolved, and the bands become continuous. They are referred to as *bulk phonon bands* projected onto the $(\boldsymbol{a}_1, \boldsymbol{a}_2)$ plane.

The correspondence between the two and three-dimensional representations of the phonon branches inside a solid with 3-D periodic boundary conditions is illustrated in Fig. 23.1. The 3-D dispersion surface in Fig. 23.1a is generated by the phonon energies as a function of the 3-D wavevector $\boldsymbol{q}$. The 2-D representation is then obtained by splitting $\boldsymbol{q}$ into a 2-D component $\boldsymbol{Q}$, which is parallel to the atomic planes of the slab, and a normal component q_z, namely $\boldsymbol{q} = (\boldsymbol{Q}, q_z)$. Each curve in the 2-D representation (Fig. 23.1b) represents

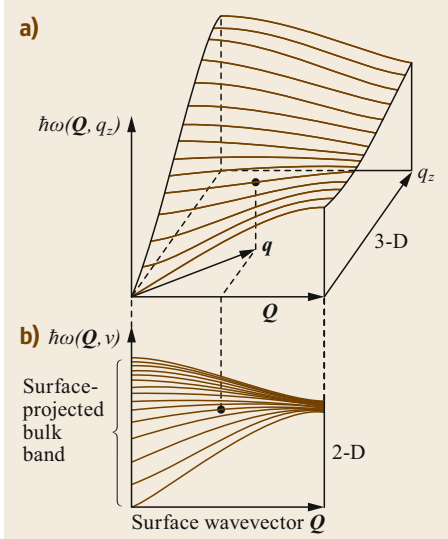

Fig. 23.1 **(a)** The energy surface $\hbar\omega(\boldsymbol{Q}, q_z)$ generated by the dispersion curves of an acoustic bulk phonon within a periodic slab with N_3 layers is plotted as a function of parallel $(\boldsymbol{Q})$ and normal (q_z) wavevector components. **(b)** This set of dispersion curves is converted into a 2-D band $\hbar\omega_{\boldsymbol{Q}\nu}$. The normal component q_z is replaced by an index ν labeling all the N_3 modes of the band with the same parallel wavevector $\boldsymbol{Q}$. In this example, there are 15 dispersion curves corresponding to the $N_3 = 15$ atomic layers of the slab. If the unit cell of the original periodic crystal contains s atoms, there will be $3s$ such bands, and index ν will label altogether $3sN_3$ modes for each value of the parallel wavevector $\boldsymbol{Q}$

the phonon energy as a function of $\boldsymbol{Q}$ for a given value of q_z. Thus, each bulk phonon branch generates just as many curves as the number of possible values of q_z, that is, N_3. The resulting set of curves is referred to as the *surface-projected* bulk band.

If the unit cell contains s atoms, then it has $3s$ degrees of freedom, and the total phonon spectrum is made up of $3s$ different, partially superimposed surface-projected bands. Thus, for each value of $\boldsymbol{Q}$ in the 2-D representation, there are altogether $3sN_3$ modes, which are conveniently labeled by a single index ν. The corresponding frequency distribution within all the bands is given by the *total* $\boldsymbol{Q}$-*selected phonon density of states* (DOS)

$$D_0(\boldsymbol{Q}, \omega) = \frac{1}{N_3}\sum_\nu \delta(\omega - \omega_{\boldsymbol{Q},\nu})\,. \quad (23.8)$$

Similarly, the $\boldsymbol{Q}$-*selected DOS projected* onto a specific plane l_3, sublattice κ, and polarization α is defined

as

$$D_{0\alpha}(\kappa l_3 \boldsymbol{Q}, \omega) = \frac{1}{N_3} \sum_{\nu} |e_\alpha(l_3\kappa, \boldsymbol{Q}\nu)|^2 \delta\left(\omega - \omega_{\boldsymbol{Q},\nu}\right), \quad (23.9)$$

respectively. Clearly $\sum_{l_3\kappa\alpha} D_{0\alpha}(l_3\kappa\boldsymbol{Q}, \omega) = D_0(\boldsymbol{Q}, \omega)$ due to eigenvector normalization.

23.1.2 Effects of the Surface Perturbation

So far, only a macroscopic-sized crystal slab with three-dimensional periodic boundary conditions has been dealt with, where the layer for $l_3 = N_3 - 1$ is connected to the first layer ($l_3 = 0$) by the same bulk interatomic forces that act between any other pair of adjacent layers (Fig. 23.2a). By the requirements of periodic boundary conditions along the $\boldsymbol{a}_3(z)$ direction, the reduction in the coordination of the atoms at a physical surface and the changes in the force constants at the surface were not accounted for in the above discussion.

A surface is created at a 2-D boundary Σ, if all the interatomic forces connecting atoms across Σ are broken apart. This way, the periodic boundary conditions along the z-axis are lifted, and two free surfaces are created at $l_3 = 0$ and $N_3 - 1$ (Fig. 23.2b). The original periodic lattice has now been transformed into a finite slab with two free surfaces. Only the atoms in the two surface regions A and B are affected by the cut of forces across Σ. This operation leads to a perturbation of the force constant matrix and a consequent change of eigenfrequencies and eigenvectors. The perturbation matrix has nonzero elements only within a subspace σ that encompasses the regions A and B. When the two surfaces are identical, the problem can be reduced to that of a single surface of a semi-infinite lattice by using a new set of symmetrized coordinates and letting $N_3 \to \infty$ (Fig. 23.2c) [23.82–84]. The size of the new perturbation subspace σ' is one half of that for a finite slab.

The 2-D Fourier transform of the perturbation matrix $\boldsymbol{\Lambda}_{\alpha\beta}(l_3\kappa, l_3'\kappa', \boldsymbol{Q})$ due to the creation of the two free surfaces needs to be added to the unperturbed lattice dynamical matrix $R_{0,\alpha\beta}(l_3\kappa, l_3'\kappa', \boldsymbol{Q})$ to give, in matrix notation, a new eigenvalue equation

$$[\mathbf{R}_0(\boldsymbol{Q}) + \boldsymbol{\Lambda}(\boldsymbol{Q})\boldsymbol{u} - \mathbf{M}\omega^2]\boldsymbol{u} = 0\,. \quad (23.10)$$

Once the perturbation matrix is known, there are two classical ways to solve it. One is the direct diagonalization of the $3sN_3 \times 3sN_3$ dynamical matrix for a sufficiently thin slab (*slab method*). If the goal is to know the surface dynamics of a macroscopic crystal, N_3 has to be much larger than the size of $\boldsymbol{\Lambda}$, although within the limits of the available computational power. This is not a serious limitation for phenomenological force-constant models, but may still be a problem for first-principles calculations.

The second way to solve (23.10) is based on the *Green's function method*. It has the advantage that the diagonalization problem is reduced from the large space of dynamical matrix to the much smaller space of the perturbation, with a modest computational effort for the calculation of complex-valued Green's functions of the unperturbed crystal. With the advent of fast computers, the direct diagonalization has become the method of choice, although the present extension of surface dynamics studies to complex surfaces and adsorbates, and the calculation of their vibrational response functions may revive the interest in the Green's function method

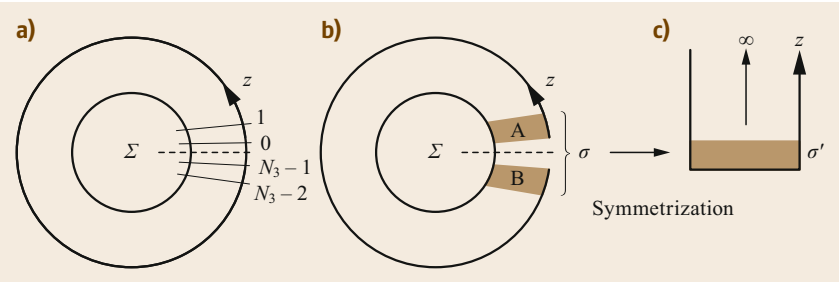

Fig. 23.2 **(a)** Representation of a lattice with periodic boundary conditions in the z direction. The *broken line* indicates the boundary plane Σ located between the 0-th and the $N_3 - 1$-st lattice planes. **(b)** When all the interactions connecting atoms across the boundary plane Σ are set to zero the periodic boundary conditions in the z direction normal to the boundary plane are lifted and the original periodic lattice is transformed into a slab with two parallel free surfaces. The periodicity is preserved in two independent directions parallel to the surfaces. The atoms affected by the perturbation are located in the surface regions A and B. **(c)** For identical surfaces, a symmetry transformation allows for the reduction of the perturbation subspace σ to one half of it (σ'), and for $N_3 \to \infty$, the slab problem transforms into that for a semi-infinite lattice with one single surface

and its implementation with density functional perturbation theory.

The Slab Method: Polarization and Classification of Surface Modes

In order to obtain useful information about the surface dynamics of the semi-infinite crystal from the direct numerical diagonalization of (23.10), the number of layers N_3 has to be chosen large enough so that the spectral features of the surface layers are clearly distinguished from those of the bulk. This is nicely illustrated in Fig. 23.3, which shows the phonon dispersion curves of a (111)-oriented slab of a monoatomic face-centered cubic (fcc) lattice for an increasing number of layers from 1 to 15. The calculation is based on the mass and nearest-neighbor force constants of copper. A single free-standing layer ($N_3 = 1$) shows only the three acoustic branches of shear vertical (SV), shear horizontal (SH), and longitudinal (L) polarization. The addition of a second layer ($N_3 = 2$) leads to three optical phonon branches, also of SV, SH, and L polarization, which have clear, avoided crossings with the acoustic branches of similar polarization. With additional layers, the number of modes increases at the rate of three new branches per layer, eventually leading to thicker and thicker phonon bands. Most of these branches are essentially those of bulk phonons projected onto the surface, as illustrated in Fig. 23.1, but already at ten layers, the effects of the surfaces become apparent with some branches that are well separated from relatively dense bands. The *spectral* localization of these isolated phonon branches corresponds to a *spatial* localization of their eigenvectors in the surface region where the perturbation is effective. These isolated branches are, therefore, attributed to *surface localized modes*.

When the penetration length of the surface wave is much less than the slab thickness, the frequencies of the pair of modes arising at the two surfaces of the slab are practically degenerate. In a slab of infinite thickness the two surfaces are independent of each other and the frequencies of the *microscopic* surface mode frequencies are equal, which is equivalent to replacing the thick slab with a semi-infinite crystal with a single surface.

The polarization and degree of localization of surface phonons can be assessed from the $\boldsymbol{Q}$-selected DOS projected on different planes and atomic coordinates, (23.9). Since the surface itself is not a mirror-symmetry plane the SV and L components of the displacements are coupled and out-of-phase with respect to each other, leading to an *elliptical* polarization. The plane containing the L and SV components is called the *sagittal plane*. When there is a sagittal plane that is also a mirror symmetry plane of the lattice, the polarization ellipse lies on the sagittal plane, and the polarization is more precisely called *sagittal*. Depending on the dominant component in the sagittal plane, the modes with sagittal polarization are designated as either quasi-transverse ($\approx$ SV) or quasi-longitudinal ($\approx$ L). On the other hand, in the case that the sagittal plane is not a mirror plane, as occurs, e.g., in the $\overline{\Gamma K}$ and $\overline{MK}$ directions of fcc(111) surfaces (Fig. 23.3), the polarization ellipse is rotated with respect to the sagittal plane, and the sagittal and SH components are mixed. Thus, the polarizations of $\approx$ SV and $\approx$ L modes may only be quasi-sagittal, and that of SH modes only quasi-SH.

Some slab eigenmodes may have a strong amplitude enhancement at the surface, and, therefore, a large projected DOS, even though their frequency lies within a bulk phonon band. This happens when their eigenvectors are either orthogonal or quasi-orthogonal to the eigenvectors of the bulk band. The first case is that of an *embedded surface mode*, giving a δ-function inside the perturbed projected DOS; the second case that of a *surface phonon resonance*, whose origin and nature are better described within the Green's function formalism introduced in the next section. Note that the eigenvector orthogonality characterizing an embedded surface mode may only occur along sagittal mirror symmetry directions; away from these directions these modes become resonances. For certain anisotropic surfaces along particular directions, the RW are actually embedded in the SH bulk band and are also known as pseudosurface modes (PSM).

Surface phonon branches are conventionally labeled by S_j ($j = 1, 2, 3, \ldots$), depending on their acoustic or optical character and polarization. In the example of Fig. 23.3, for $N_3 = 15$, the acoustic surface mode S_1 corresponds, in the long-wave limit ($Q \to 0$) to the Rayleigh wave (RW), then becomes elliptically polarized $\approx$ SV and pure (SV) at the zone boundary. The gap surface modes S_2 and S_3 are associated with the L bulk phonon band. In principle, each surface-projected bulk phonon band has its own surface branch. For example, the SH and L bulk bands generate, respectively, an SH acoustic surface branch (S_7), and an $\approx$ L acoustic surface branch, (S_6), (not shown in Fig. 23.3), which eventually end up as S_2 or S_3 at the zone boundaries. The $\approx$ L acoustic surface branch, which is detached from the lower edge of the L band, is normally superimposed on the SV transverse band and is, therefore, a resonance, sharing with the SV bulk modes its weak SV component. The velocities of both acoustic surface modes S_6 and S_7 for $\boldsymbol{Q} \to 0$, tend to the respective bulk velocities; thus, both surface modes have no surface wave counterpart in the elastic semi-infinite continuum and are, therefore, microscopic. In most metal surfaces, the $\approx$ L acoustic surface branch becomes anomalously soft with increasing $\boldsymbol{Q}$. For this reason, it is called the

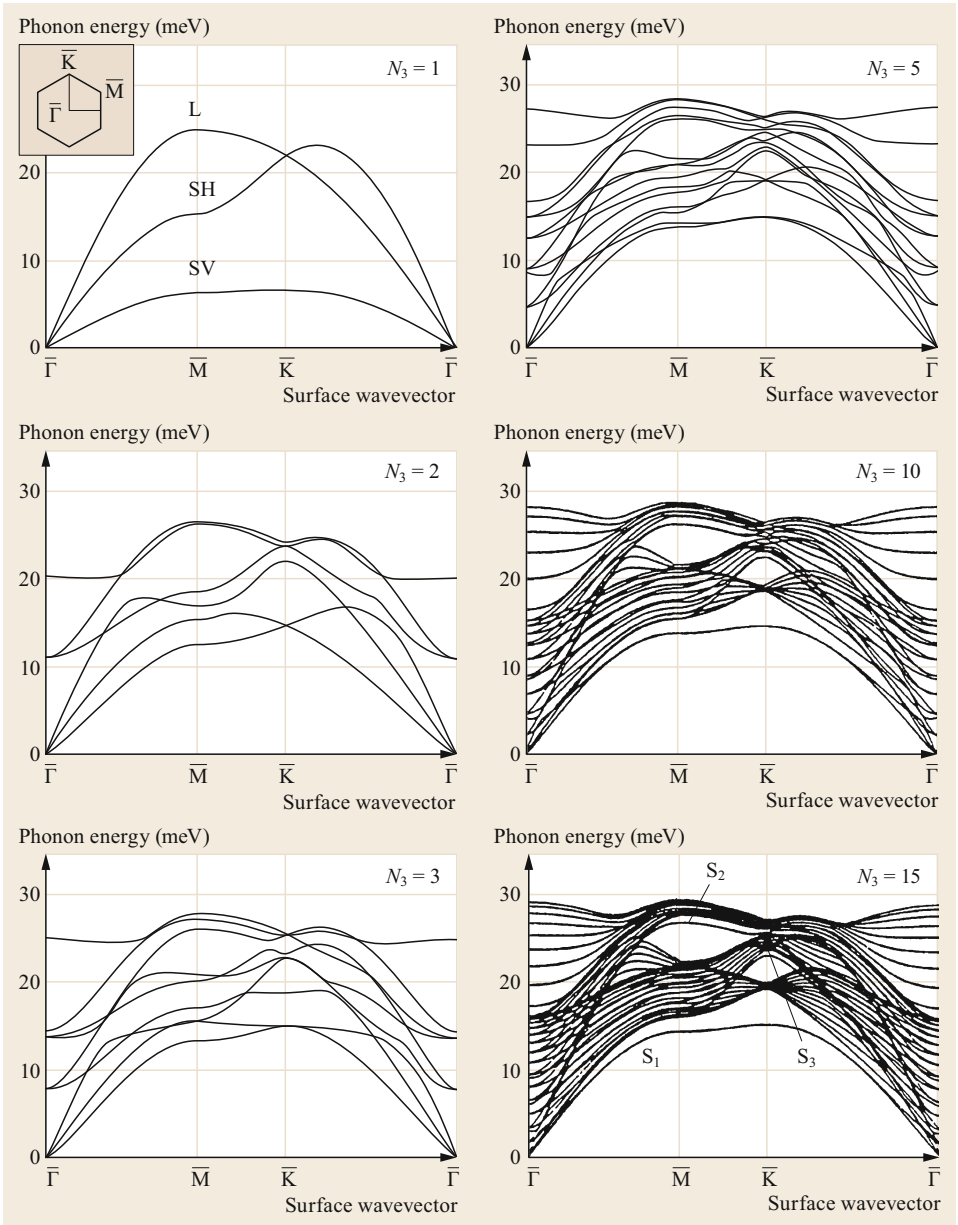

Fig. 23.3 The evolution to the surface phonon dispersion curves of an fcc(111) along the symmetry directions for an increasing number of layers, calculated with one single nearest-neighbor force constant, which gives the best fit of copper bulk phonons [23.4]. For a single layer ($N_3 = 1$) only the three acoustic modes of shear vertical (SV), shear horizontal (SH), and longitudinal (L) polarization occur (the *inset* shows the surface Brillouin zone with the symmetry directions), while for $N_3 > 1$ there are an increasing number of optical phonon branches. For $N_3 = 15$ the number of layers is sufficiently large to show a clear separation of the surface phonon branches (the Rayleigh wave branch S_1 and two gap modes S_2 and S_3) from the closely spaced surface-projected bulk bands

anomalous longitudinal surface phonon resonance and is usually labeled S_3.

In diatomic crystals, the three additional optical phonon branches lead to a corresponding number of additional surface phonon branches. In ionic crystals, e.g., NaCl, at $\boldsymbol{Q} = 0$ there is a degenerate pair of optical surface modes of L and SH polarizations, which are known as *Lucas modes* and are, respectively, labeled

S_4 and S_5. In addition, there is also a detached optical surface mode of SV polarization labeled S_2 (*Wallis mode*), which eventually ends in the gap S_2 mode at the zone boundary. Note that also monoatomic metals often behave as diatomic lattices at the surface due to surface relaxation, which confers a bilayer structure to the surface region. In this case, pairs of surface Lucas modes and an upper Wallis mode can be recognized, although, in general, they have the character of a resonance, except where they become localized gap modes. Another interesting case is that of diatomic crystals made of equal or nearly equal atom masses, which can be viewed as an approximate monoatomic lattice with a surface unit cell twice as large as the real one. In this case, additional surface optical branches originate from the folding at the zone boundaries of the acoustic modes. Folded RWs (denoted by S_8) are known to occur, e.g., in NaF(001), KCl(001), and also in Si(111)2×1.

In layered crystals, surface modes may have their largest amplitude at the n-th layer (with $n = 1$ the surface layer) and are usually labeled by SVn, SHn, and Ln, while Greek letters are often preferred for the quantum-well modes of thin films.

The Green's Function Method

For values of ω corresponding to localized surface modes that fall outside the spectrum $\{\omega_\nu\}$ of $\mathbf{R}_0(\boldsymbol{r})$, the matrix $\mathbf{R}_0(\boldsymbol{Q}) - \mathbf{M}\omega^2$ can be inverted and (23.10) can be rewritten as

$$\left\{\mathbf{I} - [\mathbf{M}\omega^2 - \mathbf{R}_0(\boldsymbol{Q})]^{-1}\boldsymbol{\Lambda}(\boldsymbol{Q})\right\}\boldsymbol{u} = 0\,, \quad \omega \notin \{\omega_n\}\,. \tag{23.11}$$

Nonvanishing eigenvectors of (23.11) are obtained for each $\boldsymbol{Q}$ at the values of ω fulfilling the equation

$$\det\left\{\mathbf{I} - [\mathbf{M}\omega^2 - \mathbf{R}_0(\boldsymbol{Q})]^{-1}\boldsymbol{\Lambda}(\boldsymbol{Q})\right\} = 0\,, \quad \omega \notin \{\omega_n\}\,. \tag{23.12}$$

The determinant of this linear equation is taken in the small subspace of the perturbation matrix $\boldsymbol{\Lambda}(\boldsymbol{Q})$ and not in the large space of the matrix $\mathbf{R}_0(\boldsymbol{Q})$. The reduction of the problem from the large space of the slab to the small space of the perturbation is the central idea of the Green's function (GF) method [23.72, 82, 84–90].

The Green's function method also provides a suitable framework to describe another important effect of the surface perturbation, the emergence of resonances in the spectrum of bulk mode frequencies. For $N_3 \to \infty$, the set of eigenfrequencies $\{\omega_\nu\}$ constituting the spectrum of the unperturbed matrix $\mathbf{R}_0(\boldsymbol{Q})$ tends to a continuum, and at any frequency ω of this spectrum, there is an eigenvector $\boldsymbol{u}_0$, which solves the unperturbed dynamical problem. The problem to be solved is, therefore, the calculation of the distortion of the unperturbed waves produced by a localized perturbation, and it can be treated within scattering theory. For a frequency ω falling inside $\{\omega_\nu\}$, (23.10) can be transformed into

$$\boldsymbol{u} = \boldsymbol{u}_0 + \mathbf{G}_0(\boldsymbol{Q}, \omega^2)\boldsymbol{\Lambda}(\boldsymbol{Q})\boldsymbol{u}\,, \quad \omega \in \{\omega_\nu\}\,, \tag{23.13}$$

where $\boldsymbol{u}_0$ is an eigenvector of $\mathbf{R}_0(\boldsymbol{Q})$ for the eigenfrequency ω and

$$\mathbf{G}_0(\boldsymbol{Q}, \omega^2) = [\mathbf{M}(\omega^2 + \mathrm{i}0^+) - \mathbf{R}_0(\boldsymbol{Q})]^{-1}\,, \quad \omega \in \{\omega_\nu\} \tag{23.14}$$

is the unperturbed GF matrix, defined as the analytical continuation of $[\mathbf{M}\omega^2 - \mathbf{R}_0(\boldsymbol{Q})]^{-1}$ into the complex plane. The shift of the frequency ω away from the real axis by the infinitesimal quantity $\mathrm{i}0^+$ into the upper complex half-plane allows for the inversion in (23.14) for ω^2 inside the spectrum of $\mathbf{R}_0(\boldsymbol{Q})$. In scattering theory, (23.13) is known as the Lippmann–Schwinger equation [23.91]. Its formal solution is given by

$$\begin{aligned}\boldsymbol{u} &= \left[\mathbf{I} - \mathbf{G}_0\left(\boldsymbol{Q}, \omega^2\right)\boldsymbol{\Lambda}(\boldsymbol{Q})\right]^{-1}\boldsymbol{u} \\ &= \boldsymbol{u}_0 + \mathbf{G}_0\left(\boldsymbol{Q}, \omega^2\right)\mathbf{T}\left(\boldsymbol{Q}, \omega^2\right)\boldsymbol{u}_0\,,\end{aligned} \tag{23.15}$$

where

$$\mathbf{T}\left(\boldsymbol{Q}, \omega^2\right) \equiv \boldsymbol{\Lambda}(\boldsymbol{Q})\left[\mathbf{I} - \mathbf{G}_0\left(\boldsymbol{Q}, \omega^2\right)\boldsymbol{\Lambda}(\boldsymbol{Q})\right]^{-1}\,, \tag{23.16}$$

is the transition matrix (or simply the **T**-matrix) and has nonzero elements only in the subspace of the perturbation $\boldsymbol{\Lambda}$. Equation (23.15) is viewed as the solution of a scattering problem with the eigenvector $\boldsymbol{u}$ given by the sum of the incident wave $\boldsymbol{u}_0$ and the scattered wave $\mathbf{G}_0\mathbf{T}\boldsymbol{u}_0$ produced by the perturbation $\boldsymbol{\Lambda}$, which here acts as a scattering potential. In general, the perturbed wave $\boldsymbol{u}$ in (23.15) is not normalized in the same way as $\boldsymbol{u}_0$ and may need to be multiplied by a normalization constant.

Owing to the factor $[\mathbf{I} - \mathbf{G}_0\boldsymbol{\Lambda}]^{-1}$, called the *resonant denominator*, the elements of the **T**-matrix are all proportional to

$$\begin{aligned}&\frac{1}{\det(\mathbf{I} - \mathbf{G}_0\boldsymbol{\Lambda})} \\ &= \frac{\mathrm{e}^{\mathrm{i}\theta}}{|\mathrm{Re}[\det(\mathbf{I} - \mathbf{G}_0\boldsymbol{\Lambda})] + i\mathrm{Im}[\det(\mathbf{I} - \mathbf{G}_0\boldsymbol{\Lambda})]|}\,,\end{aligned} \tag{23.17}$$

where the argument

$$\theta = -\arctan \frac{\mathrm{Im}[\det(\mathbf{I}-\mathbf{G}_0\mathbf{\Lambda})]}{\mathrm{Re}[\det(\mathbf{I}-\mathbf{G}_0\mathbf{\Lambda})]} \tag{23.18}$$

gives the phase shift between the incident and the scattered wave [23.86, 87]. According to (23.16) and (23.17) a resonance enhancement of the **T**-matrix and, therefore, of the amplitude of the perturbed wave with respect to the incident wave, occurs at frequencies ω where

$$\mathrm{Re}\{\det[\mathbf{I}-\mathbf{G}_0(\boldsymbol{Q},\omega^2)\mathbf{\Lambda}(\boldsymbol{Q})]\} = 0\,. \tag{23.19}$$

This equation is a generalization of (23.12). It gives the frequencies of both surface resonances, for ω inside $\{\omega_\nu\}$, and localized modes, for ω outside $\{\omega_\nu\}$. In the latter case, the determinant of (23.19) is a real function. According to (23.18) a resonance occurs when the phase shift θ between the incident and the scattered wave is equal to $\pi/2$. This corresponds exactly to the case of a forced mechanical oscillator, with the incident wave playing the role of external oscillating force and the scattered wave that of the oscillator response. The scattered part of the wave becomes very large with respect to the incident wave.

In general, the size of the matrix $\mathbf{\Lambda}$ subspace σ' is determined by the range of the interatomic force constants. However, it was shown [23.84] that even in the presence of long-range Coulomb forces, as in ionic crystals, the symmetry operation reducing σ to σ' leads to a perturbation matrix whose elements decay exponentially for increasing l_3, l_3'. This justifies using a cut-off and working with a small perturbation matrix. Moreover, for intrinsic surface perturbations resulting in a relaxed unreconstructed surface, the translational and rotational invariance conditions, which must be fulfilled by the perturbed force constant matrix, define a set of effective surface force constants in terms of $\boldsymbol{Q}=0$ elements of the inverse unperturbed projected Green's functions [23.84]. Such internal self-consistency tests of the intrinsic surface perturbation of the alkali halide (001) surfaces [23.82, 92] can probably be extended to more complex intrinsic surfaces of current interest.

Surface localized modes and resonances yield important features in the perturbed density of phonon states, as shown in the following definitions. By means of the identities

$$\frac{1}{\omega^2-\omega_\nu^2+\mathrm{i}0^+} = \frac{1}{\omega^2-\omega_\nu^2} - \mathrm{i}\pi\delta\left(\omega^2-\omega_\nu^2\right)\,, \tag{23.20}$$

$$\delta(\omega^2-\omega_\nu^2) = \frac{1}{2\omega}\left[\delta\left(\omega-\omega_\nu\right)+\delta\left(\omega+\omega_\nu\right)\right], \tag{23.21}$$

the *total unperturbed* $\boldsymbol{Q}$-selected DOS can be written as

$$D_0(\boldsymbol{Q},\omega) = -\frac{2\omega}{\pi}\mathrm{Tr}\{\mathrm{Im}[\mathbf{M}\mathbf{G}_0(\boldsymbol{Q},\omega^2)]\}\,. \tag{23.22}$$

The *total perturbed* $\boldsymbol{Q}$-selected DOS, $D(\boldsymbol{Q},\omega)$, is defined in a similar way

$$D(\boldsymbol{Q},\omega) = -\frac{2\omega}{\pi}\mathrm{Tr}\{\mathrm{Im}[\mathbf{M}\mathbf{G}(\boldsymbol{Q},\omega^2)]\}\,, \tag{23.23}$$

where

$$\begin{aligned} G\left(\boldsymbol{Q},\omega^2\right) &= \left[\mathbf{M}\left(\omega^2+\mathrm{i}0^+\right)-\mathbf{R}_0(\boldsymbol{Q})-\mathbf{\Lambda}(\boldsymbol{Q})\right]^{-1} \\ &= \left[\mathbf{I}-\mathbf{G}_0\left(\boldsymbol{Q},\omega^2\right)\mathbf{\Lambda}(\boldsymbol{Q})\right]^{-1}\mathbf{G}_0\left(\boldsymbol{Q},\omega^2\right), \end{aligned} \tag{23.24}$$

is the *perturbed GF-matrix*. The change in the DOS can be expressed, after some algebra, as

$$\begin{aligned} &\Delta D\left(\boldsymbol{Q},\omega^2\right) \equiv D\left(\boldsymbol{Q},\omega^2\right) - D_0\left(\boldsymbol{Q},\omega^2\right) \\ &= -\frac{1}{\pi}\frac{\partial}{\partial\omega}\mathrm{Im}\left\{\ln\det\left[\mathbf{I}-\mathbf{G}_0\left(\boldsymbol{Q},\omega^2\right)\mathbf{\Lambda}(\boldsymbol{Q})\right]\right\} \\ &= \frac{1}{\pi}\frac{\partial\theta}{\partial\omega}\,. \end{aligned} \tag{23.25}$$

The diagonal elements

$$D_{0,l_3\kappa\alpha}(\boldsymbol{Q},\omega) = -\frac{2\omega}{\pi}\mathrm{Im}[\mathbf{M}\mathbf{G}_0(\boldsymbol{Q},\omega^2)]_{l_3\kappa\alpha,l_3\kappa\alpha}\,, \tag{23.26}$$

$$D_{l_3\kappa\alpha}\left(\boldsymbol{Q},\omega\right) = -\frac{2\omega}{\pi}\mathrm{Im}\left[\mathbf{M}\mathbf{G}\left(\boldsymbol{Q},\omega^2\right)\right]_{l_3\kappa\alpha,l_3\kappa\alpha} \tag{23.27}$$

are the unperturbed $\boldsymbol{Q}$-selected DOS *projected* onto the l_3-th plane, the κ-th sublattice and polarization α, and the corresponding *perturbed projected* $\boldsymbol{Q}$-selected DOS, respectively.

In the limit $N_3 \to \infty$, the densities of phonon states become continuous functions for ω inside $\{\omega_\nu\}$. Moreover, the perturbed phonon densities display δ-functions at certain frequencies ω_S outside $\{\omega_\nu\}$, which correspond to the localized surface modes. When they lie in the continuum $\{\omega_\nu\}$ of bulk modes, they exhibit sharp peaks at the resonance frequencies ω_R. By expanding the resonant denominator around ω_R, where its real part vanishes, a Lorentzian peak is obtained in the phonon density change [23.82, 91, 92]

$$\Delta D\left(\boldsymbol{Q},\omega\right) \cong \frac{1}{\pi}\frac{\Gamma/2}{\left(\omega-\omega_R\right)^2+(\Gamma/2)^2}\,, \tag{23.28}$$

$$\omega \approx \omega_R\,,$$

with a full width at half maximum (FWHM) given by

$$\Gamma = \frac{2\mathrm{Im}\{\det\left[\mathbf{I} - \mathbf{G}_0\left(\boldsymbol{Q}, \omega_\mathrm{R}^2\right)\boldsymbol{\Lambda}(\boldsymbol{Q})\right]\}}{\frac{\partial}{\partial\omega}\,\mathrm{Re}\{\det\left[\mathbf{I} - \mathbf{G}_0\left(\boldsymbol{Q}, \omega^2\right)\boldsymbol{\Lambda}(\boldsymbol{Q})\right]\}|_{\omega=\omega_\mathrm{R}}} \,. \tag{23.29}$$

From (23.28) and (23.29), it follows that the perturbed GF has a pole in the complex plane at $z = \omega_\mathrm{R} - \mathrm{i}\Gamma/2$ corresponding to a resonance. In order to fulfill causality [23.86, 87], by which the response, i.e., the scattered wave, follows the stimulus, i.e., the incident wave, Γ has to be positive. The same also holds for localized modes, for which, however, $\Gamma \to 0^+$ and the corresponding peaks in $D(\boldsymbol{Q}, \omega)$, (23.28), become δ-functions. Note that a solution ω_R of (23.19), which yields a negative Γ, does not contribute a real resonance but leads to an *antiresonance*, i.e., a depletion region in $D(\boldsymbol{Q}, \omega)$ with respect to $D_0(\boldsymbol{Q}, \omega)$. Such depletion regions compensate for the density of states transferred to localized and real resonant modes.

From the computational point of view, the GF method has the great advantage that all the diagonalizations are performed in the perturbation subspace rather than in the whole slab space. This advantage, however, is lost to some extent due to the comparatively difficult task of calculating the matrix elements of the complex-valued Green's functions, which require integrations over the bulk Brillouin zone with special care for frequencies around van Hove singularities [23.75, 92, 93]. For this reason, the GF method is nowadays less popular than the direct diagonalization of the whole slab dynamical matrix discussed above, the latter method now being more expedient due to the availability of fast computers.

On the other hand, the GF method provides a convenient framework for the calculation of the various vibrational response functions of the surface, for example, the inelastic atom-scattering cross section [23.4, Chap. 7]. Such response functions can, in general, be expressed in terms of the time-dependent displacement-displacement correlation function $\langle \widehat{u}_\alpha(l\kappa, t)\widehat{u}_\beta(l'\kappa', 0)\rangle_T$, where

$$\widehat{u}_\alpha\left(l\kappa, t\right) = \sum_{\boldsymbol{Q}\nu} u_\alpha\left(l_3\kappa, \boldsymbol{Q}\nu\right) \mathrm{e}^{\mathrm{i}\boldsymbol{Q}\cdot\boldsymbol{r}_l} \left(b^+_{\boldsymbol{Q}\nu}\mathrm{e}^{\mathrm{i}\omega_{\boldsymbol{Q}\nu}t} + b^-_{\boldsymbol{Q}\nu}\mathrm{e}^{-\mathrm{i}\omega_{\boldsymbol{Q}\nu}t}\right) \tag{23.30}$$

is the displacement field operator, $b^+_{\boldsymbol{Q}\nu}$ and $b_{\boldsymbol{Q}\nu}$ are phonon creation and annihilation operators, respectively, and $\langle\ldots\rangle_T$ means the thermal average at temperature T. With some little algebra, it is found that

$$\int_{-\infty}^{\infty} \mathrm{d}t\mathrm{e}^{\mathrm{i}\omega t}\left\langle \widehat{u}_\alpha(l\kappa, t)\widehat{u}_\beta(l'\kappa', 0)\right\rangle_T = -\frac{2\hbar}{1 - \mathrm{e}^{-\hbar\omega/(k_\mathrm{B}T)}}\mathrm{Im}[G_{\alpha\beta}(l\kappa, l'\kappa', \omega^2)] \,, \tag{23.31}$$

where $G_{\alpha\beta}(l\kappa, l'\kappa', \omega^2)$ are the GF-matrix elements in the direct lattice space and the 2-D Fourier transforms of the elements of $G(\boldsymbol{Q}, \omega^2)$ [23.72, 75].

23.2 The Role of Electrons in Surface Dynamics

As anticipated in the introduction to this chapter, the experimental and theoretical study of surface phonons aims at understanding the basic atomic scale interactions operating at the surface of different classes of solid materials. The methods illustrated in Sect. 23.1 rely on the force constant matrix introduced by (23.2). After recognizing the essential role of valence electrons in determining bulk force constants in the 1960s, theoretical surface dynamics gradually moved away from force-constant models, which in various ways indirectly included the electronic degrees of freedom, to first-principles methods based on density functional theory. At the same time, powerful new experimental methods were developed, like high-resolution electron energy loss (HREELS), helium atom scattering (HAS), and, more recently, inelastic x-ray (IXS) spectroscopies. In particular, besides providing high-resolution data on surface phonon dispersion curves, HAS qualifies as a unique tool to detect deep subsurface modes in conducting materials through the so-called *quantum sonar effect* [23.94, 95]. This enables the direct measurement of the mode-selected electron–phonon coupling strength (*mode-λ spectroscopy*) in these systems [23.94, 96, 97]. A thorough report on HAS theory and data for the surface phonon dispersion curves of more than 200 surfaces of single crystals, ultrathin films, and adsorbed layers can be found in the Landolt–Börnstein collection and the chapter and monograph mentioned above [23.4, 5].

23.2.1 From Rigid Ions to Shell Models

The early lattice force-constant models considered atoms as hard massive spheres (rigid ion (RI) model)

disregarding the actual shape of the valence electron distribution and its deformation during the atomic motion. Historically, the rigid ion model was first used for the bulk [23.101] and surface dynamics of ionic crystals [23.102]. Due to its simplicity, it is still in use as a first-order approach to the surface dynamics especially in complex systems [23.103]. Moreover, it provides a fair approximation for the surface dynamics of close-shell monoatomic crystals like rare-gas solids.

The surface dispersion curves for Xe(111) measured with HAS (Fig. 23.4; [23.100]) are very well reproduced by the RI model with a single nearest-neighbor central force constant but with a 15% softening of the force constant at the surface layer [23.98]. This model, originally introduced by *Hall* et al. for Cu(111) [23.99], permits us to assign the observed modes above the RW (S_1) to the longitudinal acoustic (S_3) and to the optical surface resonances S_2 and S_4. The fact that these resonances are observed by HAS despite their prevalent localization in the second atomic layer is attributed to an unexpected electron–phonon interaction due to the comparatively large polarizability of surface Xe atoms, which also provides a mechanism for the 15% surface force constant softening at the surface. This effect of the electron–phonon interaction is confirmed by the first-principles DFPT calculation reproduced in Fig. 23.4b [23.98]. Despite the fact that the calculated S_2 resonance is about 15% above the HAS experimental data, the DFPT calculation predicts the S1 mode at the same frequency as the RI calculation with a 15% softening.

The electronic susceptibility plays a crucial role in determining the phonon dispersion relations in all three classes of solids, insulators, semiconductors, and metals. Since in lattice dynamics atoms are treated as discrete entities, the indirect forces between ion cores that are mediated by the interposed electrons can be approximately modeled by additional degrees of freedom associated either with the deformation (polarization) of the electronic shells in closed-shell insulators, or the motion of the bond charges in covalent of partially covalent semiconductors, or the charge density oscillations in free-electron conductors. There is a wide class of models where many-body effects are accounted for by a set of electronic coordinates harmonically coupled to the ion core coordinates in the adiabatic approximation [23.104–107]. In particular, the shell model (SM), formulated independently by *Dick* and *Overhauser* [23.108] and *Cochran* [23.109, 110] for the analysis of the phonon dispersion curves in insulators, gives excellent results also for the surface dynamics of ionic crystals within the slab method [23.111–117].

In the SM, the valence electron shells can be rigidly displaced with respect to ion cores, which corresponds to dipolar polarization. More sophisticated versions of the SM, including shell deformabilities of

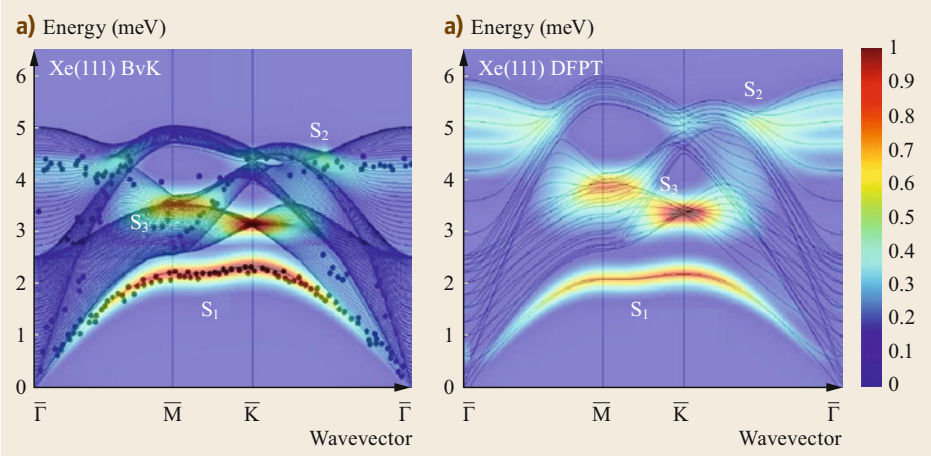

Fig. 23.4 **(a)** An RI model calculation for the Xe(111) surface [23.98], similar to the RI calculation of *Hall* et al. for Cu(111) [23.99], with one single bulk nearest-neighbor central force constant. By reducing the force constant in the first layer by 15% it was possible to reproduce the frequencies of the RW (or S_1) modes, and the S_3 and S_2 resonances observed with HAS (*black dots*) [23.98, 100]. The color code indicates the surface-projected phonon density. The prevalent second-layer displacements of the S_2 resonance and of S_3 at the $\overline{\mathbf{M}}$-point are attributed to an important electron–phonon (e–ph) interaction resulting from the large Xe atom polarizability. This also explains the 15% surface force constant softening. **(b)** This effect of the e–ph interaction is confirmed by a first-principles DFPT calculation [23.98], which is in general agreement with the HAS data, except that the S_3 and S_2 resonances are too high in frequency by about 12 and 20%, respectively

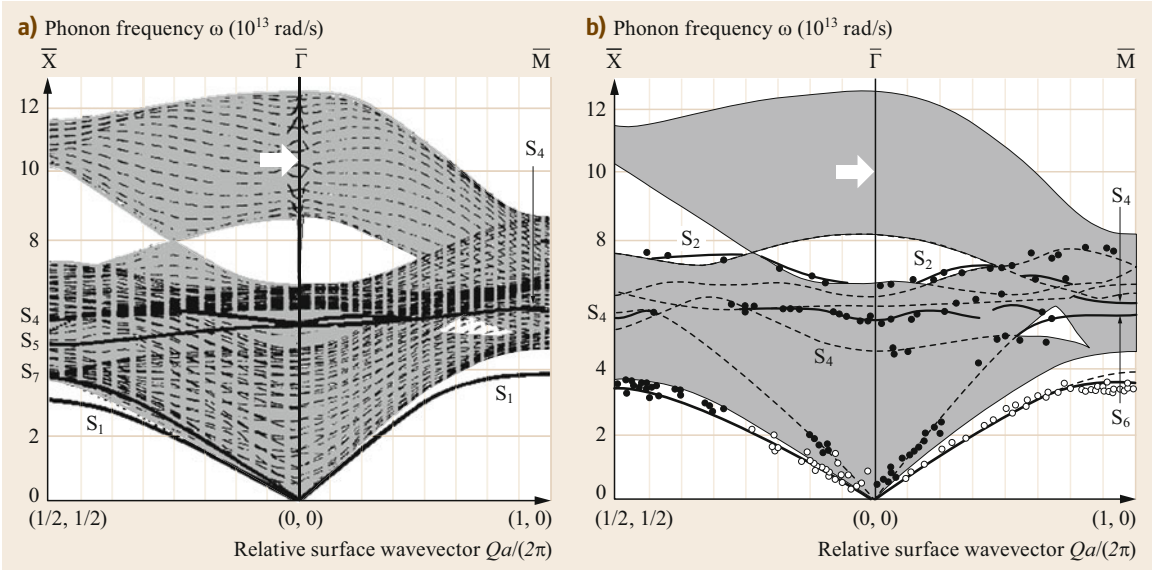

Fig. 23.5a,b Surface phonon dispersion curves of LiF(001) along the symmetry directions calculated with **(a)** the shell model (SM) and the slab method (all polarizations) [23.117] and **(b)** with the breathing-shell model (BSM) and the Green's function (GF) method (only sagittal polarization ⊥) [23.83, 118]. The better resolution of the GF method in **(b)** permits us to resolve additional surface modes, like the optical branches S_2 and S_4 and the sagittal acoustic branch S_6; S_1 is the Rayleigh wave, and S_4 the longitudinal Lucas mode [23.119]. The S_5 and S_7 branches in the SM calculation, shown in **(a)**, are the SH Lucas mode and the SH Alldredge mode, respectively [23.112]. The slab calculation also shows the signature of the macroscopic Fuchs and Kliever (FK surface phonon polariton) (*white arrow*) [23.120, 121]. The GF method predicts the existence of the FK mode, provided the surface depolarization field is added to the surface polarization [23.82]. HAS data points are from (○) [23.17–19] and (●) [23.122]. Some data points follow the band edges, where there are maxima of the surface-projected DOS

monopolar (breathing shell model, BSM [23.123, 124]) and/or quadrupolar types (quadrupolar shell model, QSM [23.125, 126]), have been used for a more precise description of the dynamical polarization phenomena in different classes of ionic compounds. In combination with the GF method, the BSM proved to give excellent results in the calculation of alkali halide surface phonons [23.82–84, 92], as seen in Fig. 23.5a for LiF(001) in comparison with a slab SM calculation (Fig. 23.5a) and the HAS data. In particular, the BSM, unlike SM, predicts the correct S_2 optical branch and the $\overline{M}$-point softening of the RW (S_1), in agreement with HAS data. Zone-boundary RW softening has been explained as being due to the surface increase of the F^- ion polarizability. As shown in the previous section, the GF method directly provides the vibrational response functions for a semi-infinite crystal, thus being particularly suited to the calculation of inelastic HAS spectra [23.118, 127, 128].

In transition metal compounds, characterized by open shells, more degrees of freedom are needed to represent the response of the valence electrons. This led to the formulation of the double-shell model (DSM), where more than one shell per atom is included [23.129], and the cluster model (CM), where hybridized shells of the transition metal atom with those of the surrounding ligand ions are considered [23.130]. The CM, combined with the GF method, proved efficient for the study of surface phonon superconducting anomalies in TiN(001) [23.131, 132], accounting for the surface DOS excess measured by neutron inelastic scattering (NIS) in nanometric powders [23.133, 134].

As seen in Fig. 23.6a, the calculated surface phonon dispersion curves present important Kohn anomalies in the quasi-L ($\underline{S_6}$) mode at about 2/3 of the Brillouin zone (BZ) in the $\overline{\Gamma M}$, the same position as for the longitudinal acoustic (LA) bulk mode, and in the RW (S_1), shifted to 1/2 of the BZ. Such features are called *superconducting anomalies*, since they are attributed to the electron–phonon interaction responsible for the superconductivity in this class of materials. The comparison between the calculated surface-excess phonon DOS (Fig. 23.6b) with that observed with NIS (above) shows a softening of the surface gap S_2 and of the RW modes indicated by vertical arrows in Fig. 23.6a and horizontal arrows in Fig. 23.6b. In order to obtain a quantitative agreement, an enhancement of the electron–phonon interaction in the surface layer is required. As discussed

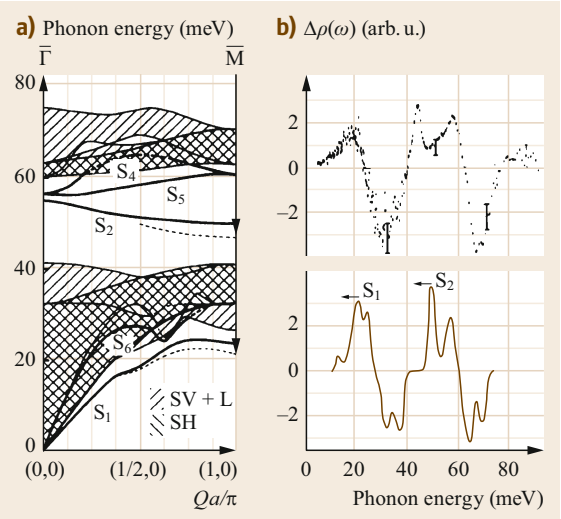

Fig. 23.6 **(a)** A cluster shell model (CM) Green's function calculation of the surface phonon dispersion curves of TiN(001) [23.131]. **(b)** The DOS from neutron inelastic scattering (NIS) from nanometric powders [23.134] (*top*) is compared with the corresponding surface-excess phonon density from the CM-GF calculation (*bottom*). The *vertical arrows* in **(a)**, which correspond to the *horizontal arrows* in **(b)**, show the softening of the surface phonon. An increase of the electron–phonon interaction at the surface yields good agreement between theory and experiment

in [23.131], this would imply a slight increase of the superconducting T_c for nanocrystals smaller in size than the coherence length.

In covalent or partially covalent crystals, the many-body effects due to the bonding electrons, e.g., the three-body angle-bending force constants, have been well described by the valence force field (VFF) theory [23.135, 136] and the Keating model (KM) [23.137, 138], with useful results in the dynamical theory of covalent semiconductors [23.139]. These methods provided the basis for the bond charge model (BCM) [23.140–146], which includes new adiabatic degrees of freedom associated with the valence electrons of the covalent bonds. Following *Fleszar* and *Resta*'s demonstration that BCM stands on a solid first-principles quantum mechanical basis [23.147], the BCM extension to treat π-bonding electrons [23.148] provided a reliable and efficient tool for surface dynamics of covalent semiconductors [23.148], III–V compounds [23.149], and graphite [23.150, 151]. Two basic examples of BCM calculations for the native Si(111) 2×1 and C(0001) surfaces are shown in Figs. 23.7 and 23.8. The 2×1 reconstructed Si(111) surface is characterized by the presence of π-bonded chains (atoms 1, 2 in the left upper inset of Fig. 23.7), which host a flat surface phonon branch at about 10 meV. The large number of surface phonon branches, substantially confirmed by subsequent DFPT calculations [23.152], is due to the extended surface perturbation associated with the sequence of five and sevenfold atomic rings (Fig. 23.7, left inset). The surface displacements of the surface phonons at $\overline{\Gamma}$ are shown in the left inset in Fig. 23.7. Of special interest are the two modes above the bulk phonon maximum with in-plane polarization normal to the chains and the $I_z(00{+}{+})$ mode at 55 meV, which is localized on the fivefold ring. It is the first microscopic surface phonon observed with HREELS by *Ibach* in 1971 [23.6].

The success of BCM in dealing with semiconductor surfaces with π-bonded chains naturally led to graphite, where BCM, although less popular, proved to be superior to the Born–von Kármán treatments with many parameters [23.165–169]. A six-parameter BCM calculation for C(0001) [23.150, 151], shown in Fig. 23.8a, compares quite well with the HREELS data [23.155–158] and to a minor extent with DFT-LDA and DFT-GGA calculations [23.154], shown in Fig. 23.8b. Some of the critical points of discrepancy are indicated in Fig. 23.8 by arrows. For example, the TA-ZO and LA-LO quasi-degeneracies at the $\overline{M}$ point predicted by a DFT-GGA calculation are not found in the HREELS data. On the other hand, DFT-GGA calculations reproduce quite well more recent inelastic x-ray spectroscopy (IXS) data [23.159], which, however, show relevant differences to the HREELS data, presumably because of the different penetration lengths of the two probes.

23.2.2 The Multipole Expansion Method

A feature common to all versions of shell and bond-charge models is the description of the electronic response to the atomic motion through suitable dynamical coordinates harmonically coupled to the ion coordinates. A unifying framework is provided by the multipole expansion (ME) method, originally formulated for lattice dynamics by *Allen* [23.170] as a special representation of the general microscopic theory constructed within a set of local basis functions [23.171–183]. This method, allowing for a general and efficient phenomenological treatment of the electronic degrees of freedom, proved quite successful in reproducing the anomalous dispersion curves of transition metals such as niobium [23.170], and later for the analysis of surface phonon anomalies in noble metals [23.184]. The microscopic basis of the ME method makes it suitable for either a first-principles calculation or a phenomenological parametrization known, in metal surface dynamics, as the pseudocharge (PC) model [23.185, 186]. Besides providing a convenient framework for the calculation of phonon dispersion curves, the ME method

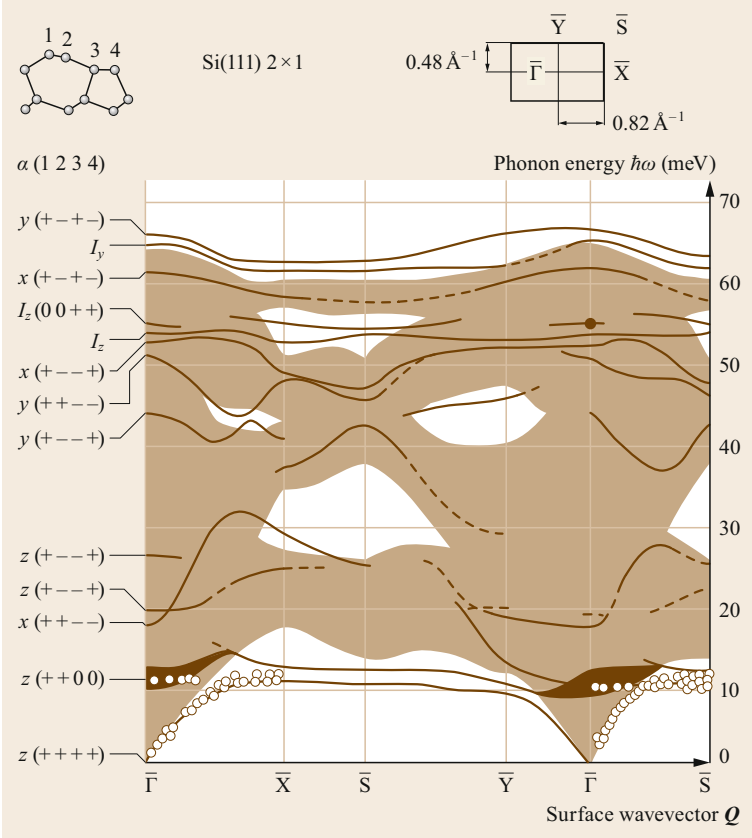

Fig. 23.7 BCM surface phonon dispersion curves of the native Si(111) 2×1 surface along the symmetry directions (*right-hand inset*) [23.148]. The zone center displacements of the four surface atoms (*left-hand inset*) are schematically indicated (I_y and I_z are modes with prevalent amplitudes at the interface between the reconstructed surface region and the undisturbed bulk below). The *hatched areas* represent the surface projected bulk phonon bands, the *dark areas* show the width of the 10 meV flat surface mode resulting from the folding of the RW and associated with the oscillations of the π-bonded chain (atoms 1–2 in *left-hand inset*). The experimental HAS data points (○) [23.153] are also shown. The large number of resonances (including the 55 meV mode (●) observed by *Ibach* with HREELS [23.6]), and optical surface modes localized in the gaps and above the bulk maximum reflect the complex surface reconstruction with a periodic sequence of five and sevenfold rings

has the special merit of providing the phonon-induced surface charge density oscillations, which are directly related to the inelastic HAS intensities and the corresponding mode-selected electron–phonon coupling. Although the ME method for the surface dynamics of ordinary metal surfaces has presently been superseded by efficient ab-initio methods such as the DFPT, it was revived recently for the interpretation of inelastic HAS spectra from more complex surfaces, such as those of topological insulators [23.187–189]. Actually, the ME method, besides providing a local-basis representation of DFPT, has the advantage of being easily extendable to treat nonadiabatic dynamics.

The essence of the ME method is the following. As in DFT, the total energy of the lattice system is written as the sum of the energy E_{ion} due to the direct interaction of the ion cores and the energy of the electrons given by a functional of the electron charge density $n(\boldsymbol{r})$ [23.190]

$$E = E_{\mathrm{ion}} + F[n(\boldsymbol{r})] + \int v_{\mathrm{ion}}(\boldsymbol{r}) n(\boldsymbol{r}) \mathrm{d}^3 r \,. \qquad (23.32)$$

The functional $F[n(\boldsymbol{r})]$ includes the electron–electron potential energy, as well as the kinetic energy; $v_{\mathrm{ion}}(\boldsymbol{r})$ is the external potential acting on the electron system. The electron density is expanded over an orthonormal set of localized basis functions $Y_\Gamma\,(\boldsymbol{r}-\boldsymbol{r}_{l\lambda})$, centered at convenient special points $\boldsymbol{r}_{l\lambda} = \boldsymbol{r}_l + \boldsymbol{r}_\lambda$, with $\boldsymbol{r}_l$ a unit cell position and $\boldsymbol{r}_\lambda$ a special point position within the unit cell

$$n(\boldsymbol{r}) = \sum_{\Gamma l\lambda} C_\Gamma(l\lambda) Y_\Gamma\,(\boldsymbol{r}-\boldsymbol{r}_{l\lambda}) \,. \qquad (23.33)$$

The basis functions $Y_\Gamma(\boldsymbol{x})$ are conveniently chosen as products of a radial function and an angular harmonic function transforming as the Γ-th irreducible representation of the point group at $\boldsymbol{r}_{l\lambda}$. Thus, Γ labels the harmonic order and its components and (23.32) is actually an ME of the charge density.

In a rigid-atom (ion) insulator, the electronic shells coincide with the atoms (ions), and no additional degree of freedom is needed. In a dipolar shell model (SM), the shells can move rigidly with respect to ion cores; in this case, Γ takes three values corresponding to the three components of an oscillating dipole, and the coefficients $C_\Gamma(l\lambda)$ are displacement vectors dynamically coupled to the atom (ion) core displacements $\boldsymbol{u}(l\kappa)$. In the breathing shell model (BSM),

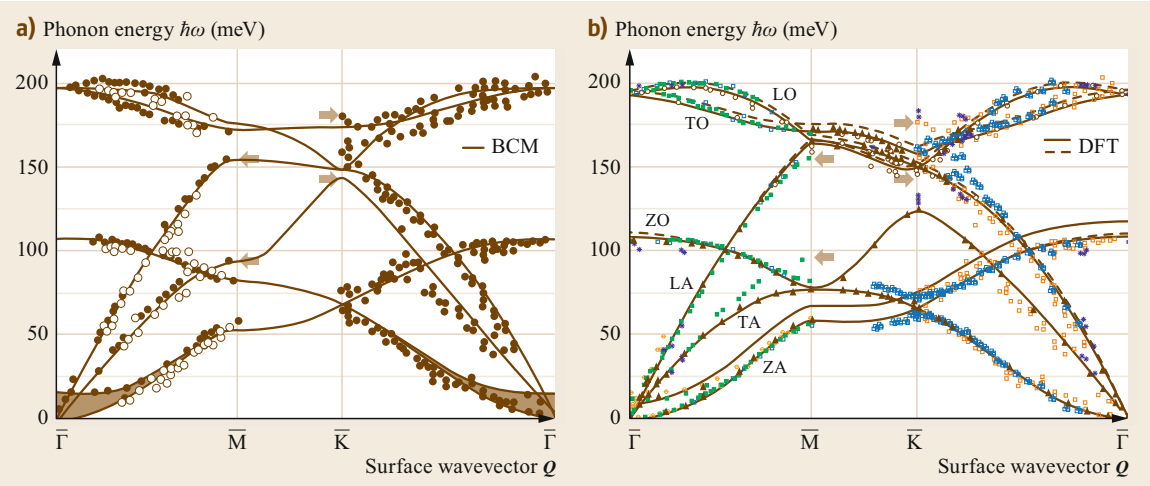

Fig. 23.8a,b Theoretical dispersion curves for the (0001) surface of graphite. **(a)** Calculated with BCM by *Benedek* and *Onida* [23.150], and **(b)** with ab-initio DFT-local density approximation (LDA, *dashed line*) and DFT-generalized gradient approximation (GGA, (*solid line*) by *Wirtz* and *Rubio* [23.154]. The data points in **(a)** are from HREELS (*open circles*: *Wilkes* et al. [23.155], *full circles*: *Oshima* et al. [23.156, 157], *Siebentritt* et al. [23.158]); data points in **(b)** from IXS (*black full triangles* [23.159], *black open circles* [23.160]), HREELS (*green full square* and *red open squares* [23.156–158], *blue open squares* [23.161]), double-resonance Raman scattering (DRRS), *blue crosses* [23.162]), infrared absorption (*open red triangles* [23.163]), and neutron scattering data (*orange open diamonds* [23.164]). The *arrows* mark the end points of the transverse acoustic (TA) and LA branches at $\overline{\mathrm{M}}$, and of the transverse optical (TO) branch at $\overline{\mathrm{K}}$ as obtained from HREELS, which are well reproduced by BCM but show significant differences from the IXS data, in turn well reproduced by the ab-initio calculations

the atomic shell can also have a breathing (spherical) deformation, and the $C_\Gamma(l\lambda)$ are scalar coefficients. For quadrupolar shell deformations, considered in the QSM, the coefficients $C_\Gamma(l\lambda)$ are (combinations of) components of a symmetric tensor. In metals, free-electron delocalization can be accounted for by electronic *shells*, denoted pseudocharges (PCs), which are centered at symmetry points of the unit cell away from ion positions, whereas valence electron shells are located at the ion positions. In general, the larger effects come from delocalized shells representing free electrons, and the dipolar components may be sufficient to account for the dynamical oscillations of the charge density.

The coefficients $C_\Gamma(l\lambda)$ are now split into their static and dynamic parts,

$$C_\Gamma(l\lambda, t) = C^0_\Gamma(l\lambda) + c_\Gamma(l\lambda, t)\,, \tag{23.34}$$

and the dynamic PC multipolar components $c_\Gamma(l\lambda)$ (omitting hereafter the argument t) are treated on the same footing as the displacement vectors. Similar to (23.1), the potential energy, is now expanded around its equilibrium value U_0 with respect to both the atomic displacements $\boldsymbol{u}(l\kappa)$ and PC components $c_\Gamma(l\lambda)$

$$\begin{aligned} U = U_0 &+ \frac{1}{2}\sum_{l\kappa\alpha,l'\kappa'\beta} R_{\alpha\beta}\left(l\kappa, l'\kappa'\right) u_\alpha(l\kappa) u_\beta(l'\kappa') \\ &+ \frac{1}{2}\sum_{l\kappa\alpha,l'\lambda'\Gamma'} \left[T_{\alpha\Gamma'}\left(l\kappa, l'\lambda'\right)\right. \\ &\left. + T^+_{\Gamma'\alpha}\left(l'\lambda', l\kappa\right)\right] u_\alpha(l\kappa) c_{\Gamma'}(l'\lambda') \\ &+ \frac{1}{2}\sum_{l\lambda\Gamma,l'\lambda'\Gamma'} H_{\Gamma\Gamma'}\left(l\lambda, l'\lambda'\right) c_\Gamma(l\lambda) c_{\Gamma'}(l'\lambda')\,, \end{aligned} \tag{23.35}$$

where the first-order derivatives are set to zero at equilibrium, and only quadratic terms in the dynamic variables are retained (*harmonic approximation*). The force-constant matrices for the atom–atom, atom–PC, and PC–PC interactions are, respectively, given by

$$\begin{aligned} R_{\alpha\beta}(l\kappa, l'\kappa') &= \frac{\partial^2 U}{\partial u_{l\kappa,\alpha}\partial u_{l'\kappa'\beta}} \\ &= \frac{\partial^2 E_{\mathrm{ion}}}{\partial u_{l\kappa,\alpha}\partial u_{l'\kappa'\beta}} + \int \mathrm{d}\boldsymbol{r} n(\boldsymbol{r}) \frac{\partial^2 v_{\mathrm{ion}}(\boldsymbol{r})}{\partial r_{l\kappa,\alpha}\partial r_{l'\kappa',\beta}} \\ &\equiv R^{\mathrm{ion}}_{\alpha\beta}(l\kappa, l'\kappa') + R^{\mathrm{el}}_{0,\alpha\beta}(l\kappa, l'\kappa')\,, \end{aligned} \tag{23.36}$$

$$T_{\alpha\Gamma}\left(l\kappa,l'\lambda'\right)=\frac{\partial^2 U}{\partial u_\alpha(l\kappa)\partial c_\Gamma(l'\lambda')}$$
$$=\frac{1}{V}\int \mathrm{d}^3 r\left[\frac{\partial\delta E_{\mathrm{tot}}}{\delta n(\boldsymbol{r})\partial u_\alpha(l\kappa)}\right]Y\left(\boldsymbol{r}-\boldsymbol{r}_{l'\lambda'}\right)$$
$$=\int \mathrm{d}^3 r\left[\frac{\partial v_{\mathrm{ion}}(\boldsymbol{r})}{\partial u_\alpha(l\kappa)}\right]Y_\Gamma\left(\boldsymbol{r}-\boldsymbol{r}_{l'\lambda'}\right), \qquad (23.37)$$

and

$$H_{\Gamma\Gamma'}\left(l\lambda,l'\lambda'\right)=\frac{\partial^2 U}{\partial c_\Gamma(l\lambda)\partial c_{\Gamma'}\left(l'\lambda'\right)}$$
$$=\frac{1}{V^2}\iint \mathrm{d}^3 r\mathrm{d}^3 r'\left[\frac{\delta^2 E_{\mathrm{tot}}}{\delta n(\boldsymbol{r})\delta n\left(\boldsymbol{r}'\right)}\right]$$
$$\times Y_\Gamma\left(\boldsymbol{r}-\boldsymbol{r}_{l\lambda}\right)Y_{\Gamma'}\left(\boldsymbol{r}-\boldsymbol{r}_{l'\lambda'}\right). \qquad (23.38)$$

As will be shown in Sect. 23.2.4, (23.48), only the pure electronic part $F(\boldsymbol{n})$ of the total energy functional will appear in (23.38). The atom–atom force-constant matrix, (23.36), is the sum of two terms, one related to the change of the atom–atom potential energy produced by a quadratic atom displacement, the other to the change of the electronic energy produced by the same quadratic atom displacement. The atom–PC force-constant matrix and its transposed PC–atom matrix express the electron–phonon interaction, while the PC–PC force constant matrix is related to the static electron susceptibility $\chi(\boldsymbol{r},\boldsymbol{r}')$ in the local basis representation, i.e.,

$$H^{-1}_{\Gamma\Gamma'}\left(l\lambda,l'\lambda'\right)=-\iint \mathrm{d}^3 r\mathrm{d}^3 r' Y_\Gamma\left(\boldsymbol{r}-\boldsymbol{r}_{l\lambda}\right)\chi\left(\boldsymbol{r},\boldsymbol{r}'\right)$$
$$\times Y^{+}_{\Gamma'}\left(\boldsymbol{r}-\boldsymbol{r}_{l'\lambda'}\right). \qquad (23.39)$$

The eigenvalue equations for the atomic and PC coordinates read

$$M_\kappa\omega^2 u_\alpha(l\kappa)=\sum_{l'\kappa'\beta}R_{\alpha\beta}\left(l\kappa,l'\kappa'\right)u_\beta(l'\kappa')$$
$$+\sum_{\Gamma l'\lambda'}T_{\alpha\Gamma}\left(l\kappa,l'\lambda'\right)c_\Gamma(l'\lambda'), \qquad (23.40)$$

$$\mu_\Gamma\omega^2 c_\Gamma(l\lambda)=\sum_{l'\kappa'\alpha}T^{+}_{\alpha\Gamma}(l\lambda,l'\kappa')u_\alpha(l'\kappa')$$
$$+\sum_{l'\lambda'\Gamma'}H_{\Gamma\Gamma'}(l\lambda,l'\lambda')c_{\Gamma'}(l'\lambda'), \qquad (23.41)$$

where ω is the angular frequency, and μ_Γ is the PC effective mass.

Equations (23.40) and (23.41) can be formally transformed into a dynamical equation for the atomic displacements and one providing the corresponding charge-density oscillations, now written in vector-matrix notation

$$\mathbf{M}\omega^2\boldsymbol{u}=[\mathbf{R}^{\mathrm{ion}}+\mathbf{R}^{\mathrm{el}}-\mathbf{T}(\mathbf{H}-\mu\omega^2)^{-1}\mathbf{T}^{+}]\boldsymbol{u}, \qquad (23.42)$$

$$\boldsymbol{c}=-(\mathbf{H}-\mu\omega^2)^{-1}\mathbf{T}^{+}\boldsymbol{u}. \qquad (23.43)$$

The *phonon dynamics* in the adiabatic approximation is obtained from (23.42) after setting $\mu=0$. The formalism coincides with the DFPT treatment (see later) [23.191] via the transcription, in the adiabatic approximation,

$$\sum_{\nu\boldsymbol{k}}^{\mathrm{occ}}\left\langle\psi_{\nu\boldsymbol{k}}\left|\frac{\partial^2 v_{\mathrm{ion}}(\boldsymbol{r})}{\partial u_\alpha(l\kappa)\,\partial u_\beta\left(l'\kappa'\right)}\right|\psi_{\nu\boldsymbol{k}}\right\rangle$$
$$=\int \mathrm{d}^3 r n(\boldsymbol{r})\frac{\partial^2 v_{\mathrm{ion}}(\boldsymbol{r})}{\partial u_\alpha\left(l\kappa\right)\partial u_\beta\left(l'\kappa'\right)}\quad\Rightarrow\quad\mathbf{R}^{\mathrm{el}}_0, \qquad (23.44)$$

$$\sum_{\nu\boldsymbol{k}}^{\mathrm{occ}}\left\langle\frac{\partial\psi_{\nu\boldsymbol{k}}}{\partial u_\alpha(l\kappa)}\left|\frac{\partial v_{\mathrm{ion}}(\boldsymbol{r})}{\partial u_\beta(l'\kappa')}\right|\psi_{\nu\boldsymbol{k}}\right\rangle+\mathrm{c.c.}$$
$$=\int \mathrm{d}^3 r\frac{\partial n(\boldsymbol{r})}{\partial u_\alpha(l\kappa)}\frac{\partial v_{\mathrm{ion}}(\boldsymbol{r})}{\partial u_\beta(l'\kappa')}$$
$$=\iint \mathrm{d}^3 r\mathrm{d}^3 r'\frac{\partial v_{\mathrm{ion}}(\boldsymbol{r})}{\partial u_\alpha(l\kappa)}\chi(\boldsymbol{r},\boldsymbol{r}')\frac{\partial v_{\mathrm{ion}}(\boldsymbol{r}')}{\partial u_\beta(l'\kappa')}$$
$$\Rightarrow\quad-\mathbf{T}\mathbf{H}^{-1}\mathbf{T}^{+}, \qquad (23.45)$$

where the sums are performed over the occupied electronic states of wavefunctions $|\psi_{\nu\boldsymbol{k}}\rangle$, band index ν, and wavevector $\boldsymbol{k}$.

The ME method offers a conceptually simple, although computationally demanding, scheme for the treatment of nonadiabatic effects, e.g., the nonadiabatic Kohn anomalies as produced by avoided crossings between a surface phonon dispersion curve and that of an electron–hole excitation [23.192, 193]. Moreover, when no adiabatic approximation is imposed, also the electronic collective excitations as represented by the dynamics of the PC coordinates, and their coupling to the phonon dynamics can be obtained from the joint solution of (23.42) and (23.43), as long as the electronic effective masses μ_Γ can be assigned in some way so as to appropriately model the frequency-dependent inverse electron susceptibility matrix $\mathbf{H}_{\Gamma\Gamma'}(l\lambda,l'\lambda';\omega)$. The dynamical equation for the PC coordinates and the equation providing the motion of atoms eventually following the electron density oscillations can be more

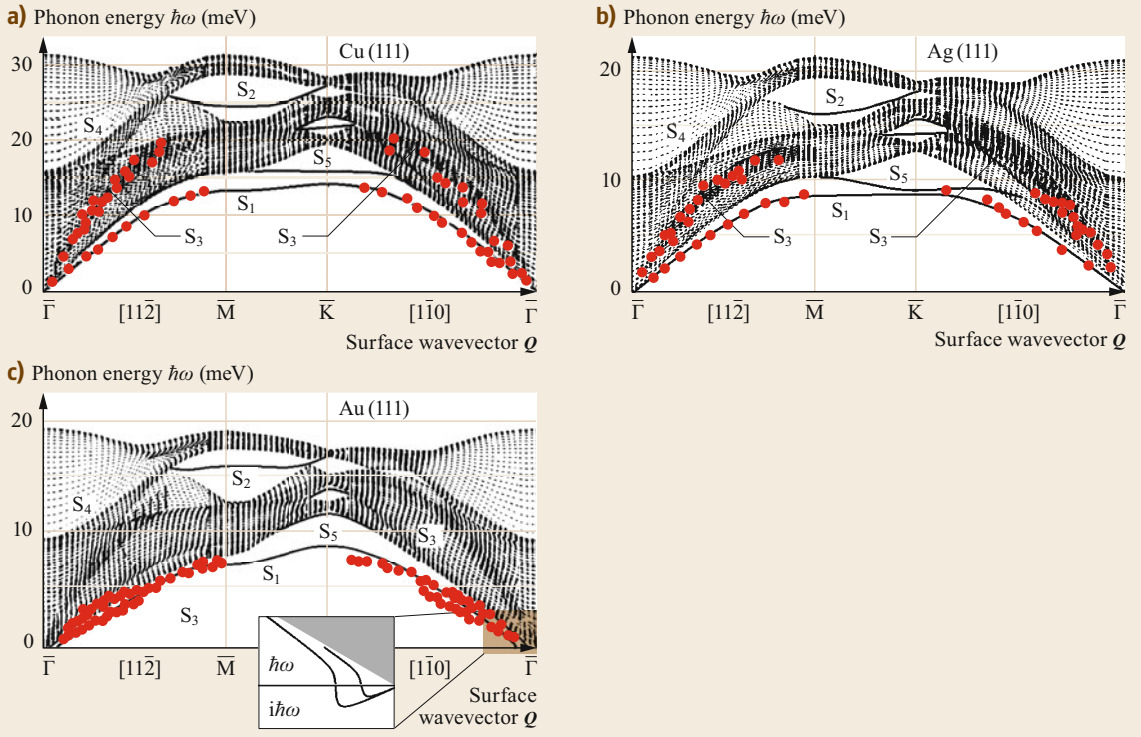

Fig. 23.9a–c PC model calculation of the surface phonon dispersion curves for **(a)** Cu(111), **(b)** Ag(111) and **(c)** Au(111) [23.184]. For Cu(111) and Ag(111), the PC model reproduces the RW (S_1) and the longitudinal acoustic resonance (S_3) dispersion curves in good agreement with HAS data (*full circles*) [23.21]. The PC calculation for Au(111), although including PC components up to octupoles, yields unstable surface acoustic branches at very small wavevectors (*inset*), consistent with the known $23 \times \sqrt{3}$ reconstruction of this surface [23.21]. The apparent doubling of the S_1 branch observed by HAS in both symmetry directions can be associated with two different domain orientations

conveniently written as

$$\mu\omega^2 \boldsymbol{c} = [\mathbf{H} - \mathbf{T}^+(\mathbf{R} - \mathbf{M}\omega^2)^{-1}\mathbf{T}^+]\boldsymbol{c}\,, \qquad (23.46)$$

$$\boldsymbol{u} = -(\mathbf{R} - \mathbf{M}\omega^2)^{-1}\mathbf{T}\boldsymbol{c}\,. \qquad (23.47)$$

In this case, the adiabatic approximation may consist in letting the atomic mass matrix $\mathbf{M}$ go to infinity so that only charge-density oscillations in a rigid lattice are obtained from the dynamical equation $\mu\omega^2\boldsymbol{c} = \mathbf{H}\boldsymbol{c}$ and $\boldsymbol{u} = 0$. When the dispersion curves of low-energy surface electronic collective excitations, such as occur in acoustic surface plasmons (ASPs), intersect the surface phonon spectrum, the coupling of the PC to the atom degrees of freedom is expected to lead to an avoided crossing between the ASP and surface-phonon branches and, even more importantly, to a renormalizing of the effective mass of the electron.

The ME method has been used in its phenomenological adiabatic PC model version with good results in the analysis of the dispersion curves and HAS spectra of 3d noble metals [23.184, 194] (Fig. 23.9). For Cu(111) and Ag(111), the PC model correctly predicts, besides the RW (S_1) dispersion curves, the longitudinal resonance S_3 observed with HAS. The S_3 resonance, later recognized as a peculiar feature of practically all metal surfaces, originates from the lower edge of the LA bulk band, showing a large anomalous softening towards the zone edge with an increasing localization on the second surface layer. Its anomalous softening, as well as its comparatively large HAS intensity were both explained by the PC model as clear manifestations of electron–phonon interaction [23.185, 186]. As originally shown by *Bortolani* et al. [23.195, 196], the S_1 and S_3 dispersion curves as well as their HAS intensities can, in principle, be reproduced with a simple BvK force constant model, at the cost, however, of a large unphysical softening of the surface constants. The PC model had the merit of elucidating the nature of the anomalous L resonance, similarly to what was obtained with another powerful approach, the embedded-atom (EA) method [23.197–203], also providing an effective semiempirical way to account for

the effects of the electron–phonon interaction in surface dynamics [23.194] (see the following section).

The PC model for the bulk dynamics of gold requires PC components to octupole order to account for the large anisotropy at the surface. When applied to the dynamics of the ideal (unreconstructed) Au(111) surface (Fig. 23.9), the PC model, while reproducing the HAS data for the RW (S_1) branch quite well, yields unstable surface acoustic branches at very small wavevectors (inset), consistently with the instability and the $23 \times \sqrt{3}$ reconstruction of this surface [23.204]. The apparent doubling of the S_1 branch observed by HAS in both symmetry directions has been attributed to an ultrasoft S_3 branch, on the basis of a molecular dynamics analysis [23.205]. An alternative explanation is a doubling of the RW due to two different domain orientations of the reconstructed surface. On the other hand, no HAS data corresponds to the anomalous resonance S_3 predicted by the PC model, suggesting that the surface PCs do not respond to the motion of the second layer atoms as a consequence of their stabilization into a charge-density wave (CDW) of the reconstructed phase. More recent high-resolution ^{3}He-spin-echo scattering measurements by *McIntosh* et al. [23.206] have given clear evidence of phason excitations of the quasi-incommensurate $23 \times \sqrt{3}$-Au(111) surface, in agreement with earlier molecular dynamics (MD) predictions [23.207]. This system offers an example where the ME method would permit a description of both phonon and phason dynamics and their possible coupling. The large size of the unit cell, and the possible need for a nonadiabatic treatment, still make this kind of dynamical problems difficult to access for present ab-initio methods.

Another interesting case is that of Xe(111) surface dynamics (Fig. 23.4). As can be seen in Fig. 23.10, the experimental HAS dispersion curves of the noble gas crystal Xe(111) [23.98, 100] exactly match also those calculated with the PC model for Cu(111) after a rescaling by about a factor of 6 for the larger mass and softer force constants. As discussed above, this agreement is also obtained with the simplest RI model, but the observation with HAS of the optical SV2 and L2 branches localized on the second layer would not be explained, unless there are corresponding surface charge density oscillations. This is actually the mechanism that is accounted for by the PC model, and is confirmed by DFPT, as is discussed in the next section.

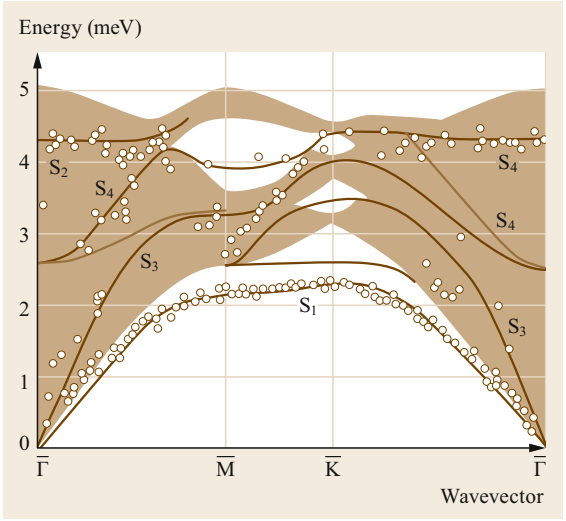

Fig. 23.10 The HAS dispersion curves of Xe(111) (*red dots*, Fig. 23.4 [23.98, 100]) are very well fitted by the PC calculation for Cu(111), Fig. 23.9, after a rescaling by a factor 6.2 to account for the larger mass and softer force constants. The observation by HAS of the optical subsurface resonances S_2 and S_3 localized on the second atomic layer is actually explained by the PC model as being due to the associated oscillations of the surface PCs. Although a closed-shell atom, Xe, has a large polarizability by which the second layer atom displacements yield large oscillations (polarizations) of the atomic shells in the surface layer

23.2.3 From Semiempirical to Full Ab-initio Methods

The great progress made in the theory and calculations of the electronic band structure in all kinds of solids during the last three decades has made it possible to evaluate the electronic contributions to the total energy of solids as a function of the atomic positions. This development has opened up a new phase in the theory of surface dynamics. In insulators and semiconductors, short-range repulsive force constants can be derived directly from the overlap of atomic orbitals. In more general terms, the interatomic force constants can be obtained from a tight-binding (TB) scheme for the electronic structure, provided that the dependence on the interatomic distances of the Coulomb and hopping integrals between neighboring atoms are known [23.213]. Such integrals are, in turn, determined either from fitting procedures (empirical TB) or from first-principles calculations of the electronic structure. The TB methods give reliable results for the surface phonon frequencies of covalent and III–V semiconductors [23.214] with a reasonable computational effort. In the semiempirical total energy method (SETE) developed by *Pollmann* and coworkers [23.215, 216] an empirical TB scheme is used to calculate the band structure contribution to the total energy, whereas the short-range repulsive contribution is expressed by phenomenological pair potentials.

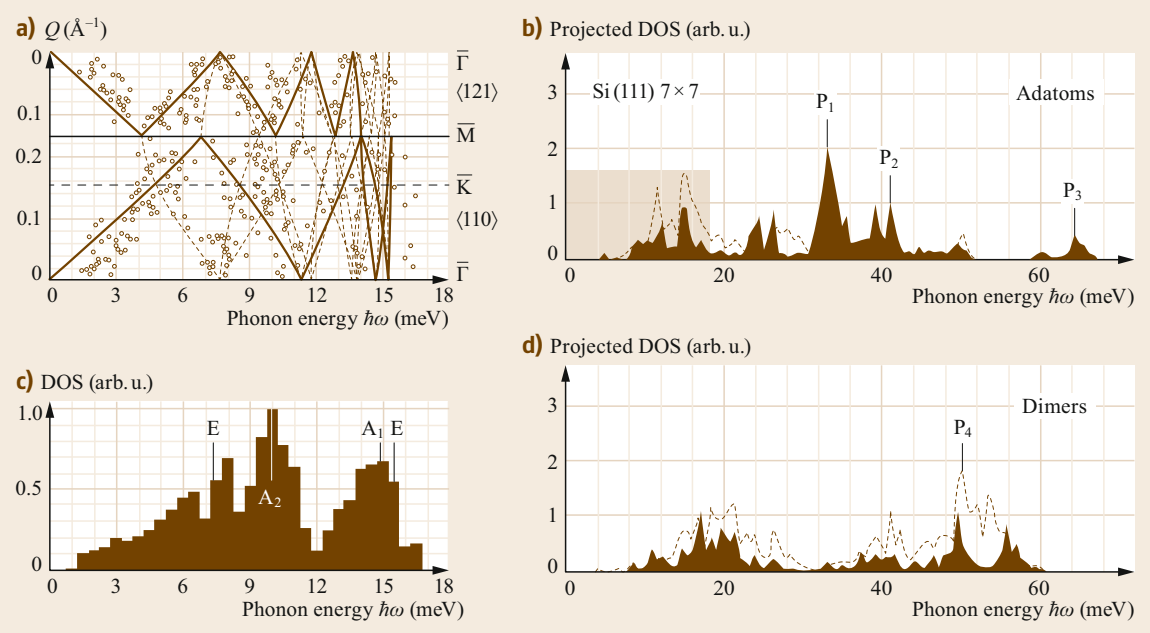

Fig. 23.11 **(a)** The RW and low-energy (acoustic) phonon dispersion curves of prevalent SV polarization along the symmetry directions of the Si(111)-7×7 reconstructed surface as measured by HAS (●) [23.208]. The data are fitted by a sine curve for the ideal 1×1 surface folded 49 times within the 7×7 surface Brillouin zone (*full lines*: ×1; *dasheed lines*: ×2). **(c)** Acoustic SV phonon DOS generated from the density of the HAS data multiplied by 2ω. The *arrows* indicate the lowest $Q = 0$ frequencies obtained by *Štich* et al. [23.209–211] with a first-principles MD and the multiple-signal classification algorithm. Symmetry labels refer to the irreducible representations of the C_{3V} group. This acoustic DOS from HAS agrees fairly well with the calculated DOS projected onto the adatoms **(b)** (*shaded rectangle*) from the Car–Parrinello molecular-dynamics simulation of *Kim* et al. [23.212] (*brown area*: SV component; *dashed lines*: horizontal component). This is consistent with the fact that adatoms are the most prominent features of the 7×7 surface [23.212]. **(d)** Poor agreement is found instead with the DOS projected onto the atom dimers or the free-surface and backbone atoms (not shown) of the 7×7 unit cell

First-principles tight-binding (FPTB) methods derived from the Varma–Weber TB theory of transition metal dynamics [23.217, 218] have been used to approach difficult problems, such as the dynamics and instabilities of tungsten and molybdenum(001) surfaces [23.219, 220]. Complex surface dynamics problems, such as those involving extensively reconstructed surfaces, have also been investigated with quantum molecular dynamics based on the tight-binding Hamiltonian. A sample of calculations by *Kim* et al. [23.212] for the Si(111)-7×7 reconstructed surface is shown in Fig. 23.11 and compared with the DOS derived from HAS measurements for the folded RW [23.208] and the zone-center phonon energies calculated by *Štich* et al. [23.209–211] with first-principles MD. Indeed, the TB scheme in combination with molecular dynamics has become an efficient tool due to the invention of linear-scaling simulation codes where the computational time increases linearly with the number N of atoms [O(N) codes] [23.221–225].

For free-electron metals, such as alkali and alkaline earth metals and aluminum, significant progress in lattice dynamics was achieved with the use of pseudopotentials [23.228–230], with which the effects of electronic screening on the electron–ion interactions can be accounted for in a perturbation calculation. Within the pseudopotential perturbation (PPP) theory, the electron-mediated interaction is shown to be proportional to the Fourier-transformed product of the squared pseudopotential times the density (dielectric) response function of the interacting electrons [23.231, 232]. Along those lines, a microscopic theory of lattice dynamics based on the density response (DR) can be formulated in general terms and implemented at various levels of approximation [23.171–183]. The DR-PPP theory was applied to the surface dynamics of alkali metals by *Calandra* et al. [23.233–235], who derived the screening from an infinite-barrier model, and by *Eguiluz* et al. [23.236–238] in a state-of-the-art, self-consistent calculation

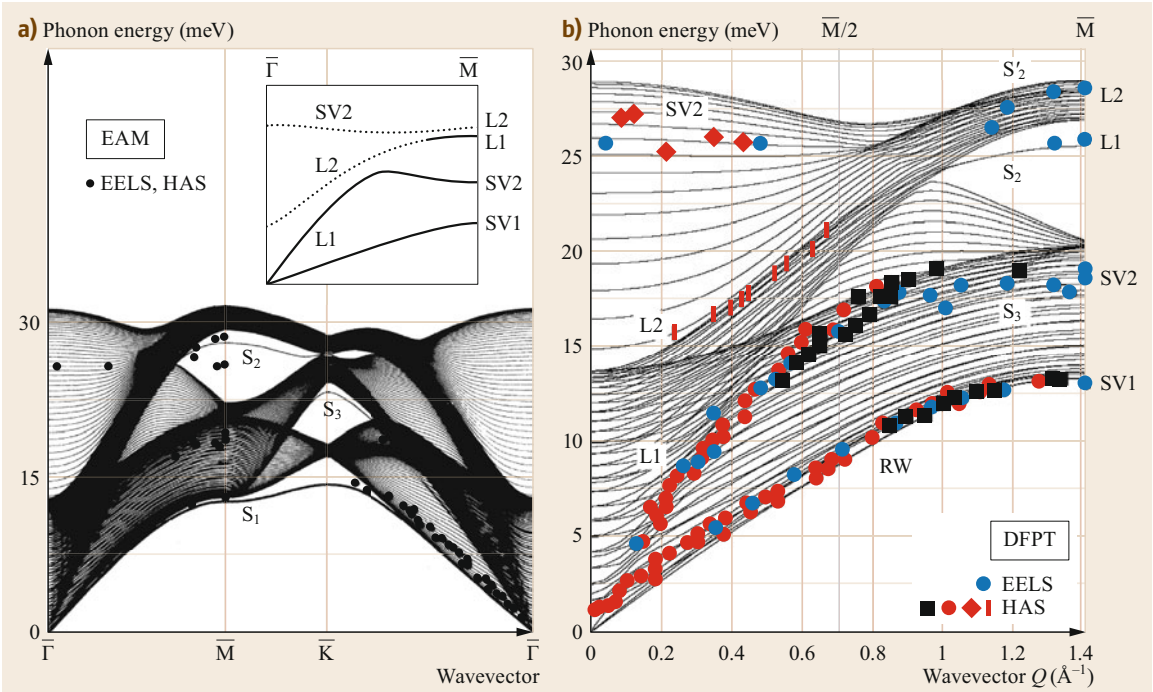

Fig. 23.12 (a) The surface phonon dispersion curves of Cu(111) calculated with the embedded-atom model (EAM) [23.226] and a selection of HAS [23.5, 185] and HREELS data [23.99, 227]. The *inset* shows the complex avoided crossings of the L1 acoustic branch in the $\overline{\Gamma M}$ direction with the optical branches of L2 and SV2 polarization [23.5, 194], where 1 and 2 indicate a prominent localization in the first and second surface layers, respectively. The EAM dispersion curves compare very well with the DFPT calculations shown in **(b)** along the $\overline{\Gamma M}$ direction together with a complete set of HAS and HREELS measurements [23.5, 185, 227]. The *black dots* in **(a)** are identical to the HREELS data plotted in **(b)**

for sp-bonded surfaces such as Al(001), (110), and (111) [23.239]. The PPP theory is less successful with noble and transition metals, where the localized d electrons contribute a strong pseudopotential that cannot be treated within a perturbation theory [23.240, 241].

The total energy of an atom in a host electronic system and the many-body interactions with the surrounding atoms mostly depend upon the immersion energy of that atom into the electron density contributed by the neighboring atoms. From the knowledge of this immersion energy and its dependence on the positions of neighboring atoms, the dynamical matrix can be obtained for the calculation of both bulk and surface phonons. The first-principles basis of this approach can be traced back to the Kohn–Sham (KS) theory of impurities in jellium [23.242], to the subsequent calculations for hydrogen [23.243–245] and He [23.246, 247] impurities, and to the theory of chemisorption [23.248, 249], as well as the quasi-atom concept introduced by *Stott* and *Zaremba* [23.250, 251] within the uniform-density approximation (UDA). Various semiempirical methods based on this concept are available [23.252]. These include the embedded atom method (EAM) [23.197–203], the effective medium (EM) theory [23.253–255], and methods relying on special forms of the many-body interaction, such as the Finnis–Sinclair (FS) [23.256] or tight-binding second moment (TBSM) potentials [23.257–259], the glue model (GM) [23.260–262], and the equivalent crystal (EC) model [23.263].

Figure 23.12 compares an EAM calculation of Cu(111) dispersion curves [23.226] with a more recent DFPT calculation and a complete set of HREELS [23.227] and HAS data [23.5, 185] in the $\overline{\Gamma M}$ direction. The agreement of both EAM and DFPT calculations with experimental data is very good. Many valuable results have been produced with the EAM approach for sp as well as for transition and noble metals, also for complex (vicinal, adsorbate) surfaces with large surface unit cells. For example, the EAM calculations by *Sklyadneva* et al. [23.264] for the (211) and (511) surfaces of copper reproduce the HAS measurements performed by *Witte* et al. [23.265] very well.

Conceptually, EAM as well as the other semiempirical methods provide a microscopic basis for the cluster shell model and, on the other hand, a surrogate for challenging ab-initio calculations based on density functional theory [23.190, 266, 267]. Moreover, these quantum semiempirical approaches are easily implemented in efficient molecular dynamics schemes and have produced a considerable number of interesting results for a wide spectrum of surface dynamical phenomena, mostly for metals.

The density functional theory of electrons in solids is founded on the Hohenberg–Kohn theorem [23.266], which states that the total energy E of a system is related in a unique way to its electron density function $n(\boldsymbol{r})$ via a (generally unknown) functional $E[n(\boldsymbol{r})]$. A trial functional is constructed through the Kohn–Sham eigenfunctions of an effective one-electron Hamiltonian [23.242], where the Coulomb interactions are derived from the density $n(\boldsymbol{x})$ itself. The exchange and correlation term, which represents the unknown part of the functional E, can be approximated with suitable local or semilocal functionals of the density [23.267, 268], commonly within the local-density approximation (LDA) [23.269] or the generalized-gradient approximation (GGA) [23.270–272]. Through a self-consistency loop the functional E is minimized and the electronic density $n(\boldsymbol{r})$ determined. This makes DFT the most powerful method for first-principles calculation of the ground-state total energy, albeit a computationally demanding one.

There are different ways to calculate the phonon frequencies from DFT. A first route to a first-principles (FP) DFT lattice dynamics is based on the determination, through molecular dynamics simulations at sufficiently low temperature, of the velocity–velocity correlation function, from which the phonon spectrum is derived by a Fourier transform. A major breakthrough in this direction was the Car–Parrinello method (CPM) [23.273], where the coefficients of Kohn-Sham wavefunctions expanded on a plane-waves basis set are treated as classical time-dependent variables, together with the nuclear coordinates. The evolution of this set of coordinates in time, within the adiabatic approximation, fully describes the quantum dynamics of the entire system. The CPM is highly demanding in terms of computer time and memory. However, nowadays it is possible to perform Car–Parrinello molecular dynamics (CP-MD) for 1000 atoms to extract velocity–velocity correlation functions. Thus, the CPM provides an important reference frame for many surface dynamical problems, including the calculation of surface phonons in semiconductors [23.274–276]. It remains a popular and efficient application of density functional theory to time-dependent problems.

In 1989, *Sankey* and *Niklewski* developed a less computationally demanding approach to ab-initio molecular dynamics based on a first-principles tight-binding (FPTB) scheme [23.277]. The tight-binding matrix elements are constructed within a density functional local density approximation (DF-LDA) theory, where the total energy is represented by a Harris functional [23.278], and the Kohn–Sham wavefunctions are approximated by a set of local pseudoatomic orbitals [23.277]. This theory was successfully applied to the calculation of the surface phonon densities for low-index surfaces of diamond by *Alfonso* et al. [23.279, 280].

A second approach to FP lattice dynamics is the frozen-phonon method (FPM) [23.281–285] where the effective interatomic force constants are obtained from a calculation of the total energy $E[n(\boldsymbol{r})]$ for the atoms slightly shifted from their equilibrium positions. There are two main variants of this method. In the first one, phonon energies are determined by a quadratic fit of the total energy changes produced by displacing the atoms according to a pattern that corresponds to a normal mode. This procedure can be applied only in those cases in which phonon eigenvectors are completely determined by symmetry and are, thus, known a priori; moreover, only phonons at $\boldsymbol{q} = 0$ can be studied using a single unit cell. To deal with phonons at finite $\boldsymbol{q}$, a supercell commensurate with $\boldsymbol{q}$ is needed. In surface dynamics, this technique encounters the difficulty that the displacement pattern of any surface phonon, even at symmetry points, is not precisely known in principle. Thus, its application is limited to particular cases, e.g., for adsorbates that are largely decoupled from the substrate.

The second variant exploits the possibility of calculating the forces with little computational effort by means of the Hellmann–Feynman (HF) theorem. Once the ground-state properties have been determined, a small displacement of atom l will produce forces acting on each atom l', and, thus, an entire row of the dynamical matrix can be computed. The complete dynamical matrix can be constructed by performing all the symmetry-independent displacements. This method has the advantage that it does not need a priori knowledge of the phonon eigenvectors and allows us to construct the whole real-space force-constant matrix. Hence, its Fourier transform provides the dynamical matrix for any arbitrary wavevector $\boldsymbol{q}$. In many cases, the effective interatomic force constants have long-range terms, due to conduction electrons in metals, which develop Friedel oscillations around a local disturbance [23.288, 289], or to electrical dipole–dipole interactions in ionic compounds. In these cases, computationally demanding large supercells must be used to

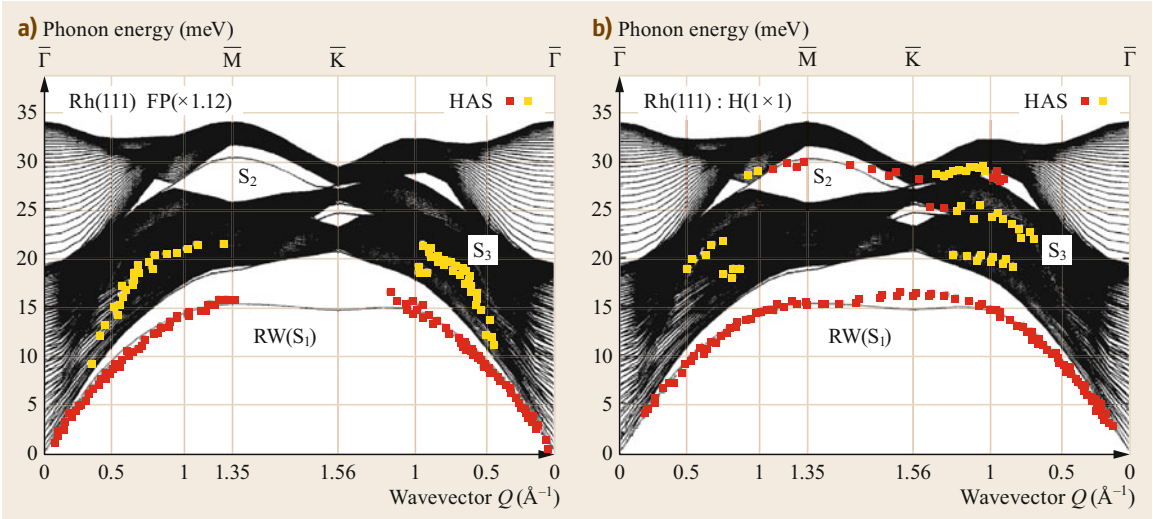

Fig. 23.13a,b First-principles calculations of the surface phonon dispersion curves for Rh(111) [23.286], rescaled by a factor 1.12 (12% stiffening) reproduce quite well the surface acoustic branches S_1 and S_3 measured with HAS [23.287] for both clean **(a)** and hydrogen-covered **(b)** surfaces, and the optical branch S_2, only observed for Rh(111):H(1×1). An additional HAS feature at 20 meV, close to the acoustic SH branch and more visible for the H-covered surface, may be related to the lack of mirror symmetry in the $\overline{\Gamma K}$ direction

ensure good convergence. Recent developments extend these force-fitting methods to anharmonic couplings, either at $T = 0$ [23.290, 291] or renormalized at finite T [23.292–294].

Bohnen, Ho, and coworkers successfully employed these methods using DFT with a pseudopotential and Kohn–Sham orbitals expanded on a plane wave basis for the surfaces of simple metals [23.295–300]. For noble metals, they obtained good results using a mixed basis of plane waves and localized orbitals [23.301–303]. Figure 23.13a shows a calculation for Rh(111) in which total energy density functional (DF) calculations of the force constants up to the 12th neighbors were performed by derivation of HF forces; both norm-conserving (P1) and ultrasoft nonnorm-conserving (P2) pseudopotentials were used [23.286]. The calculation based on P1 (displayed in Fig. 23.13 [23.286]), yields a good fit of the surface phonon dispersion curves measured with HAS for both the clean Fig. 23.13a and the hydrogen-covered Fig. 23.13b Rh(111) surfaces [23.287], after rescaling the theoretical dispersion curves by a factor 1.12 (12% stiffening). The near identity of the S1 and S3 branches for clean and H-covered surfaces and the good agreement of the HAS S_2 gap mode for the H-covered surface with the (rescaled) clean surface calculation indicate, as argued by *Witte* et al. [23.287], that H surface passivation of Rh(111), unlike that of Ni(100), Pt(111), and W(001), does not alter the surface force constants.

The third route to ab-initio surface lattice dynamics originates from the density response (DR) method, in which the dynamical matrix is obtained by calculating the second-order derivatives of the total energy directly with respect to the atomic positions. By virtue of the Hellman–Feynman theorem the derivatives of $E[n(\boldsymbol{x})]$ become integral expressions of the potential and density derivatives. Within linear response theory, the latter can be expressed in terms of a DR function. This way, a first-principles formulation of the DR theory is obtained for lattice dynamics, where the DR function is expressed as the second-order functional derivative of E with respect to $n(\boldsymbol{r})$ [23.183]. The DR function has to be obtained self-consistently by summing over matrix elements of the perturbing potential between occupied and unoccupied Kohn–Sham states [23.304–308]. With such a pseudopotential approach *Eguiluz* and *Quong* obtained very good results for the dynamics of the three low index surfaces of aluminum [23.239, 304, 305]. Since the DR is a ground-state property, the sum over unoccupied Kohn–Sham states can be avoided via the use of Green's functions, as was done in various implementations of the DR method. The Eguiluz–Quong FP-DR approach is in many respects a theory of the dielectric function and may be regarded as a different formulation of the density functional perturbation theory (DFPT) developed by *Baroni* and coworkers [23.191, 309, 310].

The good performance of DFPT in reproducing the experimental HAS and HREELS dispersion curves for most solid surfaces rests on the preliminary accurate determination of the equilibrium surface relaxation and its temperature dependence [23.311]. *Dal Corso* et al. successfully calculated the bulk phonon dispersion curves of Cu, Ag, and Au using a DFPT based on Vanderbilt's ultrasoft pseudopotentials [23.312]. The DFPT method was further applied by *dal Corso* to the surface dynamics of the Cu(001) surface [23.313] in combination with either the *Perdew*, *Burke*, and *Ernzerhof* generalized-gradient approximation (GGA) [23.272] or LDA [23.269]. The GGA yields a substantially better agreement with HAS and HREELS experimental data. A thorough analysis of the above developments in ab-initio phonon dynamics of metal surfaces up to DFPT can be found in *Heid* and *Bohnen*'s review [23.299].

A summary of the DFPT formalism is presented in the next section, as it provides not only the surface phonon dispersion curves but also the mode-selected electron–phonon coupling strengths, which are necessary ingredients in the calculation of inelastic HAS intensities for conducting surfaces.

23.2.4 Density Functional Perturbation Theory

DFT allows us to efficiently investigate the ground-state properties of a system of N interacting electrons in a generic external potential $V(\boldsymbol{x})$ by considering the electronic density $n(\boldsymbol{x})$ instead of the many-body wavefunctions as the fundamental quantity to describe the system. The theoretical basis of DFT rests on the Hohenberg and Kohn theorems [23.266], which, together with the Rayleigh–Ritz variational principle, state that the electronic part of the total energy

$$E_{\mathrm{el}}[n(\boldsymbol{x})] = F[n(\boldsymbol{x})] + \int n(\boldsymbol{x}) v_{\mathrm{ion}}(\boldsymbol{x}) \mathrm{d}\boldsymbol{x} \,, \qquad (23.48)$$

is a unique functional of the electron density $n(\boldsymbol{x})$, which is minimized by the ground-state electronic density corresponding to the external (ion) potential $v_{\mathrm{ion}}(\boldsymbol{x})$, and its minimum corresponds to the ground-state energy. The functional $F[n(\boldsymbol{x})]$ is a sum of the kinetic energy functional $T[n(\boldsymbol{x})]$ for the interacting system, of the classical Hartree term $J[n(\boldsymbol{x})]$ for the electron–electron interaction and the nonclassical contribution $E_{\mathrm{ncl}}[n(\boldsymbol{x})]$ to the electron–electron interaction. Of these functionals, only $J[n(\boldsymbol{x})]$ is known. The Kohn–Sham theorem [23.242] suggests a reasonable approximation to the $F[n(\boldsymbol{x})]$ functional. Their *ansatz* is to calculate the exact kinetic energy of a noninteracting system $T_{\mathrm{s}}[n(\boldsymbol{x})]$ in an external effective potential which provides the same ground-state density as the interacting one and rewrite the functional as $F[n(\boldsymbol{x})] = T_{\mathrm{s}}[n(\boldsymbol{x})] + J[n(\boldsymbol{x})] + E_{\mathrm{xc}}[n(\boldsymbol{x})]$, where $E_{\mathrm{xc}}[n(\boldsymbol{x})]$ incorporates the unknown terms arising from the exchange and correlation energy. Reliable approximations are available for the exchange-correlation functional, such as the local-density approximation (LDA) [23.269] and the generalized-gradient approximation (GGA) [23.272]. These have turned out to be particularly good in most cases, with the exception of highly correlated systems, especially with d and f electrons.

The variation of the energy functional, (23.48), with respect to $n(\boldsymbol{x})$ and with the constraint that the number of electrons is fixed, provides the external effective potential of the auxiliary non-interacting system, which finally leads to the Kohn–Sham equations

$$\left(-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial \boldsymbol{x}^2} + V_{\mathrm{SCF}}(\boldsymbol{x})\right)\psi_n(\boldsymbol{x}) = \varepsilon_n \psi_n(\boldsymbol{x}) \,, \qquad (23.49)$$

where the effective (self-consistent) potential V_{SCF} is given by

$$V_{\mathrm{SCF}}(\boldsymbol{x}) = v_{\mathrm{ion}}(\boldsymbol{x}) + e^2 \int \frac{n(\boldsymbol{x}')}{|\boldsymbol{x}-\boldsymbol{x}'|}\mathrm{d}\boldsymbol{x}' + \frac{\delta E_{\mathrm{xc}}}{\delta n(\boldsymbol{x})} \qquad (23.50)$$

and

$$n(\boldsymbol{x}) = 2\sum_{n=1}^{N/2} |\psi_n(\boldsymbol{x})|^2 \,. \qquad (23.51)$$

The self-consistent solution of (23.50) and (23.51), normally by iteration from an initial guess of $n(\boldsymbol{x})$, yields the ground-state charge density and energy. It is straightforward to show that the Hellmann–Feynman theorem holds in the framework of DFT. Thus, the forces and force constants and the first and second derivatives of the total energy with respect to the ionic positions can be written as functionals of the ground-state charge density as

$$\boldsymbol{F}_l = -\frac{\partial E}{\partial \boldsymbol{r}_l} = -\frac{\partial E_{\mathrm{ion}}}{\partial \boldsymbol{r}_l} - \int n(\boldsymbol{x}) \frac{\partial v_{\mathrm{ion}}(\boldsymbol{x})}{\partial \boldsymbol{r}_l}\mathrm{d}\boldsymbol{x} \,, \qquad (23.52)$$

$$\begin{aligned}
\Phi\left(ll'\right) &= \frac{\partial^2 E(\boldsymbol{r})}{\partial \boldsymbol{r}_l \partial \boldsymbol{r}_{l'}} \\
&= \frac{\partial^2 E_{\mathrm{ion}}(\boldsymbol{r})}{\partial \boldsymbol{r}_l \partial \boldsymbol{r}_{l'}} + \int n(\boldsymbol{x}) \frac{\partial^2 v_{\mathrm{ion}}(\boldsymbol{x})}{\partial \boldsymbol{r}_l \partial \boldsymbol{r}_{l'}}\mathrm{d}\boldsymbol{x} \\
&\quad + \int \frac{\partial n(\boldsymbol{x})}{\partial \boldsymbol{r}_l}\frac{\partial v_{\mathrm{ion}}(\boldsymbol{x})}{\partial \boldsymbol{r}_{l'}}\mathrm{d}\boldsymbol{x} \\
&= \frac{\partial^2 E_{\mathrm{ion}}(\boldsymbol{r})}{\partial \boldsymbol{r}_l \partial \boldsymbol{r}_{l'}} + \int n(\boldsymbol{x}) \frac{\partial^2 v_{\mathrm{ion}}(\boldsymbol{x})}{\partial \boldsymbol{r}_l \partial \boldsymbol{r}_{l'}}\mathrm{d}\boldsymbol{x} \\
&\quad - \iint \frac{\partial v_{\mathrm{ion}}(\boldsymbol{x})}{\partial \boldsymbol{r}_l}\chi\left(\boldsymbol{x},\boldsymbol{x}'\right)\frac{\partial v_{\mathrm{ion}}(\boldsymbol{x}')}{\partial \boldsymbol{r}_{l'}}\mathrm{d}\boldsymbol{x}\mathrm{d}\boldsymbol{x}' \,.
\end{aligned} \qquad (23.53)$$

In the last term of (23.53), the density derivative has been explicitly written in terms of the electron susceptibility $\chi(\boldsymbol{x},\boldsymbol{x}')$ (independent to the lowest order of ion positions) in order to show the one-to-one correspondence of (23.53) with the ME force constant matrix, (23.44)–(23.45).

In the calculation of the DFPT force constant matrix it is not necessary to evaluate first the electron susceptibility. To first-order the derivatives $\partial V_{\mathrm{SCF}}/\partial \boldsymbol{r}_l$, $\partial\psi/\partial \boldsymbol{r}_l$, $\partial n(\boldsymbol{x})/\partial \boldsymbol{r}_l$ (the latter needed in (23.53)) can be obtained by solving self-consistently the variation of the Kohn–Sham equation (23.49)

$$(H_{\mathrm{SCF}}-\varepsilon_n)\,\frac{\partial\psi_n(\boldsymbol{x})}{\partial \boldsymbol{r}_l} = -\left(\frac{\partial V_{\mathrm{SCF}}(\boldsymbol{x})}{\partial \boldsymbol{r}_l}-\frac{\partial\varepsilon_n}{\partial \boldsymbol{r}_l}\right)\psi_n(\boldsymbol{x})\,, \tag{23.54}$$

where

$$\frac{\partial V_{\mathrm{SCF}}(\boldsymbol{x})}{\partial \boldsymbol{r}_l} = \frac{\partial v_{\mathrm{ion}}(\boldsymbol{x})}{\partial \boldsymbol{r}_l} + e^2\int\frac{1}{|\boldsymbol{x}-\boldsymbol{x}'|}\frac{\partial n(\boldsymbol{x}')}{\partial \boldsymbol{r}_l}\mathrm{d}\boldsymbol{x}' + \int\frac{\delta^2 E_{\mathrm{xc}}}{\delta n(\boldsymbol{x})\delta n(\boldsymbol{x}')}\frac{\partial n(\boldsymbol{x}')}{\partial \boldsymbol{r}_l}\mathrm{d}\boldsymbol{x}'\,, \tag{23.55}$$

$$\frac{\partial\varepsilon_n}{\partial \boldsymbol{r}_l} = \langle\psi_n|\,\frac{\partial V_{\mathrm{SCF}}}{\partial \boldsymbol{r}_l}\,|\psi_n\rangle\,. \tag{23.56}$$

This approach is particularly effective, since only occupied states are needed to evaluate the right-hand side of (23.54) [23.314], whereas the standard perturbation theory approach, based on the expansion in eigenfunctions of the unperturbed Hamiltonian, would require sums over the full spectrum of the zero order Hamiltonian. An alternative formulation of DFPT, worked out by *Gonze* [23.315, 316], can be obtained on the basis of a variational principle. It can be shown [23.191] that the two formulations are substantially equivalent, although with relevant differences in their implementation; while the latter proceeds from the perturbative expansion of the Kohn–Sham energy functional and a minimization, the former requires the self-consistent solution of linear equations by means of the Green's function method.

As discussed by *Baroni* et al. in their review article [23.191], DFPT has a strong advantage over other ab-initio methods that require supercells. To treat a $\boldsymbol{q}\neq 0$ perturbation, the $\boldsymbol{q}$-space Fourier components of the perturbation in DFPT are independent, up to a reciprocal lattice vector $\boldsymbol{G}$. To first order, a $\boldsymbol{q}$-component of the perturbation can only admix an electronic eigenfunction of wavevector $\boldsymbol{k}$ with eigenfunctions of wavevector $\boldsymbol{k}+\boldsymbol{q}$. This allows us to readily obtain the Fourier components of the force constant matrix and the phonon frequencies at any arbitrary $\boldsymbol{q}$-point. In polar materials, where the contribution from the macroscopic electric field is naturally present in the ion–ion part of the force constant matrix, the effect of the electronic density response can be accounted for by simply replacing the bare ion charges in the non-analytic part of the dynamical matrix with effective Born charges [23.191], similarly to what is done with shell models [23.73, 75].

In the case of conducting materials, there may be the problem that the number of $\boldsymbol{k}$-points needed to correctly describe the effects related to the presence of a Fermi surface could be prohibitively large. An efficient implementation of DFPT for metallic systems, based on the energy level broadening by a smearing function was proposed by *de Gironcoli* [23.317]. Another effective approach, based on a different treatment of the perturbation, is that of *Eguiluz* and *Quong* mentioned above [23.304]. Even with the use of the latter technique, however, the phonon dispersion curves for metals within DFPT can critically depend on the sampling of $\boldsymbol{k}$- and $\boldsymbol{q}$-points and may meet some difficulty in dealing with Kohn anomalies.

In practical calculations, the bare electron-nucleus interaction $v_{\mathrm{ion}}(\boldsymbol{x})$ is often replaced by a pseudopotential that takes into account the effects of core electrons, and only valence electrons are treated explicitly. DFPT was first implemented within the framework of a plane-wave basis set expansion for Kohn–Sham states [23.318, 319] and using norm-conserving pseudopotentials [23.320, 321]. This paradigm was used extensively and with great success to study bulk and surface phonons of semiconductors and simple metals. The need to deal with transition metals within a pseudopotential and a plane-wave approach (without needing a huge basis set), led to the development of ultrasoft pseudopotentials [23.322]. Their use within DFPT was implemented by *dal Corso* et al. [23.312] and *dal Corso* [23.313]. The further development of fully relativistic pseudopotentials and their inclusion in the linear-response code paved the way to the inclusion of spin–orbit coupling and the study of its effect on phonon modes and electron–phonon interactions [23.323–328]. An alternative approach to materials is the use of a local or mixed basis set instead of plane waves. Significant progress in this field was made by *Savrasov* and *Andersen* [23.329], who implemented a new full potential linear muffin-tin orbital (LMTO) method, and DFPT has been implemented in several full-potential linearized augmented plane wave (FLAPW) codes [23.330–332].

The subsequent introduction of nonlocal exchange-correlation corrections provided an effective, although not yet completely satisfactory, way to treat van der Waals interactions within the framework of DFT [23.333–338]. In particular, their inclusion in DFPT codes, together with spin–orbit coupling, can

substantially improve the performance of DFPT, especially for layered crystals with heavy atoms and weak interlayer bonding.

DFPT is nowadays one of the most popular methods for the calculations of phonons and has been implemented in some of the most widely used simulation codes, like Quantum ESPRESSO [23.339], ABINIT [23.323, 340], Vienna Ab Initio Simulation Package (VASP) [23.341], and Cambridge Serial Total-Energy Package (CASTEP) [23.342]. To date, the surface phonon dispersion curves for about 50 different solid surfaces have been calculated with DFPT and have generally been found to be in good agreement with HAS and HREELS experimental data, so as to endow DFPT with highly predictive power. A fairly complete list of references of surface phonon calculations can be found in two Springer monographs [23.4, 5].

23.2.5 DFPT Surface Phonons for Heavy Elemental Solids and Compounds

A challenging testing ground for DFPT including spin–orbit coupling (SOC) and van der Waals (VdW) interaction is the calculation of the surface phonon dispersion curves and the electron–phonon interaction in 6sp metals and topological insulator compounds, for which detailed experimental HAS data are now available. This is discussed in the following sections.

Cs(110), Ba(0001)

Recent DFPT calculations of the surface phonon dispersion curves for the Cs(110) surface of a free-standing 11 monolayer (ML) slab are shown in Fig. 23.14 and compared with HAS data measured on a 25 ML Cs(110) film on Pt(111) at two different temperatures [23.343, 344]. The equilibrium configuration and the phonon dispersion curves for bulk cesium and for the Cs(110) surface were obtained with density functional theory and DFPT as implemented in the Quantum ESPRESSO code [23.339] with the Perdew–Burke–Ernzerhof (PBE) approximation for the exchange-correlation functional [23.272], norm-conserving pseudopotentials with nonlinear core corrections, and a 30 Ry cutoff on the plane wave expansion of Kohn–Sham orbitals. The experimental equilibrium lattice parameter (6.141 Å) was well reproduced by DFPT (6.171 Å) without SOC and VdW corrections, supporting the conjecture that their effects have opposite sign and cancel out to a good extent.

Besides the fact that little was known before about the phonon dispersion curves of cesium even in the bulk, another interesting aspect of the HAS study of very soft Cs films during growth beyond single monolayers was the assessment of their surface structure and

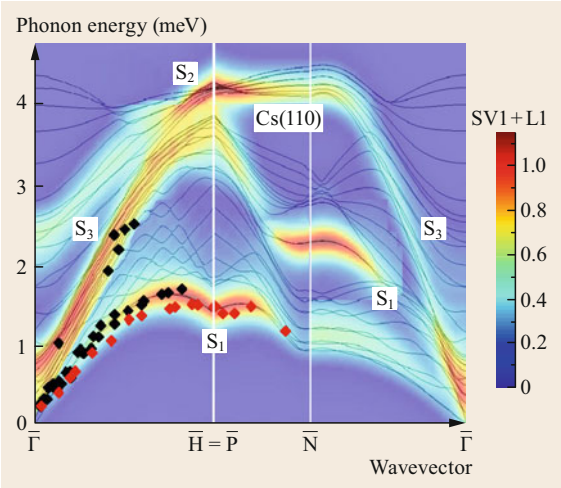

Fig. 23.14 Comparison of the surface phonon dispersion curves calculated with DFPT for 25 ML Cs(110)/Pt(111), represented with their surface-projected DOS (*color code aside*), with HAS data measured at a temperature of 40 K (*black lozenges*) and 100 K (*red lozenges*) for phonon creation processes. The colors indicate the surface-projected DOS for the sagitally polarized first-layer phonons. The comparatively weak electron–phonon interaction only permitted distinct observation of the RW (S_1) and a part of the longitudinal surface resonance S_3 [23.343, 344]

orientation [23.344, 345]. Little is known about alkali surfaces from low-energy electron diffraction (LEED) studies, besides a pioneering study on Na(110) and its oxide [23.346]. Soft materials like cesium are also characterized by a comparatively large anharmonicity, especially at the surface. The HAS data in Fig. 23.14 indicate in the Rayleigh wave dispersion curve in the $\overline{\Gamma H}$ direction a 17% softening for an increase of temperature from 40 to 100 K, corresponding to an anharmonicity coefficient $x_{e,s} = 0.037$ [23.4, 347]. This value is appreciably larger than the values found for the surfaces of other free electron metals (e.g., $x_{e,s} = 0.024$ for aluminum surfaces), consistently with a surface Debye temperature as low as 48 K [23.4, 344]. Also the electron–phonon interaction, expressed by the mass-enhancement factor λ and derived for the Cs(110) surface from the temperature dependence of the Debye–Waller (DW) exponent turns out to be slightly larger ($\lambda = 0.186$) [23.97, 343] than the bulk value $\lambda = 0.14$ known from the literature [23.348].

HAS studies of the barium surface are only available for Ba 1-3 monolayers on Cu(001) [23.349]. Of special interest is the Ba bilayer, which exhibits a twisted dodecagonal 4-D structure, Ba(0001), with $\lambda = 0.29$ [23.350], also slightly larger than the Ba bulk value ($\lambda = 0.27$) [23.348].

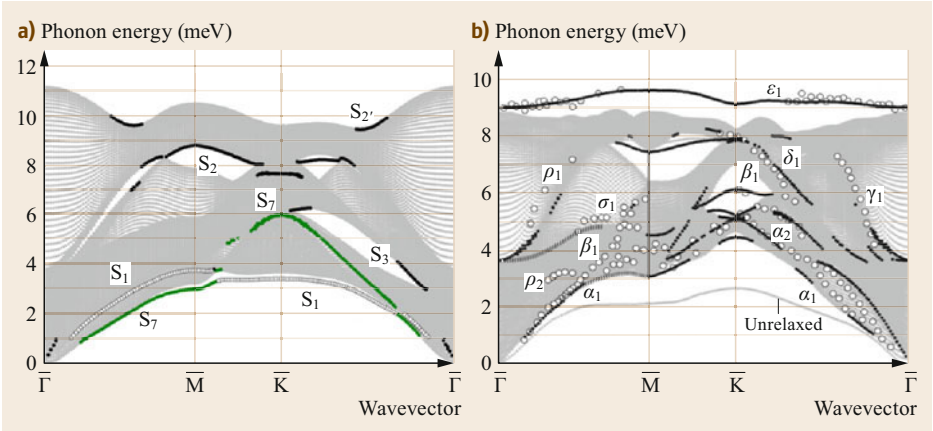

Fig. 23.15a,b The surface dynamics (*dark gray* and *small symbols*) of Tl(0001) **(a)** and Pb(111) **(b)** calculated with DFPT including SOC [23.351, 352]. For Pb(111), the soft RW branch (*light gray full line*) for the ideal unrelaxed surface is also shown. The strong surface bilayer contraction predicted at equilibrium lifts the RW branch up to the bulk acoustic edge (α_1) and the optical branch ε_1 well above the maximum of the bulk phonon band, in very good agreement with the HAS data (*open circles*) [23.353]. *Greek letter labels* are those of [23.353], while for Tl(0001), the labels S_j have the usual meaning. No important relaxation effect is predicted in Tl(0001) **(a)** due to the small surface bilayer contraction

Tl(0001), Pb(111)

The spin–orbit coupling has been found to have significant effects in the DFPT surface dynamics of 6sp metals. Figure 23.15 compares two DFPT calculations of the surface phonon dispersion curves of Tl(0001) [23.351] and Pb(111) [23.352], including SOC. Both surfaces are characterized by a contraction of the first surface bilayer, which is quite large in lead (-4.5% with SOC, -4.7% without SOC) but rather small in thallium (-0.2% with and without SOC). Such contractions, and their difference in the two surfaces, are reflected in the appearance of a localized surface phonon branch above the maximum of the bulk phonon continuum. While in Pb(111) this optical branch, denoted by ε_1 in Fig. 23.15b, lies well above the bulk density all along the surface Brillouin zone, in Tl(0001) the optical mode S_2' (Fig. 23.15b) is localized above the bulk maximum only around one half of the zone in both symmetry directions. The large surface bilayer contraction in Pb(111) also yields a strong stiffening of the RW branch towards the zone boundary. As can be seen in Fig. 23.15b, the surface relaxation shifts the RW branch for the ideal unrelaxed surface (light gray full line) upwards to very near the lower bulk band edge. In Tl(0001), the RW (S_1 in Fig. 23.15a) runs above the SH (S_7) branch in the $\overline{\Gamma}\overline{M}$ direction, and is, therefore, a pseudo-surface wave (PSW) branch, but this is due to the peculiar elastic constants and not to surface relaxation.

This unusual behavior of Pb(111) surface dispersion curves is confirmed by the available HAS data [23.353], which agree very well with the calculated upper branch ε_1 and the RW branch (α_1) running along the lower edge of the acoustic bulk band. Also, the other branches, here labeled with Greek letters as in [23.353], are well reproduced by theory, confirming the good performance of DFPT with the inclusion of SOC. It is interesting to note that VdW terms do not seem to have relevant effects, the surface equilibrium structure with relaxation and the local change of force constants having mostly a chemical origin. This may not be so for Tl(0001), where surface relaxation is much smaller, but no published HAS data are available to date for a similar comparison.

The specific contribution of SOC on the phonon spectrum can be singled out by comparing the surface-projected phonon DOS of Tl(0001) calculated with and without the spin–orbit interaction. As shown in Fig. 23.16 [23.351], the acoustic modes, notably the RWs (S_1) at the zone boundary contributing the main DOS peak at 3.1 meV, are shifted by SOC to higher energy by +7.0%, while the highest optical modes (mainly S_2') are shifted downward by about the same absolute amount, corresponding to a fractional shift of -2.3% (arrows).

The effects of SOC are more evident in Pb(111). DFPT calculations on ultrathin Pb(111) films on a (rigid) Cu(111) substrate not including SOC have been reported for different film thicknesses ranging from 3 to 7 ML [23.353–355]. The highest surface optical mode, identified as a stretching of the surface bilayer is generally above the experimental data, with the largest discrepancy of about 9% for 6 ML, but a reasonable agreement for 7 ML, which indicates an oscillatory character for the misfit, with a period similar to that of the surface bilayer contraction [23.355]. A comparison

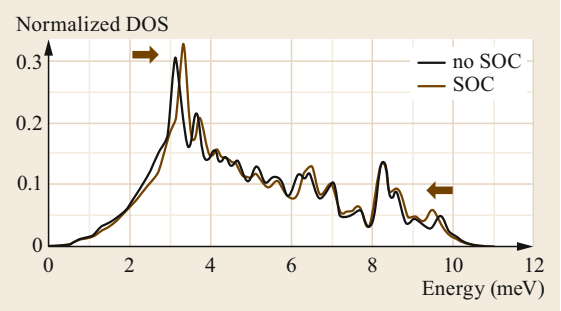

Fig. 23.16 The surface-projected phonon DOS of Tl(0001) calculated with DFPT including (*brown line*) or excluding (*black line*) SOC [23.351]. The *arrows* underscore the sections of the spectrum most affected by SOC. The first low-energy peak associated with zone-boundary RWs shifts to higher energy by +7.0% with the inclusion of SOC, whereas the highest-energy peak at 9.7 meV, corresponding to the S_2' optical mode, is softened by about −2.3%

of the HAS data for a 3 ML-Pb(111) film on a Cu(111) substrate with the DFPT dispersion curves without and with SOC is shown in Fig. 23.17. The periodicity of the Pb film is locked into that of Cu(111) with the respective lattice distances in the ratio 4 : 3 and a superstructure unit cell containing 9 Pb atoms and 16 Cu atoms (Fig. 23.17b). For this reason, the dispersion curves are conveniently represented in the Brillouin zone of the surface superstructure (Fig. 23.17c).

As shown in Fig. 23.17a, the addition of SOC generally yields an improved agreement with experiment, with the expected softening of the upper optical branch ε_1 and of the folded acoustic branch α_1. On the contrary, mode ε_2 localized at the film substrate is stiffened by SOC, also leading to a good agreement with experiment. It is, however, noted that the SOC softening of the σ_1 branch at $\overline{\Gamma}$ spoils the good agreement obtained without SOC. In general, these results are qualitatively valid for thicker films, as well as for the Pb(111) surface of the semi-infinite solid.

Bi(111)

Bismuth surfaces have been extensively investigated for a broad spectrum of interesting properties, as discussed in the excellent review by *Hofmann* [23.359]. The rhombohedral layered structure of bismuth is constituted by a pile of atomic bilayers with strong intrabilayer bonds and weaker interactions between bilayers. This leads to a peculiar set of phonon dispersion curves for Bi(111), characterized by a large gap between the acoustic bands, where bilayers move as quasi-rigid

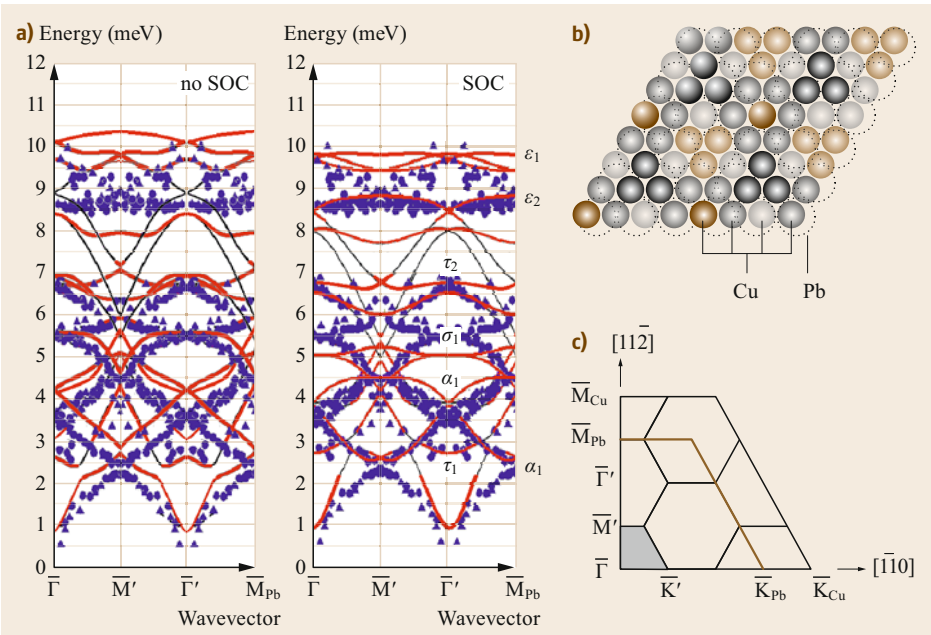

Fig. 23.17 **(a)** DFPT calculation of the phonon dispersion curves of a 3 ML-Pb(111) film on a Cu(111) substrate assumed to be rigid without (*left*) and with SOC (*right*), compared with HAS data (*blue symbols*) in the [11$\bar{2}$] symmetry direction [23.353, 354]. **(b)** The unit cell of the Pb(111)/Cu(111) superstructure with 9 Pb atoms (*broken circles*) and 16 Cu atoms (*smaller circles with different colors* indicating inequivalent atoms). **(c)** A quadrant of the Cu(111) surface BZ including the BZ of Pb(111) (*brown line boundaries*) and that of the superstructure (*gray area*) [23.354]

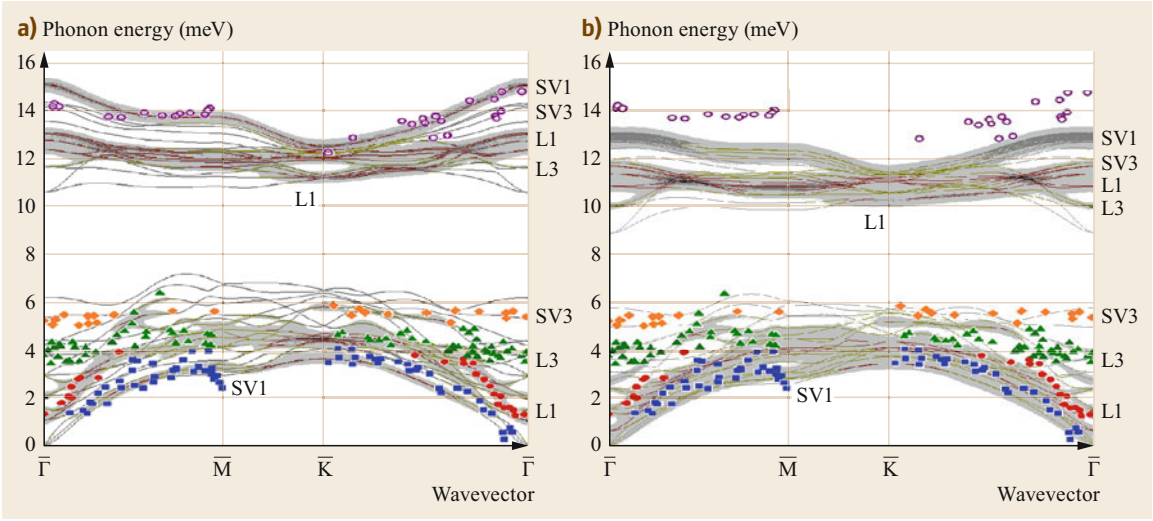

Fig. 23.18a,b DFPT surface dynamics of Bi(111) **(a)** without SOC [23.356] and **(b)** with SOC [23.95, 357] compared with HAS data [23.356, 358]

entities, and the optical bands hosting intralayer vibrations [23.356–358, 360, 361]. The trend in the surface bilayer contraction, small in Tl(0001) and large in Pb(111), in Bi(111) is manifested by a bilayer reorganization of the entire lattice. From DFPT, the softening induced by SOC of the intralayer phonon modes is found to be quite large (Fig. 23.18), whether localized mostly in the first (SV1 and L1 branches) or in the second bilayer (SV3 and L3 branches), its average amount being as large as about −15% [23.357]. Actually, *Chis* et al. showed that the spin–orbit part of the electron–phonon interaction, more than the SOC effect on the band structure, is responsible for such a large softening [23.357]. The SOC softening remains appreciable for the upper modes of the acoustic band and decreases in the lower part of the spectrum.

Surprisingly, for Bi(111) the experimental HAS data are, however, in good agreement with the DFPT calculations without SOC, whereas the DFPT-SOC calculation gives substantially softer surface optical branches. A careful HAS study of the Bi(111) optical modes exploiting resonance enhancement (Fig. 23.19; [23.358]) confirms the good agreement with a DFPT calculation without SOC for both the SV and L modes localized in the first bilayer (SV1,2 and L1), as well as for the SV mode in the second bilayer (SV3). It is likely that van der Waals interaction plays an important role in Bi(111) surface dynamics so as to compensate the misfit found with the inclusion of SOC. To our knowledge, no investigation has been made in this direction so far.

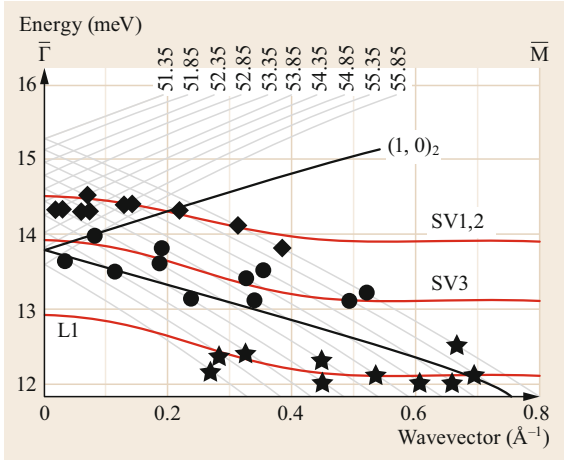

Fig. 23.19 A HAS study based on resonance enhancement of the optical surface branches of Bi(111) in the $\overline{\Gamma}\overline{\mathrm{M}}$ direction gives dispersion curves (*lozenges*, *full circles* and *stars*) in good agreement with DFPT calculations without SOC (*red curves*) [23.358]. *Light gray lines* represent the HAS scan curves for a narrow interval of incident He beam angles, whose intersections with the resonance curve $(1,0)_2$ (*black line*) for the second He bound state and the exchange of a G = (1, 0) surface reciprocal vector give the energy and wavevector of the surface phonon involved

Po(001) and the Heavier 6sp Elements

Polonium is the only elemental solid with a stable low-temperature, simple-cubic (sc) phase with one atom per unit cell (α-Po), eventually turning into a rhombohedral phase (β-Po) at around room temperature. A theoreti-

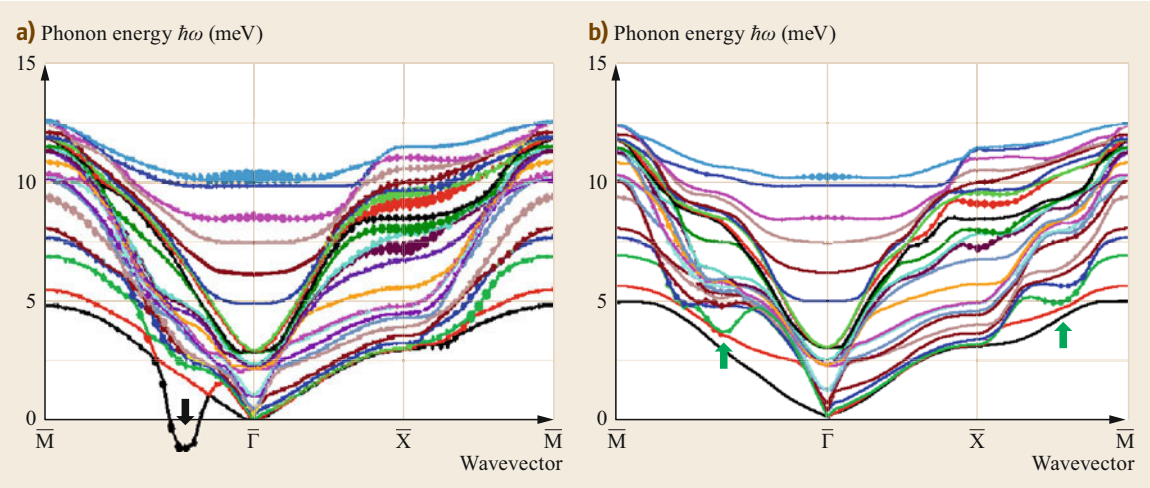

Fig. 23.20a,b DFPT calculations of the phonon dispersion curves for the (001) surface of a 8 ML free-standing slab of simple-cubic α-polonium without **(a)** and with SOC **(b)** [23.362]. In this case, SOC removes an unstable phonon ((**a**), *downward arrow*) lifting the Kohn anomaly within the bulk phonon band and inducing another one at the zone's middle ((**b**), *upward arrows*)

cal study of α-Po bulk and surface dynamics based on a force constant model [23.363] is confirmed by a state-of-the-art DFPT calculation [23.364], which demonstrated that the unusual stability of the sc lattice is due to an important change of the Fermi surface produced by the large SOC, dramatically reducing the nesting areas and the related Kohn anomalies. The DFPT Kohn anomalies lead to a hardening of the phonon energies, which is just opposite to what is found for lead and bismuth, and, in general, for simple metals. A natural question was whether the surface (001) of polonium is stable as well and what the role of SOC is. A DFPT calculation for a free-standing 8-ML slab without and with SOC [23.362], illustrated in Fig. 23.20a,b, shows that in the absence of SOC, a surface mode is, indeed, unstable in the $\overline{\Gamma}\overline{\mathrm{M}} \equiv [100]$ direction at about one third of the BZ. As can be seen in Fig. 23.20b, the addition of SOC stabilizes the surface by lifting the anomaly within the bulk phonon band and shifting its wavevector to about one half of the BZ, while leaving most of the other modes almost unchanged. Another anomaly appears, however, in the middle of the BZ boundary $\overline{\mathrm{XM}}$ with no consequence for the surface stability. No experimental study of the surface dispersion curves has been possible so far for α-Po(001) due to its radioactivity; the lifetime of the most stable natural isotope ^{210}Po is only 138.4 days, whereas the most stable synthetic isotope, ^{209}Po with a lifetime of 103 years is very expensive.

Even more difficult would be the experimental study of surface phonons for the crystalline forms of the remaining two 6sp elements, astatine and radon. From the theoretical point of view, information on the band structure of these elemental solids is found in [23.365]. The most stable (synthetic) isotope of astatine, ^{211}At, has a lifetime of only 7.21 h. A DFT calculation including SOC and dispersion forces by *Hermann* et al. [23.366] predicts that under normal conditions, it is an atomic metallic solid with a tetragonal lattice (space group $I4/mmm$), and that above 13 GPa, it has an fcc structure. Interestingly, without SOC astatine is predicted to be a molecular solid like other halogens. The only vibrational information of the atomic metallic phase of solid astatine is the calculated Debye frequency, which corresponds to an energy of 16.8 meV [23.366], which is considerably higher than the maximum bulk phonon energy of α-Po(001).

Radon, the last 6sp element, has been carefully investigated [23.367] not only for the general interest in rare gas overlayers but particularly for environmental reasons, radon being one of the main radioactive atmospheric contaminants. Far from being an inert noble gas, it has a chemistry similar to that of Xe, and in its expected fcc crystalline form it would have interesting surface properties similar to those of Xe(111) [23.98]. Unfortunately, the short lifetime of the most stable isotope ^{222}Rn (3.82 days) prevents the growth of films of even a few layers for investigation. For fcc-Rn there is, however, a calculation of the Debye temperature based on the phenomenological Mie–Lennard-Jones (MLJ) potential [23.368]. Although at the interatomic distances of the solid, the Tang–Toennies potential [23.369] would be more appropriate, the MLJ value of 53 K, corresponding to a Debye frequency in energy units of 4.56 meV, is only

slightly less than the DFPT maximum phonon energy in Xe(111), equal to 4.8 meV [23.98]. The predictive power of DFT and DFPT is severely challenged when applied to condensed forms of heavy and superheavy atoms. The future possibility to deposit a few-layer films of these highly radioactive elements for the investigation of their dynamical properties will provide an important testing ground.

Topological Insulator Surfaces

Topological insulator surfaces provide another important testing ground for DFPT surface dynamics. Figure 23.21 reproduces two recent DFPT calculations for three quintuple layers (QLs) of $Bi_2Se_3(111)$ [23.370, 371] and $Sb_2Te_3(111)$ [23.370, 372], together with recent HAS investigations of the surface phonons of the $Bi_2Se_3(111)$ surface [23.189, 371]. The first measurements by *Zhu* et al. [23.189], supported by a theoretical analysis based on the ME model, gave some evidence of a strong Kohn anomaly in the lowest optical mode at about 5 meV for a wavevector $Q = 2k_F \cong 0.23$ Å^{-1} corresponding to the Fermi level transition across the Dirac cone. More recent HAS measurements with higher resolution [23.371], reported in Fig. 23.21a, reproduce the calculated DFPT dispersion curves quite well, but do not show any anomaly. Since an electronic transition across the Dirac cone of a topological material implies a spin reversal, it can couple to a phonon only via the spin–orbit part of the electron–phonon interaction. Moreover, as discussed below for $Bi_2Te_3(111)$, the presence of a Kohn anomaly depends very much on the actual position of the Fermi level, which can be moved up and down by surface defects and doping, and eventually cut the associated quantum-well states within the surface band bending. These apparently conflicting results may actually hide a complex scenario, which it would be worth investigating further.

The spin–orbit interaction provides the fundamental mechanism for the nontrivial electronic structure of topological insulators. It is, therefore, expected to also affect the surface phonon dispersion curves, the major effect being a substantial softening of the optical modes, as observed above for Bi(111). On the other hand, the DFPT calculation with no SOC and no van der Waals (VdW) correction for $Bi_2Se_3(111)$ yields good agreement with HAS over the entire dispersion curve. The more precise micro-Raman measurements by *Shahil* et al. [23.373] on exfoliated samples of few quintuple layers (QL) of $Bi_2Se_3(111)$ and $Sb_2Te_3(111)$ predict energies of 21.5 and 20.5 meV for the highest A_{1g} Raman-active mode, respectively, slightly softer than the corresponding SV1 modes at $\overline{\Gamma}$. The discrepancy in $Bi_2Se_3(111)$ may indicate that the SOC softening exceeds the VdW hardening, while the better agreement in $Sb_2Te_3(111)$ speaks for a substantial cancellation of the two corrections.

A similar misfit occurs for $Bi_2Te_3(111)$ between the highest $\overline{\Gamma}$-point mode calculated with DFPT with no SOC or VdW (Fig. 23.22a; [23.374, 375]) and the corresponding *Shahil* et al. micro-Raman A_{1g} energy [23.373] (Fig. 23.22b), also suggesting a SOC softening larger than the VdW stiffening. The DFPT calculation of the lower part of the spectrum is in excellent agreement with the high-resolution ^{3}He-spin-echo (HeSE) scattering data shown in Fig. 23.23a. Also in this case, the deep Kohn anomaly reported at $Q =$

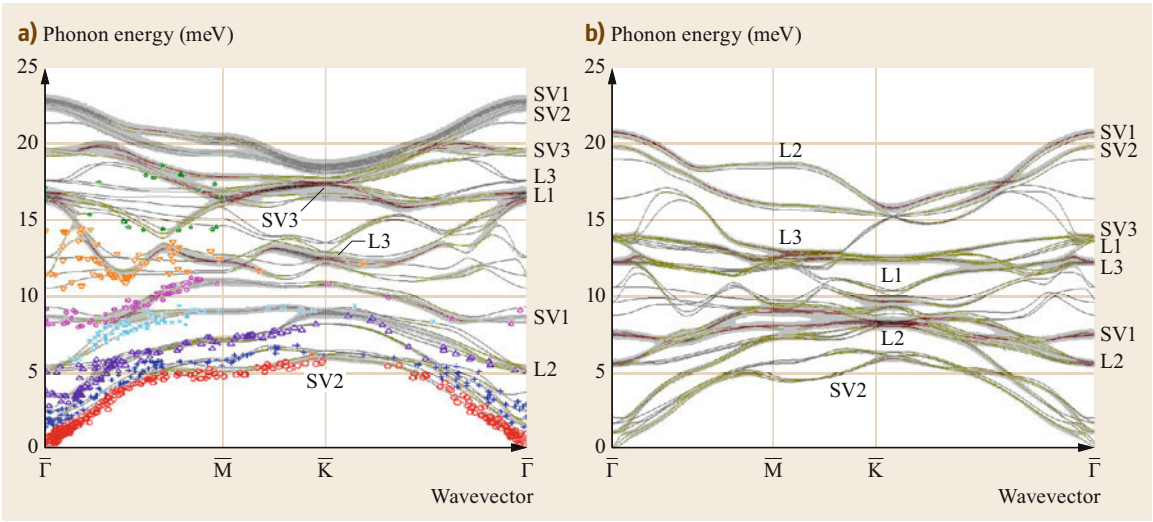

Fig. 23.21 (a) DFPT dispersion curves for three quintuple layers of $Bi_2Se_3(111)$ [23.370, 371] and **(b)** of $Sb_2Te_3(111)$ [23.370, 372]. The calculations do not include SOC or van der Waals corrections. HAS data [23.371] for $Bi_2Se_3(111)$ are also reported with symbols of different colors according to the assignment to different phonon branches

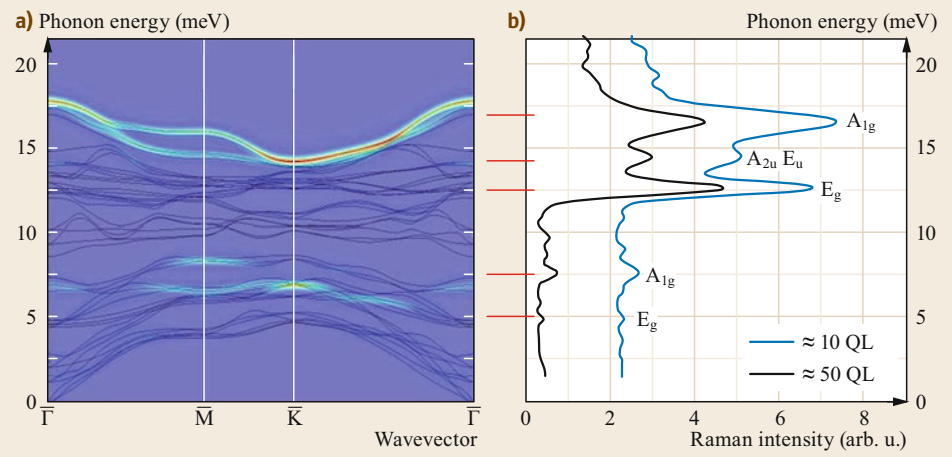

Fig. 23.22 **(a)** DFPT dispersion curves for three quintuple layers (QLs) of $Bi_2Te_3(111)$ (same color code for surface-projected DOS as in Fig. 23.14) calculated with no SOC or VdW corrections [23.374, 375]. **(b)** The micro-Raman spectra measured by *Shahil* et al. [23.373] for exfoliated few-QL samples agree well with the corresponding calculated modes at $\overline{\Gamma}$, except for the highest calculated A_{1g}, which is above the experimental value

$2k_F \cong 0.18\,\text{Å}^{-1}$ in a previous HAS study by *Howard* et al. [23.376, 377] is not found in the HeSE measurements, nor in the DFPT calculation. However, the inspection of the DOS associated with the RW and the L acoustic branches as measured with HeSE scattering (Fig. 23.23b) reveals an incipient sharp Kohn anomaly in the L branch at about one half of the zone [23.374, 375], which could correspond to an electron–phonon coupling involving Fermi-level quantum-well states within the surface band bending [23.378].

The implication of quantum-well electronic states at a band-bending accumulation layer in surface phonon anomalies is also transparent in a recent Brillouin scattering study of the RW and L dispersion curves in the GHz spectral region of a 50 nm $Bi_2Te_3(111)$ film on a GaAs substrate (Fig. 23.23c; [23.379]). The fact that the anomalies occur at a wavevector corresponding to a penetration depth of the surface waves approximately equal to the film thickness means that the electron–phonon coupling is with the excitations of the two-dimensional electron gas (2DEG) at the Bi_2Te_3/GaAs interface. The surface waves at smaller wavevectors become the Sezawa waves of the supported film.

Heid et al. [23.380] recently demonstrated (including SOC) that the weak electron–phonon interaction due to Dirac electrons in this class of topological insulators is strongly enhanced when the Fermi level is shifted above the minimum of the conduction band, so as to cut the surface 2DEG minibands. This work demonstrates that the major contribution to electron–phonon coupling comes from the higher optical phonons above 10 meV, i.e., those which most perturb the electronic states within the QLs.

A final remark concerns surface phonons in this class of topological insulators. Although the QLs are commonly considered to be held together by weak van der Waals interactions, there is no gap in the surface phonon DOS between the acoustic (interlayer) and the optical (intralayer) phonon bands, unlike what occurs in Bi(111) and Sb(111). Optical bands, as is visible in Figs. 23.21 and 23.22, exhibit unusually strong dispersions with large avoided crossings and character exchanges. This peculiar behavior appears to be a signature of the important electron–phonon effects affecting the optical branches and is represented in DFPT by the last term of (23.53).

23.3 Some Open Problems

Despite the great progress and success of DFPT in the calculation of surface phonons of all kinds of crystal lattices, there is an intrinsic limitation in the size of systems that can be approached within a reasonable central processing unit (CPU) time. The size limitation mainly concerns the number of atomic layers that can be chosen in the slab and the spatial extension of the surface unit cell. Complex structures with extended surface unit cells can be approached only at the expense of the number of layers, yielding coarse surface-projected phonon densities. As long as the surface modes are well localized, their dispersion curves can be obtained with

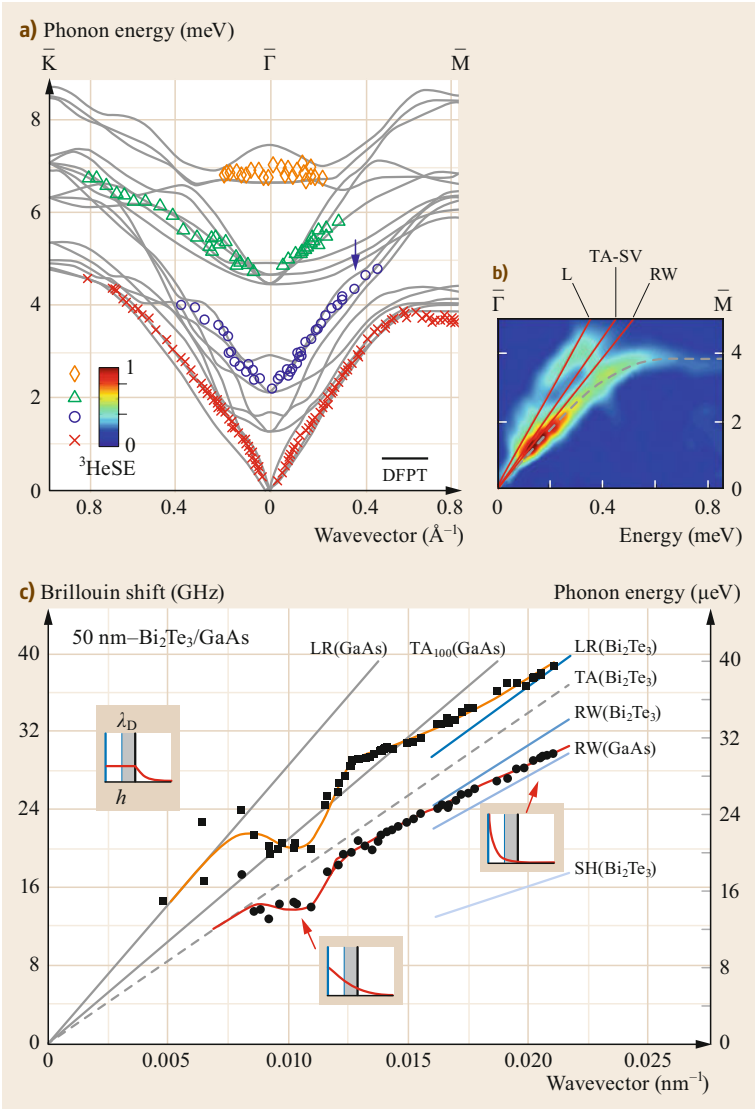

Fig. 23.23 **(a)** DFPT calculation of the dispersion curves for three QLs of Bi_2Te_3(111) in the low-energy part of the spectrum compared with HeSE scattering data (*symbols in color*) [23.375]. **(b)** The DOS associated with the RW and the L acoustic branches as measured with HeSE reveals an incipient sharp Kohn anomaly in the L branch at about one half of the zone (*arrow* in **(a)**), which could correspond to a coupling with a Fermi level transition involving surface quantum-well states [23.374, 375]. **(c)** Kohn anomalies in the RW and L branches of a 50 nm film of Bi_2Te_3(111) on a GaAs substrate are also found in the GHz spectral region with Brillouin scattering (*full circles* and *squares*) [23.379]. The fact that the anomalies occur at a wavevector corresponding to a penetration depth approximately equal to the film thickness (*insets* in **(c)**) implies that the electron–phonon coupling is with the interface 2DEG excitations

sufficient precision, even with a slab model of a few layers. The condition is that the surface phonon penetration length should be much shorter than the slab thickness. However, surface resonances are as important as localized surface modes in the calculation of various surface response functions, and their dispersion curves can hardly be recognized in slabs with a too few layers, especially in the case of large surface unit cells. In general, a simple scaling argument suggests that a semi-infinite crystal can be reliably modeled by a slab as long as the thickness is much larger than the linear size of the cell (or the number of layers is much larger than the number of atoms composing the unit cell).

This problem needs to be carefully considered for the prediction and interpretation of the HAS spectra. After being recognized to carry information on both localized surface modes and resonances and also on subsurface modes having their largest amplitude several layers beneath the surface, it became clear that ab-initio simulations with only a few atomic layers would be insufficient. Efficient expedients have to be introduced, like that of sandwiching a thick slab with ab-initio bulk force constants between the two halves of a thin slab with its ad-hoc ab-initio force constants. This way, sufficiently reliable dense surface projected DOS can be obtained and resonant features identified. From earlier discussions, it appears that the Green's function formalism is most appropriate for dealing with energy-dependent vibrational response functions and resonances. Provided that the eigenfrequencies

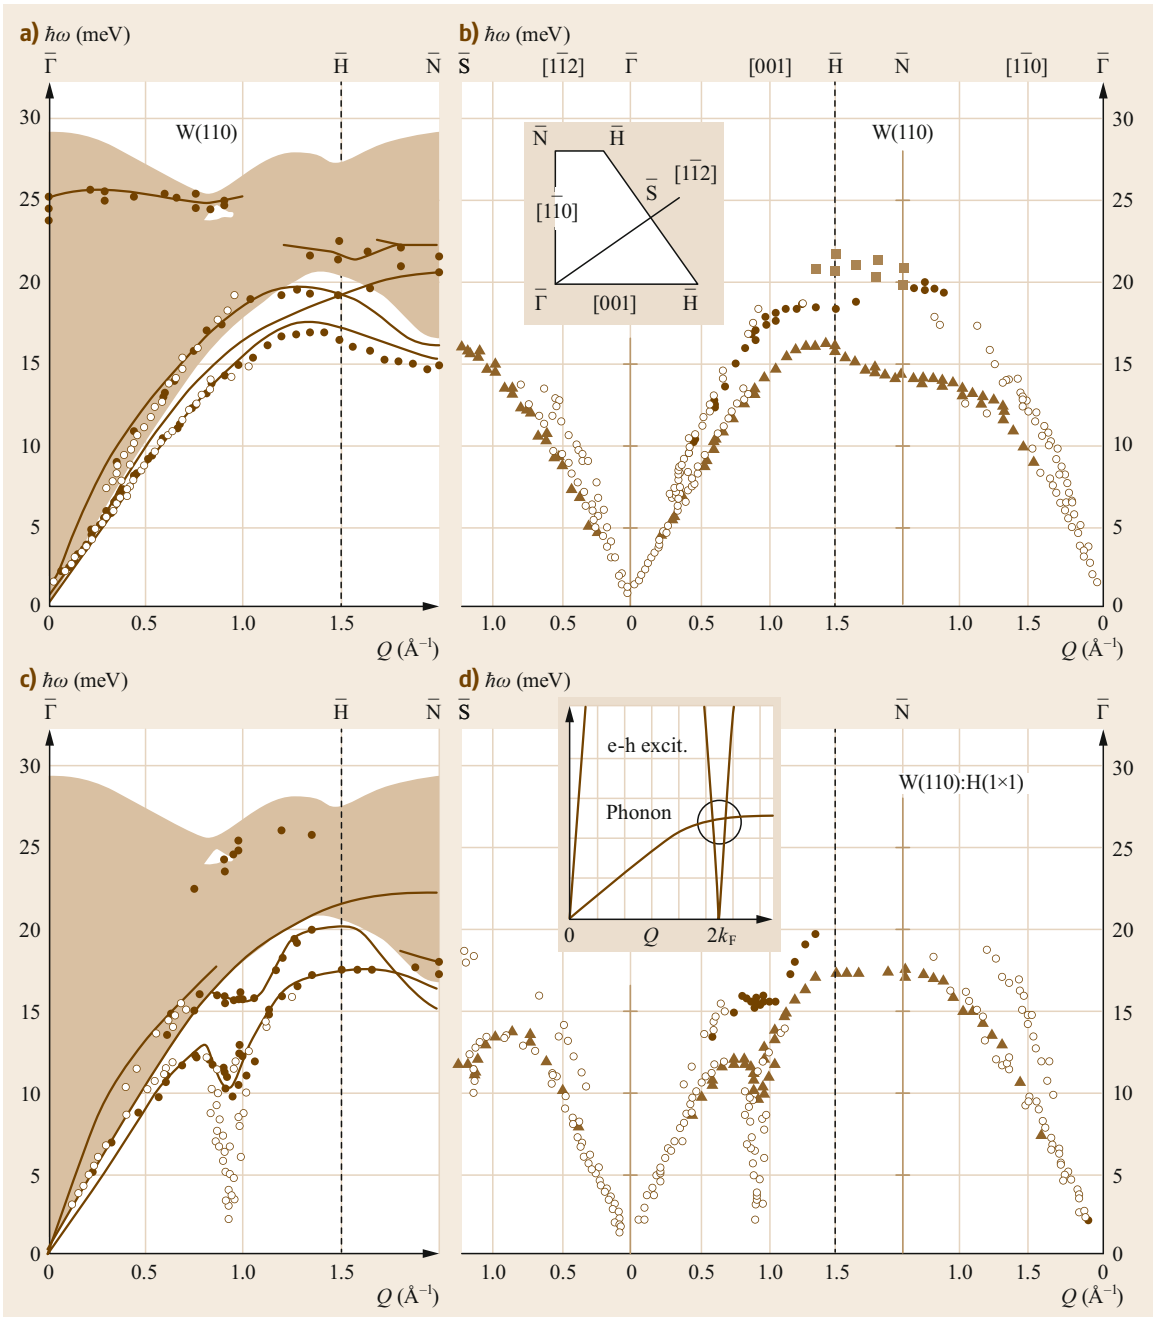

Fig. 23.24a–d Surface phonon dispersion curves of clean **(a,b)** and H-covered **(c,d)** W(110), calculated with DFPT **(a,c)** [23.381] and measured with HAS (*open symbols*) [23.382–385] and HREELS (*full symbols*) [23.386, 387]. The *inset* in **(b)** shows the irreducible part of the surface Brillouin zone with the symmetry directions. The H monolayer induces a deep nonadiabatic anomaly in the $\overline{\Gamma}\overline{\mathrm{H}}$ direction due to an avoided crossing between the surface phonons and the electron–hole (e–h) excitations in the quasi-1-D electronic band of the hydrogen rows, as is illustrated in the *inset* in **(d)**

and eigenvectors of the bulk phonons are known, the Green's function formalism can also be applied to extended surface unit cells, since the coordinate space to deal with is reduced from that of the entire slab to that of the perturbation. Thus, one of the possible and highly desired developments in the field would be the implementation of the Green's function method for DFPT surface dynamics.

Another challenge for DFPT is represented by the nonadiabatic manifestations of electron–phonon interaction, like, e.g., the sharp Kohn anomalies occurring in quasi-one-dimensional free-electron systems at the surface of metals. A well-known example is that of W(110) covered with an atomic hydrogen monolayer. Figure 23.24 collects the surface phonon dispersion curves of the clean W(110) surface (Fig. 23.24a,b) and of W(110):H(1×1) (Fig. 23.24c,d), calculated with DFPT (Fig. 23.24a,c) [23.381] and measured with HREELS (full symbols) [23.386, 387] and HAS (open symbols) [23.382–385]. The inset in Fig. 23.24b shows the irreducible part of the surface Brillouin zone with the symmetry directions on the bcc(110) surface. The H monolayer induces a deep Kohn anomaly in the $\overline{\Gamma\mathrm{H}}$ direction, whose nonadiabatic character is due to an avoided crossing between the surface phonon branches and the electron–hole excitations in the quasi-1-D electronic band of the hydrogen rows, as is illustrated in the inset of Fig. 23.24d [23.388].

While the DFPT calculation [23.381] for the clean surface accounts very well for the experimental dispersion curves, that for the H-covered surface fails to reproduce the deep anomaly. The anomalies obtained by DFPT originate, as expected, from the corresponding $2k_{\mathrm{F}}$ nesting at the Fermi level [23.389, 390], but due to the adiabatic approximation required by DFPT, the predicted anomaly in the RW is much shallower than the sharp anomaly seen in the HAS experiment. At the two avoided crossings, the surface phonon is converted into an electron–hole excitation, with atoms moving less and less and electrons oscillating more and more, and vice versa. Since HREELS in the impact regime mostly interacts with core electrons, it only detects phonon-like excitations and can follow the anomalous dispersion curve only as long as the atomic displacements are sufficiently large. If the adiabatic approximation could be avoided in DFPT calculations, then it would be possible to deal with this and other similar nonadiabatic phenomena like, e.g., phonon-induced chemical reactions at surfaces, etc. As discussed in Sect. 23.2.2, the ME method provides a phenomenological approach to nonadiabatic phonon dynamics (see, e.g., the PC model fit of W(110):H(1×1) and Mo(110):H(1×1) anomalies in [23.388]), but the specific role of the electronic band structure and electron–hole excitations at the Fermi level can only be accounted for by a full development of a nonadiabatic DFPT, hopefully in the near future.

Acknowledgments. We are grateful to Evgueni V. Chulkov, Pedro M. Echenique, and Irina Yu. Sklyadneva (DIPC, San Sebastian, Spain), Wolfgang Ernst and Toni Tamtögl (TU Graz, Austria), Daniel Farìas (Universidad Autonoma, Madrid, Spain), Salvador Miret-Artès (CSIC, Madrid, Spain), and Dick Manson (Clemson University, SC, USA) for several useful discussions and a fruitful collaboration on some of the recent and most challenging aspects of surface dynamics summarized in the last sections of the present chapter. Two of us (JPT and GB) also acknowledge several useful discussions in the early days of HAS theory and surface dynamics with the late Gian Paolo Brivio, to whose memory this review is dedicated.

Matthieu J. Verstraete is Professor of Physics at the University of Liège, Belgium, and chairs the ETSF Steering Committee. He specializes in first-principles theory of electrons, phonons, their ultrafast dynamics and coupling, with implementation in open-source codes and spearheading community-wide efforts for integration and interoperability. Applications include thermoelectric and spin-caloritronic devices, 2-D materials and their heterostructures, and metallic alloys.

24. Electron–Phonon Interaction on Metallic Surfaces, Overlayers and Thin Films

Rolf Heid, Irina Y. Sklyadneva, Evgueni V. Chulkov

The electron–phonon interaction (EPI) lies at the heart of many physical phenomena like electrical and heat conductivity, phonon-mediated superconductivity, dynamics of excited electrons and holes, and various temperature-dependent phenomena. Knowledge of EPI is therefore of profound interest in condensed matter physics.

This chapter provides an introduction to the EPI on metallic surfaces, overlayers, and thin films. Section 24.1 describes the basic concepts of the renormalization of electronic quasiparticles, which manifests itself in finite lifetimes of excited electrons or holes and kinks in electronic band dispersions. A central quantity is the electron self-energy, which incorporates dissipative processes induced by scattering of virtual phonons. Sections 24.2 and 24.3 present current computational and experimental techniques, respectively, which allow the energy- and momentum-dependence of these phenomena to be analyzed in great detail. A compilation of results for elemental and adsorbate-covered metal surfaces, thin films, and metallic states on the surface of topological insulators is given in Sect. 24.4. Finally, EPI-related phenomena are discussed from the perspective of the surface phonons in Sect. 24.5.

Electron–phonon interaction (EPI) is one of the fundamental many-body interactions always present in a solid material. In the last two decades this research field has gained new impetus in the context of surface science, because surfaces provide a unique platform for these studies as they allow a more direct and controlled access to the relevant electronic and phononic quasiparticles than the bulk counterpart. In addition, EPI is important for a detailed understanding of a variety of surface-related phenomena, like surface relaxation or surface phase transitions. As it changes the properties of both electronic and vibrational quasiparticles, it also has an impact on various dynamical processes at surfaces.

Fundamental aspects of EPI in crystalline solids have been reviewed in the classic book of *Grimvall* [24.1]. The steady improvement of experimental and theoretical techniques led to a rise in studies of EPI properties on surfaces. This research field is characterized by a fruitful interrelation of theory and experiment. On the one hand, theoretical models provide microscopic interpretations of experimental data, while on the other hand high-precision experiments serve as tests for the accu-

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-46906-1_24

racy of theoretical approaches. For further reading, we refer the reader to several review articles that deal with EPI on surfaces from different perspectives [24.2–10].

In this chapter, we will address studies of EPI for metallic surfaces, overlayers, and thin films. Not discussed are layered materials, like cuprate or iron-pnictide/chalcogenide superconductors, or charge-density wave compounds, like transition-metal dichalcogenides, where EPI has been studied with similar techniques, but where the emphasis was placed on bulk properties. We also do not include EPI studies of 2-D materials like graphene, which are topics of separate chapters in this handbook. While we briefly introduce several spectroscopic and theoretical techniques, this is done only in the context of their applications to gain information about the EPI. The reader is referred to other chapters of this handbook for more detailed presentations of these techniques.

24.1 Basic Concepts

In this section, an introduction to the fundamental aspects of electron–phonon interaction, its influence on electronic quasiparticles, and its quantification is presented. In the following, we adopt atomic units with $\hbar = 1$, where $\hbar$ is Planck's constant.

24.1.1 Renormalization of Electronic Quasiparticles

The central quantity describing the renormalization of electronic quasiparticles is the electron self-energy Σ. It is a momentum- and energy-dependent quantity that describes the effect of interactions of a quasiparticle with its environment. The relationship between the self-energy and the renormalized Green's function G is given by the Dyson equation

$$G(\boldsymbol{k}\nu,\epsilon) = [\epsilon - \epsilon_{\boldsymbol{k}\nu} - \Sigma(\boldsymbol{k}\nu,\epsilon)]^{-1} \,. \tag{24.1}$$

Here the electronic state is denoted by a momentum $\boldsymbol{k}$ and band index ν. The unrenormalized or bare energy is $\epsilon_{\boldsymbol{k}\nu}$, which is taken relative to the Fermi level ϵ_F. For not too large self-energies, the spectral function of the quasiparticle,

$$A(\boldsymbol{k}\nu,\epsilon) = -2\mathrm{Im}\{G(\boldsymbol{k}\nu,\epsilon+\mathrm{i}\delta)\} \,, \tag{24.2}$$

possesses a well-defined peak which is shifted from the original quasiparticle energy and acquires a finite linewidth. Here, δ denotes a positive infinitesimal number. The shifted energy is connected to the real part of Σ by

$$\overline{\epsilon}_{\boldsymbol{k}\nu} = \epsilon_{\boldsymbol{k}\nu} - \mathrm{Re}\{\Sigma(\boldsymbol{k}\nu,\overline{\epsilon}_{\boldsymbol{k}\nu})\} \,, \tag{24.3}$$

while the imaginary part determines the linewidth (full-width-at-half-maximum)

$$\Gamma_{\boldsymbol{k}\nu} = -2\mathrm{Im}\{\Sigma(\boldsymbol{k}\nu,\overline{\epsilon}_{\boldsymbol{k}\nu})\} \,. \tag{24.4}$$

The inverse linewidth gives the lifetime of the quasiparticle,

$$\tau_{\boldsymbol{k}\nu} = \frac{1}{\Gamma_{\boldsymbol{k}\nu}} \,. \tag{24.5}$$

The self-energy can be represented by an infinite series of Feynman diagrams. In the case of the electron–phonon interaction, the dominant contribution comes from the lowest-order diagram schematically shown in Fig. 24.1, which describes a virtual exchange of a phonon mode, and leads to [24.1]

$$\begin{aligned}\Sigma(\boldsymbol{k}\nu,\epsilon) = \frac{1}{N_q}\sum_{\boldsymbol{q}j}\sum_{\nu'} |g^{\boldsymbol{q}j}_{\boldsymbol{k}+\boldsymbol{q}\nu',\boldsymbol{k}\nu}|^2 \\ \times\left[\frac{b(\omega_{\boldsymbol{q}j})+f(\epsilon_{\boldsymbol{k}+\boldsymbol{q}\nu'})}{\epsilon+\omega_{\boldsymbol{q}j}-\epsilon_{\boldsymbol{k}+\boldsymbol{q}\nu'}+\mathrm{i}\delta}\right. \\ \left.+\frac{b(\omega_{\boldsymbol{q}j})+1-f(\epsilon_{\boldsymbol{k}+\boldsymbol{q}\nu'})}{\epsilon-\omega_{\boldsymbol{q}j}-\epsilon_{\boldsymbol{k}+\boldsymbol{q}\nu'}+\mathrm{i}\delta}\right] .\end{aligned} \tag{24.6}$$

The q-summation runs over N_q points in the first Brillouin zone. Temperature dependence enters via the Fermi and Bose distribution functions $f(\epsilon) = 1/(\mathrm{e}^{\epsilon/(k_\mathrm{B}T)}+1)$ and $b(\epsilon) = 1/(\mathrm{e}^{\epsilon/(k_\mathrm{B}T)}-1)$, respectively, where k_B is Boltzmann's constant; $\omega_{\boldsymbol{q}j}$ denotes the energy of the phonon mode with momentum $\boldsymbol{q}$, while j

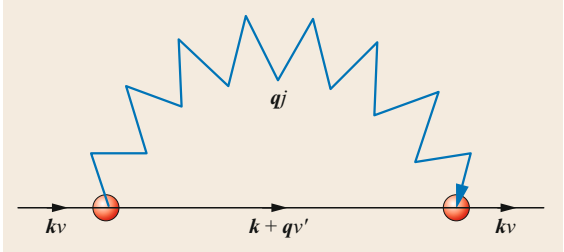

Fig. 24.1 Schematic drawing of the lowest-order contribution to the electron self-energy coming from the electron–phonon interaction. Straight and zigzag lines represent electron and phonon Green's functions, respectively

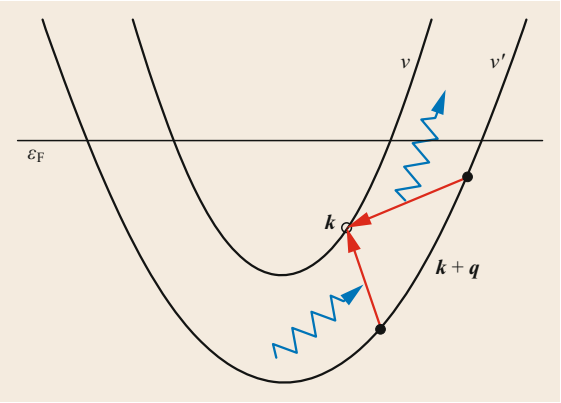

Fig. 24.2 Schematic drawing of the scattering processes that contribute to the self-energy of a hole quasiparticle ($\boldsymbol{k}\nu$), indicating electronic transitions (*red arrows*) and emitted or absorbed phonons (*blue zigzag lines*)

indexes the phonon branch. The electron–phonon vertex $g^{\boldsymbol{qj}}_{\boldsymbol{k}+\boldsymbol{q}\nu',\boldsymbol{k}\nu}$ represents the probability amplitude to scatter an electron/hole from a state ($\boldsymbol{k}\nu$) to ($\boldsymbol{k}+\boldsymbol{q}\nu'$) via the phonon mode ($\boldsymbol{qj}$). Higher order diagrams are supposed to be small in virtue of the Migdal theorem and are usually neglected [24.11].

An illustration of the physical processes described by (24.6) is given in Fig. 24.2. When a hole quasiparticle is created below the Fermi energy, electrons can scatter virtually from states with higher or lower energies, which is accompanied by a simultaneous emission or absorption of a phonon, respectively. Similarly, an electronic quasiparticle created at energies above the Fermi level can scatter virtually into other unoccupied states, again emitting or absorbing a phonon. These two types of processes are represented by the first and second term in (24.6), respectively.

The imaginary part of Σ can be written in the form [24.6]

$$\begin{aligned}&\mathrm{Im}\{\Sigma(\boldsymbol{k}\nu,\epsilon)\}\\&=-\pi\int_0^\infty \mathrm{d}\omega\,\left\{\alpha^2F^+_{\boldsymbol{k}\nu}(\epsilon,\omega)[b(\omega)+f(\omega+\epsilon)]\right.\\&\left.\quad+\alpha^2F^-_{\boldsymbol{k}\nu}(\epsilon,\omega)[b(\omega)+f(\omega-\epsilon)]\right\},\end{aligned}\tag{24.7}$$

where the two spectral functions defined by

$$\begin{aligned}\alpha^2F^\pm_{\boldsymbol{k}\nu}(\epsilon,\omega)&=\frac{1}{N_q}\sum_{\boldsymbol{qj}}\delta(\omega-\omega_{\boldsymbol{qj}})\\&\quad\times\sum_{\nu'}|g^{\boldsymbol{qj}}_{\boldsymbol{k}+\boldsymbol{q}\nu',\boldsymbol{k}\nu}|^2\delta(\epsilon-\epsilon_{\boldsymbol{k}+\boldsymbol{q}\nu'}\pm\omega)\end{aligned}\tag{24.8}$$

correspond to the emission (+) and absorption (−) processes. Combining (24.7) with (24.4) gives an expression for the quasiparticle linewidth due to electron–phonon interaction

$$\begin{aligned}\Gamma_{\boldsymbol{k}\nu}&=2\pi\int_0^\infty \mathrm{d}\omega\,\left\{\alpha^2F^+_{\boldsymbol{k}\nu}(\overline{\epsilon}_{\boldsymbol{k}\nu},\omega)[b(\omega)+f(\omega+\overline{\epsilon}_{\boldsymbol{k}\nu})]\right.\\&\left.\quad+\alpha^2F^-_{\boldsymbol{k}\nu}(\overline{\epsilon}_{\boldsymbol{k}\nu},\omega)[b(\omega)+f(\omega-\overline{\epsilon}_{\boldsymbol{k}\nu})]\right\}.\end{aligned}\tag{24.9}$$

A formula for the real part of the self-energy can be derived directly from (24.7), but in practice it is more convenient to make use of the Kramers–Kronig relation

$$\mathrm{Re}\{\Sigma(\boldsymbol{k}\nu,\epsilon)\}=\frac{1}{\pi}\int \mathrm{d}\epsilon'\frac{\mathrm{Im}\{\Sigma(\boldsymbol{k}\nu,\epsilon')\}}{\epsilon-\epsilon'}\,.\tag{24.10}$$

The second δ-function in (24.8) expresses the energy conservation and differs for emission and absorption by the sign of the phonon frequency. Because energies related to lattice vibrations are often much smaller than the relevant electronic energies, emission or absorption of a phonon mainly changes the momentum of the electron, while the associated energy change is negligible. Therefore, the difference between the two spectral functions is often very small, and one can resort to the so-called quasielastic approximation

$$\begin{aligned}\alpha^2F^\pm_{\boldsymbol{k}\nu}(\overline{\epsilon}_{\boldsymbol{k}\nu},\omega)&\approx\alpha^2F_{\boldsymbol{k}\nu}(\omega)\\&=\frac{1}{N_q}\sum_{\boldsymbol{qj}}\delta(\omega-\omega_{\boldsymbol{qj}})\sum_{\nu'}|g^{\boldsymbol{qj}}_{\boldsymbol{k}+\boldsymbol{q}\nu',\boldsymbol{k}\nu}|^2\\&\quad\times\delta(\overline{\epsilon}_{\boldsymbol{k}\nu}-\epsilon_{\boldsymbol{k}+\boldsymbol{q}\nu'})\,,\end{aligned}\tag{24.11}$$

which gives a simplified expression for the linewidth

$$\begin{aligned}\Gamma_{\boldsymbol{k}\nu}&\approx2\pi\int_0^\infty \mathrm{d}\omega\alpha^2F_{\boldsymbol{k}\nu}(\omega)\\&\quad\times[2b(\omega)+f(\omega+\overline{\epsilon}_{\boldsymbol{k}\nu})+f(\omega-\overline{\epsilon}_{\boldsymbol{k}\nu})]\,.\end{aligned}\tag{24.12}$$

The spectral function $\alpha^2F_{\boldsymbol{k}\nu}(\omega)$ bears some similarities with the well-known Eliashberg function used in the strong-coupling theory of phonon-mediated superconductivity. The important difference is that it is associated to an individual electron state ($\boldsymbol{k}\nu$) and describes the effect of coupling to all other electronic states which can be reached by exchange of a single phonon.

In the derivation presented above, the Dyson equation (24.1) is evaluated directly on the real axis. This approximation breaks down when the self-energy becomes too large. More generally, the quasiparticle properties are determined from the poles of the renormalized

Green's function in the complex plane, i.e., for complex energies ϵ. Such a scheme has been developed by *Eiguren* et al. [24.12, 13]. Application to the surface band renormalization of H/W(110) led, for large coupling strength, to a complex behavior of the renormalized spectral function like multipeak structures, which can no longer be interpreted within a simple quasiparticle picture.

24.1.2 Electron–Phonon Coupling Strength

The strength of the renormalization depends on three factors: (i) available final electronic states $(\boldsymbol{k}+\boldsymbol{q}\nu')$, (ii) available phonon modes connecting the initial to the final states, and (iii) the probability for this scattering given by $|g^{\boldsymbol{q}j}_{\boldsymbol{k}+\boldsymbol{q}\nu',\boldsymbol{k}\nu}|^2$. A convenient dimensionless measure of the average coupling strength is the electron–phonon coupling constant

$$\lambda_{\boldsymbol{k}\nu} = 2\int \mathrm{d}\omega \frac{\alpha^2 F_{\boldsymbol{k}\nu}(\omega)}{\omega} \,. \tag{24.13}$$

It is a property of the individual quasiparticle $(\boldsymbol{k}\nu)$ and depends both on momentum and band index. It can be directly connected to measurable quantities in two ways. The first one is the high-temperature behavior of electronic linewidth. Under the condition $T \gg \omega_{\max}$, where $\omega_{\max}$ is the maximum phonon frequency, the linewidth becomes linear in T and (24.12) simplifies to

$$\Gamma_{\boldsymbol{k}\nu} \approx 2\pi\lambda_{\boldsymbol{k}\nu} k_\mathrm{B} T \,. \tag{24.14}$$

Thus, $\lambda_{\boldsymbol{k}\nu}$ is given by the slope of the linear increase of the linewidth at sufficiently high temperatures. The second route is via the self-energy and is based on the exact relationship

$$\lambda_{\boldsymbol{k}\nu} = \left.\frac{\partial \mathrm{Re}\{\Sigma(\boldsymbol{k}\nu,\epsilon)\}}{\partial\epsilon}\right|_{\epsilon=\epsilon_\mathrm{F},T=0} \,. \tag{24.15}$$

Thus, $\lambda_{\boldsymbol{k}\nu}$ also determines the slope of the real part of the self-energy at the Fermi energy ϵ_F in the limit $T \to 0\,\mathrm{K}$. The real part of self-energy can be extracted from measurements of the renormalized quasiparticle dispersion at low temperatures.

Both routes, via the temperature-dependent linewidth or the low-energy behavior of the self-energy, have been widely utilized to determine the coupling constant from experimental data. We will discuss the applied techniques in more detail in Sect. 24.3.

24.2 Computational Approaches

Renormalization of electronic quasiparticles is typically a process involving many phonon modes, which also differ in the way they couple to the relevant electronic states. Interpretation of experiments is therefore quite involved and must be combined with theoretical guidance. Simple models have been widely used in analyzing experimental data, but they provide only limited information about the most relevant phonons involved. Significant advances in microscopic approaches in the last decade have made very detailed calculations of all relevant quantities possible today.

24.2.1 Simple Models

We will discuss here two types of simple models, the Einstein and the Debye model. The Einstein model provides an instructive look into the renormalization process. It assumes the coupling of a single dispersionless phonon branch of frequency Ω. The spectral function then consists of a single δ-type peak represented by

$$\alpha^2 F_{\boldsymbol{k}\nu}(\omega) = \lambda_\mathrm{E}\frac{\Omega}{2}\delta(\omega-\Omega) \,. \tag{24.16}$$

The corresponding electron self-energy for $T \to 0$ is depicted in Fig. 24.3a. In this limit, only phonon emission processes contribute and the imaginary part exhibits a characteristic step at Ω. Physically this means that if a quasiparticle is created within an energy range smaller than Ω around the Fermi level, this state cannot decay via emission of a single phonon. For energies larger than Ω this decay channel is opened. The real part of the self-energy possesses a maximum at the phonon frequency. As a result, the renormalized dispersion shown in Fig. 24.3b exhibits a kink-like structure right at the phonon energy.

The Einstein model is only appropriate if the electron–phonon interaction is dominated by a single dispersionless optical mode. A more common situation is that the surface states are coupled to many vibrations with a continuous frequency spectrum. Then, the Debye model is more appropriate. This ansatz assumes that all phonon modes contribute equally to the total coupling, such that the spectral function is proportional to the phonon density of states. The latter is approximated by a Debye spectrum [24.4, 14]

$$\alpha^2 F_{\boldsymbol{k}\nu}(\omega) = \lambda_\mathrm{D}\frac{\omega^2}{\omega_\mathrm{D}^2} \,,\ \omega \le \omega_\mathrm{D} \,. \tag{24.17}$$

The Debye frequency ω_D characterizes the maximum phonon frequency, while λ_D denotes the coupling con-

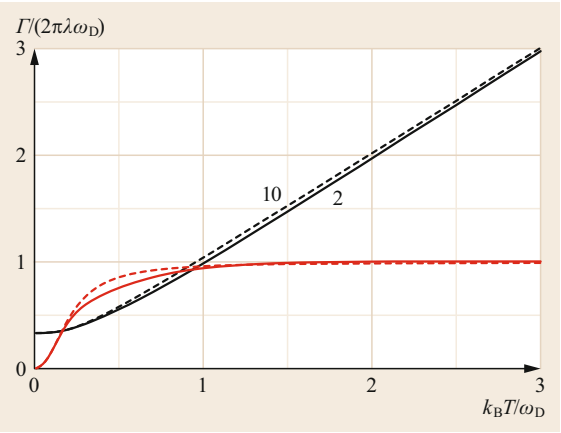

Fig. 24.4 Linewidth as a function of temperature (*black lines*) as well as the temperature derivative (*red lines*) for the Debye model for two values of the ratio $\epsilon_{k\nu}/\omega_D$

stant. The temperature dependence of the linewidth obtained with this model using (24.12) is shown in Fig. 24.4. Its functional form depends on the ratio of the quasiparticle energy $\epsilon_{k\nu}$ and ω_D. The linear-in-T regime is typically reached at temperatures slightly above ω_D/k_B.

The complete functional form of $\Gamma(T)$ provides a convenient basis for fitting data should the linear-in-T regime not be reachable. The fit result depends on the chosen ω_D and often the bulk ω_D is chosen. However, for surfaces that possess a larger surface relaxation or an electronic structure distinct from the bulk, ω_D is adjusted to account for a surface phonon spectrum that deviates from the bulk, or even two-dimensional variants of the Debye spectrum are used [24.2].

24.2.2 Microscopic Models

A calculation of EPI-related quantities requires the knowledge of three ingredients:

(i) electronic surface band structure including electronic wavefunctions
(ii) phonon spectrum comprising vibrations of the bulk material, and localized phonon modes present at the surface and
(iii) first-order variation of the screened potential induced by atom displacements, which determine the electron–phonon matrix elements.

Steps towards an atomistic calculation of EPI on surfaces were first made by the development of microscopic models, which for each of the three ingredients independently introduce simplifying approximations. Such a model approach was proposed in [24.15, 16] based on the following assumptions:

(i) The one-electron states were derived from a one-dimensional potential representing the crystal potential at the surface. The form of the potential was constructed in such a way as to reproduce various properties of the surface electronic structure, like surface-projected bulk gaps or energies of surface and image states [24.17].
(ii) Lattice dynamical properties were obtained from a force-constant model with a single parameter, and the surface vibrations were calculated by applying this model to a slab geometry [24.18].
(iii) The first-order variation of the screened potential was represented by *Ashcroft* pseudopoten-

tials [24.19], which were screened either with the Thomas–Fermi approximation or the random-phase approximation. In metals, screening is crucial to obtain realistic values for the electron–phonon matrix elements.

This model approach is restricted to surface states derived from s-p orbitals only, and works for metals with simple and compact lattice structures, where the simplified description of the lattice dynamics is justified. It was therefore applied predominantly to compact surfaces of fcc noble and transition metals, and to surfaces of Al. This approach was later extended by introducing two-dimensional potentials to describe the one-electron states, which improved the description of the electronic surface structure in the case of more anisotropic surfaces like the (110) surfaces of fcc noble metals [24.20]. To handle overlayers, phonons were calculated from the more sophisticated embedded atom model [24.21, 22].

24.2.3 Ab Initio Calculations

Density-functional theory is nowadays a well established approach to calculate electronic structure properties in a wide range of material classes. It starts from the quantum-mechanical description and provides material-specific information about the one-electron wavefunctions and energies. Besides, also the lattice dynamics and electron–phonon interaction can be calculated within the same framework. The most efficient scheme is based on a linear-response technique and is called density-functional perturbation theory [24.23–26]. It allows calculation of the first-order response of the electronic system with respect to an atomic displacement in a self-consistent procedure, from which the phonon properties can be derived. Importantly, this approach automatically incorporates screening effects. In addition, it provides the first-order variation of the potential needed for the electron–phonon matrix elements.

There are presently a growing number of studies applying this technique to the EPI on surfaces. Surfaces are represented by finite-size slabs, which must be chosen thick enough to converge to the surface properties of a semi-infinite system [24.27]. The bottleneck of such ab initio studies is usually the calculation of the phonons, which quickly becomes very expensive with increasing slab thickness. Furthermore, the evaluation of EPI quantities requires fine meshes in momentum space for both phonons and electron–phonon matrix elements, which is typically handled by elaborate interpolation schemes [24.28, 29].

24.3 Experimental Determination of Electron–Phonon Coupling Strength

In this chapter we briefly recapitulate the different experimental approaches used to extract the electron–phonon coupling in surface states.

24.3.1 Angle-Resolved Photoemission Spectroscopy

The most widely used experimental technique to obtain information about the strength of the electron–phonon interaction at surfaces is angle-resolved photoemission spectroscopy (ARPES), which allows the properties of individual electronic quasiparticles to be accessed. In the photoemission process, an incoming photon is absorbed and excites an electron from an occupied state into a vacuum state. In the so-called sudden approximation, one assumes that after photon absorption the photoelectron does not interact further with the system left behind. Without energy and momentum resolution effects, the photoemission intensity can be written as [24.30]

$$I(\boldsymbol{k},\epsilon,T) = I_0(\boldsymbol{k}) f(\epsilon,T) A(\boldsymbol{k},\epsilon,T)\,. \tag{24.18}$$

For simplicity, the discussion is restricted to a single electronic band, $\boldsymbol{k}$ denotes the momentum of the photoelectron and ϵ its energy relative to the Fermi level, I_0 is proportional to the square of the matrix element describing the excitation process and depends on the momentum of the photoelectron as well as on the energy and polarization of the incoming photon, and f is the Fermi distribution function. In (24.18) the temperature dependence of the quantities is shown explicitly. The one-particle spectral function A contains all information about the initial electronic state, and is connected to the one-particle Green's function via

$$A(\boldsymbol{k},\epsilon,T) = -2\mathrm{Im}\{G(\boldsymbol{k},\epsilon,T)\}\,. \tag{24.19}$$

This can be expressed in terms of the electronic self-energy with the help of (24.1) as

$$A(\boldsymbol{k},\epsilon,T) = -\frac{2\mathrm{Im}\{\Sigma(\boldsymbol{k},\epsilon,T)\}}{[\epsilon-\epsilon_{\boldsymbol{k}}-\mathrm{Re}\{\Sigma(\boldsymbol{k},\epsilon,T)\}]^2+[\mathrm{Im}\{\Sigma(\boldsymbol{k},\epsilon,T)\}]^2}\,. \tag{24.20}$$

On the basis of this general relationship, two major routes have been pursued to extract information about the self-energy from ARPES experiments, which are described in the following.

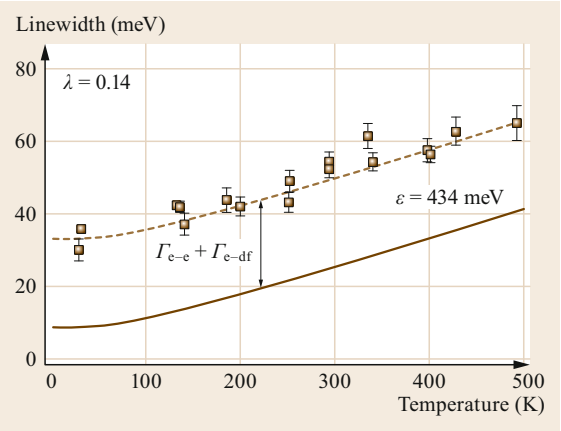

Fig. 24.5 Example of a temperature-dependent linewidth. Data points (*filled squares*) for the Cu(111) surface state at $\overline{\Gamma}$ taken from [24.31] (Data points taken from [24.6], © IOP Publishing & Deutsche Physikalische Gesellschaft. CC-BY-NC-SA)

Measurement of Temperature-Dependent Linewidth

A straightforward procedure to determine the linewidth Γ of an electronic state is by scanning the photoemission intensity as a function of energy for a fixed momentum $\boldsymbol{k}$. For electronic states with binding energies larger than typical phonon energies, the energy dependence in the self-energy can be neglected to a good approximation. Such a scan takes a Lorentzian shape with a full-width-at-half-maximum $\Gamma(T) = 2|\mathrm{Im}\{\Sigma(T)\}|$. In general, it is the sum of three contributions, $\Gamma = \Gamma_{e-ph} + \Gamma_{e-e} + \Gamma_{df}$. Apart from the linewidth from the electron–phonon interaction (Γ_{e-ph}), it contains contributions from inelastic electron–electron scattering processes (Γ_{e-e}), and elastic scattering of electrons from defects at the surface (Γ_{df}). As the latter two contributions are often very weakly dependent on temperature, $\Gamma(T)$ equals $\Gamma_{e-ph}(T)$ up to a constant shift. Figure 24.5 shows an example for a measurement of the Cu(111) surface state, which lies at the surface Brillouin zone center ($\overline{\Gamma}$) at a binding energy of 434 meV [24.31]. The measured T-dependence of the linewidth can be described by a constant plus $\Gamma_{e-ph}(T)$ calculated from (24.12) with the Debye model (24.17). Even without modeling, the coupling constant λ could be directly extracted from the data from the slope at higher temperature via (24.14). This simple analysis breaks down, however, when the concentration of surface defects varies strongly within the same temperature range, which is the case for defects with a low excitation barrier, and causes a significant T-dependence of Γ_{df}. Then the T-dependence of Γ_{e-ph} cannot be extracted directly from the data. Such a complication has been discussed for Al(100) and Au(111) surfaces [24.32, 33].

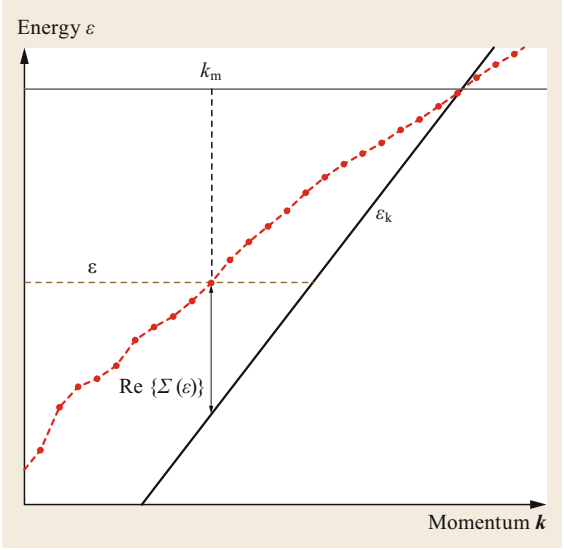

Fig. 24.6 Sketch of extraction of self-energy from ARPES measurements

Extraction of Electron Self-Energy

The most direct way to extract information about the self-energy from ARPES experiments is to record momentum distribution curves (MDCs). An MDC represents photoemission intensity as a function of $\boldsymbol{k}$ at constant kinetic energy of the photoelectron, i.e., at constant ϵ, and at constant photon energy. For an analysis of an MDC, one typically assumes that the $\boldsymbol{k}$ dependence of both the self-energy and the prefactor I_0 in (24.18) can be neglected. This approximation is reasonable, if one takes data restricted to a sufficiently small momentum range. The $\boldsymbol{k}$ dependence in (24.18) then stems solely from the bare dispersion $\epsilon_{\boldsymbol{k}}$, and an MDC along a one-dimensional direction in momentum space takes the form

$$I(k) \propto \frac{1}{[\epsilon - \epsilon_k - \mathrm{Re}\{\Sigma(\epsilon, T)\}]^2 + [\mathrm{Im}\{\Sigma(\epsilon, T)\}]^2} \,. \tag{24.21}$$

For constant ϵ and T, this MDC exhibits a maximum at k_m given by

$$\epsilon - \epsilon_{k_m} - \mathrm{Re}\{\Sigma(\epsilon, T)\} = 0 \,. \tag{24.22}$$

This relationship is sketched in Fig. 24.6. At the same time, an MDC provides also information about $\mathrm{Im}\{\Sigma\}$. This is seen most easily for the case where the bare band is described by a linear dispersion, $\epsilon_k = v(k - k_F)$, with v the slope. The MDC then takes the form of a Lorentzian, and the real and imaginary part of the self-energy can be extracted directly from the position of its

maximum k_m and from its linewidth W (full-width-at-half-maximum) as

$$\mathrm{Re}\{\Sigma(\epsilon,T)\} = \epsilon - v(k_m - k_F)\,,$$
$$\mathrm{Im}\{\Sigma(\epsilon,T)\} = -v\frac{W}{2}\,. \qquad (24.23)$$

The main difficulty of this approach lies in the fact that the determination of both real and imaginary parts of the self-energy involves the bare dispersion which is not known. Two strategies have been applied to deal with this problem. The first is to determine the bare dispersion from measurements of the band dispersion at higher binding energies, where the renormalization by phonons becomes negligible, or to take it from band structure calculations, which do not include many-body corrections.

The second approach rests on the Kramers–Kronig relation (24.10) connecting the real and imaginary part of the self-energy. Combined with the experimental information, it is used to set up a self-consistent procedure to simultaneously determine the self-energy and the bare dispersion. This approach is appealing because it does not require any a priori knowledge about the bare dispersion. Its accuracy, however, depends crucially on the proper modeling of the high-energy parts of the self-energy. These high-energy tails needed for the Kramers–Kronig relation are not directly accessible experimentally [24.34].

After having obtained the self-energy functions, the remaining task is to extract the underlying electron–phonon coupling quantities. Using (24.15), the coupling constant $\lambda_{\boldsymbol{k}\nu}$ can be determined from the slope of $\mathrm{Re}\{\Sigma(\epsilon)\}$ at ϵ_F in the limit $T \to 0\,\mathrm{K}$. Complications arise due to finite energy and momentum resolution present in actual experiments, and the presence of the Fermi distribution function in the expression (24.18) for the photoemission intensity [24.35, 36], which hampers the self-energy analysis in close vicinity to ϵ_F and limits the accuracy of the coupling constant $\lambda_{\boldsymbol{k}\nu}$ obtained via (24.15). Extraction of complete self-energies is restricted to cases where the renormalization effects are large enough to be resolved experimentally. Therefore, most commonly this technique is applied to occupied states close to the Fermi level. For further reading we refer to [24.6, 30, 37].

A more ambitious task is to extract the complete EPI spectral function $\alpha^2F_{\boldsymbol{k}\nu}$ (24.11) from the self-energy. A practical procedure, proposed in [24.38], is based on the approximate relationship between the spectral function and the real part of the self-energy [24.1]

$$\mathrm{Re}\{\Sigma(\boldsymbol{k}\nu,\epsilon)\} = \int \mathrm{d}\omega\alpha^2F_{\boldsymbol{k}\nu}(\omega)\int \mathrm{d}x\frac{2f(x+\epsilon)}{x^2-\omega^2}\,. \qquad (24.24)$$

This expression can be derived from (24.6) and (24.8) in the quasielastic approximation and by replacing the spectral function by its value at the Fermi level

$$\alpha^2F_{\boldsymbol{k}\nu}(\omega) \approx \alpha^2F_{\boldsymbol{k}\nu}(\overline{\epsilon}_{\boldsymbol{k}\nu} \to \epsilon_F,\omega)\,. \qquad (24.25)$$

These simplifications are reasonable if the electronic structure behaves smoothly around ϵ_F on the scale of phonon energies. From measurements of $\mathrm{Re}\{\Sigma(\epsilon)\}$, the spectral function is obtained by inverting the integral equation (24.24). Because a direct inversion tends to be numerically unstable, a fitting procedure employing the maximum entropy method (MEM) has been developed [24.4, 38], which allows additional physical constraints for the spectral function to be built in without severe restrictions on its shape. This scheme is more robust against data noise than the direct inversion, but still relies on high-precision data. Besides application to the EPI on the Be(0001) surface [24.4, 38–40] this MEM fitting procedure has been used in several studies of the electronic renormalization of layered cuprate superconductors [24.41–45].

24.3.2 Time-Resolved Angle-Resolved Photoemission Spectroscopy

The presence of a surface typically creates a variety of loosely bound states, whose wave functions are located close to the surface and whose energies lie between the Fermi energy ϵ_F and the vacuum energy E_{vac}. These unoccupied surface states are not accessible with the ARPES technique described so far. The state must be first populated before its dynamics can be studied. This is achieved by two-photon photoemission spectroscopy (2PPE), which is a well established technique nowadays [24.46, 47].

The principles of the 2PPE excitation process are illustrated in Fig. 24.7. A first light pulse, called the pump pulse, excites an electron from a state below ϵ_F into an

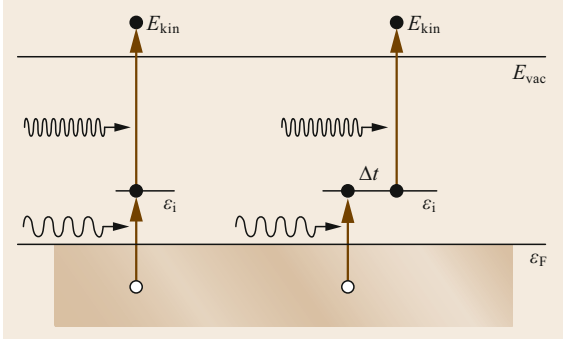

Fig. 24.7 Illustration of the two-photon photoemission process

unoccupied intermediate state with energy ϵ_i above ϵ_F. A second light pulse, also called the probe pulse, then lifts the electron above the vacuum level E_{vac}. It finally escapes the surface with a kinetic energy E_{kin} which is recorded by an energy analyzer. Further information about the dynamics of the intermediate state is gained when the probe pulse is delayed with respect to the pump pulse by a delay time Δt. For this time-dependent 2PPE, one distinguishes two modes of data acquisition:

(i) Energy-resolved 2PPE spectra: the emission rate is measured as a function of E_{kin} at a fixed delay time. Such spectra provide information about the energy and the linewidth Γ of the intermediate state.

(ii) Time-resolved 2PPE spectra: the emission rate is recorded as a function of the delay time for a particular kinetic energy. When the kinetic energy is chosen to record the intermediate state, the measured intensity is proportional to the population of this state. Time-resolved spectra then reflect the decay of the population in the time domain, which often exhibits a simple exponential behavior

$$I \propto I_0 e^{\Delta t/\tau_i} , \qquad (24.26)$$

from which the intrinsic lifetime τ_i of the intermediate state can be deduced directly.

Because the 2PPE process is a second-order excitation, analysis of the recorded intensities is quite involved. In particular, the linewidth Γ obtained by the energy-resolved 2PPE is not only determined by the intrinsic lifetime $(1/\tau_i)$, but contains further contributions from quasielastic scattering processes. The latter do not change the population of the intermediate state, but cause a relaxation of the quantum phase relation between the states involved in the excitation. This phenomenon is called dephasing. An elaborate analysis of the 2PPE linewidth is, e.g., presented in [24.47]. Therefore, the true intrinsic lifetime is determined only by mode (ii). Complications may arise if several intermediate states are present. In this case, the population dynamics must be described by a coupled set of rate equations, whose solution provides the individual lifetimes [24.48]. Determination of the electron–phonon coupling λ then proceeds in the same way as for the occupied states described in Sect. 24.3.1, namely from linear T-dependence of the intrinsic linewidths $\Gamma_i(T) = 1/\tau_i(T)$ using (24.14).

24.3.3 Scanning–Tunneling Spectroscopy

Another approach to analyze the intrinsic lifetime of surface states utilizes the scanning-tunneling microscopy (STM) technique, which is described in more detail in Chaps. 8 and 25. The metallic tip is first positioned on top of the surface. For a fixed distance between tip and surface, the tunneling current I is recorded as function of the bias voltage V between the tip and surface. This measurement mode is also called scanning-tunneling spectroscopy (STS). When the electronic structure of the tip is featureless, the differential conductance dI/dV is directly proportional to the density of states of the surface.

In the presence of a surface state, an additional tunneling channel is opened, when V is raised to the bottom of the surface band (Fig. 24.8). This is reflected as a step in dI/dV as a function of V. A finite lifetime of the surface state gives rise to a broadening of the step. *Li* et al. have utilized a numerical evaluation of the tunneling conductance within a many-body perturbation framework to establish a quantitative connection between the measured width of the step and the intrinsic lifetime [24.49]. In this way, the total linewidth of the surface state at the bottom of the surface band is probed. An advantage of this technique is that prior to the spectroscopic measurements, the STM can be used to characterize in situ the surface properties and to identify appropriate defect-free areas, which eliminates defect scattering as a contribution to the lifetime. Also this technique is applicable to both occupied and unoccupied surface states. Limitations arise from

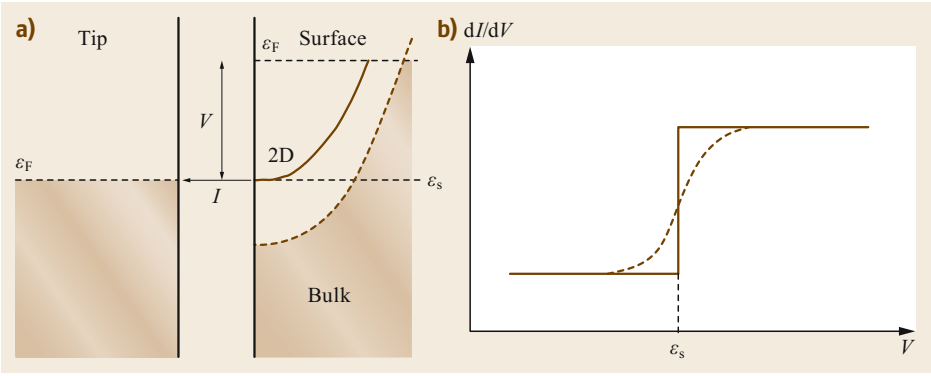

Fig. 24.8a,b Illustration of scanning–tunneling spectroscopy of a surface state: Energy level scheme **(a)** and differential conductance **(b)**

the low temperatures typically required for operating the STM, which prevents temperature-dependent studies to discriminate between the electron–electron and electron–phonon contributions to the lifetime. This has been circumvented by taking estimates for the electron–electron contribution from calculations [24.50]. Furthermore, this technique does not resolve the momenta of the tunneling electrons, and is only applicable to states at the bottom (or top) of the surface band, where the tunneling conductance shows well-resolved steps.

24.4 Electron–Phonon Coupling of Electronic Surface States

In this section, we give a compilation of the various studies devoted to the electron–phonon interaction of electronic surface states. This research is characterized by close links between experimental and theoretical investigations, which mutually stimulated each other and whose techniques were steadily improved. The field covers a wide range of metallic surfaces, ranging from elemental surfaces to adsorbate covered surfaces and recently to metallic surface states of topological insulators.

24.4.1 Elemental Metal Surfaces

A collection of results for elemental metal surfaces is given in Table 24.1. Al(100) and Mg(0001) are examples of nearly free electron metals. Both Al(100) and Mg(0001) surfaces show surface states around $\overline{\Gamma}$ with a parabolic dispersion. For Al(100) the surface band falls into a small bulk-projected band gap, while for Mg(0001) the surface state lies in the energy range of bulk-projected states and penetrates more deeply into the bulk. Experiments and ab initio calculations agree in that the electron–phonon coupling of these surface states is comparable to the average coupling in the bulk materials (0.43 [24.51] and 0.29–0.35 [24.52] for Al and Mg, respectively). A slight increase at $\overline{\Gamma}$ for Al(100) was attributed to an additional decay channel via the Rayleigh surface mode [24.51]. The similarity of the coupling between surface and bulk states indicates that the surface modes dominantly couple to bulk states, which lie close in energy because of the smallness of the bulk-projected band gap. Significantly larger couplings are predicted for the occupied and unoccupied surface states at the $\overline{\mathrm{X}}$ point. The simple electronic structure has also stimulated the application of model approaches for Al(100), but the obtained couplings deviate significantly from both experimental and ab initio results.

Extensive studies of EPI were devoted to the (0001) and $(10\overline{1}0)$ surfaces of Be [24.3]. Be bulk is characterized by strongly covalent bonding and has a very low electronic density of states (DOS) at the Fermi energy. Consequently, its EPI is rather small with $\lambda = 0.21 - 0.24$ [24.1, 96]. Be surfaces display a qualitatively different electronic structure [24.97]. At Be(0001), a surface state is located in a wide band gap, which enhances the DOS and renders the surface more metallic. For the surface state around $\overline{\Gamma}$ experiments obtained a large range of coupling values of 0.6–1.2 at ϵ_F. Part of this spread has been attributed to the difficulty of finding appropriate models to fit the T dependence of the measured linewidths. The bulk phonon spectrum extends to rather high frequencies ($\approx 80\,\mathrm{meV}$), which would require temperatures $T > 1000\,\mathrm{K}$ to reach the linear regime. Also it was suggested that the relevant surface-phonon spectrum is significantly softer than the bulk spectrum. More recent experiments based on the extraction of self-energies revealed a pronounced anisotropy of the coupling at ϵ_F. A similar anisotropy has been found in theoretical studies, although on average smaller couplings are obtained. A similar situation is encountered for Be$(10\overline{1}0)$. A free-electron like surface state exists in the wide gap around the $\overline{\mathrm{A}}$ point, which again enhances the DOS at the Fermi energy with respect to the bulk. For this surface state, discrepancies between experimental values of 0.65–0.7 and theoretical results of ≈ 0.2 remained unresolved. In contrast, for the second surface state at $\overline{\mathrm{A}}$ at higher binding energy, experiment and theory agree on an intermediate coupling of 0.45–0.5, which is still twice as large as the bulk value.

Surfaces of the noble metals Cu, Ag, and Au have played an important role in EPI research. The (111) surface of these metals possesses a Shockley-type surface state around $\overline{\Gamma}$ in the L-gap of the bulk. Another Shockley-type surface state exists at the $\overline{\mathrm{Y}}$ point of the (110) surface. These states are well localized within a few surface layers. Theoretical modeling with different degrees of sophistication has been applied to this class of surfaces. The surface states can be described by approximating the surface potential by one- or two-dimensional model potentials. Furthermore, the lattice dynamics can be approximated by a single-force-constant model, which facilitates a realistic modeling of the surface phonon spectrum. Experiment and theory coincide in that the coupling strength is rather similar for all noble metal surfaces with λ in the range of 0.1–0.2. It reflects the small coupling encountered in the bulk materials (for example, calculations gave 0.14 and 0.17 for Cu and Au, respectively [24.98, 99]). An even smaller value was obtained for another surface state at $\overline{\mathrm{M}}$ of the Cu(100) surface. An exception seemed to be the EPI in the surface state of Au(111), where ini-

tially a λ of 0.34 was deduced from the T-dependent linewidth [24.79], but a reanalysis of the data taking into account thermally excited defects showed that they are consistent with the smaller value of 0.11 obtained from calculations [24.32, 33].

The $\overline{\Gamma}$ surface state in Au(111) is well known to show a Rashba-type splitting due to spin–orbit coupling. Such a splitting could be resolved also for Cu(111) in a recent ARPES experiment, which was a prerequisite for extracting the correct self-energy at the Fermi energy. The derived λ compared favorably with ab initio calculations [24.71].

Transition metals are characterized by an active involvement of d states in the electronic structure at the Fermi energy. They often possess a sizable electron–phonon coupling in the bulk and one therefore expects them to exhibit larger surface EPI effects. Indeed the first extraction of an electron self-energy was achieved

for a surface band at the Mo(110) surface with a $\lambda = 0.52$, which was even enhanced compared to the bulk value of 0.42 [24.80]. A coupling comparable to the bulk was found for a band observed at the Mo(112) surface [24.81], although a recent analysis of the surface band structure suggested that the observed band has a dominant bulk-like character. A large surface enhancement of the coupling was found for the V(100) surface state with a measured $\lambda = 1.45$ vastly exceeding the bulk value of 0.8–1.2 [24.98].

The Shockley-type states at $\overline{\Gamma}$ of the (111) and (110) surfaces of Pd have also been investigated. In contrast to the (111) and (110) surfaces of noble elements, these Pd surface states lie above ϵ_F and are unoccupied. A very small coupling of $\lambda = 0.08$ for the (111) surface state observed in a two-photon-photoemission experiment was explained theoretically by a strong reduction of the bulk states available for the decay above ϵ_F. A more extensive theoretical calculation predicted that the coupling strength of other surface-localized states below ϵ_F varies strongly with the energy and momentum and could reach values up to 1.4 [24.100, 101], significantly exceeding the Pd bulk value (0.35–0.69 [24.98]).

α-Ga is another elemental metal with a large EPI in the bulk ($\lambda = 0.98$ [24.1]). The (010) surface supports a surface state which builds an electron pocket around the $\overline{C}$ point at the corner of the surface Brillouin zone. T-dependent linewidth measurements for the state at $\overline{C}$ suggested a very large coupling of 1.4. This value was reduced to 1.17 in a later study, which identified the presence of a surface phase transition. Still the EPI is enhanced with respect to the bulk.

The semimetals Bi and Sb are characterized by a pseudogap with small Fermi surfaces and a very low DOS. Consequently the EPI in the bulk is very small, with $\lambda = 0.13$ [24.90] and 0.17 [24.87] for Bi and Sb, respectively. In contrast, their surfaces are much more metallic due to the presence of surface states positioned in large projected band gaps. For Bi all low-indexed surfaces (100), (110), and (111) have been studied experimentally. Spin–orbit coupling (SOC) has a large effect on their surface electronic structure [24.102]. In Bi bulk, electronic states always come in pairs because of the Kramers degeneracy. The loss of inversion symmetry at the surface induces large spin splittings of the surface bands, with large impact on the band dispersion and Fermi-level crossings. The largest couplings were found for Bi(111). This hexagonal surface hosts two types of Fermi surfaces, a circular one around $\overline{\Gamma}$ and six lobes stretched along the $\overline{\Gamma M}$ direction. While the Fermi surface around $\overline{\Gamma}$ is difficult to access because it lies in a region of surface-projected bulk states, the EPI of states at the inner part of the lobe-like Fermi surface has been studied in several ARPES

experiments. It has been argued that the seemingly different results obtained could be reconciled if the finite energy resolution of the spectrometer is taken into account [24.35]. A reanalysis of the data suggested a coupling of the order of 0.4, consistent with an ab initio calculation of the momentum-averaged coupling for a five-bilayer slab [24.103]. A more detailed ab initio study of the momentum-resolved EPI for these surface states has been performed recently [24.89]. As shown in Fig. 24.9, it revealed couplings of 0.4–0.5 over a wide range of momentum and energy for states of the surface band which crosses the Fermi energy. The enhancement with respect to the bulk was in part attributed to coupling within the same surface band. However, for states close to $\overline{\Gamma}$ a strong increase of λ was found, which could be traced back to a coupling to bulk-like states at $\overline{\Gamma}$ mediated by long-wavelength phonons of low frequency [24.89].

At Bi(110) the surface states build two Fermi surfaces consisting of hole pockets at $\overline{\Gamma}$ and $\overline{M}$. Moderate

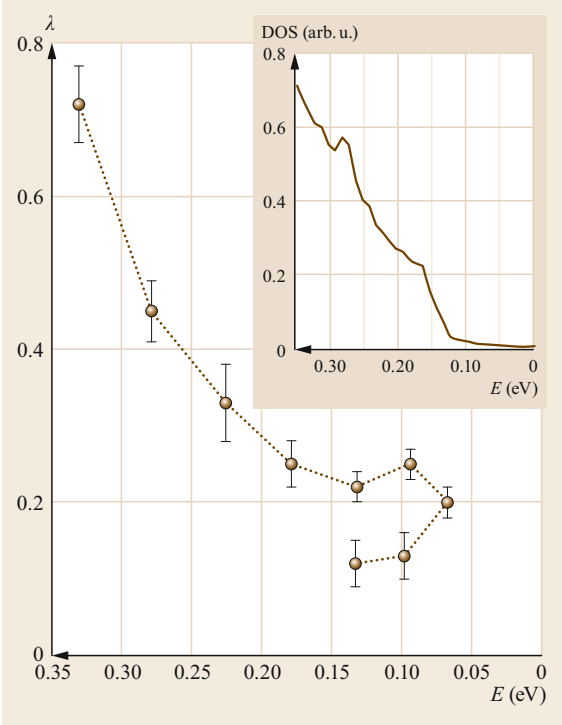

Fig. 24.10 Electron–phonon coupling λ of the surface state of Bi(100) along the $\overline{\Gamma M}$ direction as a function of the binding energy. couplings were found in both cases for surface states at ϵ_F. For Bi(100), a distinct dependence of the coupling on the binding energy was observed for a surface band along the $\overline{\Gamma M}$ line. For increasing momentum, this band disperses upwards from an energy of 330 meV below ϵ_F and reaches a maximum of 70 meV below ϵ_F. With decreasing binding energy a large drop of λ from 0.72 to 0.20 was found (Fig. 24.10). Because the bulk DOS shows a similar energy dependence, namely a drop from a high DOS at large binding energies to a low DOS region near ϵ_F, the energy dependence of the EPI was interpreted as reflecting the change in the number of bulk states available for decay via phonons. This implies that the decay of these surface states predominantly happens into bulk-like states.

Albeit SOC is smaller for Sb, dispersion of the surface bands and Fermi surface shapes at the Sb(111) surface closely resemble those of Bi(111). In this case, only weak coupling seems to exist. While one ARPES experiment suggested a coupling slightly enhanced over the bulk value [24.86], a more recent experiment could not detect any sizable renormalization of the surface band at ϵ_F [24.104]. A small EPI is also supported by an ab initio calculation of a Fermi surface average obtained for a slab geometry [24.87].

Another element with strong SOC and large bulk EPI is Pb with $\lambda = 1.55$ [24.98]. Its surfaces, however, do not support well-localized surface states. An ARPES study of the (110) surface revealed a strong band renormalization near the Fermi-level crossing of a bulk state [24.70]. A similar situation is encountered for the (0001) surface of Tl, where an ab initio investigation merely found surface resonances. Yet, the momentum-averaged coupling strength of 1.01 was enhanced with respect to the bulk value of 0.87 [24.92].

The EPI has also been investigated for the (0001) surfaces of the lanthanide metals Gd, Ho, and Lu. The (0001) surface hosts a $5d_{z^2}$-like surface state (Tamm state) in the projected band gap near $\overline{\Gamma}$. The exchange interaction with the 4f magnetic moments splits the surface state into an occupied majority-spin state and an unoccupied minority-spin state [24.105]. Both ARPES and STS experiments on Gd(0001) indicated a large EPI in the range 1.0−1.3 for the occupied majority-spin state, and an even larger coupling of 1.5 was obtained by STS for the unoccupied minority-spin state. Ho(0001) and Lu(0001) were investigated only by STS, and no estimate for λ was given.

24.4.2 Adsorbate Covered Surfaces and Thin Films

Materials with confined geometries on the nanoscale exhibit pronounced quantum-size effects, which manifest themselves in their peculiar electronic and vibrational properties. Adsorbate-covered surfaces provide a natural platform to study such quantum-size effects and to investigate their consequences for the electron–phonon interaction. When metals are deposited as monolayers (MLs) or ultrathin films on a substrate, they exhibit an electronic structure different from the bulk material. The confinement of the electronic motion in the direction vertical to the film gives rise to quantum-well states (QWS), which may interact more effectively with the adsorbate vibrations resulting in an enhanced EPI. Variation of the film thickness can be used to tailor these properties. Key results are summarized in Table 24.2.

Mono- and Submonolayer Coverage

Well-studied examples of strong electron–phonon interaction for an overlayer system are hydrogen monolayers on Mo or W metals. The EPI in the surface electronic structure of H/W(110) has been investigated by ARPES. This system hosts several hydrogen-related surface states forming different Fermi surface pockets. For the band S_1 building an elliptic hole pocket around

the $\overline{S}$ point, a split in the dispersion close to ϵ_F was observed, at a binding energy corresponding to an H adsorbate mode frequency (Fig. 24.11). By replacing hydrogen with deuterium, the split size was reduced and its energy position moved closer to ϵ_F. This isotope effect demonstrated that the renormalization is indeed invoked by the adsorbate [24.106]. A later study succeeded in extracting the real part of the self-energy for various directions around the hole pocket. Derived coupling strengths varied between 0 and 0.8 partly exceeding $\lambda = 0.2$ of W bulk [24.107]. H/W(110) was also examined by an ab initio approach, where the Dyson equation (24.1) was solved self-consistently in the complex energy plane. It was found that the interaction with the adsorbate vibrations leads to a breakdown of the simple quasiparticle picture and results in complex shapes of the spectral functions, whose maxima mimic the measured band splittings [24.12, 13]. This strong electron–phonon interaction also has a dramatic effect on the vibrational properties of the adlayer. Large phonon anomalies of the adsorbate modes have been observed for hydrogenated (100) and (110) surfaces of W and Mo, which will be discussed in more detail in Sect. 24.5.

Several experimental and theoretical studies were devoted to Na/Cu(111). Deposition of Na on the Cu(111) surface leads to a QWS inside the surface-projected bulk gap of Cu around $\overline{\Gamma}$. For a full monolayer (ML) coverage, this state resides about 0.1 eV below ϵ_F at $\overline{\Gamma}$ [24.123]. The experimental coupling of 0.24 obtained from the slope of the temperature-dependent linewidth surpassed theoretical estimates of λ for both Na (0.16) and Cu (0.15) bulk [24.109]. Several microscopic model calculations of the EPI with varying degrees of sophistication have been applied to this system [24.2, 21, 124, 125]. Results depended sensitively

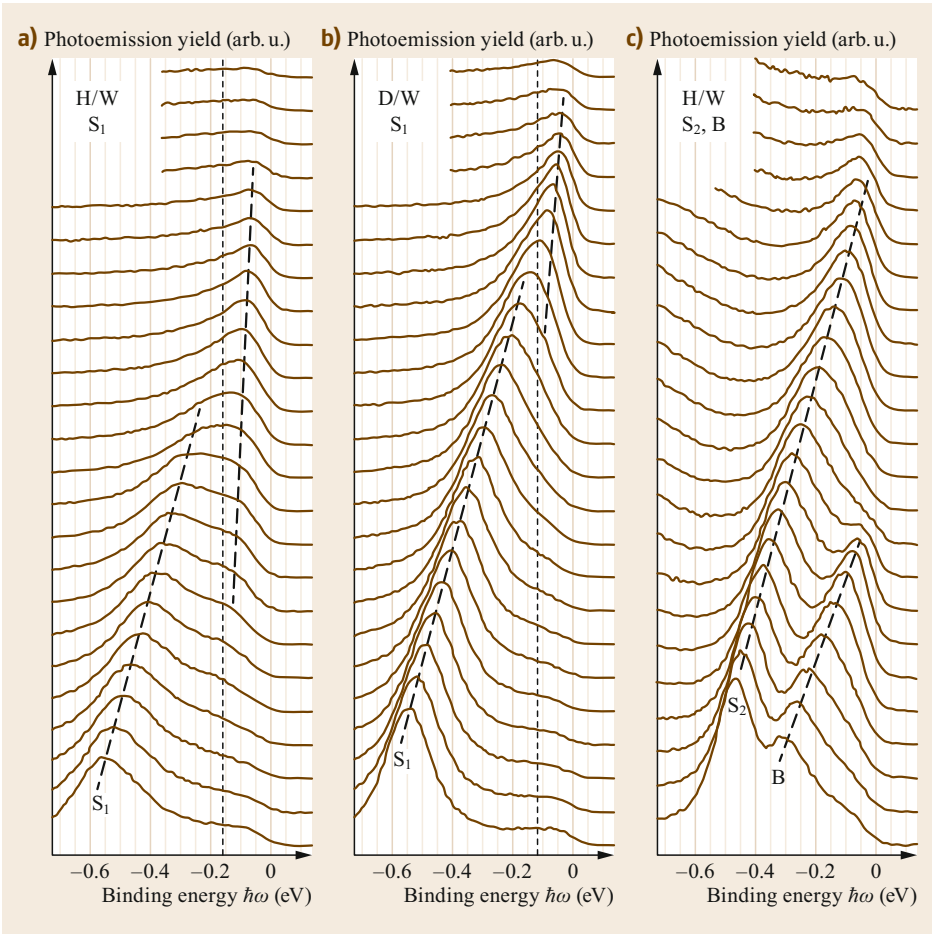

Fig. 24.11a–c Dispersion of the surface bands of H and D monolayers on W(110) as measured by ARPES along $\overline{\Gamma S}$. on the choice of the vibrational spectrum relevant for the coupling, suggesting that an accurate description of the surface vibrational spectrum including the overlayer is required for a reliable quantitative calculation of the EPI. Coupling strengths of similar magnitude have also been found in a model study of 0.25-ML coverage of Cu(111) by Cs, which builds an ordered (2×2) overlayer [24.112].

Au/Mo(112) is another example of a monolayer adsorbate system with a coupling that is significantly enhanced over the bulk value. In an ARPES experiment, bulk and (112)-derived surface states of Mo were found to strongly hybridize with a state originating from the Au overlayer. At ϵ_F a large coupling of 0.70 was derived from the self-energy. An ab initio calculation gave almost the same value for the momentum-averaged coupling at ϵ_F.

Submonolayer coverages of Bi on noble metal surfaces possess dispersive electronic states which are hybridized with the substrate electronic states and are spin-split due to the strong spin–orbit interaction related to Bi. The EPI has been studied for two cases, a 1/3 monolayer on Ag(111) and a half-monolayer coverage on Cu(100). In both cases, the surfaces reconstruct. For the $(\sqrt{3} \times \sqrt{3})$R30° Bi/Ag(111) surface, a large Rashba-type splitting of a surface band was observed near $\overline{\Gamma}$. It exhibited a strong coupling of about 0.55 with a rather weak dependence on the binding energy. For c(2×2)Bi/Cu(100), even larger values for λ were extracted for states at the surface Brillouin zone boundary $\overline{X}$ point. In both cases, the surface states are likely hybrid states involving states derived from both adsorbate and substrate atoms. These cases again exemplify that the coupling in adsorbate systems can by far exceed the bulk coupling strengths of the individual metals.

Quantum-Well States in Thin Films

The variation of the EPI in QWS with the thickness of the film has been systematically investigated for ultrathin Ag films on different metal substrates, Fe(100), V(100), and Cu(111). In each case, QWS develop in the projected band gap around $\overline{\Gamma}$. Their binding ener-

gies vary significantly with the thickness of the film and also depend on the type of substrate. In an early study, the QWS of Ag films on Cu(111) showed little variations of λ with the film thickness, and was similar to the coupling in Ag bulk [24.116]. In contrast, both studies on the (100) metal surfaces found a strong and nonmonotonous variation of λ with the thickness. The largest values of order 1 were obtained for the very thin films. Figure 24.12 exemplifies this behavior for Ag films on Fe(100) [24.115]. Most values by far exceed the value of λ for bulk Ag. It has been proposed that the large coupling is an interface effect and has its origin in a large potential step at the interface seen by the QWS, which enhances the electron–phonon coupling matrix elements. A simple modeling based on this idea could reproduce the main trends including the observed oscillatory behavior in λ as a function of thickness, but a detailed microscopic calculation to substantiate this explanation has not been performed until now.

Ultrathin films of Pb are another intensively studied overlayer system. The coupling of individual QWS were investigated in several ARPES experiments, where λ values were extracted from the T-slope of the linewidth. For films of 15–28 ML thickness, an oscillatory behavior of the EPI with the number of layers was observed [24.117]. For thinner films ($\leq$ 12 ML) the deduced λ for the QWS of the order of 0.7–1.0 was significantly lower than the bulk value. Ab initio calculations suggested that this reduction is linked to the presence of a substrate, whose impact on the EPI grows the thinner the films become [24.119].

Unoccupied QWS of Pb films with 4–10 ML thickness were studied by a combined scanning tunneling spectroscopy and ab initio approach [24.118]. From T-dependent STS measurements the electron–electron contribution Γ_{e-e} could be separated from the electron–phonon contribution Γ_{e-ph}. The linewidth showed a quadratic dependence on the QWS energy, which was attributed to Γ_{e-e}. Comparison with ab initio calculations suggested that the extracted $\Gamma_{e-ph}(T = 0)$ values are compatible to values of λ in the range 1.45–1.6 for most of the QWS, which are close to the Pb bulk value of 1.55.

Pb thin films also exhibit peculiar superconducting properties. Pb bulk is a strong-coupling superconductor with a large average coupling constant of $\lambda = 1.55$ and a bulk transition temperature of $T_c = 7.2$ K. Atomically flat islands of Pb(111) with large lateral extension can be prepared on various substrates (Si(111) or Cu(111)) with high control on the number of monolayers. Scanning tunneling spectroscopy can be used to identify the superconducting transition temperature as the temperature, where a gap in the electronic density of states opens at ϵ_F. These studies show that T_c is reduced when the film thickness decreases, but superconductivity survives for films as thin as 5 ML [24.126]. For thicknesses smaller than 30 ML, T_c showed an oscillatory dependence [24.117]. Even for a 1-ML coverage of Pb on Si(111), a superconducting transition was

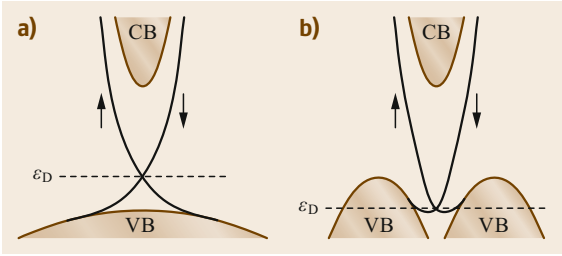

Fig. 24.13a,b Schematic drawing of the band structure at the (0001) surface of the topological insulators Bi_2Se_3 **(a)** and Bi_2Te_3 **(b)**. CB: bulk conduction band; VB: bulk valence band; ϵ_D: energy position of the Dirac point

found ($T_c = 1.83\,K$) [24.127]. In this case, however, the structure of the Pb overlayer differs from a (111) surface layer. Because of this interest in superconducting properties, several theoretical studies focused on the calculation of Fermi-surface-averaged EPI for Pb films. It has been noted that spin–orbit coupling has a significant influence on the coupling strength and cannot be neglected [24.122].

24.4.3 Topological Insulators

Topological insulators are materials whose electronic structure is topologically distinct from a normal insulator. In the bulk, they possess an electronic band gap like an ordinary insulator, but the topological property forces the presence of gapless edge states. A variety of topological insulators have been theoretically predicted and experimentally identified, and exist in both two and three dimensions (2-D and 3-D). A survey of recent work on EPI for topological insulators has been given in [24.136], and for further reading we refer to the reviews [24.137–140].

In the context of EPI at surfaces, research focused on the surface states of 3-D topological insulators. Here, the edge states manifest themselves as metallic (gapless) surface states with peculiar properties. In Fig. 24.13, the surface electronic structure of two prominent examples of 3-D topological insulators, Bi_2Se_3 and Bi_2Te_3, is sketched schematically. The metallic surface bands are located at the center of the surface Brillouin zone and span the energy-gap region between the bulk valence and conduction bands. At a single crossing point, called the Dirac point (with energy ϵ_D), they possess a linear dispersion. This 2-D dispersion represents a so-called Dirac cone, well known from the electronic structure of graphene. But here the situation differs in that each band is single degenerate, and the spin direction of each state is locked perpendicular to its momentum. This peculiar spin structure is promising for applications related to spin-polarized transport.

The topological origin of the surface state has the consequence that it is robust against perturbations at the surface, which do not break time-reversal symmetry, like nonmagnetic impurities. This argument strictly holds only in the single-particle picture, but could be violated by many-body interactions. This motivated several investigations to quantify the strength of the electron–phonon interaction in topological surface states. Studies concentrated on the (0001) surface of the 3-D topological insulators Bi_2Se_3 and Bi_2Te_3. Results are collected in Table 24.3. Both compounds are layered materials built from neutral five-layer blocks (quintuple layers), which are only weakly bound by van der Waals-type interactions. This allows an easy cleavage of samples to prepare the (0001) surface, which is oriented parallel to the layers. The existence of the topological surface state has been verified experimentally [24.141].

For Bi_2Se_3, the Dirac point falls within the bulk band gap, and for uncharged samples its energy coincides with the Fermi energy. Sample preparation typically leads to slightly electron-doped bulk materials, which results in an upward shift of the Fermi level, and may also lead to a partial filling of the bulk conduction bands. The degree of doping can be characterized by the energy distance $\epsilon_F - \epsilon_D$. ARPES measurements have given quite diverse results for the EPI. An early experiment [24.142] could not detect an electron–phonon self-energy, suggestive of a very small coupling. Later studies gave values for λ ranging from 0.08 to 0.25 [24.128, 129, 131]. Even $\lambda \approx 3$ has been deduced from the measured renormalization of the quasiparticle dispersion [24.130]. The authors suggested, however, that this large value does not originate only from the EPI, but also includes coupling to low-energy spin plasmons.

In the case of Bi_2Te_3, the Dirac point overlaps with the energy region of the bulk valence states, which naturally leads to a partial occupation of the upper part of the Dirac cone even for undoped bulk samples. ARPES experiments by *Chen* et al. [24.131] found a pronounced dependence of the EPI coupling strength on the doping. A very small λ for hole-doped samples contrasted an enhanced coupling for electron-doped ones. Anisotropy of the EPI related to the hexagonal symmetry of the (0001) surface has recently been studied in an ARPES experiment [24.143]. Close to the Dirac point, the electronic dispersion is rather isotropic. At about 200 meV above the Dirac point, the dispersion along the $\overline{\Gamma}$–$\overline{M}$ direction flattens markedly as compared to the $\overline{\Gamma}$–$\overline{K}$ direction. Constant energy contours change from a circular to a hexagonally warped shape. Simultaneously, the lifetime broadenings become anisotropic, with larger broadenings found along $\overline{\Gamma}$–$\overline{K}$. It was proposed that modifications of the spin texture in the warped Dirac cone could be responsible for an anisotropy of the spin-dependent scattering.

Beside these direct probes of the quasiparticle properties, additional experiments providing more indirect information about the coupling strength are briefly mentioned here. Time-resolved ARPES or pump-probe experiments analyzed the ultrafast carrier dynamics related to the surface state [24.144–146]. Further information was gained from transport measurements [24.147, 148] and optical spectroscopy [24.149, 150]. Finally, investigations of the surface phonon spectrum with helium-atom scattering spectroscopy indicated unusual phonon anomalies, which were attributed to a strong coupling to the topological surface states [24.151–153]. The approach to quantify the EPI from the phonon perspective will be addressed further in Sect. 24.5.

On the theoretical side, the coupling of topological surface states with acoustic modes has been studied based on a continuum model [24.132–135]. This approach considers the interaction of the surface electrons with long-wavelength acoustic phonons, which also includes contributions from surface-localized vibrations like the Rayleigh mode, but neglects contributions from optical phonons. Despite a similar framework, no consensus was reached on the strength of the EPI (Table 24.3). Contribution from optical phonon modes were taken into account in an ab initio calculation for a thin film of Bi_2Te_3 [24.103]. Results for the average λ suggested a very small coupling.

24.5 Electron–Phonon Interaction and Phonons

The interaction between electrons and atomic vibrations does not only affect the electronic quasiparticles, but also renormalizes the vibrational quasiparticles, i.e., the phonons. In analogy to the electronic quasiparticles, the EPI gives rise to changes in the phonon frequencies and evokes finite lifetimes. Because of the reduced dimensionality at the surface, these renormalization effects can be more pronounced for surface vibrations than for phonons in the bulk.

The topic of surface phonons is covered in Chap. 23 of this Springer Handbook. We briefly mention here the three spectroscopic techniques used to measure surface phonon dispersion and related properties:

(i) Helium atom scattering (HAS): it utilizes inelastic scattering of He atoms at a surface which creates or annihilates a phonon. The He atom does not penetrate the surface, but is reflected a few Å above the surface atoms. This makes this technique very surface sensitive.

(ii) High-resolution electron energy-loss spectroscopy (HREELS): this technique uses inelastic electron scattering processes to gain information about the lattice vibrations. It is less surface sensitive than HAS because electrons penetrate the surface.

(iii) Inelastic x-ray scattering (IXS) at grazing incidence: IXS is nowadays a common technique to probe bulk phonons, because x-rays penetrate deeply into the bulk. However, if the angle of the incoming x-ray is chosen to be smaller than the angle for total reflection, the so-called grazing incidence condition, the inelastic scattering acquires a much higher surface sensitivity.

In this section, we first introduce the basic quantities describing the phonon renormalization, and define related measures of the EPI. Then we give a survey of the most dramatic effects of the EPI on surface phonons. Finally, we discuss methods to extract information about the EPI from measurements of surface phonon properties.

24.5.1 Renormalization of Phonons

The starting point is the expression for the renormalized phonon Green's function in terms of the phonon self-energy Π [24.1],

$$D(\boldsymbol{q}j,\omega) = \frac{2\omega_{\boldsymbol{q}j}}{\omega^2 - \omega_{\boldsymbol{q}j}^2 - 2\omega_{\boldsymbol{q}j}\Pi(\boldsymbol{q}j,\omega)} , \qquad (24.27)$$

where the phonon is characterized by the momentum $\boldsymbol{q}$ and branch index j. It is linked to the bare Green's function $D_0(\boldsymbol{q}j,\omega) = 1/(\omega-\omega_{\boldsymbol{q}j}) - 1/(\omega+\omega_{\boldsymbol{q}j})$ by the Dyson equation $D^{-1} = D_0^{-1} - \Pi$, with $\omega_{\boldsymbol{q}j}$ denoting the bare frequency, i.e., the frequency a vibration would have without the interaction with the electrons. The spectral function of the phonon is given by $-2\mathrm{Im}\{D(\boldsymbol{q}j,\omega)\}$. For small self-energies, it will still show a quasiparticle peak, which is, however, broadened and its center is shifted away from the bare frequency $\omega_{\boldsymbol{q}j}$. The finite linewidth is proportional to the inverse lifetime and connected with $\mathrm{Im}\{\Pi\}$, while the frequency shift is related to $\mathrm{Re}\{\Pi\}$.

The phonon self-energy can be expressed as an infinite series of Feynman diagrams. Figure 24.14 shows schematically the graph for the lowest-order contribution from the EPI to the imaginary part of the self-energy, which describes a virtual electron-hole excitation. This leads to the expression

$$\mathrm{Im}\{\Pi(\boldsymbol{q}j,\omega)\} = \pi\frac{1}{N_k}\sum_{\boldsymbol{k}\nu\nu'} |g^{\boldsymbol{q}j}_{\boldsymbol{k}+\boldsymbol{q}\nu',\boldsymbol{k}\nu}|^2 \times [f(\epsilon_{\boldsymbol{k}\nu}) - f(\epsilon_{\boldsymbol{k}+\boldsymbol{q}\nu'})] \times \delta[\omega + \epsilon_{\boldsymbol{k}\nu} - \epsilon_{\boldsymbol{k}+\boldsymbol{q}\nu'}] . \qquad (24.28)$$

N_k is the number of points used in the k summation. Equation (24.28) depends on temperature via the Fermi distribution function f. The phonon linewidth induced by the EPI is given as

$$\gamma_{\boldsymbol{q}j}(T) = -2\mathrm{Im}\{\Pi(\boldsymbol{q}j,\omega_{\boldsymbol{q}j})\} . \qquad (24.29)$$

Because phonon energies are often much smaller than typical electronic energies, $\gamma_{\boldsymbol{q}j}$ has a weak T-dependence and it is justified to take its $T \to 0$ limit [24.154]

$$\gamma_{\boldsymbol{q}j}(T=0) \approx 2\pi\omega_{\boldsymbol{q}j}\frac{1}{N_k}\sum_{\boldsymbol{k}\nu\nu'} |g^{\boldsymbol{q}j}_{\boldsymbol{k}+\boldsymbol{q}\nu',\boldsymbol{k}\nu}|^2 \times \delta(\epsilon_{\boldsymbol{k}\nu})\delta(\epsilon_{\boldsymbol{k}+\boldsymbol{q}\nu'}) . \qquad (24.30)$$

To arrive at this form, the phonon frequency appearing in the δ-function in (24.28) was neglected. This approximation works usually very well, except in the limit $\boldsymbol{q} \to 0$ for metals, because there the energy difference $\epsilon_{\boldsymbol{k}\nu} - \epsilon_{\boldsymbol{k}+\boldsymbol{q},\nu}$ becomes arbitrarily small.

Equation (24.30) becomes relevant in the context of phonon-mediated superconductivity. The interaction between electrons and phonons gives rise to an effective attractive electron–electron interaction which leads to the formation of Cooper pairs as the basis of a superconducting state. The microscopic theory of superconductivity based on this phonon-mediated paring has been developed by *Bardeen* et al. [24.155] and extended by *Eliashberg* [24.156] to the strong coupling regime. The central quantity in describing the pairing interaction is the so-called Eliashberg function

$$\alpha^2F(\omega) = \frac{1}{N(\epsilon_\mathrm{F})}\frac{1}{N_q}\frac{1}{N_k}\sum_{\boldsymbol{q}j,\boldsymbol{k}\nu\nu'} |g^{\boldsymbol{q}j}_{\boldsymbol{k}+\boldsymbol{q}\nu',\boldsymbol{k}\nu}|^2 \times \delta(\omega-\omega_{\boldsymbol{q}j})\delta(\epsilon_{\boldsymbol{k}\nu})\delta(\epsilon_{\boldsymbol{k}+\boldsymbol{q}\nu'}) . \qquad (24.31)$$

Here $N(\epsilon_\mathrm{F}) = 1/N_k\sum_{\boldsymbol{k}\nu}\delta(\epsilon_{\boldsymbol{k}\nu})$ is the electronic density of states at the Fermi energy per spin. $\alpha^2F(\omega)$ represents a measure of the pairing strength mediated by phonons of energy ω. The sum in (24.31) extends over all phonon modes and averages over possible interaction paths involving electronic states at the Fermi energy, weighted by the corresponding scattering probability as given by the EPI matrix elements.

On the basis of the Eliashberg function one defines the coupling constant

$$\lambda_\mathrm{sc} = 2\int \mathrm{d}\omega \frac{\alpha^2F(\omega)}{\omega} . \qquad (24.32)$$

This quantity is a dimensionless measure of the average coupling strength of a material related to pairing, and plays a central role in characterizing superconducting properties like the transition temperature. Using (24.31)

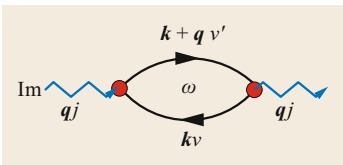

Fig. 24.14 Schematic drawing of the lowest-order contribution to the imaginary part of the phonon self-energy from interaction with electrons

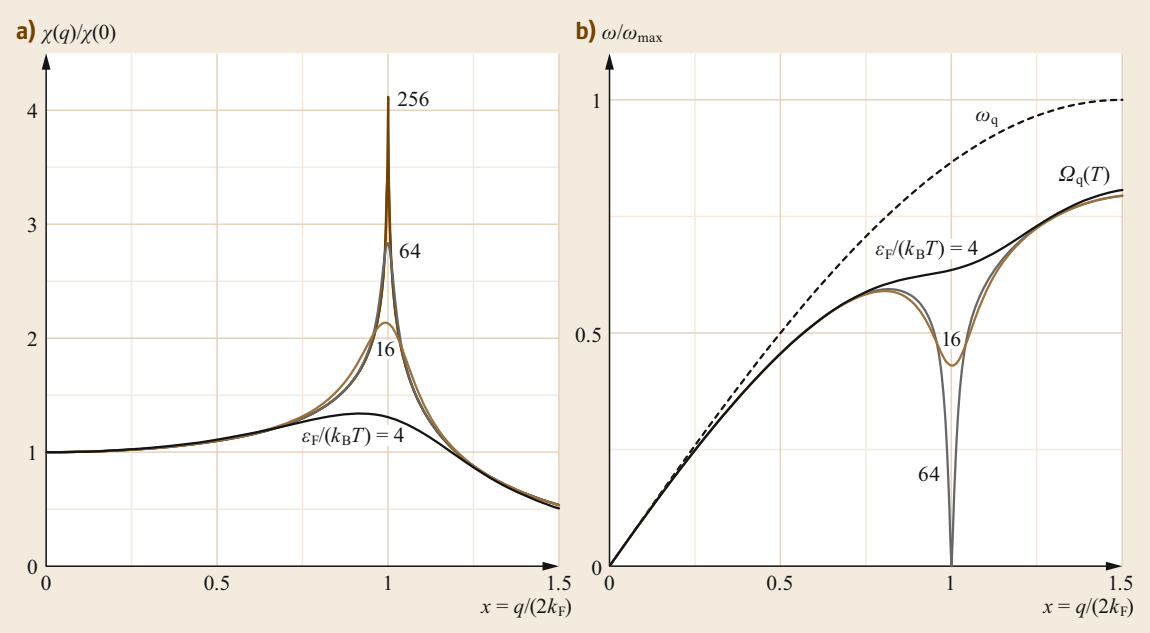

Fig. 24.15a,b Schematic drawing of a Kohn anomaly. The charge susceptibility **(a)** and phonon renormalization **(b)** as a function of temperature for a one-dimensional Fermi gas

and (24.30) the coupling constant can be expressed as a sum of contributions from individual phonon modes,

$$\lambda_{sc} = \frac{1}{\pi N(\epsilon_F)} \frac{1}{N_q} \sum_{qj} \frac{\gamma_{qj}}{\omega_{qj}^2} . \qquad (24.33)$$

This motivates the definition of a mode-selected coupling constant as

$$\lambda_{qj} = \frac{1}{\pi N(\epsilon_F)} \frac{\gamma_{qj}}{\omega_{qj}^2} , \qquad (24.34)$$

which is the property of an individual phonon. Then the total coupling is just given by the momentum average over all mode-selected coupling constants and summed over all phonon branches

$$\lambda_{sc} = \frac{1}{N_q} \sum_{qj} \lambda_{qj} . \qquad (24.35)$$

λ_{sc} can be also linked to the coupling strength defined for individual electronic states. Combining (24.11) and (24.13) one finds

$$\lambda_{sc} = \frac{1}{N(\epsilon_F)} \frac{1}{N_k} \sum_{k\nu} \lambda_{k\nu} \delta(\epsilon_{k\nu}) . \qquad (24.36)$$

Thus, λ_{sc} represents the average coupling strength of all electronic states at the Fermi level.

24.5.2 Kohn Anomalies of Surface Phonons

A Kohn anomaly is a pronounced softening of phonons which is induced by a specific coupling to electronic states in the vicinity of the Fermi level. The softening occurs in a small momentum range and becomes enhanced when lowering the temperature. If strong enough, it can result in an instability of the phonon and evokes a structural phase transition. The physics of the Kohn anomaly is most easily demonstrated for the model of a one-dimensional noninteracting electron gas. The renormalized phonon frequency can be expressed by the charge susceptibility $\chi_q(T)$ as [24.157]

$$\Omega_q^2(T) = \omega_q^2 + 2\omega_q g^2 \chi_q(T) , \qquad (24.37)$$

where ω_q denotes the bare frequency, and g is an effective coupling constant and is assumed to be independent of momentum q. Figure 24.15 sketches the renormalization of an acoustic branch coupled to a one-dimensional electron gas; χ_q is peaked at $2k_F$, where k_F is the Fermi wavevector, and diverges in the limit $T \to 0$. This induces a sharp dip in the phonon dispersion at $q = 2k_F$, which grows when lowering T, and eventually leads to a lattice instability at a finite temperature. As a consequence, the structure changes and the electronic charge density develops a spatial modulation called a charge-density wave (CDW).

In dimensions larger than one, the divergency of χ is usually washed out. Exceptions are situations where a so-called Fermi surface nesting occurs. Two larger sections of the Fermi surface exist which are parallel to each other and differ by a constant vector $\boldsymbol{q}_c$. In this case $\chi_{q_c}(T)$ exhibits a pronounced T dependence. The nesting condition can be easier fulfilled in 2-D than in 3-D. Promising candidates are layered materials with weak binding orthogonal to the layers, which exhibit quasi-2-D electronic structures. They possess Kohn-type anomalies already in the bulk. In a few cases, however, Kohn anomalies were observed in surface phonon branches, whose properties differed markedly from that of the bulk. An example is $2H$-$TaSe_2$, where the Rayleigh mode measured by HAS displayed a T-dependent anomaly. It was located at one-half of the reduced Brillouin zone, in contrast to the bulk anomaly in the longitudinal acoustic branch, which occurred at two-thirds of the zone [24.158]. In a comparative study of bulk and surface phonons of $2H$-$NbSe_2$ using IXS under grazing incidence conditions, the Kohn anomaly was found to be significantly deeper in energy at the surface than in the bulk [24.159]. It was suggested that the strengthening of the anomaly originates from a structural relaxation in the topmost layers [24.160].

Hydrogen-covered surfaces of Mo(110) and W(110) are classical examples where Kohn anomalies in the surface phonon dispersion were detected, which have no counterpart in the bulk. Figure 24.16 shows measurements from both HAS and HREELS, which indicate very sharp phonon anomalies in acoustic branches after adsorption of H on the W(110) surface [24.161]. Subsequent ab initio calculations found that the H adsorption evokes surface electronic states, whose Fermi surface contour shows the required nesting property. Thus, the observed dip was interpreted as a Kohn anomaly related to the adsorbate-induced surface state [24.162]. The anomalous acoustic branches involve to a larger extend vibrations of the substrate atoms. A complementary HREELS measurement of the adsorbate vibrations at energies of ≈ 100 meV detected similar anomalous dips, which occur at the same wave vector as for the acoustic branches [24.163]. The observation of an electronic surface state by ARPES and its very peculiar dispersion, discussed in the previous section, further corroborated this explanation [24.106].

The pronounced temperature dependence of the phonon frequency at the critical wavevector of the Kohn anomaly has been used by *Kröger* et al. [24.8, 165] to obtain a quantitative estimate of the electron–phonon coupling strength. They applied an analytic expression for the frequency renormalization which was derived for a one-dimensional free-electron gas [24.157]

$$\Omega_{q_c}^2(T) = \omega_{q_c}^2 \left[1 - \lambda_c \ln\left(\frac{1.14\epsilon_F}{k_B T}\right)\right] . \qquad (24.38)$$

Here, an effective coupling constant related to the critical phonon mode is introduced, which is connected to the coupling constant g introduced in (24.37) by $\lambda_c = 2g^2 N(\epsilon_F)/\omega_{q_c}$. From measurements of $\Omega_{q_c}(T)$ at two temperatures (100 and 293 K) and identifying ϵ_F with the bottom edge of the electron band, which takes part in the quasi one-dimensional Fermi surface nesting, they derived values of $\lambda_c \approx 0.11$ and 0.13 for H/Mo(110) and H/W(110), respectively. These values are significantly smaller than coupling constants $\lambda = 0.7-1.4$ obtained from a renormalization analysis of electronic states (Table 24.2).

Recent measurements of the (0001) surface phonon dispersion of the topological insulators Bi_2Se_3 and Bi_2Te_3 suggested the existence of an optical surface phonon branch with an unusual dispersion and a V-shaped minimum [24.151, 153]. The minimum occurs at small momenta of approximately the size of the Dirac cone of the topological surface state. This observation has been interpreted as a strong Kohn anomaly originating from the interaction of this phonon branch with the topological surface state. The dispersion was analyzed within an empirical lattice-dynamical model, which in addition to the direct ion–ion Coulomb forces also accounts for the electronic degrees of freedom by dynamically deformable pseudo charges. The presence of the surface state is modeled by dipolar pseudo charges at the surface, which are more deformable than those in the bulk. This model was able to reproduce the dispersion and the V-shaped minimum of the surface phonon branch. The dispersion of the anomalous branch was analyzed within the empirical model to obtain an estimate for the real part of the phonon self-energy [24.152, 153]. A Kramers–Kronig transformation was then utilized to calculate the related imaginary part of the self-energy. With the help of (24.29) and (24.34) this was linked to the phonon linewidth and mode-selected coupling constant λ_{qj}. Averaging over all modes of the anomalous branch gave values of 0.43 and 1.44 for Bi_2Se_3 and Bi_2Te_3, respectively. These values represent lower limits for the total coupling λ_{sc}, which would require summation over all branches. Such a strong coupling to the surface state should also result in an unusual renormalization of the electronic surface states [24.166], which has not been reported so far (Table 24.3).

24.5.3 Mode-Selected Coupling from Phonon Measurements

Details of the EPI on surfaces are encoded in the mode-selected coupling constants λ_{qj} defined in (24.34). Inelastic Helium atom scattering (HAS) experiments on thin films have shown that this technique may provide direct access to this quantity.

The inelastic scattering of an He atom off a surface happens near the classical turning point, which typically lies a few Å above the topmost surface layer. The scattering probability for creation or annihilation of a single phonon is determined by the size of the modulation of the electronic density at this turning point induced by the phonon vibration. It has been common wisdom that only surface phonons with large vibrational am-

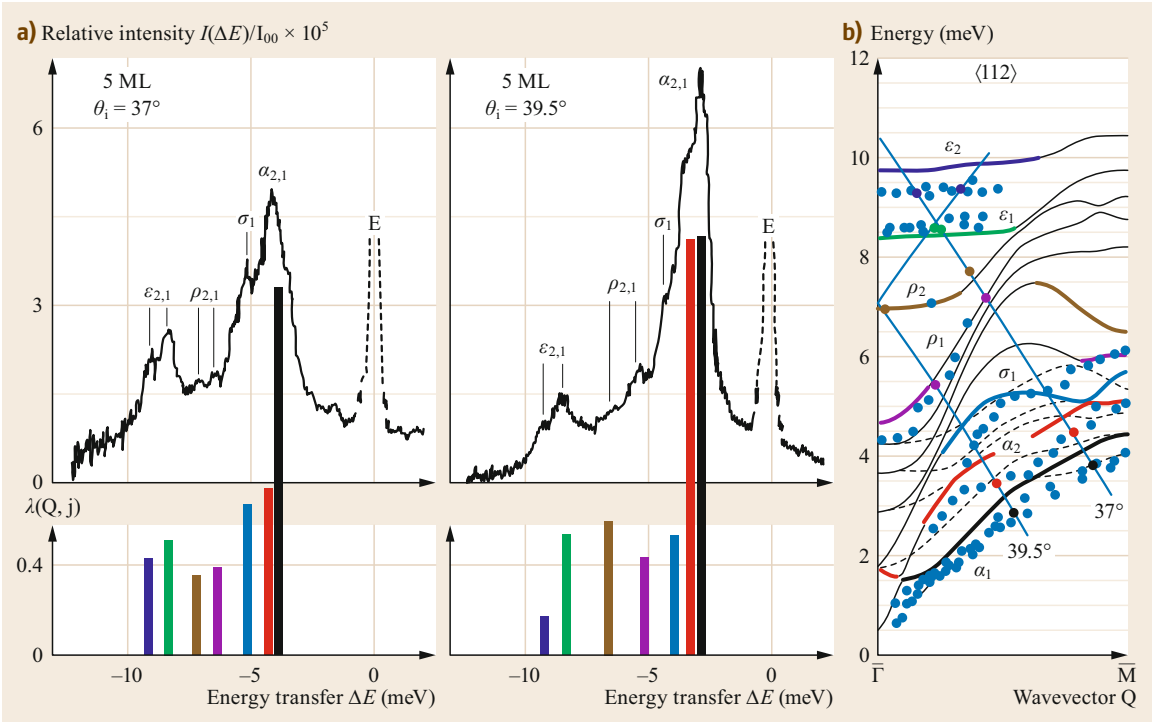

Fig. 24.17 **(a)** Example of HAS energy-gain spectra for a five-monolayer Pb film on a Cu(111) substrate in the ⟨112⟩ direction (*upper panel*), calculations of the mode-selected coupling constants (*lower panel*), and **(b)** the corresponding scan curves across the phonon dispersion. (Reproduced adapted from [24.167] with permission of PCCP Owner Societies)

plitudes in the topmost surface layer create sufficiently large density modulations to be detected by HAS. This view has been challenged by HAS measurements of the phonon modes of thin Pb(111) films on Cu(111), which resulted in surprisingly rich spectra [24.168]. Comparison with ab initio calculations suggested that modes localized deeper below the surface or even at the interface to the substrates were detected. A theoretical analysis of the scattering process showed that under conditions appropriate for the confined geometry of the film, the HAS scattering probability is [24.167, 169]

$$P(\boldsymbol{k}_i, \boldsymbol{k}_f) \propto f(\Delta E) \sum_{qj} \lambda_{qj} \delta(\Delta E - \omega_{qj}) \,. \qquad (24.39)$$

Here $\boldsymbol{k}_i$, $\boldsymbol{k}_f$ denote the initial and final momenta of the He atom, and ΔE the energy transfer in the scattering process. $f(\Delta E)$ represents a kinematic prefactor which is a slowly varying function of the energy transfer ΔE. (24.39) demonstrates that the scattering probability or the HAS amplitude is approximately proportional to the mode-selected coupling constants λ_{qj}. This relationship is supported by comparison of HAS spectra with ab initio calculations of λ_{qj}. Figure 24.17 shows an example for a 5-ML Pb(111) film on Cu(111) for two different scan curves. Both peak positions and amplitudes of the spectra agree well with calculated phonon energies and mode-selected coupling constants. These findings show that HAS is a promising spectroscopy tool to measure the branch and momentum dependence of the mode-selected coupling constants. It offers an experimental path to identify those phonon modes which are most relevant for the superconducting pairing in thin films, and to study the variation of the pairing interaction with the film thickness.

24.6 Conclusions

Surfaces provide an ideal platform to study the interaction of electronic and vibrational degrees of freedom in much detail. Steady advances in experimental techniques and computational methods led in recent years to an intensified investigation of EPI-related phenomena. The close link between experiment and theory has

been proven to be mutually fruitful. While increasing experimental resolution provides improved quantitative estimates serving as benchmarks for calculational approaches, theory gives additional insight into the interpretation of the data.

In this chapter, we presented an overview of investigations of electron–phonon interaction at metallic surfaces, overlayers, and thin films. The main focus was placed on the renormalization of electronic quasiparticles, which can be most directly probed by surface spectroscopy techniques. We have also discussed the effects of EPI on surface vibrational properties, which, when strong enough, can trigger surface phase-transitions inducing structural reconstructions. Various cases have been identified, where the interaction strength at the surface is significantly enhanced over the bulk value. A better understanding of the EPI of confined electronic states, e.g., quantum-well states of thin films, and its relation to thin film superconductivity may help to control or even allow the design of desired properties by choosing proper thicknesses or geometries. More recently, the relevance of EPI for the stability of topological surface states has been recognized. In view of the increasing number of compounds with topologically nontrivial electronic structures, like topological insulators, Dirac or Weyl metals, whose interesting physics rests on the stability of surface or edge states, precise knowledge about the intrinsic EPI of these states will become increasingly important for future applications.

Rolf Heid

Institute for Quantum Materials and Technologies
Karlsruhe Institute of Technology
Karlsruhe, Germany
rolf.heid@kit.edu

Rolf Heid received his PhD in Physics (1991) from the University of Karlsruhe and his Habilitation (2002) from the University of Regensburg, where he served as a lecturer for 10 years. His research focuses on electronic and vibrational properties of solids and as their interaction, and the development of computational tools based on density functional theory. Applications comprise various metallic compounds, superconductors, and their surfaces and interfaces, as well as nanomaterials and topological systems.

Irina Y. Sklyadneva

Donostia International Physics Center (DIPC)
Donostia/San Sebastián, Spain
swxskski@ehu.eus

Irina Sklyadneva received her PhD in Physics from Tomsk State University in 1990, focusing on electronic properties of bulk metals and metal surfaces. She has been working at the Donostia International Physics Center (DIPC) (Basque Country, Spain) since 2003. Her research interests focus on lattice dynamics and electron–phonon coupling in metals, topological insulators, Dirac and Weyl semimetals, as well as in thin films and layered materials.

Evgueni V. Chulkov

Faculty of Chemical Sciences, Materials Physics Department
University of the Basque Country, UPV/EHU
Donostia-San Sebastián, Spain
evgenivladimirovich.tchoulkov@ehu.eus

Evgueni Chulkov received his PhD in Physics from Tomsk State University (1980), focusing on electronic and thermo-dynamic properties of metals and alloys. He is Professor in the Material Physics Department at the University of the Basque Country. His research interest lies in electronic structure and single-particle and collective excitations in metallic materials and on their surfaces, topological insulators, Dirac and Weyl semimetals, thin films, and electron–electron, electron–phonon, and electron–magnon interactions.

25. Spatially Resolved Surface Vibrational Spectroscopies

Tadahiro Komeda, Norio Okabayashi

Herein, we discuss the STM-IETS (scanning tunneling microscopy-inelastic electron tunneling spectroscopy) technique in the following order. After briefly mentioning conventional IETS (inelastic electron tunneling spectroscopy), STM-IETS experimental results are introduced focusing on similarities and differences to conventional IETS. The working principle behind STM-IETS for the detection of vibrational modes is considered by reviewing recent progress in STM-IETS theoretical calculations. In addition, experimental setups to improve the quality of the IET (inelastic electron tunneling) spectrum, including low-temperature measurements, electronics (especially the use of the lock-in amplifier), and IET signal mapping are reviewed. With this information, we discuss in detail STM-IETS measurements performed on an alkanethiol self-assembled monolayer (SAM) formed on an Au(111) surface. This molecule is often employed as a standard sample for the examination of IETS observations with atom-scale electrodes, which are used in single-molecule electronics investigations. STM-IETS reveals not only C–H stretching mode, which often appears as a prominent feature in IET spectra, but also other vibrational features in the so-called fingerprint region including vibrational modes which are beneficial for distinguishing functional groups. A comparison with recent calculations shows excellent agreement. In addition, partial deuteration of the molecule can provide more information about the site of the molecule where the excitation of the vibrational mode occurs. A selection rule or propensity for IETS detection is then discussed on the basis of a combination of these experimental investigations and theoretical simulations.

This chapter reviews recent IETS studies. IETS is an all-electron spectroscopy method used to detect the energy of an excitation process at surfaces/interfaces. The ability of IETS to reveal the vibrational modes of molecules was first demonstrated by Jaklev using a metal–insulator–metal (M–I–M) tunneling device, in which the molecule is buried in the insulating layer. The successful measurement of IET spectra with a scanning tunneling microscope (STM) combines atom-scale spatial resolution with chemical

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-46906-1_25

sensitivity, and is thus considered a powerful tool for surface characterization. However, the working principle behind STM-IETS is different to other vibrational detection techniques like infrared spectroscopy for which a dipole excitation is the main excitation mechanism.

25.1 Surface Spectroscopy

IETS is a technique to observe elemental excitations of species present in the tunneling junction. IET spectra are obtained by analyzing the tunneling current variation as a function of the voltage between the tunneling gap. Thus, it is an all-electron spectroscopy technique. The capability of IETS to obtain information about chemical properties of the interface was reported soon after the invention of tunneling devices such as the Esaki diode [25.1]. IETS can extract the excitation energies of vibrational modes of a molecule, phonons of metals and insulators, magnons and spin-flip processes of the magnetic bulk or atom/molecule in the tunneling gap (Fig. 25.1a).

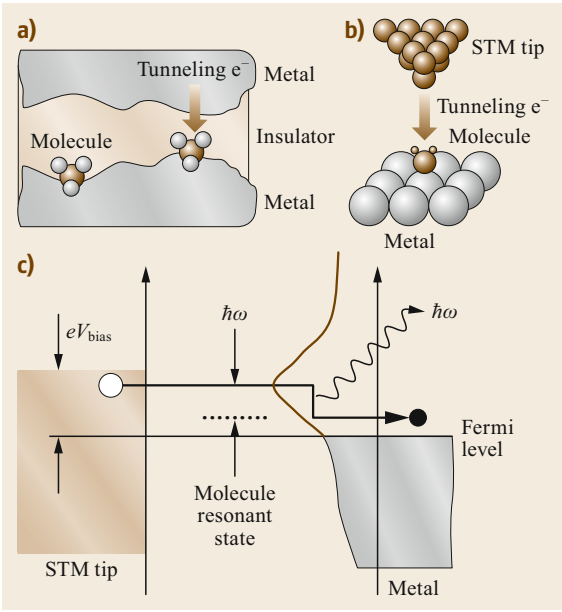

Fig. 25.1a–c Schematic drawing of an inelastic tunneling spectroscopy measurement on molecules showing **(a)** conventional IETS with a metal–insulator–metal tunneling junction (molecules buried in its interface) and **(b)** an STM setup and **(c)** a tunneling electron emitted from an STM tip is trapped in a molecule-induced resonant state. The electron moves after a short time into the metal substrate. During the process the electron could excite a phonon or molecule's vibration with an energy $\hbar\omega$. (Reprinted from [25.2], with permission from Elsevier)

25.1.1 Inelastic Tunneling Spectroscopy

The pioneering works by *Jaklevic* and *Lambe* detected clear vibrational features of molecules buried in the interface [25.3]. This result was achieved by measuring current and voltage across a metal–insulator–metal (M–I–M) device whose interface contains a target molecule. The work was followed by more research into the fields of basic science of molecular spectroscopy and applications like catalysis. The IETS technique was able to provide much higher resolution than infrared adsorption spectroscopy (IRAS) could offer at that time. These reports have already been reviewed in detail [25.4, 5].

The characteristic features of the IETS technique have been summarized by *Mazur* and *Hipps* as follows [25.6]. Firstly, IETS has much higher sensitivity than that provided by IRAS and Raman spectroscopy. With less than 10^{13} molecules, IETS can provide a complete spectrum. Secondly, overtone and combination bands usually have a low intensity, thus allowing easier identification of the fundamental modes. Thirdly, optically forbidden transitions may be observed as strong bands, and one can obtain spectra in the *IR-opaque* regions.

However, in the 1990s, IETS surface and interface research activity declined. This occurred mainly because of the availability of few methods to characterize the properties of the molecules in the interface. Moreover, to judge structural and electronic properties of adsorbates on surfaces the results of many surface science techniques must be combined, which cannot be realized for the IETS sample. In addition, the lack of a strict selection rule in IETS compared to that in IRAS measurements makes this technique less attractive to determine the molecular configuration on the surface. However, the appearance of STM has changed this situation. With STM for IETS measurements, the drawbacks of IETS can be compensated, allowing IETS to be a useful technique in the investigation of vibrations at surfaces (Fig. 25.1b).

25.1.2 Scanning Tunneling Microscope Technique

An energy diagram for the tunneling process is expressed in a simplified 1-D barrier in Fig. 25.2a. Elec-

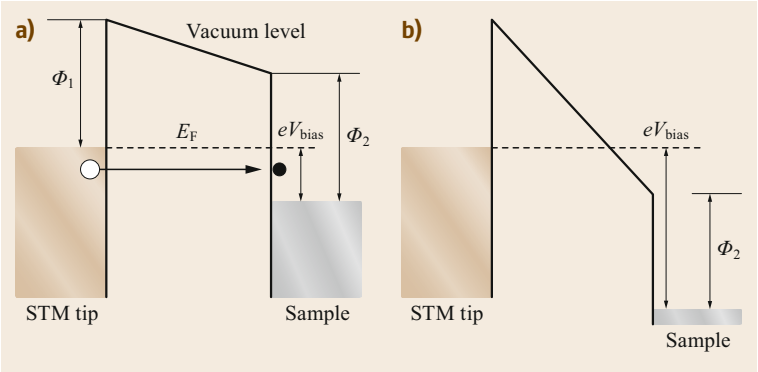

Fig. 25.2a,b Schematic drawing of an energy diagram for tunneling in a simplified 1-D barrier: **(a)** normal tunneling and **(b)** Fowler–Nordheim tunneling. (Reprinted from [25.2], with permission from Elsevier)

trons can tunnel from the tip to the unoccupied states of the substrate in the energy range between the Fermi level (E_F) and $E_F - V_{bias}$. If a slow variation of local density of state (LDOS) both for the substrate and for the tip can be assumed, tunneling current versus V_{bias} should show the Ohmic behavior.

To see characteristic features of the tunneling current compared to the conventional electron source, it is worth noting the difference in energy range of the two techniques with reference to the sample's Fermi level. The energy of electrons available from conventional electron sources should be *above* the vacuum level of the sample, while tunneling electrons can be injected to the states *below* the vacuum level.

At the same time there are several constricting conditions for the tunneling electrons. First, an available energy range of tunneling electrons is limited to that close to the work function ($\approx 4-5$ eV for normal metals). If V_{bias} exceeds the work function as shown in Fig. 25.2b, the tunneling current shows a drastic increase because the width of the tunneling barrier becomes thinner thus moving into the Fowler–Nordheim (FN) tunneling region [25.7, 8]. In the FN tunneling region, the lateral spatial resolution is limited to ≈ 30 Å [25.9, 10] so that no atomic resolution is feasible.

The next issue is the maximum value of the tunneling current. The smaller the tunneling gap, the higher the obtained tunneling current. It can be estimated that the tip is separated from the substrate by ≈ 1 Å for the tunneling gap of 1 MΩ. If the distance is further reduced then a chemical bonding appears between the two and irreversible changes to the properties of the surface are made. The expected current for 1 MΩ gap resistance is $\approx 5\,\mu$A at the maximum available voltage for the STM mode [25.11–13].

Despite these limits, the tunneling current from an STM tip can provide a variety of unique features, which have been used for electron-induced phenomena [25.14].

25.1.3 Chemical Analysis with Electron Probe

There are various surface analytical techniques with the electron-in and electron-out configuration, which include Auger spectroscopy and high-resolution electron energy-loss spectroscopy (HR-EELS). Although Auger spectroscopy has the capability to identify the element of targets, the lateral resolution of the Auger signal still does not reach the atomic-scale region.

The HR-EELS technique is a sensitive analysis method to detect vibrational modes of molecules and phonon of substrates. The energy range of the incident electrons is similar to that used in the STM measurement and practically all vibrational modes of molecules can be detected. The selection rule of HR-EELS contributes to the determination of the molecule's bonding configuration on the surface. These features mean that the HR-EELS technique is widely used.

In order to understand whether the detection mechanism of the vibration mode of HR-EELS and IETS are similar or not, we briefly review the HR-EELS technique.

25.1.4 Excitation of Vibrational Modes with Electrons

The experimental setup of HR-EELS can be described as follows. Incident electrons, which are monochromatized in energy with the use of a monochromator, are injected onto the sample surface with energy of a few eV. The electrons scattered from the sample are analyzed in terms of energy and the energy distribution of these electrons are plotted. The peaks in the spectrum correspond to the yield of the electrons that lost certain energy from that of the incident electrons due to the vibrational excitation. The energy, strength, and width of these peaks can be analyzed to identify the chemical species, adsorption sites, and electronic and structural configuration of the adsorbates [25.15].

The vibration excitation mechanism of HR-EELS has been investigated in detail both for theoretical and experimental aspects. The mechanism can be classified into three groups: (1) dipole excitation, (2) impact scattering, and (3) negative ionic resonant scattering [25.2].

Dipole Excitation

The injected electron produces an electric field that varies with time. The oscillating field causes the excitation of the vibration of the adsorbed molecules [25.16]. The interaction occurs through long-range fields, and the excitation is expected to occur far away from the molecule (typically 100 Å). Generally, the momentum transfer is small. The selection rule of dipole scattering can be derived from the analysis of the matrix elements in the Golden rule $|\langle F|\gamma E|I\rangle|^2$, where I/F are the initial/final vibrational states. The coupling Hamiltonian is expressed as γE, where γ is the dipole moment operator formed by the intra-adsorbate nuclear motion of the vibrational mode, and E is the electric field at the adsorbate site. The vibrational modes that have a nonzero matrix element are the dipole active modes. In addition, we should pay attention to the image potential for an understanding of the selection rule. The dipoles perpendicular to the surface are reinforced by their image dipoles which emphasize the excitation. Conversely, the image potential for the dipole moment parallel to the surface creates a dipole in a direction reversed from the original one, thus canceling out the total dipole moment. As the momentum transfer is small, the inelastic component due to dipolar losses is distributed along the specular direction of the reflected electrons [25.15].

Impact Scattering

A second excitation mechanism is called impact scattering, which is characteristic of EELS only [25.17]. In the impact scattering channel, the dipole selection rule is no longer valid and a contribution from dipole-inactive modes to the inelastic cross-section can be detected [25.18]. Experimentally, this component is observed in the nonspecular direction where the intensity of the dipole component is drastically reduced. These losses are excited in the proximity of the surface. The injected electron interacts with the ion core in the range of a few Å from the center. The interaction is short range compared with the dipole scattering. The interaction mechanism is more complicated than dipole scattering and multiple scattering should be considered.

Theoretically, the formation of a deformed potential due to the excitation of a vibrational mode is considered, which scatters the incoming electron to different momentum and energy. Thus, if a particular vibrational quantum (energy $\hbar\omega_s$; wavevector Q_s) is excited and the initial vector of the electron changes from k^I to k^s in momentum, the following matrix element M results [25.15];

$$M(k^I, k^s; +s) = \langle n_s + 1|f(k^s, k^I; R)|n_s\rangle = \sqrt{(n_s+1)}\sqrt{\frac{\hbar}{2M\omega_s}}\frac{\partial f}{\partial Q_s}\,, \tag{25.1}$$

$$\frac{\partial f}{\partial Q_s} = \sum_{i\alpha}\left(\frac{\partial f}{\partial R_{i\alpha}}\right)_0 \frac{\xi_{i\alpha}}{\sqrt{M_i}}\,, \tag{25.2}$$

where n_s is the occupation number of the vibration quantum, f is the scattering amplitude, R is the position of the nuclei, M is the reduced mass, and $\xi_{i\alpha}$ denotes the amplitude of the displacement of nucleus i in the Cartesian direction α due to a given vibrational motion.

Negative Ion Resonance Scattering

This excitation is well known for gas-phase molecules. In the excitation process, the incident electron is temporally trapped in an unoccupied electronic state of a molecule. The charging of the molecule can cause a structural rearrangement, including the elongation/-contraction of the distance between nuclei. Such kinetic movement of nuclei is called a shape resonance.

It is well established that the excitation of vibrational modes of molecules is greatly enhanced in this resonance scattering process for gas-phase molecules [25.19]. For example, the differential vibrational cross-section shows the resonant enhancement at ≈ 9.5 eV for gas-phase O_2, which corresponds to the resonance energy for the formation of a negative ion of O_2 [25.20].

However, there are a very limited number of reports of successful observations of negative ion resonance for molecules on surfaces using HR-EELS. One of the reasons is the shorter lifetime of the negative ionic state for adsorbed molecules compared to gas-phase molecules due to the presence of a decay path associated with the formation of a chemical bond between molecule and substrate. Experimentally, the lifetime of a negative ionic state can be evaluated from the spectra of inverse photoemission spectroscopy, where the intrinsic broadening (Γ) reflects the lifetime (τ) of the ionic state. It has been reported that $\Gamma \approx 0.4$ eV for free CO molecules, and $\Gamma \approx 1.5$–2.5 eV when chemisorbed on Ni [25.21] and Cu [25.22]. For this reason, negative ion resonance has been reported on physisorbed molecules (N_2) on evaporated silver films [25.23]. In this case, the lifetime of the resonance is indeed relatively long due to the weak coupling between the molecule and the surface, which enhances the excitation of vibrational modes. More recently, the mechanisms of inelastic electron scattering were studied for adsorbed O_2 on Ag(110) and on Ag(111) using HR-EELS [25.24].

25.2 STM-IETS Experiments and Theory

The excitation of a vibrational mode of a molecule in the STM junction is schematically illustrated in Fig. 25.1c. The model is based on resonant tunneling in which an electron tunnels from the tip to the substrate leaving a molecule in a resonant state, the energy of which is dissipated into the substrate.

25.2.1 Detection of Vibrational Mode with IETS

For electron tunneling through a molecule, in addition to the elastic electron path, processes appear in which it loses energy by exciting a vibrational mode. Since the maximum energy which can be lost in the inelastic process is eV_{bias}, the process occurs only when the energy relation of $eV_{\mathrm{bias}} > \hbar\omega$ is satisfied. The appearance of the new channel that causes the inelastic process contributes to the increase of the conductance ($\mathrm{d}I/\mathrm{d}V$). The relation of I–V, $\mathrm{d}I/\mathrm{d}V$, and $\mathrm{d}^2I/\mathrm{d}V^2$ curves are schematically shown in Fig. 25.3. In the $\mathrm{d}^2I/\mathrm{d}V^2$ curve, two peaks are expected at symmetric energy positions but with reverse polarity [25.4, 6].

Let us consider whether the vibrational excitation mechanisms shown in the HR-EELS section can account for the STM-IETS mechanism. It should be noted that there exist distinct differences in the properties of the incident electrons between the two methods. First, the interaction at long distance of ≈ 100 Å, which causes the major part of dipole scattering of HR-EELS, cannot be realized in the IET process where the electron source is located within 10 Å. Second, the electrons tunnel into and interact with the states located between E_{F} and the vacuum level (in the case where electrons are injected into a sample). Because of the lowering of the lowest unoccupied molecular orbital (LUMO) level with respect to the gas phase for adsorbed molecules, gas-induced resonance states are often observed in this energy range.

The vibrational excitation in STM-IETS is likely caused by a combination of the impact and resonant scattering processes.

25.2.2 Examples of STM-IETS

Measurements of IETS spectra within the STM setup (STM-IETS) started with the pioneering work of Ho's group. However, the phenomenon had been already predicted theoretically shortly after the invention of STM [25.26]. The first IETS measurement was per-

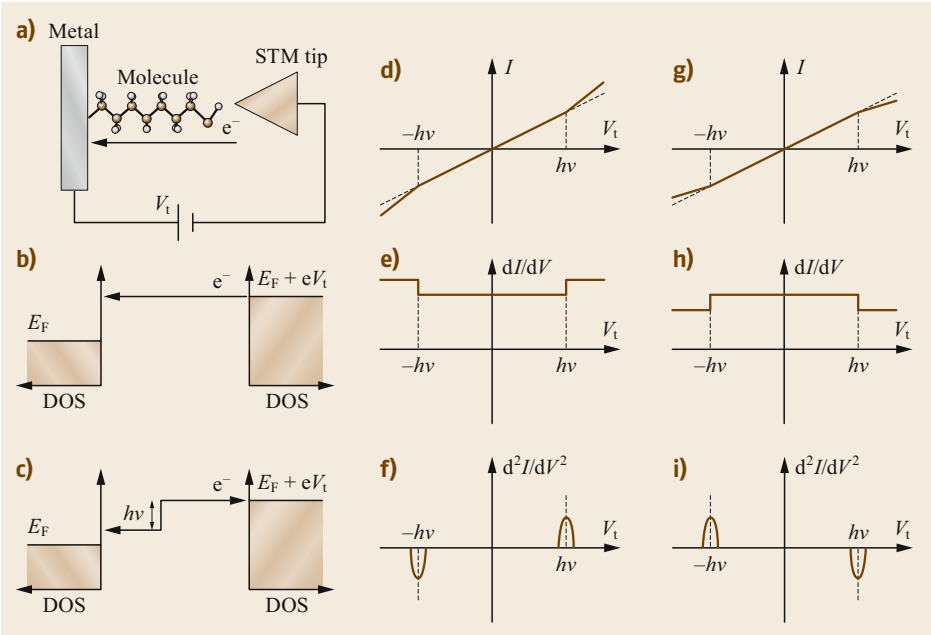

Fig. 25.3a–i Schematic view of **(a)** the tunneling process through a molecule on the surface, **(b)** elastic and **(c)** inelastic tunneling processes. **(d–f)** Effect of the inelastic process on I versus V, $\mathrm{d}I/\mathrm{d}V$ versus V, and $\mathrm{d}^2I/\mathrm{d}V^2$ versus V, respectively, where the inelastic current is increased while increasing the bias V_{t} (positive peak). **(g–i)** Similar to **(d–f)**, however, here the inelastic current is decreased while increasing the bias (negative peak). This case can be seen for O_2/Ag(110), where the density of states of the adsorbate-induced state near the Fermi level is higher, and for Au wire bridging small gap electrodes. Fig. 25.4 Background difference d^2I/dV^2 spectra for C_2H_2 (1) and C_2D_2 (2), taken with the same STM tip, showing peaks at 358 and 266 mV, respectively. The spectrum *at the bottom* corresponds to (1) subtracted by (2), which contributes more background subtraction. (Reprinted with permission from [25.29]. Copyright (1998) by the American Physical Society)

formed for an acetylene (C_2H_2) molecule adsorbed on a Cu(100) surface [25.27]. The results showed an increase in the tunneling conductance at 358 mV due to the excitation of the C−H stretching mode (ν(C−H)). An isotopic shift to 266 mV was observed for deuterated acetylene (C_2D_2) (Fig. 25.4). The conductance change due to the excitation of the ν(C−H) mode was estimated to be $\approx 4.2\%$. It is interesting to compare STM-IETS results with the ones obtained with conventional IETS, which utilize the metal–insulator–molecule–metal tunnel device, for hydrocarbons. The ν(C−H) mode was measured as the strongest feature also in the conventional IETS spectra; the conductance change of 1.8% was observed for a complex silane molecule containing aminopropyltrimethoxy [25.6, 28].

Thereafter, measurement of STM-IETS spectra of CO molecules were performed; vibrations of four isotopes of CO on Cu(001) and Cu(110) at 8 K were measured by STM-IETS [25.30]. The low-energy mode observed at 36 mV was assigned to the hindered rotation mode (R-mode) which causes a conductance change of 15%, i.e., larger than that for ν(C−H). The C−O stretch is detected at 256 mV, which is close to the energy obtained using the HR-EELS technique. However, the conductance change is small ($\approx 1.5\%$) and it was claimed that the peak intensity is close to the detection limit of STM-IETS at the time of the report. It is intriguing to note that the detected intensity for the ν(C−O) mode is weak, while this mode typically gives rise to intense features in HR-EELS. We can thus argue that the excitation mechanisms involved in IETS and HR-EELS are different.

Notably, the hindered translational mode (T-mode) and M−CO stretching mode are not observed [25.30]. It is interesting to see whether the appearance and disappearance of specific vibrational modes in STM-IETS can be related to the properties of these modes. Let us examine their relaxation time (τ), which indicates how long the vibrational mode lasts once it is excited [25.31]. Experimental results for τ are 2 ps for the CO stretch mode [25.32], and a similar value is reported for the R-mode [25.33]. Conversely, τ is ≈ 40 ps for the T-mode [25.34], and $\tau > 10$ ps for the CO−Pt(111) stretch mode [25.35]. With use of an insulating layer between the molecule and the substrate, the lifetime of the vibrational modes can be increased and the IETS yield is larger (Sect. 25.3). However, the life-time and the IETS yield of the T-mode and R-mode of the CO molecule shows a reverse tendency. This point will be discussed later with a theoretical model.

Another example of the protruded feature in the positive sample bias of IETS spectra was reported for a pyridine molecule adsorbed on a Cu(001) surface by *Lauhon* and *Ho* [25.36]. They compared IETS results for pyridine and benzene molecules, where a clear feature of the ν(C−H) mode is only observed for the pyridine molecule case.

The appearance/disappearance of the ν(C−H) feature in IETS spectra with a chemical change of the molecule was reported for a benzene molecule adsorbed on a Cu(110) surface [25.37]. A benzene molecule is adsorbed on Cu(110) with a flat-lying configuration. When electrons are injected into the benzene molecule, it causes the dehydrogenation of the molecule and changes the bonding to the upright configuration (Fig. 25.5).

IETS spectra obtained, respectively, on the Cu(110) substrate (I), on the benzene molecule (II), and on the benzene molecule after tunneling electron dosing (III) are shown in Fig. 25.6a. We see IETS features only for spectrum (III), which are marked with arrows in the figure at the energies of 372 and −380 mV. The isotope effect was also examined and the IETS spectra obtained after dosing tunneling electrons to a deuterated benzene molecule are shown in Fig. 25.6b, where we see the ν(C−H) feature shift to 275 mV for the heavy isotope. These results can be rationalized if the ν(C−H) vibrational mode appears only after the change of the bonding configuration of the benzene molecule into the upright position.

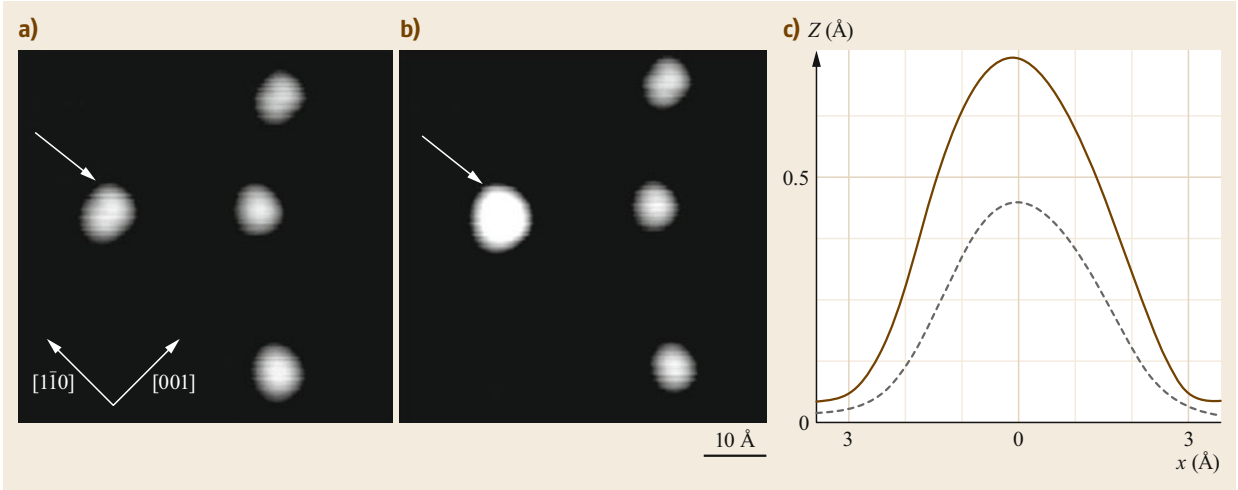

Fig. 25.5a–c Topographic image of the molecules of benzene and its reacted product. The observation conditions are the tunneling current 0.6 nA, the sample bias voltage of −500 mV, and the area 43×43 Å^2. The target molecule of benzene is shown by the *arrow* in **(a)**. It becomes brighter in **(b)** after the dosing of tunneling electrons with the energy of 4 eV (sample bias positive) for 0.2 s. **(c)** Apparent height of the benzene molecule (*dashed line*) and its reacted product (*solid line*). The height of the reacted product is 44% greater than that of the original benzene molecule. (Reprinted from [25.38], with the permission of AIP Publishing)

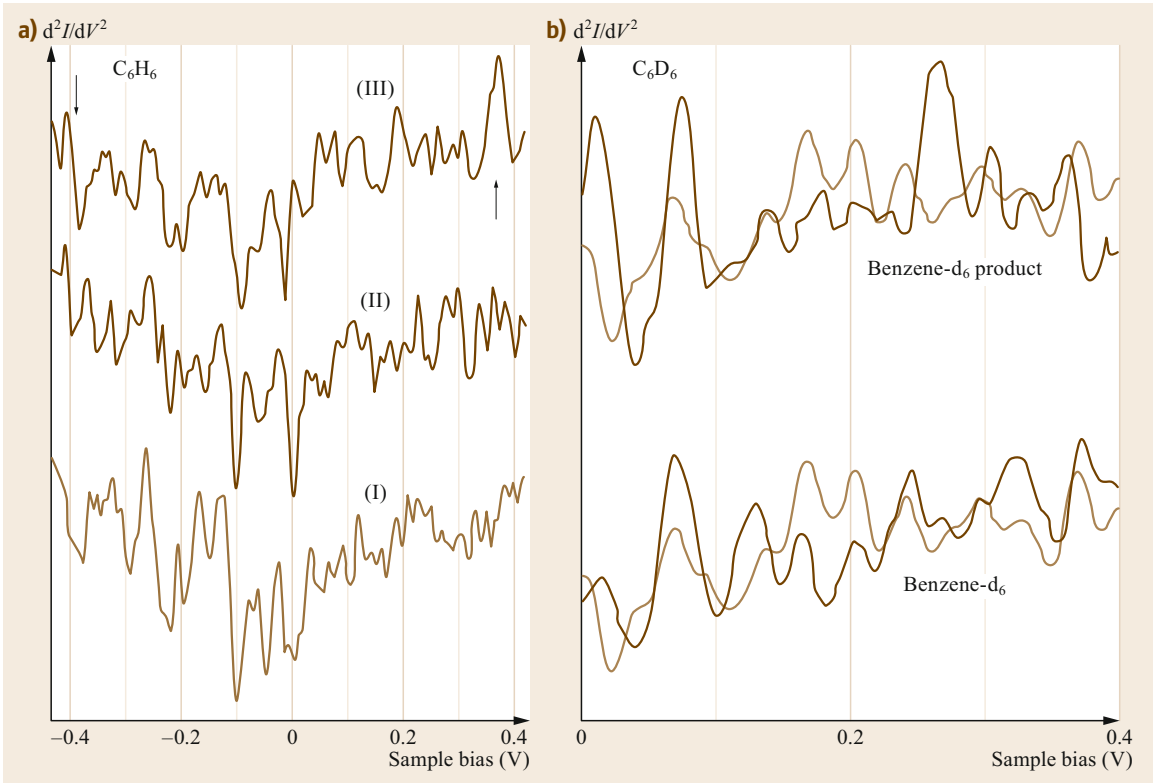

Fig. 25.6 **(a)** Vibrational spectra (dI^2/dV^2 versus V plot) obtained on the clean Cu(110) surface (I), the benzene molecule (II), and its reacted product (III) by STM-IETS taken at a gap resistance of 1 GΩ and $V_{rms} = 5$ mV modulation at 398 Hz. The spectra are the averages of 20 scans for the bias range between −0.4 and 0.4 V. **(b)** STM-IETS spectra on the deuterated benzene molecule (C_6D_6) and its reacted product. On both spectra, the spectrum of the Cu substrate is superimposed by a thin line [25.38]

There are no established selection rules for IETS, but it has been inferred empirically in the conventional IETS studies that stronger intensities are obtained for optically active modes than for the optically forbidden modes [25.4]. Since the ν(C−H) mode has a dipole moment along the surface normal for the upright configuration realized both for pyridine and dehydrogenated benzene molecules, the observed IETS spectra go along with this rule, even though the dipole excitation is less likely for STM-IETS. It can also be rationalized from a different viewpoint, i.e., the vibrational modes are effectively excited if the nuclei motions are along the tunneling current direction, which will be examined later.

25.2.3 Spectra Shape of IETS

There are several reports where the STM-IETS features in the positive energy region appear as dips instead of peaks (Fig. 25.3g,h). This shows a large difference from the results of IETS with metal oxide tunneling devices, in which almost all features appear as peaks for positive energy values.

Hahn et al. revealed two vibrational modes showing a *decrease* in conductance at ±82.0 and ±38.3 mV sample bias for a single oxygen molecule chemisorbed on the fourfold hollow sites of an Ag(110) surface at 13 K [25.37]. *Pascual* et al. detected low energy adsorbate–substrate (external or hindered) vibrational modes of benzene molecules adsorbed on an Ag(110) surface [25.39]. These IETS features are found to be strongly sensitive to the adsorption properties, and more interestingly the vibrational spectra of molecules close to kink sites exhibit a characteristic Fano-like line shape.

Agrait et al. reported similar dips in the IETS for free-standing gold atomic chains of up to seven atoms in length [25.40]. The dip features are derived from the phonon modes whose frequencies are determined by the length of the chain.

Persson and Baratoff have claimed that there appears a case where the dI/dV ($V > 0$) decreases at the threshold voltage instead of the *increase* observed for the normal case illustrated in Fig. 25.3 [25.41]. This happens when the elastic channel suffers an effect of backscattering of elastic electrons by exciting and reabsorbing a vibrational mode at the threshold energy. The backscattering might reduce the intensity of an elastic component. Experimentally, we can only measure the sum of the elastic and the inelastic component. Thus, the shape of the IETS spectra is not always protruded; it can be a dip or remain flat even if the inelastic component gives a positive contribution for the conductance change.

Such an increase of the backscattering appears when the LDOS of resonance states is high. Resonance states are defined as molecular orbitals of adsorbates broadened after interacting with metal substrate levels. When the LDOS of the resonance states is high (low) at the Fermi level, it is called on-resonance (off-resonance). Most conventional IETS experiments have been performed on molecules adsorbed on inert Al_2O_3 oxide and the off-resonant condition is expected in these cases. It is suggested that this is the main reason why protruded peaks are observed in the IET spectrum ($V > 0$) in most observations [25.41]. One of a few examples in which such a dip is observed corresponds to the case in which methyl isocyanide molecules are adsorbed on alumina-supported rhodium particles, which can be an evidence of the importance of the resonant coupling process [25.42]. *Persson* claimed that such a behavior is characteristic for negative ion resonance and neither dipole nor impact scattering induce such behavior [25.41].

Recently, *Paulsson* et al. reported a theoretical model to explain the switch between the peak and dip in IETS [25.43]. They chose four different IETS results and performed theoretical simulations. The four cases included IETS investigations of oligo phenylene ethynylene (OPE) [25.44] (Fig. 25.7a) and a gold chain connected to two Au electrodes [25.40] (Fig. 25.7b), and STM-IETS investigations of CO chemisorbed on Cu(111) [25.45] (Fig. 25.7c) and O_2 on Ag(110) [25.37] (Fig. 25.7d). In the case of OPE on gold (Fig. 25.7a) and CO on Cu(111) (Fig. 25.7c) peaks are observed at positive bias values of the d^2I/dV^2 versus V. Conversely, for the gold chain (Fig. 25.7b) and for O_2 on Ag(110) (Fig. 25.7d) peaks are present for negative bias and dips are present at positive bias.

The proposed model illustrates an electron transport between two electrodes assuming a single electronic state for each, where the electron transfer is considered in terms of the ratio of molecular coupling to two electrodes (α) and transmission (τ) [25.43]. According to this model, the maximum transmission is described by $\tau_{max} = 4\alpha/(1+\alpha)^2$ (thick line in Fig. 25.8) and a crossover point, where the shape of the d^2I/dV^2 spectrum changes from the peak to the dip, is described by $\tau_{crossover} = \tau_{max}/2$ (red dashed line in Fig. 25.8). The diagram in Fig. 25.8 indicates that for a given coupling ratio, if the transmission is higher than half-maximum, the inelastic back scattering prevails over the inelastic forward scattering, leading to the decreased tunneling probability.

The four samples treated here are located in the phase diagram as follows: (a) The OPE molecule is connected similarly to the two electrodes via strong chemical bonds ($\alpha \approx 1$) and the electronic state responsible for the transport is far from the Fermi level

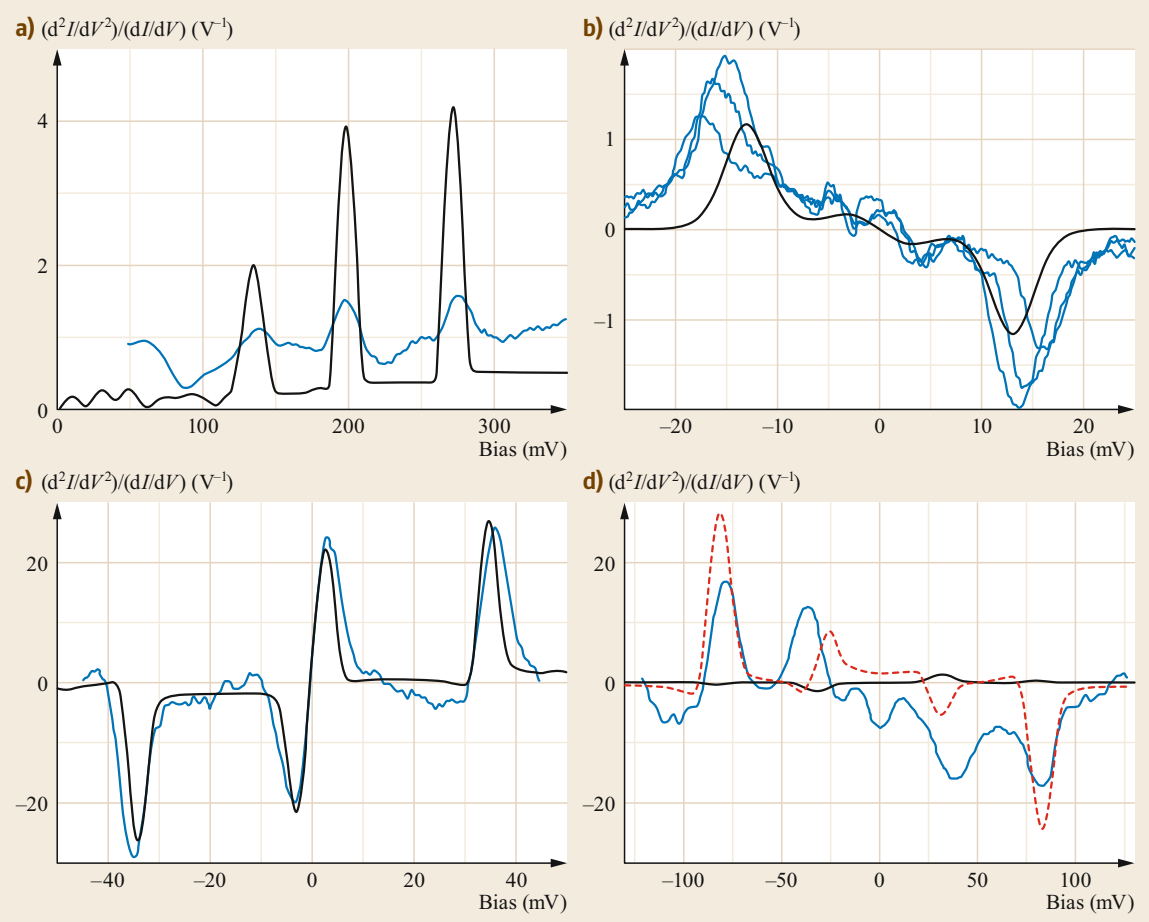

Fig. 25.7a–d Experimental (*blue lines*) and calculated (*black lines*) IETS for **(a)** OPE molecule on Au(111) electrodes [25.44], **(b)** Au chain connected to Au(100) electrodes [25.40], **(c)** CO molecule on Cu(111) [25.45], and **(d)** O_2 molecule on Ag(110) [25.37]. In case **(d)**, the Fermi energy in the calculation has been shifted manually $\Delta\varepsilon_F = -0.6\,\text{eV}$ to match the experiment (*red dashed line*). The calculation data originate from [25.46]. For the STM configurations **(c)** and **(d)**, the calculated IETS is compared with a rescaled d^2I/dV^2. (Reprinted with permission from [25.46]. Copyright (2008) by the American Physical Society)

($\tau \approx 0$). Thus, the OPE is located in the upper left part of the phase diagram, which provides the peaks in the d^2I/dV^2 versus V plot at positive bias. (b) The gold chain is also connected strongly and symmetrically to the two electrodes ($\alpha \approx 1$), however, the transmission is higher than the half-maximum, and the system ends up in the upper right corner of the phase diagram providing the dips. Systems (c) CO/Cu(111) and (d) O_2/Ag(110) have both been investigated by STM, therefore the coupling is antisymmetric ($\alpha \approx 0$). Conversely, the transmissions are considerably different between the CO and the O_2 molecule. This is caused by the different electronic structure of CO and O_2 after being adsorbed on Cu(111) and Ag(110) substrates, respectively. If the resonant states of O_2/Ag(110) and CO/Cu(111) are compared, the former, originated from $1\pi_g$ level, has a much higher density near the Fermi level than the latter. Thus, the tunneling conditions in the bias range near the Fermi level are off-resonant and on-resonant for the CO/Cu(111) and O_2/Ag(110) cases, respectively. Because of this contrast, the CO case is located to the left of the crossover line (providing the peaks) and the O_2 case is located to the right of the crossover line (providing the dips) [25.43]. Besides this qualitative consistency between experiment and theory, numerical calculations based on DFT (density functional theory) and NEGF (nonequilibrium Green's function) (Sect. 25.2) formalism reproduce the experimental observations well in quantitative terms (black lines in Fig. 25.7) [25.43].

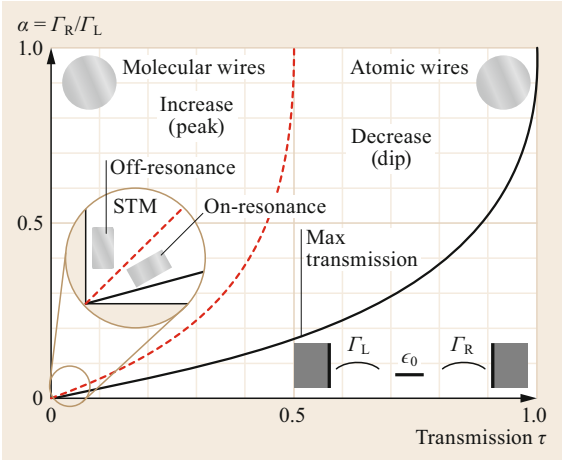

Fig. 25.8 Phase diagram for a one-level model. A state specified by ε_0 is coupled with left and right electrodes with strength Γ_L and Γ_R, respectively. For an STM measurement, electrode L and electrode R represent the substrate and the tip, respectively. The *inset* illustrates the sign of the conductance change at the onset of inelastic tunneling. At a given coupling ratio, the elastic transmission has an upper bound max (*black line*), and the inelastic conductance change undergoes a sign change at crossover $t_{\text{crossover}} = t_{\max}/2$ (*red dashed line*). 25.2.4 Theory of IETS

The IETS ν(C−H) mode features observed for the acetylene molecule, which has a much stronger intensity compared to other modes, has attracted attention and theoretical calculations have been performed. The mechanism behind the appearance of strong intensity was discussed by *Lorente* et al. [25.47] and *Mingo* and *Makoshi* [25.48]. Both of them calculated the matrix elements in which the initial electronic state i makes a transition to the final state f caused by the presence of a deformation potential [25.49]. The deformation potential is the change of one-electron potential by the nucleus movement accompanying the vibrational mode of the molecule.

More precisely, *Lorente* et al. presented the following formula for it [25.47]

$$|\langle\phi_\lambda|\delta v|\phi_\mu\rangle|^2 \,, \tag{25.3}$$

where $\langle\phi_\lambda|$ and $|\phi_\mu\rangle$ are the final and initial electronic states in the resonant states calculated by the DFT. The deformation potential δv is thereby expressed in the form of $\partial v = \sqrt{\hbar/2M\omega}\,\partial v/\partial Q$, where M is the reduced mass, Q the coordinate of the atoms involved in the vibration, and v is a one-electron potential energy.

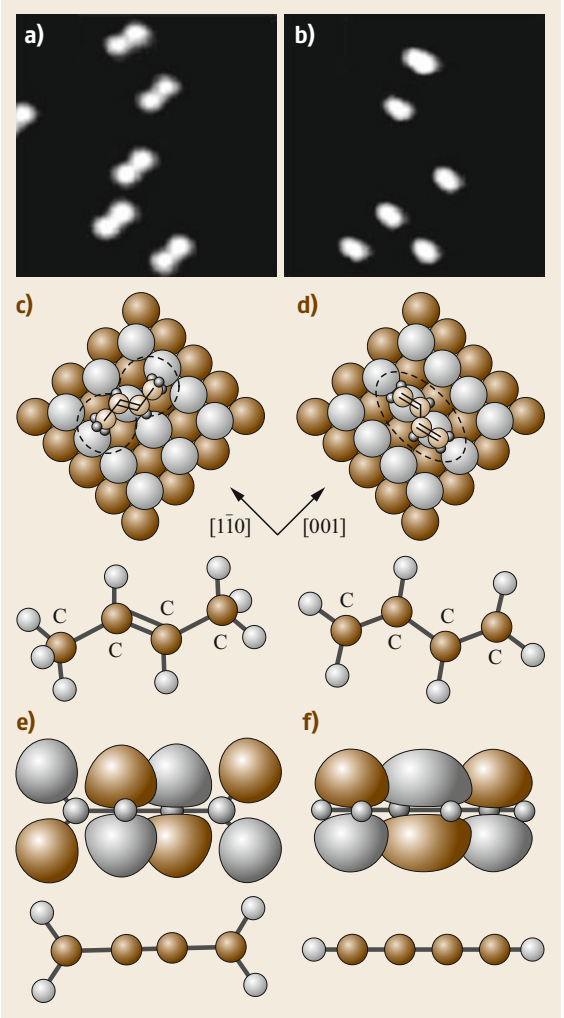

Fig. 25.9a–f The STM images, bonding configuration and structure of the molecules for **(a,c)** *trans*-2-butene and **(b,d)** 1,3-butadiene. Contour of the molecule orbital of the LUMO state is shown for **(e)** *trans*-2-butene and **(f)** for 1,3-butadiene. Note a portion of the LUMO orbital is located in the CH_3 group of *trans*-2-butene in **(e)**

Note that $\sqrt{\hbar/2M\omega}$ corresponds to the amplitude of the vibrational mode.

If we compare (25.1) for the impact scattering mechanism of HR-EELS with (25.3), we find similarities between these two theoretical treatments. The theory shown by Lorente does not include the formation of a temporary negative ion explicitly proposed by *Persson* and *Baratoff* [25.49]. Mingo et al. showed that the weak intensities of all vibrational modes detected for the acetylene molecule other than the ν(C−H) mode is due to the destructive interference between different atomic orbitals. *Mii* et al. used the Green func-

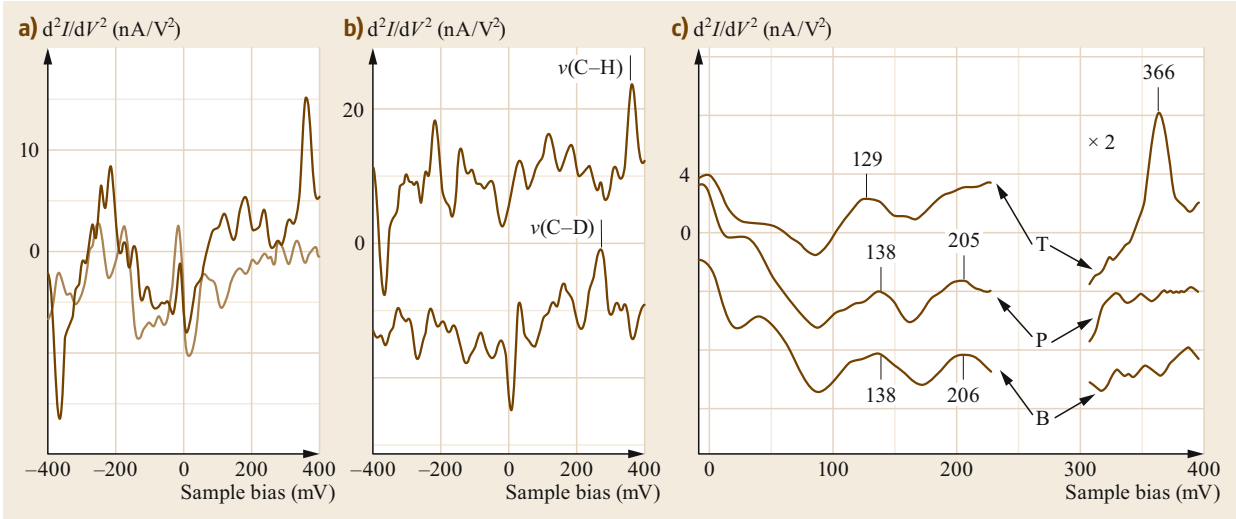

Fig. 25.10 **(a)** Vibrational spectra obtained for the clean Pd(110) surface (*light brown line*) and *trans*-2-butene (*dark brown line*) by STM-IETS reported at a gap resistance of 1 GΩ with a 14.1 mV (rms) ac modulation at 397 Hz. The spectra correspond to averages of four scans from −400 to +400 mV. **(b)** Vibrational spectra for *trans*-2-buten (*upper line*) and *trans*-2-buten-d_8 (*lower line*) after background subtraction. The change in conductance for the peaks at ±366 mV (268 mV) is 6% (5%) at positive sample bias, and 7% (3%) at negative sample bias, for the C−H (C–D) stretching mode of *trans*-2-butene (*trans*-2-butene-d_8). **(c)** Vibrational spectra for *trans*-2-butene (*curve* T), the reaction product (*curve* P), and 1,3-butadiene (*curve* B) shown in Fig. 25.9f. The spectra were taken at a gap resistance of 200 MΩ within the range of 0−230 mV, in the region where dehydrogenation does not occur, and 1.5 GΩ within the range of 300–400 mV. (Reprinted with permission from [25.50]. Copyright (2002) by the American Physical Society)

tional method on the basis of the Anderson Hamiltonian to calculate such differences in different vibrational modes [25.51, 52].

Here we examine how these theoretical treatments reproduce actual IETS spectra observed for molecules other than acetylene. *Kim* et al. reported IETS spectra measured for trans-2-butene (C_4H_8) and 1,3-butadiene (C_4H_6) molecules adsorbed on a Pd(110) surface [25.50]. The topographic image and the model of the bonding configuration are illustrated in Fig. 25.9a,c, respectively for the *trans*-2-butene molecule, and in Fig. 25.9b,d for the 1,3-butadiene molecule. The former has a C=C bond at the center of the molecule, and two CH_3 groups are attached to both ends of the C=C bond. The butadiene molecule has two C=C bonds inside the molecule.

For the IETS spectra, a clear peak was observed at 365 mV corresponding to the ν(C−H) mode for the *trans*-2-butene molecule (Fig. 25.10), whose peak intensity is almost as strong as that observed for an acetylene molecule on Cu(100) [25.27, 53]. However, this feature cannot be observed for the 1,3-butadiene molecule in spite of their similar structure and the existence of C−H species.

The origin of the different intensities of the ν(C−H) mode observed for the two molecules can be explained as follows. We see these two molecules have a significant difference in the electronic state at the energy close to the Fermi level. The molecular orbital (MO) of the LUMO level for *trans*-2-butene and 1,3-butadiene molecules are shown in Fig. 25.9e,f, respectively. The LUMO level shifts downwards from the gas phase after adsorption on the surface, and forms a resonant state near the Fermi level. The MO of the LUMO level can be seen at the C−H bond in the CH_3 group for the *trans*-2-butene molecule, but it is absent for the butadiene molecule. The model proposed by Lorente suggests that the coupling between the initial and the final state expressed in (25.3) determines the IETS signal intensity.

We can assume that the deformation potential δv should be distributed at the bond related to the vibrational mode (the C−H bond for the case of the C−H stretching mode). The IETS signal should be strong only when the densities of the electronic states of ϕ_λ and ϕ_μ have large components at the bond for the vibration mode. Thus, the absence of the MO of the LUMO level at the C−H bond for the butadiene molecule might be responsible for the weak intensity of the ν(C−H) mode.

In addition, the bonding strength between the molecule and the substrate should be considered as a factor

that determines the IETS signal strength. This is especially so in the case where the negative ion resonance participates in the vibration excitation, because the excitation probability of vibration modes should increase in the case where the lifetime of the negative ion state is longer. It is speculated that a weaker interaction between the CH_3 group and the substrate for the *trans*-2-butene molecule than that of the CH_2 group for the butadiene molecule might enhance the excitation probability of the ν(C−H) mode.

25.2.5 Calculation Methods for IETS

Recently, a calculation method combining DFT and NEGF calculations successfully reproduced the experimental results [25.49, 54, 55].

The NEGF method correctly describes the corrections to the elastic current and can describe experiments in which the current increases and/or decreases due to inelastic scattering. The calculation covers IETS phenomena not only for the STM setup but also for an atom chain which bridges two electrodes. The current variation gives rise to peaks and/or dips in the second derivative. The main disadvantage of the NEGF method is that it consumes a large computational resource. The recently developed lowest-order expansion (LOE) approximation of the NEGF method makes it feasible to calculate the IETS from large-scale DFT calculations [25.46, 54, 56]. In addition, the emission rate calculation in the LOE approximation is identical to Fermi's golden rule expression. The LOE can therefore provide physical insights into the scattering processes and allow derivation of selection rules for IETS from first-principle calculations.

NEGF clearly shows how the current is coupled with the vibrations through the junction. To simplify these expressions, two approximations are used. The first assumption is that only the lowest order e–ph coupling matters. The second is that the density of states varies slowly near the Fermi level, which allows the integration over energy to be carried out analytically.

In the low-temperature limit, the power dissipation from the electrons into the vibrational system is then given by

$$P = \sum_{\lambda} \frac{(\hbar\omega)^2}{\pi\hbar}[n_{\mathrm{B}}(\hbar\omega) - n_{\lambda}]\mathrm{Tr}(M_{\lambda}AM_{\lambda}A) + \frac{\hbar\omega}{e}\gamma_{\lambda} \begin{cases} 0; & |eV| < \hbar\omega\,, \\ |eV| - \hbar\omega; & |eV| > \hbar\omega\,, \end{cases} \tag{25.4}$$

where $\hbar\omega$ is the energy of the target vibrational mode, $n_{\mathrm{B}}(\hbar\omega)$ the Bose–Einstein distribution, n_{λ} the occupation of the vibrational mode, M_{λ} the e–ph interaction, A the spectral function, and γ_{λ} the emission rate which will be discussed later [25.54, 56]. The first term drives the vibrational system towards equilibrium with the electrons. The second term describes vibrational heating where the emission rate is given by

$$\gamma_{\lambda} = \frac{e}{\pi\hbar}(M_{\lambda}A_{\mathrm{L}}M_{\lambda}A_{\mathrm{R}}) = \frac{4\pi e}{\hbar}\sum_{l,r}|\langle\Psi_r|M_{\lambda}|\Psi_l\rangle|^2\,, \tag{25.5}$$

where A_{L}, A_{R} are the spectral functions of the two lead electrodes connecting the scattering region. The scattering rate can further be rewritten in terms of the scattering states of the two lead electrodes ($|\Psi_{\mathrm{r}}\rangle$ or $|\Psi_{\mathrm{l}}\rangle$). Equation (25.5) thereby resembles Fermi's golden rule and if the scattering states are known, selection rules based on the symmetry of the scattering states and e–ph coupling can be derived.

The forward (back) scattering forms a peak (dip) in IETS. The variation of the current can be estimated by

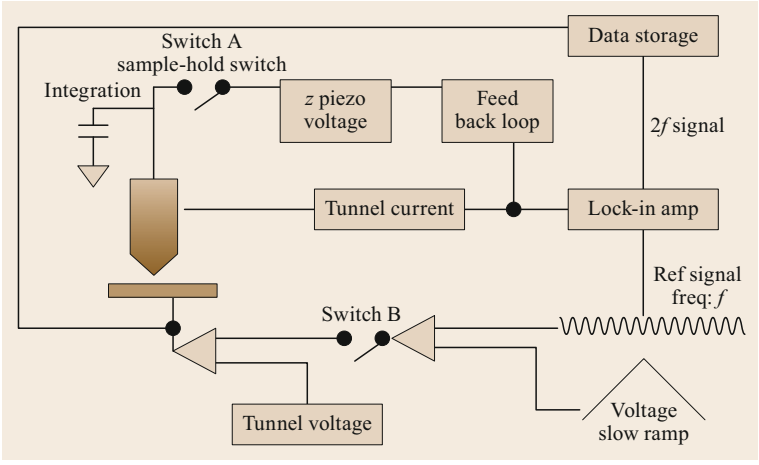

Fig. 25.11 A schematic drawing of an STM-IETS setup. IETS spectroscopy is measured by turning off the feedback circuit (switch A) and applying slow-ramping voltage in which a sine-shape modulation voltage is superimposed (frequency ≈ 797 Hz) to the sample bias by closing switch B. The differentiation of the tunneling current is executed by the use of a lock-in amplifier. (Reprinted from [25.2], with permission from Elsevier)

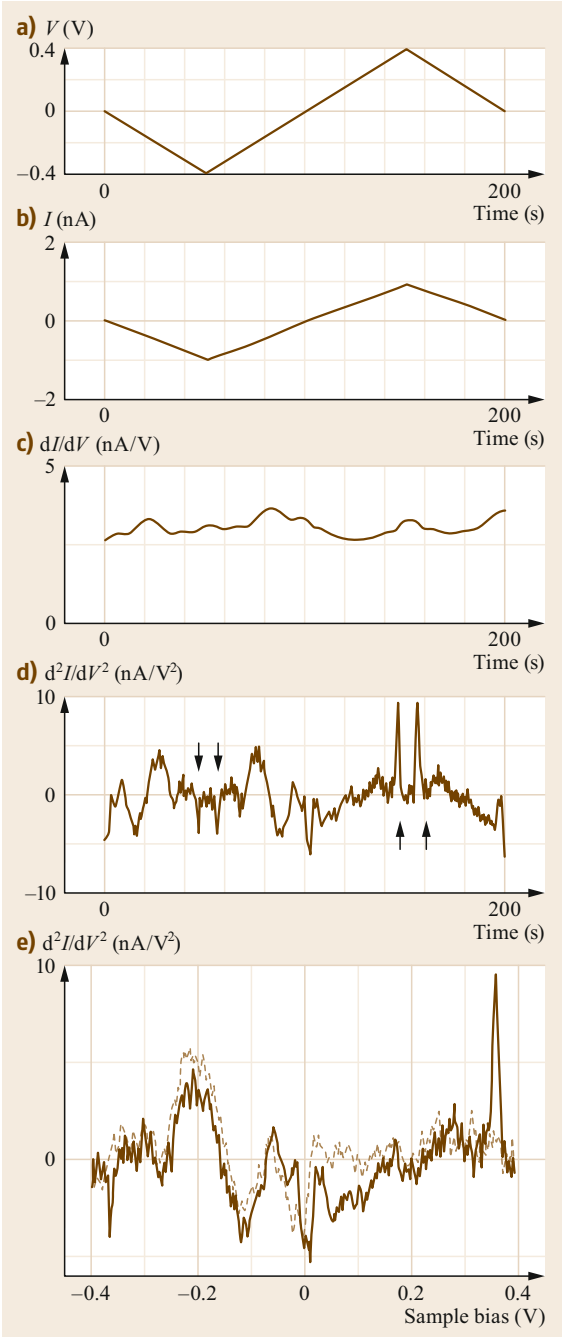

Fig. 25.12a–e Variation of sample bias **(a)**, and tunneling current **(b)**, the output of the lock-in amplifier of the harmonic **(c)**, and the second harmonic component **(d)** as a function of the measurement time of the STM-IETS of a *trans*-2-butene molecule on Pd(110). All graphs are the average of 16 cycles of the measurements (see text). The *arrows* indicate sharp features corresponding to the ν(C−H) vibrational mode. **(e)** The d^2I/dV^2 versus V spectra obtained on a *trans*-2-butene molecule (*solid curve*) and on the bare Pd(110) surface (*dashed curve*). (Reprinted from [25.59], with the permission of AIP Publishing) ►

the scattering rate which can be evaluated using (25.5), which will be introduced later on in this chapter. The crossover from peak to dip in simplified models occurs at a transmission of 1/2 [25.46].

25.2.6 Experimental Setup of STM-IETS

An example of the experimental setup used in STM-IETS is shown in Fig. 25.11. Conventional STS measurement can be executed by recording the I–V curve followed by numerical differentiation. This procedure is possible because the natural width of electronic states is of the order of ≈ 1 eV and there is no special technical difficulty in taking the numerical derivative of the I–V curve. Conversely, the vibrational features have quite a narrow peak width of the order of 1 mV, which makes it quite difficult to obtain d^2I/dV^2 by numerical differentiation. Instead, lock-in amplifier detection using a voltage modulation method is required. The measurement of the lock-in amplifier signal requires a relatively long acquisition time of the order of ≈ 100 s to get a single spectrum. The change of relative location between the tip and the molecule may then be critical; stability is therefore required both for lateral and horizontal directions. Attention should be paid to both the mechanical stability of the STM head and to the reproducibility of the control electronics [25.57, 58].

An example of an IETS measurement is shown in Fig. 25.12a–d, where the variation of bias voltage, tunneling current, dI/dV, and d^2I/dV^2 are displayed as a function of time. The data were obtained for a *trans*-2-butene molecule adsorbed on Pd(110). The curves of d^2I/dV^2 versus V are shown in Fig. 25.12e by comparing the spectra obtained on the bare metal substrate (dashed line) and on the adsorbate (solid line). Sharp features can be identified at the sample bias of −363 and 360 mV only in the spectrum obtained on the molecule. The former appears as a dip and the latter is a peak which satisfies the conditions for the assignment to a vibration-induced feature. The intensity of the positive peak is $\approx 9.5\,\mathrm{nA/V^2}$ and the full-width-at-half-maximum (FWHM) is ≈ 12 mV. Though there are several other vibrational modes, they are not as obvious as the mode identified as the ν(C−H) mode [25.59].

Low-Temperature STM System

As mentioned above, IETS is an all-electron spectroscopy method whose resolution has a linear relation with the system temperature except for the modulation

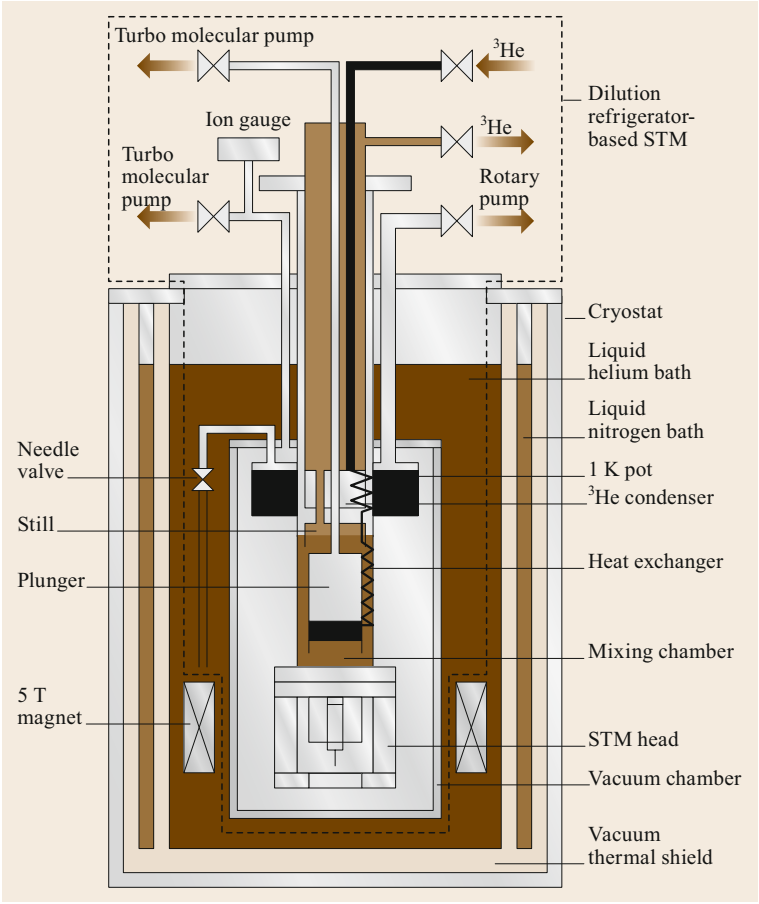

Fig. 25.13 Schematic of a compact ultralow-temperature STM system. The cryostat is mounted on a vibration-isolation table (not shown). (From [25.60]. © IOP Publishing. Reproduced with permission. All rights reserved)

voltage and the intrinsic peak width. Thus, lowering the temperature of the STM system is beneficial both for mechanical stabilization (elimination of the thermal drift) and for improvement of the resolution of the IETS spectroscopy. An example of an STM system based on a dilution refrigerator-type STM is shown in Fig. 25.13 [25.60]. The cryostat and dilution refrigerator (TC330-SCM and TS-3H100, Taiyo Nissan, Japan), and the STM unit (USSS-9990, Unisoku, Japan) are both commercially available. The cryostat consists of a 57 L liquid helium bath, a 26 L liquid nitrogen bath, a vacuum thermal shield, and a 5-T superconducting electromagnet. The cryostat is mounted on a vibration-isolation table (AWF-1510DTU, Meiritsu Seiki Co., Japan) (not shown). By using this setup and operating the dilution refrigerator, we can acquire IET spectra at a temperature of 260 mK [25.60]. However, for the vibrational spectroscopy of alkanethiol molecules the resolution of the spectra at 260 mK showed no improvement over those obtained at 4.4 K because of other experimental factors. Details of the operating principles of the dilution refrigerator are given elsewhere [25.60].

This system is operated by cooling with liquid He and once filled to full volume, the STM can work at a stable temperature of 4.4 K for 48–72 h without requiring a further supply of liquid He.

The dilution-refrigerator-based STM system is illustrated in Fig. 25.14a while the STM head is shown in Fig. 25.14b. A sample can be transferred from the bottom of the STM unit. The STM system can be operated in the following two configurations:

1. The system works in a stand-alone manner. The sample is loaded in an inert gas atmosphere, followed by pumping with a turbo molecular pump (TMP) for 24 h. After that, the system is immersed into the liquid He bath. The operation of the TMP is discontinued once the bath is filled with liquid He. The wall of the chamber works as a cryogenic pump.
2. The bottom of the STM system of Fig. 25.14a is connected to a Ultrahigh Vacuum (UHV) system via a connection which goes through the liquid He bath. With the use of a long vertical magnetic loading

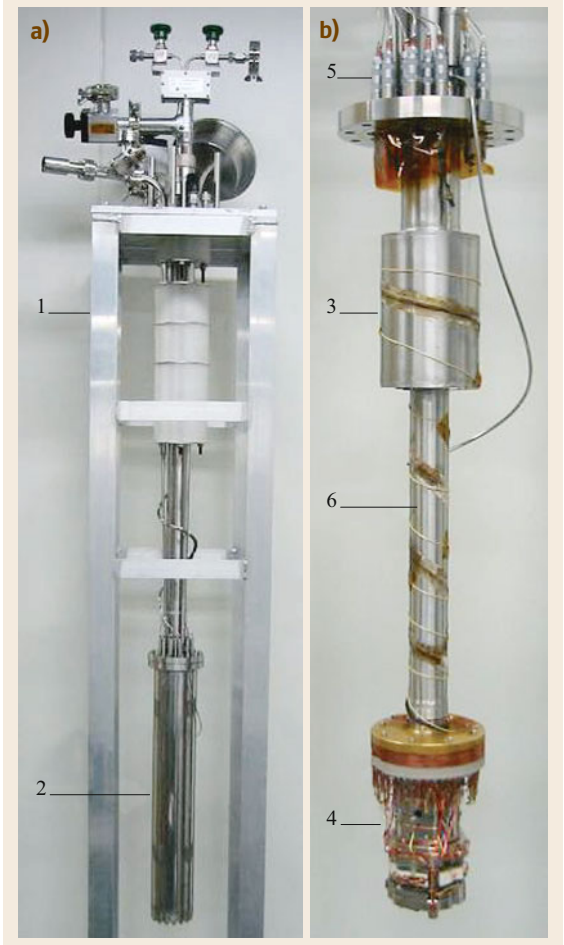

Fig. 25.14 (a) The dilution refrigerator-based STM, (1) support table, (2) vacuum chamber; **(b)** the inner structure of the vacuum chamber, (3) 1 K pot, (4) STM head, (5) wires for the scanner piezo, shear piezo, sample bias and thermometer, (6) circular cylinder. (From [25.60].)

system, the sample can be prepared in a separated preparation chamber and transferred into the STM head under UHV conditions. The second method is more straightforward in terms of the sample surface quality compared to the first one. However, the He cryostat dewar must be disassembled for the maintenance of the STM head. The particular study shown below for the alkanethiol molecule was performed using the first method.

The coarse motion of the STM is operated using a slip and stick motion, which allows for a maximum movement of the X–Y stage of ± 0.5 mm. The maximum scan area of the STM piezo tube for X–Y is $3.4 \times 3.4\,\mu m^2$ at 300 K and $1.0 \times 1.0\,\mu m^2$ below 4.4 K. The coarse motion and scanning of the STM is controlled by commercially available units (PMC100 and SPM100, RHK, Troy) and operated using their accompanied software (XPM, RHK, Troy).

Measurement of I–V Derivative by Using Lock-in Amp

The normal inelastic signal originating from a vibrational mode with energy $h\nu$ appears as a step-like feature at the sample bias of $h\nu/e$ in the dI/dV curve and a peak or a dip at the sample bias of $h\nu/e$ in the d^2I/dV^2 curve. Use of a lock-in amplifier is effective for obtaining high-precision dI/dV and d^2I/dV^2 curves. A schematic of the IETS measurement system is shown in Fig. 25.15a. The modulation voltage ($\Delta V \sin(2\pi ft)$) is applied to the sample bias (V). In this case, the tunneling current (I) can be approximated as

$$I[V + \Delta V \sin(2\pi ft)] \approx I(V) + \frac{dI}{dV}\Delta V \sin(2\pi ft) + \frac{d^2I}{dV^2}\frac{(\Delta V)^2}{4}\sin\left(4\pi ft - \frac{\pi}{2}\right) + \frac{d^2I}{dV^2}\frac{(\Delta V)^2}{4}\,. \quad (25.6)$$

Hence, dI/dV can be obtained by detecting the AC current modulated at f, and d^2I/dV^2 can be obtained by detecting the AC component modulated at $2f$ where the phase of the modulation current is delayed by $-90°$ compared to that of the modulation voltage. The modulation frequency was set in the range between 500 and 1000 Hz, and the cutoff frequency of the preamplifier was set to 1.5 kHz. The tunneling current was converted to a voltage signal by a preamplifier (IVP-PGA and IVP-200, RHK, Troy), which was then divided into two paths: one is to an input of an STM controller (SPM100, RHK, Troy), for gap control, and the other to a lock-in amplifier (NF5640, NF Corp., Yokohama), for the conductance and the IET signal measurement. The output of the lock-in amplifier was recorded using an STM controller (Fig. 25.15a).

The phase shift between the modulation voltage and output modulation current resulting from the wiring and tunnel-junction configuration should be calibrated beforehand with the method described as follows. First, the STM tip is retracted by a few tens of nm from the surface to a point where the tunneling current cannot be detected. Next, a modulation bias with frequency f is applied to the sample, producing an AC current (displacement current) with frequency f. This AC current is produced solely due to the capacitance between tip and

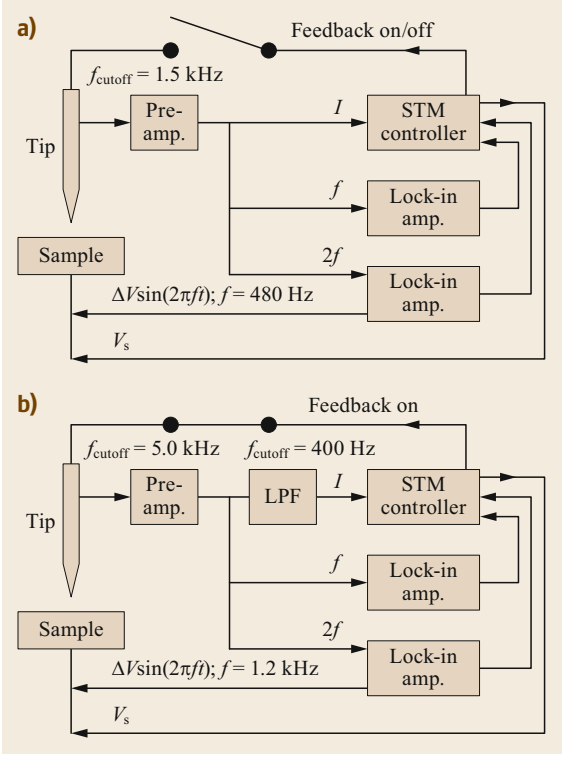

Fig. 25.15a,b Schematic drawing of **(a)** a conventional IETS measurement system and **(b)** an improved mapping system for the IET signal (From [25.61]. © IOP Publishing. Reproduced with permission. All rights reserved)

sample. By maximizing the magnitude of the AC current using the lock-in amplifier, the phase shift between the input modulation voltage and output modulation current can be determined. The phase shift for the frequency $2f$ can also be estimated by repeating the same procedure. This phase shift is stable and it is not necessary to repeat the phase determination process once it has been determined.

25.2.7 Spatial Mapping of IETS

Mapping of IET signals is an effective method for visualizing the distribution of a characteristic feature of a molecule on a surface [25.45, 62]. *Sainoo* et al. reported a mapping method of IET signals using a conventional measurement system (Fig. 25.15a), where the feedback loop is activated during the mapping process [25.59]. In order to minimize the effect of the modulation voltage on the feedback loop, they employed a high-frequency modulation voltage and a low time constant on the feedback loop. However, the restriction of the time constant on the feedback loop and remnant effects of the modulation voltage on the feedback system prevent a good topographic image and IETS mapping from being obtained for a high tunneling resistance sample like alkanethiol SAMs. Actually, in a mapping experiment using the same setup, it was not possible to obtain satisfactory IET mapping for a hexanethiol SAM.

In order to solve this problem, the AC component of the tunneling current signal, which is used for gap-distance control, is minimized [25.61]. This is achieved by inserting a low-pass filter (3314, NF Corp., Yokohama) between the preamplifier and the STM controller (Fig. 25.15b), which results in a reduction of the feedback response by the modulation voltage. The modulation frequency is set at 1.2 kHz, the cutoff frequency of the preamplifier at 5 kHz and the cutoff frequency of the low-pass filter at 400 Hz. The attenuation slope of the low-pass filter was 48 dB/oct, making the transmission rate of the modulation current less than 0.1% at 1.2 kHz. Under this condition, we could see no change in the modulation current for frequency f at the input of the lock-in amplifier, with or without the feedback loop engaged.

25.3 Survey of STM–IETS Reports for Various Systems

Here we examine examples of STM-IETS measured for various systems.

Organic molecules have often been targeted by IETS measurements. Investigation of a pyridine molecule on Ag(110) was reported by *Hahn* and *Ho* [25.63]. It revealed a C−H stretching mode at 378 meV and the isotope shift to 282 meV when deuterated.

Sainoo et al. reported a measurement for the cis-butene molecule on Pd(110) [25.64]. The IETS features were detected at 37 and 358 meV, which are assigned to the metal-molecule stretching mode and the C−H stretching mode, respectively.

In addition, they measured the yield of the rotation of the molecule as a function of the energy of the injected electrons, which they called *action spectroscopy* and is supposed to yield supplemental information for the vibration modes detected by STM-IETS. The result shows an enhancement of the rotation at 110 and at 115 meV, which are assigned to the excitations of C−C stretch and C−H bending modes, respectively, according to the energies reported for those modes. They claim that some modes are more apparent in action spectroscopy than in STM-IETS.

Since the bonding strength between the molecule and the substrate, and consequently the life-time of the vibrational mode has a substantial effect on the yield of the STM-IETS signal, much effort has been put into the search for a good substrate. The substrate NiAl(110) after oxidation was used to decrease the interaction between the molecule and the substrate, since the oxide can still show an atomic-scale flatness. *Nilius* et al. demonstrated that an attachment of CO molecules to a Pd atom, both of which are adsorbed on oxidized NiAl(110), is possible by using the atom manipulation technique [25.65]. The CO's hindered rotational mode is then measured at 40 meV and the C−O stretching mode at 258 meV, whose energies are appropriate for the formation of metal-CO clusters. Liu et al. measured the STM-IETS for the molecule of 4,7,12,15-tetrakis[2,2]paracyclophane (DMAS-PCP) on the same surface. A feature at 25 meV is assigned to out-of-lane C−C−N and CC−C bending, and that at 179 meV is assigned to in-plane CC−H bending, in addition the feature at 365 meV corresponds to the C−H stretch in the CH_2 group [25.66].

Organic molecules consisting of a large number of atoms have also been investigated with STM-IETS techniques. One example is a tetramantane diamondoid molecule adsorbed on Au(111), in which a feature was detected at 356 meV corresponding to the C−H stretching mode [25.62]. A tetracyanoethylene (TCNE) molecule on Cu(111) was reported to show features at 5.1, 13.3, 21.9, 35.7 meV originating from $=C-(CN)_2$ rocking modes [25.67]. Phthalocyanine molecules, a popular molecule in surface science investigations, have also been investigated with the IETS technique. A double-layer island of cobalt phthalocyanine (CoPc) on Cu(111) showed a feature at 20 meV, which was attributed to a vibration mode of the benzene ring against the substrate [25.68]. Mugarza reported the vibration modes of CuPc and NiPc adsorbed on an Ag(100) surface. Various modes in the energy range between −100 and 100 meV were detected. The authors claimed that the observed modes imply distortion of Cu−N bonds. The vibrational features are observed when the tip is placed in the center of the molecule, while the Kondo resonance feature due to the presence of an unpaired π orbital is observed at the perimeter of the molecule [25.69].

In addition, fullerene groups have been studied by STM-IETS from the early stages of this research. *Pascual* et al. measured STM-IETS for C_{60} on Ag(110), in which a feature at 52 meV was detected and was assigned to the $H_g(\omega_2)$ mode [25.70]. They found an intensity variation which is correlated with the adsorption configuration. The results were explained considering that symmetry of the resonant states associated with the vibrational mode determines the intensity of the IETS feature. The IETS spectrum of metallofullerene of Gd@C82 adsorbed on Ag(001) shows a feature at 43 meV which appears in a spatially restricted region. This feature is assigned to the cage mode and the spatial localization is attributed to the distribution of the electronic state with which the vibrational mode is coupled [25.71].

Phonons of metal substrates were investigated by *Gawronski* et al. using STM-IETS. They detected phonons at surfaces at 9 and 21 meV for Au(111) and Cu(111) surfaces, respectively. It should be noted that the spatial variation of the phonon excitation for Au(111) measured by mapping IETS signals displays an atomic resolution, which is explained in terms of site-specific phonon excitation probabilities [25.72].

25.4 In-Depth Analysis of IETS of an Alkanethiol Molecule

As stated already, the combination of STM and IETS can be beneficial. STM can give atomic-scale resolution and be combined with other surface-science analysis techniques. Meanwhile, in recent studies of molecular electronics or single-molecule devices there has been rising interest in IETS measurements. Such studies became feasible thanks to the development of electrodes with an atomic-scale gap, between which a molecular bridge is formed. It is necessary to execute chemical analysis for a molecule in the gap, and IETS is a promising technique. However, even for an identical molecule, the IETS spectra fluctuate among various types of devices [25.25]. Thus, an effort has been made to compare IETS data systematically for alkanethiol SAM films. The molecules form a well-defined SAM on a Au(111) surface, which has been characterized with a variety of surface analysis techniques [25.73].

25.4.1 Nonisotope Alkanethiol SAM

Several devices with such atomic-scale electrodes and alkanethiol SAM are illustrated in Fig. 25.16. Figure 25.16a shows a mechanical break junction (MBJ) system [25.74]. By bending a thin foil of metal mechanically, it is possible to make a crack in the foil and use it as a nm-scale gap. The gap size can then be controlled by the pushing force.

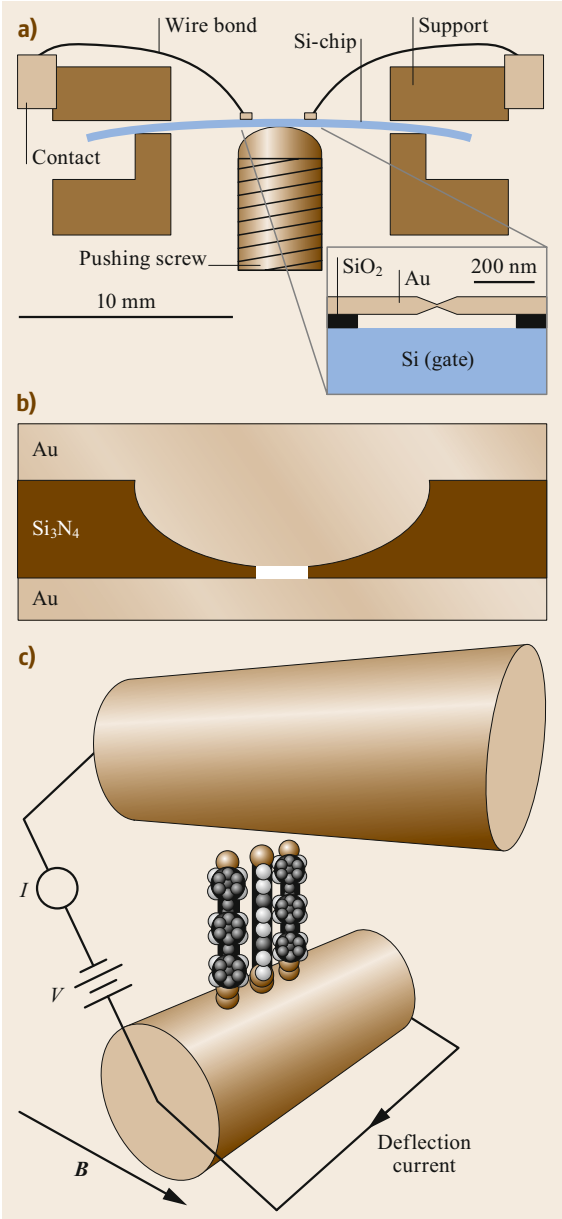

Fig. 25.16a–c Devices employed for single-molecule measurement: **(a)** mechanical break junction. (Reprinted with permission from [25.76]. Copyright 2002 by the American Physical Society)

A device fabricated with a more sophisticated Si process is shown in Fig. 25.16b and called the *nanopore* device [25.77]. In the particular device shown here, an Si_3N_4 film is formed above an Au substrate, which is scratched by an etching technique. The etching makes the Si_3N_4 thinner with a shape described in the figure. Eventually a hole appears in the center and the etching is stopped. By using this procedure, it is possible to make a nm-scale hole on an Au substrate. On the Au surface through the hole, the alkanethiol SAM is formed, which is covered by a top Au electrode. The final device consists of a monolayer of alkanethiol molecules of limited lateral size.

A *cross wire* device is shown in Fig. 25.16c [25.76]. First, an Au wire whose surface is covered with the alkanethiol SAM is prepared. Then a second Au wire with a bare surface is placed near the first wire. The two wires are attached using the electromagnetic force between them.

Macroscopic vibrational spectroscopies using IRAS and HR-EELS have been reported for alkanethiol SAMs. For example, the investigation of vibrational modes with energies between a few tens and 200 meV provides information inherent to the molecules in question. These modes can be used to identify the molecules investigated, thus they are called fingerprint modes. As already discussed, the vibrational modes corresponding to changes in the dipole moment perpendicular to the surface normal appear as strong peaks [25.78].

Before going into the discussion of IETS, we examine the results of HR-EELS measurements for vibrational features of an alkanethiol SAM. *Kato* et al. prepared alkanethiol SAMs on Au(111) surfaces with various lengths $(CH_3(CH_2)_{n-1}S/Au(111)$, $2 \leq n \leq 18)$ [25.79]. With their sample preparation, they could fabricate a SAM with large, well-ordered domains. By virtue of this sample property, they were able to obtain good EELS signals in dipole scattering. Vibrational modes like the CH_2 rocking mode at 89 meV, the CH_3 s-deformation mode at 171 meV, and the CH_3 d-deformation or CH_2 scissor modes at 180 meV are clearly visible (Fig. 25.17). Besides these large signals, weak features are identified, including Au–S stretching modes at 28 and 32 meV, a CH_3 rocking mode at 113 meV, a C–C stretching mode at 130 meV, and a CH_2 twist mode at 157 meV.

Among these detected signals, the CH_3 s-deformation mode with the energy of 171 meV shows a strong even–odd effect on the number of carbon atoms that constitute the alkyl chain. When it is even (odd), the signal becomes strong (weak). This result is consistent with the geometrical structure of the alkanethiol SAM shown in the inset of Fig. 25.17. In the case of the even number, the terminal methyl group points in a direction perpendicular to the surface. Thus, the change in dipole moment perpendicular to the surface is large, providing strong dipole scattering. Conversely, in the case of an odd carbon number, the terminal methyl group points in

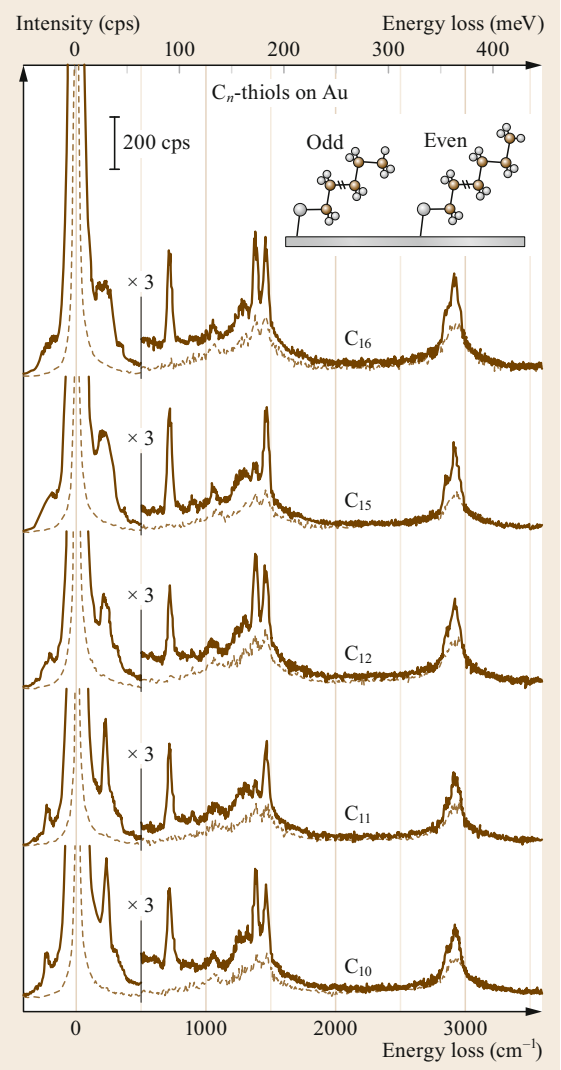

Fig. 25.17 HR-EEL spectra for various alkanethiol (C_n-thiol) SAMs on Au. The *solid* and *dashed lines* correspond to specular spectra detected at 60° and off-specular spectra detected at 42°, respectively. The *inset* shows schematic models of an alkanethiol SAM structure for an odd and even number of carbons. (Reprinted adapted with permission from [25.79]. Copyright (2002) American Chemical Society)

a direction parallel to the surface, resulting in a smaller change in the dipole moment in the perpendicular direction and little dipole scattering.

Kato et al. also investigated impact scattering for alkanethiol SAMs with EELS, where the vibrational signals, prominent in dipole scattering, such as the CH_2 rocking mode at 89 meV, the CH_3 s-deformation mode at 171 meV, and the CH_3 d-deformation or CH_2 scissor mode at 180 meV, are decreased and become comparable to the peak intensity of the C−C stretching signal at 130 meV (see the dashed lines in Fig. 25.17). In other words, the selection rules for impact scattering are more relaxed than those for dipole scattering.

The even–odd effect of an alkanethiol SAM is also observed in IRAS for the C−H stretching mode of the terminal methyl group [25.80]. The terminal methyl group points in a perpendicular direction when the carbon number is even. In this case, the change in dipole moment originating from the symmetric stretch of the methyl group is larger than that in the case of an odd carbon number. Thus, the strong C−H symmetric stretching signal is detected in the case of an even carbon number, but not when there is an odd number of carbons.

Formation of Alkanethiol SAM and STM

A SAM film of alkanethiol can be formed following established methods [25.73]. First, Au/mica sample (Keysight Technologies, Santa Rosa) is annealed in air using a hydrogen torch. Immediately upon annealing, the sample is immersed in an ethanol solution of octanethiol (1 mM) for 24 h or hexane solution of octanethiol (1 mM) for 6 min, and rinsed with ethanol before being inserted into the vacuum chamber for the STM inspection.

The use of partially/fully deuterated alkanethiol SAMs contributes to the peak assignment of the IETS peaks. Partially deuterated alkanethiols can be synthesized from commercially available $CD_3(CH_2)_7Br$ and $CH_3(CH_2)_6CD_2Br$ (C/D/N Isotopes, Point-Claire) following the established scheme [25.81]. Gas chromatography–mass spectrometry showed that the purity of the final product was 94.4% ($CD_3(CH_2)_7SH$) and 98.7% ($CH_3(CH_2)_6CD_2SH$), respectively.

Figure 25.18 shows a topographic image of the prepared octanethiol SAM on an Au(111) surface measured at 4.4 K, where the sample bias (V_s) and current (I_t) of the set point are $V_s = -2.5$ V and $I_t = 83$ pA, respectively [25.82]. An ordered structure of the octanethiol SAM with $(\sqrt{3} \times \sqrt{3})$R30° structure in register with the substrate of Au(111) is visible, which is consistent with previous reports [25.73] and the theoretical simulations (Fig. 25.19). Note that this well-ordered structure is usually observed before and after IETS measurements, i.e., showing the stability of the surface condition.

The gap between the tip and molecule should be measured before performing the IETS measurement. This can be examined by monitoring the tunneling current while the gap distance is varied, which is often called I–z spectroscopy. The I versus z curve shown in Fig. 25.20 was measured by approaching the tip at a rate of ≈ 0.35 Å/s from the initial position ($z = 0$)

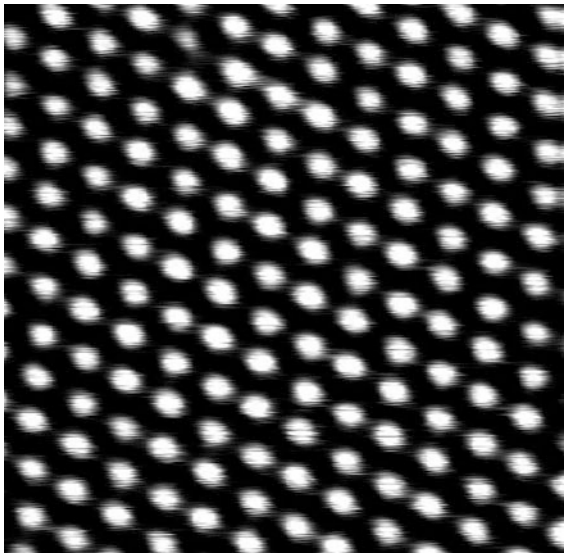

Fig. 25.18 Topographic STM image of an octanethiol SAM on Au(111) ($5.4 \times 5.4\,\mathrm{nm}^2$, $I_t = 83\,\mathrm{pA}$, and $V_s = -2.5\,\mathrm{V}$). (Reprinted with permission from [25.82]. Copyright (2008) by the American Physical Society)

defined by the conditions of $I_t = 10\,\mathrm{pA}$ and $V_s = 500\,\mathrm{mV}$, where the vertical axis is expressed on a log scale [25.82]. The measured I versus z curve can be fitted with a straight line at the initial stage of approach ($z < -1.5\,\text{Å}$). This fitting curve can be expressed as $I \propto \exp(-\alpha z)$ with $\alpha = 2.0\,\text{Å}^{-1}$, where the decay constant α is comparable with those previously reported for the vacuum tunneling barrier of $\alpha = 2.4\,\text{Å}^{-1}$ [25.83]. After reaching $z = -1.5\,\text{Å}$, which gives $I_t \approx 0.2\,\mathrm{nA}$ at $V_s = 500\,\mathrm{mV}$, the curve shows a bend and is deviated from a straight line. The slope after the bend can be estimated as $I \propto \exp(-\beta z)$, with $\beta = 1.1\,\text{Å}^{-1}$ at its initial stage. However, β becomes smaller when the tip gets closer to the surface. The decay rate of the tunneling current through a monolayer of alkanethiol SAM was previously analyzed by *Bumm* et al. for SAMs with various chain lengths ($CH_3(CH_2)_{n-1}S$) [25.84]. They employed a two-layer model in which the vacuum layer and the SAM layer were assumed to have independent decay constants for the electron tunneling. With this model, the tunneling current variation with the SAM layer thickness was estimated to be $I \propto \exp(-\beta z)$ with $\beta = 1.2\,\text{Å}^{-1}$ [25.84]. The tip and the SAM are in contact at $z = -1.5\,\text{Å}$ and the electron decay length in the SAM layer is close to the value that has been determined by Bumm et al. shortly after the contact. The decay length becomes smaller with further approach of the tip to the substrate, which is speculated to be due to a conformational change in the molecule layer caused by the tip.

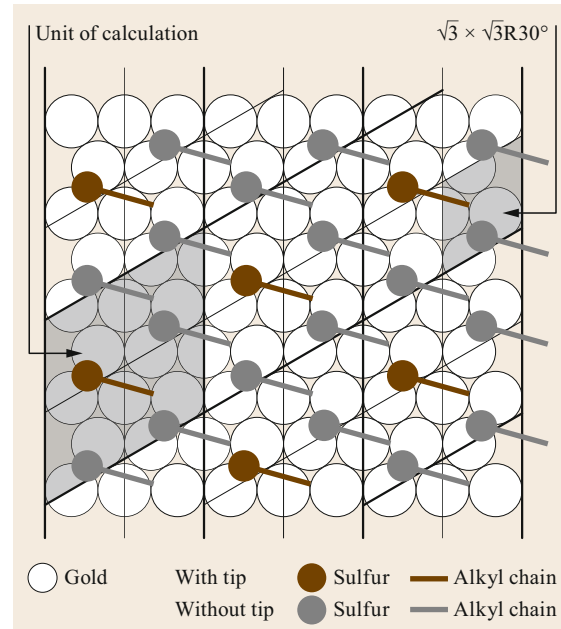

Fig. 25.19 Schematic showing an octanethiol SAM on Au(111). The unit cell used in the IETS calculation is shown by *thick black lines*. The STM tip modeled by one protruding Au atom was placed approximately over the end group of the octanethiol whose alkyl chain and sulfur atom are depicted in *brown* (*gray* for without the tip). (Reprinted from [25.25], with permission from Elsevier)

IETS of Alkanethiol SAM

In this section, we examine the detail of an IET spectrum for an octanethiol SAM on Au(111) at 4.4 K. Before recording the IETS measurement a good topographic image like that shown in Fig. 25.18 is collected with a junction resistance of usually a few tens of GΩ. For the IETS measurement, the tip was placed on a protrusion of the STM image and was brought close to the surface and the junction resistance is reduced to 0.5 GΩ ($V_s = 500\,\mathrm{mV}$, $I_t = 1\,\mathrm{nA}$). This set point was chosen because higher current is required for the IETS than for topographic imaging to improve the signal-to-noise ratio. Judging from the I–z curve in Fig. 25.20, the tip is about 1.5 Å inside the molecule layer from the contact point. Further lateral tracking of the tip position was not executed. However, the drift of the tip along the lateral direction was limited and was less than one unit of the alkanethiol lattice (5 Å) for 1 day. The data of I versus V, $\mathrm{d}I/\mathrm{d}V$ versus V, and $\mathrm{d}^2I/\mathrm{d}V^2$ versus V were simultaneously recorded both for the increasing and decreasing voltage ramp between 500 and −500 mV, where the feedback loop was open for 14 min. For this interval, the current change due to the

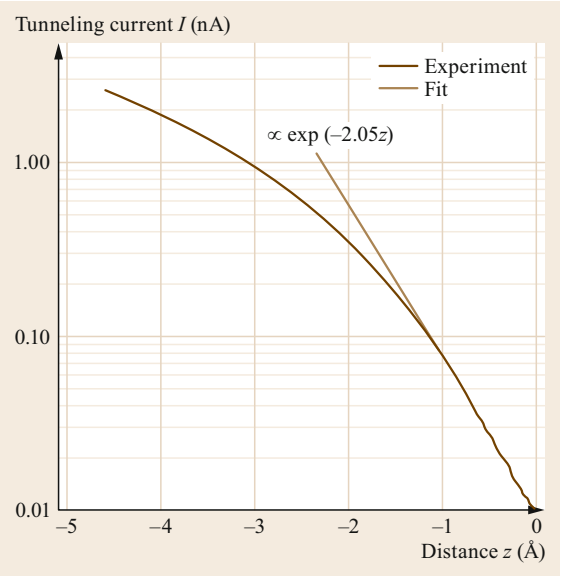

Fig. 25.20 Variation in the tunneling current when the tip approaches the surface (I–z curve). The tip approached at a rate of ≈ 0.35 Å/s from the initial position of $I_t = 0.01$ nA and $V_s = 500$ mV. The *linear line* is the result of a least square fit with a function of $I \propto \exp(-\alpha z)$. (Reprinted with permission from [25.82]. Copyright (2008) by the American Physical Society)

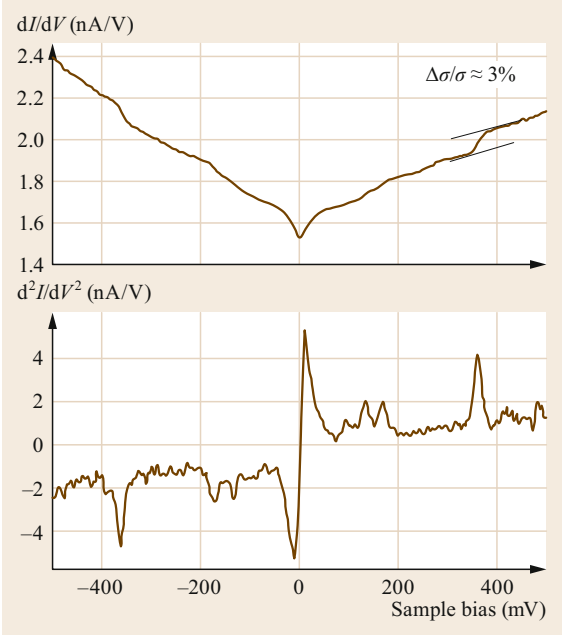

Fig. 25.21 Plot of d^2I/dV^2 versus V for an octanethiol SAM on Au(111) at 4.4 K. The tip was positioned at $I_t = 1$ nA and $V_s = 500$ mV. A modulation voltage of $V_{rms} = 7.2$ mV has been added. The plot is an average of 32 cycles of measurements, taking ≈ 7 min for each cycle. (Reprinted with permission from [25.82]. Copyright (2008) by the American Physical Society)

thermal drift along the vertical direction was less than 3% in average. The spectra in Fig. 25.21 are an average over 32 scans, each of which took 7 min, with a total acquisition time of about 4 h. A modulation voltage of 7.2 mV (rms) and a modulation frequency of 480 Hz were used. It was confirmed that the tunneling current at 480 and 960 Hz contained no periodic noise by executing its fast Fourier transform. The time constants of the two lock-in amplifiers were both set at 100 ms.

The acquired d^2I/dV^2 versus V and dI/dV versus V plots are shown in Fig. 25.22 [25.82]. The vertical axis was calibrated by comparing the numerical derivation of the I versus V and dI/dV versus V curves with the outputs of the lock-in amplifiers. The d^2I/dV^2 versus V curve shows features that appear at symmetric energy positions with respect to the Fermi level with a reversed polarity (Fig. 25.22). These features satisfy all the conditions required to assign them as vibrational features [25.4]. Among several peaks originating from vibrational modes, we can see that a prominent feature appears at the energy of ± 361 mV which can be attributed to the C−H stretching mode (ν(C−H)). In the papers so far reported, the ν(C−H) feature dominates the IET spectra. The other vibrational features are less obvious, except for the metal–molecule vibration modes [25.27, 50, 58, 64]. Conversely, the spectrum of Fig. 25.21 shows clear peaks between 50 and 200 meV. They also satisfy the criteria for assigning them to the vibrational modes, which include C−H bending modes and a C−C stretching mode. The conductance change ($\Delta\sigma/\sigma$), estimated from dI/dV, is $\approx 3.0\%$ for the C−H stretching mode (361 mV) and $\approx 1.2\%$ for the CH bending mode (171 mV). The measured $\Delta\sigma/\sigma$ for the C−H stretching mode exceeds 10% in the case of the C_2H_2 molecule [25.27]. However, other modes like C−H bending and C−C stretching were not detected. Thus, the detection of C−H bending and C−C stretching modes in the current study indicates a high yield of these modes for the alkanethiol SAM. Precise assignment of these modes and reasons for the high yields are discussed in later sections.

Tuning of Experimental Conditions for Better IETS

Here the calibration of the IETS spectra is discussed. As an example, the spectra obtained for the alkanethiol SAM is shown in Fig. 25.22. The brown lines in Fig. 25.22a–c, correspond to I, dI/dV (output of the lock-in amplifier), and d^2I/dV^2 (output of the other

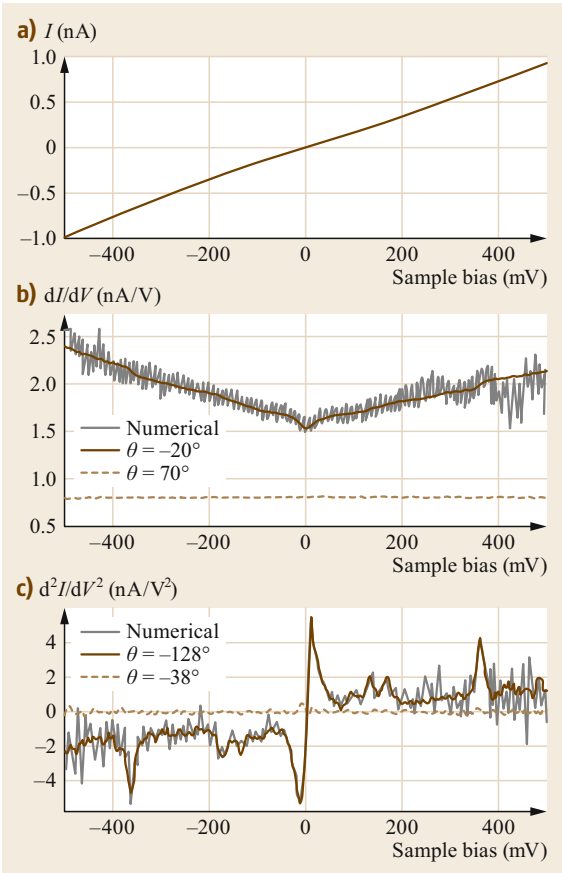

Fig. 25.22 **(a)** I versus V for the octanethiol SAM at 4.4 K ($V_s = 500$ mV, $I_t = 1$ nA). **(b)** The *brown line* corresponds to the dI/dV versus V acquired by the lock-in amplifier with the adjusted phase condition. The *gray line* is the numerical derivation of the I versus V. The *dashed line* is the output of the lock-in amplifier measuring the f component where the phase was 90° different from that in the case of the *brown line*. **(c)** The *brown line* is the d^2I/dV^2 versus V acquired by the other lock-in amplifier with the adjusted phase condition. The *gray line* is the numerical derivation of the dI/dV (*brown line* in **(b)**). The *dashed line* is the output of the other lock-in amplifier measuring the $2f$ component where the phase is 90° different from that in the case of the *brown line*. (From [25.60]. © IOP Publishing. Reproduced with permission. All rights reserved)

lock-in amplifier), respectively [25.60]. The gray line in Fig. 25.22b is the numerical derivation of I versus V, by which the absolute value of dI/dV versus V, obtained with the lock-in amplifier, is determined. The one for the d^2I/dV^2 (brown line in Fig. 25.22c) is also determined by repeating the same process. Note that the fluctuation in the noise level of the dI/dV versus V and d^2I/dV^2 versus V curves by the lock-in amplifiers are smaller than those obtained by the numerical derivations.

The dashed line in Fig. 25.22b is the output of the lock-in amplifier for the f component, where the phase is rotated by 90° from that of the brown line in Fig. 25.22b. The dashed line is almost constant for the entire bias voltage range, indicating that the phase of the lock-in amplifier for the measurement of the dI/dV versus V is correct. The capacitance between the tip and the sample, calculated from the magnitude of the dashed line, is 250 fF. The dashed line in Fig. 25.22c is the current component at the frequency of $2f$ detected by the other lock-in amplifier where the phase is rotated by 90° from that of the brown line in Fig. 25.22c. It also shows that the magnitude of the dashed line is zero for the bias range, which indicates that the phase for the d^2I/dV^2 versus V measurement is also correct.

The FWHM of the IET signal is described by the following relation

$$W^2 = (1.7V_{\mathrm{mod}})^2 + \left(\frac{5.4kT}{e}\right)^2 + W_1^2 , \qquad (25.7)$$

where k is the Boltzmann constant, T is the temperature, V_{mod} is the modulation voltage (rms), and W_1 is the intrinsic width of the peak [25.85]. Figure 25.23a shows a normalized d^2I/dV^2 versus V spectra in the energy range near the C–H stretching mode ($T = 4.4$ K, $V_s = 500$ mV, $I_t = 1$ nA), where the modulation voltage was systematically changed from 25.2 to 5.2 mV (rms) [25.60]. We can see a decrease of the peak width with a decrease in the modulation voltage. By further decreasing the modulation voltage to 2.7 mV, the peak seems to split into two components with energies located at 359 and 365 mV (Fig. 25.23b), both of which appear in the symmetric position around the Fermi level with the inversed polarity. To reach this accuracy, the spectra were averaged over 680 and 1600 scans, which took about 11 and 27 h, for the positive sample bias and the negative sample bias, respectively. In Fig. 25.23c, an IRA spectrum examined for the prepared octanethiol SAM on the Au surface is shown as a reference. Similar results had been reported previously [25.86–88] with the following peak assignment: peak A at 354 meV CH_2 symmetric stretch, peak B at 357 meV the CH_3 symmetric stretch by Fermi resonance, peak C at 362 meV the CH_2 antisymmetric stretch, peak D at 364 meV the CH_3 symmetric stretch by Fermi resonance, and peak E at 368 meV the CH_3 antisymmetric stretch.

In the IETS spectra obtained with $V_{\mathrm{mod}} = 2.7$ mV, a saddle is visible in the peak of Fig. 25.23b. In order to further discuss the origin of these two peaks, a smaller modulation voltage must be employed to obtain a higher resolution. However, the signal-to-noise

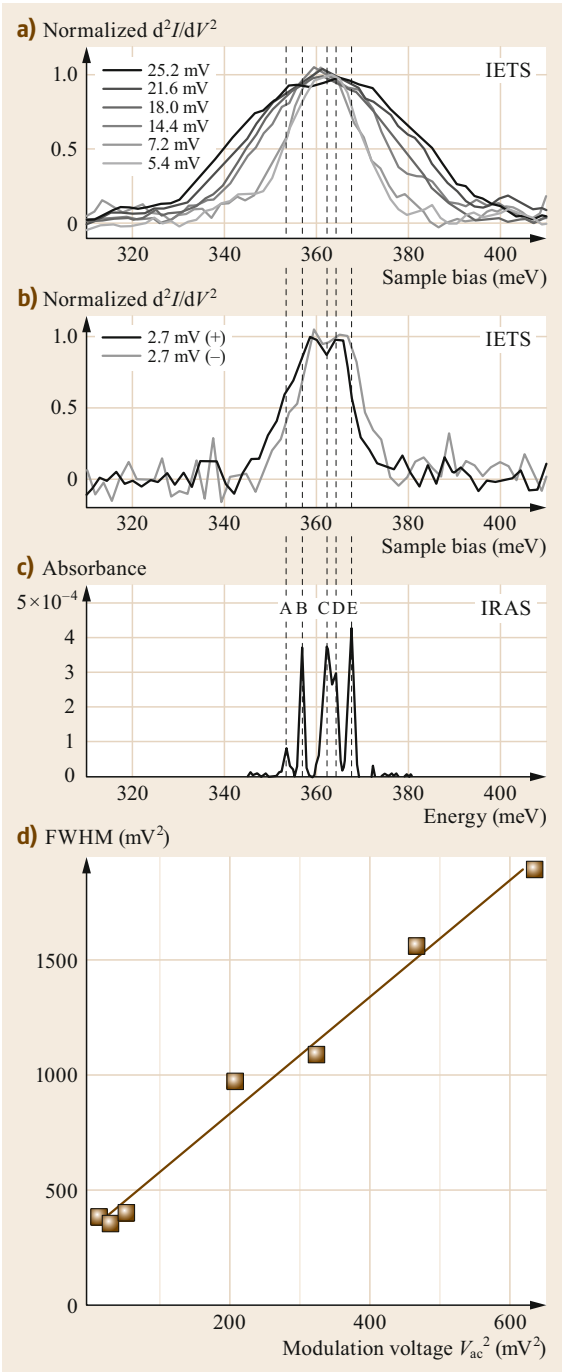

Fig. 25.23 **(a)** Normalized d^2I/dV^2 spectra around the energy of a C−H stretching mode for the octanethiol SAM at 4.4 K, where the modulation voltage is systematically varied ($V_s = 500$ mV, $I_t = 1$ nA). **(b)** The same as **(a)**, but in this case, the modulation voltage is 2.7 mV and the d^2I/dV^2 spectrum for negative bias is also shown. **(c)** Infrared reflection absorption spectrum for the octanethiol SAM on an Au surface at room temperature. **(d)** The square of FWHM of the CH stretching peak is plotted as a function of the square of the modulation voltage. ratio hampers the use of a smaller modulation bias voltage. Instead, a partial deuteration method is employed where all hydrogen atoms of the methyl group are replaced by deuterium atoms.

In Fig. 25.23d, the squares of FWHM of the C−H stretching peaks are plotted as a function of the square of the modulation voltage [25.60]. The solid line is the result of a least square fitting of the experimental results expressed by $W^2 = (1.6V_{mod})^2 + 352$. This experimental observation is reproduced by (25.7), though because of experimental error there is a slight discrepancy in the prefactor of V_{mod}. This relationship between the FWHM and modulation voltage is consistent with the previous report for C_2H_2 molecules on Cu(100) [25.57]. Considering that $5.4kT/e = 2.0$ mV at $T = 4.4$ K, W_1 is estimated to be 19 mV. This value is similar to the energy difference between peak A and E in Fig. 25.23c (14 meV).

In the previous section, we see that a higher resolution of the C−H stretching mode in IETS spectra can be obtained by reducing the modulation voltage. The same thing can be seen for the vibrational modes in the fingerprint region, as shown in Fig. 25.24 [25.82]. The modulation voltage V_{mod} is decreased to 3.6 meV, i.e., half of that used in Fig. 25.22 ($V_s = 500$ mV, $I_t = 1$ nA, $T_{sample} = 4.4$ K). The data is an average over 464 scans, which took about 24 h to be collected. Reference EELS data is shown in Fig. 25.24a. The energy positions of the detected vibrational features are compared with the result of the HR-EELS, and the assigned modes are listed in Table 25.1 with reference to HR-EELS, IRAS, and Raman spectroscopy [25.79, 86–89]. By comparison to these spectroscopic data, the IETS peaks can be assigned as follows: peak A is Au−S stretching, D is C−S stretching or CH_2 rocking, E is CH_3 rocking, F is C−C stretching, K is CH_3 s-deformation or CH_2 wagging, and L is CH_2 scissoring or CH_3 d-deformation. For some peaks, such as peaks E, K, and L, there are two candidates that can be discriminated using the technique of partial deuteration, as discussed later. Through such a comparison with the HR-EELS and IRAS data, we can conclude that STM-IETS is a useful tool for vibrational analysis of adsorbates.

Theory Versus Experiment

The overall property of the IET spectrum for an octanethiol SAM is compared to that obtained theoreti-

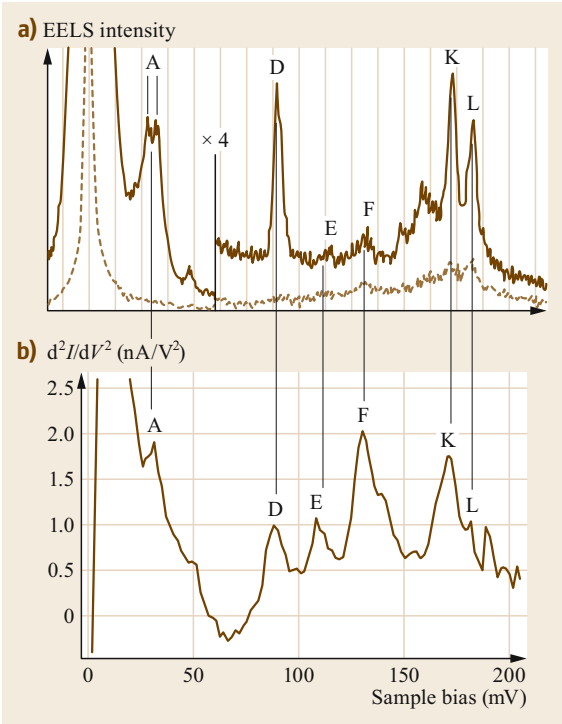

Fig. 25.24 **(a)** HR-EEL spectrum for an octanethiol SAM [25.79] and **(b)** high-resolution IET spectrum for the energy region of the C−C stretching mode and C−H bending mode of the octanethiol SAM ($V_s = 500$ mV, $I_t = 1$ nA, $V_{mod} = 3.6$ mV (rms), and $T = 4.4$ K) [25.82]. The peaks can be assigned as (A) Au−S stretching, (D) C−S stretching or CH_2 rocking, (E) CH_3 rocking, (F) C−C stretching, (K) CH_3 s-deformation or CH_2 wag, and (L) CH_2 scissor or CH_3 d-deformation. F	130	130	ν(C−C)
K	171	172	CH_3 s-deform./CH_2 wag
L	182	180	CH_3 d-deform./CH_2 scissor

cally in Fig. 25.25 [25.90]. The IETS peaks deduced both by experiment and theory are approximately symmetric with the applied bias and the features of the IET spectrum can be divided into (i) the low bias anomaly caused by the large number of low-energy vi-

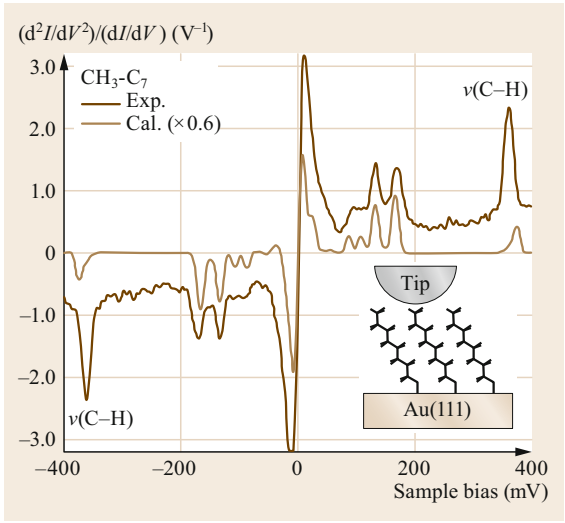

Fig. 25.25 Comparison between experimental (*dark brown*) and calculated (*light brown*) IET spectra for an octanethiol SAM. The broadening in both experiment and theory is determined by the temperature (4.4 K) and the lock-in modulation voltage ($V_{mod} = 7.2$ mV). (From [25.91]. © IOP Publishing. Reproduced with permission. All rights reserved)

brations, including gold phonons, (ii) the fingerprint region (≈ 50–200 meV, that can be used for a chemical identification of the molecule) that includes ν(C−S), ν(C−C), and CH bending modes, and (iii) C−H stretch modes (ν(C−H) ≈ 360 meV). Overall, the calculated IET spectrum reproduces that obtained by experiment. However, there are the following discrepancies: (i) magnitude of the zero bias anomaly [25.44], where we note that the low-frequency vibrations originating from the Au(111) substrate are not included in the calculations, (ii) intensity of the ν(C−H) mode is severely underestimated by theory. To investigate the latter problem, a partially deuterated alkanethiol is employed in a later section.

Comparison to Other Tunneling Junctions

In this section, we compare the STM-IETS results with those of the crossed-wire electrodes [25.44] and nanopore electrodes [25.77] (Fig. 25.26). The IET spectra measured using crossed-wire electrodes show extraordinarily good agreement with the current data, both in the energy positions and the relative intensities of the peaks. Even the anomaly at low bias shows a good agreement. Conversely, the comparison with the results obtained by using nanopore electrodes shows a poor agreement with those of STM-IETS. The results obtained by the nanopore experiment show a low intensity for the C−H stretching mode with a derivative-like line

shape, and unidentified peaks at ≈ 250–500 meV. Recently, *Yu* et al. fabricated a molecular junction using a crossed-wire whereby metal impurities were intentionally incorporated among the molecules [25.92]. The junction with metal impurities shows peaks similar to those observed by *Wang* et al. [25.77], suggesting the possibility of the incorporation of metal impurities during the formation process of the top electrodes in the nanopore device. We should consider that the crossed-wire junction lead electrodes to less damage of the alkanethiol molecules in the junctions.

25.4.2 IETS Using Isotope Labeling of an Alkanethiol SAM

The use of deuterated molecules of an octanethiol SAM enables a more precise assignment of the IETS peaks. Both partially deuterated alkanethiols and fully deuterated alkanethiols can form a SAM on Au(111) surfaces, where $(\sqrt{3}\times\sqrt{3})R30°$ periodicity in relation to the Au(111) substrate is observed, as is also the case for the normal alkanethiol.

Isotope Labeling for IETS

The results of IETS for partially and fully deuterated octanethiols, including normal octanethiols, are summarized in Fig. 25.27 ($V_s = 500$ mV, $I_t = 1$ nA, and $T = 4.4$ K) [25.90]. We show the calculated energy positions of several expected vibrational modes for those molecules in Fig. 25.27b, where the vibrational modes (labeled D–L) are specified at the top. For the non-deuterated molecule, a conclusive peak comparison with the experiment is hampered by the overlapping of peaks at similar energies. However, further analysis using the isotope shift of the deuterated molecules enables a much more precise assignment, wherein calculated isotope shifts (Fig. 25.27b) were compared to the corresponding IET spectra (Fig. 25.27c).

Among the expected vibrational peaks, some were not detected in the experimental IET spectra. We mark the detected peaks by solid lines and undetected peaks by dashed lines in Fig. 25.27b, so that we can identify the dominant vibrational mode in the overlapping peaks. For example, peak E is composed of two overlapping peaks, the CH_3 rock and CH_2 twist modes, in the nondeuterated molecule. These two modes are separated in energy by the deuteration of the methyl group $CD_3(CH_2)_7$, but the CH_2 twist mode is not observed at the expected position. This result indicates a small yield for the CH_2 twist mode, and it is concluded that peak E is dominated by the CH_3 rocking mode for the normal molecule. Through similar arguments, the peaks K and L can be assigned to CH_2 wag and CH_2 scissor modes, respectively.

The fully deuterated molecule shows more complicated isotope shifts due to the coupling between the C–C stretching and CD bending modes. In this case, the calculated IET spectra can be employed to identify peaks g and h. The calculation shows that peak g is a vibrational mode with the combined character of C–C stretching and CH_2 wagging, and peak h is a vibrational mode that accompanies the C–C stretch and

Table 25.2 Summary of IETS peaks

Molecule	Mark	Experiment (meV)	Calculation (meV)	Main mode
$CH_3(CH_2)_7S$	D	88	87	ν(S−C)[a]
	E	108	107	CH_3 rock
	F	130	132	ν(C−C)
	K	171	165	CH_2 wag[b]
	L	182	173	CH_2 scissor[c]
	M	361	368	ν(C−H)
$CD_3(CH_2)_7S$	D/E	90	88	ν(S−C)/CD_3[d] rock
	F	132	135	ν(C−C)
	K	167	166	CH_2 wag
	L	178	172	CH_2 scissor
	i	255	256	$\nu_s(CD_3)$
		273	278	$\nu_{as}(CD_3)$
	M	360	364	$\nu(CH_2)$
$CH_3(CH_2)_6CD_2S$	D	83[e]	82[e]	ν(S−C)[a]
	E	108	108	CH_3 rock
	F	132	133	ν(C−C)
	K	169	165	CH_2 wag[b]
	L	180	173	CH_2 scissor[c]
	i	265	282	ν(C−D)
	M	360	374	ν(C−H)
$CD_3(CD_2)_7S$	c	68	63	CD_2 rock[f]
	d	84[e]	82[e,g]	ν(S−C)
	e	95	–	CD_3 rock[h]
	f	123	124	CCC deform
	g	140	137	ν(C−C)[i]
	h	152	154	ν(C−C)[i]
	i	271	277	ν(C−D)

[a,b,c] Overlap with small contributions from [a] CH_2 rocking, [b] CH_3 s-deformation, and [c] CH_3 d-deformation.
[d] By deuteration of the methyl group, CH_3 rocking overlaps with peak D.
[e] Deuteration of the bottom methylene red-shifts the ν(S−C) mode by ≈ 5 meV.
[f] Deuteration of the methylene groups shifts the CH_2 rocking mode, previously overlapping with peak D, to peak c.
[g] From theory, peak d originates from the prominent ν(C−S) at 82 mV and a weak CD_3 rocking mode at 85 mV.
[h] Tentative assignment.
[i] Coupled with CD bending modes. The isotope shifts in the full-deuteration case are not straightforward; sometimes the isotope shift couples modes, e.g., peaks g and h [25.90]

CH_2 scissor. We can see that the character of the vibrational mode for fully deuterated alkanethiols is similar to that for the normal molecules.

We note that the calculated vibrational energies agree with those obtained by experiment within an accuracy of a few percent (Table 25.2). In addition, both the relative peak heights and the absolute magnitude of the IETS peaks are well reproduced, the latter showing an agreement within a factor of three (although additional broadening mechanisms are not considered).

Selection Rule or Propensity

As shown in previous sections, we precisely assigned IETS active modes for alkanethiol molecules. Here, using Fermi's golden rule we discuss why such modes are active in IETS. The first eigenchannel with the largest transmission for the alkanethiol SAM has σ-type symmetry originating from the C−C bonds (Fig. 25.28). This eigenchannel exponentially decreases as the electrons tunnel through the molecule. The σ-character implies a strong coupling of tunneling electrons to vibrational modes modifying the C−C bond lengths of the alkyl chain, since these modes also show σ-type symmetry. In fact, many of the IETS active modes, i.e., C−C stretch (peak F), CH_2 wag (K), and scissor (L), accompany a substantial displacement in the C−C bond length. In contrast, the inactive modes, CH_2 rock and twist, do not accompany a C−C displacement. By using this simple rule, we can also understand the strengths of the IETS sig-

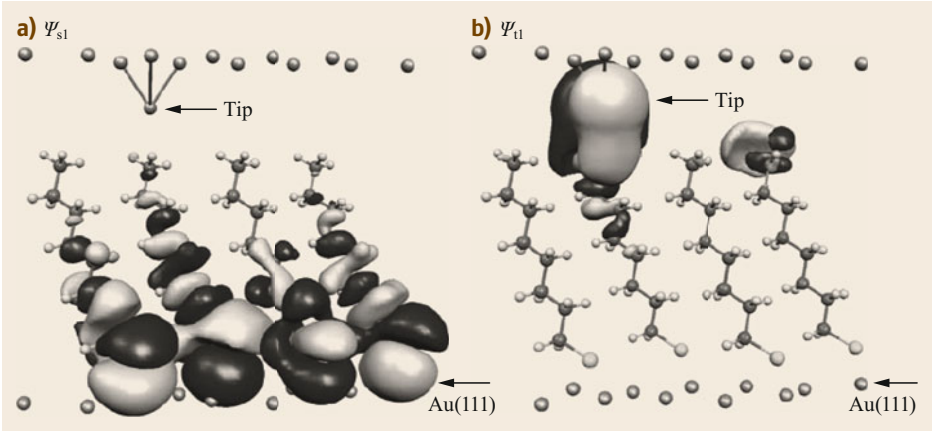

Fig. 25.28a,b Scattering states at the Fermi level. Maximally transmitting scattering states (eigenchannels) incident from (**a**) substrate side and (**b**) tip side. Fig. 25.29 ν(C−D) and ν(C−H) regions of IET spectra. Experimental and theoretical IET spectra for $CH_3(CH_2)_7S$ (H17), $CD_3(CH_2)_7S$ (D3), $CH_3(CH_2)_6CD_2S$ (D2), and $CD_3(CD_2)_7S$ (D17) ($V_{rms} = 7.2$ mV). The *dashed lines* show the estimated background signal. (Reprinted adapted with permission from [25.90]. Copyright (2010) American Chemical Society)

nals, e.g., the scissor mode has less C−C character than the wagging mode, which is reflected in the IETS intensity.

Site Selectivity of IETS

Upon identification of the vibrational signals we can qualitatively understand how each part of a molecule contributes to the IET spectra. As shown in Fig. 25.27c, the IETS intensity of peaks F (ν(C−C)), K (CH_2 wag), and L (CH_2 scissor) do not appreciably change with deuteration of the CH_2 closest to the sulfur atom ($CH_3(CH_2)_6CD_2S$). The IETS weight is therefore not predominantly determined from this part of the molecule in contrast to the report by *Beebe* et al. [25.93].

A more quantitative discussion is possible by examining the C−H stretch modes. For the four alkanethiol molecules with different deuterated groups, the ν(C−D) and ν(C−H) regions of the IET spectra are shown in Fig. 25.29. In contrast to the fingerprint area, the comparison between the experiment and theory for the C−H stretching region is not straightforward. When we compare the nondeuterated and fully deuterated cases shown in Fig. 25.29, the C−H vibrational energy shows an isotope shift from 361 to 271 meV, which agrees well with what is expected from the effective mass variation. The IETS intensity in the fully deuterated case also decreases by a factor of $\approx 1\sqrt{2}$. The decrease in IETS intensity might be due to the weakened e–ph coupling which originates from the lowered vibration amplitude of the normal mode with the mass increase [25.54–56]. In order to estimate the IET signal amplitude and the position dependence, the experimental IET signals are integrated after subtracting the interpolated background as indicated in Fig. 25.29a. The estimated intensities after this process are shown in Table 25.3. The integrated peak areas of the C−H stretching mode for the normal molecule and the C−D stretching modes for the fully deuterated molecule are denoted by ν(C−H, all) and ν(C−D, all), respectively.

As can be seen from Table 25.3, the measured signal intensity of ν(C−H) and ν(C−D) can be well explained with a model in which all hydrogen atoms in the molecule contribute equally to the IETS signal, i.e., the signal is proportional to the number of H and D atoms. When the terminal methyl group is deuterated (Fig. 25.29b), the area of the ν(C−D, CD_3) peak is $\approx 28\%$ of ν(C−D, all), while the ν(C−H) peak is decreased from ν(C−H, all) by $\approx 16\%$. Although there is a certain discrepancy between the two numbers, the increase/decrease is roughly consistent with a substitution ratio of 18% (3 out of 17 hydrogen atoms). We also find a similar tendency for the methylene group, where the peak area of ν(C−D) is $\approx 14\%$ of ν(C−D, all) and the ν(C−H) is reduced by $\approx 23\%$ from ν(C−H, all), which is comparable to $2/17$ ($\approx 12\%$). This behavior is also consistent with the discussion earlier for CH_2 wagging and CH_2 scissoring modes, where we showed that the contributions from the methylene group closest to the Au electrode are small. These discussions do not agree with the previous report [25.93] that the contribution of the methylene group closest to the electrode is notably enhanced due to its location close to the metal substrate. From a theoretical viewpoint, the exponential decay in the scattering states originating from the Au electrode and STM tip (Fig. 25.28) will cancel in Fermi's golden rule. On the basis of this picture, it is difficult to imagine that the IETS weights are significantly different for different parts of the molecule.

Table 25.3 Relative peak area of ν(C−D) and ν(C−H) signals in the experiment. The standard (100%) of the ν(C−D) (ν(C−H)) signal is the peak area for $CD_3(CD_2)_7S$ ($CH_3(CH_2)_7S$) [25.90]

Molecule	ν(C−D)	ν(C−H)
$CH_3(CH_2)_7S$	–	100%
$CD_3(CH_2)_7S$	28%	84%
$CH_3(CH_2)_6CD_2S$	14%	77%
$CD_3(CD_2)_7S$	100%	–

The intensity of the ν(C−H) mode deduced by theory is severely underestimated compared to that found by experiment. Comparing the IET spectra of normal alkanethiol (hereafter denoted by CH_3-C_7) to the one of the methyl group deuterated alkanethiol (hereafter denoted by CD_3-C_7) allows us to investigate this problem in more detail [25.90]. The isotope-shifted ν(C−D) signal was observed for CD_3-C_7 (Fig. 25.30b). A small peak at 255 meV and a large peak at 273 meV are then compared to IRAS data [25.94], the higher energy peak with the larger intensity can be assigned to the asymmetric C−D stretching mode of CD_3 (275 meV by IR-$\nu_{as}(CD_3)$ [25.94] and 278 meV by theory) and the lower energy peak with smaller intensity to the symmetric C−D stretching mode of the CD_3 (258 meV by IR-$\nu_s(CD_3)$ [25.94] and 256 meV by theory). The measured peak area ratio of $\nu_{as}(CD_3)$ to $\nu_s(CD_3)$ was 80 : 20, as estimated using Gaussian fitting. This value is comparable to the theoretical values of 84 and 16%, underlining the quantitative agreement for the CH_3 modes.

As mentioned for the tip position on the octanethiol SAM film, there is no gap between the tip and the molecule if the IETS is measured with the set-point mentioned above. One might wonder whether the touching of the tip and the molecule might have some effect on the spectra. This can be checked by using shorter alkanethiols (methyl-group deuterated hexanethiols: $CD_3-(CH_2)_5-S$) where IETS measurement

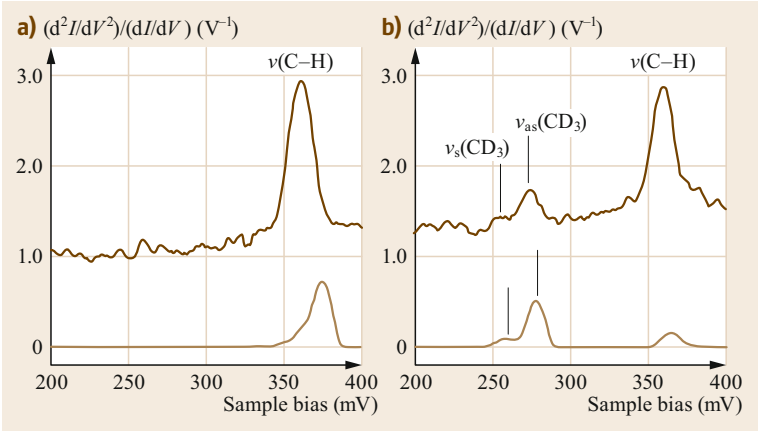

Fig. 25.30a,b IET spectra for the C−D and C−H stretch regions (ν(C−D) and ν(C−H)) for CH_3-C_7 **(a)** and CD_3-C_7 **(b)** SAMs on Au(111). The *dark brown* and *light brown* are the experimental and theoretical spectra, respectively ($V_{mod} = 7.2$ mV). (Reprinted adapted with permission from [25.90]. Copyright (2010) American Chemical Society)

with a tunneling gap between tip and molecule is possible. The result shows that the asymmetric mode in $\nu(CD_3)$ is still dominant in the IET signal even when a vacuum gap exists between the sample and the tip.

The analysis of $\nu_s(CH_3)$ and $\nu_{as}(CH_3)$ modes enables the examination of the empirical selection rule discussed for the conventional IETS that is mentioned in the previous section, e.g., stronger intensities are obtained for optically active modes than for the optically forbidden modes [25.4]. This implies a mechanism that tunneling electrons interact with the dynamic dipole moments of a molecule via the long-range Coulomb force [25.95]. The strength of these dipole moments will be enhanced by image charges when they point along the surface normal and reduced when they lie parallel to the surface. Thus, one can argue that the main IET signal comes from the vibrational modes whose dynamic dipole moments point along the surface normal. However, the results for the $\nu_s(CH_3)$ and $\nu_{as}(CH_3)$ modes obtained by the STM-IETS measurements are inconsistent with this rule. This is because the strong IET signal comes from the asymmetric CH_3 stretch mode which has a much smaller dynamic dipole moment along the surface normal than the symmetric stretch [25.87]. The discrepancy implies that it is inadequate to consider the long-range Coulomb interaction as the mechanism for the vibration excitation, which was discussed in the conventional IETS experiments.

The changes in the ν(C−H) region of the IET spectra upon deuteration of the methyl group can help the

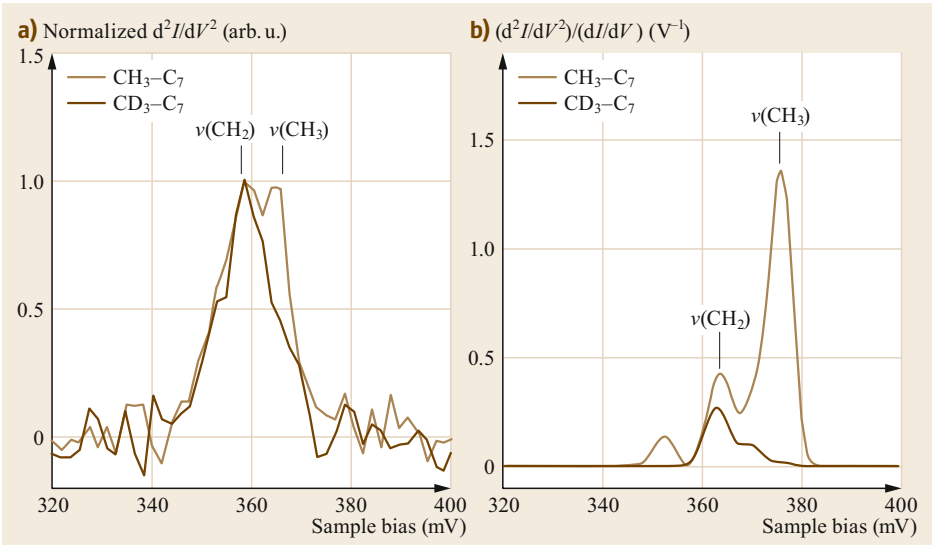

Fig. 25.31 **(a)** Experimental and **(b)** theoretical high-resolution IETS around the ν(C−H) modes for CH_3-C_7 (*dark brown*) and CD_3-C_7 (*light brown*) SAMs on Au(111) ($V_{mod} = 2.7$ mV). The experimental IETS intensity is normalized such that the peak height is 1 for both cases. (Reprinted with permission from [25.82]. Copyright (2008) by the American Physical Society)

assignment of the modes in the ν(C−H) region. The dark brown and light brown lines in Fig. 25.31a show the high-resolution IET spectra for CH_3-C_7 and CD_3-C_7, respectively. IETS spectra with a higher resolution are obtained with a smaller modulation voltage (V_{mod} = 2.7 mV). For the CH_3-C_7 (light brown line), two peaks can be seen at energies of 359 and 365 meV, while for CD_3-C_7 (dark brown line) we only observe a single peak whose energy is identical to that of the lower energy component of the light brown curve. The peak-area ratio of the low energy component to the high energy one was estimated using Gaussian functions to be 5 : 1. Since the ν(C−H) signal for the CD_3-C_7 molecule is expected to originate only from the CH_2 group, we can assign the components of 359 and 365 meV to the CH_2 and CH_3 groups, respectively. Taking into account the fact that using IRAS the CH_2 symmetric and asymmetric modes are observed at 354 and 362 meV, respectively [25.87, 88], the presence of a lower energy CH_2 IET peak centered at 359 meV indicates that the IET intensity is composed of the asymmetric and symmetric CH_2 stretch modes with an approximately equal contribution. Note that the symmetric C−H stretching mode of the CH_2 and the asymmetric C−H stretching mode of CH_2 are not distinguished in IETS (Fig. 25.31a) owing to the small energy splitting (8 meV), however, that is not the case for the C−D stretching mode of the CD_3 (Fig. 25.30b) owing to the large energy splitting (17 meV). IRAS data further provides the symmetric and asymmetric stretch modes of the CH_3 group ($\nu_s(CH_3)$ and $\nu_{as}(CH_3)$) at 360 and 367 meV. The latter value is close to the high-energy peaks of the IET spectra and is consistent with the conclusion that the asymmetric mode is dominant for the methyl group. The experimental data therefore indicate that the majority of the C−H stretch IET signal originates from the CH_2 groups with approximately equal weights for $\nu_s(CH_2)$ and $\nu_{as}(CH_2)$. It is observed that a smaller ratio (1 : 5) of the ν(C−H) signal originates from the CH_3 group, for which the asymmetric CH_3 stretch dominates over the symmetric stretch mode.

Intermolecular and Intramolecular Tunneling

In the previous section, we summarized the experimentally observed features of the C−H stretching signal. In the C−H stretching energy region ($\approx$ 350−380 meV), the comparison between experimental and theoretical calculations is less satisfactory than that for the fingerprint region. For example, the calculated vibrational energies are consistently 5−10 meV larger than the experimental data ($\nu_s(CH_3)$ = 353 and 365 meV, $\nu_{as}(CH_3)$ = 375 meV, $\nu_s(CH_2)$ = 363 meV, and $\nu_{as}(CH_2)$ = 369 meV). In addition, the IETS amplitude for the $\nu(CH_2)$ mode is severely underestimated by theory (Fig. 25.30) [25.91]. Since the quantitative agreement between the experiment and the calculation is good for the $\nu(CD_3)$ modes, the poor performance for the $\nu(CH_2)$ modes is puzzling. However, one may propose the hypothesis that the discrepancy is due to inelastic intermolecular scattering. The process is either that the $\nu(CH_2)$ modes scatter the intermolecular tunneling electrons, and/or that the existence of the excited $\nu(CH_2)$ modes change the transport through the molecule under the tip (Fig. 25.32a). This idea could explain the poor agreement between theory and experiment since DFT is not well suited for describing intermolecular interactions. In addition, the magnitude of the e–ph coupling for the $\nu(CH_2)$ modes should be large between the molecules and could thus enable intermolecular hopping.

The calculations indicate that intermolecular scattering is indeed important. As shown in Fig. 25.32b, the majority of the current is carried by the elastic process whose energy-resolved current density [25.91] is shown in Fig. 25.32c for a positive tip bias case. Here, approximately 75% of the current passes through the molecule closest to the tip (second molecule from the left in the figures), i.e., intramolecular tunneling (Fig. 25.32a) is dominant in the elastic process. The change in current densities due to the inelastic scattering is also calculated focusing on the $\nu(CH_2)$ excitation process. In this case, electrons start at E_{high} and end at E_{low} by exciting the vibration of $h\nu$ (Fig. 25.32b). The current densities at E_{high} (before excitation) and E_{low} (after excitation) are shown in Fig. 25.32d,e, respectively, where the former gradually decreases throughout the SAM as the electrons are scattered to E_{low}. In the inelastic tunneling case, 62% of the current enters through the molecule closest to the tip (second molecule from the left in the figures). This value is lower than that found in the case of the elastic process and indicates that the electrons take a more intermolecular path than in the elastic process. In addition, Fig. 25.32d,e show a smaller part of the current entering the molecule under the tip (second molecule from the left in Fig. 25.32d) than exiting (Fig. 25.32e). The enhancement of the $\nu(CH_2)$ component with the increase of the intermolecular current can be understood with a simplified model with using a propensity rule of IET spectroscopy that the C−H stretching mode is efficiently excited with electron flow along the C−H bond direction [25.4, 5]. Since the bond of C−H of CH_2 in the alkanethiol molecule is rather normal than parallel to the molecular axis, the increase of the intermolecular component of the current flow enhances the IET component from the C−H stretching mode of the CH_2 species.

The intermolecular tunneling was examined for an elastic process, where the conductivity of a SAM

sample was measured by a conductive atomic force microscopy (AFM) [25.96–98]. The result shows that the conductivity of alkanethiol SAMs increases with the tilt angle of the molecules [25.96–98]. In order to understand this observation, *Frederiksen* et al. performed first-principle calculations for SAMs by changing the density of alkanethiol molecules on a substrate while keeping the SAM structure [25.98]. They found a slight increase of conductance with increasing molecular density, which supports the contribution of intermolecular tunneling.

Despite the support from such a DFT calculation, there is still no definitive proof that the underestimated intensity of the $\nu(CH_2)$ component originates from the lack of the intermolecular scattering in the current DFT calculation. Alternative models such as supramolecular structures in the SAM should therefore be studied further.

25.5 Mapping of IETS Signals

In this section, we examine how the spatial mapping of the IETS can contribute to the recognition of a single molecule. The first example is a simultaneous observation of the topographic image and the vibrational mapping where *trans*-2-butene and butadiene molecules are coadsorbed. In the experiments, the bias voltage is set at $V_s = 360\,\text{mV}$, which gives the maximum intensity for $\nu(\text{C}-\text{H})$ of the *trans*-2-butene molecule, and the tunneling current is set at 1 nA. The modulation voltage ($V_{pp} = 18\,\text{mV}$, 797 Hz) is superimposed on the sample bias. A scanning from left to right takes 10 s. The time constant of the lock-in amplifier is set at 30 ms.

25.5.1 Spatial Mapping of IETS Features

The topographic image is shown in Fig. 25.33a. The area contains two *trans*-2-butene molecules and one butadiene molecule, which are labeled T and B, respectively. The *trans*-2-butene molecule appears as a dumbbell-shaped protrusion [25.50]. The separation of the two protrusions observed within the molecule is less prominent than the one obtained with smaller bias voltages ($V_s = 100\,\text{mV}$) [25.50]. The butadiene molecule is observed as an oval-shaped protrusion. The frequency of the modulation is high enough for the feedback loop setup, and the effect of the superimposed modulation voltage cannot be identified in the topographic image.

The mapping of the vibrational feature shows a clear increase in $\text{d}^2I/\text{d}V^2$ at the positions of the *trans*-2-butene molecules. As is indicated by the color index, the maximum $\text{d}^2I/\text{d}V^2$ intensity is $\approx 10\,\text{nA/V}^2$ which is close to the value obtained by the single-point IETS. The positions of the feature obtained in the forward scan and in the backward scan show little change, which

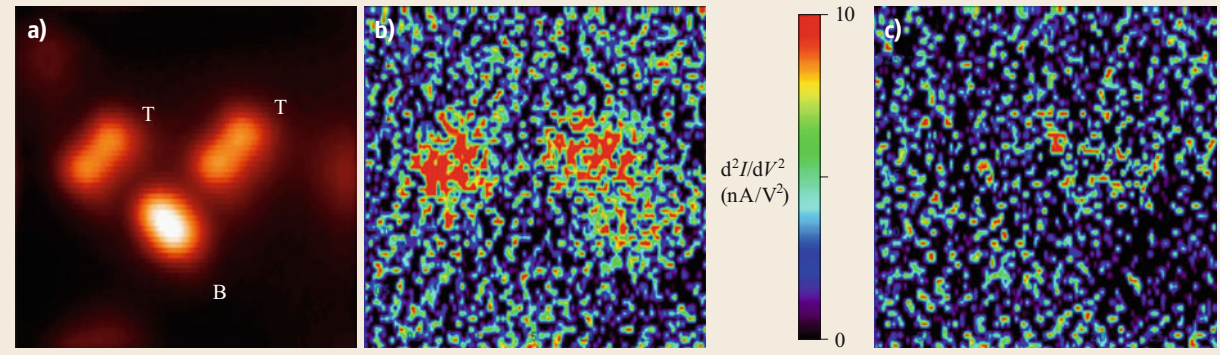

Fig. 25.33a–c Simultaneous observation of the topographic image **(a)**, and the mapping of d^2I/dV^2 intensity **(b)**, on the surface which contains both *trans*-2-butene (label T) and butadiene (label B) molecules. The tip scans the area with the feedback loop on (tunneling conditions of $V_{sample} = 360\,mV$ and $I_{tunnel} = 1\,nA$, area $43 \times 43\,Å^2$). The color bar index for d^2I/dV^2 intensity corresponds to the range from 0 to $10\,nA/V^2$. No image processing including the Fourier transfer process is performed. **(c)** A reference image of d^2I/dV^2 mapping obtained at $V_{sample} = 300\,mV$, which shows no obvious structures at the positions of the molecules. (Reprinted from [25.59], with the permission of AIP Publishing)

indicates that the combination of the scan speed and the time constant of the lock-in amplifier is adequate. However, we cannot see any characteristic feature at the position corresponding to the butadiene molecule. This is consistent with the previous report [25.50]. In spite of the existence of a C−H bond in the butadiene molecule, the ν(C−H) feature is hardly observed.

As a reference, the mapping of d^2I/dV^2 obtained at $V_s = 300\,mV$ is shown in Fig. 25.33c. In this image no features are observed either for the *trans*-2-butene molecules nor the butadiene molecules. These results have clearly indicated that chemically sensitive molecular recognition is possible using this simple d^2I/dV^2 mapping technique.

25.5.2 Hydrogenated Alkanethiol in a Matrix of Deuterated Alkanethiol SAMs

Mapping of IET signals for an alkanethiol SAM composed of hydrogenated alkanethiol (H-alkanethiol) and deuterated alkanethiol (D-alkanethiol) can provide information on the tunneling passage of electrons in the SAM. In order to execute this investigation, an identification of the isotope molecule inserted into the matrix of alkanethiol is required. A SAM sample composed of H- and D-alkanethiol can be prepared by dipping the Au substrate into an ethanol solution containing a minority of H-alkanethiol and a majority of D-alkanethiol. If the length of the molecule is different, e.g., using $CH_3(CH_2)_7S$ as the H-alkanethiol and $CD_3(CD_2)_5S$ as the D-alkanethiol, the mixture of the molecules can be confirmed from a topographic image of the SAM (Fig. 25.34). Here, bright and dim spots correspond to the H-octanethiols and D-hexanethiols, respectively. The ratio of the number of bright to dim spots is 1 : 19, which is identical within errors to the ratio of the constituents (1 : 25) in the ethanol solution from which the SAM was prepared. This observation indicates that when the length of the molecule is similar, the mi-

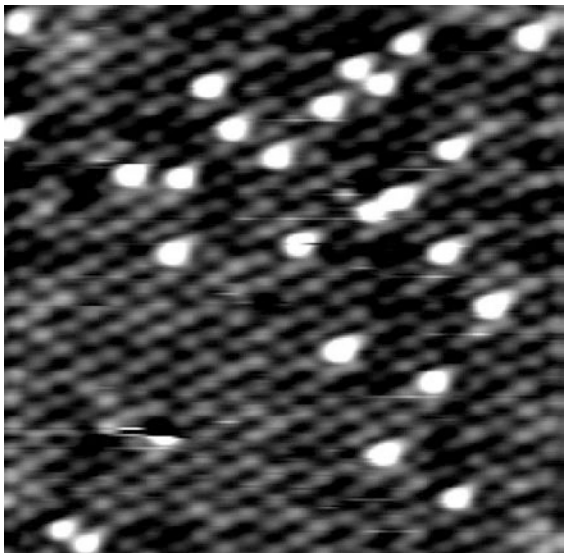

Fig. 25.34 STM image of $CH_3(CH_2)_7S$ and $CD_3(CD_2)_5S$ coadsorbed SAM on Au(111). Sample bias of 1.5 V, current of 9 pA, scan area of 10 nm × 10 nm, temperature of 4.4 K. *Bright* and *dim spots* correspond to the hydrogenated octanethiols and deuterated hexanethiols, respectively. The ratio of the number of bright to dim spots is 1 : 19, which is almost identical to the ratio of the constituents (1 : 25) in the ethanol solution from which the SAM was prepared. nor molecule is inserted into the matrix of the major molecule in an isolated manner, i.e., phase separation does not occur, in contrast to the case of the SAM formed by two molecules with significantly different molecular lengths [25.99, 100].

25.5.3 Mapping the IET Signal for an Alkanethiol SAM

Next, we look at the case where D-alkanethiol and H-alkanethiol molecules with the same length are mixed [25.90]. The ratio of the H-alkanethiol to D-alkanethiol in the solution was 1 : 9. Figure 25.35a,b shows topographic images of the thus-prepared SAM surface with a sample bias of 264 mV (corresponding to the C−D stretching mode) and 362 mV (C−H stretching mode), respectively. No obvious differences in either topographic image can be seen, which is in contrast to the case of Fig. 25.34. Note that the lateral drift of the STM image was less than 0.2 Å in a single mapping process (1.4 h), therefore the scan areas of Fig. 25.35a,b are almost identical. Figure 25.35c,d shows the IET maps simultaneously acquired with topographic images of Fig. 25.35a,b, respectively. In contrast to the identical topographic images, we can see a decrease in the signal from the C−D stretching mode around the cross mark, see Fig. 25.35c, and an increase in the C−H stretching signal around the same mark, see Fig. 25.35d.

This can be more clearly visualized by differentiating Fig. 25.35c,d. By this method we can identify an H-hexanethiol molecule at the cross mark (Fig. 25.35e). There is an additional molecule in the upper right image that can be attributed to an H-hexanethiol molecule, and thus two H-hexanethiol molecules are identified out of a total of 25 molecules. This is a reasonable value considering that the mixture ratio of the H- to D-molecules was 1 : 9.

The tunneling resistance used in these IET maps was 1 GΩ (264 mV/264 pA or 362 mV/362 pA). When the resistance is lowered, the signal-to-noise ratio of the IET signals improves. However, this induces the problem of the interaction between the tip and sample. The tunneling resistance of several tens of GΩ is used for topographic imaging, which yielded routinely good data. We speculate that a slight shift of the bright areas in the IET map and the topographic image is due to such tip-substrate interaction problems.

This problem may be solved by improving the signal-to-noise ratio in the tunneling current, which would allow us to use a smaller tunneling current and hence a wider tunneling gap. If this can be realized, the modulation voltage can be decreased from the current setting of 28.8 mV to a smaller value, which should contribute to visualizing the small energy differences between vibrational modes. This improved signal-to-noise ratio also clarifies the importance of the intermolecular tunneling process. The degree of the intermolecular process is shown by comparing the IET spectra for the case where the STM tip is above an H-alkanethiol molecule surrounded by D-alkanethiols with the case where the STM tip is placed above an H-alkanethiol molecule surrounded by the same H-alkanethiol molecules. Investigation of the intermolecular process using the IETS mapping technique is ongoing.

25.6 Summary

Recent progress of STM-IETS is reviewed. After the pioneering work of Ho's group on the detection of vibrational modes of a C_2H_2 molecule on a Cu surface, STM-IETS measurements have been performed for a variety of systems. In addition, we see a greater variety of molecules and electrodes have been in-

vestigated, which include STM-IETS measurement of atomic chains of metals and the use of other types of nanoscale devices with an atomic-scale gap distance. In most cases, vibration/phonon features appear as an increase of the conductance at the threshold energy of a vibrational mode (corresponding to a peak in a d^2I/dV^2 spectrum for $V > 0$). This is consistent with the results of the conventional M–I–M tunneling devices, in which only a few examples showed a decrease of the conductance out of the vast number of investigated molecules. For this type of IETS feature, a theoretical model using an approach similar to the one used to describe impact scattering in HR-EELS can account for the observed STM-IETS behavior. Conversely, the decrease of the conductance for $V > 0$ is observed for cases of adsorbates with a strong bonding with the substrate and a metal chain connected to two electrodes. The dip of d^2I/dV^2 for $V > 0$ is explained using a resonant model which is realized with a strong coupling of the gap species to the electrodes. The absence of this type of signal in the IETS data of M–I–M tunneling devices might be due to the fact that no strong bonding is formed between the molecule and the electrode. We introduced an advanced theoretical simulation that can account both for the increase and decrease of the conductance.

We discussed the IETS measurement of alkanethiol SAMs in detail, which may be used as a standard molecule for comparisons of IET spectra obtained with various configurations of electrodes. The IET spectrum obtained for the octanethiol SAM shows clear features in the fingerprint region, which can be directly compared with HR-EELS data and proves the ability of STM-IETS. Using isotope labeling, precise peak assignment is enabled, which suggests that IETS active modes are accompanied by a substantial C−C displacement. A comparison between the experimental IETS data and theoretical simulations shows a good overall agreement. In addition, fine features, such as the ratio of the symmetric CH_3 stretching signal to antisymmetric CH_3 stretching signal, are reproduced well by the simulation. The only exception is found in the large underestimation of the CH_2 stretching signal by the calculation. In order to interpret this discrepancy, a hypothesis that the intermolecular tunneling process enhances the CH_2 stretching signal has been proposed. The process of intermolecular hopping of the electron is underestimated by DFT.

In the final section, we demonstrated the effectiveness of IET mapping for a butene molecule and alkanethiol SAM. Increasing the sensitivity of the IETS mapping methods is pivotal to clarifying the importance of the intermolecular process.

The demand for chemical identification with atomic-scale resolution is increasing. As we can see, vibrational spectroscopy can play a crucial role in chemical identification, and we therefore expect an expansion of research utilizing the IETS technique.

Norio Okabayashi is an Assistant Professor at the School of Mathematics and Physics at Kanazawa University. He obtained his PhD at the University of Tokyo in 2004. After completing 3 postdoctoral fellowships, at Tohoku University and elsewhere, he started working at his current position in 2012. His present research concerns inelastic electron tunneling spectroscopy combined with atomic force microscopy.

26. Adsorption Sites, Bonding Configurations, Reactions and Mass Transport Surface

Eric C. Mattson, Yves J. Chabal

Section 26.2 discusses the essential concepts of infrared (IR) spectroscopy as it pertains to studies of surfaces and interfaces, focusing on different potential measurement geometries and the type of information that can be extracted from an IR absorption measurement. Section 26.3 provides a brief overview of low-energy ion scattering (LEIS)-based quantification of surface composition and thin film structure. The fundamentals of x-ray photoemission spectroscopy (XPS) have already been covered in a previous chapter and are therefore not addressed here. Section 26.4 presents examples from a variety of different fields to illustrate how the combination of these three techniques has yielded quantitative information on adsorption sites, bonding configurations, surface reactions, and mass transport. These examples include ultrashallow monolayer doping of semiconductors, growth of ultrathin metal oxide layers, characterization of catalyst model surface structure, reactivity of transition-metal surfaces with nitrogen and hydrogen plasmas, dielectric surface etching and functionalization, and gas storage in nanoporous materials.

Infrared (IR) spectroscopy, low-energy ion scattering (LEIS), and x-ray photoemission spectroscopy (XPS) are widely used techniques for a broad range of studies of surface chemistry and composition. IR absorption measurements directly probe the chemical bonds at surfaces and in thin films through excitation of vibrational transitions, providing a fingerprint of the bonds present in the absorbing material. LEIS measurements probe the elemental composition of an ultrashallow (< 1 nm) surface region and can yield static depth profiles of the first 5–10 nm of a surface region. XPS measurements detect the photoelectron yield and binding energy of the core level of each particular element, thereby providing in-depth information on the nature of the chemical bonds and oxidation states of the elements present. When used in combination, these three techniques can provide a detailed description of the amount and types of chemical species present at surfaces, which yields quantitative insight into many surface chemical and physical processes such as thin film growth, surface functionalization, catalysis, and near-surface diffusion. In this chapter, we review some basic principles of IR

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-46906-1_26

spectroscopy and LEIS spectroscopy, noting that XPS has been covered in detail in another chapter of this handbook. We discuss how these three complementary techniques can be applied to understand surface reactions and mass transport for a variety of different applications, and we discuss specific problems that highlight the type of information that can be extracted from the combined techniques.

26.1 Surface Techniques Survey

Adsorbate bonding and structure, surface reaction products and mechanisms, and mass transport are complex elements underlying many important technological problems ranging from microelectronics to energy conversion and storage. Fundamental studies of these phenomena often require a multi-technical approach in order to quantitatively evaluate a given process or reaction. While there exist many experimental probes that can determine adsorption sites and bonding configurations, or characterize surface reactions and mass transport, the combination of vibrational spectroscopy, core-level photoemission, and low-energy ion scattering (LEIS) spectroscopies is uniquely suited to study all of these phenomena in situ on quantitative footing when performed together. The most convenient choice for vibrational spectroscopy is infrared (IR) absorption, which provides the highest energy resolution, good sensitivity, and structural information obtained from polarized radiation (thanks to versatility in experimental geometries). Additionally, IR measurements can be carried out under conditions that do not require ultrahigh vacuum. IR absorption measurements not only offer a direct probe of the chemical bonds present in an adsorbed layer by excitation of optically active vibrational modes, but can also provide rich information on the electronic structure of condensed-phase systems, although the latter is less frequently done. LEIS measurements can directly determine the identity and concentration of atoms present in the outermost layer of a surface, and can also offer static depth profiles of subsurface species within a depth of 5−10 nm. Finally, XPS measurements give the identity and chemical state of the elements present in the outermost ≈ 5 nm of the surface region. The collective strengths of these techniques enable a quantitative analysis of surface chemical structure, composition, and reactivity, and resolve ambiguities that could arise from the measurements of the individual techniques taken on their own.

26.2 IR Measurements of Surfaces and Thin Films

Vibrational spectroscopic methods, and IR spectroscopy in particular, have played an important role in the development of surface science. The strength of vibrational spectroscopy lies in its ability to identify the chemical nature of adsorbates and reaction products and their local symmetry and bonding configuration through measurements of the vibrational frequencies and intensities of adsorbates. Under the most favorable conditions, the number frequencies of modes observed in a vibrational spectroscopy experiment can be used to deduce the site symmetry of an adsorbate on the basis of factor group analysis of the possible bonding configurations. In the investigation of thin films, vibrational measurements probe, depending on the measurement conditions, the transverse-optical (TO) and/or longitudinal-optical (LO) phonon modes of the adlayer, which can yield information on structure, crystallinity or local order, thickness, and dielectric properties.

Many aspects of IR spectroscopy offer unique advantages over other surface-sensitive vibrational spectroscopic techniques such as high-resolution electron energy loss spectroscopy (HREELS) or sum-frequency generation (SFG) spectroscopy. Some of these advantages include excellent energy resolution (10^{-4} eV), high sensitivity ($< 1\%$ of a monolayer, depending on dynamic dipole moment and measurement geometry), versatility of potential measurement geometries, and the ability to simultaneously probe optically active electronic transitions such as free carrier absorption. While these characteristics render IR spectroscopy a very powerful technique, the nature and degree of quantitation that can be extracted from experiments can be further improved when performed in conjunction with other quantitative techniques that provide additional information on coverage and chemical state of the substrate. For example, IR measurements provide rich information on the chemical and structural nature of an adsorbate, but are not always sensitive to the chemical state of the substrate atoms. Additionally, quantification of the amount of a given species on a surface (i.e., the coverage) from an IR measurement alone is challenging without some form of calibration. In contrast,

techniques such as XPS and LEIS are inherently quantitative and sample both the adsorbate and substrate. They can supplement the information gaps and provide information that, when used in conjunction with IR measurements, provides a comprehensive and quantitative picture of structure and chemical bonding at surfaces. These techniques will be addressed in subsequent sections. In this section, we focus on important aspects of IR spectroscopic measurements specific to the study of surfaces and interfaces, many of which have been the subject of numerous books and reviews [26.1–8]; here we summarize some of the most important topics with emphasis on the type of information that can be extracted from different experimental approaches. We further note that, though IR spectroscopy is the focus of the current section, the strength of other vibrational techniques (such as HREELS) with their own respective advantages should not be underestimated. Similarly, in the context of this chapter, numerous multi-technique approaches combining HREELS, photoemission, ion scattering methods, or combinations thereof [26.9–12] have also been conducted to address many complex scientific problems.

26.2.1 IR Absorption and Normal Vibrations

The fundamental principles of IR spectroscopic measurements ranging from molecular to extended systems have been discussed at length in numerous books and review articles; here we discuss the most important aspects of the theory as it pertains to an understanding of surface phenomena, and a more detailed theoretical framework can be found in the references given. IR radiation interacts with matter primarily through coupling of the electric field of the IR photons with the motion of charges in a molecule or material. In the case of vibrational excitation, a photon excites a vibrational mode such that a time-dependent dipole moment (i.e., *dynamical dipole moment*) is formed as a result of the atomic displacements that occur during the vibration. Analogously, a photon can couple to the motion of electrons in a solid to promote an electron to a higher energy state through dynamical dipoles formed as a result of electronic motion or the difference in charge distribution between the two states. In both cases, photon absorption is mediated by the formation of time-dependent dipole moments that form as a result of the excitation, which comprises a general selection rule for IR absorption: for a given transition to have IR activity, the excited state must produce a dynamical dipole moment. This selection rule, applicable to both molecular and condensed-phase systems, is derived from the golden rule for the transition probability per unit time, where the radiation field is treated as a time-dependent perturbation. In the case of a vibrational excitation, it is found that the integral over space τ

$$\int \psi_f^* \boldsymbol{\mu}_\xi \psi_i \mathrm{d}\tau \,, \tag{26.1}$$

must be nonzero in order for a transition to occur [26.13]. Here, $\boldsymbol{\mu}_\xi$ is the component of the dipole moment along the direction of the electric field polarization, and ψ_i and ψ_f the initial and final vibrational states. The intensity of an IR mode in the gas phase is ultimately dependent upon the value of the integral (26.1), which can be evaluated to give the intensity of a vibrational mode

$$\int \psi_f^* \boldsymbol{\mu}_\xi \psi_i \mathrm{d}\tau = \left(\frac{h}{8\pi^2 c\upsilon}\right)^{1/2} \frac{\partial \boldsymbol{\mu}_\xi}{\partial Q} \,. \tag{26.2}$$

Here, h is Planck's constant, c the speed of light, ν the vibrational frequency, and Q the normal coordinate, which describes the atomic displacements that occur during vibration. Thus, IR intensities are governed by the *change* in the dipole moment of the molecule that occurs as a result of the vibration.

The normal modes of vibration of molecules, or phonons in the case of extended systems, are determined with the methods of discrete group theory, which use symmetry to evaluate both the atomic displacements that occur during a vibration and the selection rules that determine which types of modes are IR (or Raman) active [26.13, 14]. Using standard methods that take into account the symmetry of the vibrating moiety, the number and character of normal modes of vibration of a given molecule or solid can be determined, allowing for the modes observed in an IR experiment to be linked to a specific chemical structure. It can be shown that the dipole moment transforms under symmetry operations in the same way as translation (e.g., x, y, and z), and therefore any vibration belonging to the same irreducible representation as x, y, or z will be IR active. When an atom or molecule adsorbs on a surface, the symmetry is lowered by the presence of the substrate, and the vibrations of the adsorbed complex may be different from those of the gas-phase molecule. While in simple cases the normal modes of the adlayer can be intuitively inferred, in general a full group-theoretical treatment is used to understand the normal modes of a given adsorbate structure [26.3], particularly for large or complex molecules. The vibrations of an adlayer are connected to those of a gas-phase analog by correlation tables that relate the irreducible representations of the point group of the molecule to those of the surface unit cell group. Often, the reduced symmetry in the adsorbed state can lead to splitting of otherwise degenerate modes, or activity of otherwise IR-inactive modes.

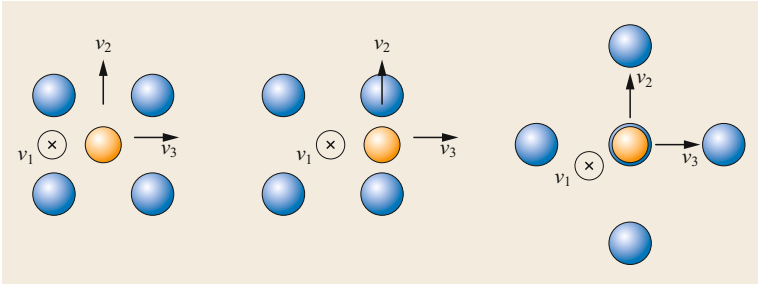

Fig. 26.1 Frustrated translational modes of an adatom adsorbed at surface sites of different symmetry

In addition, translational and rotational degrees of freedom of the free molecule become vibrational degrees of freedom of an adsorbed molecule. Therefore, consideration of the symmetry of an adsorbate complex is often critical in properly identifying its chemical state and adsorption configuration.

As an example, we first consider adsorption of a single atom on a surface. In its free state, a single atom has only translational degrees of freedom, which in turn become frustrated translational modes in the adsorbed state. Thus, three modes are in principle detectable in a vibrational measurement. The number of modes observed in an IR (or HREELS) experiment can be used to infer the site symmetry of the atom. Consider first adsorption of the atom at a fourfold hollow site as in Fig. 26.1a; here, one mode is associated with the frustrated translation perpendicular to the surface (ν_1), and the remaining two modes (ν_2, ν_3) are frustrated translations parallel to the surface. Because of the symmetry of the site group, however, the two remaining translational modes are equivalent, and therefore their frequencies degenerate. Consider next adsorption at a bridge site, as in Fig. 26.1b; in this case we have, as before, a frustrated translation normal to the surface (ν_1) and two frustrated translations parallel to the surface (ν_2, ν_3). In this case, however, the degeneracy between the ν_2 and ν_3 modes is lifted, and the two modes would be expected to have distinct frequencies. In the case of adsorption on an atop site as in Fig. 26.1c, the ν_2 and ν_3 are again degenerate, and it would therefore be difficult to distinguish the adsorption configurations in Fig. 26.1a,c; however, the frequency of the ν_1 mode would be expected to be significantly different between the atop and hollow configurations due to the different levels of coordination to the surface. Similar mode-counting arguments can be made to understand the bonding configuration for small molecules, although the situation becomes more complicated because both internal modes and frustrated rotations must also be considered. In some cases, the internal modes can also be used to infer the symmetry of the adsorption site; for instance, the C−O stretching frequency of CO adsorbed on metal surfaces is known to decrease with increasing coordination to the surface [26.15], and can therefore be used to deduce its adsorption configuration. While mode-counting arguments can potentially be very useful in vibrational spectroscopy, the challenge, particularly with IR spectroscopy, is that often not all modes are observed. This can result from selection rules associated with the substrate (discussed below) or, more often, a limited accessible spectral range. Frustrated rotations and parallel translations often lie in the far-IR region, which is a particularly difficult region due to the need for special sources, detectors, and window materials; therefore, low-frequency vibrations are more readily detectable with HREELS. Nevertheless, for light adsorbates, mode-counting arguments in conjunction with measured frequencies and intensities can shed a great deal of light on bonding configuration, particularly when used in conjunction with first-principles modeling.

26.2.2 Measurement Geometries

External Reflection

For the case of strongly absorbing substrates, in particular metals, the external reflection geometry is most frequently used (Fig. 26.2a). Because of selection rules discussed below, an IR beam is incident upon a reflective surface at a large angle of incidence, and the spectrum of the adlayer is determined by the difference in reflectivity of the clean versus adsorbate-covered substrate. Early calculations by *Greenler* [26.16] showed that the coupling of the normal (p-polarized) component of the electric field at a metal surface to an adsorbate mode with a dynamical dipole moment component oriented perpendicular to the surface was significantly enhanced at grazing-incidence angles (Fig. 26.3), with the optimal incidence angle determined by the dielectric function of the metal substrate. In contrast, the parallel (s-polarized) component of the electric field immediately above the surface cancels out almost entirely due to the phase change that occurs upon reflection. Thus, measurements employing the reflection geometry are most frequently performed at grazing (83−88°) angles of incidence to maximize the signal due to

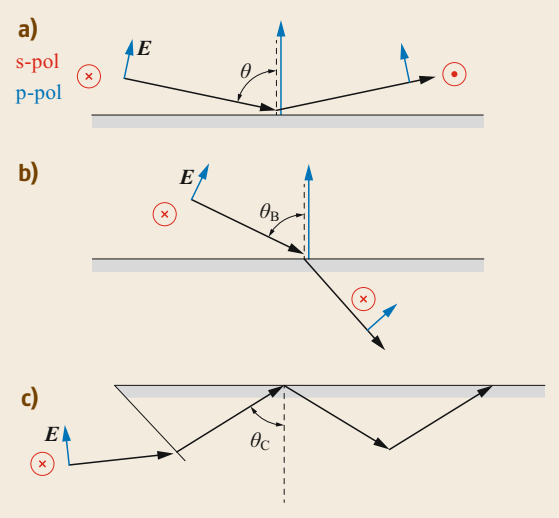

Fig. 26.2a–c Schematic diagram of measurement geometries used for IR spectroscopic measurements. **(a)** In the external reflection geometry, the beam is incident at a large angle with respect to the surface normal. A standing wave is generated between the incident and reflected beams. The normal components of the two beams add constructively, while the tangential components cancel one another due to the phase change occurring upon reflection. **(b)** Depiction of the transmission geometry with the angle of incidence equal to the Brewster angle, as discussed in the text. Here, reflection of the p-polarized component of the light is suppressed, leading to a partially polarized transmitted beam. **(c)** In the multiple internal reflection geometry, the beam is incident upon the sample from a beveled edge, and the beam transmitted into the sample is incident at an angle of incidence greater than the critical angle. The beam undergoes multiple internal reflections from both faces of the sample before finally exiting from the opposite beveled edge

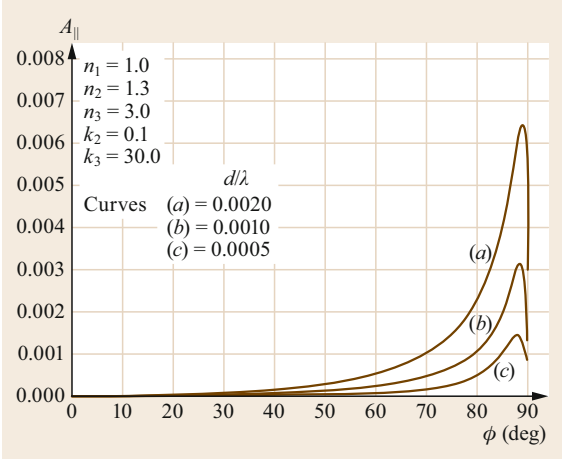

Fig. 26.3 Absorption factor for the three-layer model for reflection measurements from metal surfaces as a function of angle of incidence for p-polarized radiation (Reprinted from [26.16], with the permission of AIP Publishing)

the adlayer. Experiments performed in this fashion are frequently referred to as infrared reflection-absorption spectroscopy (IRRAS) or reflection-absorption infrared spectroscopy (RAIRS). Such measurements have traditionally been used to study adsorption and reactivity at metal surfaces, but the technique has recently been shown to be useful for the study of adsorbed layers on transparent oxide substrates as well [26.17, 18].

The detection of vibrational modes of an adlayer on a metallic substrate is subject to the so-called metal surface selection rule. The selection rule dictates that only vibrational modes that produce a dynamical dipole moment with a component perpendicular to the surface can be detected in an IRRAS experiment. The physical origin for this rule is as follows: The formation of a dipole moment immediately above the surface results in image charges that screen the field of the dipole in the metal. In the case of a dipole moment oriented parallel to the surface, the image charges produce a dipole moment oriented opposite that of the vibration, leading to a cancellation of the net dipole moment associated with the vibration. In contrast, the dipole moment associated with the image charge induced by a perpendicular adsorbate vibration is oriented parallel to that of the adsorbate; consequently, the adsorbate and image dipoles add constructively so that the net dipole moment is nonzero and the vibration is IR active. While the metal surface selection rule provides an intuitive picture for IR activity at metal surfaces, care must be taken when correlating atomic displacements of a particular vibration with dynamical dipole moments to infer whether the vibration is IR active or not. Some cases are straightforward; for instance, the adsorption of CO on most metal surfaces results in the molecular axis nearly parallel to the surface normal. Consequently, the C–O stretch produces a strong dynamical dipole moment perpendicular to the surface, and the vibration is readily detected. An example is illustrated in Fig. 26.4a, which shows RAIRS spectra from CO adsorbed on Pd(100) at 300 K [26.19]. Bands at 1983 and 2096 cm^{-1} are readily detected and assigned to CO bonded at bridge and atop sites. In other cases, however, the situation is more complex. The O–O stretching mode of O_2 adsorbed on Pt(111) provides such an example. Here, it is well established through near-edge x-ray absorption fine structure (NEXAFS) measurements [26.21] that the molecule adsorbs at a Pt-top site with its molecular axis parallel to the surface. Therefore, a stretching vibration that yields atomic displacements parallel to the

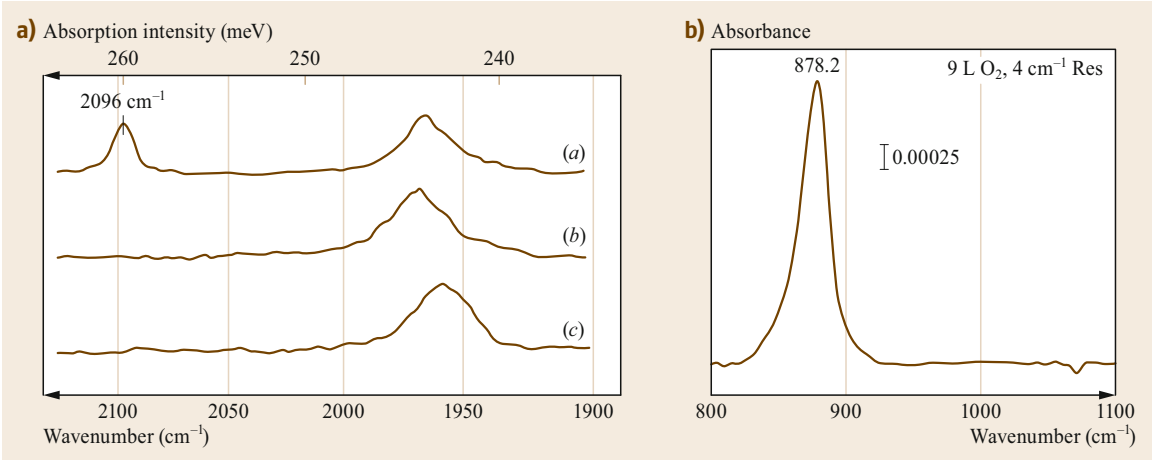

Fig. 26.4a,b IRRAS spectra of CO adsorbed on Pd(100) **(a)** and O_2 adsorbed on Pt(111) **(b)**. **(a)** Reprinted from [26.19], with permission from Elsevier. **(b)** Reprinted adapted with permission from [26.20]. Copyright 1994 American Chemical Society

surface would not be expected to have IR activity, and yet experiments show [26.20] that the mode is clearly observed, as in Fig. 26.4b, *Fan* and *Trenary* [26.20] framed the metal surface selection rule into a simple group theoretical argument: a vibrational mode is considered to be symmetry-allowed if it belongs to the same irreducible representation as the surface normal. In the case of the O_2/Pt(111) system, the molecule adsorbs with C_{2v} site group symmetry, and therefore the surface normal, which transforms like z, belongs to the A_1 irreducible representation. Therefore, the group theoretical arguments presented by Fan and Trenary would suggest that any vibration of the Pt−O_2 complex with A_1 symmetry should be IR active according to the selection rule. Indeed, both the O−O stretch and the Pt−O_2 stretch belong to the A_1 irreducible representation and are therefore IR active. Several notes were made regarding the physical origin for the IR activity of the O−O stretch. First, in conjunction with expansion/contraction of the O−O bond, a net perpendicular displacement of the entire molecule takes place during the O−O stretching vibration, accounting for $\approx 10\%$ of the total atomic displacements during the vibration. Second, a perpendicular charge transfer between the metal substrate and adsorbate takes place in registry with parallel O−O stretching displacements, giving rise to a dipole moment perpendicular to the surface and responsible for the considerable intensity of the mode. A similar reasoning was invoked for the case of the IR activity of the (totally symmetric) C−C stretching mode on ethylene/Pt(111), another case where the C−C bond was known to be parallel to the surface. For this system, the IR activity was proposed to originate from mixing of the C−C bond stretching with the wagging motion of the methylene groups, which is perpendicular to the surface. The possibility of adsorbate–substrate charge transfer during the C−C bond stretching/compression was also acknowledged as possibly contributing to the appreciable intensity of the mode.

Transmission

The IR transmission geometry (Fig. 26.2b), arguably the most versatile geometry for IR absorption measurements, can be applied to surface studies of a range of different types of substrates, from transparent or weakly absorbing materials, to powders and supported catalysts, and even sufficiently thin metal thin films on transparent substrates. Developments in spectrometers, sources, and detectors over the past 20 years have improved the throughput of the beam for typical benchtop sources such that the signal-to-noise ratio (SNR) obtainable for a single pass (through both surfaces of a double-side polished crystal) is sufficient to observe submonolayer coverage of adsorbed species, as will be shown below. Unlike the multiple internal reflection (MIR) geometry (1.1.3), the beam enters the sample from the surface of interest, and there is no need for edge beveling. This enables a much simpler configuration for temperature control of the sample through direct resistive heating of the sample itself, in the case of semiconductor surfaces. Furthermore, the measurements can be performed at arbitrary angles of incidence and, coupled with the use of polarization, provide detailed information on the structure of adsorbed complexes. The IR intensity transmitted through a sample of thickness d follows a Beer's law dependence, $I = I_0 e^{-\alpha d}$, and the absorbance is defined as $A = -\log(I/I_0)$. Here, I_0 is the intensity of the incident

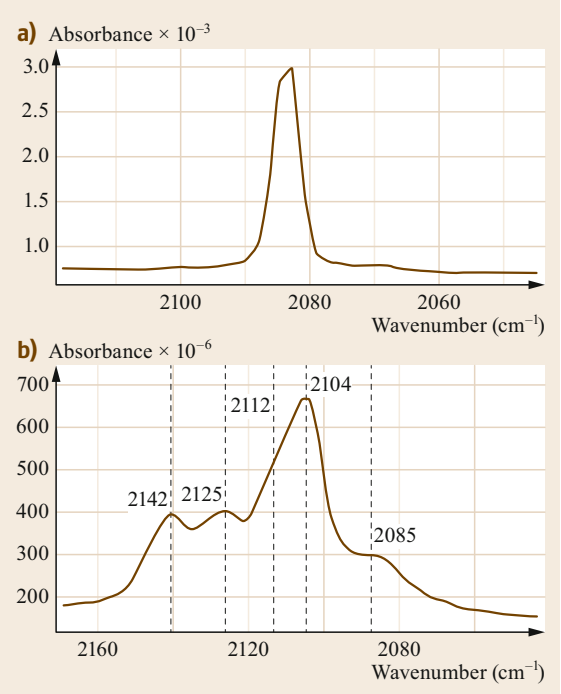

Fig. 26.5a,b IR absorption spectra of H-terminated Si(111) prepared by HF and NH_4F etching **(a)** and H-terminated Si(100) prepared NH_4F etching **(b)** measured using the Brewster's angle transmission geometry

IR beam, I that of the transmitted beam, and α the absorptivity of the material. In the case of semiconductor substrates, which are usually partially absorbing in the IR, the background attenuation due to bulk absorption can be substantial. With transmission measurements, an interesting option is to use p-polarized radiation at the Brewster angle of the substrate (Fig. 26.2b), thus suppressing reflection losses (i.e., interferences) and enhancing the transmitted signal. Another advantage of this geometry is that, since the incident beam contains electric field components both parallel and perpendicular to the surface, vibrational modes of all orientations are probed. When measurements are used in conjunction with a polarizer, this allows for the determination of the orientation of adsorbate bonds. In studies of supported thin films, both LO and TO modes are detected. In contrast, at normal incidence the beam is naturally polarized perpendicular to the plane of incidence (s-polarized), and therefore only the parallel components of adsorbate or TO phonon modes are detected. In supported particle or pressed powder samples, normal incidence is ordinarily used for simplicity, since the constituents are randomly oriented. Alternatively, for highly scattering powders or pellets, the diffuse reflectance geometry can be used. In this case, the beam is incident along the surface normal, and mirrors collect the diffusely scattered light and refocus into the detector. A procedure known as the Kubelka–Munk transformation is applied to the spectra to account for mixing of the real and imaginary parts of the refractive index that result from resonant Mie scattering.

As an example, Fig. 26.5a,b shows IR absorption spectra of NH_4F-etched Si(111) and Si(100) surfaces, respectively, collected from Brewster's angle transmission measurements. Here, the reference measurements are those of the same crystals prior to etching. In the case of Si(111) surfaces, a single intense peak is observed, associated with the atop monohydride species that fully passivate the surface [26.22]. In the case of Si(100) surfaces, a much more complicated absorption profile is observed. Previous scanning tunneling microscopy (STM) investigations showed the surface morphology to be quasi-atomically flat, and polarized multiple internal reflection (MIR) measurements (discussed later) identified bands associated with strained monohydride, strained dihydride, and unstrained dihydride [26.23]. In the spectrum shown in Fig. 26.5b recorded in transmission mode, the bands observed at 2104 and 2112 cm^{-1} are associated with unstrained dihydrides, those at 2085 and 2142 cm^{-1} with strained dihydrides, and the band at 2125 cm^{-1} with strained monohydride. Several important points can be taken from these spectra. First, the SNR obtained from a single-pass transmission measurement is sufficient to clearly observe bands associated with surface species, at least for reasonably high coverage and/or strong or sharp modes. Second, the higher spectral resolution obtainable with IR measurements than with corresponding HREELS permits examination of distinct chemical species located within close spectral proximity.

Multiple Internal Reflection

In the MIR geometry (Fig. 26.2c), the beam is internally incident upon the surface–vacuum interface at an angle exceeding the critical angle, such that the beam is totally internally reflected multiple times by the front and back surfaces of the sample. This is typically accomplished by beveling the edges so that an external beam can enter the crystal at normal incidence with a bevel angle that achieves the angle of incidence required for total internal reflection. The clear advantage of this experimental geometry is the amplification of the signal from the surface due to the fact that the IR beam interacts with the surface multiple times, and is therefore the geometry of choice for examining very low-coverage and/or low-intensity modes. Another advantage of MIR spectroscopy is that, for typical angles of incidence, the measurements are equally sensitive to normal and parallel components of surface vibrations [26.1]. As

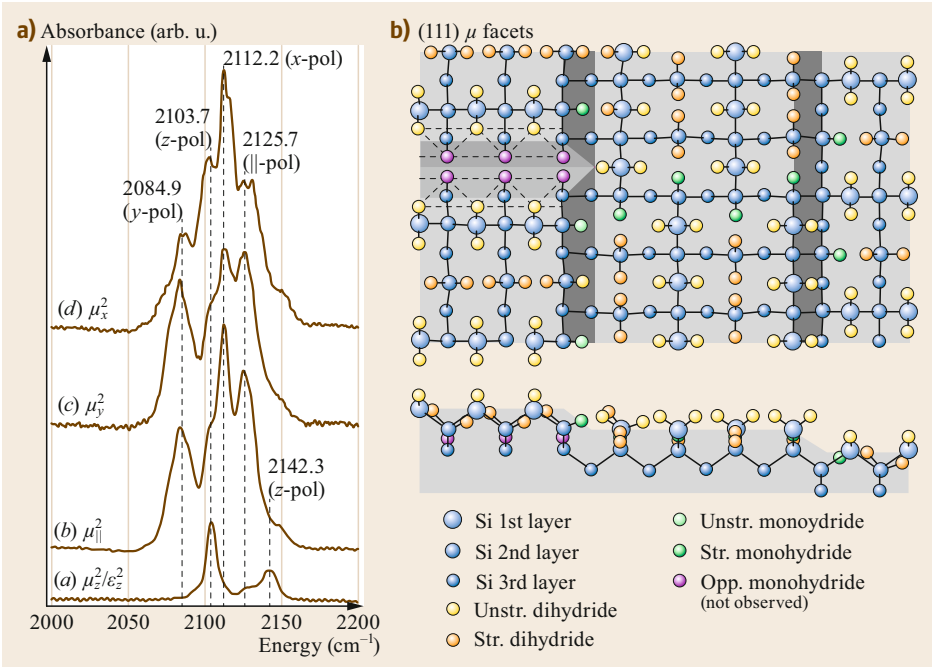

Fig. 26.6a,b Polarization-resolved MIR measurements enabled extraction of the Cartesian components of the dynamical dipole moment in the NH_4F-etched Si(100) **(a)**, and enabled the structural characterization of a complex hydride termination of the surface **(b)** (Reprinted adapted with permission from [26.23]. Copyright (2010) American Chemical Society)

for the case of the transmission geometry, polarization can be employed to extract information on the structure of adsorbed layers. One drawback of MIR measurements is the need to bevel the short edges of the samples and to keep them clear for IR beam access. The latter requirement prevents a uniform resistive heating because the short edges cannot support metal clamps over their whole length. In addition, the much longer optical path length of the radiation results in complete attenuation even in regions of weak substrate absorption. For example, the weak multiphonon absorption of Si renders the entire spectral region below 1400 cm^{-1} completely inaccessible. Nevertheless, MIR spectroscopy has offered significant insight into a number of complex systems [26.23–29]. *Hines* and coworkers performed polarization-resolved MIR spectroscopic studies of NH_4F-etched Si(100) surfaces in conjunction with scanning tunneling microscopy measurements [26.23]. STM images of the etched surfaces showed a structure composed of long rows, 0.9 Å in height and separated by 7.7 Å (exactly twice the distance between adjacent Si atoms). Polarized MIR spectra offered chemical insight into the identity of terminal H atoms. The spectra were computationally decomposed to deconvolute the Cartesian components of the dipole moments associated with each of the vibrations in the Si–H stretching region (Fig. 26.6a). A total of five distinct modes were observed, two of which had IR activity originating from dynamical dipole moments perpendicular to the surface, while three had activity originating from mostly parallel dipole moments. From existing literature and their relative splitting, two bands (2103.7 and 2112.2 cm^{-1}) were readily assigned to the asymmetric and symmetric vibrations, respectively, of unstrained dihydride species. Based on high-resolution STM imaging, these groups were found to exist in one-atom-thick rows, with the molecular plane perpendicular to the row direction. The adjacent missing rows showed characteristics consistent with dihydride termination in the STM images, and the polarization and splitting of the bands at 2084.9 and 2142.3 cm^{-1} were assigned to the asymmetric and symmetric vibrations of strained dihydrides rotated 90° about the surface normal with respect to the orientation of the unstrained dihydrides. The remaining band at 2125.7 cm^{-1} was attributed to strained monohydrides present at surface defects. The integration of high-resolution STM imaging and polarization-resolved MIR spectroscopy therefore led to the structural model depicted in Fig. 26.6b. Structural determination in the case of such a complex chemical termination highlights the advantages of the MIR technique: high sensitivity, spectral resolution, and polarization specificity.

Microscopy

While surface science has evolved primarily through the investigation of well-defined model systems, many current directions involve complex and inhomogeneous systems that may have variability at microscopic length scales. Potential applications include catalyst particles,

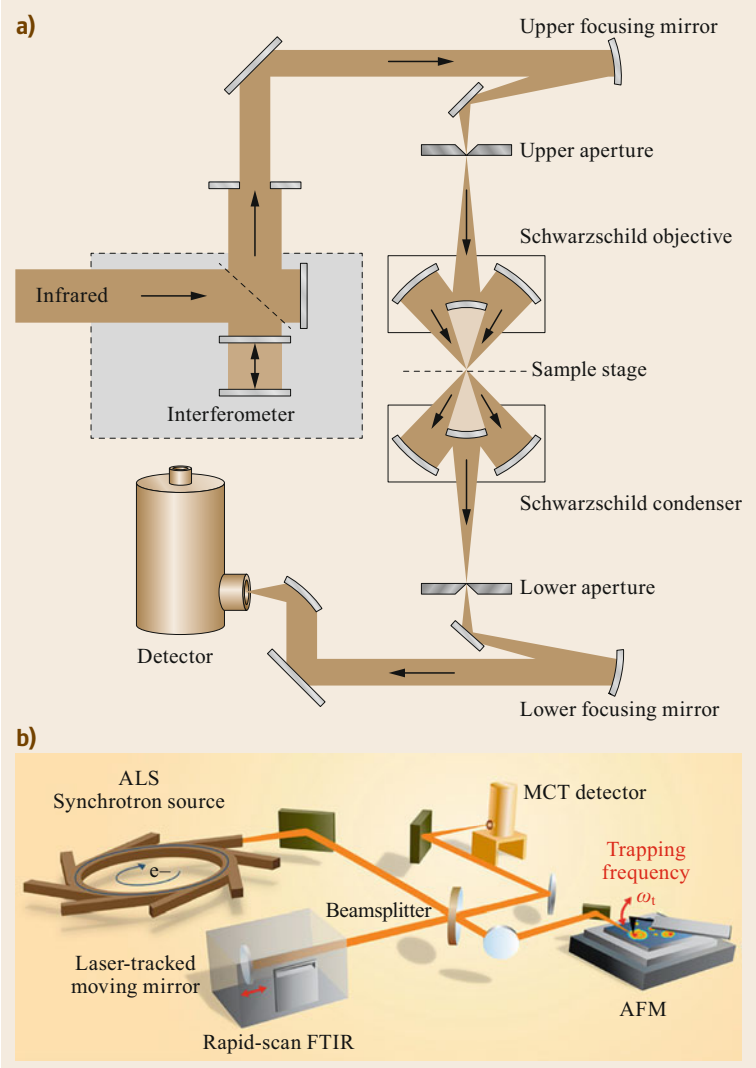

Fig. 26.7 **(a)** Optical arrangement used in typical far-field-based IR microspectroscopy, employing Schwarzschild optics and transmission geometry. **(b)** Experimental arrangement for broadband s-SNOM coupled to a synchrotron source (Reprinted from [26.30, 31], with the permission of AIP Publishing)

exfoliated films and 2-D (two-dimensional) materials, and microelectronic devices. In addition to conventional ultrahigh vacuum UHV-based surface science techniques that sample macroscopic sample areas, microscopic techniques (e.g., IR microscopy) have recently emerged and can be employed to study surface phenomena under high or atmospheric pressure. IR-based microscopy is particularly challenging, for a number of reasons. First, the comparatively long wavelength of IR radiation limits the obtainable resolution due to diffraction [26.30, 32, 33]. Second, the amount of light that can be focused on the sample is limited by the source size; typical lab-based Globar sources have a relatively low emittance, and therefore measurements performed at magnifications such that the resolution is diffraction-limited are usually subject to very poor SNR, hindering the study of weak signals originating from surfaces. The use of synchrotron radiation overcomes this problem, however, as the effective source size is small but has very high brightness. Most surface science-based studies using microscopy configurations have employed a synchrotron-based source.

Conventional far-field IR microscopy employs a Schwarzschild optical design (Fig. 26.7a). In the normal-incidence transmission geometry, an IR beam is focused onto the sample by a condenser lens, transmitted through the sample, and refocused onto a detector by an objective lens. In the normal-incidence reflection geometry, the incident and reflected beams are focused using the same Schwarzschild lens. Apertures are used before and after the condenser and objective lenses, respectively, to control the area illuminated and

measured. In this confocal geometry, imaging is accomplished by raster-scanning the sample through the illuminated area to generate spatially resolved spectral maps. Alternatively, recent developments in focal-plane array (FPA) detectors have also enabled wide-field imaging [26.35] that circumvents the need for raster scanning. Specialized optics also exist for grazing-incidence reflection microscopy.

While the constraints imposed by conventional microscope optics and stage control make vacuum conditions challenging, a number of groups have developed cells to enable simultaneous microscopy and in situ modification of surfaces or films. *Stavitski* and *Weckhuysen* [26.34] used in situ synchrotron-based IR spectromicroscopy to study the catalytic conversion of thiophene derivatives over a single microcrystal of the zeolite catalyst H-ZSM-5. Synchrotron-based transmission measurements, in conjunction with coherent anti-Stokes Raman scattering (CARS) measurements, were able to identify the chemical nature of the reactants and products, as seen from the IR spectra taken as a function of reaction time (Fig. 26.8b,c). In addition, polarization analysis has enabled the evaluation of the relative orientation of the product molecules with respect to the channel structure of the crystal (Fig. 26.8f). Imaging studies as a function of time have verified that both the reactants and products are concentrated within the interior of the crystal rather than the edges, demonstrating the potential of imaging studies in determining reactive sites of catalyst particles.

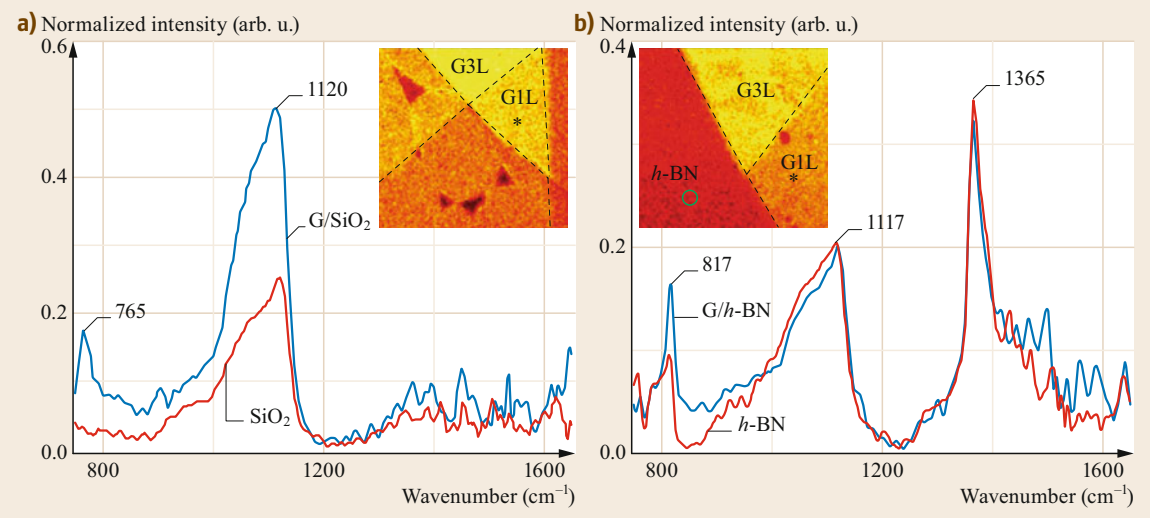

Fig. 26.9 **(a)** Synchrotron infrared nanoscopy (SINS) spectra of clean and graphene-covered SiO_2. **(b)** SINS spectra of BN and graphene-covered BN, showing enhancement of the LO BN phonon mode at 817 cm^{-1} (Reproduced from [26.36] with permission of The Royal Society of Chemistry)

In addition to conventional far-field spectromicroscopy, near-field IR spectromicroscopy coupled with atomic force microscopy AFM has recently been demonstrated [26.37, 38], as shown in Fig. 26.7b. Here, an IR beam is focused onto the apex of an AFM tip; the tip effectively serves as an antenna, and the scattering amplitude is measured. Ultrabroadband spectrally resolved images are obtainable when a synchrotron beam is used as the light source [26.31], and the technique is referred to as scattering-scanning near-field optical microscopy (s-SNOM) or synchrotron infrared nanospectroscopy (SINS). In this geometry, AFM images are collected in parallel with IR spectra; the obtainable spatial resolution is not limited by diffraction but rather by the size of the AFM tip, yielding spatial resolution much higher than that achieved with conventional optics. In one recent demonstration, *Barcelos* et al. [26.36] used SINS to examine graphene/BN heterostructures on SiO_2. Figure 26.9 shows SINS spectra from heterostructures composed of graphene/SiO_2 (Fig. 26.9a) and graphene/h-BN (Fig. 26.9b). The insets show the corresponding s-SNOM images, generated from the total spectral intensity integrated over the entire bandwidth, enabling visualization of the locations of single- and few-layer graphene flakes. The positions from which the spectra are extracted are indicated in the s-SNOM maps in the insets. The spectra in Fig. 26.9a compare the intensity of the SiO_2 surface phonon for a bare SiO_2 surface and a graphene/SiO_2 interface. The increase in the SiO_2 mode originates from coupling of the charge carriers in the graphene sheet to the SiO_2 surface phonon. SINS spectra acquired from graphene/hBN/SiO_2 are compared with those acquired from hBN/SiO_2 in Fig. 26.9b. As before, the SiO_2 surface phonon mode is identified at 1120 cm^{-1}, and modes due to hBN phonons can be observed at 1365 cm^{-1} (TO out-of-plane mode) and 817 cm^{-1} (LO in-plane mode). Interestingly, the spectra from the graphene/hBN heterostructure showed a significant enhancement (70%) of the LO hBN mode at 817 cm^{-1}, and this enhancement was ascribed to a coupling between the plasmons in the graphene sheet and the surface phonons of the hBN to form a hybrid surface plasmon–phonon polariton (SPPP). Additional measurements were performed on a region in which a bubble formed between the graphene sheet and the hBN substrate such that a void of ≈ 40 nm was formed. Interestingly, the SiO_2 and TO hBN modes were no longer detectable, as they were outside the ≈ 25–30 nm interaction volume of the AFM tip; however, the (enhanced) LO hBN mode at 817 cm^{-1} was detected, confirming the long-range nature of the interaction between the LO hBN phonons and the graphene plasmons. Such measurements highlight the unique information that can be obtained when IR spectroscopy can be performed with < 50 nm spatial resolution.

26.2.3 Low-Energy Electronic Excitations at Surfaces

In addition to exciting vibrational modes of adsorbates, IR light can couple to electronic excitations near the Fermi level, providing information on the electronic structure of a surface or film, similarly to how optically

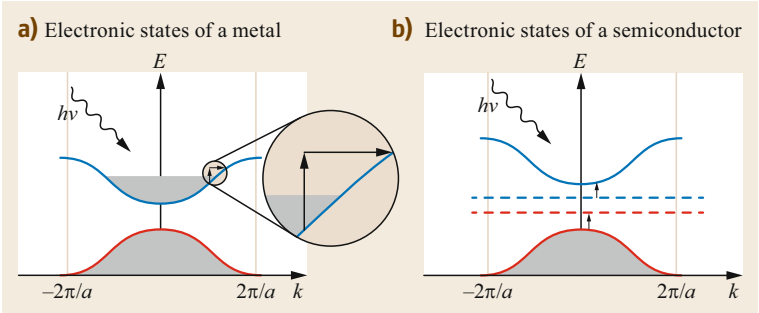

Fig. 26.10a,b IR active electronic excitations in solids. In the intraband absorption process **(a)**, an electron is promoted to a higher energy state within the same band, and momentum is conserved via phonons or other scattering processes. In the interband absorption process **(b)**, a photon promotes an electron to a higher energy state within a different band. Transitions of this type can occur, for example, between the valence and conduction bands of semiconductors, impurity states, and bulk valence and conduction bands, or between surface-state bands and bulk valence and conduction bands (Reprinted from [26.2], with permission from Elsevier)

active transitions are probed in the bulk. Figure 26.10 shows a schematic describing the different types of absorption processes that can take place in metals and semiconductors. In a metal or doped semiconductor, the conduction band is partially filled, and intraband excitations, in which an electron is promoted to a higher energy state within the same band, can be excited. Interband transitions, also commonly referred to as free carrier absorption, give a characteristic Lorentzian line shape centered at zero frequency that decays throughout the mid-IR or visible region at a rate depending on the carrier density, effective mass and relaxation time. An electronic absorption of this type is often well described within the Drude model, in which the frequency-dependent conductivity σ is related to the relaxation time, carrier density, and effective mass as

$$\sigma(\omega) = \frac{Ne^2}{m^*} \frac{1}{\frac{1}{\tau} - \mathrm{i}\omega} , \qquad (26.3)$$

where N is the carrier density, τ the relaxation time, e the electronic charge, m^* the effective mass, and ω the frequency. Within the context of this model, fitting a broadband IR absorption spectrum to a Drude-type functional dependence (26.3) can be used to quantify the conductivity of a surface or thin film; the primary challenge is discriminating between signals arising from the surface and bulk, particularly in the case of metals. One approach is to collect the spectrum of the clean surface of interest, and then quench the associated surface states (e.g., by dosing the surface with oxygen or another species) to prepare a reference surface in which intraband transitions are not present. Alternatively, one can study a differential spectrum to examine the *change* in the conductivity of the surface resulting from a certain process (adsorption, surface reconstruction, etc.). Quantification of the differential spectrum can then proceed through the differential analog of (26.3).

A field of current interest in which optical probes of the conductivity of the surface provide unique insight is the investigation of topological insulators. Stoichiometric crystals of these materials are expected to possess an insulating bulk phase, while the surfaces are characterized by symmetry-protected metallic states. A challenge in optical studies of metallic surface states in topological insulators is that crystal impurities incorporated during growth can give rise to a free carrier response that may be difficult to distinguish from that of the metallic surface states. One such study was conducted by *Post* et al. [26.39], where IR spectroscopic studies were performed on the alloyed topological insulator (TI) $(Bi,Sb)_2Te_3$. In that work, a combination of Fourier transform and time-domain spectroscopic measurements were used to extract the optical conductivity of the sample (Fig. 26.11). Contributions due to phonon modes (6 and 8 meV) were deconvoluted from the Drude peak due to the free carrier response (broadband modulation that increases with decreasing frequency). The oscillator strength of the Drude peak in the experimental conductivity spectra was compared with that obtained from calculations of the free carrier response from a linearly dispersing metallic surface state. The authors found that at sufficiently low temperature (< 100 K), the magnitude of the Drude oscillator strength reached the upper limit predicted by the theoretical model, indicating that the free carrier response was not dominated by bulk carriers. This finding was significant for the field, as it provided a road map for discriminating bulk and surface free carrier absorption to enable future studies of the physics of TIs.

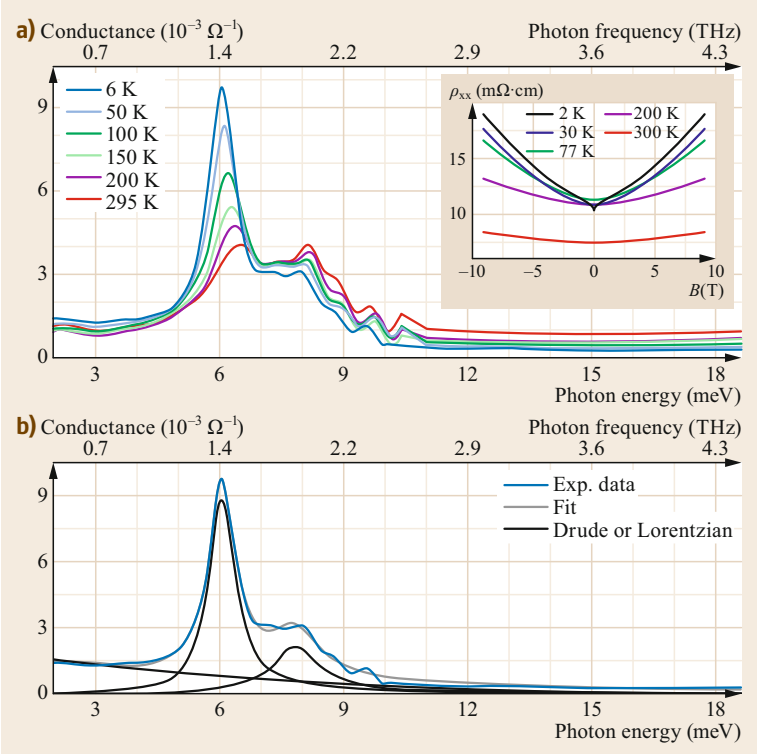

Fig. 26.11 **(a)** Temperature-dependent spectrum of the conductance spectra of $(Bi, Sb)_2Te_3$ as a function of temperature. The bands at 6 and 8 meV are due to phonon resonances, and the broad baseline change is due to the free carrier response. **(b)** Drude–Lorentz model fit of the 6 K experimental conductance (Reprinted with permission from [26.39]. Absorption of IR light can also excite interband excitations from metals and semiconductors, as depicted in Fig. 26.10b. Here, an electron is promoted from a state in a band below the Fermi level to a different band above the Fermi level. These transitions can take place for states in the bulk valence and conduction bands, between surface states and bulk bands, or between donor or acceptor impurity states and bulk or surface bands. The distribution of optically active interband transitions in a material as a function of energy is referred to as the joint density of states (JDOS), the general expression of which follows the form

$$\rho_{cv}(\hbar\omega) = \frac{2}{8\pi^3}\iint \frac{dS}{|\nabla_k (E_c - E_v)|_{E_c - E_v = \hbar\omega}} , \quad (26.4)$$

where the integral is carried out over the Fermi surface, and E_c and E_v are the bottom and top of the conduction and valence bands, respectively. The points at which the denominator vanishes, known as critical points, provide distinct optical markers in the JDOS that provide information on the curvature of the bands giving rise to the transition. The shape of the singularities in the JDOS can follow one of several different functional forms (four possibilities exist for a 3-D (three-dimensional) system versus three for a 2-D system) depending on the dispersion of the bands of interest, and therefore be used to infer details on the electronic band structure of the system through a process known as critical point analysis. As for the case of intraband transitions, the challenge is discriminating the surface versus bulk signals; similar approaches can be used for those described above, i.e., quenching the surface state or examining the overall change in absorption.

IR spectroscopic measurements of interband transitions in graphene and its multilayer analogs have yielded much insight into its electronic structure. In one such example, IR spectroscopy was used to measure the band gap of bilayer graphene as a function of electrical gating. In work by *Zhang* et al. [26.40], field-effect transistor devices employing graphene as the semiconducting element were fabricated and examined as a function of gate voltage using synchrotron-based transmission measurements (Fig. 26.12). In comparing the measured absorption spectra with predictions based on the tight-binding model, they were able to demonstrate tunability of the band gap of bilayer graphene by varying the voltage of the top and bottom gate electrodes.

An important consideration arises when studying the surface electronic structure of metals using the reflection-absorption geometry. Calculations of the electric field of a grazing-incidence IR beam reflected from a metal surface have shown that, immediately

above the surface, the tangential (s-polarized) component of the field is suppressed due to the phase change upon reflection (or alternatively the boundary condition requiring the s-component to be continuous), while the normal component of the p-polarized radiation is enhanced by addition of the incident and reflected components. In contrast, *below* the surface, the radiation is strongly refracted, resulting in a much stronger tangential component than normal component [26.1]. An example of such a measurement is shown in Fig. 26.13, where the electronic absorption of clean, unreconstructed W(100) is shown to give rise to a strong broadband feature throughout the mid-IR [26.41]. In light of the geometric considerations discussed above, the origin of this feature was associated with d-band surface states with x^2-y^2 symmetry.

In certain cases, the dominance of the excitation of transitions parallel to the surface (below the surface) leads to nonadiabatic coupling of these electronic levels to adsorbate vibrations parallel to the surface (above the

surface) [26.43–45], detected as a Fano-shaped modulation of the electronic absorption. Persson has argued the generality of the phenomena, demonstrating that parallel frustrated adsorbate translations or vibrations with zero dynamical dipole moment parallel to the surface should always manifest strong anti-absorption resonances or Fano line shapes [26.43]; however, later work established selection rules determined by the parity of the vibrational and electronic states involved, as well as the magnitude of the density of states at the Fermi level, that determine whether such vibrations are detectable [26.45, 46]. Experimentally, the first observation of detection of a formally dipole-forbidden mode was reported by *Chabal* [26.41] for IRRAS measurements of H on W(100) (Fig. 26.13b). Here, the symmetric stretch is observed as a normal absorption band (1070 cm^{-1}), while an additional mode is detected at 1270 cm^{-1} with a highly asymmetric line shape. This mode was originally assigned to the overtone of the W−H wag mode, but later suggested to be associated with the W−H asymmetric stretch on the basis of the symmetry of the surface electronic states measured by photoemission and believed to be involved in the coupling; these states have an even symmetry with respect to the (001) mirror plane, suggesting that the vibrational mode should also have even parity such as the asymmetric stretch. Similar anti-absorption resonances originating from parallel adsorbate modes have since been observed for H/Mo(100) [26.41], CO/Cu(100), and H/Cu(111) [26.47].

26.3 Low-Energy Ion Scattering

Low-energy ion scattering (LEIS), also known as ion scattering spectroscopy (ISS), is a highly surface-sensitive experimental method that enables the determination of the elemental composition of the outermost atomic layer of a solid, and can provide varying degrees of insight into surface atomic structure [26.48–51]. In this technique, a beam of noble gas atoms is ionized and accelerated to an energy within the range 0.1−10 keV before being directed onto a sample surface. A fraction of the incident ions undergo collisions with the surface atoms and are scattered without being neutralized (possibly through reionization processes). The scattered ions are detected after passing through an energy analyzer and, based on their final kinetic energy, the masses of the atoms by which they scatter are determined. In this fashion, the different elements present at the surface of a material are quantified. The surface selectivity of LEIS signals originates from the low energy of the incident ions and the very high probability that an incident ion will become neutralized upon interaction with a solid surface. The concepts of shadowing and blocking can be used to further understand the preferential selectivity of surface signals in LEIS versus ion scattering measurements performed at higher energies (e.g., MEIS, RBS). Shadowing arises from the scattering of an incident projectile, which modifies its trajectory such that atoms situated within a certain volume behind the target atom cannot act as scattering centers and are therefore invisible to the incident beam. The volume shadowed by the target atom is referred to as the shadow cone. Similarly, an ion scattered by a target atom and subsequently scattered again by another target atom establishes an additional shadowed region behind the second target atom, known as the blocking cone. As illustrated in Fig. 26.14, the relative sizes of the shadow cones (relative to a typical inorganic crystal structure) depend on the ion incident energy. At high energies (MeV), as is the case of RBS, the shadow cones are narrow. In contrast, at energies typical of LEIS, the shadow cones are of the order of interatomic spacings, since the low energy of the projectile will cause its trajectory to deviate strongly around a relatively weak interaction potential. The larger shadow cone in the case of LEIS means that the probability for an incident projectile to

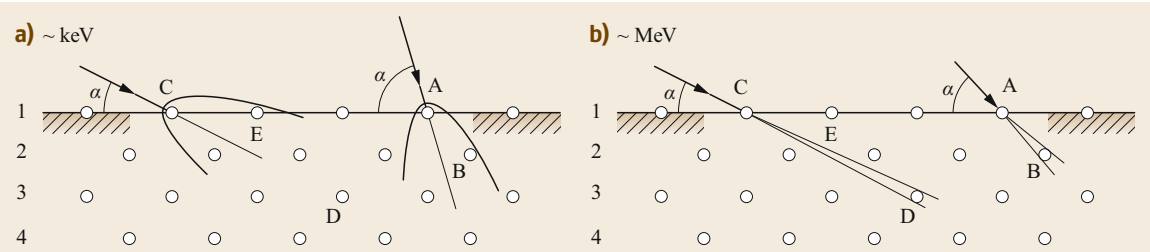

Fig. 26.14a,b Schematic diagrams of the shadow cone relative to interatomic dimensions in the case of LEIS **(a)** and RBS **(b)** (Reprinted from [26.52], with permission from Elsevier)

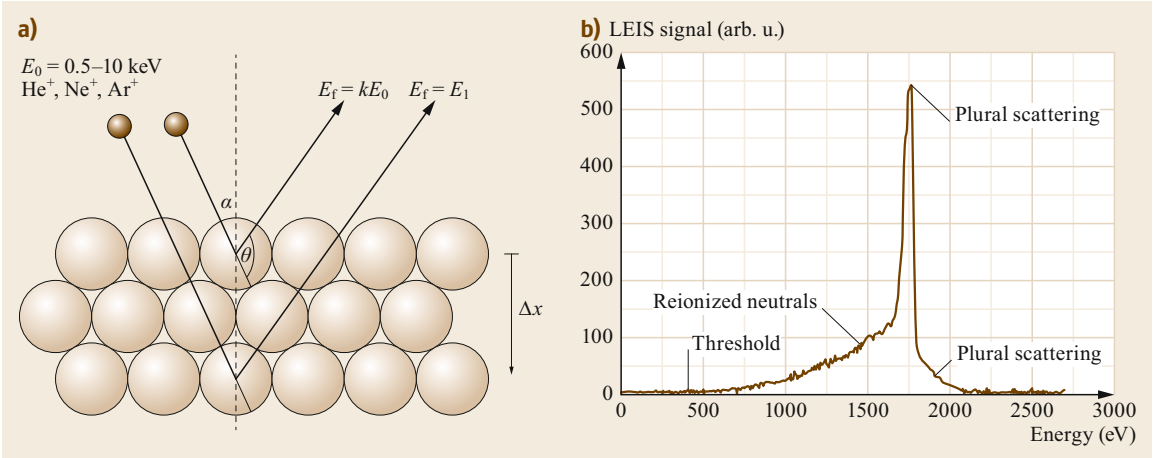

Fig. 26.15 **(a)** Experimental scheme for LEIS measurements; noble gas ions incident upon a surface at an angle α from the surface normal are scattered into an angle θ with energy kE_0. **(b)** Features in a typical LEIS spectrum illustrated for 3 keV He^+ scattered from polycrystalline Al (Reprinted from [26.50], with permission from Elsevier)

penetrate and exit the surface without scattering and/or becoming neutralized is negligibly small, and therefore the binary scattering peaks in LEIS spectra are generally representative of elements present at the outermost layer of the surface.

Quantification of the relative amounts of the respective elements at the surface may be carried out by evaluating the total ion yield associated with each element and scaled by a calibration factor determined by measurement of samples with known surface concentrations. This poses the most challenging problem, for a number of reasons. First, calibration can be challenging because of the need to obtain well-defined standards with known surface concentrations. This is often done using a pure crystal or thin film for the reference measurement; however, for many elements (such as N, O, Cl, F, and many others) there exists no pure elemental material that can be used for this purpose. Second, there exist certain cases in which the ion yield is dependent upon the coverage or density of the species in question, and such cases are referred to as suffering from *matrix effects*.

In addition to providing information on the composition of the outermost atomic layer, analysis of experimental LEIS spectra also provide a static, nondestructive depth profile of the first 5−10 nm within the surface of a sample [26.50, 53]. Quantification of depths and concentrations of relevant species is accomplished through the use of simulations that statistically treat the interaction between an atom beam of interest with a target sample [26.54]. Lastly, information from LEIS has the potential to give valuable insight into surface structure and bonding configurations, and measurements performed under certain conditions enable surface crystallography with elemental specificity [26.55]. In the following sections, we review the fundamental principles of LEIS measurements, with emphasis on recent developments of the technique and illuminating examples that highlight the type of information that can be extracted.

26.3.1 Identification of Surface Elements and Concentrations from Binary Collisions

In a typical LEIS measurement, a monochromated beam of ions (typically noble gases; He, Ne, and/or Ar) is ionized, accelerated and incident upon a sample surface at an angle α, as shown in Fig. 26.15. Some fraction of the incident ions undergo a single elastic scattering process without being neutralized, and subsequently scatter at an angle θ with respect to the angle of incidence. The ions scattered within some angular range are then collected into an energy analyzer and subsequently detected to produce a spectrum showing the number of ions detected as a function of energy. Within the binary collision approximation (BCA), conservation of energy and momentum gives for the final energy E_f of an ion of mass m_1 scattered from an atom of mass m_2 through an angle θ with respect to the surface normal [26.48–50]

$$E_f = \left(\frac{\cos\theta \pm \sqrt{(m_2/m_1)^2 - \sin^2\theta}}{1 + \frac{m_2}{m_1}} \right)^2 E_0 \,. \quad (26.5)$$

The final energy of the ions in an LEIS measurement is a direct function of the mass of the scattering atom, and can therefore be used to deduce the elemental composition of the surface atoms. There are, however,

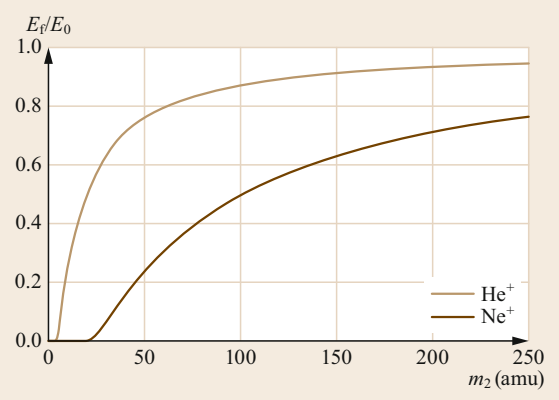

Fig. 26.16 Energy lost during binary collisions for He^+ and Ne^+ projectiles as a function of the mass of the scattering atoms based on (26.5). Here, a scattering angle of 145° is assumed

combinations of masses and angles for which backscattering does not occur. For instance, elements lighter than that of the probing ions cannot be detected (e.g., H using He^+); similarly, first-row elements cannot be detected by backscattering when Ne^+ is used as the projectile. In practice, the choice of probe ion is made on the basis of the elements being targeted. While Ne^+ cannot detect first-row elements, He^+ may not be sufficient to resolve heavy elements that are close in mass. Figure 26.16 shows the dependence of the final projectile energy as a function of the mass of scattering atoms for He^+ and Ne^+ projectiles based on the solutions of (26.5), assuming a scattering angle of 145°. Clearly, the values of E_f/E_o for heavy masses (e.g., > 50 amu) are very similar when He^+ is used as the projectile and therefore may not be sufficient to resolve elements of similar mass. In contrast, the values of E_f vary much more rapidly in the 50−100 amu region when Ne^+ is used as the projectile. For resolving even heavier elements, Ar^+ or Kr^+ can be used.

The ions scattered from binary collisions generally give the most prominent features in an LEIS spectrum and are used for evaluation of surface concentrations, but ions that undergo more complicated scattering processes are also detected. In addition to ions that undergo single scattering, many of the incident ions will penetrate below the surface and suffer multiple inelastic events. Of these neutralized ions, some will undergo trajectories that bring them back to the surface, and a fraction will become reionized at the surface such that they can be detected in a measured spectrum. As these species undergo multiple collisions as well as potential inelastic scattering events, they will ultimately be detected with final energies lower than that of the binary collision peak. The reionized neutrals can give rise to various structures in an LEIS spectrum ranging from tails to distinct peaks depending on the distribution of the scattering elements. Additionally, an incident ion can also scatter elastically from two or more surface atoms without becoming neutralized. Such multiple scattering events can be described by applying (26.5) twice, with the initial energy of the second collision treated as the final energy of the first collision. In such events, the final energy of the scattered ions is actually greater than that of an ion scattered through the same angle with a single binary collision; consequently, features due to plural scattering are observed at energies greater than that of the binary collision peak. Figure 26.15b shows an LEIS spectrum for 3 keV He^+ ions scattered from a polycrystalline Al target, where these representative scenarios are illustrated. A clear sharp peak from the He^+–Al binary collision is observed with a low-energy tail due to ions that become neutralized and are ultimately reionized after undergoing multiple scattering events below the surface. On the high-energy side of the binary collision peak, a shoulder due to elastic plural scattering is observed.

While the features due to plural scattering and reionized neutrals can yield valuable information, as will be discussed below, the binary collision peak (also referred to as the *surface peak*) is generally the most useful and widely used feature in the spectrum for quantification of surface species. The yield of ions scattered from a particular element is directly related to the surface concentration of the element in question

$$S_i = \frac{I_p}{e} t \xi R \eta_i N_i \tag{26.6}$$

Here, S_i is the number of ions detected, I_p the primary beam current, e the electronic charge, t the measurement time, R a correction factor determined by surface roughness (equal to 1 for flat surfaces), η_i and N_i the sensitivity factor and surface concentration, respectively, for the element in question, and ξ an instrumental factor into which the characteristics of the analyzer and detector are absorbed. The elemental sensitivity factor is determined by the differential scattering cross section $d\sigma_i/d\Omega$ and the fraction incident ions that do not become neutralized upon interaction with the surface, known as the ion fraction P_i^+

$$\eta_i = P_i^+ \frac{d\sigma_i}{d\Omega} \tag{26.7}$$

In general, the elemental sensitivity factors are not necessarily known, and ξ and η_i are determined through calibration measurements of appropriate standards. If the η_i is independent of the number and type of surrounding atoms, i.e., absent matrix effects, the calibration can be performed on any sample in which

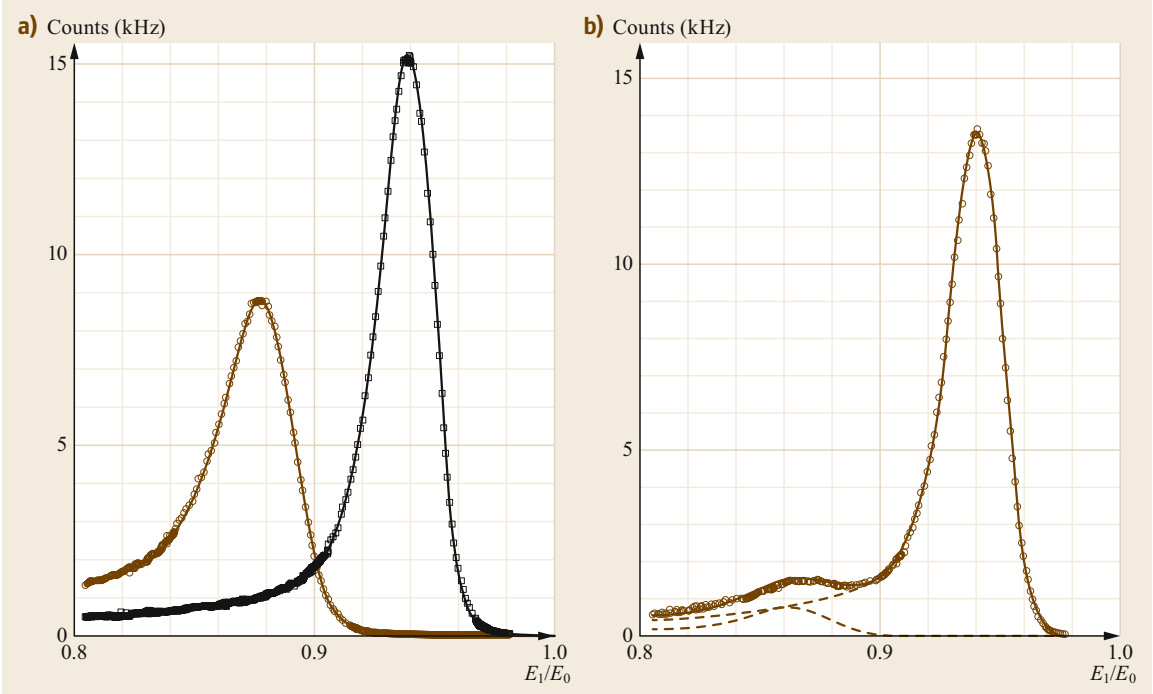

Fig. 26.17a,b 2 keV He^+ LEIS spectra of pure Pt and Ru standards **(a)** and an annealed PtRu alloy **(b)** (Reprinted from [26.56], with permission from Elsevier)

the atomic surface concentration is known. One such application in which this approach is readily used is quantification of the elemental composition of alloyed metals used in catalysts, as this knowledge provides insight into the active sites in various catalytic processes [26.57–61]. For example, *Gasteiger* et al. [26.56] used LEIS to determine the surface composition of a series of PtRu alloys following sputtering or annealing. In their work, pure Pt and Ru reference samples were prepared and measured to evaluate the ion yield of the respective elements (Fig. 26.17a). With this calibration, it was possible to determine the surface composition of the alloy materials from measurements such as that in Fig. 26.17b. In doing so, they were able to determine that the surface concentration was predominantly bulk-terminated in the case of surfaces cleaned only by Ar^+ sputtering, whereas a differential enrichment of surface Pt was observed for surfaces annealed to 800 °C.

In the case of the a surface partially covered by an adsorbate layer, the signal due to the substrate atoms is reduced due to blocking by the adlayer [26.48, 49]. Consequently, the form for the signal of the substrate atoms (26.6) is modified to incorporate blocking by the adsorbates as

$$S_s = \frac{I_p}{e} t\xi R\eta_i \left(N_S - \alpha N_{ads}\right), \tag{26.8}$$

where N_s is the density of surface substrate atoms and N_{ads} that of adsorbate atoms; α is a factor introduced to describe how many substrate atoms are blocked by a single adsorbate, and is determined by the adsorbate geometry and scattering cross-section, which determine the shape of the adsorbate's shadow cone. At high coverage, the shadow cones from neighboring adsorbates merge and the shadowing coefficient decreases. The latter generally has a unitary order of magnitude, and if known can be used to determine the coverage of an adsorbate-covered surface. Similarly, this information can be used to determine various aspects of the adsorbate geometry, discussed in more detail below.

26.3.2 Charge Transfer Processes

As discussed above, the fate of an ion in the 0.1–10 keV energy range incident upon a surface can follow one of several paths. While ions that undergo binary collisions without being neutralized provide the most straightforward evaluation of the surface composition, understanding neutralization and reionization can give insight into the sensitivity of the measurement toward different materials and structures. The processes underlying charge exchange between a surface and a fast projectile are complex, and a comprehensive discussion is available elsewhere [26.48, 50] and is beyond the scope

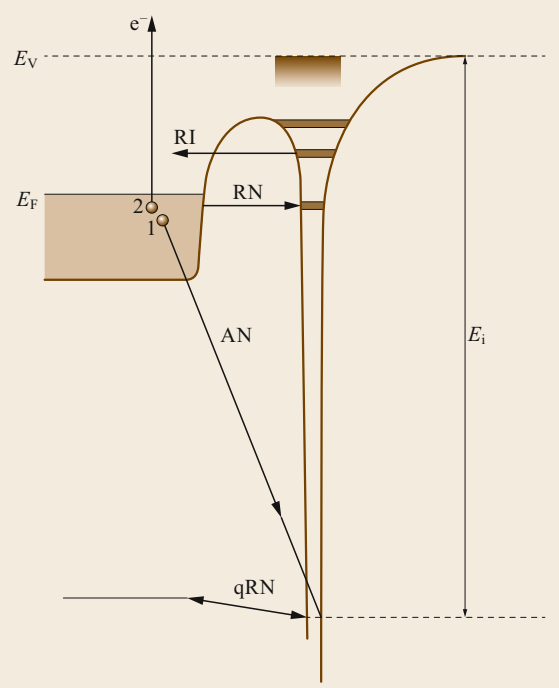

Fig. 26.18 Schematic energy diagram representing the processes of RN, RI, AN, and qRN in terms of the projectile and target levels (Reprinted from [26.48], with permission from Elsevier)

of this chapter. Here we present a qualitative review of the basic principles of neutralization and reionization that are of significance for LEIS measurements. Figure 26.18 shows a scheme depicting the principle charge exchange processes that give rise to neutralization and reionization of ions in the LEIS regime. When a fast, typically positively charged projectile approaches a surface, image charges induced in the solid lead to a broadening and can decrease the binding energy of the electronic states of the projectile due to repulsion between the electrons of the projectile and surface, leading to an increase in the energy of the highest electronic levels of the projectile relative to vacuum [26.62]. As the distance between the surface and projectile becomes increasingly small, the states of the projectile can begin to interact with those of the surface. In the process of resonant neutralization (RN), electrons in the conduction band of the crystal are resonant with unoccupied states of the projectile and proceed to tunnel into the unoccupied states, as depicted in Fig. 26.18. In the reverse process (*resonance ionization*, RI), electrons from the highest occupied orbital of a neutral projectile atom tunnel into the conduction band of the crystal, and the projectile becomes reionized. In *quasi*-resonant neutralization (qRN), electrons in a core-level of the surface may be nearly resonant with the ground state of the projectile, and tunneling between the levels can lead to neutralization. Such processes are heavily dependent on the energy of the projectile atom, since the probability for tunneling oscillates as a function of the time integral of the potential energy difference between the incoming (ionized) and outgoing (neutralized) states. This effect leads to strong oscillations in the ion fraction as a function of the incident projectile energy that are also dependent on the matrix, and such oscillations have been observed in systems such as He^+ scattering from Pb [26.63] and Ne^+ scattering from Au [26.64]. In Auger neutralization (AN), an electron from the substrate neutralizes the projectile, either by directly decaying to the ground state or through an intermediate metastable excited state, in conjunction with excitation of another substrate electron or plasmon. Alternatively, a substrate electron can fill a core-hole of the projectile, leading to emission of an Auger electron originating from an excited state of the projectile in a process known as indirect Auger de-excitation. Lastly, neutralization of an incident ion or reionization of a neutralized projectile can occur via collision-induced processes [26.65]. Here, a neutralized projectile atom becomes reionized when it approaches sufficiently close to a target atom as to promote a core-level state (e.g., the He 1s) to an energy that, at a certain critical distance from the target atom, is equal in energy to an excited (ionized) state. Consequently, an electron can be transferred to the target, and the projectile scatters in an ionized final state. Similarly, the reverse process can occur to yield collision-induced neutralization. Importantly, reionization provides a pathway of detection for which ions that become neutralized penetrate the surface and, through multiple scattering events, return to the surface.

The cycle of neutralization and reionization comes with an energy cost. It has been reported that for He projectiles in general, the complete neutralization and reionization process costs a total of $20+\varepsilon$ eV to transfer an electron to a He level at an energy ε above the Fermi level of the substrate. Thus, ions detected from reionization processes are always detected at energies below that of the binary collision peak. Take for example the hydrogen-terminated Si(111) surface. Figure 26.19 shows 3 keV He^+ spectra taken from Si(111)−H surfaces prepared by HF and NH_4F etching as-prepared and after sputtering with Ar^+ to remove the adsorbed H and yield a clean Si(111) surface. While in the case of the clean surface a clear, intense Si binary collision peak is observed, the H-terminated surface shows only a weak peak due to blocking of the Si atoms by atop H. In addition, the Si peak in this case appears shifted by ≈ 20 eV to lower energy. The physical interpreta-

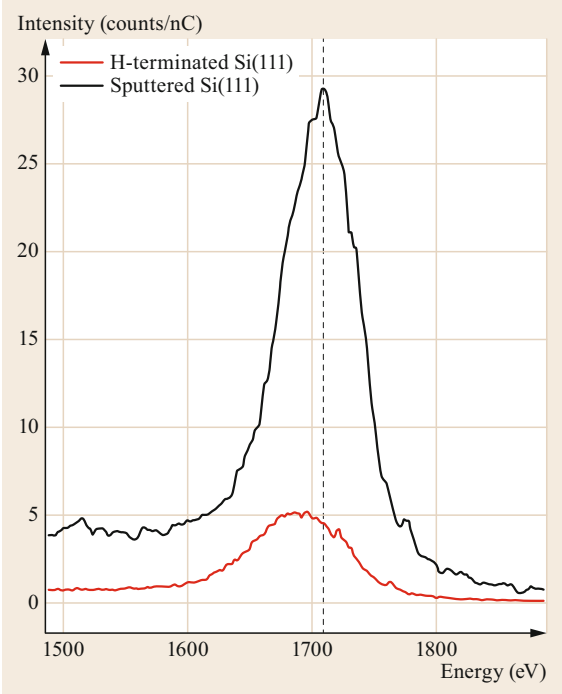

Fig. 26.19 3 keV He^+ LEIS spectra of hydrogen-terminated Si(111) before (*red*) and after (*black*) Ar^+ sputtering, demonstrating a ≈ 20 eV shift of the Si peak

tion for this effect is that the incident He^+ ions have undergone multiple scattering processes, initially with adsorbed H, that allowed them to penetrate the surface and scatter from Si atoms before being reionized. This neutralization and reionization cycle occurs at an energy cost close to 20 eV, leading to a lower apparent energy at which the Si atoms are detected.

26.3.3 Analysis of Subsurface Signals

Projectile ions that penetrate the surface and undergo multiple scattering trajectories within the bulk suffer additional energy losses as a result of various elastic and inelastic processes. Of the fraction of these particles that scatter back to the surface and are reionized, the total energy lost will be greater than the minimum required for the neutralization and charging cycles. With the appropriate a priori knowledge of the system, these signals can provide important information on the identity, location, and density of subsurface atoms. For example, Fig. 26.20a shows an 8 keV He^+ LEIS spectra of a multilayer system comprising a 1.2 nm HfO_2 film with a 2 nm Al_2O_3 cap. Here, the surface peaks for Al and O are at their expected positions for a binary collision based on (26.5), but the Hf peak is shifted to lower energy than that expected for surface Hf. In general, for the subsurface signals, the redshift in the peak position correlates with the depth of the scattering elements, while the width of the peak is related to their depth distribution or thickness. *Brüner* et al. [26.54] developed a method for quantification of these subsurface signals using a variation of the transport of ions in matter (TRIM) code [26.66] developed for Rutherford backscattering (RBS) data, known as TRBS. The approach involves calculating the scattering trajectory of a neutral projectile of a given energy for a particular model structure. The charge state of the projectiles is taken into account by assuming that the measured spectra are the product of the energy distribution of backscattered neutral particles with the ion fraction of the surface. In general, the material-dependent parameters needed for the calculations are not necessarily known, in particular the electronic stopping correction factor, which determines the projectile energy lost through nuclear and electronic processes within the material, and the reionization function, which determines the probability that an ion of a particular energy will be reionized at the surface. Fortunately, these parameters can be evaluated through the measurement of the appropriate standards in conjunction with TRBS modeling. The electronic stopping factor for a given material can be determined by comparing measurements of thin film structures of thickness known from other methods with TRBS simulations to determine the value that accurately reproduces the characteristics of the experiment. The probability for reionization at the surface or ion fraction is a function that is acutely dependent on the composition of the surface, and therefore must be determined specifically for the surface of interest. In practice, measurements of standards are performed over a reasonably large energy range such that the functional dependence of the ion fraction can be accurately determined and is unobscured by low-energy features due to secondary sputtered ions. Once measured, the surface peaks are subtracted off, and the measured spectrum is assumed to be the product of the ion fraction with the spectrum of backscattered neutrals; therefore, the ion fraction is determined by dividing the experimental spectrum by the simulated spectrum. Once these parameters have been determined, simulated LEIS spectra can be calculated for arbitrary structures for comparison with experiment. Brüner and coworkers found that for the case of the Al_2O_3/HfO_2 system used for the initial study, the approach described above was largely successful for determining the thicknesses of the respective components of the heterostructures (Table 26.1) despite some minor discrepancies in one sample.

26.3.4 Structural Analysis

LEIS measurements, in addition to providing the complete elemental composition of a surface, can yield valuable information on surface atomic structure. Depending on the measurement configuration, projectile characteristics, and numerical analysis, different types of information and degrees of detail on the structure of surfaces can be obtained. Such structural information can range from qualitative orientation of adsorbates and surface terminations to local symmetry and identity of nearest neighbor atoms, and even crystallographic studies yielding the complete structure of the surface unit cell.

The first and most straightforward approach to characterization of the surface atomic structure employs the principle of shadowing to make qualitative inferences regarding the bonding position of different elements on the surface. With some a priori knowledge of the surface structure, the idea that atoms that lie within the shadow cone of another atom will be invisible in single-scattering peaks can be used to qualitatively deduce the locations of the atoms of interest. Some of the earliest demonstrations of the strength of LEIS were in evaluating the surface terminations of non-centrosymmetric crystals such as CdS and ZnS [26.67]. Early studies on the opposite ⟨111⟩ polar faces of ZnS and the ⟨0001⟩ faces of CdS detailed the termination of these crys-

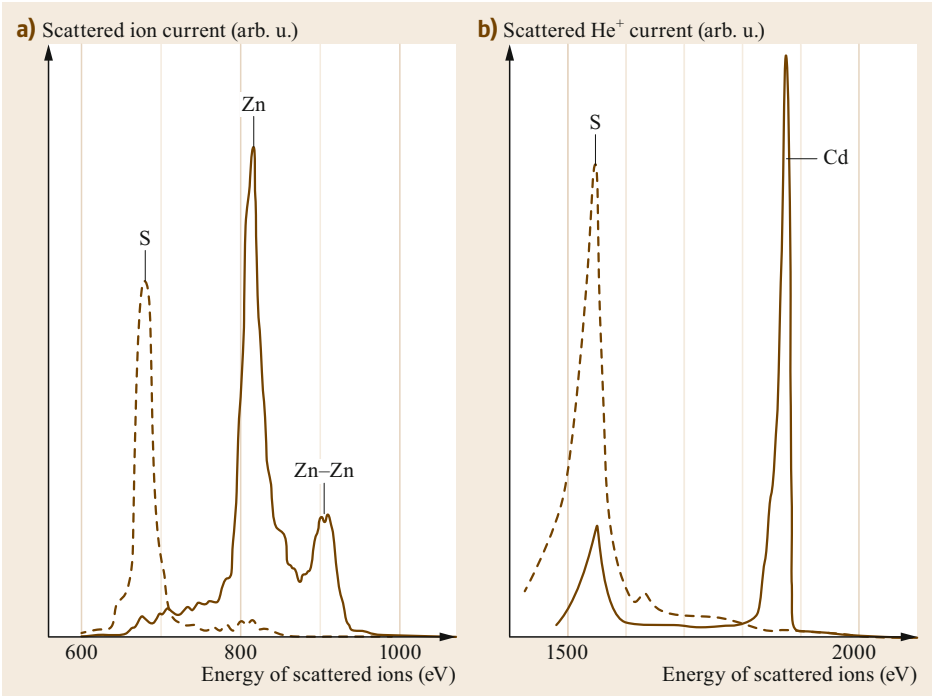

Fig. 26.21a,b He^+ LEIS spectra from opposite polar faces of ZnS **(a)** and CdS **(b)** (Reprinted from [26.67], with permission from Elsevier)

tals. In the case of ZnS, 1 keV Ne^+ spectra (Fig. 26.21) showed terminations in which only Zn and S, respectively, were detected for the opposite faces, suggesting a bulk termination as a reasonable approximation of the surface structure. Similar results were obtained for the opposite faces of CdS.

The approach in which the shadowing of atoms is employed to deduce their relative location can be further used to characterize adsorbate structures, as was done for an early study of CO adsorption on polycrystalline Ni [26.68]. Here, 1.8 keV He^+ LEIS spectra were taken from Ni foils dosed with CO, and an O peak of area approximately five times that of C was observed. The author noted that, with the similar masses and therefore scattering cross sections of O and C, a ratio of approximately 1 : 1 would be expected if the C and O atoms were randomly distributed on the surface. The observation of such a larger magnitude of the O peak was taken to mean that the CO molecules bonded perpendicular to the surface via the C atom, leading to increased visibility of O relative to C. This conclusion was in agreement with structural models derived from previous IR [26.69] and LEED [26.70] studies on similar systems. While the interpretation here is straightforward and could have been derived by complementary techniques alone, other cases in which the symmetry of the surface is evaluated by LEED are often less straightforward, as a given LEED pattern could originate from a number of potential structures. One of many such instances in which LEIS data have aided in structure determination is in the O/Ag(110). *Heiland* et al. [26.71] used LEIS in conjunction with LEED to determine the structure of the (2×1) reconstruction of the Ag(110) surface formed after dosing with 7000 L oxygen. In their work, they measured the ion yield for 500 eV He^+ ions scattered along the [100] and [110] directions (parallel and perpendicular to the atomic rows of the (110) surface) and observed a very strong variation in the O signal along these different directions (Fig. 26.22a). On the basis of this variation, they were able to discriminate between three possible structural models that could give rise to a (2×1) LEED pattern (Fig. 26.22b–d). From inspection, the structure depicted in Fig. 26.22b would not be expected to give strong azimuthal shadowing dependence, since the O is situated in the outermost plane and its nearest neighbors along the [100] direction are spaced comparatively far apart. Similarly, it was argued that only a moderate shadowing effect could be expected for the structure in Fig. 26.22c. In contrast, the structure depicted in Fig. 26.22d would be expected to give a strong shadowing effect for scattering perpendicular to the atomic rows due to the close proximity of the bridge site to the Ag nearest neighbors, which are situated at an elevated position relative to the O atoms. Arguments of this nature can be used to differentiate between different structural models, and the approach is most favorable in the case of well-ordered crystalline substrates.

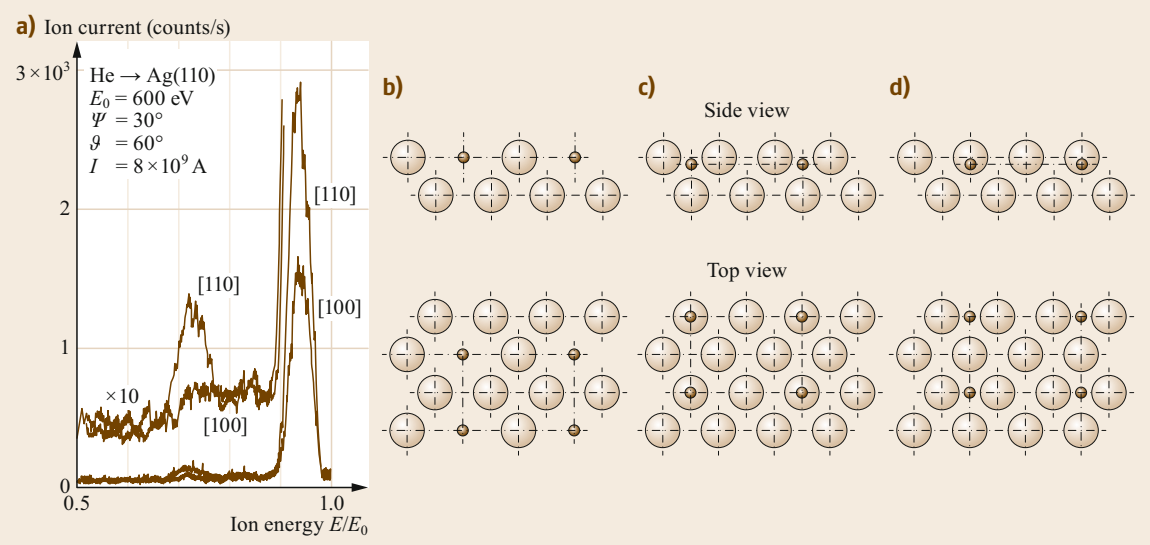

Fig. 26.22 **(a)** Experimental He^+ LEIS spectra of O-covered Ag(110) taken along different crystallographic orientations. **(b–d)** Potential structural models for O on Ag(110) that could give rise to a (2×1) LEED pattern (Reprinted from [26.71], with permission from Elsevier)

A second approach to atomic structure characterization using LEIS employs the principles of multiple scattering to infer information about the relative positions and identities of nearest neighbor atoms. In addition to undergoing binary collisions, an incident ion can undergo multiple collisions involving smaller scattering angles that add up to the total scattering angle. The final projectile energy in such a process is greater than that which would be measured for a single binary collision with the same total scattering angle, which can be seen by applying (26.5) twice. While this effect can be undesirable in the identification or quantification of surface elements, it can yield valuable insight into local structural environments. The final energy of the projectile after two or more collisions is dependent on the masses of all target atoms involved, and multiple scattering peaks can be used to infer the identity and potentially the location of nearest neighbor atoms. Some early theoretical work was performed to correlate multiple scattering features with underlying structures by employing simple models of the surface, such as simple atom chains [26.72], and this approach was largely successful for qualitatively reproducing many of the physical aspects of the experiments. Quantitative structural analysis, however, requires the use of indirect methods for structure determination through simulation of ion scattering experiments for different structural models [26.72–75]. Even so, in the case of close-packed and well-ordered surfaces, multiple scattering features in experimental data can often yield the identity of nearest neighbor atoms by inspection. Multiple scattering effects tend to be most pronounced in the case of low energies, heavy projectiles, and small angles of incidence and scattering angles. Therefore, while the use of high energies is typically used to circumvent multiple scattering features in experimental spectra, the use of heavy, (e.g., Ne^+, Ar^+) projectiles at low energy ($\approx 500\,eV$) can be used to amplify the measurability of multiple scattering features. In addition, the use of alkali projectiles has been shown to increase the ion fraction significantly [26.76, 77], and therefore the prospects for observing features due to multiple scattering are much more favorable.

Brongersma and *Mul* [26.78] performed measurements on the (111) and $(\bar{1}\bar{1}\bar{1})$ surfaces of GaP, as shown in Fig. 26.23. Here, the measurements are performed in a specular geometry along the $\langle 11\bar{2}\rangle$ direction with 350 eV Ne^+ and a scattering angle of 45°. The surfaces measured at room temperature are dominated by a broad feature due to recoiled Ga and P atoms; this effect is circumvented when the measurements are performed at 450 °C. In the case of the (111) surface, a binary collision peak due to Ga was observed in conjunction with new peaks due to Ga–P and Ga–Ga scattering, whereas only a Ga single-scattering peak was observed from measurement of the $(\bar{1}\bar{1}\bar{1})$ surface. The observation of the latter peak was indicative of surface reconstruction, since in the case of the unreconstructed surface, calculations indicated that blocking by P would make double scattering by nearest-neighbor Ga atoms impossible. This assessment was in agreement with a previous LEED study showing a (2×2) LEED

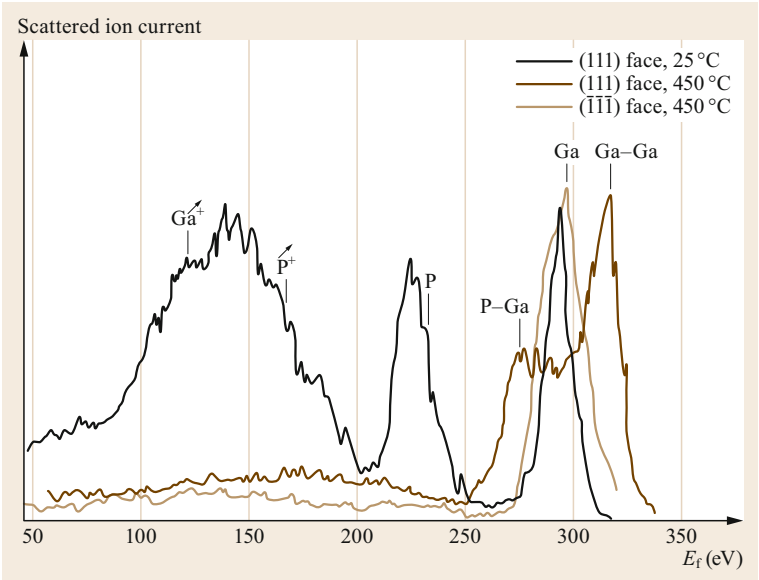

Fig. 26.23 350 eV Ne^+ LEIS spectra from GaP(111) and $(\bar{1}\bar{1}\bar{1})$ surfaces at room temperature and 450 °C (Reprinted from [26.78], with permission from Elsevier)

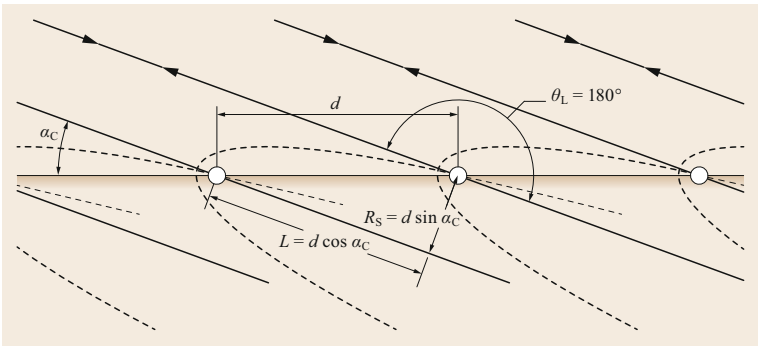

Fig. 26.24 Experimental geometry from ICISS. Backscattered ions are measured as a function of incidence angle. For angles less than some critical angle α_c, shadowing effects prevent backscattering, so that angle-dependent measurements can yield the dimensions of the shadow cone (Reprinted from [26.52], with permission from Elsevier)

pattern on the same surface upon annealing to 500 °C. In addition, the observation of a Ga–P peak indicated a position of the surface P atoms different from that of the bulk, and the authors suggested that additional measurements as a function of scattering angle and azimuth could further clarify the details of the reconstruction.

The most quantitative approach for determination of the atomic structure of surfaces originates from methods that measure the shape of the shadow cone. In impact-collision ion scattering spectroscopy (ICISS) [26.52, 55], the energy distribution of a beam of scattered ions is measured as a function of incidence angle at grazing angles along specific crystallographic directions. Rather than measuring the specularly reflected beam, the ions which are backscattered through a scattering angle of approximately 180° are measured. The principle of the measurement of the shadow cone can be understood by considering a chain of atoms as in Fig. 26.24a. For incidence angles greater than some critical angle α_c, the shadow cones of neighboring atoms completely block one another, and no backscattering occurs. As the angle of incidence approaches the critical angle, backscattering begins to increase. By considering the geometry of the system, it can be seen that the angle at which backscattering becomes possible is directly related to the interatomic spacing and the radius of the shadow cone. Since the shadow cone is specific to the element under consideration, the dimensions of the shadow cone for a particular element can be determined by measurement of systems in which the lattice constants are known and then applied to the unknown system. Importantly, for this geometry, only shadowing effects affect the measured data, and the combined effects of shadowing and blocking that are intractable in specular scattering are decoupled.

Aono et al. [26.79] used ICISS to study the (2×1) reconstruction of Si(100), performing measurements as a function of both the polar (incident) angle and azimuthal angle of the surface with respect to ⟨110⟩, as in Fig. 26.25a. In particular, the spectra measured at graz-

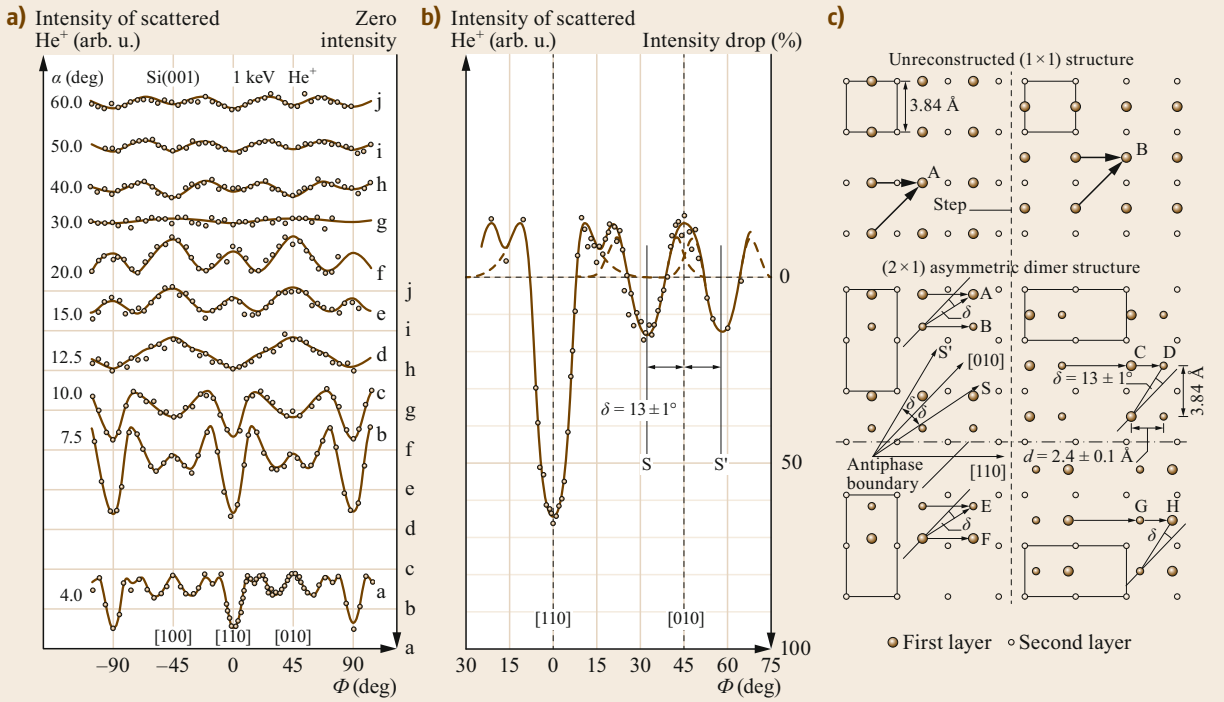

Fig. 26.25 **(a)** 1 keV He^+ ICISS spectra taken as a function of incident angle and azimuth, with a magnified version of the 4° spectrum shown in **(b)**. **(c)** Shows structural models of the Si(100) surface, comparing the directions for shadowing in the unreconstructed (top) and (2 × 1) (bottom) surfaces (Reprinted with permission from [26.79]. Copyright (1982) by the American Physical Society)

ing incidence (magnified in Fig. 26.25b) show several distinct minima due to shadowing effects, accompanied by maxima at their periphery due to channeling. These minima, along the [110] direction and along directions rotated by 13° with respect to [100], indicate shadowing effects in orientations different from those expected for the bulk-terminated surface (along both [110] and [100], Fig. 26.25c), as was expected. Rather, these observations are consistent with the asymmetric dimer structure, as shown in Fig. 26.25d. Here, shadowing effects are expected for the [110] azimuth and for azimuths at some angles denoted δ from [100], in good agreement with the measured data. From the measured value of δ, the authors where able to determine the Si−Si dimer bond length of 2.4 Å. Such approaches have been used to investigate the structure of a number of systems ranging from metals to adsorbate systems and defect analysis [26.80–86].

26.3.5 Matrix Effects

In all cases discussed above, matrix effects, in which the ion yield is determined by its surrounding environment, can have a significant impact on the quantitation of LEIS data. Previous reviews have discussed in detail the origin of matrix effects arising from different charge transfer processes, and *Brongersma* et al. [26.50] discussed several methods for identifying whether matrix effects are present in a given system in conjunction with approaches to remedy matrix effects of different physical origins. The most straightforward of these approaches, in an approach developed by *Jacobs* et al. [26.87], involves comparison of the energy dependence of the ion yield of the elements in the sample of interest. Because the ion fraction is acutely dependent on the incident ion energy, any potential differences in the neutralization probability between the unknown and standard samples will be highlighted. In the absence of matrix effects, the ratio between the LEIS intensity of a given element in the unknown and reference samples should remain constant as a function of energy. Similarly, another approach for evaluating whether matrix effects are present involves plotting the logarithm of the ion fraction against the perpendicular component of the projectile velocity. A linear relation is expected, and its slope is given by a characteristic velocity that should be the same for a given element in different matrices, assuming that neutralization via Auger processes

is dominant. Additional experimental checks on matrix effects are described in detail in [26.50]. These include examination of the energy dependence of the ion yield ratios in the case of compounds, which should be independent of incident energy on the basis of the above arguments, measurement of the angular dependence of the ion yield, and use of the total signal in the case of binary compounds in which samples of varying composition are available.

Once it has been established whether matrix effects play a significant role in the system of interest, quantification can proceed in one of several ways. In the absence of matrix effects, evaluation of the concentrations of surface atoms can be done in a straightforward manner using the appropriate calibration samples and appropriately applying (26.6). If it is determined that matrix effects are present, the manner in which the quantification proceeds is dependent on the type of neutralization mechanism. For the case in which the matrix effects arise from b-RN, oscillations in the ion yield as a function of energy are observed and represent the dependence of the probability for tunneling between core-level states of the target and discrete states of the projectile given the projectile velocity. It was pointed out, given a survey of systems with known matrix effects, that effects of this origin can almost always be circumvented by using Ne^+ as the projectile rather than He^+ [26.50]. In addition, working at higher energies (> 3 keV) can suppress the matrix effects, since the amplitude of the oscillations of the ion yield is damped at high energies. In general, the use of higher energies is effective in suppressing matrix effects of different origins, as the perpendicular component of the projectile velocity is increased and the time of interaction between the projectile and target is reduced.

The other primary class of matrix effects is found with low-work-function systems; here, the situation is more complicated because the effects of the matrix on the ion yield cannot be attributed to one specific neutralization mechanism, since energy-dependent RN processes play a large role in addition to other mechanisms, particularly collision induced (CI) neutralization. While the use of higher energies can potentially alleviate matrix effects in low-work-function systems, a more rigorous approach to quantification for low-work-function materials was presented by *Cortenraad* et al. [26.88]. Here, it is assumed that when the work function of the surface reaches a sufficiently low value, RN becomes pronounced- and the ion fraction is determined by the population of the projectile atomic level at a distance from the target atoms known as the freezing distance. The ion fraction associated with RN processes can then be described as

$$P^+_{\mathrm{RN}} = \exp\left(-C\frac{|\varepsilon_\mathrm{a} - \varepsilon_\mathrm{F}|}{v}\right), \tag{26.9}$$

where ε_a is the energy of the first excited state of the projectile at the freezing distance, ε_F is the Fermi energy, v is the perpendicular component of the projectile velocity, and C is a constant. In the correction process, the ion fraction is first determined as a function of the work function range of interest, enabling determination of the constant C in (26.9). With this information, the contribution to the ion fraction from RN can be determined. If the contribution to the ion fraction from other mechanisms is known from, e.g., low coverage measurements, then the contribution from RN can be discriminated. From such a process one can generate a curve of the ion fraction due to RN as a function of work function, enabling subsequent quantification for surfaces of arbitrary elemental composition.

26.3.6 Conclusions

LEIS has been shown to be a highly sensitive tool for the determination of the elemental composition of the outermost layer of a surface. Quantification in the majority of cases is straightforward, with the use of appropriate standards with known surface concentrations. The presence of matrix effects, in which the ion fraction of a given element is determined by its surroundings, can be readily identified using standard methods. While quantification can be more challenging in these few cases, a number of methods exist to circumvent these challenges and perform quantitative analysis. Beyond the determination of the surface composition, LEIS measurements afford the possibility of performing static depth profiles in the outer 5–10 nm of the surface region, enabling examination of multilayer structures and diffusion processes. Lastly, the high surface sensitivity of LEIS can be exploited to extract structural details of surfaces and, under certain measurement conditions, perform surface crystallography.

26.4 Combining IR, XPS, and LEIS Measurements

The previous two sections have described the principles of IR absorption and LEIS spectroscopy in investigating a variety of surface phenomena. Here, we illustrate how the combination of all three techniques (IR, LEIS, XPS) is a necessary and powerful means for deriving quantitative information regarding surface composition,

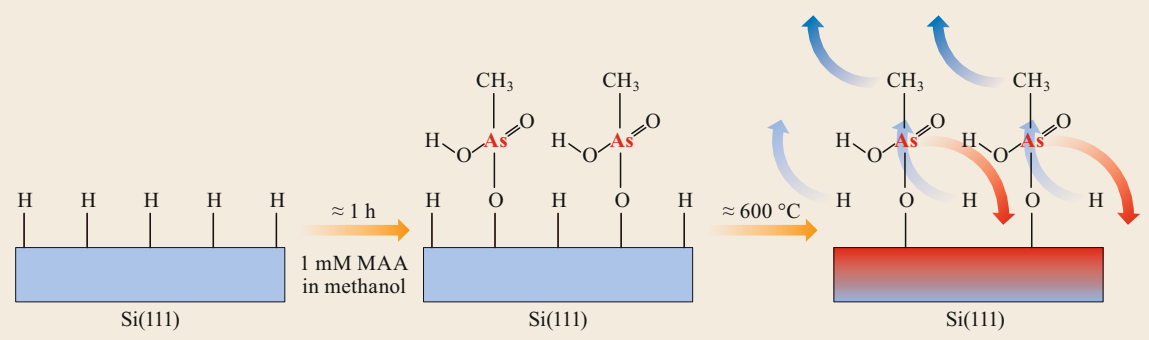

Fig. 26.26 Schematic of MAsA functionalization of Si(111)−H and subsequent MLD process. As-grafted surfaces contain MAsA coordinated via monodentate Si−O−As bonds to the substrate. Annealing to 600 °C results in loss of the organic tail and subsequent diffusion of As into the bulk

structure, and reactivity that would not have been accessible in experiments with one or even two of these techniques taken on their own. We have selected relatively recent examples of systems that are important for microelectronics, catalysis, and energy (e.g., gas storage).

26.4.1 Ultrashallow Doping with Methylarsenic Acid/Si(111)–H

Progressive device downscaling and new device structures have given rise to challenges in semiconductor device manufacturing, as many of the approaches for materials engineering used in existing device technology have reached fundamental limits in the length scales for which they are practical. For example, the design of 3-D ultrashallow junctions requires precise and shallow doping, which is not possible with conventional doping processes such as ion implantation. Consequently, monolayer doping (MLD) has recently been developed [26.89, 90] for doping semiconductor nanostructures that circumvents this issue. In the MLD process, a semiconductor surface is first functionalized with an organic molecule containing the desired dopant (e.g., P, B, As). The essential attributes of this molecule are the ability to chemically bond with the surface (Si−H or SiO_2−OH) and to self-assemble on the surface thanks to an organic tail. The procedure then involves annealing to sufficiently high temperature to decompose the ligands of the adsorbed functional group and subsequently drive the dopants into the bulk via diffusion processes. Initially, it was not clear whether the dopant atom might evaporate during this annealing step, and an oxide capping layer was deposited on the organic layer. However, the example below shows that such a capping layer is not necessary. While this approach has shown great promise for doping ultrashallow surface regions [26.89–95], quantitative mechanistic studies of these processes are needed to obtain sufficient information to properly engineer the combined process.

For instance, *Longo* et al. [26.96] examined MLD of H-terminated Si(111) and Si(100) surfaces using methylarsenic acid (MAsA) to achieve n-type doping via As diffusion into the bulk. Here, a combination of in situ transmission IR absorption (Brewster's angle incidence), XPS, and LEIS measurements were used as experimental probes to guide the ab initio modeling of the entire MLD process. Si(111)−H surfaces were prepared using conventional HF and NH_4F treatments [26.22] and functionalized with MAsA by immersion into a 10^{-3} mol methanol solution at 65 °C in a glove box for 12 h [26.96]. Specifically, the MAsA is chemically attached to Si−H in a monodentate structure by reaction of one of its As−OH bonds to form a Si−O−As bond as in Fig. 26.26, similar to grafting of methylphosphonic acid to H-terminated Si(111) [26.92, 97]. Figure 26.27a shows the absorption spectrum of the as-grafted surface referenced to the surface following HF etching. The data show modes associated with C−H stretching of methyl groups (2800–3000 cm^{-1}), As=O stretching (1180 cm^{-1}), As−O stretching (1080 cm^{-1}), and As−O-H bending (925 cm^{-1}). Analysis of the Si−H stretching mode from ex situ IR spectra of the functionalized surfaces indicated that, due to steric interactions, the MAsA coverage was approximately two-thirds monolayer, with the rest of the surface remaining H-terminated. For this study, all subsequent annealing was performed in a UHV cluster system combining separate chambers for LEIS, IR, and XPS measurements, with in situ UHV sample transfer. As illustrated in Fig. 26.27b, the IR absorption spectra recorded as a function of annealing temperature provided insight into the thermally driven evolution of the adlayer; upon annealing to 600 K, loss of the hydrocarbon stretching band and a blueshift of the Si−H stretching band were observed, indicating the decomposition of the molecule

with the insertion of one oxygen atom in the Si−Si back-bonds. In addition, an increase in the intensity of the As−O stretching mode at 1100 cm^{-1} was observed, likely due to changes in the dynamical dipole moments associated with the vibration following the loss of the organic tail, accompanied by relaxation of the geometric structure. Upon annealing to 700 K, the hydrocarbon band intensity continued to weaken, and the appearance of further blueshifted Si−H stretch bands indicated that additional oxygen atoms from the AsO_x groups were incorporated into the Si back-bonds into higher oxidation states for Si (O_2−Si−H at 2200 cm^{-1}

and O_3−Si−H at 2270 cm^{-1}). The incorporation and local agglomeration of oxygen was clearly identified by the appearance of SiO_x TO and LO Si−O phonon bands at 960 and 1178 cm^{-1}, respectively, involving Si−O−Si stretching vibrations [26.98–100]. Finally, upon annealing to 800 K, a loss of intensity of the As−O band at 1100 cm^{-1} was observed with a consolidation of the Si−H stretch band at 2270 cm^{-1}, associated with the O_3−Si−H groups, indicating complete decomposition of the arsonate groups and further incorporation and agglomeration of O atoms into the substrate. In summary, the IR absorption data provide good markers for chemical modification (e.g., loss of organic tail, oxygen incorporation in Si) but cannot determine exactly the behavior of As. In particular, it cannot be established whether As desorbs.

XPS measurements provided complementary information by determining the oxidation state of As and the evolution of C and O atoms during the annealing process, as illustrated in Fig. 26.28. For instance, the carbon concentration originating from the organic tail of the molecules starts to decrease at 500 K, at which stage the oxidation state of the As begins to change, as seen by the emergence of a shoulder of lower binding energy in the As $2p_{3/2}$ spectrum. Further reduction of the As atom continues at higher temperatures, until the C 1s core level is below the limit of detection by 1000 K, an important finding given that prior MLD studies found that incorporated capping layers suffered from residual C contamination [26.89].

While the chemical evolution of all species (As, O, C, H) could be determined from IR and XPS measurements, providing a guide as to the chemistry taking place as a function of temperature, these techniques provided no information on the spatial diffusion of As, and even the fact that As would not desorb from the surface. To answer this question, LEIS is by far the best technique, as it can track and quantify the As concentration in the near-surface region. Using 3 keV He^+ ions that are best suited to detecting both light (C, O) and heavier (As) atoms, spectra were recorded as a function of temperature. Figure 26.29a shows the energy range corresponding to the As binary collision region (Fig. 26.29a), providing evidence that little change takes place between 300 and 973 K apart from intensity variations due to blocking effects. Upon annealing to 1023 K, however, a low-energy tail emerged; by 1073 K, the binary collision peak had split into a doublet with a redshifted component at 2300 eV, and the intensity of the surface peak at 2375 eV had decreased dramatically. Annealing to 1125 K resulted in a reduction of the surface peak to below the detection limit, and only the 2300 eV peak remained; further annealing led to an additional low-energy peak at 2225 eV, with a broadened distribution of the intensity in that region. The origin of these peak shifts can only be attributed to diffusion of As into the subsurface region. In Sect. 26.3, it was shown that LEIS can detect sub-

surface elements via neutrals that penetrate into the bulk and subsequently become reionized at the surface following backscattering by subsurface atoms, as demonstrated for $Al_2O_3/HfO_2/SiO_x$ multilayers. Here, the progressive shifts to lower energy and the intensity decreases of the As peak are attributed to the migration of As below the surface, and the depth of the As was inferred by TRBS simulations in a manner similar to that demonstrated by *Brüner* et al. [26.54] for the $Al_2O_3/HfO_2/SiO_x$ multilayer system. The initial shift seen at 1073 K corresponds to a depth of 0.7 nm, and the systematic shift to lower energy demonstrates unambiguously the diffusion of As into the bulk. Furthermore, quantification of the signal allows for the extraction of the dopant concentration. The reionization function of the surface can be determined, as discussed in Sect. 26.3, by dividing the measured LEIS spectrum by the spectrum simulated by TRBS for backscattered neutrals with the same projectile/target combination and experimental geometry. The resulting function has a linear dependence on energy, as was observed for the case of HfO_2 (Fig. 26.29b). With this knowledge, the concentration of As could be extracted, and was found to be 3×10^{21} As/cm^3. These values are consistent with all the As penetrating into the Si substrate, even though there was no oxide capping layer to confine the dopant (thought to be necessary in previous studies) [26.89, 90, 102, 103]. The doping effect was further demonstrated by broadband IR spectra (i.e., focusing on the electrical response of the Si substrate) recorded over a large temperature window (Fig. 26.29c). Spectra obtained by referencing 973 K data to 573 K, for instance, show a characteristic Drude response and a broad high-frequency absorption band between the conduction band and unoccupied higher-lying bands (Fig. 26.29c), an unequivocal demonstration of n-type doping. Thus, the combination of these three techniques, supplemented with first-principles modeling, was essential to derive a rigorous quantification of the complete MLD process for As doping of oxide-free Si(111) surfaces. This work provides a methodology that is applicable to other systems with arbitrary substrate/dopant concentrations.

26.4.2 Metal Oxide Growth: VO_x/Pt(111)

Vanadium oxides have interesting physical and chemical properties, particularly valuable for heterogeneous catalysis, as they support a number of reactions [26.104, 105]. In light of the appealing properties of supported VO_x catalysts (and similar systems), fundamental studies on the relationships between film structure and oxidation states with functional properties such as catalytic activity and selectivity are of importance for their development and optimization. In one such study, *Tang* et al. [26.101] combined LEIS, XPS, HREELS, and IRRAS to study the growth and oxidation of ultrathin vanadium films on Pt(111) substrates. Here, ultrathin films (0–3 ML) were deposited under ultrahigh vacuum (UHV) by evaporation of V onto a clean Pt(111) crystal, followed by oxidation under different conditions. Initial oxidation was done by exposing the VO_x-evaporated

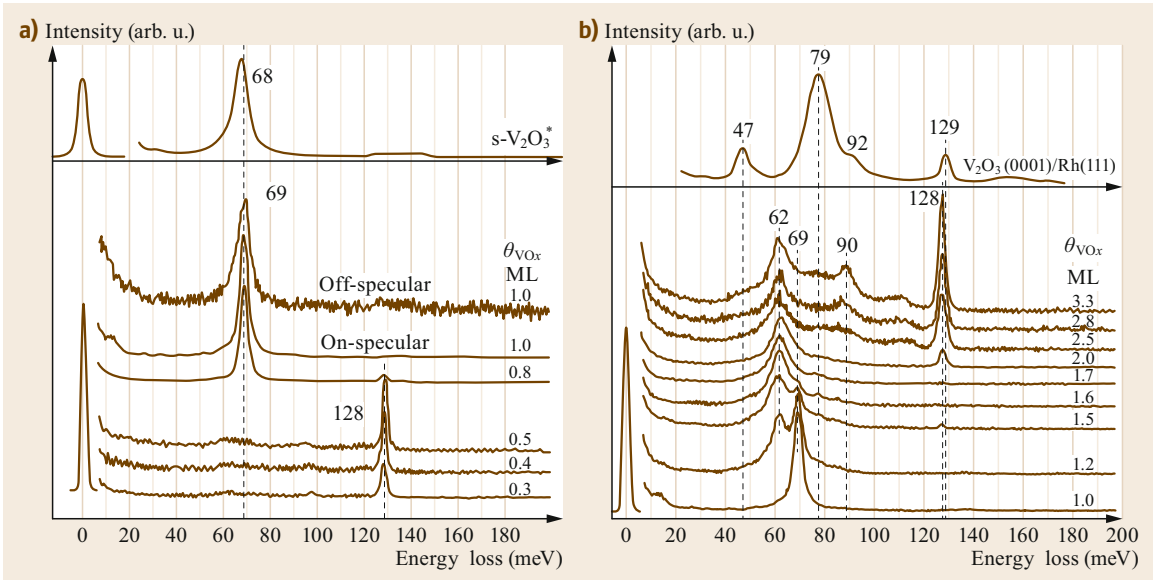

Fig. 26.31a,b HREELS spectra of VO_x overlayers as a function of coverage for **(a)** $0\,\text{ML} < \theta \leq 1\,\text{ML}$ and **(b)** $1\,\text{ML} \leq \theta \leq 3\,\text{ML}$ (Reproduced from [26.101] with permission of The Royal Society of Chemistry)

layer to 10^{-7} Torr O_2 for 10 min at 623 K. Different durations of evaporation and subsequent oxidation were used to control the coverage and number of monolayers deposited. LEIS and Auger electron spectroscopy (AES) were used to monitor the surface coverage and termination of the VO_x films. HREELS and IRRAS measurements were used to characterize the bonding between V and O, while XPS correlated the oxidation states of the films with the oxidation treatments.

Figure 26.30 shows the variation in the LEIS and AES signals observed as a function of V deposition time and subsequent VO_x coverage θ after 10^{-7} Torr O_2 oxidation. For low coverage, $0\,\text{ML} < \theta < 1\,\text{ML}$, the signal due to the Pt substrate gradually decreases until becoming undetectable as a complete monolayer is formed. Taken with the Auger data, these results provide a measure of the coverage of the substrate. In addition, the O/V intensity ratio extracted from the LEIS spectra show a marked decrease for coverage greater than 0.5 ML. The O/V ratio remains nearly constant between 1 and 2 ML, before undergoing a sharp increase for > 2 ML.

Figure 26.31a shows HREELS spectra taken from the corresponding coverage in Fig. 26.30. For coverage ≤ 0.5 ML, the spectra are dominated by a single peak at 128 meV ($1032\,\text{cm}^{-1}$), attributed to vanadyl V=O stretching, originating from structures such as those depicted in Fig. 26.32a. At coverage greater than 0.5 ML, the 128 meV peak disappears, and a new mode at 69 meV is observed, similar to that observed in s-V_2O_3. Thus the data indicate that as the coverage increased, isolated VO_x groups coalesced to form a continuous layer in which the V=O double bonds are broken to link neighboring VO_x groups. On the basis of mode-counting arguments, the authors were able to distinguish between potential ML structures, citing a structure of the type shown in Fig. 26.32b*(a)* as most consistent with the data. The decrease in the O/V LEIS intensity ratio for coverage less than 0.5 ML is consistent with this model, given the more open structure in Fig. 26.32b*(a)* than that in which the O atom is directly on top of the V, as in Fig. 26.32a*(a)–(c)*. This mechanism, in which the isolated VO_x units coalesce at high coverage to form bridging O at the expense of vanadyl groups, was further verified by performing co-adsorption studies in which CO was dosed for coverage < 0.5 mL; here again the authors observed only the 69 meV band and concluded that the isolated VO_x units are *compressed* into continuous V_2O_3 units due to competition for adsorption sites.

For overlayers between 1 and 2 ML, the structure formed is more complex and is observed in conjunction with a $(3\sqrt{3} \times 6)$ LEED pattern. The phonon modes observed in the HREELS spectra in this regime (Fig. 26.31b) show new features below 100 meV, but no modes indicative of vanadyl groups. A band is observed at 62 meV, and its intensity increases at the expense of the 69 meV band intensity; furthermore, the frequency of this feature can be used to infer a bonding configuration as shown in Fig. 26.32c*(a)* based on the frequencies expected for VO_x in different oxidation states. For films between 2 and 3 ML, new modes at 80 and 90 meV are

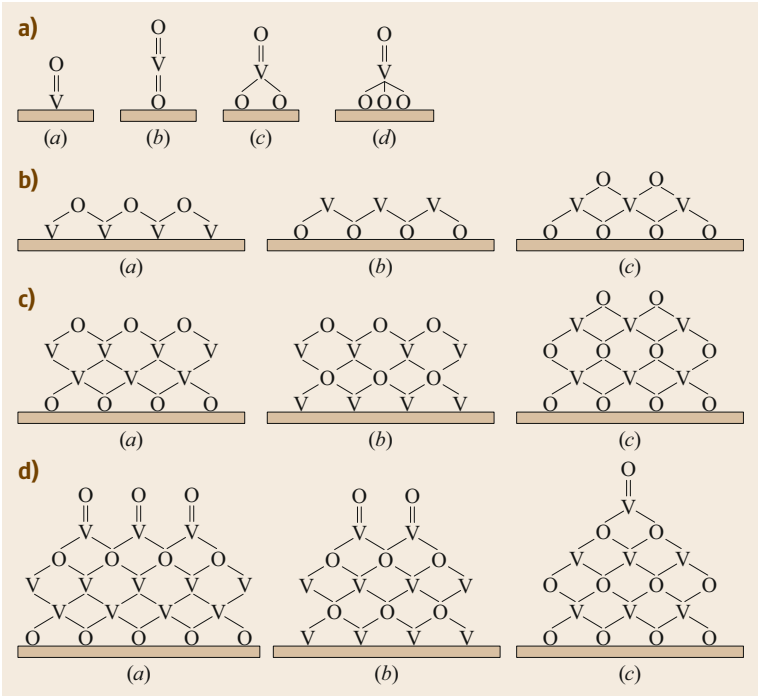

Fig. 26.32a–d Potential structures of VO_x overlayers for coverage of **(a)** < 0.5 ML, **(b)** 1 ML, **(c)** 2 ML, **(d)** 3 ML (Reproduced from [26.101] with permission of The Royal Society of Chemistry)

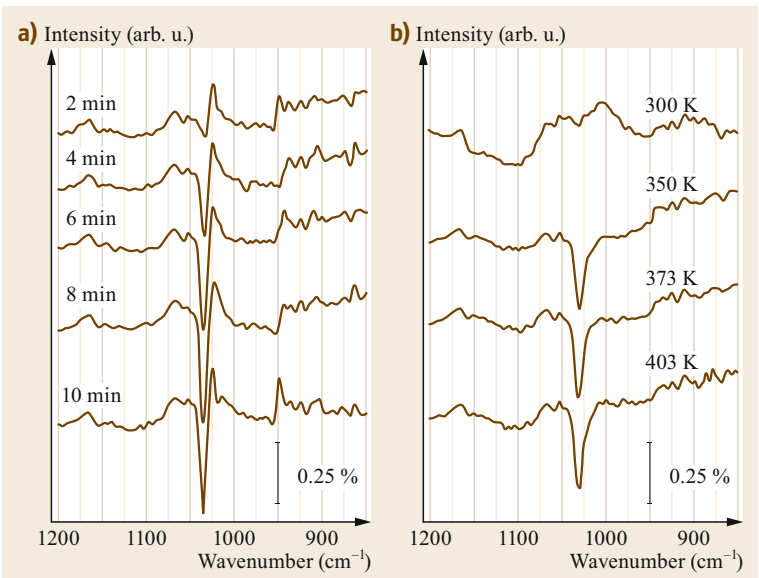

Fig. 26.33a,b IRRAS spectra of **(a)** 0.9 ML VO_x exposed to 1 Torr O_2 at room temperature and **(b)** 3 ML VO_x exposed to 1 Torr O_2 at indicated temperatures (Reproduced from [26.101] with permission of The Royal Society of Chemistry)

observed in conjunction with the reappearance of the mode at 128 meV, while the mode at 62 meV remains, suggesting that the formation of the third monolayer did not perturb the structure of the underlying 2 ML. In addition, above 2 ML, the intensity ratio O/V extracted from the LEIS of O and V increases quickly, and together with the reappearance of the 129 meV band, these observations point to a vanadyl termination. Thus, structural models such as those shown in Fig. 26.32d*(a)–(c)* describe the complete 3 ML structure.

In an attempt to further increase the V oxidation state, samples with 1 and 3 ML VO_x layers were brought to a high-pressure chamber connected to the UHV chamber and oxidized with 1 Torr O_2 at different times and temperatures while in situ IRRAS measurements were performed (Fig. 26.33a). In both the 0.9 and 3 ML sam-

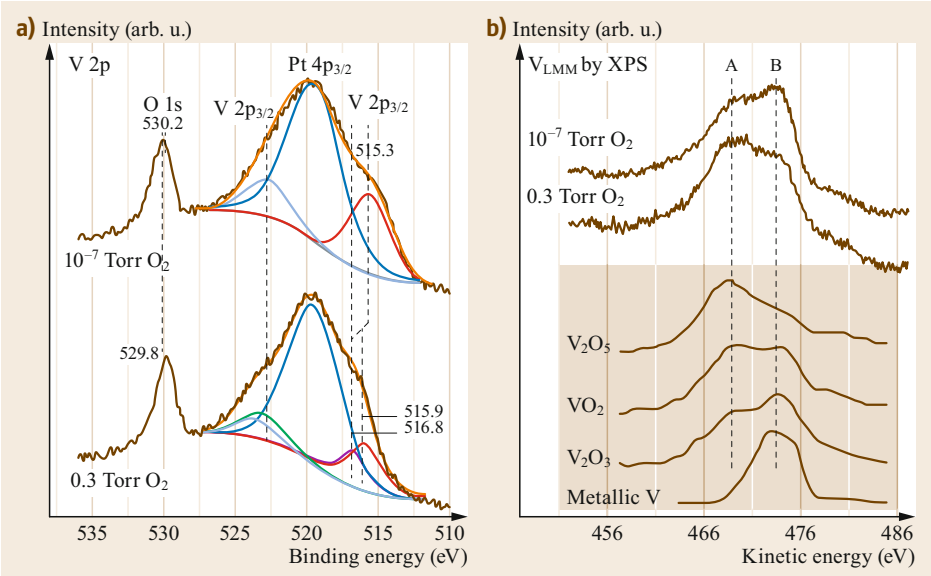

Fig. 26.34 **(a)** V 2p and O 1s spectra of 3 ML VO_x exposed to 10^{-7} Torr O_2 (*top*) and 0.3 Torr O_2 (*bottom*), with corresponding LMM Auger spectra shown in **(b)** with comparison to V/VO_x standards (Reproduced from [26.101] with permission of The Royal Society of Chemistry)

ples, additional oxidation could be achieved by formation of additional vanadyl units, as evidenced by a strong mode at the V=O stretching feature at 1038 cm^{-1} in the IRRAS spectra. The fact that the exposure to higher partial pressures of O_2 led to oxidation states greater than that observed for V_2O_3 was further verified by XPS measurements, as shown in Fig. 26.34a,b. Here, 3 ML VO_x films oxidized with 10^{-7} Torr O_2 and 0.3 Torr O_2 were examined; analysis of small core-level shifts toward higher binding energy by careful deconvolution of the spectrum of the sample oxidized with 0.3 Torr O_2 revealed the presence of higher oxidation states as inferred from IRRAS measurements. While these data are complicated by the overlapping Pt $4p_{3/2}$ line of the substrate, the V_{LMM} Auger lines from the XPS data also show the same trend when compared with standards of V, V_2O_3, VO_2, and V_2O_5. Together with the V 2p spectra, the data indicate that the 3 ML films oxidized using 10^{-7} Torr O_2 are in the oxidation state of V_2O_3, while films oxidized with 0.3 Torr O_2 are in mixed valence states that appear similar to a mixture of VO_2 and V_2O_5. Thus, the combination of vibrational spectroscopy (in this case both IR and HREELS measurements) with LEIS and XPS was again essential to derive quantitative information on the atomic structure and bonding configurations of thin films. This work demonstrates a powerful approach for studying growth reactions.

26.4.3 Catalyst Surface Structure: Au–Pd Alloys on Mo(110)

Bimetallic alloys have long been recognized for their unique, often enhanced or selective catalytic activity, which is generally very different from that of the constituent components [26.106]. As catalytic processes are dominated by the interaction between the target molecules and the outermost atoms present at the catalyst surface, a thorough understanding of the surface composition and structure is essential for a mechanistic understanding and optimization of catalytic reactions. In these systems, it is generally thought that both ligand effects (due to heteronuclear charge transfer) and ensemble effects (due to a particular number of atoms in some geometric orientation) potentially play a role in catalytic activity. XPS, LEIS, and IR measurements are frequently used for the characterization of catalyst materials and associated reactions, as in situ techniques can yield information including the complete surface composition, chemical state of the elements at the surface, and details regarding the identity and structure of adsorbates *under* reaction conditions. When performed in parallel, the combination of these approaches can provide a comprehensive picture of surface chemistry that can then be linked to catalytic activity.

Goodman and coworkers [26.107, 108] performed such mechanistic studies to establish the correlation of surface structure with catalytic activity for Pd-Au alloy surfaces. Such Pd-Au catalysts are effective for CO oxidation, vinyl acetate synthesis, hydrodechlorination of $CClF_2$, hydrogenation reactions, and other surface reactions [26.109–112]. For these studies, they synthesized the alloys by physical vapor deposition of Pd and Au onto Mo(110) substrates followed by annealing to various temperatures to tune the surface composition. To investigate a potential role of the order in which the respective metals were deposited, experiments were

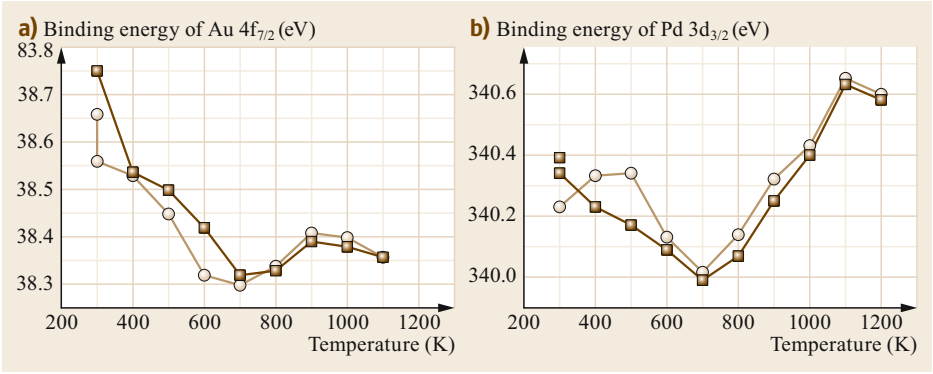

Fig. 26.35a,b Binding energy of the Au $4f_{7/2}$ **(a)** and Pd $3d_{3/2}$ **(b)** levels from Au-Pd alloys as a function of temperature determined from XPS measurements (Reprinted adapted with permission from [26.107]. Copyright (2005) American Chemical Society)

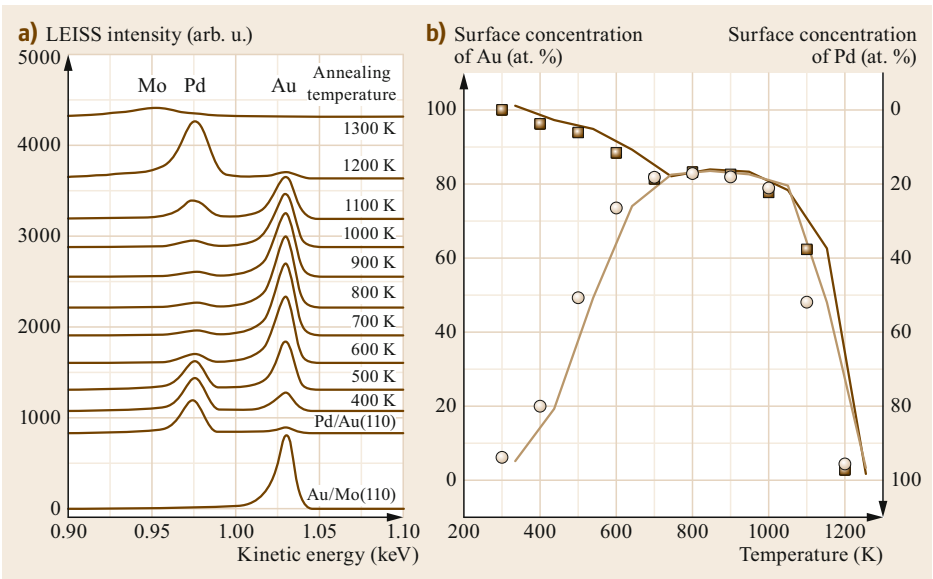

Fig. 26.36 **(a)** LEIS spectra of Pd/Au/Mo(110) as a function of annealing temperature, and **(b)** extracted surface concentrations for Au-Pd alloys annealed to different temperatures for films in which Pd was deposited first (*circles*) and Au was deposited first (*squares*) (Reprinted adapted with permission from [26.107]. Copyright (2005) American Chemical Society)

carried out for both 5 ML Au/5 ML Pd/Mo(110) (i.e., Pd deposited first) and 5 ML Pd/5 ML Au/Mo(110) (Au deposited first). Figure 26.35 shows the binding energies, measured by XPS, of the Au $4f_{7/2}$ and Pd $3d_{3/2}$ peaks following deposition and subsequent annealing. Clearly, similar results were observed for both Pd deposited first and Au deposited first. Upon annealing to 700 K, both the Au 4f and Pd 3d levels continuously shift to lower binding energies by 0.45 and 0.15 eV, respectively, as compared with pure Au and Pd. Upon annealing to higher temperatures (1000 K), the Pd 3d level progressively shifts toward higher binding energy, while Au begins to desorb (disappearance of Au $4f_{7/2}$ level). Some important results were derived from these data. First, the core-level shifts provided direct evidence of alloying following annealing. Second, the core-level shifts observed were attributed to a charge-compensation model, where Au gains sp electrons and loses d electrons, whereas the opposite is the case for Pd. Charge compensation such as that described above falls under the classification of ligand effects, one potential factor determining the catalytic properties of bimetallic alloys.

LEIS was then used to determine the surface composition at each stage of annealing. Figure 26.36a shows 1.1 keV He^+ LEIS spectra of the Pd/Au/Mo(110) films

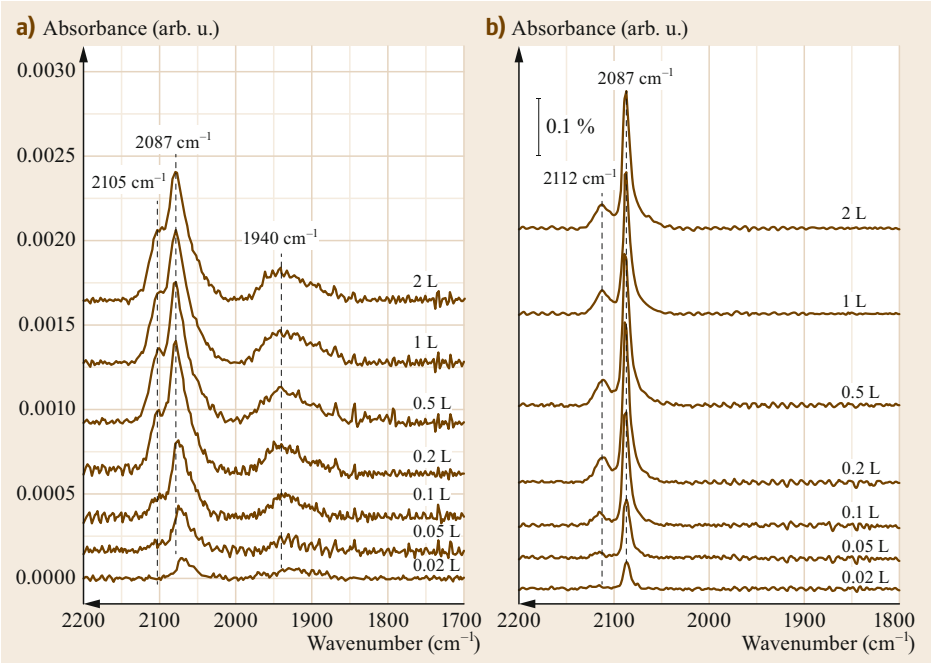

Fig. 26.37a,b IRRAS spectra from Pd-Au alloys taken as a function of CO exposure in films annealed to 600 K **(a)** and 800 K **(b)** (Reprinted adapted with permission from [26.107]. Copyright (2005) American Chemical Society)

as a function of deposition and processing. Deposition of 5 ML Au onto Mo(110) leads to a total disappearance of the Mo peak, indicating complete wetting of the surface. Following deposition of 5 ML Pd onto the 5 ML Au/Mo(110) surface, a peak emerges at the position expected for Pd, while a small feature due to Au is still observable, indicating that some degree of intermixing takes place at room temperature. Above 700 K, the intensity of the Au peak increases continuously, and the relative Pd and Au intensities remain nearly constant between 700 and 1000 K. Upon annealing to temperatures > 1000 K, the intensity of the Au peak begins to decrease because of Au desorption, leading to a Pd-enriched surface. From the measured data and use of the appropriate standards, the authors are able to compute the surface concentration of Au and Pd at each annealing temperature, as shown in Fig. 26.36b. Beginning from room temperature, the surface Au concentration increases continuously until a stable $Au_{0.8}Pd_{0.2}$ alloy is formed at 700 K, which remains until 1000 K.

Further experiments studying the IR response of adsorbed CO on surfaces prepared under different conditions provided additional insight into the surface structure. Here, the surfaces were dosed with CO at 80 K and measured using the IRRAS geometry (discussed in Sect. 26.2). Figure 26.37a shows IRRAS spectra obtained from of a 5 ML Pd/5 ML Au/Mo(110) film annealed to 600 K following exposure to different doses of CO. Such annealing leads to a surface Pd concentration of 27%. At low doses (0.1 L), two modes are observed at 2087 and 1940 cm^{-1}. The mode at 1940 cm^{-1} is characteristic of CO bonded at a bridge site, while that at 2087 cm^{-1} is in the frequency region expected for CO adsorbed at an atop site. Above 0.2 L, an additional band is observed at 2105 cm^{-1} and saturates for doses > 5 L. On the basis of existing literature, the 2105 cm^{-1} band is assigned to CO adsorbed at an Au atop site, the band at 2087 cm^{-1} to a Pd atop site, and the band at 1940 cm^{-1} to a Pd bridge site. Similar experiments were performed on an analogous sample annealed to 800 K, leading to a lower (18%) surface Pd concentration. Below 0.1 L, a single feature was observed at 2087 cm^{-1}, while a feature was observed at 2112 cm^{-1} with additional exposure (> 0.1 L). In this case, no features due to multi-coordinated CO are observed, supporting the assignment of the 1940 cm^{-1} band as originating from a Pd bridge site. Rather, only adsorption at Pd and Au atop sites takes place at low Pd concentrations. These observations point to the absence of Pd ensembles (dimers, trimers, patches, etc.) on the 800 K-annealed surface, but clearly indicate their presence on the 600 K-annealed surface (containing 27% surface Pd). With the combination of in situ IR, XPS, and LEIS techniques, both ligand effects and ensemble effects can be investigated in detail, and ultimately correlated to catalytic reaction mechanisms and performance.

26.4.4 Magnetic Surfaces: Metal Plasma Cleaning and Nitridation

Ferromagnetic thin films form the basis for spintronics devices, commonly used for memory and logic applications [26.113]. For instance, multilayer structures have been constructed to separate ferromagnetic, typically first-row transition metal, layers and insulating spin-filter layers. Central to the performance of these devices is the chemical state of the interface between the ferromagnetic electrode and the spin-filter layer, as antiferromagnetic oxide impurities can lead to scattering and spin decoherence. Nitridation is one potential route toward modification of such surfaces, and transition-metal nitrides that interface easily with the magnetic electrode layers could therefore be used as barrier and/or spin valve layers. Additionally, transition metals and their nitrides are becoming increasingly utilized in a wide variety of catalytic processes [26.114–118]. Consequently, understanding the surface composition, structure, and reactivity of these materials is of high importance.

In one study, hydrogen and nitrogen plasmas were used to etch the native oxide from Co thin films and subsequently form an ultrathin surface nitride layer [26.119]. In situ IRRAS, LEIS, and XPS were employed to thoroughly investigate the surface composition and structure during each step of the treatment. In this study, Co thin films on Si were first cleaned in UHV using an H_2/Ar inductively coupled plasma (ICP) with the sample maintained at 200 °C, and the surface chemical composition was monitored by in situ IRRAS measurements performed as a function of plasma exposure time. The IR spectra were collected in reflection during plasma exposure and referenced to the reflectivity of the surface immediately before plasma exposure (Fig. 26.38). The dependence on the plasma exposure measured by IRRAS revealed that surface carbonates (1400–1600 cm^{-1}) were etched first, and that the metal oxide ($\approx 600\,cm^{-1}$) was etched only after the carbonates were removed, presumably due to initial protection of a cobalt carbonate overlayer. The O 1s and Co 2p XP spectra associated with plasma-cleaned surfaces (Fig. 26.39) showed Co primarily in its metallic form, with a submonolayer coverage of O primarily in the form of adsorbed hydroxyl groups with relatively little metal oxide (Fig. 26.39c). The respective coverage of hydroxyl and metal oxide was estimated from measurements to be 21 and 4% of a monolayer, respectively. It was postulated that the relatively high partial pressure of water present when backfilling the UHV chamber with an H_2 plasma ($> 10^{-8}$ Torr, measured from a mass spectrometer after turning off the plasma source) was mainly responsible for both hydroxyl and metal oxidation during H_2 plasma treatment.

Nitridation of the cleaned surface was then achieved at room temperature via nitrogen ICP under UHV conditions, *after* removal of the native metal oxide. As in the case of the hydrogen plasma treatment, IRRAS measurements were performed in situ to monitor the evolution of the surface species as a function of N_2 plasma exposure time, as shown in Fig. 26.40. Several important features were noted. First, a band at 1795 cm^{-1} in the spectrum collected within the first

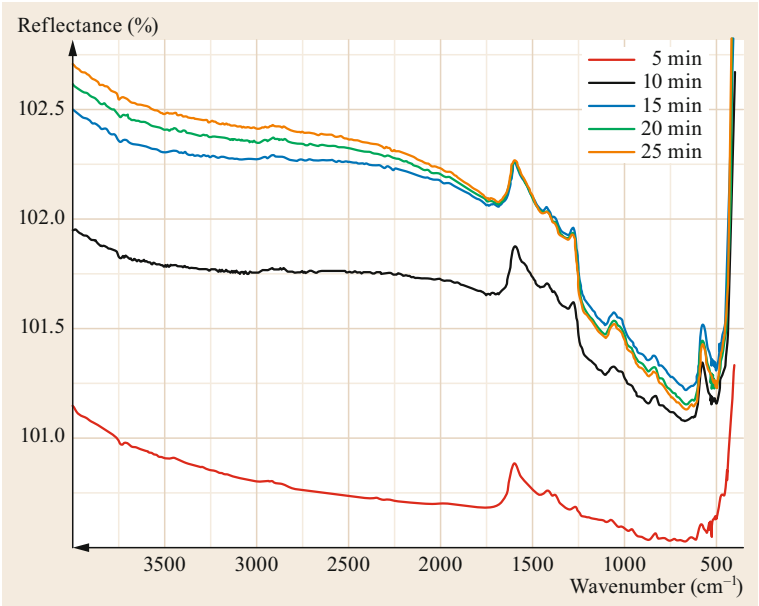

Fig. 26.38 In situ IRRAS spectra taken from Co surfaces at 473 K as a function of exposure to hydrogen plasma

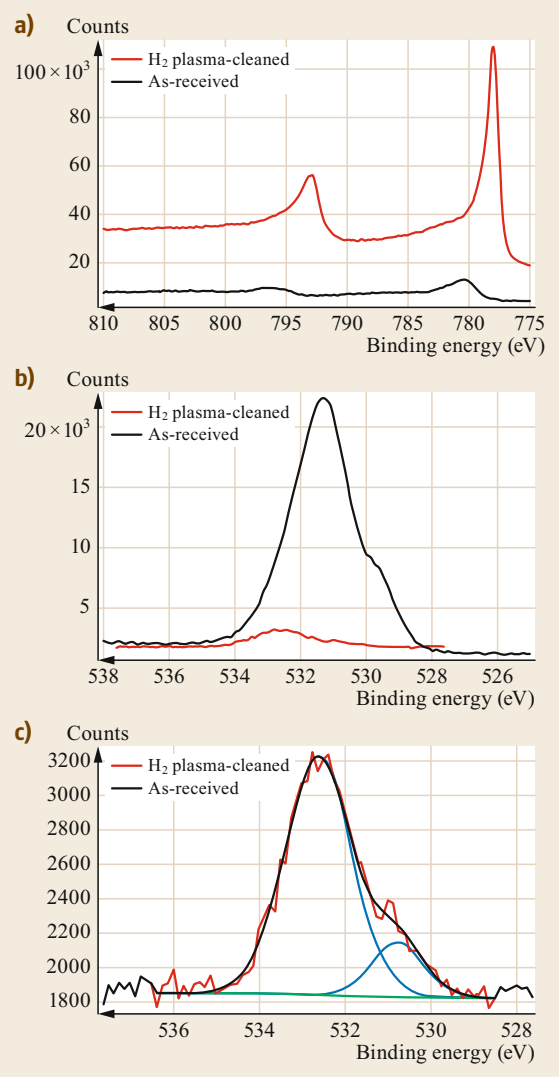

Fig. 26.39a–c XPS spectra of as-received and plasma-cleaned Co films. **(a)** Co 2p and **(b)** O 1s levels, **(c)** deconvolution of the O 1s spectrum into peaks due to hydroxyl (533 eV) and metal oxide (530.5 eV)

2.5 min of plasma exposure was attributed to adsorbed NO. With progressive exposure to the plasma, the intensity of this band diminished concomitantly with the emergence and growth of a band at 2187 cm^{-1}, associated with NO^+. The presence of NO likely originated from interactions between the N_2 plasma and the oxygen in the silica tube of the plasma source, initially leading to the incorporation of oxygen into the film in the form of NO. In addition to these sharp vibrational features, a change in the broadband absorption was noted (centered around 1700 cm^{-1}), assigned to internal transitions between degenerate d levels split by spin–orbit coupling, which was observed in many compounds containing Co in the 2+ state, including CoO [26.120]. Finally, a weak positive contribution at 600 cm^{-1} was attributed to Co–N stretching vibrations. The observation of an upward-pointing band associated with bond formation was unusual for the case of an absorbing layer on a metal substrate, as ordinarily the presence of an absorbing moiety on a metal surface will result in a downward-pointing band in the reflectivity spectrum (signifying light absorption). The observation of an upward-pointing band due to Co–N bond formation was ultimately determined to result from a complex optical effect arising from the intense broadband electronic absorption due to spin–orbit split d–d excitations. An investigation employing optical modeling of the substrate and overlayer dielectric functions revealed that the CoN electronic resonance induces a strong dispersion of the dielectric function in the low-frequency region in which the Co–N peak was observed, leading to a positive contribution of the Co–N band relative to the baseline. The weak features between 1000 and 1300 cm^{-1} were attributed to incomplete cancellation of the SiO_2 phonons of the underlying SiO_2 layer, arising from differences in the degree of attenuation following nitridation.

An analysis of the Co 2p core-level position (0.4 eV shift from the metallic Co position) and the relative intensities of the Co 2p and N 1s core levels in the XPS measurements (Fig. 26.41a,b) indicated that the ultrathin surface layer is CoN, with a Co/N stoichiometry of 1 : 1. Based on the attenuation of the substrate signal (Fe 2p core level), the intensity of thickness of this layer was derived to be 1.5 nm.

To determine the chemical composition of the surface layer, LEIS measurements were performed after surface nitridation. Interestingly, the LEIS spectra of the nitrided surface displayed only a very weak Co peak (Fig. 26.41c,d), shifted with respect to its position on the clean surface by 10–20 eV, indicating that the Co atoms are subsurface. This finding is consistent with the first layer being fully passivated by N and O. In addition, measurements performed as a function of Ar^+ sputtering showed that the O signal was localized at the outer surface, and not present throughout the entire 1.5 nm of the film. Through the application of these three combined techniques, the chemistry of the near-surface region could be tracked at each stage of treatment to show that (i) an ultrathin CoN layer is formed when clean Co surfaces are exposed to nitrogen plasma, (ii) oxygen is incorporated into the films from the plasma source in the form of NO^+, and (iii) the oxygen impurities are predominantly localized at the outermost surface and not throughout the entire nitrided region.

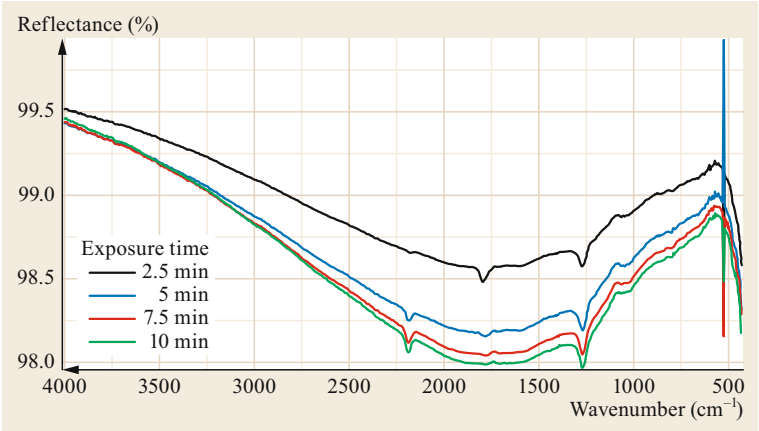

Fig. 26.40 IRRAS spectra obtained during nitrogen plasma treatment of Co surfaces. Here, the reference measurement is that of the clean surface before exposure to nitrogen plasma

A similar approach was employed to study the more complex but industrially relevant alloy surface CoFeB [26.121]. In that case, the films were crystallized by annealing to 673 K, followed by Ar^+ sputtering to remove the remaining oxide. In situ IRRAS spectra taken during nitrogen plasma treatment showed trends similar to those observed for Co nitridation, with the formation of NO^+ and a variation in the broadband absorbance throughout the mid-IR. In this case, two vibrational bands were observed in the Co–N/Fe–N

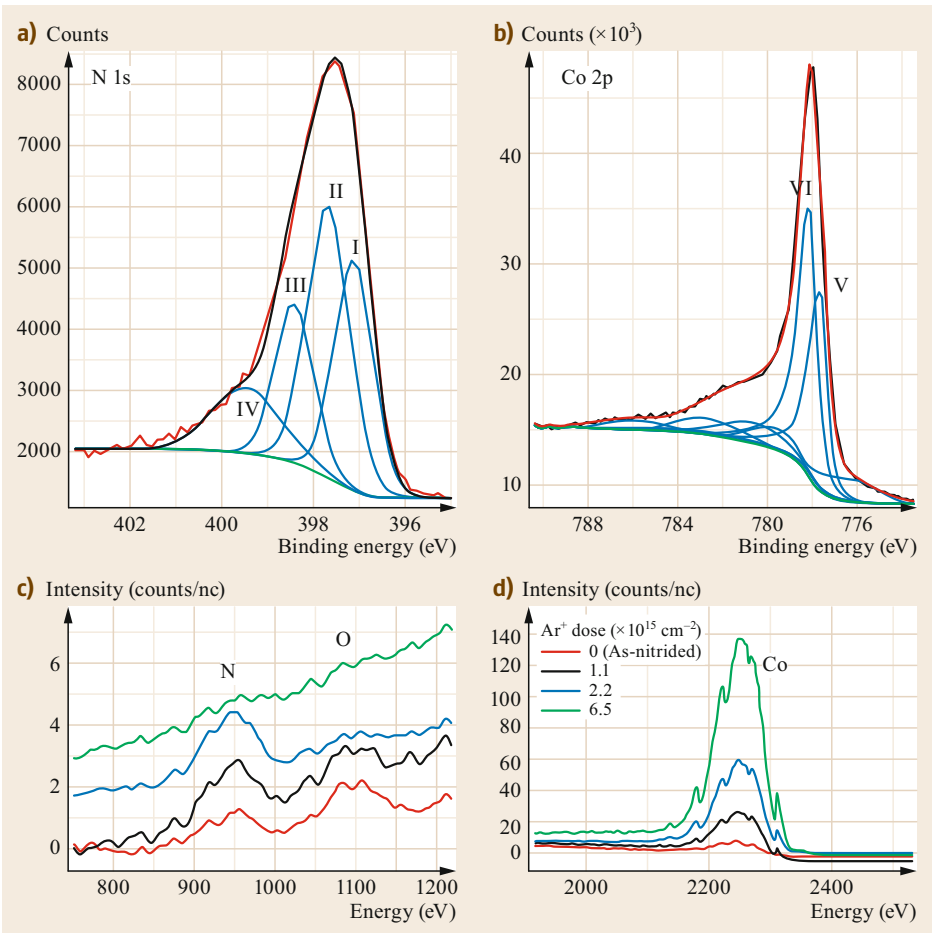

Fig. 26.41 **(a)** N 1s and **(b)** Co 2p spectra from nitrided Co films. Peaks labeled I, II, III, and IV in **(c)** are due to surface-shifted CoN, fully coordinated CoN, Co oxynitride, and NO^+, respectively. Peaks V and VI in **(d)** are due to the underlying Co substrate and the CoN overlayer, respectively. **(c,d)** 3 keV He^+ LEIS spectra from the same films taken as a function of Ar^+ sputtering (Reprinted from [26.119], with the permission of AIP Publishing)

stretching region, consistent with the formation of a nitrogen-rich film, such as Fe_2N_3.

XPS and LEIS measurements were collected for the clean surface and following nitridation. The XPS spectra revealed a substantial shift of the Fe 2p core level but not the Co 2p core level, the intensity of the latter being much more heavily attenuated (Fig. 26.42a,b). These results suggest a preferential reactivity of the Fe atoms with nitrogen in the alloy and little reactivity of Co, which was further supported by LEIS measurements using 5 keV Ne^+ to resolve the similar masses of Co and Fe. The LEIS measurements showed that both Fe and Co were initially present on the clean surface, but only Fe was detectable following nitridation (Fig. 26.42c), consistent with Co absorption into the film after Fe reaction with N to form iron nitride. These results suggest that the formation of iron nitride is energetically more favorable than cobalt nitride. Quantification of the Fe 2p and N 1s spectra suggest that the stoichiometry of the iron nitride film is Fe_2N_3, significantly higher than the FeN obtained through plasma nitridation of an Fe(100) single crystal. This finding is further supported by the number, frequencies, and relative intensities of the bands observed in the Fe−N stretching region. Additional measurements of the surfaces following annealing showed that the process was partially reversible, and that the Fe_2N_3 layer decomposed following annealing to 673 K, leaving some residual N likely occupying interstitial sites in the form of Fe_4N [26.122]. The Fe/Co surface concentration did not reach the original level observed for the clean surface, but rather had a Co surface concentration less than half that of the clean surface, pointing to a potential method to tune the Fe/Co ratio of the surface of CoFeB alloys relative to the bulk. This example illustrates again how the three techniques are used in a complementary fashion, each providing critical information that would not have been unambiguous from the individual techniques taken on their own. Furthermore, the in situ capabilities of the system used in this work enabled all three techniques to be performed on the exact same sample without contamination during transfers, providing an extra degree of confidence in the results.

26.4.5 Dielectric Surfaces: Termination of HF-etched Si_3N_4

Silicon nitride (Si_3N_4) is employed for a number of applications in microelectronic devices, such as dielectric spacers and diffusion barriers. The surfaces of Si_3N_4 films readily oxidize when exposed to ambient conditions to form a Si-rich N-depleted region, which can interfere with applications dependent on the surface composition (functionalization or integration with other materials). It is therefore important to remove the native oxide or oxynitride and to control and understand the resulting termination after oxide removal typically achieved by HF etching. HF etching of Si_3N_4 had been studied by several groups [26.124–127], with conflicting reports on the resulting surface species present after etching, ranging from complete NH_x termination to surficial Si–H and Si–F. To clarify the relationship between the chemical termination of the etched surfaces and conditions used for HF treatment and subsequent rinsing, *Liu* et al. [26.123, 128] performed a combination of IR absorption, XPS, and LEIS measurements as a function of chemical treatment. Figure 26.43 shows the IR absorption spectra of the Si_3N_4 samples following HF etching and either direct nitrogen drying or rinsing with toluene, methanol water, acetonitrile (ACN), or dimethyl sulfoxide. The intense negative peaks at 838 and 1122 cm^{-1} are associated with the weakening of Si_3N_4 phonon modes associated with etching of the bulk nitride. When HF-etched surfaces were not immediately rinsed in deionized (DI) water, intense modes were observed at 3330 and 1440 cm^{-1} associated with N–H stretching and bending vibrations, respectively. However, a more careful examination of these spectra revealed that they could not be due to NH_x termination of the Si_3N_4 surfaces. Instead, the frequency of the 1440 cm^{-1} mode is known to be characteristic of the bending mode of NH_4^+

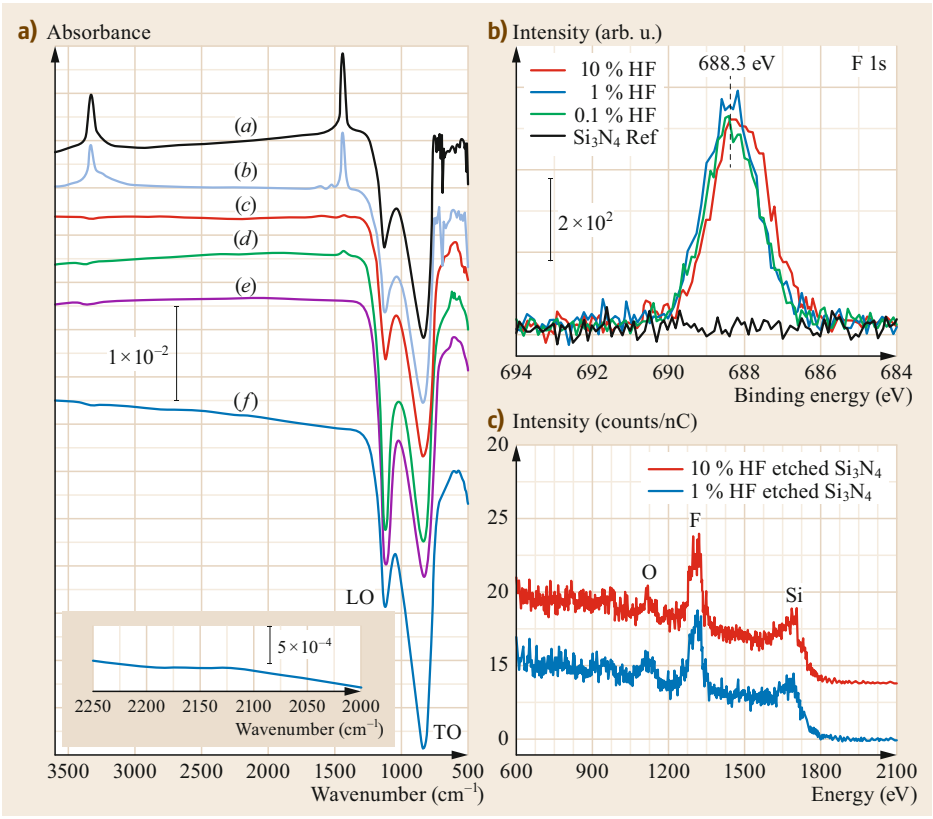

Fig. 26.43 **(a)** Transmission IR absorption spectra of HF-etched Si_3N_4 films and *(a)* directly dried with N_2 with no water rinsing, *(b)* dried with nitrogen and soaked in toluene overnight, *(c)* dried with nitrogen and soaked in methanol overnight, *(d)* directly rinsed with dimethyl sulfoxide and dried with nitrogen, *(e)* directly rinsed with acetonitrile and dried with nitrogen, and *(f)* directly rinsed with deionized water and dried with nitrogen. **(b)** F 1s XP spectra of Si_3N_4 films etched with different concentrations of HF and directly rinsed with water. **(c)** 3 keV He^+ LEIS spectra of Si_3N_4 etched with 1% and 10% HF and directly rinsed with water (Reprinted from [26.123], with the permission of AIP Publishing)

ions, pointing to the adsorption of ammonium salts on the surface.

Indeed, subsequent atomic force microscopy (AFM) measurements of surfaces prepared without immediate rinsing or rinsing with a nonpolar solvent clearly showed the presence of deposits at the surface with typical dimensions > 100 nm. On the basis of the reactants involved and position of the observed IR modes, these particles were determined to be $(NH_4)_2SiF_6$ salts. The finding that improper rinsing could yield IR features that were previously interpreted as originating from NH_x surface chemical functionalities explained these previous observations of HF-etched surfaces, since immediate rinsing was not reported, particularly because IR measurements of surfaces that were immediately rinsed with appropriate solvents showed only a very weak band at 1550 cm^{-1} (instead of 1440 cm^{-1}) that could originate from no more than ≈ 10% of a NH_x monolayer, and its quantification is discussed below. Furthermore, no features that could be attributed to surficial Si−H bonds were detected. Thus, despite reports claiming complete hydrogen termination of the HF-etched surfaces, the data pointed to the need for a more refined model for the composition of the etched surface.

XPS (Fig. 26.43b) and LEIS (Fig. 26.43c) measurements were employed to identify the elements present at the surface and their chemical state. Both He^+ LEIS and XPS measurements showed the presence of Si, F, and O at the surface, in relative amounts that were independent of the HF concentration used for etching (from 0.1 to 10%). The F 1s core level (Fig. 26.43b) is characterized by a single symmetric peak at 688.3 eV binding energy, consistent with the formation of a Si−F bond and not N−F bonding, indicating a single-chemical environment for surface F atoms. Residual physisorbed atmospheric contaminants were ruled out as the origin of this signal, as the F signal did not initially disappear as gentle gas-cluster ion beam (GCIB) sputtering (Fig. 26.44) was used to remove weakly adsorbed species in a gradual layer-by-layer fashion. Interestingly, prolonged GCIB bombardment of the surface led to complete elimination of F, but not of O; rather, there was an additional component in the O 1s spectrum shifted by ≈ 0.6 eV toward lower binding energy (after accounting for charging effects). The redshifted position, and the fact that this peak persists even after all surface F is removed, point to the fact that some O atoms are located in the subsurface region. All the observations taken together suggest that there are two chemically distinct oxygen moieties as a result of HF etching: a surficial hydroxyl group and O atoms inserted into the Si back-bonds to form Si−O−Si.

Quantification of the relative amounts of the surface species present (atop F, hydroxyl, and amine groups) posed a challenging problem that required a multifaceted approach to yield physically meaningful results. Often, XPS coverage is evaluated based on the attenuation of the substrate due to an adlayer, and the degree of attenuation is determined from measurements of the substrate under identical conditions with and without the adlayer. Unfortunately, since the substrate comprises largely light elements, even the comparatively gentle GCIB method used to remove the F and O lead to preferential sputtering of the N in the substrate, rendering this approach inaccurate. An alternative method was used to circumvent this problem: a system with a well-defined one-third monolayer coverage [26.129] of atop Si−F species was produced and measured as a calibra-

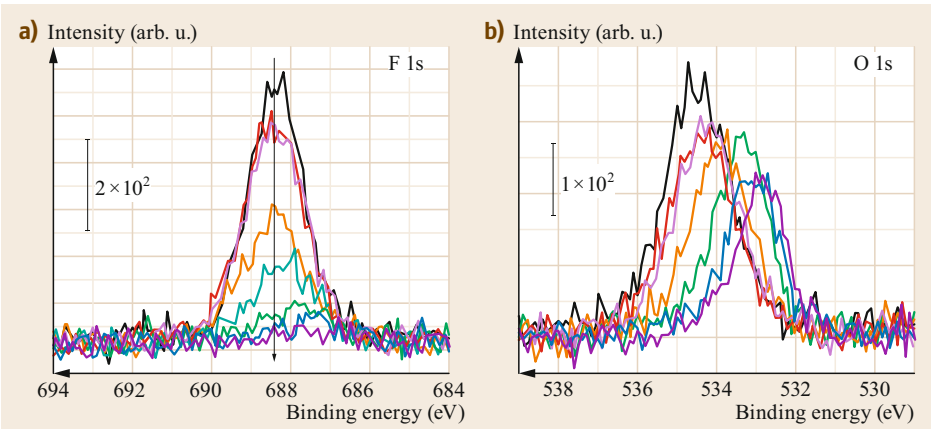

Fig. 26.44 F 1s **(a)** and O 1s **(b)** XP spectra of HF-etched Si_3N_4 films prepared with proper water rinsing as a function of GCIB sputtering. The spectra correspond to the following GCIB-sputtering sequence: no sputtering, 5 kV 30 s and 1 min net sputtering, followed by 10 kV for net sputtering times of 15 s, 45 s, 2 min, 6 min, 11 min, and 16 min (Reprinted from [26.128], with the permission of AIP Publishing)

tion for XPS intensities. With this information, it was possible to then quantify the amount of F present at the surface of the HF-etched Si_3N_4 surfaces: ≈ 70% F monolayer.

Quantification of the coverage of $-NH_2$ groups at the surface cannot be accomplished through the XPS measurements with calibrations standards, as the N 1s is dominated by the signal from the substrate; an alternative method for evaluating the coverage involved performing a chemical titration of existing NH_x surface groups via surface reactions and quantification of the resulting reaction products. In particular, the IR intensity of the C−H stretching modes in organic aldehydes, known to be preferentially reactive toward amine groups, were used to quantify the amount of $-NH_2$ initially present. In this manner, the total number of molecules reacted with the HF-etched surface was estimated at $17 \pm 5\%$ of a monolayer, when an organic functionalized SiO_2 surface was used to calibrate the C−H stretching intensity of a complete monolayer.

Similarly, quantification of surface Si−OH was achieved using a target molecule that reacts preferentially with hydroxyl groups, in this case chlorodimethyloctadecylsilane (CDMODS). Following reaction, the measured loss at the O−H stretch intensity was $\approx 37 \pm 16\%$ of the loss following identical reaction conditions with a fully OH-terminated SiO_2 surface. Assuming complete reaction with all surface hydroxyl groups, the OH coverage is therefore estimated at $37 \pm 16\%$ monolayer. Interestingly, despite having lost considerably less OH than for the corresponding reaction on SiO_2, the etched Si_3N_4 surface showed hydrocarbon content nearly equal to that observed for SiO_2, suggesting additional potential reaction sites. LEIS measurements of CDMODS-functionalized Si_3N_4 (Fig. 26.45) after annealing to remove the organic groups showed an F/Si ratio of $76 \pm 11\%$ of that observed for the etched Si_3N_4 surface with similar thermal treatment but no CDMODS functionalization, indicating that surficial F atoms are removed during the reaction to expose additional reactive sites as one additional route toward incorporation of CDMODS onto the surface.

In this complex and inhomogeneous system, identification and quantification of the final surface termination was particularly challenging, as several chemical moieties were present depending on the treatment, and no technique taken on its own was sensitive to all species present at the surface. Only the combination of IR, XPS, and LEIS made it possible to identify and control the HF-etched Si_3N_4 surface and arrive at a method for selective functionalization, by first performing a Schiff base reaction with aldehydes and the NH_2 groups, and then reaction with silanes and the OH groups, using molecules with different head groups.

26.4.6 Mass Transport in Complex and Irregular Surfaces and Nanostructures

Metal–organic frameworks (MOFs), crystalline nanoporous materials comprising metal ions or clusters linked by organic ligands, are emerging as key materials for applications such as energy storage, gas capture and separation, sensors, and even biomedicine. A major challenge in optimizing their performance for these applications is the relatively weak adsorption energy and therefore inefficient retention of many target molecules. While modification or functionalization of the ligands is one route toward selective retention of specific molecules, *Tan* et al. [26.130] examined a new and more universal approach to enable retention of molecules in MOFs by adding a capping layer to the surface of the MOF channels to prevent out-diffusion following gas loading. Focusing on a particular MOF with a channel structure (MOF-74, Fig. 26.46a), they demonstrated that by introducing a *sticky* molecule (4 Torr) such as ethylenediamine (EDA) after CO gas loading (40 Torr), a monolayer-thick molecular cap was formed, preventing the escape of loaded CO molecules. The rationale for this approach was to block the channel structure with a relatively bulky molecule that interacts sufficiently with the MOF surface to remain adsorbed and prevent out-diffusion of the trapped molecules, as shown by the schematic in Fig. 26.45b.

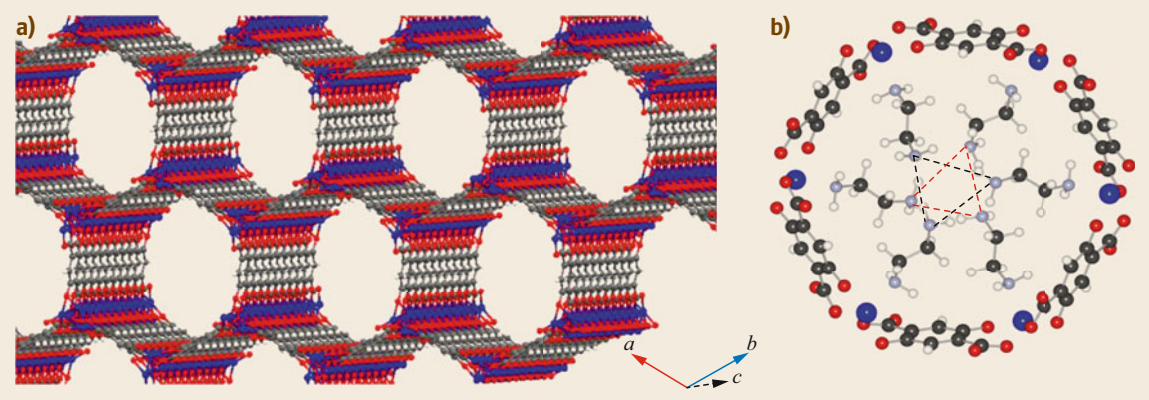

Fig. 26.46 **(a)** Schematic of the MOF-74 structure. **(b)** Optimized geometry of EDA adsorbed at the channel openings (Reprinted by permission from [26.130], © Nature 2016)

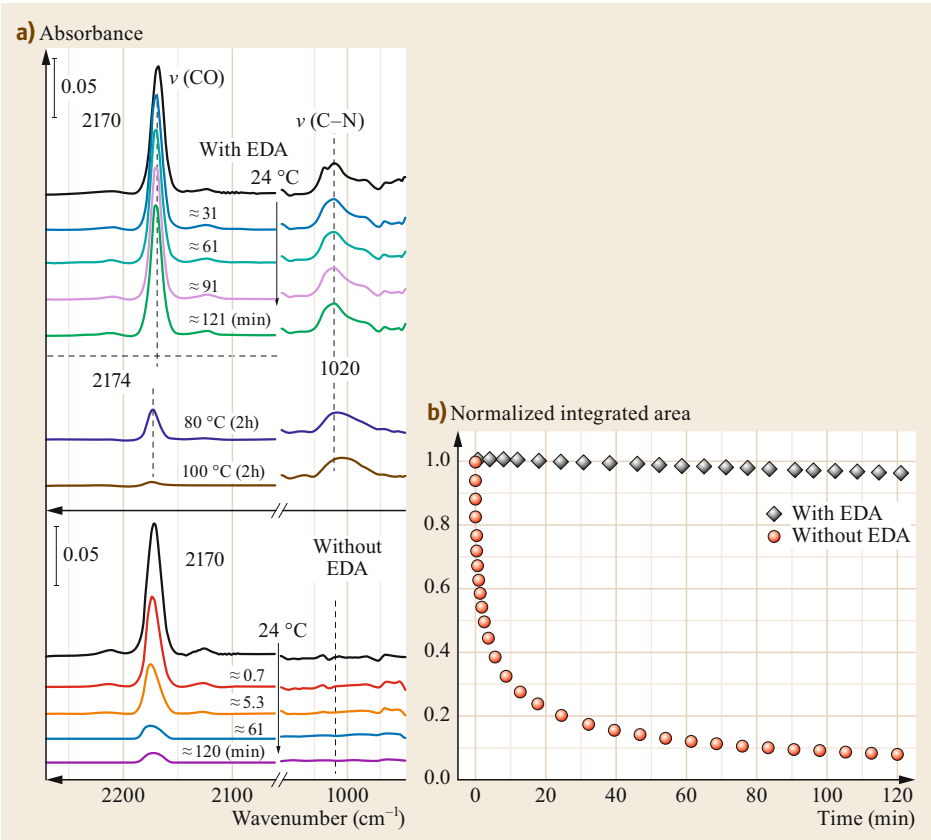

Fig. 26.47 **(a)** *Top panel*: IR absorption spectra following CO loading and capping as a function of evacuation time. *Middle panel*: thermal stability of the loaded/capped system. *Bottom panel*: IR absorption spectra as a function of evacuation time following CO loading in the absence of an EDA cap. **(b)** Integrated area of the CO stretching features in Fig. 26.39a as a function of evacuation time (Reprinted by permission from [26.130], © Nature 2016)

The gas loading, capping, and pump-down process was monitored in situ and as a function of time using IR spectroscopy. The measurements were performed in a high-pressure cell enabling normal incident transmission measurements on pressed powders of the MOF material. Figure 26.47a shows differential IR spectra taken as a function of time following CO loading, EDA capping, and pump-down. The data show modes assigned to the C≡O stretch of the trapped molecules and C−N stretching of the adsorbed EDA, both of which remain nearly constant over the course of the two hours during which the experiment was performed. In contrast, the bottom panel shows analogous measurements taken on samples loaded

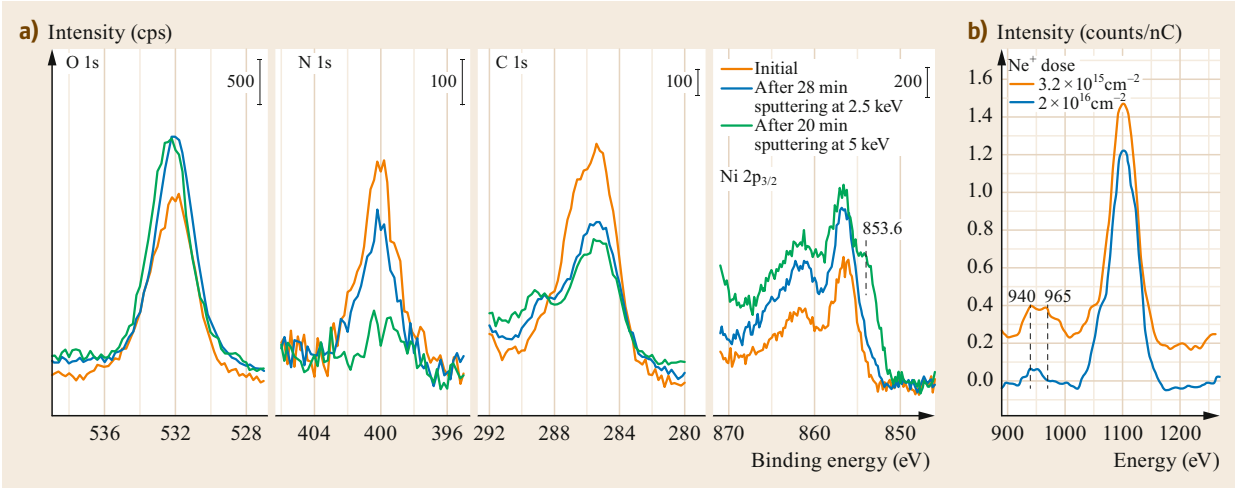

Fig. 26.48 **(a)** O 1s, N 1s, C 1s, and Ni 2p core-level spectra of loaded and capped Ni-MOF74 as a function of GCIB sputter time. **(b)** 3 keV He^+ LEIS spectra of loaded and capped Ni-MOF74 as a function of sputtering using 5 keV Ne^+ (Reprinted by permission from [26.130], © Nature 2016)

identically with CO but not capped with EDA; the data show that, following evacuation for 2 h, the CO signature is reduced to less than 10% of its initial value. To quantify the temporal stability of trapped gases, the integrated intensity of the C≡O stretch recorded as a function of time after pump-down is shown in Fig. 26.47b for the experiments with and without the EDA capping layer. Clearly, the presence of the EDA has the effect of preventing the trapped CO molecules from exiting the MOF through the pore channels, and therefore serves to confine the gases within the MOFs.

To test the theory that the EDA was adsorbed on the exterior surface of the channels, XPS and LEIS measurements were performed. Figure 26.48a shows O 1s, N 1s, C 1s, and Ni 2p XP spectra of the loaded, capped MOF system as-prepared and as a function GCIB sputtering. Again, the GCIB can be regarded as a *gentle* sputtering technique that is ideal for removing light elements at the surface one layer at a time. The data show that, as a function of GCIB sputtering time, the surface N signal decreases to the detection limit of the instrument, but the C, O, and Ni peaks, representative of the bulk of the MOF, are maintained. These data point to the fact that any N-containing moieties are located close to the surface. LEIS measurements were performed on loaded, capped MOF samples to further verify the localization of the EDA layers. Data collected with 3 keV He^+ (Fig. 26.48b) clearly show a peak due to N at the surface of the MOF samples. The peak appeared as a doublet with components centered at ≈ 940 and 960 eV, showing unambiguously that N is present at the outermost region of the surface, and supporting the model of the EDA molecules residing in a position as depicted in Fig. 26.46b to *cap* the channels. Prolonged sputtering with 5 keV showed an elimination of the 960 eV component, and only the 940 eV component remained. These data can again be interpreted as N atoms lying directly below the surface, as the 20 eV shift observed relative to the position of the surface peak is well matched for the energy cost for a complete neutralization and reionization cycle, as discussed in Sect. 26.3. The persistence of this subsurface peak following further sputtering was ascribed to the irregular geometry of the (powder) samples, rendering many sites, such as those residing at grain boundaries or regions blocked by neighboring particles, invisible to the sputtering beam but accessible through the process of multiple scattering and reionization. This work thus demonstrates an approach for characterizing surface reactions and mass transport in complex and irregular surfaces and nanostructures, even hybrid organic-inorganic materials.

26.5 Conclusions and Outlook

This chapter has illustrated how combined vibrational (in particular IR), XPS, and LEIS measurements enable quantitative, comprehensive analysis of studies of adsorbate structures and bonding configurations, sur-

face reactions, and mass transport for a wide variety of systems. The examples presented above demonstrate how the information derived from experiments combining these techniques can unravel specific properties (e.g., catalytic reactivity, thin film growth, semiconductor doping) of the system of interest. From these examples, several overarching conclusions are reached:

1. More often than not, a single experimental probe is insufficient to fully understand a given surface structure, reaction, etc. The combined assets of the techniques discussed here can strengthen the conclusions of each individual technique, enabling quantitation and insight that would not be possible for a single technique used alone.
2. The different interaction volumes of IR photons, XPS photoelectrons, and LEIS ions can be used in a complementary way to deduce the relative location of a given species with respect to the surface. IR absorption measurements probe the greatest depth (throughout the complete sample for the case of transmission and MIR measurements and one-half the skin depth for the case of IRRAS with metal surfaces, typically ≈ 30 nm), but signals originating only from the surface can be discriminated through the use of a proper reference measurement. XPS effectively performs an average over the outermost $\approx$ 5 nm weighted by the depth of the atom from which the photoelectrons originate. The surface peaks in LEIS originate from only the outermost 1–2 atomic layers, although subsurface signals (characterized by a shift in the energy of the backscattered ions) can provide static depth profiles up to $\approx 5-10$ nm. These effects can yield information on different aspects of a given system; for example, details on chemical bonding of an adsorbate overlayer from IR absorption, chemical state of the substrate from XPS, and diffusion processes from LEIS.
3. While the examples presented here have shown a synergistic marriage between IR, LEIS, and XPS measurements, other combinations of surface-sensitive techniques are also clearly valuable for studies of bonding configurations, surface reactions, and mass transport. For example, many of the studies discussed in this chapter combine LEIS or IR measurements with LEED in the study of ordered structures, which can provide further structural insight into many systems. Similarly, combining the spectroscopic techniques discussed above with scanning probe microscopy such as STM can provide further information on coverage, surface morphology, bonding configurations, and surface electronic structure [26.9]. As is often the case, the most useful combinations (e.g., STM and IR) are also the most difficult to realize in practice, but the efforts are worth it!

As experimental developments have continued to improve, and initial results on these combined techniques have demonstrated the value of this multi-technique approach, the motivation for developing other synergistic combinations increases. Hopefully, this chapter will add to this motivation.

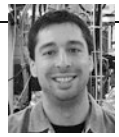
Eric C. Mattson

Dept. of Materials Science and Engineering
University of Texas at Dallas
Dallas, TX, USA



Eric Mattson obtained his BS and PhD degrees in Physics from the University of Wisconsin-Milwaukee. He joined the Chabal research group in the Materials Science Department at UT-Dallas as a Postdoctoral Researcher in 2014. His research has focused on understanding surface modification and reactivity of industrially- relevant systems using ultrahigh vacuum-based in-situ spectroscopic methods.

Yves J. Chabal

Dept. of Materials Science and Engineering
University of Texas at Dallas
Dallas, TX, USA
chabal@utdallas.edu

Yves Chabal holds a Texas Instrument Distinguished Chair in Nanoelectronics at the University of Texas at Dallas, where he directed the Laboratory for Surface Modification, an interdisciplinary research center. His research has included development of sensitive spectroscopic methods to characterize surfaces and interfaces, atomic layer deposition, biosensors, materials and surface modifications for energy, photovoltaics and hydrogen storage applications, twodimensional materials, and nanoenergetic materials and interfaces.

Gas Surfa

Part G

Part G Gas Surface Interaction

Part G deals with the gas–surface interaction, a process that is pivotal to our understanding of catalysts and sensors and their optimization. Interactions between gas species and surfaces depend on the nature and strength of the bond between the atom or molecule and the surface, the site occupied by the admolecules (for nondissociative adsorption) or the fragments or adatoms (if bond breaking occurs), the formation of ordered overlayers, and the interactions between the adsorbates. This information is required to obtain a fundamental understanding of adsorption and desorption processes. Adsorption may be governed by physical forces alone (van der Waals interactions between the atom/molecule and the substrate responsible for physisorption) or by the formation of chemical bonds with the substrate (chemisorption). In the former case, the molecule is barely affected, and its vibrational modes are almost unchanged. In the latter case, the internal bonds may be significantly modified and the frequencies of the vibrational modes exhibit important shifts. The chemisorption interaction can then lead to partial or complete dissociation of the reactants, and the resulting radicals can act as promoters or poisons in catalytic reactions. Interactions between adsorbates and their ability to diffuse on the surface can lead to the formation of ordered adlayers stabilized by either direct interactions between the admolecules or substrate-mediated interactions. Such ordered structures can be used as templates or active coatings in applications.

Chapter 27 provides an introduction to the topic of this section, and describes recent first-principles methods employed to calculate the adsorption energy. These methods are explored in great length by examining the subtleties of CO adsorption on a number of metal and nonmetal surfaces. Surface reactions are then addressed using transition state theory and activation energy calculations performed via first-principles methods. The chapter also discusses the solution to the so-called CO puzzle—the long-standing disagreement between experimental results and theoretical predictions regarding the adsorption site of CO on Pt(111).

Chapter 28 covers nonadiabatic effects in most common gas–surface reactions in the local density friction approximation (LDFA). In particular, the chapter describes the roles of friction and energy dissipation in the scattering of atoms and molecules, in their dissociation, and in the subsequent relaxation of hot atoms. It also addresses Eley–Rideal and hot-atom abstraction processes as well as desorption induced by intense femtosecond laser pulses, thus exemplifying the power of the LDFA approach.

Chapter 29 provides an overview of self-assembling monolayers (SAMs) formed by organic molecules at surfaces. This topic is particularly relevant to molecular electronics, sensor design, pharmacology, biocompatibility, hygiene, and biofouling. The formation of covalent structures and the self-assembly of thiols and amino acids are given as examples. The apparently huge number of possible arrangements is rationalized by considering the relative magnitudes of the interactions of the molecules with the substrate and each other, as well as the constraints imposed by the structure of the substrate on which the overlayer is grown.

Chapter 30 deals with the energetics of adsorption. The chapter reviews data obtained with a single-crystal calorimeter for the adsorption of simple molecules at single-crystal surfaces, as well as more recent results regarding the adsorption of molecules at clusters and the adhesion of metal atoms at oxide surfaces. Microcalorimetry can provide information on atom/molecule–surface interaction strengths that is not attainable with other experimental methods, and can act as a benchmark to test state-of-the-art theoretical calculations.

Chapter 31 describes a rigorous kinetic approach to adsorption, diffusion, desorption, and surface reactions in terms of macroscopic variables such as rate equations for local coverage or partial coverage. When local equilibrium is not applicable, an approach based on nonequilibrium statistical mechanics involving time-dependent distribution functions is required. The chapter covers the theory for adsorbates that remain in quasi-equilibrium throughout the desorption process and the theory for a lattice gas model with multiple interactions. Examples are provided for the adsorption and desorption of hydrogen on Rh(311) and the coupled desorption and site conversion of coadsorbates for $(NO + O)/Ru(001)$. In the final part, recent advances in the theory of kinetic lattice gas models regarding nondissociative adsorption and precursor-mediated adsorption and desorption are discussed.

Chapter 32 reviews results on the dependence of the sticking probability on the vibrational and rotational states of the reactants in the gas phase. Initially, information about the role of the internal degrees of freedom in adsorption was obtained by examining the internal states of scattered molecules and making use of a detailed balance. Later, methods of preparing gas-phase molecules in well-defined rotational and vibrational states were developed. This permitted the direct measurement of the sticking probability in at least partially defined quantum states. Selected results obtained by preparing molecules in supersonic beams through laser, hexapole, and collisional alignment are presented. These demonstrate the pivotal role of stereodynamics in the reaction at hand and the role of vibrational and rotational energy in overcoming activation energy barriers.

27. Gas Surface Interaction and Surface Reactions

Ziyun Wang, Peijun Hu, Qingfeng Ge

The gas–surface interaction and surface reactions are important aspects of surface science. In this chapter, fundamental concepts along with some of the latest findings in these two subject areas are reviewed, with a focus on the results of first-principles calculations. The chapter is divided into two parts, with the first exploring the gas–surface interaction (Sect. 27.1) and the second discussing surface reactions (Sect. 27.2).

In the first part, we summarize recent developments in the use of first-principles methods to calculate the adsorption energy of a gas on a surface, and we illustrate these developments using the adsorption of CO as an example. Furthermore, the relationship between surface electronic structure and adsorption energy is explored for the adsorption of a gas on surfaces of both metallic and sp^2-carbon materials. Two models for predicting adsorption are then considered, and an example of catalyst screening using the chemical potential is given.

In the second part of the chapter, we first explain transition state theory and show how to calculate the activation energy using first-principles methods. The Brønsted–Evans–Polanyi (BEP) relationship and representative surface reaction mechanisms are then reviewed. After that, the characteristics of active sites on the surfaces of metals and metal oxides are illustrated with examples. Finally, a short perspective on the future of research into gas–surface interactions and surface reactions using first-principles methods is provided.

The gas–surface interaction and surface reactions are of great importance in surface science and heterogeneous catalysis, so they have been extensively studied using many experimental techniques. However, the microscopic details of gas–surface interactions and (especially) surface reactions are still unclear due to the limited time and size resolutions of such techniques. First-principles calculations offer an alternative method of studying gas–surface interactions and surface reactions at atomic scales. In the last few decades, a large number of investigations of gas–surface interactions and surface reactions have been carried out using first-principles calculations. Indeed, due to increased computing power and the development of computational algorithms, first-principles calculations have become one of the most important tools used in surface science and heterogeneous catalysis research. In this chapter, the results of first-principles calculations are used to review some theories regarding gas–surface interactions and surface reactions. Some examples of these kinds of interactions and reactions are included for illustrative purposes. We also discuss some related computational methods and their development. This chapter is divided into two sections corresponding to gas–surface interactions and surface reactions, respectively.

27.1 The Gas–Surface Interaction

Gas–surface interactions have many important applications in physics and chemistry. In particular, such interactions are crucial to heterogeneous catalysis. Almost all gas–solid reactions in heterogeneous catalysis start with the adsorption of the reactant molecules on a surface. The adsorption of the product species that form on a surface following a catalyzed reaction is dependent on their interaction with that surface. The gas–surface interaction influences the level of catalytic activity and selectivity during heterogeneous catalysis and is central to the behavior of many getter materials, such as zeolites and activated carbon.

The adsorption energy is one of the main properties associated with any gas–surface interaction. This energy can be determined using first-principles calculations: the energy of a gas molecule adsorbed on a surface and the corresponding energies of the gas molecule and the surface alone can be calculated directly by solving the Schrödinger equation, and the energy difference between these states yields the adsorption energy. However, approximations are used in first-principles methods, especially in density functional theory (DFT), which is the most widely used first-principles method, and this utilization of approximations can lead to low accuracy when using first-principles methods to calculate the adsorption energies for some systems. For instance, DFT fails to correctly predict the adsorption energy and site for CO on some metal surfaces; this issue is known as the *CO puzzle* [27.1]. In an attempt to solve the CO puzzle, many computational methods have been applied to improve the accuracy of the adsorption energies generated by first-principles calculations. In this section, we provide a general overview of the use of first-principles calculations to derive adsorption energies, and we discuss the development of new methods that could be used to solve the CO puzzle by providing a more precise description of the gas–surface interaction.

A detailed knowledge of the electronic structure of the surface involved is essential when probing gas–surface interactions. This is because a deep understanding of the relationship between the surface electronic structure and the gas–surface interaction is needed to elucidate the changes in the surface electronic structure that occur upon the adsorption of a gas molecule at a surface and the differences in gas adsorption strength between different surfaces. Therefore, some studies of the relationship between electronic structure and adsorption energy are discussed in Sect. 27.1.2.

As mentioned above, the gas–surface interaction is crucial to the activities of many catalytic and getter materials. The adsorption strength is a very important influence on the activities of these materials. Indeed, better catalysts have been developed by tailoring the adsorption energy through appropriate engineering of the surface structure [27.2, 3]. Furthermore, the rational design of catalytic materials can be achieved by searching for surface structures with desirable adsorption energies [27.4]. Therefore, understanding the relationship between adsorption energy and surface structure is key to speeding up the discovery of novel materials with particular gas–surface interactions. In Sect. 27.1.3, some recent results on the relationship between adsorption energy and surface structure are discussed.

In Sect. 27.1.4, we present an example of determining the gas–surface interaction using first-principles calculations. This example illustrates catalyst design based on the calculation of adsorption energy using density functional theory. The application of the concept of chemical potential to heterogeneous catalysis, which represents the most recent approach to understanding catalytic activity based on the adsorption energy, is also discussed. Finally, an example involving the design of an active counter electrode (CE) material for application to the triiodide reduction reaction in dye-sensitized solar cells is provided.

27.1.1 Calculating the Adsorption Energy

Before describing first-principles calculations of the adsorption energy in gas–surface interactions, it is important to introduce the model used to describe the surface in the calculations. Two basic models are used in adsorption energy calculations: the cluster model and the slab model. The former normally treats the adsorbate, the adsorption site atoms, and the nearby surface atoms as a supermolecule (cluster), whereas the latter considers the surface to be a periodic slab. One of the advantages of the cluster model is that, because it involves fewer atoms, less computation is needed than for the slab method. However, the accuracy of the cluster model is usually insufficient. Thus, although the slab model normally requires more computational effort, it gives a more accurate description of surface structure and properties in general. Advances in computational power have therefore led to the increasing use of the slab model to study gas–surface interactions. Herein, we focus on adsorption calculations performed using the slab model.

Figure 27.1 shows a typical example of a slab model of a CO molecule interacting with Pd(111), where Pd(111) is modeled using a (2×2) periodic unit cell containing four surface Pd atoms. In normal first-principles calculations of adsorption energy, the

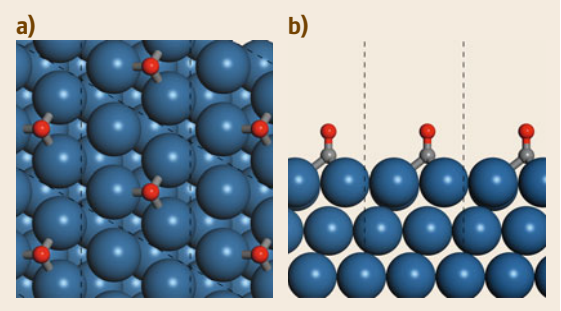

Fig. 27.1a,b Illustration of the slab model of the interaction of a CO molecule with Pd(111). Pd, C, and O atoms are shown in *blue*, *gray*, and *red*, respectively

adsorption energies of the adsorbate at different adsorption sites are determined in turn, and the most stable site is treated as the adsorption site. As shown in Fig. 27.1, the most favorable adsorption site of CO on Pd(111) is the threefold hollow site. The adsorbate is replicated through the application of periodic boundary conditions (Fig. 27.1). Therefore, the size of the unit cell needs to be large enough to avoid interactions with the adsorbate in neighboring unit cells. Alternatively, a small unit cell can be employed to measure the adsorbate–adsorbate interaction when the surface coverage is high. Using the slab model, the adsorption energy of the gas molecule on the surface (E_{ads}) can be obtained as the difference between the energy of the gas bonded with the surface ($E_{\text{gas+surf}}$) and the sum of the energies of the gas molecule (E_{gas}) and surface (E_{surface}) when they are not interacting, i.e.,

$$E_{\text{ads}} = E_{\text{gas+surf}} - E_{\text{gas}} - E_{\text{surf}} \,. \tag{27.1}$$

According to this definition, the more negative the adsorption energy, the stronger the gas surface interaction. Using this method and model, the adsorption energies associated with both physical adsorption and chemisorption of the gas molecule on the surface can be calculated. The accuracy of the calculated adsorption energy value depends on the first-principles method applied. In most cases, especially for metal surfaces, DFT gives values that are reasonably close to the corresponding experimental values; however, rather inaccurate adsorption energies and even incorrect adsorption site predictions are generated for some systems using normal DFT methods. This section begins with a discussion of one of the most famous failures of DFT: its inability to accurately calculate the adsorption energy of CO on Pt(111). The reasons for this *CO puzzle* are discussed in terms of the electronic structures of the CO molecule and the surface, and some corrections based on an understanding of these electronic structures are also explored. The last section focuses on the utilization of different calculation methods (DFT+U and the random phase approximation) to solve this puzzle. The process of solving the CO puzzle illustrates how first-principles methods are used and developed to better understand the electronic structures of gas–surface interactions and to more accurately predict adsorption energies and sites.

The CO Puzzle

The CO puzzle refers to the strong disagreement between the adsorption sites of CO on (mainly) Pt(111) predicted by first-principles calculations and those observed experimentally. This discrepancy was first discussed by *Feibelman* et al. [27.1]. Experimentally, CO is found to prefer atop or bridge sites on Pt(111). For example, *Blackman* et al. [27.5] examined a disordered one-third monolayer of CO on Pt(111) at 160 K using diffuse low-energy electron diffraction analysis. Their results suggested that (88±5)% of the CO molecules are located at atop sites while (12±5)% are at bridge sites. Furthermore, *Schweizer* et al. [27.6] developed an empirical potential energy surface for CO/Pt(111) by fitting infrared measurements of the CO stretch frequency and peak width at different temperatures and for various CO coverages. They found that the difference between the atop and bridge sites was around 60 meV upon extrapolating to zero coverage, and that the atop site was more favorable. Similar results have also been obtained using many different techniques, such as diffraction, vibrational spectroscopy, and scanning probe microscopy, which are reviewed in the original paper on the CO puzzle [27.1]. Experimental results indicate that each CO molecule binds to a single Pt atom and agree with the theoretical determined energy difference between adsorptions at atop sites and bridge sites. Threefold hollow adsorption was only very rarely observed in the experimental studies.

Interestingly, most DFT methods fail to predict the preferred adsorption site. *Feibelman* et al. [27.1] calculated CO adsorption on Pt(111) using different calculation methods and codes, as shown in Table 27.1, including the Vienna ab initio simulation package (VASP) with ultrasoft pseudopotentials (USP), Blöchl's projector augmented wave (PAW) approach, the Dacapo code with USP, and full-potential, linearized, augmented plane wave (FP-LAPW). The exchange-correlation functionals in both the local density approximation (LDA) and the generalized gradient approximation (GGA) were considered too. A series of coverage values were taken into account, ranging from 1/12 to 1/3. The results shown in Table 27.1 suggest that the binding energies at the fcc hollow site are stronger than those at the atop site—a conclusion at odds with the

Table 27.1 Binding energies at a fcc hollow site relative to those at an atop site on CO/Pt(111) for different supercells, coverages (θ), methods, and exchange-correlation (XC) functionals. The binding energy is defined as shown in (27.1), so a more negative value indicates stronger binding. All data are adapted from the paper by *Feibelman* et al. [27.1]

experimental results. This disagreement is known as the CO/Pt(111) puzzle. In addition to Pt(111), calculations on Cu(111) also predict the wrong preferred adsorption site: angle-resolved photoemission extended fine structure (ARPEFS) and spectroscopic analysis indicated that CO prefers atop sites at a coverage of 1/3 ML, while DFT-GGA calculations predicted that the hcp hollow site would be the most stable. On the other hand, DFT-GGA calculations correctly predicted that CO/Pd(111) and CO/Ni(111) were the threefold sites.

Feibelman et al. [27.1] also explored some possible reasons for the disagreement between the experimentally observed and theoretically deduced preferred sites for CO adsorption. First, they proposed that the experimentally observed phenomenon may be due to the adsorption of CO at a Pt adatom on Pt(111). They calculated the CO adsorption energy at a Pt adatom on Pt(111) and found it to be 40 meV greater than that at a fcc hollow site. However, the energy gain is not sufficient to stabilize Pt adatoms on Pt(111), as the adatom formation energy is unfavorable by 1.07 eV. Secondly, the possible influence of hydrogen atoms on the experimentally observed adsorption energy and sites was examined using a model that included subsurface hydrogen. However, the inclusion of subsurface hydrogen did not make the atop-bridge configuration more favorable than the hollow sites. Thirdly, the relativistic correction and spin polarization were accounted for, but neither led to a preference for atop-site bonding. Lastly, the effects of correcting for the zero-point energy and the vibrational entropy were examined. The zero-point energies of CO adsorbed at the atop and fcc sites were found to be 218 and 196 meV, respectively, meaning that the zero-point energy destabilizes the atop site more than the fcc site. The vibrational entropy contribution, calculated via the harmonic approximation, is 0.083 meV/K higher for an atop site than for a fcc site at ≈ 300 K. Consequently, even though the entropic contribution stabilizes adsorption at the atop site by 25 meV at 300 K, this contribution is not enough to make the atop site more stable than the fcc site at 300 K. Furthermore, most surface science experiments are performed at low temperatures, which reduces the entropic contribution. Therefore, DFT calculations underestimate the preference of CO for adsorption at low-coordination sites.

The HOMO–LUMO Gap and the Singlet–Triplet CO Excitation Energy

As mentioned above, normal DFT methods fail to correctly predict the preferred site for the adsorption of CO on Pt(111). In order to solve this CO puzzle, a better understanding of the adsorption of CO on Pt(111) is required. The Blyholder model [27.7] is one of the most widely accepted models of CO adsorption on a transition metal surface. With some modifications [27.8, 9], this model can be used to probe the difference between adsorption at atop sites and adsorption at hollow sites. According to the model, there are two main contributions to CO adsorption on Pt(111): 5σ donation and 2π backdonation. The former refers the mixing of the highest occupied molecular orbital (HOMO) of CO, 5σ, with the d_{z^2} states of the surface, while the latter corresponds to the interaction between the lowest unoccupied molecular orbital (LUMO) of CO, 2π, and the d_{yz} and d_{xz} states of the surface. Donation from 5σ and backdonation to 2π occur during CO adsorption at both atop and hollow sites, although donation from 5σ tends to make CO adsorb at the atop site whereas 2π backdonation favors the hollow sites.

Kresse et al. [27.10] investigated CO adsorption on Pt(111) using four different PAW potentials generated with different core radii. The adsorption energies at atop and hollow sites obtained with the four potentials are quite different, as shown in Table 27.2. As the pseudopotential core radius increases, the adsorption energy

Table 27.2 Difference in binding energy ΔE between CO adsorption at an atop site and CO adsorption at a fcc sites on Pt(111), the adsorption energy for a fcc site E_{fcc}, and the one-electron DFT HOMO–LUMO ($5\sigma - 2\pi$) gap E_{gap} for various PAW potentials. The pseudopotential core radius of the p wavefunction r_c and the optimized CO bond length d are also listed for each PAW potential. The binding energy is defined as shown in (27.1) (i.e., a more negative value indicates stronger binding). All the data are adapted from the paper by *Kresse* et al. [27.10]

	r_c (arb. u.)	d (Å)	E_{gap} (eV)	ΔE (meV)	E_{fcc} (eV)
Hard PAW	1.1	1.134	7.01	−105	−1.67
Standard PAW	1.5	1.142	6.91	−126	−1.72
PAW	1.7	1.162	6.71	−180	−1.83
Soft PAW	1.85	1.18	6.48	−243	−1.91

of CO at fcc Pt(111) strengthens. At the same time, the HOMO–LUMO gap decreases. The downwards shift of the LUMO enhances the interaction between the 2π orbital and d states. As discussed above, 2π backdonation contributes more to adsorption at the hollow sites than adsorption at the atop sites. Thus, the decrease in the HOMO–LUMO gap leads to a preference for the hollow site, as shown in Table 27.2. Based on the aforementioned facts, increasing the HOMO–LUMO gap may be a promising way to make atop sites more favorable than hollow ones. However, there is an upper limit on the HOMO–LUMO gap within the PAW approximation, which gives an energy difference of −105 meV, as shown in Table 27.2. A DFT+U-inspired method of shifting the LUMO of CO further upwards was proposed by *Kresse* et al. [27.10]. DFT+U is a revised electronic method based on the framework of traditional DFT. The basic idea of DFT+U is to treat the strong on-site Coulomb interaction of localized electrons with an additional term that is not correctly described by LDA or GGA. The correction proposed by Kresse et al. is

$$E_{DFT+U} = E_{DFT} + \frac{U}{2}\sum_{\sigma=1}^{2}\sum_{i=1}^{2}\left(\rho_i^{\sigma} - \rho_i^{\sigma}\rho_i^{\sigma}\right) , \quad (27.2)$$

where E_{DFT+U} and E_{DFT} are the modified and conventional density functionals; σ is an index for the spin, and ρ_i^{σ} are the occupancies of the two LUMO orbitals for the up and down spins. *Kresse* et al. [27.10] found that when U equals 0.5 eV, the adsorption energies given by this DFT+U functional for both atop and hollow sites are the same. When $U = 0.75$ eV, the atop site is 60 meV more favorable than the hollow site and the adsorption energies decrease from 1.72 to 1.39 eV, which is in better agreement with experiments. These results suggest that the position of the LUMO plays an important role in the site preference prediction.

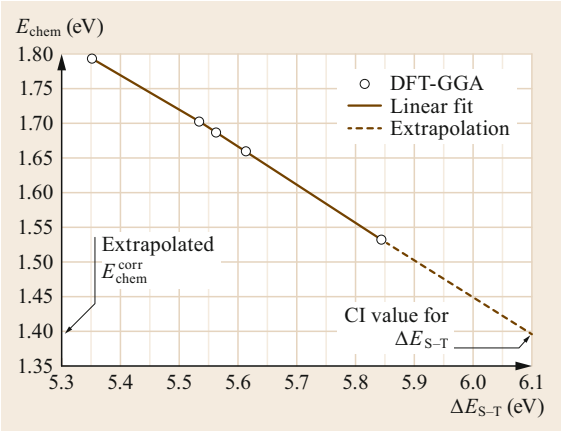

Fig. 27.2 Relationship between the adsorption energy of CO on Pt(111) E_{chem} and the singlet–triplet excitation energy ΔE_{S-T} for five pseudopotential sets (*circles*). (Reprinted with permission from [27.11], Copyright (2004) by the American Physical Society)

The DFT+U-type functional mentioned above provides one possible solution to the CO puzzle. However, the value of U is not known and can only be determined by fitting the experimental data, which is a difficult task. *Mason* et al. [27.11] proposed a first-principles extrapolation method to evaluate CO adsorption energies on a series of metal surfaces, including Pt, Rh, Pd, and Cu. They found that, like the HOMO–LUMO gap, there was a linear relation between the CO adsorption energy E_{chem} and the singlet–triplet excitation energy ΔE_{S-T}, as shown in Fig. 27.2. Similar linear relationships were also observed for the other investigated surfaces, including Pt(111), Rh(111), Pd(111), Cu(111), Pt(100), Rh(100), Pd(100), and Cu(100).

The value of ΔE_{S-T} obtained from coupled-cluster and configuration-interaction (CI) quantum-chemical calculations is very accurate and agrees well with the experimental value of ΔE_{S-T} (6.095 eV). However, *Mason* et al. [27.11] showed that the DFT-GGA always underestimates the value of ΔE_{S-T} no matter which pseudopotential set is used, which is one of the main reasons that the adsorption energies of CO on transition metal surfaces are overestimated by DFT-GGA. This led to the proposal of a first-principles extrapolation method based on the aforementioned linear relation and the ΔE_{S-T} value from the coupled-cluster and CI methods,

$$E_{chem}^{corr} = E_{chem}^{GGA} + \left(\Delta E_{S-T}^{CI} - \Delta E_{S-T}^{GGA}\right)\frac{\delta E_{chem}^{GGA}}{\delta E_{S-T}^{GGA}} , \quad (27.3)$$

where E_{chem}^{corr} and E_{chem}^{GGA} are the corrected adsorption energy determined by this extrapolation method and the

original energy from DFT-GGA, respectively. ΔE_{S-T}^{CI} and ΔE_{S-T}^{GGA} are the CO singlet–triplet excitation energies from the CI and DFT-GGA methods, respectively. $\delta E_{chem}^{GGA}/\delta E_{S-T}^{GGA}$ is the slope of the linear relation shown in Fig. 27.2b. Using this extrapolation method, the adsorption site for CO on Pt(111) was correctly predicted, as the adsorption energy at the atop site 0.163 eV was found to be more favorable than that at the hcp hollow site. Furthermore, the adsorption energy of CO on Cu(111) was calculated as 0.621 eV at the atop site and 0.610 eV at the bridge site, respectively, which reproduce the experimental results mentioned in the last section. In general, the average error of this extrapolation method was found to be 0.16 eV (13%)—much lower than the average error of 0.38 eV (30%) of PBE, which is a simple yet reasonably accurate method for correcting the results of normal DFT.

Hybrid DFT and the Random Phase Approximation

In the previous section, the CO puzzle was mainly attributed to the incorrect estimation of the HOMO–LUMO gap from DFT calculations. Two different methods based on parameter fitting with respect to the experimental values and high-level quantum chemistry calculations were introduced. However, these methods can only be used for the adsorption of CO on transition metals and similar systems with known experimental results. General methods that more accurately reflect the electronic structures of both the gas molecule and the surface, thus providing a better quantitative description of the gas–surface interaction, are necessary to solve the CO puzzle for all systems. In this section, two successful state-of-the-art methods of predicting the adsorption site for CO/Pt(111) are reviewed: hybrid DFT and the random phase approximation (RPA).

The exact exchange-correlation (XC) functional should be a truly nonlocal quantity that depends on the electronic density at two different points. However, the most popular DFT methods use either LDA or GGA XC functionals, which are local and semilocal, respectively. Furthermore, the use of independent exchange and correlation causes a general self-interaction error in DFT. One way to reduce the errors caused by these issues is to use a hybrid DFT method with a Hartree–Fock exchange component. *Reimers* and coworkers [27.12] showed that the hybrid PBE0 XC functional can predict the correct adsorption site for CO on Pt(111). The Hartree–Fock exchange component is included in the PBE GGA functional by introducing an extra parameter, i.e.,

$$E^{PBE0} = \alpha E^{exx} + (1-\alpha)E_{PBE}^{X} + E_{PBE}^{c}\,, \qquad (27.4)$$

where E^{exx} is the Hartree–Fock exchange and E_{PBE}^{X} and E_{PBE}^{c} are the exchange and correlation energies for the PBE GGA functional, respectively. The parameter α is optimized to 0.25 for PBE0. Using the hybrid DFT method, the HOMO–LUMO gap energy is calculated to be 9.42 eV, which is more than 2 eV higher than the HOMO–LUMO gap energies given by all of the local and semilocal functionals. The PBE0 HOMO and LUMO energies are -10.01 and -0.60 eV, respectively, while PBE gives -8.40 eV for the HOMO energy and -1.37 eV for the LUMO energy. Therefore, the HOMO–LUMO gap for gas-phase CO calculated using PBE0 is much higher than that calculated by PBE, which indicates that PBE0 and PBE should give significantly different adsorption energies based on the discussion in the last section. The PBE0-calculated adsorption energy of CO at the atop site is -1.80 eV according to *Reimers* and coworkers [27.12], which is 0.27 eV higher than that provided by PBE. Interestingly, the PBE0-derived adsorption energy of CO at the fcc site is -1.67 eV, indicating that PBE0 correctly predicts the preferred adsorption site. Therefore, hybrid DFT offers one way to solve the CO puzzle without using fitted parameters from experiments (except for the exchange contribution α in (27.4)). However, as suggested in the original paper [27.12], a band gap is artificially introduced by the hybrid functional for calculations of the Pt(111) surface, even though Pt is a conductor with a continuous band structure. In summary, even though the hybrid DFT method correctly identifies the preferred adsorption site, some minor defects in the approach it uses to calculate the band structures of conductors may limit its use in metal systems.

Besides their inability to correctly identify the preferred adsorption site, *Schimka* et al. [27.13] suggested that semilocal density functionals also tend to underestimate the surface energy. As shown in Fig. 27.3, there is a linear relation between the adsorption energies and the adsorption energies of CO at Pt atop and Rh atop sites for various semilocal and hybrid functionals. However, the experimental values for Pt and Rh (the orange points in Fig. 27.3) are far from the lines, suggesting that none of these functionals can accurately reproduce the experimental values for both the adsorption energy and the surface energy at the same time. Therefore, it is necessary to trade off accuracy in the adsorption energy for inaccuracy in the surface energy or vice versa. For instance, the Becke–Lee–Yang–Parr (BLYP) functional, a strong gradient correction, gives an accurate value for the adsorption energy of CO on Rh(111) but fails to precisely predict the surface energy. One the other hand, PBEsol, which corresponds to

an extremely weak semilocal gradient, reproduces the surface energy reasonably well but overestimates the adsorption energy. In order to solve this issue, *Schimka* et al. [27.13] implemented a state-of-art RPA method, GW-RPA [27.14], with exact Hartree–Fock exchange and RPA correlation energy. As shown in Fig. 27.3, the CO adsorption energies and surface energies of both Pt and Rh calculated using GW-RPA are not correlated with any of the other functionals. The points relating to GW-RPA data for both Pt and Rh (the green points in Fig. 27.3) are close to the corresponding points for the experimental data (orange points). Furthermore, the GW-RPA-predicted adsorption sites on various surfaces (e.g., Cu, Rh, Ru, Pd, and Pt) agree with those observed experimentally. The electronic structures of CO and the surfaces were also obtained using different methods and then compared. The PBE functional was found to give a good fit to the electronic structure of Pt(111) but to underestimate the HOMO–LUMO gap of the CO molecule, as mentioned above. Hybrid functionals are electronic methods that admix a certain amount of Fock exchange with a local or semilocal density functional. One hybrid method, HSE, reproduces the experimental HOMO and LUMO positions and the HOMO–LUMO gap rather accurately, but its description of the band structure of Pt(111) is rather inaccurate. GW-RPA, on the other hand, offers reasonable fits to the electronic structures of both Pt(111) and gas-phase CO. In summary, RPA is an excellent parameter-free tool for calculating the adsorption energy in gas–surface interactions. With the development of new first-principles methods, descriptions of gas–surface interactions will become more accurate and will be obtained more rapidly.

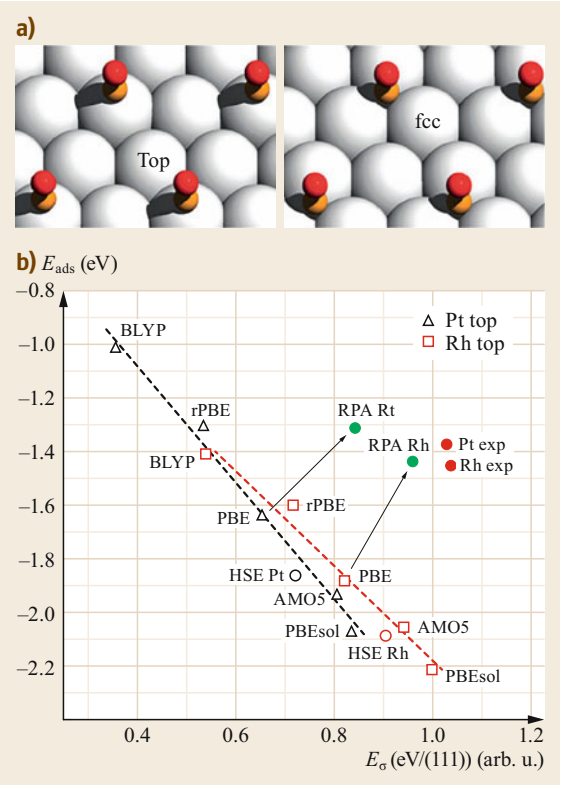

Fig. 27.3 **(a)** CO adsorption geometries considered for a (2×2) surface cell. **(b)** Plot of the adsorption energy at the atop site versus the surface energy (specified per unit area, u. a.) for Pt(111) and Rh(111). The data obtained using various semilocal functionals are plotted. (From [27.13])

27.1.2 Electronic Structure and Adsorption Energy

The relationship between the electronic structure of the surface and the adsorption energy is very important for gas–surface interactions. This relationship gives us considerable insight not only into the electron transfer that occurs in a gas–surface interaction but also into the general trend in adsorption energy for metal surfaces across the periodic table. One of the most popular models of electronic structure and adsorption energy is the d-band center, which was first proposed by *Hammer* and *Nørskov* to explain the inertness of gold [27.15]. In this section, we first review the d-band center model to unravel the relationship between electronic structure and adsorption energy. An example of the use of the d-band center theory is given. Finally, a model that allows us to understand the relationship between the electronic structure and the activity of an sp^2 material is provided.

The d-Band Center

Gold is the noblest of all metals. It has the lowest bond strength of most gas and liquid molecules. In order to understand the nobility of gold, *Hammer* and *Nørskov* [27.15] calculated the adsorption and desorption of a hydrogen molecule on four different surfaces (Au, Cu, Ni, and Pt) using a self-consistent DFT method. They found that the activities of these metal surfaces increased in the order Au < Cu < Pt < Ni. On Ni(111) and Pt(111), the dissociation of hydrogen is barrierless and hydrogen atoms on these surfaces are more stable than gas-phase hydrogen. On Cu(111), there is a small barrier to hydrogen dissociation and the enthalpy change involved is slightly negative. Au(111) is the most inert surface. It is unfavorable for hydrogen dissociation both thermodynamically and kinetically.

In order to elucidate why a gold surface is so noble, Hammer and Nørskov studied electronic transfer during the adsorption and dissociation of hydrogen on

various surfaces. As shown in Fig. 27.4, two different components contribute to the interaction between hydrogen and a transition metal surface. The first is the interaction of the 1s state of hydrogen with metal s bands (Fig. 27.4a), which causes the adsorption state to broaden. Interactions with metal s bands should therefore be attractive, and they should be similar for all four surfaces (Au, Cu, Ni, and Pt) because the s–s coupling matrix element is similar for all metal surfaces. The second component is the interaction between the 1s state of hydrogen and metal d states, which gives rise to both bonding and antibonding orbitals, as shown in Fig. 27.4b. If only bonding orbitals are occupied, this interaction should be attractive, while there is no hybridization energy if both bonding and antibonding orbitals are filled. Therefore, the gas–surface interaction depends strongly on whether an antibonding state is filled. Because the antibonding states lie above the d states, the energy of the center of the d states relative to the Fermi level is a good indicator of the gas–surface interaction. As shown in Fig. 27.5, there is only one resonance on a metal surface with a low d-band center position (DOS on the left in Fig. 27.5), indicating weak chemisorption. Upon increasing the d-band center position, the antibonding states become more significant and the gas–surface interactions become stronger. Therefore, the inertness of gold is due to its low d-band center. It is worth mentioning that the inertness of gold (as compared to other group 11 metals) is also due to the relativistic effect. The relativistic effect scales as approximately Z^2 and therefore becomes very important for heavy elements. The stability of the $6s^2$ configuration of gold due to relativistic contraction makes it much harder for gold than for Ag and Cu to adsorb hydrogen.

The d-Band Center and Adsorption Energy

The d-band center model is one of the most successful models, and the d-band center position has been found to be correlated with the adsorption energy in many different systems. In this section, the relationship between the d-band center position and the adsorption energy on near-surface alloys (NSAs) is reviewed.

NSAs are alloys where a solute metal is present near the surface of a host metal. Such alloys are used in heterogeneous catalysis to tune the adsorption properties. For example, the CO adsorption energy on thin platinum layers over Ru(0001) is lower than that on Pt(111) [27.17]. *Greeley* and *Mavrikakis* [27.18] screened the hydrogen adsorption and dissociation processes on a group of NSAs using DFT calculations. Two different NSA models were considered, namely overlayers and subsurface alloys. Overlayer alloys have one layer of solute metal on the host metal surface, whereas

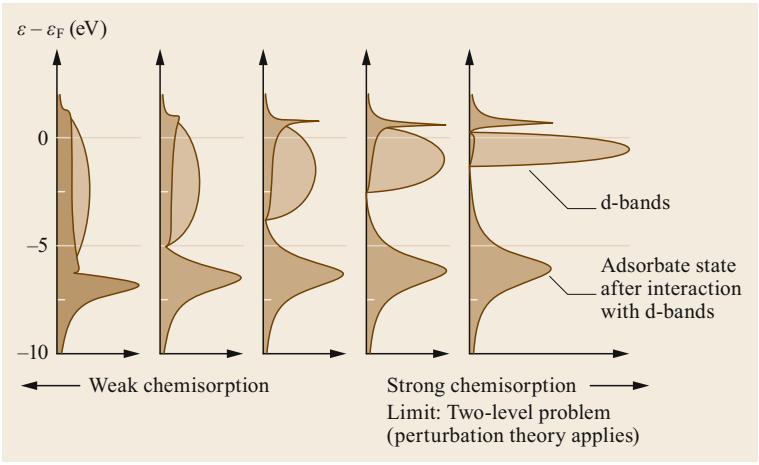

Fig. 27.5 The local DOS projected onto an adsorbate state interacting with the d bands at a surface. (Reprinted from [27.16], with permission from Elsevier)

the surface and bulk atoms in subsurface alloys are host metal atoms and there is one layer of solute metal in the subsurface.

Greeley and Mavrikakis first evaluated the stabilities of the NSAs using two different criteria: the segregation energy and the difference in hydrogen binding energy between the solute and the host metal (more details can be found in [27.18]). The hydrogen atom adsorption energies and hydrogen molecule dissociation barriers on stable NSAs were calculated. The hydrogen atom adsorption energies were found to be lower than those on pure metals. The adsorption energies on the NSAs were generally weaker than those on most pure metal surfaces, and the adsorption strengths on the NSAs were mostly found to be weaker than those on Pt and comparable to those on Cu and Au. As discussed in the last section, Cu and Au do not permit hydrogen adsorption and dissociation at their surfaces; thus, given their similar adsorption strengths to Cu and Au, these NSAs should not permit hydrogen dissociation. Interestingly, the dissociation barriers on all the NSAs were found to be below 0.6 eV, and most were as low as 0.2 eV, making them much lower than the barriers on Cu and Au. In order to understand the trends in adsorption energy on these NSAs, the position of the d-band center was calculated for each NSA. As shown in Fig. 27.6, a linear relation was observed between the binding energy of a hydrogen atom and the position of the d-band center for the alloy. As the d-band center increases in energy, the bond energy of the hydrogen atom increases, suggesting that the d-band center model is sufficient to accurately model the gas–surface interactions on NSAs. Note that three different linear relations

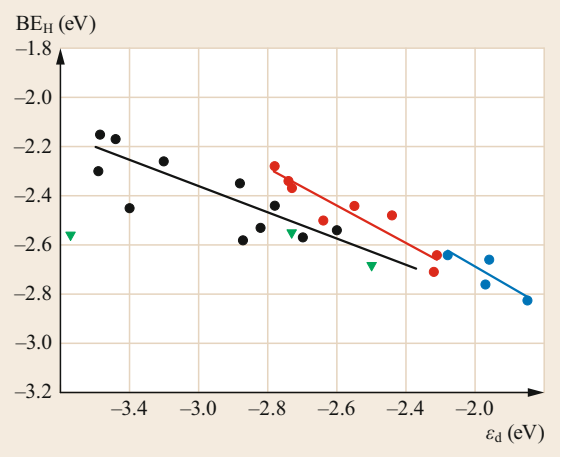

Fig. 27.6 Correlation of the binding energy of atomic hydrogen, BE_H, with the d-band center of the corresponding surface. (From [27.18])

are evident in Fig. 27.6; this can be explained by the different coupling matrix elements of the host metals.

Electronic Structures of Nonmetal Surfaces

In addition to metals, nonmetallic materials—especially sp^2-carbon materials—have attracted a great deal of attention in the field of heterogeneous catalysis. For example, *Su* and coworkers [27.19] found that carbon nanotubes with modified surfaces can efficiently catalyze the dehydrogenation of *n*-butane to butenes with good recyclability. The relationship between electronic structure and adsorption strength is key to understanding the adsorption process in these sp^2-carbon materials and developing new catalysts based on nonmetallic materials.

Hu and coworkers [27.20] investigated the adsorption energies of oxygen molecules and oxygen atoms on graphene and graphene oxide with different oxygen-containing groups at different sites. They considered armchair edge, zigzag edge, and basal plane sites along with five different groups: carboxyl, hydroxyl, ketone, aldehyde, and epoxy groups. The dissociation barrier for an oxygen molecule was also calculated. All of the results are shown in Table 27.3. Based on these results, the adsorption energy of an oxygen atom at particular sites on graphene without any oxygen-containing groups decreases in the order armchair > zigzag > basal plane. However, the introduction of oxygen-containing groups affects the adsorption energy dramatically. In order to understand the variations in adsorption energy that occur upon changing the adsorption site and the oxygen-containing group present, the electron transfer process must be investigated. During the adsorption and dissociation of the oxygen molecule, electrons are transferred from the graphene surface to the antibonding orbital of the oxygen molecule, weakening the O–O bond. The easier it is for electrons to be transferred, the more favorable the adsorption and dissociation of oxygen molecules. On the other hand, the electrons are in a delocalized orbital on the graphene surface. As the electron transfers from the surface to the oxygen molecule, the hybridization of the carbon changes from sp^2 to sp^3, meaning that a new atomic p orbital can bond with the adsorbed oxygen atom. Therefore, the ease with which carbon atoms can switch from sp^2 to sp^3 hybridization is another important indicator of the adsorption energy.

Based on the discussion above, the trend in the adsorption energy of oxygen at different sites on graphene without oxygen-containing groups can be explained as follows. The adsorption of oxygen molecules on the basal plane requires that two carbon atoms change from sp^2 to sp^3 hybridization. These two carbon atoms are involved in four six-atom rings, so the reaction will affect

Table 27.3 Results of DFT calculations of the initial state (IS) and the transition state (TS) and final state (FS) for the dissociation of oxygen on graphene and graphene oxide. The chemisorption energy of O (O_{atom}) is also listed in the table for comparison. All of the energies are given in eV with respect to the gas-phase molecule. All results are adapted from [27.20]

Site	Group	IS	TS	FS	O_{atom}
Armchair	Graphene	0.62	1.19	0.33	−0.15
	Ketone	0.61	0.99	−0.68	−0.26
	Carboxyl	0.48	1.08	0.12	−0.32
	Hydroxyl	0.28	0.88	−0.14	−0.29
	Aldehyde	0.26	0.89	−0.41	−0.46
	Epoxy	0.32	0.72	−0.02	−0.41
Zigzag	Graphene	1.05	1.42	0.03	0.18
	Ketone	0.69	1.29	−0.34	−0.16
	Carboxyl	0.93	1.51	−0.07	0.18
	Hydroxyl	0.83	0.96	−0.68	0.13
	Aldehyde	0.83	1.31	−0.14	0.02
	Epoxy	0.23	0.70	−0.69	−0.48
Basal plane	Graphene	2.05	2.69	1.47	0.90
	Hydroxyl	1.14	1.56	0.73	0.26
	Epoxy	1.37	2.03	0.87	0.42

the delocalization of the electrons in those four rings. Therefore, shifts in hybridization are difficult for carbon atoms in the basal plane. The weakest adsorption energy of an oxygen atom in the basal plane is therefore 0.90 eV. For adsorption at zigzag edges, the oxygen molecule is adsorbed on two carbon atoms, but only two rings are affected in this case due to the structure of the zigzag edge. Thus, the adsorption energy of an oxygen atom at a zigzag edge is much more favorable than it is on the basal plane. The adsorption of an oxygen atom at an armchair edge is also favorable, with an adsorption energy of −0.15 eV. When the oxygen molecule is adsorbed on the armchair edge, only one ring structure is affected (the geometries of these surfaces are explained in [27.20]). In summary, the adsorption at each site is related to the number of six-atom rings that are affected by the adsorption, indicating the presence of a structural effect. This variation in adsorption energy with site is, however, an electronic effect, namely differences in the ease of deconstructing the delocalized orbitals on graphene.

The effect of changing the oxygen-containing group present does not seem to be as clear as the above-described trend in adsorption energy upon changing the adsorption site. Unlike the metal surface, the electrons involved in the adsorption of the oxygen molecule on sp^2-carbon material are the delocalized electrons (the p_z electrons). The projected density of states (PDOS) of the p_z band of graphene with different oxygen-containing groups was obtained using DFT. In Fig. 27.7, PDOSs are shown for zigzag edges without any oxygen-containing group (Fig. 27.7a), with an epoxy group (Fig. 27.7b), and with a carboxyl group (Fig. 27.7c). Due to the existence of different oxygen-containing groups, the electronic structures of these surfaces are quite different. To quantitatively evaluate the difference between the electronic structures of these surfaces, we introduced the concept of the p_z-band center, which is defined in a similar manner to the d-band center. The position of the p_z-band center for each of the three graphene structures is indicated by a dashed line in Fig. 27.7. This corresponds to −3.53 eV for the pure zigzag edge, −3.02 eV for the zigzag edge with an epoxy group, and −3.71 eV for the zigzag with a carboxyl group. Interestingly, the oxygen dissociation barrier on a zigzag edge is highest for the zigzag edge with a carboxyl group (1.51 eV). The p_z-band center has the lowest value for the carboxyl group at all three sites. The p_z-band center of the epoxy group is the highest for all three sites. The presence of this group also leads to the highest oxygen dissociation activity at zigzag edges, as shown in Table 27.3. A linear relation between the p_z-band center energy and the oxygen dissociation barrier is shown in Fig. 27.7, suggesting that the p_z-band center is a good indicator of the activity of an sp^2-carbon material. A similar relation between the adsorption energy of the oxygen molecule on zigzag edges with oxygen-containing groups and the HOMO energy of a benzene molecule with the corresponding groups was found by *Hu* and coworkers [27.20]. Both energies depend on the level of electron delocalization, illustrating the effects of oxygen-containing groups on the delocalized electrons.

The *dashed lines* indicate the positions of p_z-band centers

27.1.3 Predicting the Adsorption Energy

The ability to accurately predict the adsorption energy is crucial when attempting to rationally design materials with specific adsorption properties. In other words, a quantitative description of the relationship between surface structure and adsorption energy can enhance our understanding of adsorption energy trends among various materials and speed up the design of new materials. The relationship between electronic structure and adsorption energy mentioned in the last section permits a deep understanding of the electron transfer involved in gas–surface interactions. It can also be used to predict adsorption energies. However, calculating the projected DOS for surface atoms is a very time-consuming task compared to calculating the adsorption energy, which limits its applicability to the high-throughput screening of materials. Moreover, even though the electronic structure of a material is one of its fundamental structural properties, it is hard to engineer the electronic structure based on our current knowledge of surface science. More direct properties need to be introduced if we are to predict adsorption energies. In this section, two examples of methods that allow adsorption energy prediction are discussed for two different systems, namely nanoparticles and alloys.

Generalized Coordination Numbers

Almost all surfaces have different types of sites (e.g., terrace, edge, and corner sites). Some of these sites are associated with high catalytic activities; for instance, B5 sites are important in ammonia [27.21] and Fischer–Tropsch synthesis [27.22]. Furthermore, the activities of some catalytic systems are correlated with particle size. Thus, the relationships between the adsorption energy and the properties of different sites on metal particles are very important.

Calle-Vallejo et al. [27.23] carried out a systematic investigation of the prediction of adsorption energies of various species on nanoparticles based on DFT cal-

culation results. Palladium nanoparticles were chosen due to their important applications in heterogeneous catalysis and electrochemistry. They calculated the adsorption energies of *O, *O_2, *OH, *OOH, *H_2O, and *H_2O_2 (* denotes the adsorption site) on three different nanoparticles: Pt_{201}, Pt_{79}, and Pt_{38} (more details on the modeling performed can be found in the original work [27.23]). One of the most important differences between types of adsorption sites is the chemical environment, namely the number of neighboring atoms—the coordination number. This parameter is arguably the easiest surface property which can be calculated directly. For example, a Pt atom on the Pt(111) surface is surrounded by six surface atoms and three subsurface atoms, giving a coordination number of nine. *Calle-Vallejo* et al. [27.23] compared the adsorption energies of *OH at different sites on nanoparticles. They are plotted as the coordination numbers of the corresponding adsorption sites in Fig. 27.8. In general, there is a linear relation between the coordination number and the adsorption energy: as the coordination number decreases, the adsorption energy increases because the level of unsaturation at the adsorption site rises. However, the mean absolute error (MAE) in this relation is 0.09 eV and the maximum error is 0.33 eV, which could be improved.

To improve the prediction accuracy for the adsorption energy, *Calle-Vallejo* et al. [27.23] introduced the concept of the *generalized coordination number* ($\overline{\mathrm{CN}}$) of an atom i with n_i nearest neighbors, which they defined as

$$\overline{\mathrm{CN}}(i) = \sum_{j=1}^{n_i} \mathrm{cn}(j) \frac{n_j}{\mathrm{cn}_{\max}} , \qquad (27.5)$$

where cn(j) is the coordination number of the j-th neighboring atom and $n_j/\mathrm{cn}_{\max}$ is the weight of the given atom. This definition incorporates the environments of neighboring atoms (note that examples of the calculation of the generalized coordination number can be found in [27.23]). Using the generalized coordination number instead of the usual coordination number roughly halves the MAE (to 0.056 eV) and the maximum error (to 0.161 eV), as shown in Fig. 27.8. The adsorption energies of all the other species mentioned above were also found to correlate well with the generalized coordination number, which therefore represents an efficient approach to adsorption prediction. Recently, *Calle-Vallejo* et al. [27.24] proposed the use of coordination–activity plots to predict catalytic activity based on the generalized coordination number. This approach led to the discovery of highly active sites of Pt(111), which were subsequently confirmed experimentally.

Bonding Contribution Equation

The generalized coordination number offers an efficient approach to predicting adsorption energies at different sites on nanoparticles. However, at present, only the generalized coordination numbers of pure metal surfaces and nanoparticles are considered. This is a problem because surfaces containing more than one metallic element, such as alloys, play a very important role in heterogeneous catalysis. For example, the $Pt_3Ni(111)$ alloy surface was found to be tenfold more active in the oxygen reduction reaction than the pure Pt(111) surface [27.2]. Given that there are a large number of possible combinations of metals, and that the ratio of the metals can also be varied, there are an enormous number of possible alloys with a wide range of adsorption properties—an ideal situation for catalyst design. Elucidating the relationship between alloy structure and adsorption energy is therefore the key to accelerating

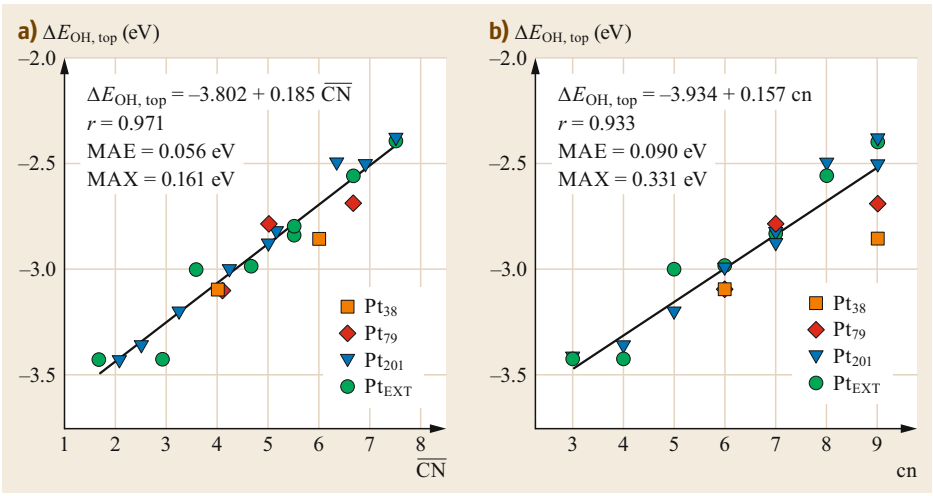

Fig. 27.8a,b Plots of the adsorption energy of *OH atop versus the generalized **(a)** and usual **(b)** coordination numbers of the site to which the adsorbate is bound. (Reprinted by permission from [27.23], © 2014 Wiley)

the design of alloy surfaces with defined adsorption properties.

We proposed an explicit equation with three chemically meaningful terms, which we denoted the *bonding contribution equation* [27.25], to quantitatively account for the surface structures and the adsorption energies of alloy systems. To begin with, we considered the adsorption of oxygen atoms on alloys with one solute metal. If the oxygen is adsorbed at a fcc hollow site, there are four possible types of adsorption site atoms: an atom connected to oxygen (type I), a surface atom near a type I atom (type II), and two types of subsurface atoms (types III and IV; the types of adsorption site atoms are discussed in more detail in [27.25]). We found that the adsorption energy of an oxygen atom on the surface of an alloy with one solute metal can be evaluated using the equation

$$E_{\text{predicted}} = gca \,, \tag{27.6}$$

where g is the generalized parameter, c is the contribution factor, and a is the intrinsic bonding ability of the solute metal. The intrinsic bonding ability is the adsorption energy of oxygen on the close-packed surface of solute metal atoms. The contribution factor is used to distinguish between the different substitution positions. A bond-counting contribution factor (BCCF) was introduced, with values of $7/27$, $-2/9$, $-2/27$, and $-3/27$, respectively, for types I, II, III, and IV in a Pt(111)-p(2×2) unit cell (more details are given in [27.25]). We compared the adsorption energies predicted using this equation with those calculated from DFT and found that the MAE was only 0.07 eV, as shown in Fig. 27.9.

In real alloy systems, the surface may contain multiple solute metals or more substitutions. We therefore extended the bonding contribution equation to consider alloys with n substitutions and obtained

$$E_{\text{ad}} = \sum_{i=1}^{n} gc_i a_i \,. \tag{27.7}$$

This equation can be used to calculate the adsorption energies of multiple solute metals in an alloy. We randomly generated 100 alloy surfaces based on Pt(111)-p(2×2) with two or three substitutions, and a comparison of the energies predicted using this equation with those calculated using DFT is shown in Fig. 27.9b. In general, the MAE for the comparison of predicted and calculated adsorption energies was 0.10 eV. Considering that alloys are relatively complicated systems, this MAE is reasonable and implies that the equation could be used as a prescreening method during catalyst design. To further test the generality of our bonding contribution equation, we also considered alloy surfaces with a different unit cell size, namely Pt(111)-p(3×3) (Fig. 27.9c), and a different adsorbate, namely CO (Fig. 27.9d). The corresponding MEAs were found to be below 0.12 eV, suggesting that the bonding contribution equation accurately predicts the adsorption energy.

27.1.4 Catalyst Design Based on the Adsorption Energy

The adsorption energy plays an important role in catalytic activity, and effective catalysts should facilitate adsorption energies that are in the optimal range for reactants, intermediates, and products. Determining this optimal range is a pivotal step when designing or screening catalytic materials. In this section, we discuss how this interval can be evaluated based on the chemical potential. Design work that uses this interval is then briefly reviewed.

To obtain the optimal adsorption energy interval, *Cheng* and *Hu* [27.26] introduced chemical potentials into the theory of heterogeneous catalysis [27.26]. In their work, using the Langmuir adsorption paradigm, they expressed the chemical potential of surface species i as

$$\begin{aligned}\mu(T,\theta_i) &= \mu_i^0(T) + RT\ln\left(\frac{\theta_i}{\theta_*}\right)\\ &= E^{\text{total}} + \Delta\mu_i(T) + RT\ln\left(\frac{\theta_i}{\theta_*}\right),\end{aligned} \tag{27.8}$$

where θ_i and θ_* are the coverage of species i and the free-site coverage, respectively, while $\mu_i^0(T)$ is the standard chemical potential of i at temperature T, which can be calculated by applying a thermal correction $\Delta\mu_i(T)$ to the total energy E^{total}. The process of a normal reaction involving heterogeneous catalysis starts from the reactant in the gas phase. After a series of adsorption and surface reactions, the key intermediate forms. Then, after surface reactions of the intermediate, the products desorb from the surface. During this catalyzed process, the chemical potentials should decrease step by step from reactants to intermediates to products, i.e.,

$$\mu_{\text{R}} > \mu_{\text{I}} > \mu_{\text{P}} \,. \tag{27.9}$$

Based on (27.9), the chemical potential of the intermediate state is

$$\mu_{\text{I}} = \mu_{\text{I}}^0 + RT\ln\left(\frac{\theta_{\text{I}}}{\theta_*}\right). \tag{27.10}$$

Furthermore, as proposed in [27.26], the coverage of free site θ_* is often on the order of 10^{-2}–10^{-1} ML in

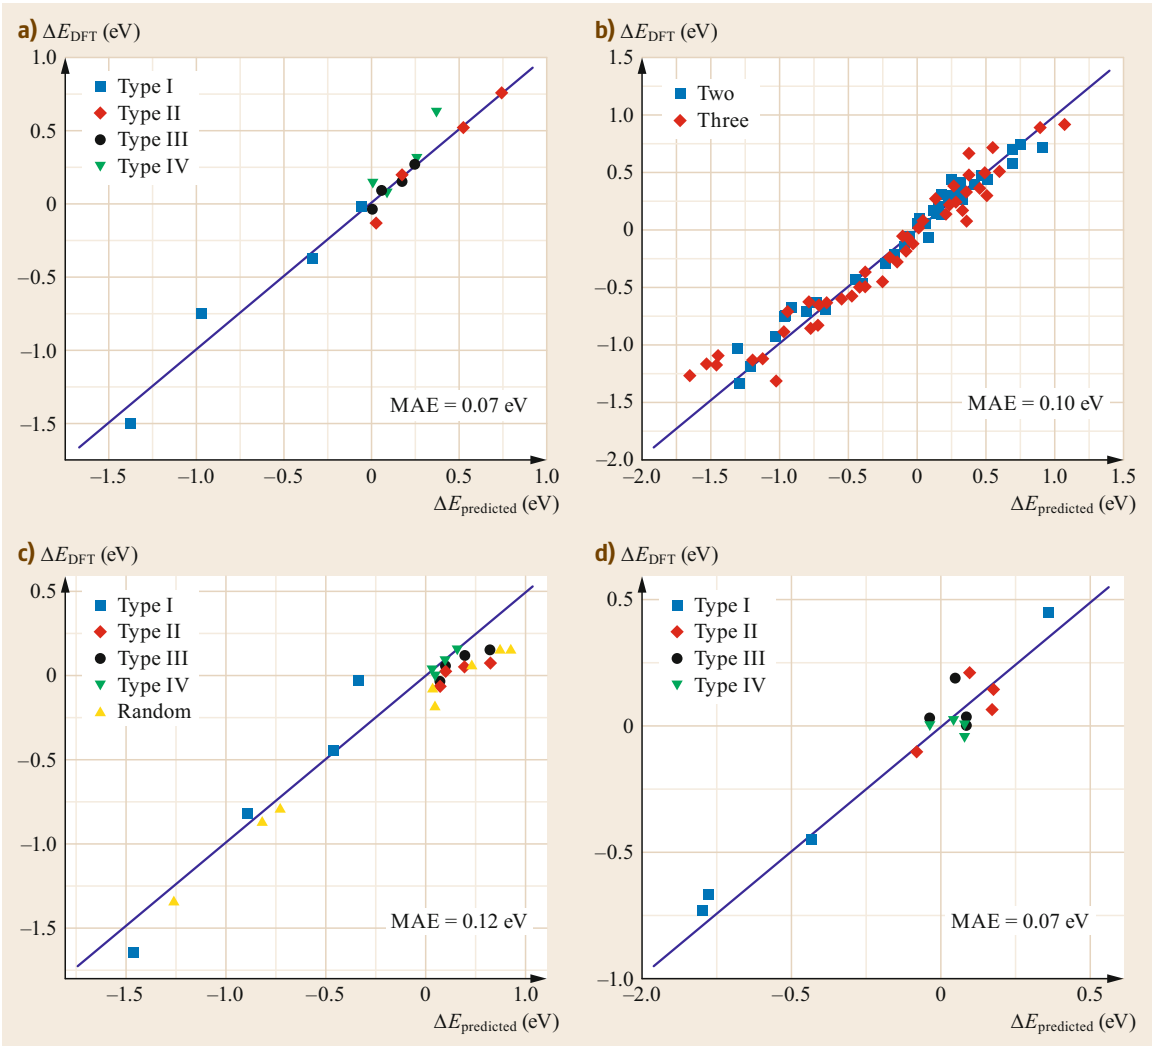

Fig. 27.9a–d Comparison of the adsorption energies predicted using the bonding contribution equation with those calculated using DFT for **(a)** oxygen on alloys of Pt(111) p(2 × 2) with one substituted atom, **(b)** oxygen on randomly generated alloys of Pt(111) p(2 × 2) with two or three substituted atoms, **(c)** oxygen on alloys of Pt(111) p(3 × 3) with one substituted atom, and **(d)** CO on alloys of Pt(111) p(2 × 2) with one substituted atom. (This figure is from our unpublished work [27.25])

the steady state, which leads to a coverage-dependent term $RT\ln(\theta_I/\theta_*)$, denoted ε, which takes values in the small interval 0.1–0.2 eV at 500 K. In other words, the chemical potential of intermediate I for a good catalyst should be

$$\mu_I^0 + \varepsilon > \mu_I > \mu_I^0 - \varepsilon \text{ or } \mu_I \approx \mu_I^0 \,. \qquad (27.11)$$

Combining (27.10) and (27.11) yields a general principle for identifying a good catalyst,

$$\mu_R + \varepsilon > \mu_I^0 > \mu_P - \varepsilon \,, \qquad (27.12a)$$

or approximately

$$\mu_R > \mu_I^0 > \mu_P \,. \qquad (27.12b)$$

Based on this principle, a good catalyst can be identified using the following approach. A chemical potential region (the blue zone in Fig. 27.10) is formed which has the chemical potential of the reactants μ_R and the chemical potential of the products μ_P as upper and lower bounds, respectively. A catalyst with a chemical potential in this zone is most likely to be reactive according to (27.12) (e.g., catalyst C with $\mu_{I,C}^0$ in Fig. 27.10). Due

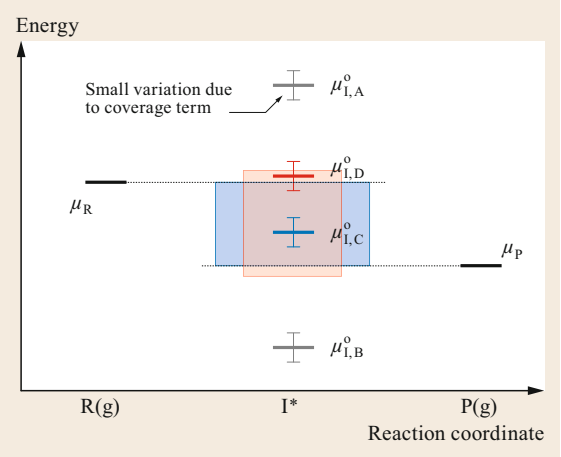

Fig. 27.10 Searching for good catalysts based on their chemical potentials. (Reprinted by permission from [27.26], © 2011 Wiley)

to the coverage-dependent term ε, the region can be extended (red zone in Fig. 27.10). The chemical potential of a good catalyst (such as catalyst D in Fig. 27.10) should occur within this region, whereas catalysts with chemical potentials outside the red zone (e.g., catalysts A and B in Fig. 27.10) are unlikely to be good catalysts.

Based on the design strategy mentioned above, a novel counter electrode (CE) material for use as an catalyst in the triiodide reduction reaction (IRR) employed in dye-sensitized solar cells was discovered. In the IRR, the chemisorption energy of the key intermediate—an iodine atom—on the catalyst should be in the approximate interval 0.33−1.20 eV, as derived from (27.12). The adsorption energies of an iodine atom on many promising CE materials were calculated and checked to see if they were within the adsorption energy window mentioned above. Several known good catalysts for IRR were found to give adsorption energies within the desired range, including Pt, WO_3, WC, NiS, CoS, MoC, and MoN. Furthermore, two surfaces that had not previously been considered in this context were also found to give adsorption energies within the required range, namely the $Fe_2O_3(012)$ and $Fe_2O_3(104)$ surfaces of α-Fe_2O_3. To verify these theoretical predictions, pure-phase Fe_2O_3 was synthesized via a simple modified hydrothermal method [27.27]. Based on its photovoltaic data, the overall energy-conversion efficiency of this α-Fe_2O_3 was found to be 6.96%, which is remarkably similar to that of Pt (7.32%). These results suggest that α-Fe_2O_3 is a suitable catalyst for the reduction of triiodide to iodide.

27.2 Surface Reactions

Surface reactions are another important area of surface science. In heterogeneous catalysis, the adsorbed reactants undergo a series of surface reactions that lead to the final products. Understanding these surface reactions is crucial if we are to optimize the activity and selectivity of heterogeneous catalysts, determine the limitations of current catalysts, and develop better catalytic materials.

The reaction rate of a surface reaction is arguably the most important kinetic property. In the first part of this section, we introduce the use of transition state theory to quantitatively evaluate the reaction rate in terms of the activation energy. We then describe the calculation of the activation energy using first-principles methods and consider the details of the reaction process at the atomic level. The BEP relation, one of the most important relations in heterogeneous catalysis, is also discussed.

The steps involved in a surface reaction (i.e., the reaction mechanism) are a fundamental aspect of heterogeneous catalysis. Three different reaction mechanisms are reviewed, using the most recent results from DFT calculations as examples. We also briefly introduce the concept of active sites and give examples of such sites on a metal and a metal oxide.

Besides these topics, there are many other active areas of research in surface reactions using DFT calculations, such as microkinetic modeling, the effects of surface reconstruction, the volcano curve, and new catalytic materials. In this section, we choose three fundamental areas that have strong connections to surface science and the gas–surface interactions discussed earlier in the chapter.

27.2.1 Reaction Rate and Activation Energy

The reaction rate is one of the most important kinetic properties of a surface reaction. For an elementary reaction in which the reactants and products are located on a surface, the reaction rate is related to the rate constant of the reaction and the surface coverages of the reactant and product species. In his well-known equation, Arrhenius proposed that the rate constant (k) depends on the temperature as

$$k = Ae^{-\frac{E_a}{RT}} , \qquad (27.13)$$

where A is the pre-exponential factor, T and R are the temperature and the universal gas constant, respectively, and E_a is the activation energy. When this equation was proposed, the physical meanings of the pre-exponential factor and the activation energy were unclear. However, transition state theory (TST)—introduced by Eyring, Polanyi, and Evans—provides a solid theoretical foundation for the Arrhenius equation. TST assumes an equilibrium energy distribution among all possible quantum states at all points along the reaction coordinate. The probability of finding a molecule in a particular quantum state is proportional to the Boltzmann distribution $\exp[\Delta E/(k_B T)]$. It is also assumed that a chemical reaction proceeds from one local minimum (corresponding to the reactants) to another (corresponding to the products) via a saddle point (known as the transition state, TS) on the potential energy surface of nuclear coordinate space. If the transition-state molecule is in equilibrium with the reactant, the reaction rate constant is given by

$$k = \frac{k_B T}{h} e^{-\frac{\Delta^{\neq} G^{\circ}}{RT}} , \tag{27.14}$$

where $\Delta^{\neq} G^{\circ}$ is the standard Gibbs free energy difference between the IS and the TS, k_B is Boltzmann's constant, and h is Plank's constant, respectively. Using the equation

$$\Delta^{\neq} G^{\circ} = \Delta^{\neq} H^{\circ} - T\Delta^{\neq} S^{\circ}, \tag{27.15}$$

the rate constant can be written as

$$k = \frac{k_B T}{h} e^{-\frac{\Delta^{\neq} S^{\circ}}{R}} e^{-\frac{\Delta^{\neq} H^{\circ}}{RT}} , \tag{27.16}$$

where $\Delta^{\neq} H^{\circ}$ and $\Delta^{\neq} S^{\circ}$ are the enthalpy and entropy differences between the IS and the TS, respectively. In TST, the reaction rate is directly linked to the activation energy. The activation energy can be calculated as the energy difference between the TS and the IS. We now show how the transition state is located and the activation energy is calculated for CO oxidation on Pt(111) using DFT, and we discuss the relation between the change in enthalpy and the activation energy, which is known as the *BEP relation*.

Transition State for CO Oxidation

CO oxidation is a typical surface reaction that is effectively catalyzed by certain transition metals such as platinum, which has been used to remove CO and other pollutants from exhaust emissions. Understanding the process of CO oxidation and the reaction barrier on platinum is therefore important both scientifically and industrially. *Alavi* et al. [27.28] carried out a pioneering study on the transition state for and activation energy of CO oxidation on Pt(111).

Alavi et al. [27.28] used both the LDA and GGA functionals to investigate the oxidation of CO on Pt(111)-p(2×2). The reaction was assumed to start with the coadsorption of the oxygen atom and CO, with the oxygen atom at the hollow site and CO at the atop site. A new method of searching for the transition state, namely the *constrained minimization scheme*, was introduced to locate the transition state for CO oxidation. The distance between the carbon atom in CO and the adsorbed oxygen atom (O–CO) is fixed in this method, and the structure is optimized by relaxing all remaining orthogonal degrees of freedom. The state with vanishing forces along the reaction coordinate (O–CO) is considered to be the transition state. The pathway for CO oxidation from the IS to the FS via the TS was identified using this method, as shown in Fig. 27.11. In the geometry of the IS (Fig. 27.11a), oxygen is adsorbed at a hollow site and CO is adsorbed at an atop site nearby. As the reaction proceeds, the CO moves from the atop site to another neighboring atop site near the oxygen atom (Fig. 27.11b–e), while the oxygen atom also moves from the hollow site to a lower bridge site (Fig. 27.11e). The forces on both CO and O vanish at the geometry shown in Fig. 27.11e, suggesting that CO and O are at atop and bridge sites, respectively, in the transition state for the oxidation of CO on Pt(111). After the transition state, the CO moves towards O, as shown in Fig. 27.11f–h. Figure 27.11f shows the final state of the CO oxidation process—a chemisorbed CO_2 molecule. This CO_2 molecule is highly bent and asymmetric, and the length of the newly formed CO bond is significantly longer than that of the gas-phase molecule. Regarding the changes in energy, the reaction barrier is 1.01 eV when calculated using LDA and 1.05 eV according to GGA. This work reported the first transition state and low-energy pathway for CO oxidation on Pt(111), and the constrained minimization scheme for locating the transition state is still widely used today [27.29, 30]. This work suggests that DFT calculations are a powerful tool for understanding surface reaction processes and calculating the activation energies of these reactions.

The oxidation of CO on other transition metals such as Ru(001) and Rh(111) was also studied by *Hu* and coworkers [27.31, 32] using the constrained minimization scheme. They found that CO oxidation only proceeds on these metal surfaces when (i) the surface oxygen becomes activated upon shifting from the hollow site to the bridge site (as discussed above) and (ii) the CO approaches the activated surface oxygen atom from the correct direction. They also found that the energy change of the CO movement in the CO oxidation is negligible, while the activation of the oxygen atom upon moving from the hollow site to the bridge site

requires a considerable amount of energy. Thus, the reaction barrier is mainly determined by the scission of the O–metal bond. One may ask why the oxygen atom must move from a hollow site to a bridge site to become activated for catalytic CO oxidation. In order to answer this question, *Zhang* and *Hu* [27.31] investigated CO oxidation on Rh(111) using DFT. They discovered that the 2p orbitals of oxygen are almost completely filled due to strong bonding with three metal atoms at the hollow site. As shown in Fig. 27.12a, when the oxygen atom is activated upon shifting from the hollow to the bridge site, there is no significant change in the LDOS along the p_x axis but the LDOS decreases considerably along the p_y axis, which suggests that the p_y orbital is activated and available to form a new bond. At the same time, CO needs to diffuse to the atop site in the p_y direction, as shown in Fig. 27.12. Therefore, the oxygen atom is inactive at the hollow site because its 2p orbitals are almost fully occupied, so it must be activated by moving to the bridge site before it can react with CO.

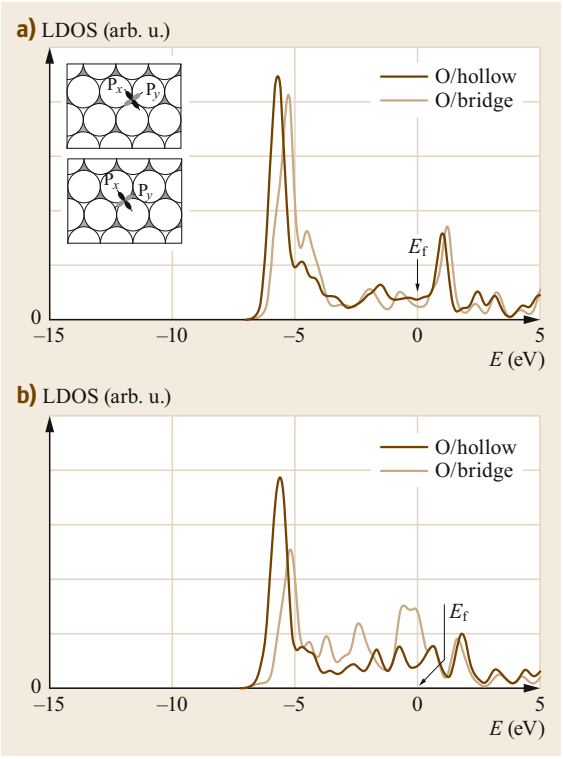

Fig. 27.12a,b Local density of states (LDOS) projected onto a point 0.4 Å away from the center of the oxygen atom along the p_x axis **(a)** or the p_y axis **(b)** for the oxygen at the hollow and bridge sites. The BEP Relation

In previous sections, we discussed the calculation of the adsorption energy and the activation energy—two of the most important energetic results for gas–surface interactions and surface reactions—using DFT. Are these two properties, one of which is from thermodynamics and the other is from kinetics, correlated? According to DFT calculations, they are indeed related. The BEP relation is a widely utilized relation between the adsorption energy and the activation energy that is used to analyze elementary surface reactions. The typical form of the BEP relation for an elementary surface reaction is

$$E_a = \alpha \Delta H + \beta \,, \qquad (27.17)$$

where E_a and ΔH are the activation energy and the enthalpy change for this reaction, respectively. α and β are the two BEP parameters, which vary with the type of surface reaction considered. The BEP relation therefore suggests that the activation energy is linearly correlated with the enthalpy change for surface reactions of the

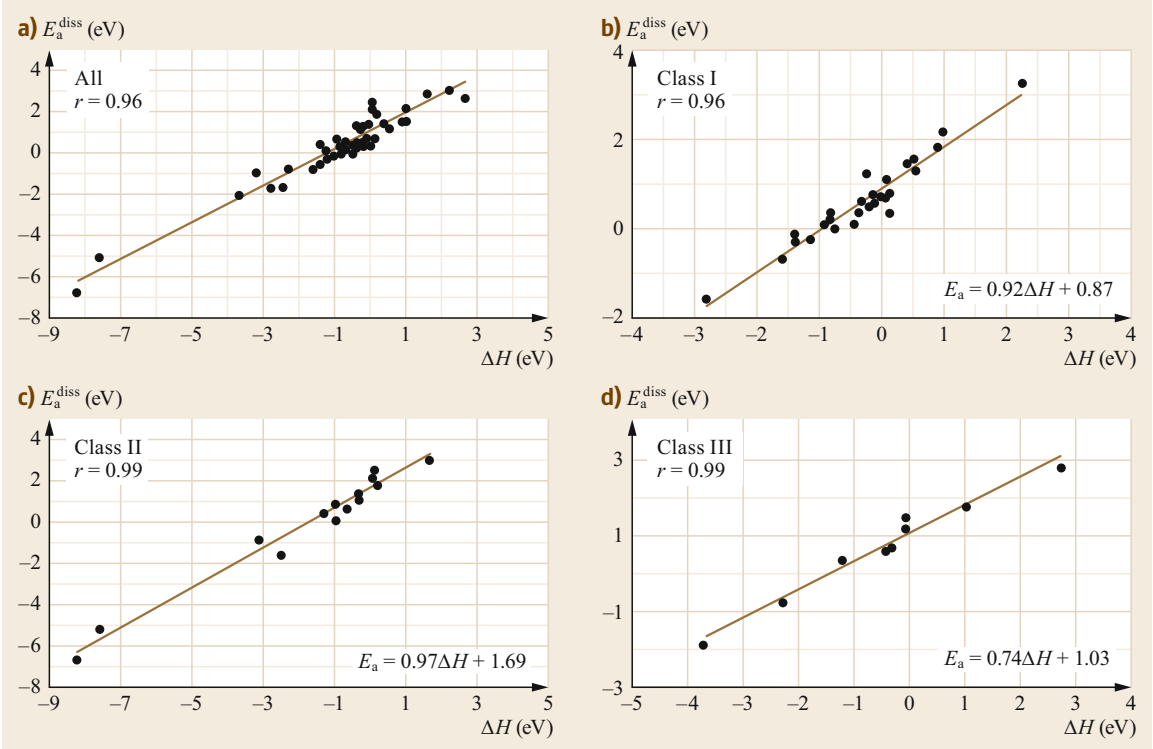

Fig. 27.13a–d Plots of activation energy (E_a^{diss}) against enthalpy change (ΔH) for **(a)** more than 50 elementary reaction steps, **(b)** discrete adsorbate dehydrogenation reactions (class I); **(c)** diatomic dissociation and hydrocarbon cracking reactions (class II), and **(d)** triatomic dissociation reactions (class III). same type. In other words, the more thermodynamically favorable the reaction, the lower the activation energy is likely to be. The BEP relation for surface reactions was proposed by several groups around the year 2000 based on DFT calculations. *Pallassana* and *Neurock* [27.34] demonstrated that both the hydrogenation and dehydrogenation of ethylene follow the BEP relation on bimetallic Pd alloy surfaces. *Logadottir* et al. [27.35] found that the adsorption energy of N_2 and the activation energy for N_2 dissociation are linearly correlated in ammonia synthesis. Two different lines with different α and β values are found for different reaction structures, namely terrace and step sites. *Liu* and *Hu* [27.36] also developed a model that links the activation energy, chemisorption energies, and the bonding energy. Following these pioneering reports, many other examples of BEP relations for different reactions that explain the activities of many surface reactions were reported; these have been reviewed by van *Santen* et al. [27.37].

The parameters α and β in the BEP relation are very important and are the key to predicting activation energies from enthalpy changes. They vary for different types of reactions and reaction sites. In order to explore how these parameters vary for different reactions, *Michaelides* et al. [27.33] investigated the activation energies and enthalpy changes for more than 50 dissociation reactions. As shown in Fig. 27.13a, they found a linear relation between the activation energies and enthalpy changes of all these reactions. Interestingly, the reactions were classified into three different classes, each of which had its own BEP relation. The first class corresponded to dehydrogenation reactions, including O–H and C–H bond cleavage. The values of the slope and the intercept for the BEP relation in this case were found to be 0.92 and 0.87, respectively (Fig. 27.13b). The α and β values for class II reactions, corresponding to diatomic dissociation and hydrocarbon cracking, were very different from those for class I, as shown in Fig. 27.13c. The third class of reaction corresponded to triatomic activation (Fig. 27.13d), for instance the dissociation of molecules such as CO_2, NO_2, and N_2O. Michaelides et al. suggested that the differences in the BEP parameters of the three classes are related to the activation energies of the reverse association reactions.

27.2.2 Reaction Mechanisms

In the previous section, we described the use of DFT to calculate the activation energy and locate the transition state. These results can then be used to determine the detailed steps involved in the surface reaction, i.e., the reaction mechanism. In this section, we discuss the investigation of reaction mechanisms using DFT. Two main reaction mechanisms, namely the Langmuir–Hinshelwood (LH) and Eley–Rideal (ER) mechanisms, are reviewed using the oxidation of CO as an example. The Mars–van Krevelen (MvK) mechanism, which is widely used for metal oxide and some other surfaces, is also introduced.

The Langmuir–Hinshelwood and Eley–Rideal Mechanisms

There are two main widely accepted reaction mechanisms for surface reactions: the LH and ER mechanisms. The processes involved in these two mechanisms are illustrated in Fig. 27.14. In the LH mechanism (Fig. 27.14a), the reaction begins with the adsorption of both reactants. The adsorbed reactant species then diffuse across the surface, eventually coming into contact, reacting, and generating the product species. Finally, the products desorb to the gas phase. On the other hand, only one reactant is initially adsorbed at the surface in the ER mechanism, as shown in Fig. 27.14b. The other reactant (the white ball in Fig. 27.14b) couples with the adsorbed reactant (the brown ball in Fig. 27.14b) from the gas phase. The last step is the desorption of the resulting products. Both mechanisms are found to occur in various surface reactions; interestingly, most catalytic surface reactions prefer the LH mechanism [27.38].

To understand why the LH mechanism is generally preferred in catalytic surface reactions, *Baxter* and *Hu* [27.38] investigated the LH and ER pathways for CO oxidation on Pt(111). Both of these mechanisms start with CO in the gas phase and oxygen atoms (generated by the dissociation of adsorbed oxygen molecules) on the surface. In the LH mechanism, the CO is first adsorbed on the surface. The CO then couples with surface oxygen, forming CO_2. In the ER mechanism, CO from the gas phase couples directly with the surface oxygen. Using the constrained minimization scheme, *Baxter* and *Hu* located the transition states of both reactions [27.38]. Surprisingly, the activation energies of the ER and LH mechanisms were calculated to be 0.72 and 1.05 eV, respectively. The same phenomenon was also observed on the Ru(001) surface; in this case, the activation energy for CO oxidation via the ER mechanism was found to be 0.41 eV lower than that for the LH mechanism [27.39]. Furthermore, a linear relation between the total bond strength of the initial reaction state and the reaction barrier was found [27.38]. This linear relation helped to explain why the ER mechanism had a lower activation energy than the LH mechanism: to allow oxygen atoms to couple with gas-phase CO in the ER mechanism, the bonding between the oxygen atoms and surface metal atoms needs to be relatively weak. In the LH mechanism, the surface CO and oxygen must be activated before they can react, which requires more energy than the ER mechanism. Therefore, the barrier to the ER mechanism is generally lower than that to the LH mechanism.

These findings obviously contrast with the statement that most surface reactions follow the LH mechanism. To answer this paradox, the energy profiles for both mechanisms of CO oxidation on Pt(111) were compared, as shown in Fig. 27.15. The ER mechanism has two conditions: first, the gas-phase CO should be located above the surface oxygen in the correct orientation; second, the CO must possess enough energy to

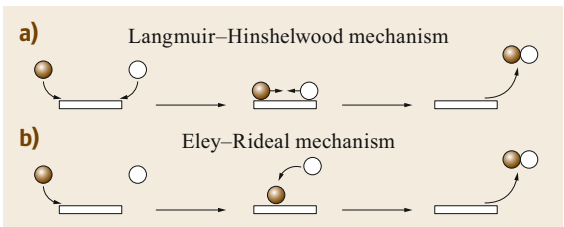

Fig. 27.14a,b Schematics of the (a) Langmuir–Hinshelwood and (b) Eley–Rideal mechanisms. The *brown* and *white balls* represent the two reactants

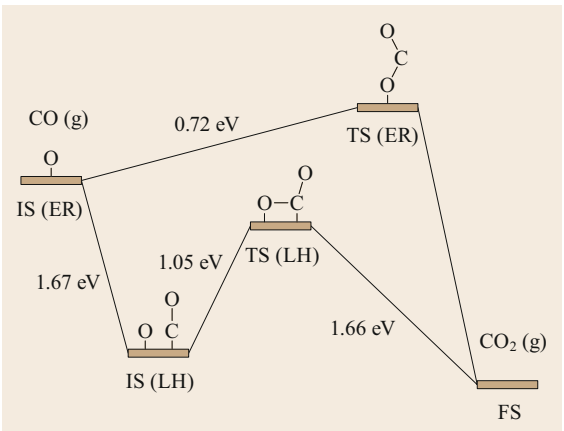

Fig. 27.15 Total energy profiles for CO oxidation on Pt(111) via the LH and ER mechanisms. (Reprinted with permission from [27.33], Copyright (2003) American Chemical Society)

overcome the reaction barrier to the ER mechanism. On the other hand, the adsorption energy of CO on Pt(111) is 1.67 eV, so the adsorption of CO is favorable thermodynamically, and the surface coverage of CO should be high. Thus, surface oxygen is more likely to couple with surface CO than with gas-phase CO. Furthermore, the entropy of gas-phase CO at the reaction temperature can also change the overall picture. When entropy is taken into account, the barrier to the ER mechanism increases due to the increase in the entropy of the gas-phase CO. On the other hand, changing the entropy of the gas-phase CO only affects the adsorption energy of CO. Therefore, taking the effect of temperature into consideration, the barrier to the ER mechanism will increase whereas the barrier to the LH mechanism will be almost unaffected. Thus, even though the total energy barrier to the LH mechanism is higher than that to the ER mechanism, CO prefers to react with oxygen via the LH mechanism.

MvK Mechanism

Another common mechanism besides the LH and ER mechanisms is the MvK mechanism. In MvK, the lattice components of the surface are involved in the reaction. For example, the lattice oxygen on a metal oxide surface may react with an adsorbate, forming an oxygen vacancy. The lattice oxygen is then regenerated via the dissociation of a gas-phase oxygen molecule. In this section, we explore the mechanisms for methane oxidation on nickel-doped cobalt oxide, which are typical examples of the MvK mechanism.

Nickel-doped cobalt oxide ($NiCo_2O_4$) was found to be an excellent catalyst for complete methane oxidation by *Tao* et al. [27.30]. This catalyst facilitates the complete oxidation of methane at temperatures from 350 to 550 °C. To investigate the reaction mechanism for enhanced methane oxidation on $NiCo_2O_4$, DFT calculations were implemented [27.30]. To begin with, the stabilities of all the facets with low Miller indices were evaluated based on the surface energies. $NiCo_2O_4$(100), $NiCo_2O_4$(110)-A, and $NiCo_2O_4$(110)-B were found to be stable, given their low surface energies. The barriers to the dissociative adsorption of methane on these three surfaces were then calculated to evaluate their activities. The Ni on the $NiCo_2O_4$(110)-B surface was observed to be the most active site for methane activation, with a dissociation barrier of 0.52 eV. Based on all of the above knowledge, the mechanism for methane oxidation on $NiCo_2O_4$(110)-B was investigated. Two favorable reaction pathways were discovered, as shown in Fig. 27.16; both are typical examples of the MvK mechanism as they involve the lattice oxygen.

On the $NiCo_2O_4$(110)-B surface, both the nickel and cobalt atoms are bonded to two lattice oxygen atoms, as shown in Fig. 27.16. The reaction starts with the dissociative adsorption of CH_4, in which CH_3 is adsorbed at a nickel site while the dissociated hydrogen atom is accepted by a nearby lattice oxygen, forming

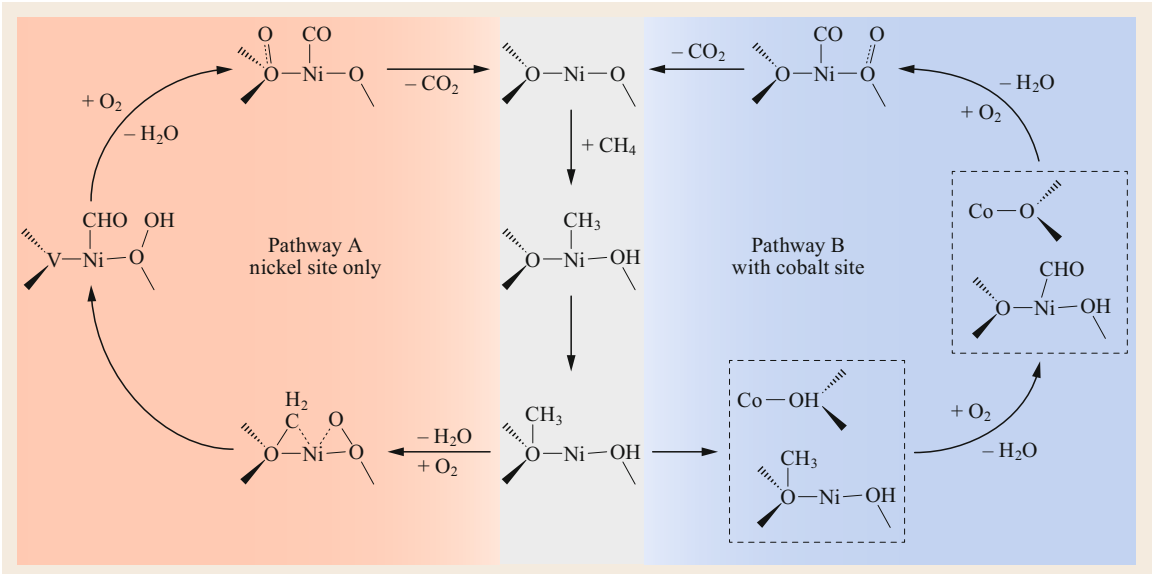

Fig. 27.16 Two reaction pathways for the complete oxidation of methane on a type I $NiCo_2O_4$(110)-B crystal. Pathway A (*red*) involves dehydrogenation at a nickel site only, whereas pathway B (*blue*) also involves Ni but includes dehydrogenation at a nearby Co site. V donates the oxygen vacancy

a OH group. It is then favorable for the CH_3 to couple with another lattice oxygen, yielding CH_3O. Next, there are two possible pathways: pathway A, which only involves the nickel site, or pathway B, which involves both nickel and cobalt sites. These pathways are depicted in red and black, respectively, in Fig. 27.16.

In pathway A, CH_3O is dehydrogenated by the surface OH group. The resulting H_2O desorbs, leaving an oxygen vacancy, and an oxygen molecule is adsorbed at this vacancy (lower left in Fig. 27.16). The formation of an oxygen vacancy and the regeneration of lattice oxygen are central processes in the MvK mechanism. As shown in Fig. 27.16, the C–H bond in CH_2O then dissociates with the help of the adsorbed oxygen molecule, which leads to CHO and OOH species (middle left in Fig. 27.16). Further dehydrogenation of CHO is favorable, and the H_2O that is generated desorbs before another oxygen molecule is adsorbed, just as in the step described above. At the end of the reaction cycle, the CO is oxidized by the oxygen molecule and the resulting CO_2 desorbs to the gas phase.

Pathway B is similar to pathway A except that the dehydrogenations of CH_3O and CH_2O are assisted by the lattice oxygen of a nearby cobalt site. According to DFT calculations, pathway B is more favorable than pathway A, suggesting that the synergistic effect of the nickel and cobalt sites is the reason for the enhanced catalytic activity of $NiCo_2O_4$(110)-B. The lattice oxygen plays very important roles in both pathways, which are two typical examples of the MvK mechanism. The assistance provided by lattice oxygen atoms in the dehydrogenation and oxidation steps and the regeneration of the lattice oxygen are the main reasons for the unique catalytic properties of metal oxide materials.

27.2.3 Active Sites

There are many reaction sites on most catalyst surfaces. These sites possess different chemical environments, oxidation states, and local geometries, and therefore different catalytic behaviors. Normally only a few sites exhibit high catalytic activities for a specific reaction. These sites are known as the *active sites*. Some reactions are catalyzed by only one specific site on a surface (the other sites are completely inert). In heterogeneous catalysis, a good understanding of the active sites is required to appropriately engineer the structure of the catalyst at the atomic level. In this section, we provide examples of active sites with different oxidation states.

Under realistic reaction conditions (especially those required for oxidation), there may be sites with different oxidation states, which tend to have different catalytic activities and associated reaction mechanisms. One well-known example is the so-called pressure gap in catalytic CO oxidation at a ruthenium surface [27.40, 41]. Under ultrahigh vacuum conditions, the ruthenium surface exhibits a low activity for CO oxidation, whereas the surface can efficiently catalyze CO oxidation under oxygen-rich conditions. The high activity of ruthenium under these reaction conditions was discovered to be due to the formation of a ruthenium oxide film that is active in CO oxidation [27.41]. The reason for the difference in activity between the metal and the metal oxide is very complex. Below, we review a recent DFT study of the dehydrogenation of cyclohexanol on copper and copper oxide surfaces that highlights the difference between a metal and a metal oxide in this context.

The catalytic dehydrogenation of cyclohexanol to cyclohexanone is of great importance in the manufacture of nylon, and copper-based catalysts are among the most promising. However, experimental studies were unable to clarify the active site for cyclohexanol dehydrogenation on copper-based catalysts. Therefore, to identify the active site and the mechanism for cyclohexanol dehydrogenation on copper-based catalysts, *Wang* et al. [27.42] carried out a DFT+U study of the dehydrogenation of cyclohexanol on copper and copper oxide. Two sites with different oxidation states—monovalent copper oxide and metallic copper—were considered. Six facets were taken into account: Cu(100), Cu(110), Cu(111), Cu_2O(100), Cu_2O(110), and Cu_2O(111). Based on their calculated surface energies, the Cu(111) and Cu_2O(111) were found to be the most stable metallic and oxide facets, respectively. As shown in Fig. 27.17, the surface structures of Cu(111) and Cu_2O(111) are quite different: there are four reaction sites on close-packed Cu(111), namely the top, bridge, and two hollow sites (fcc and hcp); whereas Cu_2O(111) is hexagonally structured, with two different copper sites—coordinatively saturated (Cu_{CSA}) and unsaturated (Cu_{CUS}) copper. These completely different surface structures are likely to result in different catalytic activities.

Using DFT calculations, the adsorption free energy of the reactant cyclohexanol at the reaction temperature, 260 °C, was found to be 0.74 and −0.45 eV on Cu(111) and Cu_2O(111), respectively. Therefore, reactant adsorption on the metallic copper surface is unfavorable under reaction conditions; adsorption on Cu_2O(111) is preferred. The adsorption sites on Cu(111) and Cu_2O(111) are the top and Cu_{CUS} sites, respectively. Thus, the high adsorption energy on Cu_2O(111) may be due to the activity of the low-coordination copper site. The dehydrogenation of cyclohexanol was then investigated, and the effective barriers on Cu(111) and Cu_2O(111) were calculated to be 1.77 and 1.53 eV, respectively, which suggests that Cu_2O(111) is likely

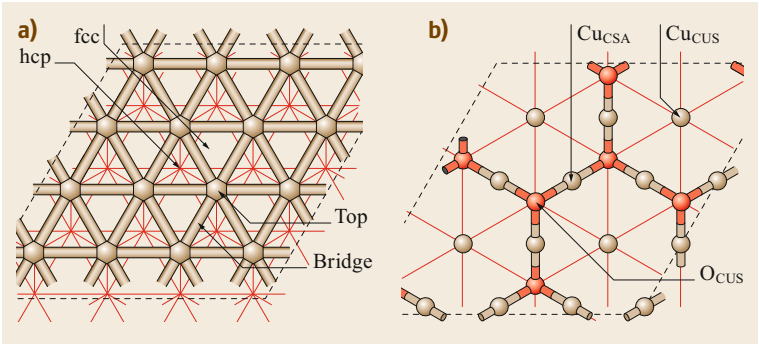

Fig. 27.17a,b The surface structures of and the possible reaction sites on **(a)** Cu(111) and **(b)** Cu_2O(111). The ball and stick notation is used for surface atoms whereas all of the subsurface atoms are depicted using a point and line notation. (Reprinted from [27.42], with permission from Elsevier)

to be the active site in cyclohexanol dehydrogenation. Based on this work, it is apparent that the significant structural differences between sites with different oxidation states are a major reason for the difference in catalytic activity between these sites.

Active site determination is one of the most complicated aspects of modeling surface reactions. Aside from oxide sites, carbide, hydride, sulfide, and/or nitride sites may be active sites in some reactions. Furthermore, there are many facets of metallic surfaces with different structures, such as terrace, step, and kink structures. The active sites for some novel catalysts such as metal-organic frameworks, metal-free catalysts, and single-atom catalysts are largely unknown. First-principles methods may offer efficient approaches for probing the active sites of these materials.

27.3 Perspectives

In this chapter, we have seen that first-principles calculations are powerful tools that allow us to obtain a deeper understanding of the gas–surface interaction and surface reactions. Results for energy parameters such as the adsorption energy and the activation energy can easily be obtained from first-principles calculations, as can structural details such as the geometries of the adsorbed molecules, transition states, and intermediate states in surface reactions. These results lead to a clearer understanding of gas–surface interactions and surface reactions. Aided by first-principles calculations, some new theoretical frameworks have been proposed, including the d-band center theory, the generalized coordination number, the bonding contribution equation, and the BEP relation, all of which were reviewed in this chapter. First-principles calculations were also found to be helpful for understanding the reaction mechanisms and the active sites of surface reactions, as mentioned above. Even though first-principles calculations have become an important tool in surface science, the following challenges must still be addressed:

- The affordable first-principles methods that are currently used to investigate gas–surface interactions and surface reactions are not yet accurate enough to achieve high chemical accuracy, while high-level first-principles methods are generally too expensive. Accurate first-principles methods for reasonably large systems are still to be developed.
- Most of the energy values obtained using first-principles methods are total energies. In real systems, free energies must be accounted for when determining gas–surface interactions and surface reactions. While it is straightforward to compute free energy gas-phase molecules or species on surfaces, it is quite time-consuming for systems containing liquids. Fast methods to calculate the free energies of solid/liquid interfaces are desirable.
- Under realistic reaction conditions, there are many factors that may change the behavior of ideal models in first-principles calculations, such as the effects of water and the adsorbate–adsorbate interaction. These effects must be considered, as doing so should lead to a better understanding of gas–surface interactions and surface reactions in real systems.

Dr. Qingfeng Ge is a professor and Distinguished Scholar at the Department of Chemistry and Biochemistry of Southern Illinois University in Carbondale, as well as Associate Editor of the *Journal of CO_2 Utilization*. Dr. Ge was educated in Tianjin University, worked as a research associate at Copenhagen University and Cambridge University, and was a research scientist at the University of Virginia before joining SIUC in 2003.

28. Nonadiabatic Effects in Gas–Surface Dynamics

Maite Alducin, Ricardo Díez Muiño, J. Iñaki Juaristi

In this chapter, we will provide the theoretical foundations on which the local-density friction approximation (LDFA) is based and examples of its application to gas–surface interaction problems. With this aim, first in Sect. 28.2 we will review the derivation of the stopping power (energy lost per unit path length) for an atom or molecule traveling through a uniform electron gas in the strong coupling limit, i.e., when its velocity is lower than the Fermi velocity of the system. Real systems present electronic density nonlinearities. For this reason in Sect. 28.3, we show how this method for calculating the stopping power has been successful to reproduce and explain experimental energy-loss measurements for ions/atoms traveling through real solids and interacting with metal surfaces. The last part of Sect. 28.3 is devoted to the description of the LDFA method that accounts for the effect of energy losses in the dynamics of thermal and hyperthermal gas particles interacting with metal surfaces. Its implementation both in molecular dynamics performed in precalculated potential energy surfaces (PESs) and in ab-initio molecular dynamics is also discussed. Finally, an overview of the knowledge acquired during last years by the application of the LDFA will be presented in Sect. 28.4. In particular, we will analyze the importance of electron–hole (e–h) pair excitations in different gas–surface elementary processes that involve atoms and molecules of practical interest, such as H, N, H_2, N_2, and H_2O. The analysis will mostly review the results obtained for the dissociative and nondissociative adsorption, for the Eley–Rideal and hot-atom recombinations and for the scattering of these gas species on different metal surfaces. As a general conclusion, it will be shown that e–h pair excitations are typically relevant for long-lasting processes. The last part of this section will review recent applications of the LDFA to model the desorption dynamics of atoms or molecules induced by femtosecond laser pulses. A summary of this chapter is provided in Sect. 28.5.

In regard to metal surfaces, there is ample consensus in accepting that low-energy electrons can already be excited by thermal and hyperthermal atoms and molecules. Still, the remaining open question is how the different gas–surface elementary processes are affected by such low-energy electronic excitations. Here, we review recent progress in the theoretical understanding of nonadiabatic effects in most common gas–surface elementary reactions. The LDFA, which is the focus of this chapter, provides the ideal theoretical framework to

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-46906-1_28

efficiently account for the low-energy electronic excitations in present state-of-the-art gas–surface simulations and, as such, the LDFA has been decisive in achieving this understanding. The LDFA has been applied to study nonadiabatic effects in the scattering of atoms and molecules, in the dissociation of molecules and subsequent relaxation of the nascent hot atoms, and also recently in Eley–Rideal and hot-atom recombinative abstraction processes. All these studies provide us with some hints to establish under what circumstances these excitations become efficient and may, hence, affect a specific process. A general observation is that the nature of these excitations usually requires long-lasting interactions at the surface in order to observe deviations from the adiabatic behavior. As a final and interesting remark, we will also show that the LDFA has been successfully applied to simulate desorption processes induced by intense femtosecond laser pulses, provided that desorption is actually mediated by the laser–created hot-metal electrons.

28.1 Modeling Gas–Surface Interaction

Modeling the interaction dynamics of thermal and hyperthermal molecules and atoms with metal surfaces is relevant to understanding the mechanisms and properties that rule the reactivity of a given gas–surface system. In the end, this understanding will pave the way to the control of surface processes at the atomic and molecular scale. Traditionally, theoretical studies of the elementary processes arising in gas–solid interfaces relied on the Born–Oppenheimer approximation (BOA), which assumes that electrons adapt instantaneously to the nuclear motion. As a consequence, the interaction between the gas particle and the metal can be described using a single adiabatic potential energy surface to perform either classical or quantum molecular dynamics calculations.

Obviously, the adiabatic approximation facilitates the theoretical treatment of these processes. Nevertheless, since the incidence energy of the gas particles is quite low, in the range of tens of meVs up to a few eV, an accurate theoretical description of the dynamical gas–surface interaction usually requires first principles at the level of density functional theory (DFT), as well as inclusion of at least all the degrees of freedom of the gas species involved in the event. Once these conditions are fulfilled, there are various examples in the literature proving the reasonable success of the adiabatic approximation in describing the fundamental properties in most elementary gas–surface processes: dissociation [28.1–7], recombination between incoming gas-atoms and adsorbates [28.8–10], angular distribution and rovibrational states of the scattered gas species [28.11–14], and diffraction peaks [28.1, 15–17], to cite few.

However, since in a metal there is no energy threshold for electronic excitations, even a slow atom/molecule moving close to the surface excites e–h pairs. The chemicurrents measured upon adsorption of thermal atoms and molecules on metal surfaces provide experimental evidence supporting this idea [28.18]. The aim is then to understand how these low-energy excitations revert on the different processes occurring at the gas–solid interface. In this respect, the challenge in present gas–surface dynamics simulations is to provide a reliable description of these electronic excitations while keeping the level of accuracy reached with the full-dimensional adiabatic calculations. Different models have been developed to account for this energy-dissipation channel in the scattering and adsorption of gas species on metals [28.19–25]. Among them, one method that allows us to include this effect in both of the advanced approaches used in multidimensional dynamics simulations—molecular dynamics performed in precalculated potential energy surfaces of DFT quality and ab-initio molecular dynamics—is the local-density friction approximation (LDFA) [28.23]. Briefly, in this method a friction force is introduced in the classical equations of motion. The corresponding friction coefficient is a function of the value of the surface electronic density, calculated with DFT, at the position of the moving atom. The value of the friction coefficient itself is also calculated with DFT for the same atom moving through a uniform electron gas of that density.

28.2 Theory of Electronic Friction in a Free Electron Gas

The uniform electron gas model has been widely used in condensed matter physics to describe metallic systems. Its origins go back to the early work of Drude, Bohr, and Sommerfeld. According to the electron gas model, the valence electrons of a solid move freely through the volume. This approximation can be further

supported with the use of the jellium model, in which the solid ion cores are smoothed into a constant background of positive charge that compensates in average the Coulomb interaction of a constant electronic density n_0.

For decades, the theoretical study of the interaction between moving atomic particles and metallic media was based on the electron gas picture. An ion traveling through an electron gas creates a perturbation in the electronic density. A rearrangement of the medium electronic density is generated due to the Coulomb potential of the projectile. The metal electrons are piled up in a spatial region near the charge in order to screen the long-range Coulomb interaction. In this framework, the stopping power, i.e., the energy lost per unit path length by the particle, is the retarding force that this screening charge exerts on the atom.

Starting in the 1950s, a large body of literature on stopping power based on linear theory emerged. In the linear approximation, the moving projectile is considered a small perturbation to the electronic medium. The response of the latter can, thus, be represented by a linear response function, quite often in the random-phase approximation. Linear response is, however, quantitatively inaccurate in the regime in which the Sommerfeld parameter Z/v is not much lower than 1 ($Z/v \ll 1$; atomic units, a.u., are used throughout unless otherwise stated). In the definition of the Sommerfeld parameter, Z is the charge of the moving projectile, and v is the relative velocity of the collision between the projectile and the medium electrons. The relative velocity in the collision v is roughly the projectile velocity, when this is large enough. For very slow projectiles, however, v can be estimated from the Fermi velocity of the medium electrons. In practice, then, linear theory works well for low charges, fast projectiles, or high-electron density media. Under other circumstances, alternative nonperturbative models must be used.

In the strong perturbation regime, a customary way to introduce the theoretical calculation of the energy loss in an electron gas is scattering theory. The energy lost by a projectile in motion inside a free-electron gas is, thus, obtained from the change in linear momentum arising in the collisions between the moving projectile and the medium electrons. Taking advantage of the difference in masses between the incoming atomic projectile and the electrons, the rest frame of the projectile can be considered as the system of reference in the calculation. The change in projectile velocity and, therefore, the projectile energy loss is in this picture a consequence of the momentum transfer in the electron scattering off the projectile potential.

The practical difficulties in this scheme are, in principle, twofold. The first one is the calculation of the scattering potential and the scattering properties in an accurate way. In the limit of vanishing velocities of the projectile, the scattering potential can be self-consistently calculated using density functional theory (DFT). For increasing velocities, however, the calculation of the self-consistent potential can be more involved. The second difficulty is a correct evaluation of the flux of electrons colliding with the projectile. In the case of vanishing velocities, again, the problem is simplified, and only electrons at the Fermi level contribute. For larger velocities, the level occupancy can be described using the shifted Fermi sphere (SFS) description introduced by *Schönhammer* [28.26].

In 1999, *Salin* et al. showed [28.27] that this scattering approach is equivalent to an adiabatic evolution of the electron gas from its initial homogeneous distribution to a final state in which the projectile is dynamically screened. They proved this equivalence by using the ensemble Kohn–Sham (KS) method within the local-density approximation. The equivalence requires, of course, that the KS potential and the KS wave functions are used to obtain the scattering properties. In [28.27], it was demonstrated that the stopping power must be linearly dependent with its velocity for low values and shows that, in practice, it is roughly linear up to velocities similar to the Fermi velocity of the medium electrons. It nicely also shows the connection between the scattering theory of energy loss and DFT-like approaches based on the calculation of the asymmetric change in the electronic density induced by the projectile.

It is only in recent years that more sophisticated calculations based on time-dependent density functional theory (TDDFT) have become available. TDDFT provides a self-consistent, nonperturbative, time-domain treatment of electron dynamics in many body systems. Therefore, TDDFT calculations of the energy loss are, in principle, valid over the full range of velocities, from the quasistatic limit to the high-velocity regime, keeping the accuracy of nonperturbative methods. *Quijada* et al. used big jellium clusters to mimic the stopping power in metallic solids [28.28]. Beyond the electron-gas picture, TDDFT has been also used to obtain the stopping power of atoms in solids [28.29–33] and to study general electronically nonadiabatic effects of slow atoms and molecules on metal surfaces [28.22, 34].

28.2.1 Scattering Theory

In the following, we will restrict ourselves to the case of an atom or molecule moving inside an infinite homogeneous electron gas with a velocity $\boldsymbol{v}$ much lower than the Fermi velocity of the electrons in the medium v_F

($v \ll v_F$). The mass of the projectile M is much larger than that of the electrons in the medium ($M \gg 1$). We will use the scattering-theory formulation to obtain simplified expressions for the stopping power in terms of some scattering magnitudes. We mentioned before that this approach, even if based on classical binary collisions between the moving projectile and the medium electrons, is actually equivalent to a fully quantum-mechanical DFT description of the energy-loss process. We proceed with the scattering approach, nevertheless, because it provides an intelligible picture of the mechanisms that give rise to the energy exchange.

The density of the electron gas before the entrance of the incident particle is constant n_0. The electron gas parameter r_s can be obtained from the density through $1/n_0 = 4\pi r_s^3/3$ and is related to the Fermi momentum k_F through $k_F^3 = 9\pi/(4r_s^3)$. For zero temperature, all occupied electron states have a momentum q lower than k_F, obeying a Fermi distribution $g_0(\boldsymbol{q})$

$$g_0(\boldsymbol{q}) = \frac{1}{4\pi^3}\Theta(k_F - q)\,, \tag{28.1}$$

where $\Theta(x)$ is the Heaviside step function. The electronic density of the electron gas is recovered by integration

$$n_0 = \int \mathrm{d}^3\boldsymbol{q}\, g_0(\boldsymbol{q})\,. \tag{28.2}$$

The energy lost by the moving projectile arises from the exchange of momentum with the medium electrons due to sequential individual collisions along the trajectory. The net momentum transferred to the projectile by the flux of electrons is, thus, the origin of the retarding force.

It is easier to calculate the momentum transfer in the inertial system of reference of the moving projectile. Under the infinite-mass approximation ($M \gg 1$), the projectile system of reference actually coincides with the center of mass of the system. Let us, respectively, call $\boldsymbol{P} = M\boldsymbol{v}$ and $\boldsymbol{P}' = M\boldsymbol{v}'$ the linear momenta of the projectile before and after the collision. The change in momentum of the projectile will be then $\Delta\boldsymbol{P} = \boldsymbol{P}' - \boldsymbol{P}$. In the same way, we define $\boldsymbol{k}$ and $\boldsymbol{k}'$ as the momenta of a single electron before and after the collision in the center-of-mass reference frame; $\Delta\boldsymbol{k} = \boldsymbol{k}' - \boldsymbol{k}$ is thus the change in momentum. Conservation of momentum and energy requires that

$$\Delta\boldsymbol{P} = -\Delta\boldsymbol{k}\,, \tag{28.3}$$

$$\Delta E = -\Delta\epsilon\,, \tag{28.4}$$

where ΔE is the kinetic energy transferred to the projectile

$$\Delta E = \frac{(P')^2}{2M} - \frac{(P)^2}{2M} \tag{28.5}$$

and $\Delta\epsilon$ is the change in kinetic energy of the electron after the collision

$$\Delta\epsilon = \frac{(k')^2}{2} - \frac{(k)^2}{2}\,. \tag{28.6}$$

Using these equations and substituting $\boldsymbol{P}' = \boldsymbol{P} - \Delta\boldsymbol{k}$ in (28.4), we find that

$$\begin{aligned}\Delta E &= \frac{1}{2M}\left[(\Delta k)^2 - 2\boldsymbol{P}\Delta\boldsymbol{k}\right] \\ &= \frac{\boldsymbol{P}}{M}(\boldsymbol{k} - \boldsymbol{k}') = \boldsymbol{v}(\boldsymbol{k} - \boldsymbol{k}')\,,\end{aligned} \tag{28.7}$$

where terms of order $\approx (1/M)$ have been neglected. This infinite mass approximation implicitly implies that changes in the projectile velocity v during the collision are negligible. Otherwise said, there is no recoil.

So far, we have obtained the energy transferred to the moving projectile due to a well-defined collision with a single electron. The next step is to obtain the total energy transferred to the projectile due to the total flux of electrons encountered by the projectile per unit time. In the system of reference of the projectile (i.e., the center of mass), the homogeneous electron gas moves with a velocity $-\boldsymbol{v}$. The velocities of the incident electrons are correspondingly shifted by a vector $-\boldsymbol{v}$ following a simple Galilean transformation. Therefore, again in the case of zero temperature, the occupancy of the electronic states can be obtained from a shifted Fermi sphere distribution $g(\boldsymbol{k})$

$$g(\boldsymbol{k}) = \frac{1}{4\pi^3}\Theta(k_F - |\boldsymbol{k} + \boldsymbol{v}|)\,. \tag{28.8}$$

The flux of electrons $N(\boldsymbol{k})$ with momentum $\boldsymbol{k}$ per unit area and per unit time is, thus,

$$N(\boldsymbol{k}) = k\, g(\boldsymbol{k})\, \mathrm{d}^3\boldsymbol{k}\,. \tag{28.9}$$

In order to know how many of them emerge with a final momentum $\boldsymbol{k}'$ after the collision, we need to introduce a new function, namely, the differential scattering cross section $\sigma(\boldsymbol{k}, \boldsymbol{k}')$ [28.35]. In scattering theory and for a fixed center of scattering, i.e., a static potential $V(\boldsymbol{r})$, $\sigma(\boldsymbol{k}, \boldsymbol{k}')$ measures the proportionality factor between the number of particles scattered with a final momentum $\boldsymbol{k}'$ and the initial number of incident particles per unit area and per unit time with a momentum $\boldsymbol{k}$. It can be expressed in terms of the complex scattering amplitude $f(\boldsymbol{k}, \boldsymbol{k}')$ through

$$\sigma(\boldsymbol{k}, \boldsymbol{k}') = |f(\boldsymbol{k}, \boldsymbol{k}')|^2\,. \tag{28.10}$$

For a spherically symmetric potential $V(r)$, the angular dependence is much simplified, and the scattering cross

section $\sigma(\boldsymbol{k},\boldsymbol{k}')$ only depends on the relative angle between $\boldsymbol{k}$ and $\boldsymbol{k}'$. Here, we will, in principle, keep the more general nonspherical case and go to the spherical limit later. If there is no energy transferred to additional channels in the global collision, the scattering in the center of mass is elastic, and the moduli are equal $k = k'$. With these ingredients, and knowing the energy transferred in a single collision given by (28.7), it is easy to calculate the total energy transferred per unit time to the projectile by the electron gas $\mathrm{d}E/\mathrm{d}t$ as

$$\frac{\mathrm{d}E}{\mathrm{d}t} = \frac{\boldsymbol{P}}{M}\int \mathrm{d}^3\boldsymbol{k}\,\mathrm{d}\Omega_{k'}\,k\,g(\boldsymbol{k})\,(\boldsymbol{k}-\boldsymbol{k}')\,\sigma(\boldsymbol{k},\boldsymbol{k}')\,. \tag{28.11}$$

Using that $\boldsymbol{P} = M\boldsymbol{v}$, we can obtain the stopping power S, defined as the energy lost by the projectile per unit path length as

$$\begin{aligned} S &= -\frac{1}{v}\frac{\mathrm{d}E}{\mathrm{d}t} \\ &= -\boldsymbol{u}_v\int \mathrm{d}^3\boldsymbol{k}\,\mathrm{d}\Omega_{k'}k^2\,g(\boldsymbol{k})\,(\boldsymbol{u}_{\boldsymbol{k}}-\boldsymbol{u}_{\boldsymbol{k}'})\,\sigma(\boldsymbol{k},\boldsymbol{k}')\,, \end{aligned} \tag{28.12}$$

where we have denoted $\boldsymbol{u}_{\boldsymbol{a}}$ as a unitary vector along the direction defined by vector $\boldsymbol{a}$ and we use a global negative sign to follow the traditional sign convention. The stopping power has dimensions of force and can be viewed as the retarding force acting on the projectile.

In scattering by a spherically symmetric potential, it is customary and useful to define an additional magnitude, the momentum-transport cross section, or transport cross section, for a given initial electron momentum $\boldsymbol{k}$. For the general case of a nonspherical potential, the correspondent magnitude $\boldsymbol{\sigma}^{\mathrm{T}}(\boldsymbol{k})$ keeps a vectorial character and can be defined as

$$\boldsymbol{\sigma}^{\mathrm{T}}(\boldsymbol{k}) = \int \mathrm{d}\Omega_{k'}\,(\boldsymbol{u}_{\boldsymbol{k}}-\boldsymbol{u}_{\boldsymbol{k}'})\,\sigma(\boldsymbol{k},\boldsymbol{k}')\,. \tag{28.13}$$

The combination of (28.12) and (28.13) conveys a simplified expression for the stopping power

$$S = -\boldsymbol{u}_v\int \mathrm{d}^3\boldsymbol{k}\,k^2\,g(\boldsymbol{k})\,\boldsymbol{\sigma}^{\mathrm{T}}(\boldsymbol{k})\,. \tag{28.14}$$

If we call $\sigma_v^{\mathrm{T}}(\boldsymbol{k}) = \boldsymbol{u}_v\boldsymbol{\sigma}^{\mathrm{T}}(\boldsymbol{k})$, the component of the transport cross section $\boldsymbol{\sigma}^{\mathrm{T}}(\boldsymbol{k})$ along the direction defined by the velocity $\boldsymbol{v}$ and we explicitly express that the integration over $\boldsymbol{k}$ is constrained by the shifted Fermi sphere (SFS) distribution $g(\boldsymbol{k})$ defined by (28.8), we can further simplify the equation for the stopping force

$$S = \frac{-1}{4\pi^3}\int_{\mathrm{SFS}} \mathrm{d}^3\boldsymbol{k}\,k^2\,\sigma_v^{\mathrm{T}}(\boldsymbol{k})\,. \tag{28.15}$$

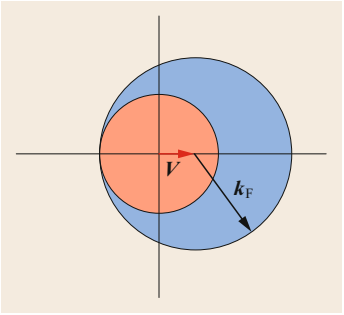

Fig. 28.1 Simplified sketch of the shifted Fermi sphere distribution of electron momenta. The *blue sphere* represents the $\boldsymbol{k}$-distribution of occupied electron states, shifted by a vector $\boldsymbol{v}$ from the origin. The *red sphere* shows the electron states that can be neglected in practice

Figure 28.1 shows a graphical representation of the SFS in $\boldsymbol{k}$-space. Since the scattering is elastic in the system of reference of the center of mass, the Pauli principle forbids all scattering events within the orange sphere. Effective scattering events are only available from occupied states in the blue area into unoccupied electron states, outside the Fermi sphere. In practice, we notice that the imposed SFS restriction (i.e., the Heaviside function $\Theta(k_{\mathrm{F}} - |\boldsymbol{k}+\boldsymbol{v}|)$) only accounts for all electronic states that are initially occupied. Due to the Pauli principle, an additional constraint should be imposed, namely that the final states with momentum $\boldsymbol{k}'$ must be unoccupied before the collision. However, there is no need to enforce this condition in the calculation because of the symmetry properties of the scattering cross section. Time-reversal symmetry implies that

$$\sigma(\boldsymbol{k},\boldsymbol{k}') = \sigma(-\boldsymbol{k}',-\boldsymbol{k})\,. \tag{28.16}$$

In addition, for potentials with parity symmetry [$V(\boldsymbol{r}) = V(-\boldsymbol{r})$], the following condition is fulfilled

$$\sigma(\boldsymbol{k},\boldsymbol{k}') = \sigma(-\boldsymbol{k},-\boldsymbol{k}')\,. \tag{28.17}$$

Therefore, the scattering from $\boldsymbol{k}$ to an occupied final state $\boldsymbol{k}'$, which is quantum mechanically forbidden, will be in the calculation canceled by the contribution from the process $\boldsymbol{k}' \to \boldsymbol{k}$.

Under these symmetry properties, the overall angular integration, when the full solid angles Ω_k and Ω_k' are

scanned, vanishes

$$\int \mathrm{d}\Omega_k \, \mathrm{d}\Omega_{k'} \, (\boldsymbol{u}_{\boldsymbol{k}} - \boldsymbol{u}_{\boldsymbol{k}'}) \, \sigma(\boldsymbol{k}, \boldsymbol{k}') = 0 \, . \tag{28.18}$$

The initial $\boldsymbol{k}$ states that contribute to the integration must, therefore, fulfill the following conditions

$$\begin{aligned} |\boldsymbol{k}| &\geq k_\mathrm{F} - v \\ |\boldsymbol{k} + \boldsymbol{v}| &\leq k_\mathrm{F} \, . \end{aligned} \tag{28.19}$$

In practice, the SFS constraint means that there are some restrictions in the angular integration over the angle Ω_k. If it were not the case, the total integration over Ω_k and Ω'_k in (28.11) would be zero (see (28.18)) and so would be the energy loss $\mathrm{d}E/\mathrm{d}t$. If we call γ_{kv} the angle between the vectors $\boldsymbol{k}$ and $\boldsymbol{v}$, then

$$|\boldsymbol{k} + \boldsymbol{v}| = (k^2 + v^2 + 2kv \cos\gamma_{kv})^{1/2} \, . \tag{28.20}$$

In the limit $v \to 0$,

$$|\boldsymbol{k} + \boldsymbol{v}| =_{v\to 0} k + v \cos\gamma_{kv} \, , \tag{28.21}$$

the allowed values of k are

$$k_\mathrm{F} - v \leq k \leq k_\mathrm{F} - v \cos\gamma_{kv} \, , \tag{28.22}$$

and the stopping force of (28.15) can be approximated as

$$S = \lim_{v\to 0} \left[\frac{-1}{4\pi^3} \int \mathrm{d}\Omega_k \int_{k_\mathrm{F}-v}^{k_\mathrm{F}-v\cos\gamma_{kv}} \mathrm{d}k \, k^4 \sigma_{\boldsymbol{v}}^\mathrm{T}(\boldsymbol{k}) \right] . \tag{28.23}$$

This limit can be easily obtained. If we call

$$F[\boldsymbol{k}] = \int \mathrm{d}k \, k^4 \, \sigma_{\boldsymbol{v}}^\mathrm{T}(\boldsymbol{k}) \, , \tag{28.24}$$

then the stopping force of (28.23) can be obtained through a Taylor expansion

$$\begin{aligned} S &= \frac{-1}{4\pi^3} \int \mathrm{d}\Omega_k \lim_{v\to 0} \left[\int_{k_\mathrm{F}-v}^{k_\mathrm{F}-v\cos\gamma_{kv}} \mathrm{d}k \, k^4 \sigma_{\boldsymbol{v}}^\mathrm{T}(\boldsymbol{k}) \right] \\ &= \frac{-1}{4\pi^3} \int \mathrm{d}\Omega_k \lim_{v\to 0} \left\{ F[\boldsymbol{k}]|_{k=k_\mathrm{F}-v\cos\gamma_{kv}} - F[\boldsymbol{k}]|_{k=k_\mathrm{F}-v} \right\} \\ &= \frac{-1}{4\pi^3} \int \mathrm{d}\Omega_k \left\{ F[\boldsymbol{k}_\mathrm{F}] - v\cos\gamma_{kv} \frac{\partial F[\boldsymbol{k}]}{\partial k}|_{k=k_\mathrm{F}} \right. \\ &\qquad \left. - \left[F[\boldsymbol{k}_\mathrm{F}] - v \frac{\partial F[\boldsymbol{k}]}{\partial k}|_{k=k_\mathrm{F}} \right] \right\} \\ &= \frac{-1}{4\pi^3} \int \mathrm{d}\Omega_k \, (1 - \cos\gamma_{kv}) \, v \, k_\mathrm{F}^4 \, \sigma_{\boldsymbol{v}}^\mathrm{T}(\boldsymbol{k}_\mathrm{F}) \, . \end{aligned} \tag{28.25}$$

Because of (28.18), the first term of the integral in (28.25) vanishes, and we can keep a simplified expression for the stopping force

$$S = \frac{1}{4\pi^3} \, v \int \mathrm{d}\Omega_k \, \cos\gamma_{kv} \, k_\mathrm{F}^4 \, \sigma_{\boldsymbol{v}}^\mathrm{T}(\boldsymbol{k}_\mathrm{F}) \, . \tag{28.26}$$

Notice that this stopping force depends linearly on velocity and, therefore, is a friction force. Quite often, the friction force is written in terms of a friction coefficient η that is simply the proportionality factor between S and v

$$\eta = \frac{S}{v} = \frac{1}{4\pi^3} \int \mathrm{d}\Omega_k \, \cos\gamma_{kv} \, k_\mathrm{F}^4 \, \sigma_{\boldsymbol{v}}^\mathrm{T}(\boldsymbol{k}_\mathrm{F}) \, . \tag{28.27}$$

28.2.2 Spherical Symmetry

Now let us go to the simplest case, in which the scattering potential is spherically symmetric. When $V(\boldsymbol{r}) = V(r)$, the modulus of the transport cross section (28.13) does not depend at all on the incident direction of the electron momentum $\boldsymbol{k}$. The only angular variable that plays a role is the scattering angle $\beta_{kk'}$ between the incident momentum $\boldsymbol{k}$ and the exit momentum $\boldsymbol{k}'$. The angular integral in (28.13) can then be easily performed by considering the $\boldsymbol{k}$ vector as the OZ-axis (Fig. 28.2). In this way, $\beta_{kk'}$ becomes the polar angle $\theta_{k'}$, and the integral over the azimuthal angle $\varphi_{k'}$ keeps as contributions to the final output only the projections of $\boldsymbol{u}_{\boldsymbol{k}'}$ over $\boldsymbol{u}_{\boldsymbol{k}}$. Therefore, the transport cross section in the spherical case can be obtained from (28.13) as

$$\begin{aligned} \boldsymbol{\sigma}_\mathrm{sph}^\mathrm{T}(\boldsymbol{k}) = 2\pi \int \mathrm{d}\,(\cos\beta_{kk'}) \, [(1 - \cos\beta_{kk'}) \\ \times \sigma(k, \cos\beta_{kk'}) \, \boldsymbol{u}_{\boldsymbol{k}}] \, . \end{aligned} \tag{28.28}$$

Formally speaking, this is still a vectorial quantity along the $\boldsymbol{u}_{\boldsymbol{k}}$-direction, which has been considered as the OZ-axis. In practice, however, let us keep just the scalar

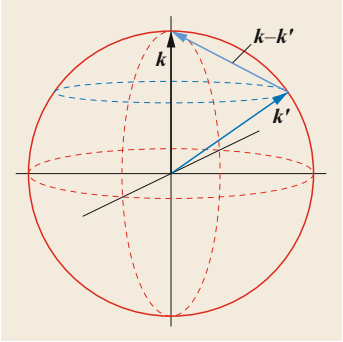

Fig. 28.2 The geometry used in momentum space to perform the integration. The OZ-axis is considered to be along the direction of the vector $\boldsymbol{k}$

value as

$$\sigma^{\mathrm{T}}_{\mathrm{sph}}(k) = 2\pi \int \mathrm{d}\,(\cos\beta_{kk'})\,(1-\cos\beta_{kk'}) \times \sigma(k,\cos\beta_{kk'})\,, \tag{28.29}$$

which is the standard definition of the transport cross section in scattering theory when applied to spherical potentials [28.36].

The calculation of the stopping power in the spherical case is now obtained directly from (28.26). The component of the transport cross section on the $\boldsymbol{v}$-direction is

$$\sigma^{\mathrm{T}}_{\boldsymbol{v}}(k_{\mathrm{F}}) = \sigma^{\mathrm{T}}_{\mathrm{sph}}(k_{\mathrm{F}})\,\cos\gamma_{kv}\,, \tag{28.30}$$

and the stopping force can be obtained as

$$\begin{aligned} S &= \frac{1}{4\pi^3}\,v \int \mathrm{d}\varphi_k \mathrm{d}(\cos\gamma_{kv})\cos^2\gamma_{kv}\,k_{\mathrm{F}}^4\,\sigma^{\mathrm{T}}_{\mathrm{sph}}(k_{\mathrm{F}}) \\ &= \frac{1}{2\pi^2}\,v\,k_{\mathrm{F}}^4\,\sigma^{\mathrm{T}}_{\mathrm{sph}}(k_{\mathrm{F}}) \int_{-1}^{1} \mathrm{d}(\cos\gamma_{kv})\,\cos^2\gamma_{kv} \\ &= \frac{1}{3\pi^2}\,v\,k_{\mathrm{F}}^4\,\sigma^{\mathrm{T}}_{\mathrm{sph}}(k_{\mathrm{F}}) \\ &= n_0\,v\,k_{\mathrm{F}}\,\sigma^{\mathrm{T}}_{\mathrm{sph}}(k_{\mathrm{F}})\,. \end{aligned} \tag{28.31}$$

Equation (28.31) again shows explicitly that, in the limit of zero velocity (quasistatic limit), the stopping power depends linearly on the velocity v. This linear dependence is actually a consequence of the shift in the Fermi sphere of occupied electronic levels. One can show, however, that the linearity in v is kept for increasing values of the velocity, provided that the scattering potential includes terms beyond the monopolar term [28.27].

One of the advantages of (28.31) is that it can be used to simplify the actual calculation of the electronic stopping. For spherical potentials whose range is shorter than the Coulomb potential, the transport cross section $\sigma^{\mathrm{T}}_{\mathrm{sph}}(k)$ can be easily expressed in terms of the phase shifts $\delta_l(k)$ of the continuum wave functions. For each partial wave l, the phase shift measures the difference in phase between the asymptotic forms of the radial wave function with or without the scattering potential [28.35]. The phase shifts $\delta_l(k)$ determine completely all properties of the scattering process at infinity. The transport cross section can be obtained from the phase shifts as [28.36]

$$\sigma^{\mathrm{T}}_{\mathrm{sph}}(k) = \frac{4\pi}{k^2}\sum_{l=0}^{\infty}(l+1)\sin^2\left[\delta_l(k)-\delta_{l+1}(k)\right]\,, \tag{28.32}$$

and the electronic stopping, or friction force, can consequently be written from (28.31) as

$$S = \frac{4\pi}{k_{\mathrm{F}}}\,n_0\,v\sum_{l=0}^{\infty}(l+1)\sin^2\left[\delta_l(k_{\mathrm{F}})-\delta_{l+1}(k_{\mathrm{F}})\right]\,. \tag{28.33}$$

Let us here explicitly write the form of the friction coefficient η that, according to (28.27), is just the proportionality factor between S and v

$$\eta = \frac{4\pi}{k_{\mathrm{F}}}\,n_0\sum_{l=0}^{\infty}(l+1)\sin^2\left[\delta_l(k_{\mathrm{F}})-\delta_{l+1}(k_{\mathrm{F}})\right]\,. \tag{28.34}$$

In practice, the number of phase shifts that is required in the sum over l-components is usually very limited. The calculation of the electronic stopping power in the limit of zero velocities is, therefore, reduced to the obtention of a few partial-wave phase shifts in a spherical scattering potential, which is a relatively simple numerical problem. The accuracy of the final result for S will certainly depend on the accuracy of the scattering potential employed.

In the case of a charged atomic projectile moving inside a free-electron gas, accurate calculations date back to the early 1980s and based the calculation of the scattering potential on density functional theory (DFT) [28.37]. DFT provides, in principle, an exact description of the scattering problem in the static limit, although approximations are required to account for the exchange-correlation term. The electronic density around the projectile is calculated in a self-consistent way, and so it is the effective potential.

Early DFT-based calculations of the electronic stopping power already showed the necessity of using a nonperturbative description of the projectile screening and remarked the quantitative difference with previous calculations based on linear theory [28.37, 38] in the quasistatic limit. Figure 28.3 explicitly shows this difference for the case of hydrogen and helium projectiles in an electron gas. A great success of DFT-based calculations was the prediction of oscillations in the stopping power dependence on the projectile charge, the so-called Z_1-oscillations [28.38]. The oscillating structure is a signature of the formation of closed shells and of the appearance of resonances in the continuum. We will discuss these in further detail in Sects. 28.3.1 and 28.3.2.

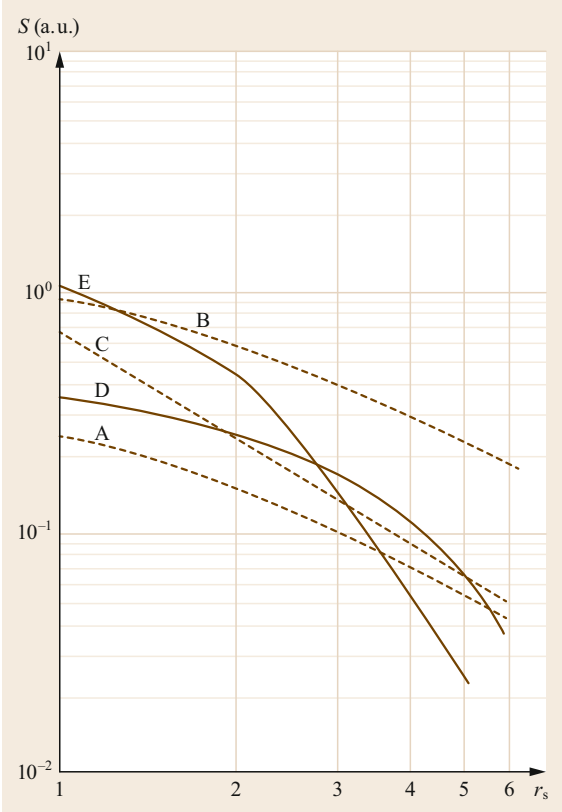

Fig. 28.3 Stopping power (here $S = (\mathrm{d}W/\mathrm{d}R)/v$) of different atomic particles as a function of the electron density parameter r_s. *Curves* A and B show the results of linear response theory for hydrogen and helium, respectively. *Curve* C is a different linear response calculation for singly-ionized helium. *Curves* D and E, respectively, are the DFT results for hydrogen and helium (Reprinted with permission from [28.38]. 28.2.3 Axial Symmetry

Although there is no additional complication from the conceptual point of view, the algebra and numerics of the computation of the electronic stopping power when the scattering potential presents axial symmetry is more cumbersome. This is the case, for instance, in the calculation of the stopping power for diatomic molecules or in the study of the vicinage effect, which is defined as the difference between the energy loss of the molecule and that of the isolated atoms forming the molecule.

A convenient geometry in this case is to consider that the velocity vector $\boldsymbol{v}$ lies on the XZ-plane and that the symmetry axis of the potential is the OZ-axis. Let us denote by α the angle between $\boldsymbol{v}$ and the OZ-axis and again by γ_{kv} the angle between $\boldsymbol{k}$ and $\boldsymbol{v}$.

The vectorial transport cross section $\boldsymbol{\sigma}^{\mathrm{T}}(\boldsymbol{k})$ of (28.13) can then be projected into two components, namely $\sigma_{\parallel}^{\mathrm{T}}(\boldsymbol{k})$ and $\sigma_{\perp}^{\mathrm{T}}(\boldsymbol{k})$. They represent the components parallel and perpendicular to the symmetry axis, respectively. In the case of a moving dimer, for instance, they would correspond to the components parallel and perpendicular to the dimer axis. The stopping power or friction force S is now a function of the angle α, i.e., of the angle between the velocity $\boldsymbol{v}$ and the symmetry axis, and can be written as [28.39]

$$S(\alpha) = \eta_{\parallel}\, v\, \cos^2\alpha + \eta_{\perp}\, v\, \sin^2\alpha\,, \tag{28.35}$$

with

$$\eta_{\parallel} = \frac{k_{\mathrm{F}}^4}{4\pi^3}\int \mathrm{d}\Omega_k\, \sigma_{\parallel}^{\mathrm{T}}(\boldsymbol{k}_{\mathrm{F}})\, \cos\theta_k\,, \tag{28.36}$$

and

$$\eta_{\perp} = \frac{k_{\mathrm{F}}^4}{4\pi^3}\int \mathrm{d}\Omega_k\, \sigma_{\perp}^{\mathrm{T}}(\boldsymbol{k}_{\mathrm{F}})\, \sin\theta_k\, \cos\varphi_k\,; \tag{28.37}$$

$\eta_{\parallel}$ and $\eta_{\perp}$, respectively, are the friction coefficients for an axially symmetric system moving in a direction parallel or perpendicular to its symmetry axis. Due to the axial symmetry of the problem, the parallel component $\eta_{\parallel}$ accounts for the friction coefficient in both the OX and OY-directions. For any other orientation of the symmetry axis, the friction force is a combination of $\eta_{\parallel}$ and $\eta_{\perp}$ through (28.35).

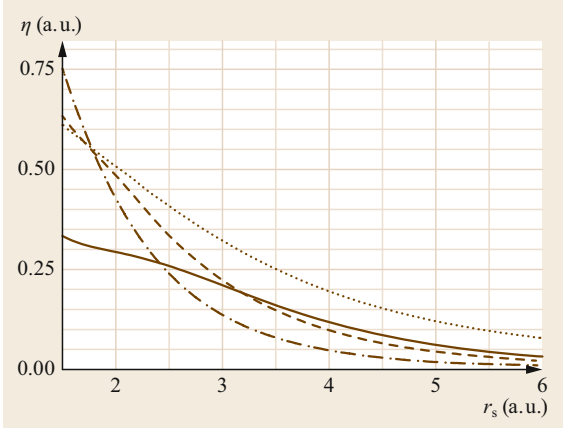

Fig. 28.4 Friction coefficients for H_2 as a function of the electronic density parameter r_s. *Solid line*: H_2 moving parallel to its axis ($\eta_{\parallel}(H_2)$). *Dashed line*: H_2 moving perpendicular to its axis ($\eta_{\perp}(H_2)$). *Dotted line*: twice the friction coefficient of atomic H ($2\eta(H)$). *Dash-dotted line*: friction coefficient of He ($\eta(He)$). The solution of the scattering problem in the axially symmetric case permits to go beyond the independent atom approximation in the calculation of the friction force. The energy lost by a dimer in a metallic medium, for instance, is not equivalent to the energy lost by its two atomic components independently. This effect was quantitatively evaluated in [28.39] for the case of a hydrogen molecule moving in a free-electron gas. Figure 28.4 shows that the friction force of the molecule, either with the axis aligned in a direction perpendicular or parallel to the velocity vector, is of the same order of magnitude as the friction force that the two hydrogen atoms would suffer independently considered. Some differences arise in the final value, however, due to interference effects between the two centers.

28.3 Fundamentals of the Local-Density Friction Approximation

As shown in the previous section, the energy loss in the excitation of electrons by low-velocity atomic particles traveling through systems in which the electronic density is constant is well established. However, in all real systems, the electronic density is not uniform, and it is a function of the position. In particular, this is the case in the surface of a solid, where there exist large density gradients, but also in the bulk of metals in which the electronic density is correlated with the atomic positions and for which the uniform jellium model represents just an approximation.

This section aims to show how the friction coefficients obtained within the jellium model have been used to successfully describe the energy loss of atomic particles in real systems. We will first focus on the energy loss of keV ions traveling with velocities lower than the Fermi velocity of the electrons, both inside the bulk and at the surface of metals. Next, we will describe how this methodology has been extended in order for it to be applied for thermal and hyperthermal gas–surface dynamics simulations within the so-called local-density friction approximation (LDFA) [28.23]. The section will end by presenting the latter developments, which allow incorporating the LDFA into ab-initio molecular dynamics simulations (AIMD), in what is known as ab-initio molecular dynamics with electronic friction (AIMDEF) [28.40–43].

28.3.1 Energy Loss of keV Ions in Metals

The first comparison of the theoretical model of Sect. 28.2 with experiments was performed for H projectiles in [28.44] shortly after introduction of the model in [28.37]. Specifically, the stopping power (i.e., friction force) calculated via (28.33) was compared to the experimental data measured in 20 different metals and semiconductors. The energy of the H projectiles was of the order of the keV, which implies velocities lower than the Fermi velocity of the target. The level of agreement between theory and experiments was considered satisfactory in all cases. At this point, some clarifications on the comparison done in [28.44] are in order. First, although the ions traveling through the solid do necessarily probe regions of different electronic density, these variations were disregarded in this work. In fact, the results for each solid depended on just a single parameter, namely, the average valence band electronic density. Second, (28.33) is, in principle, only strictly valid in the quasistatic limit ($v \to 0$) in virtue of the approximations done in its derivation, as explained above. However, the agreement with the experiment was observed up to velocities of the projectile close to the Fermi velocity of the target, i.e., the proportionality of the stopping power with the projectile velocity was kept up to these velocities. Lastly, no band-gap effect was observed for semiconductors, which showed the same behavior as metals. This last fact is, indeed, related to the relatively high energy of the projectiles used in these experiments. Note that in the quasistatic limit, (28.33), which assumes no threshold for electronic excitations, does not apply to semiconductors.

The calculations were extended to projectiles with atomic number $Z_1 > 2$ in [28.38]. Remarkably, the experimentally observed Z_1 oscillations in the stopping power were naturally obtained within this level of theory. These oscillations reflect the shell structure of the atomic projectile. Briefly, the appearance of scattering resonances close to the Fermi level for some values of Z_1 lead to relatively large values of the stopping power. For increasing values of Z_1, former resonances become bound states, but at the same time, new scattering resonances may appear at certain Z_1. As a result, a nonmonotonic dependence of the stopping power on Z_1 is found. Furthermore, note that the values of Z_1, for which the maxima and minima of the stopping power take place, also depend on the screening, or in other words, on the electronic density of the target. In [28.38], the authors compared available experimental data for $1 \leq Z_1 \leq 20$ ions traveling within bulk carbon and aluminum with velocities in the range $v = 0.25–0.83$ a.u. [28.45–48] with the theoretical predic-

tions for the stopping power. As done in [28.44], each material was modeled in the calculations by the average valence electronic density. As an overall trend, the experimental Z_1 oscillations were qualitatively reproduced by the theory. However, quantitative agreement was only obtained for $Z_1 < 7$, while the stopping power was underestimated by the theory for larger values of Z_1. Likely reasons for the quantitative differences could be the neglect of electronic density variations inside the solid, as well as deviation from straight trajectories not considered in the theoretical calculations. This conclusion can be reached by a comparison with the experimental data obtained for well-channeled ions, which was also performed in [28.44]. In a given crystal channel, the electronic density variations are lower than for random conditions, therefore the neglect of electronic density variations and deviation in the trajectories should be less important in this case. Experimental data obtained for projectiles traveling through the ⟨110⟩ and ⟨111⟩ channels of Si [28.49] were compared with the theoretical stopping power calculated using the average electronic density of each channel. In accordance with the previous argument, it was observed that the quantitative agreement between experiments and theory in this case was much better than for random conditions. Subsequent works in which the experimental stopping power for ions traveling through the ⟨110⟩ channel of gold [28.50] was compared with the nonlinear theory of [28.38], showed a similar good agreement for the Z_1 oscillations [28.51, 52].

28.3.2 Energy Loss of keV Ions Scattered off Metal Surfaces

A clear situation in which the electronic density probed by the projectile along its trajectory is nonuniform is that of an ion/atom scattered off a metal surface. Typically, in these experiments, grazing incidence conditions are used in order to keep the normal energy of the projectiles low. The latter condition is important to guarantee that the projectiles are reflected above the surface without penetration even for incidence energies in the keV range [28.53, 54].

For projectiles velocities larger than the Fermi velocity of the metal electrons, an accurate description of the energy loss at metal surfaces can be obtained within linear response theory [28.55–60] (see also the discussion of the Sommerfeld parameter in Sect. 28.2). Briefly, one calculates the energy loss per unit path length of an ion traveling parallel to the surface at different distances from it in terms of the surface response function. In this way, one obtains the so-called distance-dependent stopping power that combined with a calculation of the projectile trajectory allows one to obtain the energy loss experienced by the reflected particle.

However, at velocities lower than the Fermi velocity of the metal electrons, the projectile represents a strong perturbation, and linear response theory is no longer a valid description. A successful way to treat this problem has been to calculate the friction coefficient using the formalism presented in the previous section. The justification for using a bulk model to calculate the electronic energy loss at the surface of a metal is that most of the energy loss of the scattered particle takes place in the part of its trajectory close to the turning point [28.61]. In this region, the projectile is close to the surface atomic layer, i.e., well embedded in the surface electronic density, and, therefore, a bulk calculation of the friction force must necessarily be a good approximation.

Several works have used this idea in order to understand experimental measurements of the energy loss of keV atomic projectiles grazingly scattered off metal surfaces. The simplest model that has been used is based on the calculation of an interaction length L between the projectile and the surface. This interaction length is defined as the length of the trajectory of the projectile that lies within a given distance from the surface topmost atomic layer. Typically, this distance is of the order of the jellium edge. In order to obtain the energy loss in a given trajectory, the interaction length L is subsequently multiplied by the bulk stopping power S, i.e., $\Delta E = LS$. This approach has been used successfully to explain, for instance, the channeling effects in the energy loss of ions scattered off metal surfaces [28.62, 63]. Another application has been the study of the dependence on the charge state of nitrogen ions scattered off aluminum surfaces [28.64, 65].

A step forward from the previous scheme consists in evaluating distance-dependent stopping powers in terms of the average electronic density at a given distance from the surface. Let us discuss in more detail the combined experimental and theoretical work of [28.66], in which this approach was used. In experiments performed by *Winter* [28.66], the energy loss of ions with atomic numbers $1 \leq Z_1 \leq 20$ scattered off an Al(111) surface was measured as a function of the incidence angle ϕ_{in}. All ions had the same velocity $v = 0.5$ a.u. By performing trajectory calculations using Moliere-type interatomic potentials, these data allowed us to extract the experimental distance-dependent stopping powers $S_{\text{exp}}(z)$. The corresponding theoretical results were obtained as follows. For each distance from the surface z, the lateral average ab-initio electronic density of the aluminum surface $n_0(z)$ was calculated.

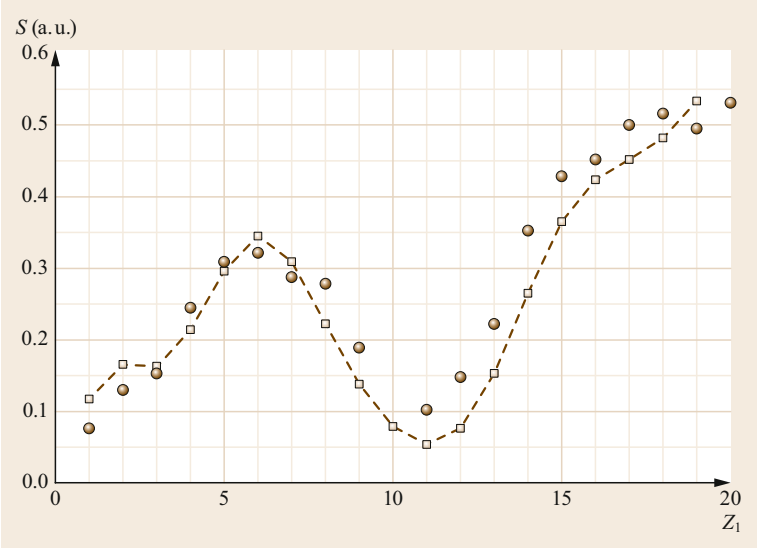

Fig. 28.5 Stopping power of ions with velocity $v = 0.5$ a.u. as a function of their atomic number Z_1 moving parallel to the Al(111) surface at a distance of 0.6 Å from the topmost layer. The data from grazing scattering experiments $S_{exp}(z)$ (*solid circles*) is compared to the theoretical $S_{theo}(z)$ obtained using (28.33) for the lateral average electronic density at 0.6 Å from the surface (*open squares*). *Dashed lines* are used to guide the eye. Data taken from [28.66]

Subsequently, the theoretical distance-dependent stopping powers $S_{theo}(z)$ were obtained for the 20 ions by introducing $n_0(z)$ in (28.33). Figure 28.5 shows the comparison between $S_{exp}(z)$ and $S_{theo}(z)$ for a distance to the topmost layer of 0.6 Å. The agreement is excellent and shows the adequacy of the local density picture. In fact, it is the most stringent test of the theory so far and represents strong support for the use of the local density friction model that we will present in the next section. It should be mentioned that for larger distances from the surface, the agreement was not that excellent, mostly for ions with $Z_1 > 14$. The discrepancies were attributed to the nonuniformity of the density and the increasing importance of the density gradients at large distances from the surface. However, it must be stressed that for ions with $Z_1 < 14$, the order of magnitude of the experimental and theoretical stopping powers were the same. In fact, except for $Z_1 = 2$ and $Z_1 = 3$ at the largest analyzed distances, the ratios between the two quantities were well below a factor of 2.

28.3.3 The Local-Density Friction Approximation (LDFA)

When going from keVs to thermal and hyperthermal energies, the chemical aspects of the interaction of atoms and molecules with metal surfaces in a way becomes richer. Thus, in addition to scattering events, a variety of elementary reactive processes can be identified: adsorption of atoms and molecules, dissociation, recombination between gas-phase species and adsorbates, desorption, etc. Considering that the incidence energy of the gas particles is quite low, in the range of tens of meV up to a few eV, accurate and precise theoretical calculations based on DFT that accounts for the full dimensionality of the problem are required in order to understand the properties that rule all these processes.

As stated in the introduction to this chapter, state-of-the-art simulations of the dynamics of gas–surface elementary process are based on the BOA and consist in solving either classically or quantum mechanically the equations of motion that are ruled by the adiabatic forces acting on those atoms involved in the process. Typically, one defines the initial conditions of the simulations by fixing the initial energy and angle of incidence of the incoming atom/molecule, which are usually the variables that are controlled in molecular beams experiments, and performing a Monte Carlo sampling over the rest of the degrees of freedom. For a given experimental situation, reliable statistics require the calculation of a large number of trajectories that differ in the initial value of the dynamical variables that are not controlled by the experimental setup.

The so-called ab-initio molecular dynamics (AIMD) is a powerful and flexible method to deal with gas–surface dynamics [28.67, 68]. In AIMD, the adiabatic forces between the atoms in the system are calculated at each integration step of the classical dynamics equations using DFT and the Hellmann–Feynman theorem. A clear advantage of AIMD is that it enables the description of the surface-atom movement in a natural way. Therefore, AIMD calculations are instrumental in studying events where the gas–surface interaction times are comparable to those of the surface motion (phonons). As a disadvantage, we note that

AIMD numerical calculations can be computationally expensive. However, their use has become affordable in the last years, even for multidimensional problems requiring refined statistics. Thus, in Sect. 28.3.4, we will describe how the effect of electronic excitations has been incorporated into AIMD.

Nonetheless, in recent years, most state-of-the-art calculations of gas–surface processes performed have relied on the construction of the multidimensional adiabatic PES that can be later used for classical or quantum calculations of the dynamics. Adiabatic PESs are usually built from thousands of DFT-calculated energies that are subsequently interpolated following one of the accurate numerical schemes developed for this purpose [28.69–72]. Compared to AIMD, the great advantage of this alternative approach is that once the PES has been constructed, the additional computational cost of the classical dynamics calculations is negligible. The latter enables us to run a large number of trajectories to achieve a reliable statistical sampling of the process under consideration. The main disadvantage of this approach is the difficulty to obtain high accuracy in the interpolation procedure, which may affect the evaluation of the energy exchange with the surface lattice and temperature effects.

The (energy-conserving) adiabatic approximation applied to either AIMD or molecular dynamics simulations performed on multidimensional frozen-surface PESs have been very successful in describing many gas–surface interaction phenomena. Nevertheless, since in a metal there is no energy threshold to create electronic excitations, any atom/molecule interacting with a metal surface will generate these excitations and, in principle, their effect should be included in the dynamics.

Nonadiabatic effects due to low-energy e–h pair excitations can be effectively introduced in the classical equations of motion through a dissipative force acting on the gas-phase species, as (28.33) suggests, and as also derived within a different theoretical framework in [28.19]. Determining a realistic value of the friction coefficient specific for each system has been the focus of several theoretical studies [28.19, 20, 25, 73, 74]. Among these, the local-density friction approximation (LDFA) [28.23] provides an efficient framework to calculate the position-dependent friction coefficient, while capturing the relevant physical aspects of the low-energy electronic excitations. The physics behind the LDFA is grounded in the practical application of (28.33) to the stopping power of atoms on metal surfaces described in Sect. 28.3.2. Within the LDFA, the position-dependent friction coefficient $\eta(\boldsymbol{r}_i)$ of a gas-phase atom i is simply a function of the (bare) surface-electron density at the position of the atom, $n_{\mathrm{sur}}(\boldsymbol{r}_i)$. In the original LDFA [28.23], $n_{\mathrm{sur}}(\boldsymbol{r}_i)$ was calculated with DFT using the same conditions used to calculate the adiabatic PES—but without including the gas-species. The friction coefficient at each point of the trajectory is, subsequently, approximated by that corresponding to an electron gas with electronic density $n_0 = n_{\mathrm{sur}}(\boldsymbol{r}_i)$. As a further approximation when applied to molecules, correlation effects in η between the atoms conforming the molecule, i.e., the vicinage effect described in Sect. 28.2.3, are neglected. Therefore, in the case of a diatomic molecule and assuming the frozen-surface approximation, the equation of motion for each of the atoms of the molecule takes the following form

$$m_i \frac{\mathrm{d}^2 \boldsymbol{r}_i}{\mathrm{d}t^2} = -\nabla_i V(\boldsymbol{r}_i, \boldsymbol{r}_j) - \eta(\boldsymbol{r}_i) \frac{\mathrm{d}\boldsymbol{r}_i}{\mathrm{d}t} \,, \tag{28.38}$$

where $\boldsymbol{r}_i, \boldsymbol{r}_j$ are the position vectors of atoms i, j of the molecule, and m_i is the mass of atom i. The first term on the right-hand side of (28.38) is the adiabatic force obtained from the six-dimensional (6-D) PES $V(\boldsymbol{r}_i, \boldsymbol{r}_j)$, and the second term on the right-hand side is the dissipative force experienced by atom i. Note that, for simplicity, (28.38) assumes that the electronic system is at 0 K. This is a good approximation for the usual surface temperatures employed in most gas–surface experiments, since the e–h-pair distribution hardly deviates from its ground state at 0 K. In cases of extremely high electronic temperatures ($T_e > 1000$ K), the effect of the excited electrons on the gas atom/molecule can be incorporated by adding a random force, as described below. In Sect. 28.4, we review different studies that use the LDFA formalism to analyze the effect of e–h excitations in the reaction and scattering of hyperthermal atoms and molecules at metal surfaces.

Although without using a DFT-based PES to calculate the adiabatic force, molecular dynamics with electronic friction, in which the friction coefficient is calculated in terms of the local density and using (28.33), have been performed by various groups. It is worth mentioning the work of *Li* and *Wahnström* [28.75], in which the dynamics of hydrogen diffusion in Pd was analyzed using a potential based on the embedded-atom method. Also *Valdés* and coworkers performed molecular dynamics with local electronic friction to study the energy loss of keV ions in different projectile–surface interaction systems using parametrized interatomic potentials and image potential corrections [28.76–80].

Another interesting aspect is that the LDFA method can be readily combined with the generalized Langevin oscillator model (GLO) [28.81, 82]. This way, energy

exchange with both lattice vibrations and electronic excitations can be incorporated into the dynamics, while keeping the accuracy of a multidimensional ab-initio PES for the gas–metal interaction. The joined LDFA+GLO dynamics formulation [28.83] has allowed us to disentangle the relative importance of electronic and phononic excitations in the scattering and adsorption of gas particles at surfaces, as well as in recombinative processes between gas particles and adsorbates, as will be reviewed in Sect. 28.4.

Nonadiabaticity is undoubtedly the driving force behind the ultrafast photochemistry on metals triggered in femtosecond laser experiments [28.84]. The theoretical challenge is to disentangle the mechanisms that rule this complex phenomena and, in this respect, the LDFA can also be a powerful tool in certain cases, which we describe next.

As was shown by *Tully* et al. [28.85, 86], molecular dynamics with electronic friction based on precalculated multidimensional ground-state PESs can also be used to simulate desorption of adsorbates from metal surfaces induced by femtosecond laser pulses working in the so-called DIMET (desorption induced by multiple electronic transitions) regime. In DIMET, the desorption process is surface mediated [28.84]. The laser pulse generates the excitation of the metal electrons, and the energy is subsequently transferred from the electronic system to the adsorbates that can eventually desorb. As a consequence, the simulation of DIMET can be efficiently performed with a two step approach. First, the excitation of the electronic system by the laser pulse is accounted for in terms of a time-dependent electronic temperature T_e that is obtained within the two-temperature model (2TM) [28.87]. In this model, one solves the following coupled equations for the electron T_e and phonon T_{ph} temperatures

$$C_e \frac{\partial T_e}{\partial t} = \frac{\partial}{\partial z}\kappa \frac{\partial T_e}{\partial z} - g\,(T_e - T_{ph}) + S(z,t)\,,$$
$$C_{ph} \frac{\partial T_{ph}}{\partial t} = g(T_e - T_{ph})\,. \qquad (28.39)$$

In these equations, C_e is the electron heat capacity, C_{ph} is the phonon heat capacity, κ is the electron thermal conductivity, g is the electron–phonon coupling constant, and $S(z,t)$ is the absorbed laser power per unit volume. Subsequently, the dynamics of each desorbing adsorbate i is modeled using a Langevin equation that is obtained by extending (28.38) to finite electronic temperatures. The latter consists in including a random fluctuating force $\boldsymbol{R}_i$ that results from the scattering of heated electrons with the adsorbate. The resulting Langevin equation reads

$$m_i \frac{\mathrm{d}^2 \boldsymbol{r}_i}{\mathrm{d}t^2} = -\nabla_i V(\boldsymbol{r}_i, \boldsymbol{r}_j) - \eta(\boldsymbol{r}_i)\frac{\mathrm{d}\boldsymbol{r}_i}{\mathrm{d}t} + \boldsymbol{R}_i[T_e(t), \eta(\boldsymbol{r}_i)]\,. \qquad (28.40)$$

The electronic fluctuating force $\boldsymbol{R}_i$ is connected through the second fluctuation-dissipation theorem to the electronic friction force via the electronic temperature T_e and is modeled by a Gaussian white noise with the following variance

$$\mathrm{Var}[\boldsymbol{R}_i(T_e, \eta)] = \frac{2k_B T_e(t)\eta(\boldsymbol{r}_i)}{\Delta t}\,, \qquad (28.41)$$

where k_B is the Boltzmann constant, and Δt is the integration time step of the simulation. Combining (28.40) with the GLO model, the effect of the laser-heated phonons on the desorption process can also be modeled. In such a case, the phonon temperature $T_{ph}(t)$, obtained from the 2TM, is taken as the temperature of the corresponding thermal bath. The two-step approach described, combined or not with GLO, has been successful in simulating femtosecond laser-induced desorption experiments in the DIMET regime [28.88–91].

28.3.4 Ab-initio Molecular Dynamics with Electronic Friction (AIMDEF)

Standard AIMD simulations can naturally include the energy transfer between the gas-phase species and the surface lattice by just allowing the surface atoms to move according to the DFT-calculated forces. The temperature of the metal during the simulation can also be controlled using any of the thermostats available in the present ab-initio codes. Still, standard AIMD does not incorporate electronic excitation effects. In this respect, the first realization of an accurate and joint description of the two main energy exchange channels (e–h pairs and phonons) in gas–surface dynamics simulations is the AIMDEF method developed in [28.40] and later improved in [28.41, 42]. Within AIMDEF, the effect of low-energy electronic excitation on the dynamics of the gas species is obtained via an electronic friction force that is also calculated on-the-fly. This is done by incorporating the LDFA scheme in the ab-initio program.

This methodology has been implemented in the VASP package [28.92, 93], and it was first applied to study the relaxation of the nascent hot atoms created upon dissociation of H_2 on Pd(100) [28.40]. In this first AIMDEF implementation, the bare surface-electron density, which determines the LDFA friction coefficients, was approximated by the electron density

of the bare frozen-surface calculated self-consistently with DFT, $n_{\mathrm{sur}}^{\mathrm{FS}}$. In other words, the surface-electron density changes caused by the surface-atom displacements were neglected. This is a reasonable approximation only in those cases where the surface atoms barely move, as was the case in [28.40, 94] due to the large mass mismatch between the hydrogen atoms and the target palladium/platinum atoms. Unfortunately, in most situations, the surface-atom displacements are expected to cause appreciable changes in the surface-electron density n_{sur}. This means that this density needs to be known at any instant t. The latter complicates the use of the LDFA in usual AIMDEF simulations because only the electron density of the whole system, i.e., gas species and surface atoms, is calculated self-consistently at each integration step. This limitation was solved in [28.41–43], where two valid methods were proposed that enable calculating an approximated surface-electron density of the moving surface atoms at almost no additional computational cost.

In the first one, the surface-electron density is calculated at each time step t as the superposition of the ground-state electron densities of the isolated individual surface atoms n_j^{atom}, i.e.,

$$n_{\mathrm{sur}}^{\mathrm{AS}}(\boldsymbol{r}_i, t) = \sum_{j=1}^{N_{\mathrm{sur}}} n_j^{\mathrm{atom}}(\boldsymbol{r}_i, t) \,, \tag{28.42}$$

where the summation index j runs over all surface atoms N_{sur}. This method successfully accounts for the movement of the surface atoms at each time step, but it obviously misses the charge redistribution upon formation of bonds between the surface atoms.

The second method corrects this misbehavior by making use of the Hirshfeld partitioning scheme [28.95] in order to subtract the contribution of the gas-phase atoms from the self-consistent density of the whole system $n^{\mathrm{SCF}}(\boldsymbol{r}_i, t)$. More precisely, the bare surface-electron density is approximated at each t by

$$n_{\mathrm{sur}}^{\mathrm{H}}(\boldsymbol{r}_i, t) = n^{\mathrm{SCF}}(\boldsymbol{r}_i, t)\left[1 - \sum_{n=1}^{N_{\mathrm{A}}} w_n(\boldsymbol{r}_i, t)\right],$$
$$w_n(\boldsymbol{r}_i, t) = \frac{n_n^{\mathrm{atom}}(\boldsymbol{r}_i, t)}{\sum_{m=1}^{N} n_m^{\mathrm{atom}}(\boldsymbol{r}_i, t)}, \tag{28.43}$$

where the indexes m and n run, respectively, over the total number of atoms in the system N and in the gas-phase species/adsorbate N_{A}. In this equation, the Hirshfeld weighting factor $w_n(\boldsymbol{r}_i, t)$ represents the contribution of the n-th atom to the electron density of the whole system at $\boldsymbol{r}_{\mathrm{i}}$. Thus, the factor

$$\left[1 - \sum_{n=1}^{N_{\mathrm{A}}} w_n(\boldsymbol{r}_i, t)\right],$$

defines the weight corresponding to the system without the contribution of the adsorbate. These new methods to calculate the bare surface electronic density when performing AIMDEF simulations [28.41–43] have also already been implemented in VASP. A detailed discussion on the performance of each of them can be found in [28.42]. Note in passing that the Hirshfeld partitioning scheme was used by *Rittmeyer* et al. to calculate the vibrational lifetimes of molecules on metal surfaces [28.96]. The authors propose using it as an attempt to include correlation effects between the atoms forming the molecules in the original LDFA scheme, but noting that its use is only justified for adsorbates on metals and not for the general gas–surface scattering dynamics. The difference with respect to (28.43) is that only the weighting factor of the atom for which the friction coefficient is calculated, i.e., $w_i(\boldsymbol{r}_i, t)$, is subtracted from n^{SCF}.

28.4 The Local-Density Friction Approximation Applied to Elementary Gas–Surface Processes

Even if e–h pair excitations were soon recognized as an efficient energy drain in the interaction of fast atoms with solids and surfaces [28.31, 53, 56, 66, 97–99], their relevance in gas–surface interactions that involve energies up to a few eV can depend strongly on the specific elementary process and the specific system under study. The aim of this section is to provide an overview of the knowledge acquired in recent years in this matter and for which the different *flavors* of the LDFA applied to molecular dynamics simulations have proven to be very useful. We present this analysis for each of the elementary gas–surface processes that are usually treated in the literature.

28.4.1 Scattering of Atoms and Molecules off Metal Surfaces

The advantages of scattering experiments conducted with supersonic molecular beams in characterizing the dynamics of gas–surface interactions are conveniently discussed in the literature [28.102–105]. Combined with other techniques, one can extract valuable infor-

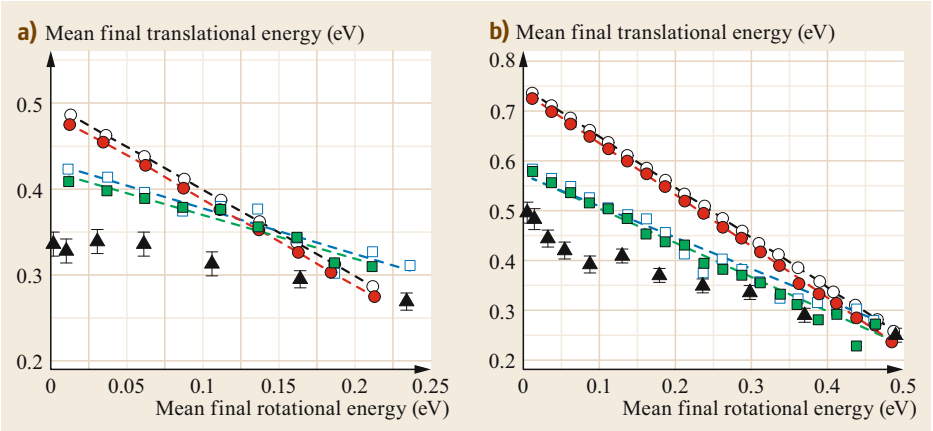

Fig. 28.6a,b Mean final translational energy versus mean final rotational energy of the N_2 molecules reflected from W(110) for normal incidence and detection angles and two incidence energies: **(a)** $E_i = 0.5\,\text{eV}$, **(b)** $E_i = 0.75\,\text{eV}$. The results of the simulations performed in [28.100] with the adiabatic approximation (*open circles*), the LDFA (*red, filled circles*), the GLO (*blue, open squares*), and the LDFA+GLO (*green, filled squares*) calculations are compared to the experimental data of [28.101] (*black, filled triangles*) for $T_s = 1200\,\text{K}$

mation by directly measuring different properties of the scattered beam, as these references show.

A magnitude directly accessible in scattering experiments is the energy-loss distribution of the reflected molecules/atoms. In the case of molecules, inelastic scattering can occur not only as a consequence of the energy loss into the surface by either phonon or electronic excitations, but also because of possible rovibrational (de)excitations facilitated by the interaction with the surface. The rovibrational inelastic contribution can be experimentally identified using sophisticated quantum-state detection techniques [28.106–110]. Still, the contribution of phonons and e–h pairs seems inaccessible at present, and it is at this point that theoretical simulations become a useful counterpart. Next, we provide selected examples where the LDFA contributed to us gaining further insight into the role of e–h pairs and phonon excitations.

The LDFA was used in combination with the GLO model to understand the factors contributing to the rotationally inelastic scattering of a rotationally cold N_2 beam from W(110). Experimentally, the molecules were found to lose around 30% of their incidence energy for low-exit rotational states, while the energy loss was lower for those molecules scattered at high-exit rotational states [28.101]. Classical molecular dynamics simulations performed in [28.100] with different approximations:

(i) using the frozen-surface adiabatic approximation (sometimes denoted BOSS from Born–Oppenheimer with static surface)
(ii) including only e–h pair excitations (LDFA)
(iii) including only energy exchange with the lattice (GLO), and
(iv) including both energy-dissipation channels by combining the LDFA and the GLO model in the equations of motion (LDFA+GLO)

showed that the contribution of e–h-pair excitations is very minor, most of the energy being dissipated into the surface lattice (phonons). This is shown in Fig. 28.6, where the results of the four types of simulations are compared with the experimental data. Figure 28.6 represents the average exit-translational energy as a function of the exit-rotational energy E_{rot} for the scattered molecules for two incidence energies. The steep decrease obtained in the adiabatic calculations (constant total energy), which simply reflects that rotational excitation occurs at expense of translational energy, are at variance with the experimental observations. Inclusion of e–h-pair excitations does not alter these results significantly. Only those simulations that account for phonon excitations (GLO and LDFA+GLO) capture the experimental observation that more energy is lost at low-exit rotational states. The authors argued that those molecules that are rotationally excited at the expense of the translational energy while approaching the surface—as dictated by the PES corrugation—, are more inefficient at transferring energy to the lattice. This idea was already illustrated in [28.112] by using a simplified kinematic model. Focusing on the comparison between the GLO(+LDFA) results and experiments in more detail, the still slightly larger loses observed in experiments at low E_{rot} might be due to recombination of the dissociated molecules that desorb at the exper-

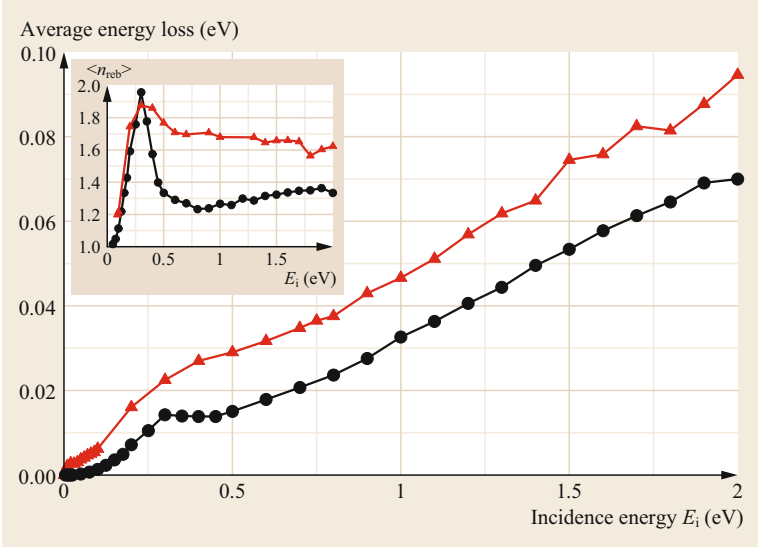

Fig. 28.7 Mean energy loss of the N_2 molecules reflected from W(110) (*black circles*) and W(100) (*red triangles*) as a function of the incidence energy E_i and for normal incidence. *Inset*: corresponding average number of rebounds. Results taken from the LDFA simulations of [28.111]

imental $T_s = 1200\,K$, but preferentially at the lowest internal energies.

Theoretically, more direct evidence for the minor energy losses caused by e–h pair-excitations in this system is provided in Fig. 28.7, which displays the mean energy loss into e–h pair-excitations as a function of the incidence energy of the scattered N_2. The results were obtained from LDFA simulations [28.111]. In all cases, the energy loss is less than 10% of the N_2 incidence energy. Slightly larger energy losses are obtained for N_2 scattered off the W(100) surface. This difference between the two crystal faces was rationalized in terms of the different N_2 dynamics. The molecules stay close to the surface on W(100) longer than on W(110), which contributes to exciting more electrons. The number of rebounds plotted in the inset is an example of the more prominent trapping-like dynamics followed on W(100). The energy-loss distributions taken from [28.111] and plotted in Fig. 28.8 provide a better understanding of the factors ruling the differences between the two surfaces. In both cases, there is a two-peak structure that correlates with the classical turning point Z_{min} of the reflected N_2. In general, the high-energy loss peak is mainly due to those molecules that probe the closest distances to the surface, where the electronic density is high. In contrast, the low-energy peaks correspond to molecules that are reflected at larger distances, i.e., in low electron density regions. This is what we observe in the insets of Fig. 28.8, where the Z_{min} distributions are plotted separately for the trajectories that give rise to the low-energy (shadow bars) and high-energy (open bars) loss peaks. As mentioned above, the number of rebounds is another factor that can affect the energy losses. A close inspection of the trajectories contributing to the low-energy loss peak shows that only around 0.1% of these trajectories show more than one rebound before being reflected. However, in the case of the high-energy loss peak, 62% (24%) of the trajectories with $E_i = 0.75\,eV$ ($E_i = 1.5\,eV$) experience two to four rebounds before being reflected from the W(100) surface. Similarly, percentages of about 30% (6%) are found for the high-energy loss peak in the W(110) case. Comparing both surfaces, the larger percentages found on the W(100) surface contribute to also explaining that the high-energy loss peak is shifted to higher energies as compared with the one appearing in the W(110) energy-loss spectra.

Also minor seems to be the role of e–h pairs in the scattering of O_2 off Ag(111). This system was extensively studied by *Raukema* et al. using a supersonic molecular beam apparatus that permitted incidence energies ranging from 0.4 to 1.8 eV [28.113]. Among other magnitudes, the authors measured the energy loss distribution of the scattered molecules using different incidence conditions (Θ_i, E_i). The distributions exhibit a distinctive behavior that was not observed with N_2 or Ar beams on the same surface. These individual features were particularly apparent at final scattering angles close to the surface normal. The O_2 scattered above the specular angle are characterized by high-energy losses that under large normal incidence energy conditions can exceed those predicted from the *hard-sphere scattering* or Baule model. The latter is a simplified model that describes a two-body collision assuming energy and momentum conservation while neglecting the internal degrees of freedom [28.114]. Molecular dynamics calculations performed with the GLO model and a DFT-based 6-D PES were already able to nicely

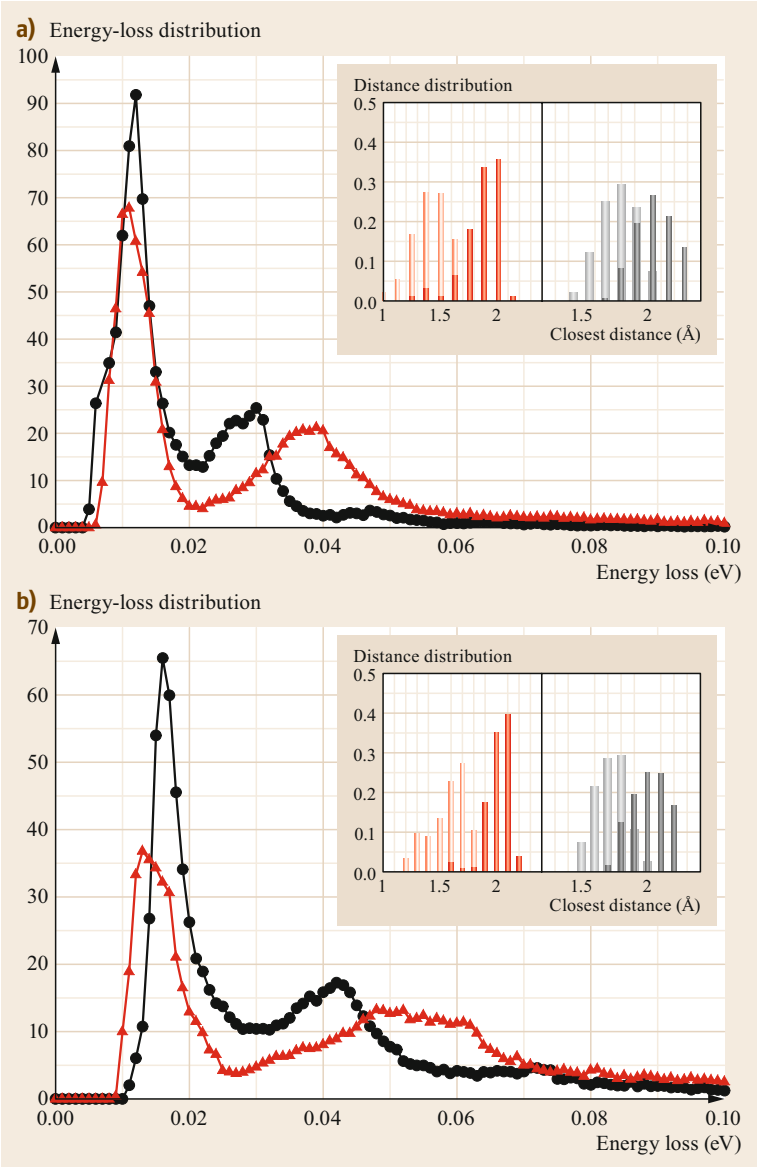

Fig. 28.8a,b Energy-loss distribution of the N_2 molecules reflected from the W(110) (*black circles*) and W(100) (*red triangles*) surfaces when impinging normal to the surface with an initial incidence energy $E_i = 0.75\,\text{eV}$ **(a)** and $E_i = 1.5\,\text{eV}$ **(b)**. The *insets* show for each incidence condition and surface the classical turning point distribution of the molecules contributing to the low-energy (*shadowed bars*) and high-energy (*open bars*) peaks. Results taken from the LDFA simulations of [28.111]

reproduce all these experimental features [28.14]. The experimental energy-loss distributions are compared with the GLO simulations in Fig. 28.9. Specifically, this figure shows the angularly resolved final-to-initial translational energy ratio distributions of O_2 scattered from Ag(111) at different incidence conditions. Values of $\langle E_f\rangle/\langle E_i\rangle < 1$ show that the molecule has lost translational energy after reflection, and the larger energy losses correspond to the smaller energy ratios. In general, the experimental data (Fig. 28.9a) show that the energy loss increases with the incidence energy, the former being higher at $\Theta_i = 40°$. The results of the GLO calculations, which only include energy exchange and dissipation with the surface lattice, are plotted in Fig. 28.9b. The qualitative agreement with the experimental data is remarkable. In spite of its simplicity, the GLO model reproduces the shape and trends of the $\langle E_f\rangle/\langle E_i\rangle$ distributions, as well as the dependence on E_i and Θ_i. A detailed analysis on how the parallel and perpendicular translational energy are effectively exchanged due to PES corrugation explains the peculiar shape of the distributions. Energy exchange with the surface is favored under backscattering conditions, i.e., the higher the perpendicular energy during the collision, the larger the energy loss. Hence, the energy transfer from parallel to perpendicular motion experienced by

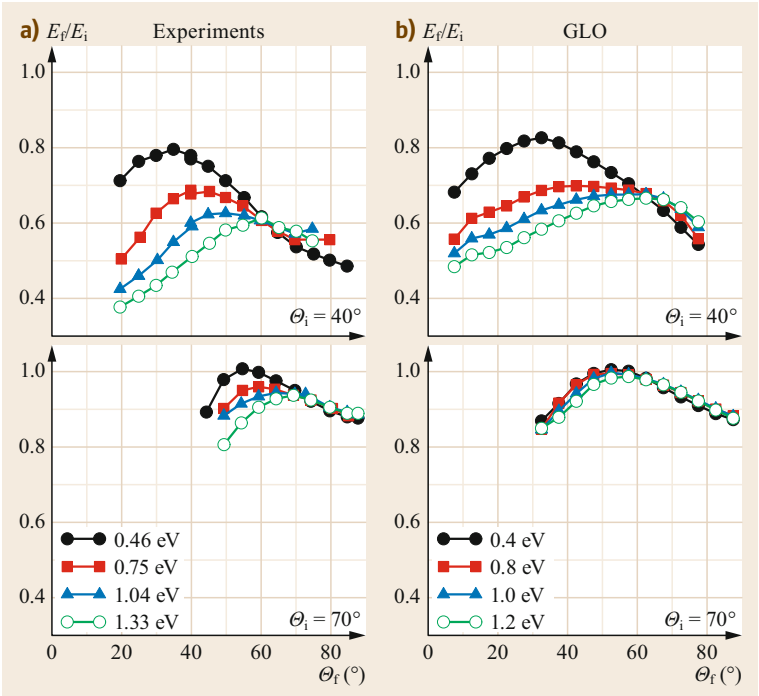

Fig. 28.9a,b Angularly resolved final-to-initial energy distributions of O_2 scattered off Ag(111) under different incidence conditions (Θ_i, E_i). The experimental data by *Raukema* et al. [28.113] **(a)** are compared with the GLO simulations performed in [28.14] **(b)** (Reprinted with permission from [28.14]. Copyright (2014) by the American Physical Society)

the O_2 molecules scattered above the specular angle ($\Theta_f < \Theta_i$) is the reason why they have a larger energy loss than those scattered quite below the specular angle whose energy has been predominantly transferred into the parallel motion. Furthermore, as E_i increases, the molecules get closer to the surface, and the result is a larger energy transfer, as observed in Fig. 28.9.

Meyer and *Reuter* also found that the energy loss of O_2 scattered off Pd(100) is dominated by energy exchange to the lattice rather than to e–h pairs [28.115, 116]. The authors performed calculations of a few trajectories following the method of [28.25] to calculate the energy dissipated into electronic excitations, while phonons excitations were modeled with their own QM/Me method [28.116].

Considering the molecule-to-surface atom mass ratios, the minor effects that e–h pair excitations seem to have on the scattering properties of the aforementioned systems can, to some extent, be masked by the more efficient phonon excitation mechanism. In this respect, the scattering of H_2 on metals can be considered a better alternative to gain further insight into the ingredients that determine the relevance of e–h pairs. Actually, this interaction has been widely investigated for decades as the prototype to test the validity of the Born–Oppenheimer approximation in the thermal/hyperthermal regime [28.1, 4, 5, 117–119]. Among the magnitudes that can be particularly sensitive to the fine details of the molecule–surface interaction—i.e., to its multidimensional nature and to the existence of nonadiabatic contributions—are the state-to-state elastic and inelastic scattering probabilities.

In [28.120], the LDFA was used to analyze possible nonadiabatic effects in the state-to-state scattering of H_2 and D_2 off the Cu(111) surface. The results for the vibrational survival probabilities of $H_2(v_i = 1, J_i = 1)$ and $D_2(v_i = 1, J_i = 2)$ obtained from quasi-classical (QC) calculations, which include the initial zero-point energy of the molecules, are reproduced in Fig. 28.10a,b, respectively. In general, the LDFA survival probabilities are slightly larger than the adiabatic ones. The calculations were performed for two 6-D PESs that differ from each other in the exchange-correlation functional (PW91 and SRP). The effect of e–h pairs is slightly larger for the more reactive PW91-PES because the molecules can approach closer to the surface, where the electron density and, hence, the effective coupling to the valence-band electrons is larger. A common feature observed in all the 6-D calculations is the decrease of the vibrational survival probability as increasing the incidence energy, the decrease being more pronounced for H_2 than for D_2. This kind of behavior has been experimentally observed in the scattering of H_2 off Cu(111) [28.121], as well as in the scattering of H_2 [28.122] and D_2 [28.123] from Cu(100), for which a similar isotope effect to that ob-

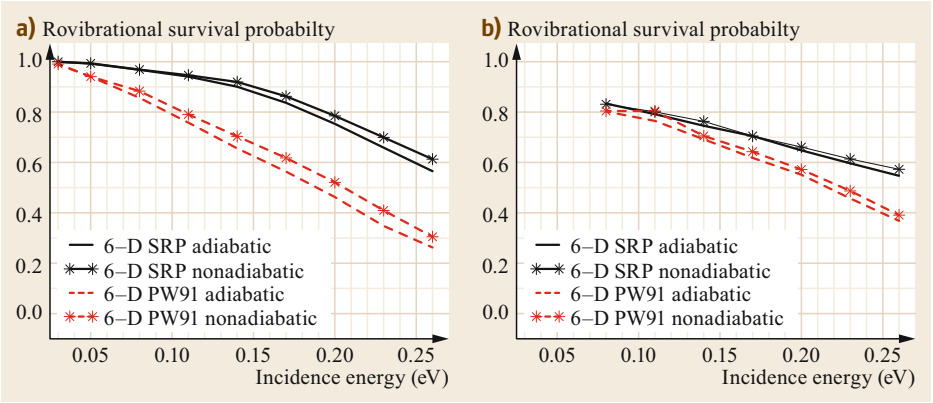

Fig. 28.10a,b Adiabatic (*lines*) and nonadiabatic (*lines with stars*) QC simulations of the rovibrational survival probability as a function of the incidence energy for **(a)** $H_2(\nu_i = 1, J_i = 1)$ and **(b)** $D_2(\nu_i = 1, J_i = 1)$ impinging on Cu(111) at normal incidence. Results obtained in [28.120] from 6-D molecular dynamics calculations performed with the SRP-PES developed by *Diaz* et al. [28.4] (*black lines* and *stars*) and a 6-D PW91-PES (*red lines* and *stars*)

tained theoretically by Muzas et al. with the PW91-PES is also observed. The same authors showed that the rotational excitation/de-excitation probabilities do not change significantly either when accounting for e–h pair excitations (Fig. 28.11). Interestingly enough, the effect is to decrease the excitation probabilities while increasing the survival and de-excitation probabilities. In principle, one would be tempted to assume that at each E_i, the changes caused by e–h pair-excitations in the D_2 isotopologue should be smaller because of its slower velocity. While this is the case for the survival probabilities of Fig. 28.10, in the case of the rotational excitation probabilities of Fig. 28.11, this is not that clear and seems to depend on the exchange correlation functional, which shows the complexity of the 6-D dynamics in a corrugated PES.

The scattering of thermal/hyperthermal atoms off metal surfaces has also motivated various experimental and subsequent theoretical studies in an attempt to gain further insight into the energy transfer mechanisms and, in particular, into the role played by e–h-pair excitations.

Using effusive beams of N atoms scattered from Ag(111) at $T_s = 500\,\mathrm{K}$ and an incidence angle (with respect to the surface normal) $\Theta_i = 60°$, *Ueta* et al. in-

vestigated the energy loss as a function of the in-plane (polar) scattering angle [28.124]. The final-to-initial energy ratio measured increases with the outgoing (polar) angle Θ_f of the scattered N atoms (Θ_f is also referred to the surface normal). Specifically, it yields values between 0.6 and 0.9 for angles $\Theta_f < \Theta_i$, and it steeply increases above 1 for the grazing outgoing angles ($\Theta_f > 50°$), suggesting an unexpectedly large energy transfer from the surface to the atoms. The effusive beam with a nominal average kinetic energy $\langle E_i \rangle = 4.3\,\text{eV}$, however, carries a mixture of N atoms with diverse kinetic energies, as the large full-width-at-half-maximum (FWHM) of $\approx 5.0\,\text{eV}$ manifests. Classical dynamics simulations performed for monoenergetic N beams with a well-defined incidence energy showed that N always loses energy ($\langle E_f \rangle / \langle E_i \rangle < 1$ for all Θ_f), although in agreement with experiments, the energy losses are larger, the larger the outgoing angle Θ_f [28.125]. The experimental measurements were only reproduced when performing simulations that mimic the experimental effusive beam. A careful analysis of the trajectories showed that the apparent energy gain occurs because only the most energetic atoms in the beam ($E_i > 4.3\,\text{eV}$) are scattered at grazing angles. As a result, the average final energy at these angles exceeds the initial $\langle E_i \rangle = 4.3\,\text{eV}$. Furthermore, by comparing the results obtained from simulations that include or do not include e–h-pair excitations and/or phonons, the authors demonstrate that only a small percentage of the energy is lost into e–h pairs [28.125].

Interestingly enough, a completely different conclusion is obtained in the case of H atoms scattered from Au(111) and Cu(111) [28.126–128]. AIMD simulations of the scattering of 5 eV H-atoms predicted experimentally realizable conditions where only about 2% of the incident energy should be lost into metal phonon excitations [28.126, 127]. Higher experimental losses should, hence, be attributed to e–h pairs. As a rough estimation, the authors used the position and velocities from the AIMD trajectories to compute within the LDFA the energy lost into e–h pairs and already predicted that the electronic and not the phononic would be the dominant energy-loss channel in these systems. Similar conclusions were obtained for H/Au(111) from nonadiabatic molecular dynamics simulations based on the LDFA and the effective-medium theory [28.128], which were finally confirmed experimentally in [28.129]. Using incidence and detection angles $\Theta_i = \Theta_f = 45°$ along the $[10\bar{1}]$-direction and incidence energies ranging from 0.99to 3.33 eV, both theory and experiments found a considerable fractional energy loss $(E_i - \langle E_f \rangle)/E_i = 0.33 \pm 0.01$, which the theoretical simulations permit us to identify as being dominated by the electronic excitations.

28.4.2 Adsorption of Atoms and Molecules on Metals

The validity of the BOA in describing the interaction of (thermal/hyperthermal) molecules with metal surfaces has been extensively investigated in the context of dissociative adsorption. There are various examples showing that the experimental adsorption probabilities are rather well described within the adiabatic approximation, provided that an accurate potential-energy surface and the relevant degrees of freedom are included in the dynamics simulations. Unfortunately, the inherent limitations of present DFT to accurately describe on the same footing the large and small gradient density regions important in gas–surface interactions complicates this task in many cases. As a result, the calculated dissociation probabilities can vary strongly with the exchange-correlation functional used in the description [28.4, 130–132], a methodological restriction that cannot be overlooked when the comparison to experiments is used to extract the possible effects of e–h pairs in the dissociation mechanism.

Electronic nonadiabatic effects in the dissociative adsorption have been studied using the LDFA for a few systems that are, however, representative of most relevant situations. Dissociation of H_2 on Cu(110) is an activated process that requires the molecule to have a minimum energy to overcome the potential energy barrier leading to dissociation. The lowest barriers are located close to the surface (below 1 Å), where the electron density is usually large, and for the molecule quite elongated (i.e., for an internuclear distance $r \geq 1.17$ Å). In this type of late-barrier systems, the effect of e–h pairs is to decrease the dissociation probability because the molecule loses part of its total energy before arriving at the barrier. Classical trajectory simulations performed for H_2/Cu(110) showed that this reduction is, however, very minor [28.23]. Similar conclusions have been obtained for the dissociative adsorption of H_2O [28.133], as well as CH_4 and their partially deuterated isotopologues on Ni(111) [28.134]. These systems are particularly interesting because state-resolved gas–surface experiments have revealed a strong mode dependence in promoting dissociation [28.135–137]. Quasiclassical simulations performed on these systems that accounted for e–h-pair excitations show through the LDFA that none of these mode-specificity properties are significantly altered by e–h pairs [28.133, 134].

There are different factors that contribute to the generally minor effects that e–h-pair excitations have in the final dissociative probabilities of those systems characterized by a direct and fast dissociation process. The energy loss into low-energy electronic excitations is proportional to the friction coefficient, the projectile

velocity, and the length traveled. In the region where the density is high, the molecule–surface potential is, in many cases, highly repulsive and causes a substantial reduction of the kinetic energy of the molecules. In addition, a common property of the aforementioned dissociation processes is that all of them involve short time scales. Therefore, even if friction coefficient values were large because of the high-density regions the molecule might be probing, the short time spent by the molecules in those regions together with the reduction in the velocity cause a marginal energy loss that hardly affects the dissociation process itself.

The role of e–h pairs in the dissociation of N_2 on W(100) and W(110) was studied within the LDFA in [28.23, 111]. The process is in both cases quite complex, as it strongly depends on the incidence conditions. At normal incidence and energies $> 0.5\,\mathrm{eV}$ dissociation is dominated by a rather direct process. However, the difference is that the energy barriers to N_2 dissociation are located in the so-called *entrance channel*, i.e., at larger distances from the surface where the molecule still preserves its gas-phase equilibrium bond length because of a still weak interaction with the surface. Under such conditions it is not surprising that the contribution to the dissociation probability of the direct dissociation events is basically unchanged by e–h pairs. The dissociation dynamics change drastically at lower E_i, namely, $< 0.2\,\mathrm{eV}$ for $N_2/W(100)$ and $< 0.5\,\mathrm{eV}$ for $N_2/W(110)$. Under such circumstances, dissociation proceeds in both W surfaces through an indirect mechanism, in which the molecules are first dynamically trapped around the molecular chemisorption wells during a few picoseconds (1−2 ps on W(110) and 5−10 ps on W(100)) before finding the path leading to dissociation. The analysis in [28.111] shows that the effect of e–h pairs is to increase the dissociation probabilities mediated by this indirect mechanism. Interestingly, such an effect is opposite to that observed on the aforementioned examples of direct and late-barrier dissociation events, but can be easily understood once we recognize the different energy landscapes ruling the process in each case. A common feature in $N_2/W(110)$ and $N_2/W(100)$ is that from the bottom of the adsorption well, the energy barriers to desorption are, on average, higher than those to dissociation. Hence, once the molecule is trapped on the surface and starts to dissipate energy, dissociation becomes energetically favored. Yet, the effect is quite minor with corrections to the dissociation probabilities on both surfaces of about 10−15% at most. Even if the time the molecules spend on the surface probing the high-density regions before dissociation is considerably long, the dissociation event itself, being ruled by early barriers, is actually decided once the molecules become trapped by the chemisorption well, or, in general, by the attractive parts of the PES. Thus, the excitation of the low-energy electrons that become important at ulterior times cannot alter the outcome of the dissociating trajectories much.

Taking into consideration all the above examples, we can speculate that the ideal dissociation conditions for which nonadiabatic effects may still be determinant should combine late-barrier together with trapping-mediated dynamics. Unless these conditions are met, one should expect that the adiabatic approximation suffices to provide a reasonable description of the dissociation process, at 1250 least in its initial stages, as we discuss next.

At first sight, the theoretically predicted insignificance of e–h pairs in the gas–surface processes described so far contrasts with existing experiments, proving that they are efficiently excited even under thermal gas–surface conditions. Detection of low-energy solid-state e–h-pair excitations is technically feasible by means of Schottky diode devices, which consist of ultrathin metal films grown on semiconductor substrates. Hot charge carriers (electrons/holes) excited during the exothermic adsorption of atoms and molecules on metals are detected as *chemicurrents* on the diode [28.18, 138, 139]. Using this technique, a variety of exothermic chemical reactions that constitute a representative sample of relevant gas–surface interactions, such as physisorption, chemisorption, dissociation, and recombinative desorption, have been investigated to conclude that a large fraction of the energy is dissipated into e–h pairs in view of the correlation found between chemicurrent intensities and adsorption energies. The question, then, is how to reconcile theory and experiments in this matter.

Studies focused on the subsequent relaxation of the adsorbing gas species rather than on the initial adsorption process itself have been decisive in understanding the role of the low-energy excited electrons [28.40–43, 140]. In [28.141], the relaxation of the nascent H atoms formed upon dissociation of H_2 on Pd(100) was first studied using AIMD, which only includes dissipation into phonons, and more recently in [28.40, 41, 43] using the newly developed AIMDEF method explained in Sect. 28.3.4. The authors show that, although e–h-pair effects are usually irrelevant on the molecule bond-breaking timescale—which explains the success of the adiabatic approach and the minor corrections to the dissociation probabilities discussed above—, it is an efficient dissipative channel in the subsequent relaxation of the resulting hot products that propagate until they reach thermal equilibrium with the surface. The results for H relaxation are particularly striking, as it was found that energy dissipation into e–h pairs occurs at a rate

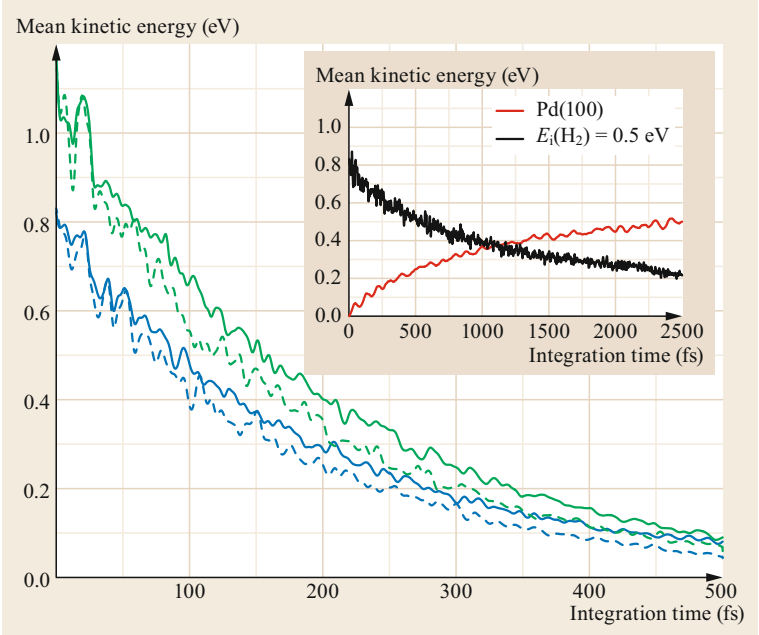

Fig. 28.12 Time evolution of the mean kinetic energy of H_2 upon dissociation on Pd(100) as calculated from the LDFA-based AIMDEF simulations in [28.40]. *Blue* (*green*) *lines* correspond to H_2 impinging with $E_i = 0.5(1.0)$ eV. *Solid* (*dashed*) *lines* represent the AIMDEF results obtained in frozen-surface (nonfrozen-surface) simulations. *Inset*: mean H_2 (*black line*) and Pd (*red line*) kinetic energy obtained from nonfrozen-surface AIMD simulations without electronic friction (Reprinted with permission from [28.40]. Copyright (2014) by the American Physical Society)

five times faster than dissipation into phonons. This can be observed in Fig. 28.12, where the H_2 kinetic energy averaged over all the dissociated trajectories is plotted as a function of time for H_2 beams with 0.5 and 1.0 eV of incidence energy. The evolution is represented from the instant at which the molecule is considered dissociated (i.e., when the internuclear distance is > 1.5 Å). Note that the kinetic energy starts at a value larger than the initial E_i because of the energy gained by the molecule in the dissociation process. In order to quantify the contribution of phonons and e–h pairs to the relaxation process, the authors performed three types of simulations: frozen-surface (FS) AIMDEF calculations in which the surface atoms are not allowed to move (FS+AIMDEF; nonfrozen-surface (NFS) AIMDEF calculations that allow for the movement of the atoms in the two topmost surface layers (NFS+AIMDEF); and nonfrozen surface AIMD simulations that do not include electronic friction (NFS+AIMD).

In the 0.5 eV H_2 beam case, ≈ 1 ps is needed to reduce the kinetic energy down to 0.4 eV when only the phononic channel is included (NFS+AIMD, see inset in Fig. 28.12), while ≈ 0.14 ps are enough to observe the same decrease, when only e–h pairs excitations are considered (blue solid line in Fig. 28.12). Comparing the NFS+AIMDEF and FS+AIMDEF results, the relaxation rate is slightly larger in the former case, i.e., when both energy dissipation mechanisms are included, than in the latter. However, the small differences found between both types of simulations (dashed versus solid lines in Fig. 28.12) is a clear indication of the relaxation process being strongly dominated by e–h pairs.

The minor role of phonons in the relaxation of H on metals is directly related to its small mass compared with that of the usual metal atoms of interest. The competition between e–h pairs and phonons during the adsorption and relaxation processes of heavier atoms and molecules was also studied in [28.41–43, 140]. Together, all these studies cover different mass ratios between the gas species and the metal atoms that provide a wider perspective on the role played by each energy-dissipation channel. The adsorption of N atoms on Ag(111) was investigated by *Martin-Gondre* et al. [28.140], who performed molecular dynamics simulations on a three-dimensional (3-D) PES and included the role of phonons and e–h-pairs by combining the GLO and the LDFA. The same system was later analyzed by means of AIMDEF simulations, which permits, in principle, a more accurate and realistic description of the surface-atom movement and, importantly, of the interplay between the two energy dissipation mechanisms. The overall conclusions extracted in both studies are similar though, and we will only review those of [28.140] that take advantage of the low computational cost to monitor the adsorption process until the atom is fully accommodated and relaxed in the well.

Figure 28.13 shows the total energy of the adsorbing N atoms against time as calculated when accounting for energy dissipation into both phonons and e–h pairs (LDFA+GLO), and when only one of the mechanisms is considered (the LDFA for e–h pairs and the GLO

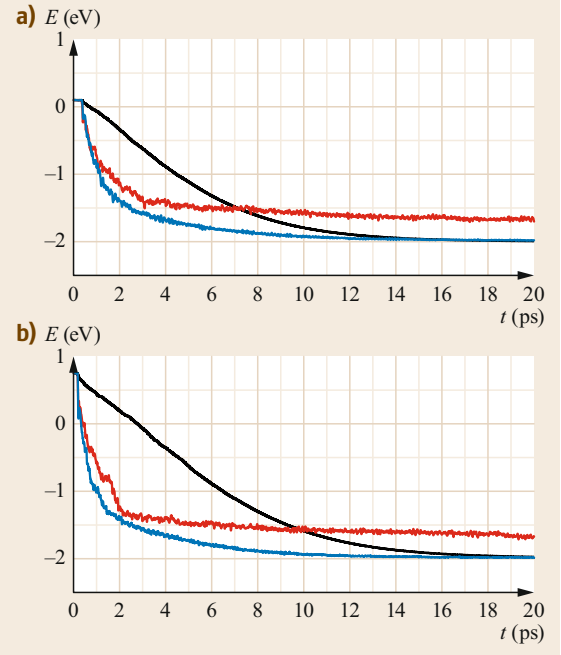

Fig. 28.13a,b Time evolution of the total (potential plus kinetic) energy of N atoms adsorbing on Ag(111). Results obtained in [28.140] from three-dimensional (3-D) molecular dynamics based on the LDFA (*black curves*), GLO (*red curves*), and LDFA+GLO (*blue curves*) simulations for an incidence angle of 40° and two different energies: **(a)** $E_i = 0.10\,\text{eV}$, **(b)** $E_i = 0.75\,\text{eV}$. Surface temperature is $T_s = 500\,\text{K}$ (Reprinted from [28.140], with permission from Elsevier)

for phonons). Figure 28.13 corresponds to N atoms impinging from vacuum at 40° with respect to the surface normal and with an initial kinetic energy of 0.1 eV (Fig. 28.13a) and 0.75 eV (Fig. 28.13b). Compared with the somehow similar initial decay of the LDFA+GLO and GLO curves at times below 1(2) ps for $E_i = 0.1(0.75)\,\text{eV}$, the slower decay of the LDFA one at each E_i shows that, in contrast to the relaxation of H atoms, the initial steps of the adsorption of N on Ag(111) are primarily controlled by the energy exchange to the surface lattice. It is at longer times when the contribution of e–h pairs becomes crucial. We can infer this statement from the comparison between the LDFA+GLO and GLO curves at times 1(2)–10 ps. While the GLO results reach an almost steady plateau, the additional incorporation of e–h pairs (LDFA+GLO curves) results in a slow but continuous decay that causes an additional energy loss of around 0.5 eV at 10 ps.

It is meaningful to follow the evolution of the adsorbing N over the surface unit cell that is plotted in Fig. 28.14 at times $t = 10$ (red dots) and $t = 20$ ps (blue

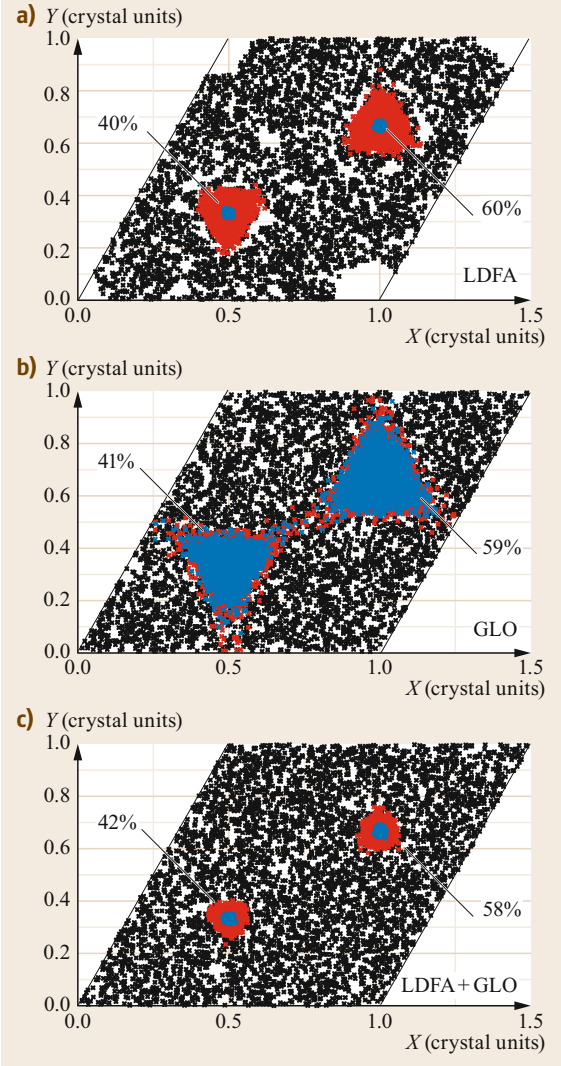

Fig. 28.14a–c Initial (*black dots*) and final (*colored dots*) (X, Y) positions of the adsorbing N over the Ag(111) surface unit cell as obtained in [28.140] for the LDFA **(a)**, GLO **(b)**, and LDFA+GLO **(c)**. Incidence conditions: $E_i = 0.1\,\text{eV}$ and $\Theta_i = 40°$. *Red* (*blue*) *dots* correspond to the final atomic positions after an integration time of 10(20) ps. The percentage of atoms adsorbed at the fcc and hcp sites is also indicated. For clarity, all points have been merged into one elementary cell with the Ag atoms located at the corners of the cell and the fcc(hcp) hollow located in the upper (lower) part of the cell. The GLO and LDFA+GLO simulations performed at $T_s = 500\,\text{K}$ (Reprinted from [28.140], with permission from Elsevier)

dots), as obtained from the three types of simulations. In all cases, the atoms are already located over the fcc and hcp hollow sites that correspond to the position of the stable and metastable adsorption wells,

respectively. Apart from this common feature, there are notable differences in the (X, Y)-distributions obtained by each model. At $t = 10$ ps, the LDFA+GLO distribution is the narrowest, showing that the adsorbing atoms are quite well localized already at the adsorption wells. Interestingly, the GLO model gives a quite broad distribution, also when compared to the LDFA one. The different degrees of localization observed in the three cases is well correlated with the amount of energy lost by the N atoms in each type of simulation. The increasing efficiency of the electronic dissipation channel in the long-time term is more apparent after noting the still broad distribution obtained with the GLO model at 20 ps, which contrasts highly to the well-defined LDFA and LDFA+GLO positions. All in all, the in-depth analysis of [28.140] shows that the relevant energy dissipation channels at the beginning and at the end of the dynamics are different. Indeed, the fast energy loss due to phonons during the 2 or 3 first picoseconds of the dynamics will promote the trapping of N atoms, preventing any reflection process. Nevertheless, since e–h pairs are continuously excited as long as the adsorbing species moves, the final position of the adsorbed atoms is ruled by the latter dissipation channel.

Molecular adsorption of N_2 on Fe(110) is an additional and more extreme example of adsorption dominated by energy dissipation into phonons. Using the different types of AIMD and AIMDEF simulations aimed to isolate the contribution of each energy-dissipation channel that were described above, *Novko* et al. [28.41, 43] showed that no adsorption event occurs when only e–h-pair excitations are included in the simulations (FS+AIMDEF). Furthermore, the relaxation rates obtained when accounting for phonons with (NFS+AIMDEF) and without (AIMD) e–h-pair excitations are rather similar. Figure 28.15 shows the time evolution of the N_2 mean kinetic energy, which is obtained as an average over all adsorbing NFS+AIMDEF trajectories. This system is characterized by three molecular adsorption wells that have quite different properties regarding their adsorption energies and their position and configuration on the surface. For this reason, Figure 28.15 shows the mean kinetic energy separated for each of the wells. The *top-vertical* well with $E_a = -0.31$ eV occurs for the molecule atop an Fe atom and oriented vertical to the surface, while the *bridge-parallel* ($E_a = -0.22$ eV) and *hollow-parallel* ($E_a = -0.49$ eV) wells correspond to the molecule lying parallel to the surface with their center of mass over bridge and hollow sites, respectively. At the end of the simulation, the kinetic energy of those molecules that end up on the less bounded bridge site is only of few tens of meV, as an indication of the molecules having reached the bottom of the well (note that the zero-point energy was neglected in all the simulations). At

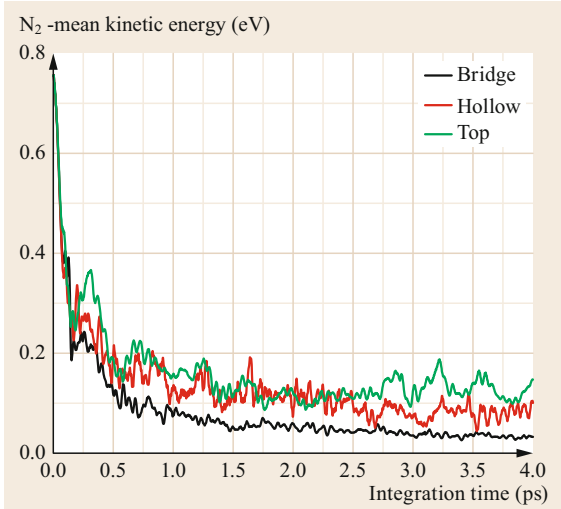

Fig. 28.15 Time evolution of the mean kinetic energy of N_2 adsorbing on Fe(110) at each of the three different molecular wells. Results obtained from the LDFA-based AIMDEF simulations in [28.41, 42] using the Hirshfeld density partitioning scheme to account for the surface density changes caused by the Fe displacements in nonfrozen-surface calculations. Incidence conditions $E_i = 0.75$ eV and normal incidence

first thought, the results showing that the kinetic energy of the molecules adsorbing at the *top-vertical* well remains larger than that of the molecules adsorbing on the *hollow-parallel* one seems contradictory to the corresponding E_a values and show the slower thermalization of the molecules on the top well. As shown in [28.43], this happens because both energy-loss channels depend strongly on the adsorption configuration. At the top site, the molecule lies further from the surface, where the electron density is lower, and thus, the e–h-pair excitations are less efficient. The comparison of the additional AIMD simulations performed in [28.43] showed that the phonon excitation channel is also less efficient at the top site.

The competition between the two energy dissipation channels can easily be quantified by calculating the amount of energy transferred from the adsorbates to e–h pairs and to the lattice. For a single atomic trajectory, the former contribution as a function of time can be evaluated from the path integration of the friction force on each gas atom along its trajectory, i.e.,

$$E_{eh}(t) = \sum_{i=1}^{N_{step}} \eta(\boldsymbol{r}_i)|\boldsymbol{v}_i|^2 \Delta t \,, \qquad (28.44)$$

where $\eta(\boldsymbol{r}_i)$ and $\boldsymbol{v}_i$ are, respectively, the friction coefficient and velocity of the atom at the integration step i,

and Δt is the constant time step used in the integration. The mean energy lost into e–h pairs is calculated as an average over the available number of trajectories $\langle E_{eh}(t)\rangle$. In the case of molecules, the contributions of all the atoms are added. The energy transferred to the lattice atoms is the sum of the instantaneous kinetic energy of the surface atoms $\langle E_{kin}(t)\rangle$ and the instantaneous variation of the potential energy due to lattice distortions $\langle E_{pot}(t)\rangle$. The former can be easily calculated at each time step t during the AIMDEF simulation, while the latter requires additional and separated calculations of the potential energy associated to the distorted surface lattice but without including the adsorbing gas species (see [28.41, 43] for a detailed description).

Figure 28.16 reproduces the mean energy dissipated into each mechanism for the relaxation of the nascent H atoms formed upon dissociation of H_2 on Pd(100) and the adsorption of N_2 on Fe(110), as calculated in [28.41]. In the e–h-pair-dominated H/Pd(110) system, the energy transferred to e–h pairs is around more than two times larger than the total energy transferred to the lattice after just 0.5 ps. A completely opposite behavior is obviously observed for the phonon-dominated N_2/Fe(110) system in which we observe that the energy lost into phonons at the end of the simulation time (4 ps) is almost four times the energy released into the e–h pairs. In the first stages of the dynamics, at $t < 0.5$ ps, a rapid energy transfer takes place from the molecule to the surface lattice. In fact, this fast energy transfer fully accounts for the adsorption process in the N_2/Fe(110) system. After this short period of time, while $\langle E_{ph}\rangle$ reaches a plateau, $\langle E_{eh}\rangle$ increases monotonically. Interestingly, we observe that despite the phononic channel dominating the N_2 relaxation, the energy lost to e–h pairs is by no means negligible. Actually, no matter how dissimilar the adsorption and relaxation processes are, in close similarity to the observations made for the adsorption of N on Ag(111), we also observe for H/Pd(100) and N_2/Fe(110) that the energy loss into the lattice occurs at the initial stages of the adsorption process. Specifically, the sum of the $\langle E_{kin}(t)\rangle$ and $\langle E_{pot}(t)\rangle$ curves remains basically constant in H/Pd(100) and N_2/Fe(110) after the first ≈ 0.1 and 0.8 ps, respectively. In contrast, since neither the H atoms nor the N_2 molecules are fully relaxed and accommodated in their respective wells, the e–h pairs are still an active energy drain, as is apparent from the increasing behavior of the corresponding curve during the whole integration time. The H atoms that are close to the bottom of the well exhibit an almost saturated $\langle E_{eh}\rangle$ curve.

28.4.3 Atom–Atom Recombinative Abstraction on Covered Surfaces

The catalytic properties of surfaces depend on the competition among the different elementary processes that characterize the gas–surface interaction [28.142]. While molecular and dissociative adsorption are usually the initial steps responsible for populating the surface with at least part of the desired reactants, most surface reactions involve at the latest stage the recombination of two or more species to conform the final molecular compound that desorbs. The surface catalycity and the replenishment of the surface active sites will depend on the efficiency of these recombi-

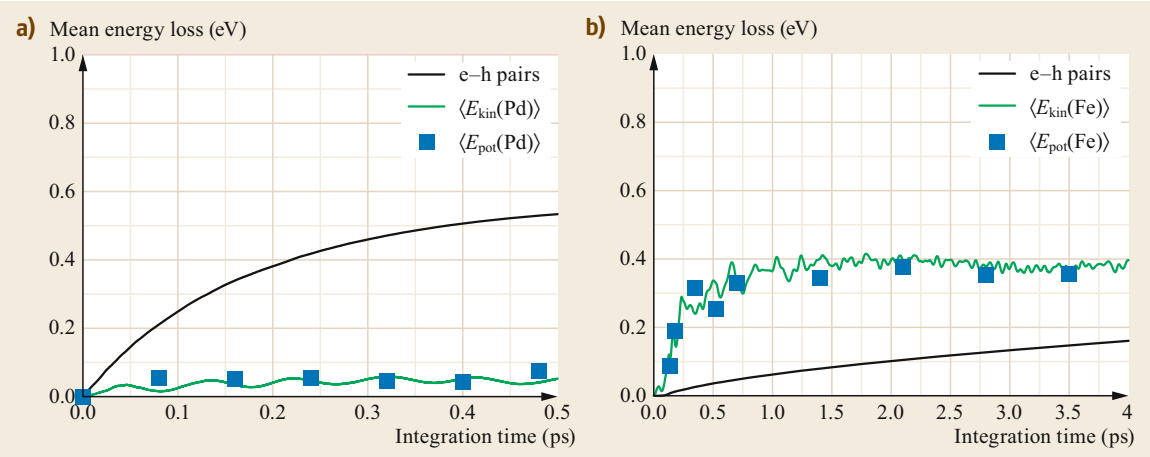

Fig. 28.16a,b Energy transferred to the surface upon adsorption of H on Pd(100) **(a)** and N_2 on Fe(110) **(b)** resolved into the different energy dissipation channels: e–h-pair excitations (*black curves*), kinetic energy of surface atoms $\langle E_{kin}(t)\rangle$ (*green curves*), and potential energy of the surface $\langle E_{pot}(t)\rangle$ (*blue squares*). Results obtained in [28.41] from AIMDEF simulations based on the LDFA with the Hirshfeld density partitioning scheme proposed in [28.42]

nation processes. Then, it comes as no surprise that many pioneering investigations were focused precisely on identifying all possible processes involving recombination [28.143–146]. Originally postulated as an atom exchange, the single-collision Eley–Rideal (ER) process is now assigned to the direct recombination of an incoming gas-phase species with a surface adsorbate to conform a molecular compound that desorbs during the collision. Closely related to it, the hot-atom (HA) abstraction process differs in that the gas-phase species experiences few collisions with the surface prior recombination. The extreme alternative to the ER mechanism is the Langmuir–Hinshelwood recombination, in which the species involved in the reaction are fully thermalized with the surface. In this section, we will focus on the recombination processes triggered by incident gas atoms, namely, ER and HA abstraction events.

Due to the usual fast nature of the single-collision ER abstraction, most of the theoretical studies performed on different systems were conducted under the adiabatic approximation or by only taking into account energy dissipation into the lattice phonons [28.8, 148–155]. The effect of e–h pairs in ER processes has been analyzed by *Galparsoro* et al. [28.147]. The authors investigated the ER recombination of H–H and N–N on two different W surfaces and performed 6-D quasiclassical dynamics simulations in which both energy dissipation mechanisms, namely, e–h pairs and phonons, were included within the LDFA and GLO models. Among other observations—all focused on the ER recombination in the ideal limit of a single adsorbate—, it was found that phonon excitations reduce the N–N ER cross section by about 10–50%, depending on the incidence energy and the crystal face. However, phonon excitations hardly affect the H–H abstraction due to the large mismatch between the masses of H and W atoms. Regarding e–h-pair excitations, the behavior observed when comparing N–N ER and H–H ER is just the opposite. Specifically, e–h pairs have a very minor effect on the N–N ER recombination cross section, but they can modify the adiabatic H–H ER cross section by as much as 36%.

The authors also evaluated the energy exchanged between the molecule and the metal separating the contributions of each of the energy-dissipation channels. The results for the H–H and N–N recombinations are reproduced in Figs. 28.17 and 28.18, respectively. By comparing both figures, we observe that the energy loss due to phonon excitations is about one order of magnitude higher for the N–N recombination than for the H–H recombination, in agreement with the mass mismatch between N and W being smaller than that between H and W. In contrast, energy dissipation due to e–h pair excitations is about three times larger for the H–H recombination than for the N–N recombination, despite the fact that the friction coefficients at equal electron density are significantly higher for N than for H [28.23, 37]. The authors attribute this somewhat counterintuitive result to the combination of two main factors. First, the comparative analysis of the trajectories showed that H atoms get closer to the surface and, therefore, probe regions of higher electronic density than N atoms do. Second, for similar collision energies the friction force and, hence, the electronic energy loss is larger for H than for N, due to the corresponding higher velocity of the former (28.44). As a final remark on the comparison between the two energy dissipation channels, note that even if phonons are the main energy-loss channel for N_2 formation, the electronic excitations are by no means negligible in this case. However, the H–H recombination on W surfaces can be safely described without including phonon excitations, as their

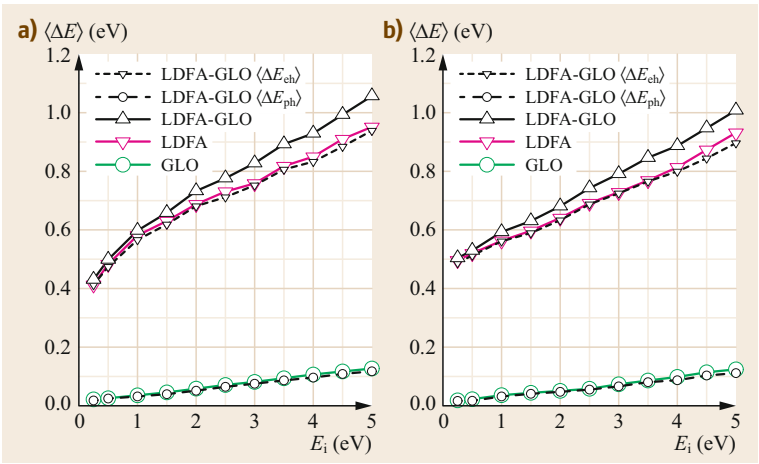

Fig. 28.17a,b Dependence of the average energy loss $\langle \Delta E \rangle$ on the incidence energy E_i for **(a)** H–H/W(100) and **(b)** H–H/W(110). Results obtained in [28.147] for the LDFA (*magenta down-triangles*), GLO (*green circles*) and LDFA-GLO (*black up-triangles*) simulations. For the LDFA-GLO calculations, the average energy loss into phonons $\langle \Delta E_{ph} \rangle$ (*black circles* and *dashed lines*) and into e–h-pair excitations $\langle \Delta E_{e-h} \rangle$ (*black down-triangles* and *dashed lines*) are also shown (Reprinted with permission from [28.147]. effect on the cross sections and energy loss is negligible [28.147].

The analysis provided in [28.147] on the time evolution of each energy-loss process along the ER trajectories is very instructive. Figure 28.19 displays the average energy-loss rate to phonons $\langle \Delta E_{ph}/\Delta t \rangle$ and to metal electrons $\langle \Delta E_{eh}/\Delta t \rangle$ as a function of time for N + N/W(100) at $E_i = 1.5$ eV. For each ER trajectory, the energy-loss rates are calculated by evaluating at each integration step Δt the contribution of each energy-loss channel (see [28.147] for details). The average over trajectories is calculated after setting in each case the origin of time ($t = 0$) at the instant the projectile reaches the classical turning point. As is shown in Fig. 28.19, most of the energy dissipated into the surface lattice occurs at the classical turning point (see the large symmetric peak centered at $t \approx 0$ fs, which amounts to ≈ 0.76 eV). Afterwards, the forming molecule gains and loses energy, but the energy exchange in these cases is considerably smaller. At first sight, the electronic energy-loss rate, which vanishes at the classical turning point with the z-component of the projectile velocity, is rather symmetric around this point, although slightly smaller along the outgoing ($t > 0$) part of the trajectory as compared to the losses experienced for $t < 0$. Even if the surface-electron density is rather similar along the incoming ($t < 0$) and outgoing ($t > 0$) parts of the trajectory, the projectile loses an important part of its kinetic energy into phonons upon the first collision with the surface. As a result, the electronic friction force and, correspondingly, the energy loss decrease for the remaining (outgoing) part of the trajectory. A similar analysis of the time evolution of each energy-loss mechanism is plotted in Fig. 28.20 for H + H/W(100) at $E_i = 1.5$ eV. Qualitatively, the behavior of the electronic and phononic channels is similar to that described for the N–N recombination case. Thus, the largest energy transfer to the surface lattice occurs close to the classical turning point as expected, while the energy-dissipation rate into e–h pairs, despite being rather symmetric along the incoming and outgoing parts of the trajectories, is slightly smaller in the latter part. It is very illustrative, however, that there are large quantitative differences that exist between the two systems, which provide evidence as to what mechanism rules the total energy loss in each case.

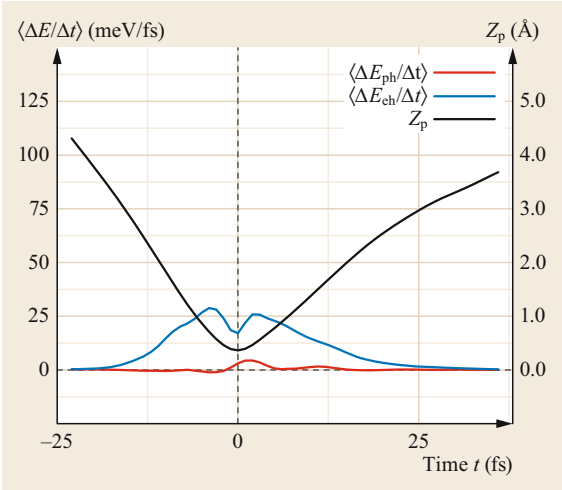

Fig. 28.20 Same as Fig. 28.19 for H + H/W(100) and $E_i = 1.5$ eV. Data extracted from the LDFA+GLO simulations performed in [28.147]

The usually long-lasting HA recombination, which involves hyperthermal diffusion of the impinging atom on the surface, in principle, meets all the necessary conditions for being significantly affected by the dissipation of energy into e–h-pair excitations. This problem has been studied for the scattering of H atoms from the H-covered W(110) surface [28.156]. Strikingly, the commonly accepted idea of HA recombination being dominant over the single-collision ER mechanism—and actually confirmed with adiabatic simulations performed for the same system [28.9]—is drastically affected when e–h-pair excitations come into play. This is what the LDFA simulations performed by *Galparsoro* et al. show in [28.156]. According to these authors, the HA recombination process is notably diminished in favor of H adsorption on the surface, particularly at low coverages and E_i. The comparison between the adiabatic and the LDFA cross sections *per* adsorbate is reproduced in Fig. 28.21 for all possible recombination processes and for two distinct coverages, namely, $\Theta = 0.25$ and 1 ML. In these simulations, a H–H recombination event is counted as ER when the molecule is formed after the first rebound of the projectile and moves definitively toward the vacuum and as *primary* HA when the projectile suffers more than one collision before recombining. Finally, when recombination involves two target atoms, the event is classified as *secondary* HA recombination. Figure 28.21 shows that nonadiabatic effects mainly affect the two HA recombination mechanisms, while the ER recombination hardly changes in agreement with what was also found in the single-adsorbate limit discussed above. The reduction experienced by the primary and secondary HA cross sections is more severe at the low-coverage and low-incident energies. Additional analysis of the energy lost by the projectile along the trajectory reveals that the incoming H atom rapidly dissipates into the efficient e–h pair production all the necessary energy the molecule requires to escape from the attractive surface regions. At low coverages, the longer time required for a projectile to collide with an adsorbate increases the efficiency of the electronic energy loss and, in turn, decreases the probability of recombination and desorption.

28.4.4 Femtosecond Laser-Induced Desorption

As described in Sect. 28.3.3, *Tully* and coworkers showed that the physics ruling the femtosecond laser-induced desorption of adsorbates from metal surfaces can be reasonably modeled by a Langevin-type equation in the case of UV/Vis lasers operating at large fluences, i.e., when desorption occurs via multiple electronic excitations (DIMET regime) [28.85, 86]. These early works simulated the laser-induced desorption of CO from Cu(100) using empirical potentials to describe the molecule–surface interaction. The recombinative desorption of H_2/D_2 from a saturated Ru(0001):H/D(1×1) surface was experimentally investigated in [28.157, 158] using 120−130 fs laser pulses at a wavelength centered ≈ 800 nm. Among their findings, the large isotope effect observed between the H_2 and D_2 desorption yields ($Y(H_2)/Y(D_2)$) that decreases from about a factor 22 to 5 as the laser fluence is roughly varied from 50 to 120 J/m^2 was particularly remarkable. As reported on other DIMET experiments, a nonlinear increase of yields with laser fluence was also observed. Other key observations were a clearly nonequal partitioning of the energy of desorbing particles into translation, vibration, and rotation, the linear increase of energies with fluence, a Maxwell–Boltzmann velocity distribution of desorbing particles with an unusually *hot* temperature, and a preference of helicopter versus cartwheel rotation. All these issues were studied by *Saalfrank* and coworkers using different level theories in [28.88, 159, 160]. Of interest for the present chapter devoted to the LDFA, it is remarkable the success of the 6-D molecular dynamics simulations performed in the context of the Langevin equation and the LDFA to account for the friction and random forces at each integration step [28.88]. The authors conclude that most of the experimental observations are actually consequence of the corrugated adiabatic PES. This conclusion notes first the importance of accounting for at least the degrees of freedom of the adsorbates (6-D), and second, that the recombination is a *low* nonadiabatic process in the sense that it is governed by low-energy electron excitations. These are the ideal working conditions under which the LDFA is particularly efficient, and it thus explains its adequacy in describing most of the experimental observations quantitatively.

Even if electrons are the driven agents in most of the fs-laser desorption systems studied, and, therefore, theoretical models have primarily focused on them, the recent theoretical study of [28.89] predicts that also the laser-excited phonons can contribute and rule the desorption process. Following the aforementioned works, *Lončarić* et al. treat the laser-induced surface excitation trough the 2TM [28.87] (Sect. 28.3.3), while the multidimensional dynamics of the adsorbates is described by a classical Langevin equation, in which the friction and random forces account for the action of the heated electrons, the latter being calculated with the LDFA as in [28.88]. The novelty of [28.89] is the additional use of the GLO model to also include the effect of the energy exchange between the molecule and the heated surface lattice in the desorption dynamics. The effect of the laser-induced excited phonons in photodesorption is compared with that of electronic excitations, taking the desorption of O_2 from Ag(110) as a case study. The system is theoretically appealing for this purpose, because DFT-PBE predicts the existence of the four distinct O_2 adsorption wells depicted in Fig. 28.22 that correspond to the molecule lying parallel to the surface at different heights Z from the surface, the latter being relevant because of the different surface-electron densities that the O atoms probe. In the 6-D (frozen surface) PES, the adsorption energies E_a, surface-electron density at the position of the O atom (given in terms of the electron mean radius r_s), and the geometries are as follows:

(i) The short-bridge site (SB) well with $E_a = -0.33$ eV and $r_s = 3.57$ a.u. has the molecular center of mass (CM) at $Z = 2.20$ Å over the short-bridge site with the molecular axis oriented along the $[1\bar{1}0]$-direction
(ii) The long-bridge site (LB) well with $E_a = -0.24$ eV, $r_s = 3.82$ a.u., and CM at $Z = 1.98$ Å over the long-bridge site is oriented along the [001]-direction
(iii) The H001 well with $E_a = -0.24$ eV, $r_s = 2.62$ a.u., and its CM at $Z = 1.29$ Å over the hollow site is oriented along the [001]-direction, and
(iv) The H110 well with $E_a = -0.21$ eV, $r_s = 2.57$ a.u., and CM at $Z = 1.09$ Å is also over the hollow site, but oriented along the $[1\bar{1}0]$-direction.

Figure 28.22 reproduces the theoretical desorption yields Y as a function of the laser fluence F for each adsorption well. In all cases, we observe the characteristic superlinear desorption yields ($Y = aF^n$ with $n > 1$) expected for multielectron excitations. For all the laser fluences considered, the highest desorption yields are obtained for H110, followed by H001, LB, and SB. The exponent n of the power law is also different for each well, its value decreasing from $n = 5.8$ for desorption from the SB well down to $n = 2.6$ for desorption from the H110 well. Both results can be mostly related to the differences in the adsorption energies of the dif-

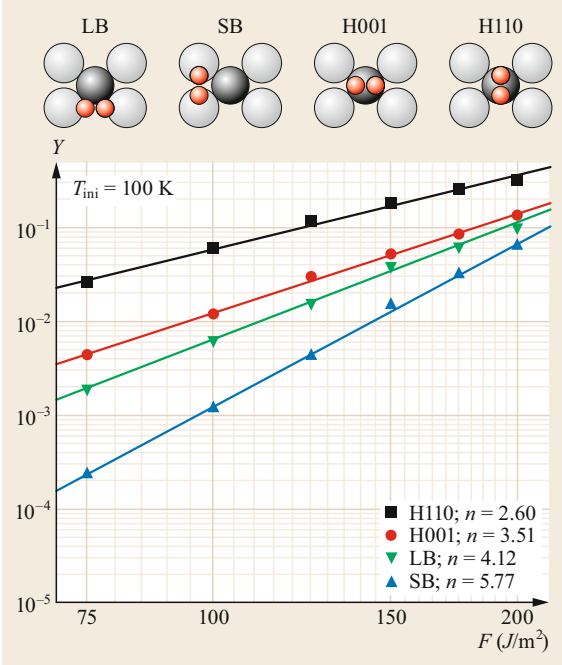

Fig. 28.22 Desorption yields Y as a function of the laser fluence F calculated in [28.89] for each of the O_2 adsorption wells that exists on Ag(110) (see *inset*). *Lines* are obtained by fitting each set of data to the equation $Y = aF^n$ (Reprinted with permission from [28.89]. ferent wells. The highest desorption yield and lowest exponent correspond to the well with the lowest E_a and vice versa. However, the adsorption energy itself is not the only property ruling the desorption process. The LB and H001 wells have the same adsorption energy (−0.24 eV), but the yields are consistently larger for desorption from the H001 well than from the LB one. The authors showed by comparing the time dependence of T_e and T_{ph} as obtained from the 2TM to the desorption rates from each of the wells that this effect is related to the desorption process being, respectively, ruled by the laser-excited phonons and the laser-excited e–h pairs in the bridge and hollow wells. These results are shown in Fig. 28.23 for $F = 200\,\mathrm{J/m^2}$. There are remarkable differences between the bridge wells (LB and SB) and the hollow wells (H001 and H110) observed not only in the magnitude of the desorption rates, but also in their time evolution. While the desorption rates for the hollow wells seem to follow the time evolution of T_e—with a delay of around 3.5 ps though—, the desorption rates from the bridge sites are not much affected by the high increase of T_e at short times, and it is at longer times, once T_e and T_{ph} are equilibrated, when the desorption rates from LB and SB reach their highest values. It is worth to mentioning that the desorption rate from SB seems to follow the time evolution of T_{ph}, but also with a certain delay. All these observations suggest that while desorption from the hollow sites is mainly an electron-mediated effect, where the energy transfer from the electrons excited by the laser pulse to the adsorbed molecule plays a dominant role, its effect on desorption from the bridge sites is less relevant. In these cases, desorption seems to occur as a consequence of the laser-mediated phonon excitations. The authors further confirmed these ideas by performing additional calculations in which only the effect of either the heated electrons (LDFA with $T_e(t)$) or heated phonons (GLO with $T_{ph}(t)$) was included in the desorption dynamics. In the case of desorption from the hollow sites, the LDFA yields and rates were significantly larger than GLO ones, while the opposite behavior was observed for desorption from the bridge wells. The minor effect of the heated electrons on the bridge wells can be understood by realizing that the molecule on these wells is located at intermediate distances from the surface where the electron density is small (compare the aforementioned different r_s values probed by the O atoms at the different adsorption wells). The general predic-

tion that can be extracted from the theoretical analysis of [28.89] is that multiple electron excitations are, indeed, expected to be the main mechanism ruling fs-laser desorption in the case of chemisorbed species, while the laser-heated phonons will dominate in the case of physisorbed adsorbates.

28.5 Conclusion

In this chapter, we have reviewed recent developments based on the LDFA to study the effect of low-energy electronic excitations in elementary gas–surface processes. We have shown that the LDFA constitutes a valuable tool to incorporate such effects in multidimensional molecular dynamics calculations and that its flexibility has already allowed its implementation in AIMD simulations.

Several conclusions have been already made by the application of the LDFA to different gas–surface interaction problems. In the case of the scattering of hyperthermal molecules, such as N_2 or O_2 and atoms as N from metal surfaces, the contribution of the electronic excitations to the energy loss has been found to be very minor. In these cases, the energy loss is dominated by phonon excitations that take place as a result of the collision of the projectile with the surface. On the contrary, for the lighter H projectiles, phonon contribution to the energy loss is much reduced. Indeed, in this case, electronic excitations have been found to be the dominant mechanism, and the LDFA has successfully reproduced the energy loss measured.

Regarding dissociative adsorption of molecules at surfaces, two different scenarios can be distinguished. In the case of activated direct dissociation, electronic excitations reduce the adsorption probabilities, because the molecule loses part of its energy before arriving at the energy barrier that governs the process. However, since the time scale for this process is usually very short, the amount of energy loss is very reduced, and the adsorption probabilities remain nearly unchanged. A different picture arises in the case of indirect dissociation preceded by trapping of the molecule in the adsorption well. In this case, once the molecule is trapped it starts to lose energy efficiently by exciting e–h pairs. If from the bottom of the chemisorption well the barriers to desorption are on average larger than those of dissociation, energy loss favors the latter over the former, giving rise to an increase in the dissociative adsorption probabilities. Nevertheless, even in this case, the effect is usually very minor, because most of the dissociation is decided before the trapping of the molecule takes place.

Although the effect of electronic excitations in the adsorption probabilities is very minor, their role on the relaxation and thermalization of hot adsorbates at surfaces is very important. Depending on the mass ratio between the adsorbate and the surface atoms, phonon excitations or electronic excitations dominate the relaxation process. For instance, the relaxation of hot H adsorbates is fully dominated by the electronic excitations, while for N atoms and N_2 molecules, phonon excitations have been shown to be the dominant energy-dissipation channel. Nevertheless, it has been demonstrated that even in these phonon-dominated cases, the energy transferred to the electronic system during the relaxation process is substantial, since e–h pairs are responsible of the final accommodation in the adsorption wells.

Similar conclusions are extracted for Eley–Rideal and hot-atom recombinative abstraction processes occurring between gas-phase and adsorbed atoms at metal surfaces. Phonon excitations can substantially affect N–N recombination probabilities but can be safely neglected in the case of H–H recombination. On the contrary, electronic excitations have a large impact in H–H recombination probabilities but hardly affect N–N recombination. A remarkable result found recently is the dramatic reduction of the hot-atom mechanism for H–H recombination when electronic excitations are included at low coverages and low projectile-incidence energies.

Finally, we have shown how the LDFA can also be used to describe energy transfer from heated electrons to adsorbates at metal surfaces in terms of a classical Langevin equation. This has a direct application to the simulation of femtosecond laser-induced desorption of adsorbates at metal surfaces in the DIMET regime. Combination of the LDFA with the GLO method allows us to treat the coupling of the adsorbates to the laser-excited electrons and phonons. In this way, for instance, it has been shown that the desorption of O_2 from the Ag(110) surface can be governed by phonon or by electron excitations simultaneously, depending on the characteristics of the adsorption well in which the molecule is initially located. A natural future development in this field would be the implementation of the Langevin dynamics with heated electrons within the AIMDEF scheme. This would allow us to model laser induced desorption dynamics within AIMD for the first time, allowing for independent atom-surface movement. Such a methodology will represent an important step forward in the modelization and understanding of the photodesorption dynamics.

Maite Alducin

Centro de Física de Materiales CFM/MPC (CSIC-UPV/EHU)
Donostia-San Sebastián, Spain
maite.alducin@ehu.eus

Maite Alducin obtained her PhD degree in Physics from Euskal Herriko Unibertsitatea (UPV/EHU). In 2007, she obtained a permanent position as CSIC researcher in Centro de Física de Materiales (CFM) in Donostia-San Sebastián. Her initial research focused on linear response theory and charge transfer processes of ions at metals. At present, her research is mainly focused on gas–surface reactive dynamics with a special interest in nonadiabatic effects at metal surfaces.

Ricardo Díez Muiño

Centro de Física de Materiales CFM/MPC (CSIC-UPV/EHU)
Donostia-San Sebastián, Spain
rdm@ehu.eus

Ricardo Díez Muiño received his PhD from Euskal Herriko Unibertsitatea (UPV/EHU) in Donostia-San Sebastián. In 2003, he obtained a permanent position as CSIC researcher in Centro de Física de Materiales (CFM). In addition to his position at CFM, he is Director of DIPC. His main fields of research are condensed matter theory and chemical physics, in particular the theory of electronic excitations in metallic systems, and atomic and molecular physics.

J. Iñaki Juaristi

Depto de Física de Materiales
Facultad de Químicas UPV/EHU
Donostia-San Sebastián, Spain
josebainaki.juaristi@ehu.eus

Joseba Iñaki Juaristi obtained his PhD degree in Physics (1996) from Euskal Herriko Unibertsitatea (UPV/EHU), where he became Tenured Professor in 2001. His initial research focused on the theoretical study of the electronic excitations generated in the interaction of atomic particles with metals and their surfaces. His research currently focuses on the modelization of gas–surface interactions, with special attention paid to the role played by electronic excitations in the dynamics.

29. Self-assembly of Organic Molecules at Metal Surfaces

Gianangelo Bracco, Marco Smerieri, Letizia Savio

Adsorption and self-assembly of organic molecules at surfaces is a key issue in nanoscience and nanotechnology for the many possible uses of hybrid organic–inorganic interfaces. Depending on the nature of the molecules, applications are foreseen in the fields of molecular electronics, sensoristics, pharmacology, biocompatibility, hygiene and biofouling. As a consequence, there has been a large effort in the last few years to determine the structure of the layers and to unravel the mechanisms at the basis of the self-assembly process.

In Sect. 29.1 we describe the different possibilities of self-assembly at metal surfaces. For sake of clarity, we group the different examples depending on the category of molecules which are employed. Section 29.2 will deal with covalent bonding and formation of organometallic compounds starting from hydrocarbon precursors. Section 29.3 will be dedicated to noncovalent bonding and divided into three subsections devoted, respectively, to π-conjugated systems, to the formation of self-assembled monolayers of thiols and to small biological molecules, mainly amino acids (Sect. 29.3.3), at surfaces.

29.1 Molecular Engineering of Surfaces

The characterization of the physical–chemical interactions at the hybrid organic–inorganic interface and the assembly mechanisms of the so-called hybrid nanocomposites is a major challenge in nanoscience. In fact, depending on the nature of the molecule, many possible applications are foreseen in several fields of science and engineering. Large aromatic compounds are particularly interesting for their use in nanoelectronics [29.1, 2], sensoristics and, if coupled with a suitable metal atom in an organometallic compound, for nanocatalysis and spintronics. On the other hand, clarifying the interaction of small biological molecules as amino acids and peptides with metal and oxide surfaces is mandatory to gain useful insight for the possible use of such systems in pharmacology applications [29.3], to solve biocompatibility issues and to prevent fouling and biocorrosion phenomena. Finally, we remark that the presence of an organic layer can modify the interfacial properties of the surface on which it is deposited, for instance by changing the reactivity of surface atoms or behaving as an electrically insulating film. Therefore, solid surfaces coated with an organic self-assembled monolayer (SAM) can present well-defined properties: SAMs provide a convenient, flexible, and simple way to tailor the interfacial properties of metals, metal oxides, and semiconductors.

Molecular engineering is an important field of research in nanoscience, since the accurate control of the position, electronic properties, intermolecular interactions and molecule–substrate interface of functional molecules is fundamental for molecular electronics [29.4]. Several techniques for the construction of well-defined molecular architectures have been developed so far, e.g., manipulation, nanofabrication and nanolithography [29.5–7]. Exploiting the spontaneous assembly of the molecular units on suitable surfaces or nanoparticles is of course a simple and advantageous method to realize low-dimensional quantum-confined

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-46906-1_29

geometries [29.2, 8] and to achieve reproducible and scalable results. On the other hand, the availability of extended and regular patterns at the nanoscale is a key issue also for fields as sensoristics, nanocatalysis and spintronics. Indeed, suitable guest molecules/atoms can be selectively accommodated in the cavities of nanoporous networks for sensing purposes, molecular (chiral) recognition, or templating. E.g., fullerene and fullerene derivatives are prospective building blocks for functional nanostructures when deposited on metal surfaces but, at low coverage, they are too mobile and not stable enough for use in molecular devices. When deposited on a template formed by a self-assembled glycine layer on Cu(111), isolated fullerene molecules can be immobilized and form a regular pattern [29.9]. Similarly, the nanocavities can provide functional spaces for heterogeneous catalytic reactions if they host a reactive molecular species or a metal atom acting as catalyst. Depending on the magnetic properties of the metal, metal–organic networks may also be relevant for spintronic applications.

Molecular engineering involves quite often large organic molecules, typically aromatic compounds, which may also be specially designed or modified for specific purposes, e.g., by adding a metal atom or a desired functional group [29.10–13]. However, self-assembly is a process occurring very often with molecules present in nature and especially with molecules of biological interest. Indeed, the term was firstly used in biology to indicate the phenomenon in which complementary molecular units find each other and form a stable complex (sub)system. It is remarkable, in this respect that one of the first observations was that of spontaneous association of entire and infectious viruses from their separated nucleic acid and protein components [29.14]. The self-assembly of biomolecules at surfaces opens up wide perspectives [29.15–18]. Due to the complexity of the systems, so far only the simplest species have been investigated at the molecular level. The natural selectivity of nucleic acids suggests these molecules to be a good model system and, indeed, several 1-D and 2-D hydrogen-bonded structures were observed on Cu(111) [29.19, 20] and Cu(110) [29.21]. However, achieving unique routes toward low-dimensional nanostructures of nucleic acids is often nontrivial [29.20]. For this reason, the attention has concentrated on amino acids and oligopeptides [29.17, 18]. Amino acids are the basic constituents of proteins. Short peptides are the simplest organized structure formed by amino acids and still do not present the additional complication of folding, typical of proteins or of long peptides. Therefore, they have a structure simple enough to be assumed as a model for the chemisorption of biofunctional molecules but they are also suitably *complex* to offer precious information on the fundamental mechanisms governing the hybrid organic–inorganic interface. Last but not least, all the natural amino acids except glycine are chiral. Since the surface reactivity can be modified by exploiting the intrinsic chirality of amino acids and peptides, their action as a chiral modifier is a crucial issue for chiral separation or enantioselective heterogeneous catalysis.

Before proceeding with the description of the self-assembly concepts, it is worth mentioning that there is some confusion in literature about the proper terminology to be employed. In fact, spontaneous organization of separate units in an ordered system can occur at the nanoscale, but it can also be a mesoscale phenomenon, especially when dealing with biological systems. In this latter case, the term self-organization is probably more appropriate. A potential classification scheme is the one proposed by *Barth* [29.15], according to which:

- *Self-assembly* consists in the spontaneous formation of spatially textured architectures of well-defined geometry, stable under equilibrium conditions. Self-assembly proceeds in closed systems by synergic interaction of clearly identifiable functional units. The free energy minimization leads to identical and reproducible patterns.
- The term *self-organized growth* indicates regular arrangements of units controlled by mesoscale force fields or kinetic limitations arising in processes accompanying matter accumulation. These structures are uniform to a certain extent but, a priori, not identical at the atomic or molecular scale.
- *Self-organization* is associated with spatiotemporal order phenomena in open systems and away from thermodynamic equilibrium.

Only self-assembly phenomena at the nanoscale will be treated in this chapter. The examples reported here will deal mainly with noble metal surfaces since they (especially Cu) are the most common substrates used to investigate the hybrid organic–inorganic interface [29.17, 22–24].

Formation of spatially organized molecular architectures at surfaces can involve different kinds of intermolecular and molecule–substrate bonding, which can be roughly classified as covalent or noncovalent bondings.

Covalent bonding implies bond-breaking and subsequent saturation of the dangling bond towards the surface, towards a metal adatom with the formation of an organometallic compound or towards another molecule. Usually the molecule dissociates by loosing a H atom. This is indeed the case for all amino acids adsorbing in the anionic form [29.24], for thiols binding at the metal surface through their sulfur group [29.3, 25] and

for some aromatic compounds [29.11, 26]. However, if the molecule is modified by introducing an additional element or functional group (such as a halogen atom or a methyl group), this particular bonding is probably the weakest and the first one to be broken [29.11, 13, 27]. This process has been observed and exploited, e.g., for the formation of organometallic chains from halogenated hydrocarbon precursors.

Finally, formation of covalent bonds within adjacent molecules may lead to the synthesis of new molecular species, e.g., to peptides when starting from amino acids or to polymeric structures when the precursor is a hydrocarbon molecule, preferably already inserted in an organometallic assembly. Since this last process requires energy, it is usually activated by providing external energy in the form of heat, light, or even electron injection.

Noncovalent bonding, on the contrary, is driven mainly by electrostatic forces. Van der Waals interactions and hydrogen bond formation are the most common driving mechanisms, though other ionic interactions and substrate-mediated long-range forces may play a role [29.24, 28, 29]. In addition, supramolecular ordered patterns, i.e., a hierarchical organization of self-assembled structures, can take place under some conditions. Van der Waals interactions are evident, e.g., in lamellar structures of flat-lying chain-like hydrocarbon species realized at solid–liquid interfaces [29.23] or in self-assembled monolayers of alkanethiols [29.25], but they are present for whatever system. Their weakness often prevents a clear understanding of their relevance, though with recent progress in density functional theory (DFT) their contribution can now be taken into account with a good degree of approximation [29.30, 31]. Hydrogen bonding, which is mostly due to electrostatic interactions [29.32], is probably the most common type of noncovalent intermolecular interaction [29.22, 24]. More generally, charged or polar moieties can form H bridges or other electrostatic coupling schemes. An even stronger, albeit nonselective, bonding occurs in the ionic self-assembly, explored in solution-based systems [29.33]. In 3-D, the strength of ionic bonds typically exceeds that of H-bridges; however, appreciable screening may intervene on metals. A special electrostatic interaction is the zwitterionic bonding in amino acids [29.18]. In addition, indirect substrate-mediated effects may be operative and influence the molecular mobility and self-assembly process [29.29].

To understand the self-assembly mechanisms and to unravel the geometry of the molecular patterns, several factors have to be considered, among which adsorption, mobility, lateral interactions and molecule–substrate interactions. All of them depend on the atomic environment, chemical nature and symmetry

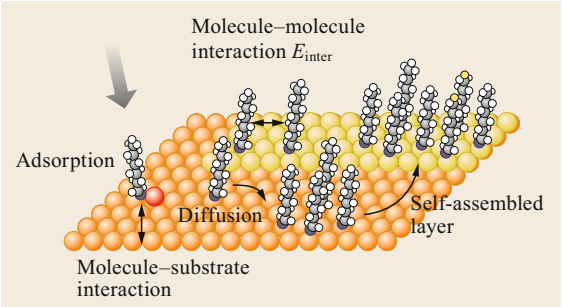

Fig. 29.1 Scheme of the mechanisms controlling molecular self-assembly on surfaces. *From left to right*: (i) Molecules from the gas phase hit the surface and are adsorbed on it. (ii) The molecules diffuse on the surface and get into contact with other molecules. (iii) Intermolecular bonds are established and an ordered layer forms. (Reprinted from [29.37], with permission from Elsevier)

of the substrate [29.12, 17, 34]. The accurate balancing of all these factors allows for the appearance of supramolecular order and determines the stable geometry of the self-assembled pattern. As an example, we anticipate here that alanine adsorb on Cu(110) in the anionic form [29.35], as many other amino acids. Since the molecule–substrate interaction is quite strong, this molecule organizes to form chiral clusters of six or eight units, interspersed with chiral channels exposing the bare metal atoms, in order to release the stress due to the lattice mismatch and to keep registry with the substrate. Glutamic acid on Ag(100), on the contrary, arranges in extended monolayer islands fully covering the Ag terraces, since the interaction with the silver substrate is weak and intermolecular forces prevail [29.36].

Noncovalent self-assembly between molecules can be schematized with the three-step process represented in Fig. 29.1 and including: adsorption, diffusion, molecular recognition and islands formation:

i) *Adsorption.* A flux of molecules is directed towards a well-prepared surface and the single units adsorb on it, usually in a definite configuration and at specific sites. For small organic species on metals, typical adsorption energies of $0.5\,\mathrm{eV} < E_{ad} < 10\,\mathrm{eV}$ per molecule and molecule–substrate bond energies in the range of 0.3–5 eV per functional group are reported [29.38], the precise value being strongly dependent on substrate reactivity, symmetry and electronic properties. Since the structures of interest must be stable at room temperature (RT), E_{ad} should exceed $\approx 1\,\mathrm{eV}$ according to the desorption rate equation for an isolated species

$$\Gamma_{des} = \nu_0 \mathrm{e}^{-\beta E^*} , \qquad (29.1)$$

where $\nu_0 = 10^{13}\,\mathrm{s}^{-1}$, $\beta = [k_\mathrm{B}T]^{-1}$ and E^* is the corresponding energy barrier.
The coupling of the molecule to the atomic lattice confines the adsorbate and influences its conformation. If the molecules are anchored to the substrate with a specific functional group, the adsorption configuration may depend on coverage and/or annealing of the layer [29.36, 37, 39, 40]. If the species is flexible enough, molecular deformation can occur [29.41, 42], while the symmetry reduction associated with the 2-D confinement may induce a rich variety of chirality phenomena [29.17, 21, 43]. All this information is indicative of the key role of the molecule–substrate interaction in the adsorption process and in the determination of the final self-assembled geometry. In addition, if molecule–substrate interactions are relevant, rearrangements of the substrate atomic lattice may occur. Step faceting and bouncing has indeed been observed on deposition of amino acids at Cu(001) [29.18, 44]. Conversely, naturally reconstructed or artificially patterned surfaces can provide anisotropic templates with preferential adsorption sites, thus steering peculiar self-assembled geometries [29.45, 46].

ii) *Diffusion.* The molecules diffuse on the surface. Surface migration and 2-D rotation are thermally activated processes associated with energy barriers $0.05\,\mathrm{eV} < E_\mathrm{m} < 3\,\mathrm{eV}$ and $E_\mathrm{rot} \approx E_\mathrm{m}$, respectively [29.15]. Considering the simplified case of a unique migration energy barrier for diffusion of isolated species and using a rate equation of the same form as (29.1), it is evident that self-assembly at RT can be achieved if $E_\mathrm{m} \leq 0.5\,\mathrm{eV}$. Migration barriers are adsorption configuration-dependent [29.47] and usually reflect the anisotropy of the surface. They can be tuned also by suitable modification of the molecular structure, e.g., by adding specific functional groups.
For site-specific bonding, the adsorbates have a specific orientation with respect to the substrate atomic lattice. Two-dimensional rotations are therefore possible and, as diffusion, require thermal activation and follow a similar rate law. Detailed studies characterizing rotational motion are rare and limited to small molecules [29.48] but the order expressed in 2-D self-assembly provides clear indirect evidence of this phenomenon [29.17, 22, 23].

iii) *Molecular recognition and formation of regular architectures*. The mobile molecules are adsorbed in configurations promoting molecular recognition and the formation of lateral noncovalent bonds between functional groups. Then, the self-assembly of low-dimensional nanosystems is mediated by the selectivity and directionality of hydrogen bonds or metal–ligand interactions, but also by bonding schemes based on nonspecific interactions. One or more types of noncovalent bond formation mechanisms can be involved, depending on the characteristics of both the surface and the molecular species; the typical energy gain for the formation of the self-assembled geometry is $0.02\,\mathrm{eV} < E_\mathrm{as} < 2.5\,\mathrm{eV}$ [29.15].

The study of the detailed adsorption configuration and of the self-assembly patterns of molecules at surfaces is often an experimental challenge, which requires a combination of powerful tools. The scanning tunneling microscope (STM) is certainly a fundamental instrument for this kind of investigation. It allows to determine the surface morphology at the atomic level, to manipulate individual molecules to create specific patterns or to induce specific chemical reactions [29.49–51], but also to gain spectroscopic information (scanning tunneling spectroscopy, STS) on individual molecules [29.52]. The limit of this technique is the lack of chemical information, since STS analysis is limited to the valence band region and it is extremely local and technically demanding. For this reason, microscopic investigation is usually complemented by spectroscopic experiments aimed at defining the chemical state of the molecule as a whole and of its different functional groups. Core level photoemission spectroscopy, either with laboratory and synchrotron x-ray sources, is largely employed in this respect. For the simplest molecules, as amino acids, also infrared (IR) spectroscopy is of common use. Though interpreting a vibrational spectrum can be a bit more complicated than reading an XPS one, IR spectroscopy is a photon-based technique and thus presents the great advantage of working also in ambient conditions, not necessarily in ultrahigh vacuum. This is important in the study of biological molecules, which are often deposited from solution and investigated in liquid environment. Moreover, in some cases, biointerfaces may be damaged by x-ray irradiation, while they are not perturbed by the less-energetic photons in the IR region.

Experimental investigation must be complemented by DFT and other model calculations, which help to shed light onto structure and properties of the molecule–surface system. For example, the following points can be addressed:

i) The nature of the intermolecular interactions at play in molecular layers at surfaces
ii) The structure of the layer
iii) For chiral adsorbates, the mechanisms by which the chirality at the molecular level is expressed in the 2-D system
iv) Chiral recognition.

The theoretical approach can bring spectacular breakthroughs in the description of adsorbed molecules and provide precious information to interpret experimental data and to better understand the structural and environmental factors affecting molecular adsorption and ordering on a surface. The first DFT studies of complex systems neglected Van der Waals interaction and were thus affected by a systematic error in their predictions; these forces are taken into account in the more modern functionals, thus increasing significantly also the quantitative agreement with the experimental data.

In this chapter we will provide a brief overview of this topic by presenting a few examples for significant categories of molecules and considering the nature of the interaction with the substrate and with the neighboring adsorbates. We will start describing the formation of covalent structures and the surface-assisted polymerization of organic compounds. Then, we will move to noncovalent, intermolecular bonding, analyzing first the case of self-assembled monolayers of thiol molecules and then focusing on small biological molecules, such as amino acids.

29.2 Organometallic Compounds and Covalent Bond Networks

Recent research interests in the field of surface-supported organic monolayers focus on two main topics: the growth of epitaxial grapheme [29.53, 54] and the production of surface covalent organic frameworks [29.13, 26, 55–57]. In fact, nowadays it is well established that bottom-up fabrication of surface nanostructures guarantees a final product of better quality in terms of uniformity, low defectivity and, hence, transport properties with respect to the top-down approach. In this frame, 1-D and 2-D organometallic compounds and coordination polymers have attracted large attention because they are often thermally more stable [29.10, 58] than structures based on the weaker electrostatic interactions or hydrogen bonds [29.59]. Organometallic structures may evolve into polymeric chains/networks through activated formation of new covalent bonds, while in other cases the covalent assembly forms without this intermediate step.

Most of this surface-confined chemistry has been directed by specific functionalization of the organic components—typically introducing halogen atoms or carboxylate, pyridyl, or carbonitrile functionalities—in order to create covalently bound macromolecular structures with controlled shape and size. The concept of surface-assisted covalent bonding is schematized in Fig. 29.2 for the tetra(4-bromophenyl)porphyrin (Br_4TPP) molecule [29.26]: a chemically stable, central molecular unit with a specific function (e.g., a peculiar electronic/magnetic/catalytic property) is equipped with several legs, some of which may be modified by the introduction of a functionalized termination. After thermal dissociation of the substituent atoms (either on the surface or in the evaporator), the monomer building blocks are connected with each other through the activated legs, directly on the surface, by thermal diffusion. The ability to design and synthesize molecules with a different number and relative arrangement of predefined connection points allows the construction of various topologies, such as dimers, linear chains and two-dimensional arrays. This is shown in the bottom part of Fig. 29.2 for tetraphenylporphyrin (TPP) modified with one, two or four Br terminations and deposited on Au(111). Upon sufficient heating, the molecules become activated and connect on the surface forming molecular arrays, the topology of which depends on the molecular design (Fig. 29.2b). If only one Br substituent is used (BrTPP), each building block provides only one reactive site and dimer formation occurs. If the porphyrin building blocks are modified with two Br atoms in a linear geometry (*trans*-Br_2TPP), long, linear chains are observed, while the use of four Br substituents (Br_4TPP) enables the construction of two-dimensional networks. Accordingly, no macromolecular structures can be formed starting from pure (i.e., nonhalogenated) TPP molecules. These results clearly show that the architecture of the nanostructures can be precisely controlled through the position of active endgroups in the chemical structure of the molecular building blocks. The covalent nature of the formed bonds is confirmed by DFT calculations and manipulation experiments.

If a similar process occurs with the participation of metal atoms, usually provided by the substrate, we assist with the formation of organometallic chains as those reported in the examples of Fig. 29.3 and in top panels of Fig. 29.4. *Fan* et al. [29.60] deposited 4,4″-dibromo-*meta*-terphenyl (DMTP; see Fig. 29.3c for the molecular structure) on Cu(111) at $T \geq 300$ K. DMTP dissociates by C–Br bond scission and the resulting *meta*-terphenyl fragments form stable organometallic structures based on C–Cu–C bonds. At RT (Fig. 29.3a), both cyclic oligomers of the type (*meta*-terphenyl-Cu)$_n$ (with $n = 6, 8, 14, 16, 18, 22$ marked by *arrows*) and zig-zag polymer chains form. The latter ones have a repeat unit length of 26.5 Å, are oriented $\pm 5.0°$ off the $\langle 0\bar{1}1 \rangle$ direction of the underlying Cu(111) substrate and can bend by angles of 60°, 120° or 180° (i.e., backfold). Islands formed by these chains are elongated

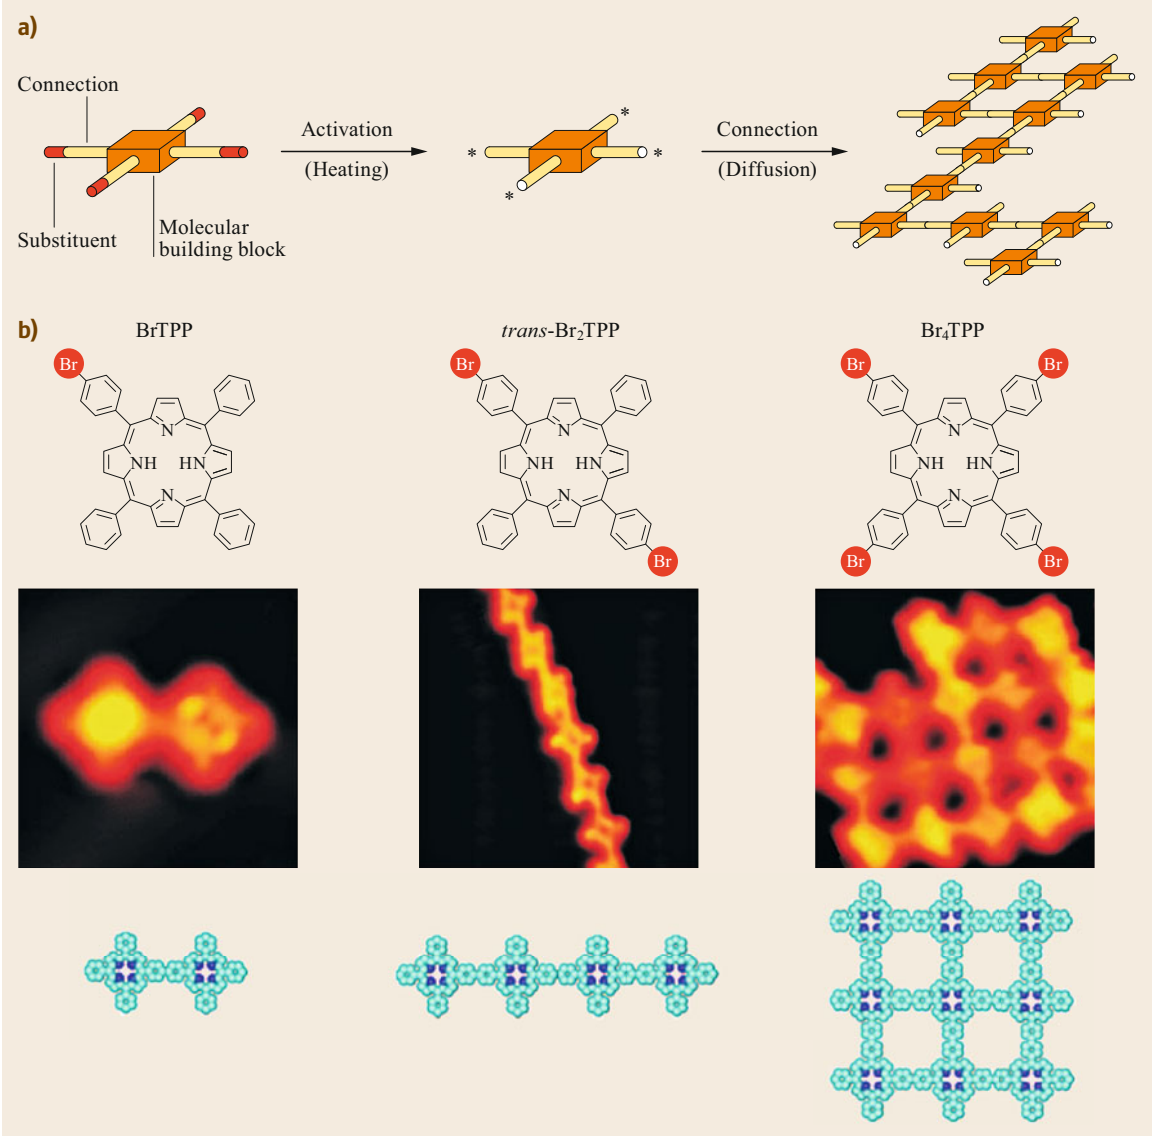

Fig. 29.2 **(a)** Schematic representation of the formation of covalently bound networks by connecting activated molecular building blocks. **(b)** Macromolecular architectures obtained from different TPP monomer building blocks modified with one, two and four Br substituents. The *top row* shows the chemical structure of the molecular precursors; the *middle row* reports detailed STM images of the nanostructures formed upon covalent bonding ($5 \times 5\,nm^2$, $10 \times 10\,nm^2$ and $8.5 \times 8.5\,nm^2$, respectively). The chemical structure of the final assemblies is schematized in the *bottom row*. (After [29.26])

along the chain direction. The Cu atoms involved in the metal–organic structure stem partly from the terraces, as witnessed by the formation of vacancy islands at high coverage. Macrocycles appear at room temperature and below, whereas only chains are formed at higher T (Fig. 29.3b). Such behavior indicates that chains are thermodynamically favored, probably because of the high packing density that is reached when they organize into islands and that allows a maximum of lateral van der Waals interactions. Finally, the evidence of C–Cu–C bond formation but not of direct C–C bond formation suggests that Cu adatoms participate in the C–Br bond scission, so that Br is directly replaced by Cu.

Halogenated (aromatic) hydrocarbons often form organometallic compounds with carbon–metal–carbon bonds. These nanostructures may then act as intermediates in the surface-assisted Ullmann reaction [29.62, 63] leading to the synthesis of covalent assemblies [29.57,

64–66]. This process consists of two steps since the dehalogenation of the precursor molecule and the formation of an organometallic intermediate with metal atoms extracted from the surface is followed by a surface-catalyzed C–C bond formation. Ullman coupling has been deeply investigated and exploited in several surface-mediated polymerization processes [29.51, 60, 67]. In fact, if additional energy is provided, dehydrogenation and C–C bond formation may occur and the formation of polymer chains or networks is observed [29.11, 68, 69]. Recently, this process has been exploited especially for the controlled growth of graphene nanoribbons (GNRs). These 1-D nanostructures are of extreme interest for the use of graphene-based materials in nanoelectronics because, contrary to extended graphene layers, they have a band gap. Since the latter depends on the width and on the edge geometry of the ribbons [29.13, 70], their fabrication presents strong requirements of uniformity and reproducibility, which are usually not satisfied by top-down fabrication methods [29.71, 72]. The bottom-up approach gives better results and, indeed, the synthesis of GNRs is a good example of surface-assisted covalent coupling. The large variety of studies performed evinces how the final product strongly depends on growth parameters as the nature and geometry of the substrate and the molecular structure. E.g., 10,10′-dibromo-9,9′-bianthryl (DBBA), a very common precursor used for the synthesis of $N = 7$ armchair GNRs, polymerizes into GNRs both on Au(111) and on Cu(111) but on the less-reactive substrate higher temperatures are necessary to activate the intermediate and final steps of the reaction [29.69]. On the other hand, the same thermal treatment that leads to GNR formation on Cu(111) produces quasizero dimension flat nanographene units on Cu(110) because, in this case, the Ullman coupling reaction is blocked by the strong anisotropy of the surface [29.73]. The nature of the molecule is another crucial ingredient to determine the geometry of the final self-assembled covalent structures and of the GNRs in particular. On Ag(111), straight $N = 7$ armchair GNRs can be fabricated starting from DBBA, while chevron-type GNRs with alternating widths of $N = 6$ and $N = 9$ are obtained using 6,11-dibromo-1,2,3,4-tetraphenyltriphenylene monomers [29.13]. Several aromatic molecules self-assemble in well-organized organometallic compounds [29.65, 74, 75] but only in a few cases complete dehydrogenation and C–C covalent bond formation are reported [29.11, 13, 57, 76]. Recently, a comparison between the thermal evolution of 5,11-dibromotetracene (DBT) [29.61] and of 1,6-dibromopyrene (DBP) [29.11] layers deposited on

Ag(110) has revealed a completely different behavior of these dihalogenated molecules, having very similar molecular weight but different conformation (Fig. 29.4). In both cases, debromination of molecules in contact with the metal substrate and formation of organometallic structures involving Ag adatoms occur already at RT. This is witnessed by the observation of elongated chains in the STM images (top row in Fig. 29.4a,b) and by the presence of Br–Ag and C–Ag components in the XPS spectra (bottom row in Fig. 29.4c,d). However, for DBT, organometallic dimers (as the one simulated in the top row in Fig. 29.4c) and trimers are the most common configurations at submonolayer coverage. Longer structures as those of the top row in Fig. 29.4a may be observed only at a nominal coverage close to 1 ML. Such features are stable up to $T = 300$ °C (bottom row in Fig. 29.4a), above which temperature the majority of the organic overlayer desorbs, as confirmed also by the significant reduction of the XPS intensity. On the contrary, at $\approx$ 300 °C the organometallic –DBP–Ag-chains disappear and the DBP monomers undergo further dehydrogenation and C–C coupling. Between 300 and 475 °C, GNRs are observed on the surface (bottom row in Fig. 29.4b), arranged in disordered patterns, in ordered arrays or in a polymer network depending on annealing temperature and preparation conditions. The graphenic nature of these ribbons is deduced from the up-shift towards 285 eV of the C 1s binding energy observed in the XPS spectra > 300 °C. Their internal structure could be determined by comparison of high-resolution STM images with the outcome of DFT simulations for a DBP trimer (top row in Fig. 29.4d).

The different results obtained in the experiments of Fig. 29.4 are explained considering that, for the DBT/Ag(110) system, significant substrate-precursor interaction leading to a flat-lying geometry and steric hindrance between the molecular units inhibit covalent coupling. Substrate directed adsorption between the $\langle 1\bar{1}0 \rangle$ atomic rows also suppresses dehydrogenative coupling at mild temperatures. This does not hold for DBP, which has a roundish shape. This result underlines the importance of geometrical and steric factors in the choice of the precursor molecule. In addition, as evident in the top row in Fig. 29.4d, the GNRs produced from the DBP precursor present a regular sequence of edge sites, with two zig-zag sites alternating to one armchair site. This opens the way to the perspective of tuning the shape and dimension of nanoribbons (and hence the correlated electronic properties) by choosing suitably tailored or purposefully designed molecular precursors.

As is evident from the previous examples, the use of halogenated precursors, as well as of molecules modified with other functionalized terminations, is very common. The presence of specific and often interlocking functional groups helps to achieve the assembly of a desired structure, e.g., by providing a privileged direction for new covalent bond formation. However, there are significant examples of organometallic structures and surface-assisted polymerization of nonfunctionalized molecules.

Schulz et al. [29.77] followed the synthesis of chiral GNRs on Cu(111) from three different bianthryl precursors (dibromo-, dichloro-, or halogen-free bianthryl) and found that, irrespective of the bianthryl precursor, the Ullmann route is inactive, and instead, identical chiral (3,1) GNRs are formed. This behavior, at variance with the one observed on the corresponding Ag and Au surfaces [29.13, 78], is due to the stronger molecule–surface interaction on Cu(111), which stabilizes the radical after halogen–carbon bond scission and reduces the energy barrier for C–H bond activation. Consequently, C–H bond activation occurs at a lower temperature than aryl–aryl coupling, resulting in similar intermolecular carbon–carbon bond formation for halogenated and nonhalogenated bianthryl species. The ring-closure reaction through cyclodehydrogenation yields, as a final product, the fully aromatic chiral GNR.

Haq et al. and *Hanke* et al. [29.10, 79] recently demonstrated that formation of organometallic

chains can be achieved with completely unfunctionalized porphyrins (H_2-porphyrin, Cu-porphyrin, Zn(II)-diphenylporphyrin and diphenylporphyrin) adsorbed on Cu(110) and subsequently heated to several hundred °C. Figure 29.5 shows the case of unsubstituted Cu-porphyrin. In a heat-to-connect assembly strategy, the surface was used as the only means to activate, connect, and direct the self-assembly into 1-D chains that are coupled by organometallic C–Cu–C bonds. In fact, the structures obtained after annealing to $T \geq 375\,°C$ are highly ordered and form one-dimensional chains on the surface only in the ⟨001⟩ direction (i.e., perpendicular to the Cu rows as shown in Fig. 29.5c). By combining STM analysis with DFT calculations and by considering several possible geometries, the authors explain this effect as related to the commensurability of the adsorbate with the surface. During the annealing process, several different porphyrin–porphyrin couplings occur with increasing numbers of connecting Cu adatoms. Extended 2-D assemblies were never observed but, at $T = 400\,°C$ (Fig. 29.5d), parallel chains could sometimes bind together forming fused double-rows, which are predicted to be the most stable adsorbate structure. Therefore, a chemical and energetic driving force toward a full two-dimensional self-assembly exists, though the process is self-limited to two to three parallel coupled chains. The impossibility of forming an extended 2-D pattern is explained in terms of the stress induced in the adsorbate by the self-assembly: only the ⟨001⟩ direction provides the proper lattice spacing that enables the molecule to fit without significant distortion. This result highlights the critical role of the Cu(110) surface structure in directing the assembly and opens perspectives in surface engineering.

29.3 Noncovalent Bonding

When noncovalent bonding occurs, self-assembly is driven by other kinds of interactions, which are usually weaker and mainly of electrostatic nature: ionic bonding, hydrogen bonding, Van der Waals interactions and, sometimes, long-range interactions mediated by the substrate. Except for the last one, all these forces

are also active in three dimensions and are responsible not only for the formation of molecular aggregates (e.g., the formation of molecular crystals) but also for the particular conformation of complex molecules (e.g., peptide or protein folding). The molecules within the noncovalent assembly can form a covalent bond with the substrate, as in the case of thiol SAMs [29.80–83] and of deprotonated amino acid species [29.18], or be physisorbed [29.84, 85]. The same molecular species can adsorb in either of the two chemical states depending on experimental conditions [29.36, 85].

The selectivity and directionality of hydrogen bonds [29.32] offer an excellent means for noncovalent synthesis [29.86] and for the formation of 2-D architectures on surfaces. Hydrogen-bonded nanostructures with distinct shape can be realized on surfaces starting from a wide variety of molecules, especially when exploiting suitable functional groups. The geometrical complementarity, promoting the formation of multiple weak linkages [29.86], is important and at the basis of molecular recognition phenomena. More generally, H-bridges can form between charged or polar moieties. Ionic bonds are expected to be stronger than H-bridges. This is, indeed, true in three dimensions, while for molecules supported on a metal surface they can be weakened by the presence of an appreciable screening effect.

Noncovalent self-assembly has been observed for many kinds of molecules. In the following we will briefly report a few examples of planar, extended π-systems, of thiol SAMs and of ordered patterns of small biological molecules, which we consider the most representative categories when discussing self-assembly phenomena at surfaces.

29.3.1 π-Conjugated Molecules

On appropriate substrates, π-systems adsorb in flat-lying geometries favoring lateral molecular recognition. If the molecules are modified with peripheral functional groups favoring H-bond formation, the supramolecular assembly process takes advantage of both the energetics and the directionality of H-bonding. Moieties for head-to-tail or lateral coupling have been tested and the results suggest that, in general, species with functional groups providing geometrical (steric) or electronic complementarity can be employed. A typical example is provided by carboxyphenyl-substituted porphyrins deposited on Au(111). These molecules interact with each other by forming a double H-bond bridge between the terminal carboxyl groups; depending on the number and position of carboxyl terminations in each porphyrin, two- or four-membered clusters are observed [29.87].

In the following we discuss the cases of trimesic acid [29.85] (TMA, 1,3,5-benzenetricarboxylic acid, $C_6H_3(COOH)_3$) and 4-[*trans*-2-(pyrid-4-ylvinyl)] benzoic acid [29.88] (PVBA), which represent prototype materials for supramolecular self-assemblies. Due to its trigonal structure, TMA is a model system for the understanding of supramolecular geometries in 2-D. PVBA, on the contrary, is a linear molecule and therefore tends to organize into 1-D structures. Presenting two chiral enantiomers when constrained in 2-D, it is of interest for the understanding of chiral recognition at surfaces.

In the temperature range $192\,\mathrm{K} < T < 280\,\mathrm{K}$, TMA on Cu(001) [29.85] forms islands of flat-lying molecules in which the honeycomb motif prevails, though some small areas of more densely packed molecules are always present (Fig. 29.6a–d). As represented in the scheme of Fig. 29.6d, the honeycomb superstructure is stabilized by hydrogen-bond-mediated dimerization of the self-complementary carboxyl groups. Due to the chemical activity of the Cu substrate, the low-temperature arrangement is substituted by stripe-shaped supramolecular structures if deposition is performed at $T = 300\,\mathrm{K}$ (Fig. 29.6e–g). This organizational change is associated with a deprotonation of the molecules, leading to carboxylate formation and an upright bonding geometry, as schematically shown in Fig. 29.6g.

The molecule 4-[*trans*-2-(pyrid-4-ylvinyl)] benzoic acid (PVBA; see Fig. 29.7a for the molecular structure of λ- and δ-enantiomers) was adsorbed at Au(111) and at Ag(111) surfaces [29.88] and it was demonstrated that chiral correlation can extend over mesoscopic length without intimate molecular contact.

When small amounts of PVBA are evaporated on the achiral surface, because of the stochastic nature of the deposition process, an equal and evenly distributed population of λ- and δ-species is expected. However, at RT PVBA molecules are quite mobile and they self-assemble in supramolecular twin chains stabilized by formation of hydrogen bonds (Fig. 29.7b). As evident from STM images, the constituent molecular rows can have two relative displacements, related by a mirror symmetry. Therefore, chiral recognition is active and the twin chains display supramolecular chirality. To understand the mechanism driving this chiral recognition process, molecular dynamics (MD) simulations based on a force field were performed. The most stable configuration, schematized in Fig. 29.7b, is the one in which the chains are stabilized by strong head-to-tail OH$\cdots$N hydrogen bonds between PVBA endgroups. In addition, antiparallel arrangement of adjacent rows and their relative shift allows the negatively charged double-bonded O atoms to point towards the pyridile moiety of the
