Springer Handbook of Surface Science

Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical and applied sciences. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of scientific and technical information.

The volumes are designed to be useful as readable desk book to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Springer Handbook of Surface Science

Mario Rocca, Talat S. Rahman, Luca Vattuone (Eds.)

With 840 Figures and 66 Tables

Dedicated to the memory of Gian Paolo Brivio

Foreword

The study of processes on well-defined solid surfaces is a relatively young discipline. It first gained prominence during the 1960s, when the advent of ultrahigh vacuum technology enabled the production and maintenance of clean and well-defined ordered single-crystal surfaces of solids. The first issue of the journal *Surface Science* appeared in 1964; by the end of 2018, around 680 volumes of this journal had been published, reflecting the enormous growth of this field. This period also saw the development of a wide variety of experimental techniques enabling the investigation of different aspects of the energetic, kinetic, structural, electronic, magnetic, and dynamic properties of surfaces with great accuracy. The advent of scanning probe methods allowed atomic processes to be studied in unprecedented detail.

More recently, the study of "real" surfaces at elevated pressures became possible, which has since developed into a mature field of research ranging from phenomena associated with nanotechnology and thin-film formation to the heterogeneous catalysis of industrial processes.

The present handbook consists of contributions written by numerous experts in this field and covers the main aspects of this fascinating branch of science. It should prove invaluable to all those interested in this discipline.

Gerhard Ertl

Gerhard Ertl, recipient of the 2007 Nobel Prize in Chemistry for his studies of chemical processes on solid surfaces

Preface

Surfaces have always attracted the attention and curiosity of humans, since they define the outer limits of objects—those that we can see with our eyes and feel with our hands. One of the earliest mentions of surfaces in the literature was a comment by Pliny the Elder, who reported that choppy waves at the surface of the sea could be calmed by pouring oil on the water. This observation was later also made by Benjamin Franklin, who mentioned that a spoonful of oil could cover a lake. Unfortunately, he did not perform the easy calculation which would have told him that the sea would then have been covered by a film one molecule thick. When studying earthquakes, Thomas Strutt—also known as Sir Rayleigh—noticed that the greatest destruction was caused by surface waves, because they shake buildings laterally. At the beginning of the nineteenth century, Berzelius became fascinated by surfaces because they are the sites for chemical reactions and useful catalytic processes. Later on, electronic surface states came to the forefront when an understanding of the junctions between differently doped semiconductors was needed to realize the transistor. However, it was only after the Second World War that scientists began to comprehend the behavior of surfaces at the atomic scale, due to the development of clean vacuum systems that allowed well-defined surfaces to be prepared and kept clean for long enough to permit their characterization. It soon became clear that surfaces are not simply discontinuations of crystals; they can include rather complicated structural reconstructions. Catalytic activity is often facilitated by these reconstructions, as well as defects in the outermost atomic layers of a body. On the other hand, a theoretical understanding of surfaces at the atomistic limit also became possible during this period due to the availability of inexpensive computing power that allowed the simulation of more and more atoms, thus loosening the restrictions imposed by the application of periodic boundary conditions, which—by definition—do not hold at surfaces and interfaces.

Nowadays, there is a vast community of surface scientists comprising physicists, chemists, and materials scientists and engineers. The wide range of backgrounds of surface scientists is advantageous, as it means that different surface scientists will approach the same problem in different ways. Once the simple systems were understood, more complex and thus more realistic situations could be addressed on a knowledge basis.

Indeed, it is difficult to imagine how nanotechnology could have developed as it has without a background knowledge of surface science. Surfaces are used as templates to grow films just one or a few monolayers thick, as well as nanoparticles and nanowires that are used for catalytic and electronic applications. Issues as complex as biofouling and biocompatibility, involving adsorbates consisting of millions of atoms, can be tackled using surface science. Lately, interest has focused on the fantastic properties of purely two-dimensional materials: sheets of atoms without any underlying volume. Their properties were found to be different from those of a surface of the same material in bulk form (e.g., graphene versus a graphite surface). This led to the discovery of new phenomena with the potential for novel applications.

There are approximately 40 chapters in this Handbook, to which over a hundred scientists, physicists, chemists, and engineers have contributed. The authors are distributed across different countries and continents and belong to strongly interdisciplinary groups. The Editors embarked on this adventure in 2015, sending out the first invitations in 2016. This work constitutes a milestone in the field of surface science. It should help young people who are entering the field while also providing a useful base that allows expert colleagues to assess the state of the art. We hope that this Handbook will stimulate further interest in surface science and that its readers will find it as useful as we believe it to be.

This Handbook is dedicated to Professor Gian Paolo Brivio, who wrote one of its chapters together with Guido Fratesi, and who unfortunately passed away on May 25th, 2020.

Gian Paolo graduated with a PhD in physics in 1973 under the supervision of Professor Giorgio Benedek at the University of Milano. After performing postdoctoral research at the University of Liverpool with Professor T.B. Grimley, he returned to Milano and started his academic career at the University of Milano. In 1986 he became Associate Professor in Condensed Matter Physics, after which he moved to the Department of Materials Science at the University of Milano-Bicocca, where he was promoted to Full Professor in 2000.

All three Editors of the present Handbook met him for the last time at the workshop on Atoms and Molecules on Solid Surfaces (AMOSS) in Milano, on his 70th birthday.

His contributions to surface science focused on the theoretical treatment of the dynamics of gas–surface in-

teractions (sticking, scattering, desorption), and more recently on the application of density functional theory to more realistic adsorption conditions. To this end, he investigated magnetic effects in the interactions of molecules with graphene and the adsorption of organic molecules on solid surfaces, concentrating on the role played by excited states and the timescales over which the molecule–surface interaction takes place.

He published around 120 papers in peer-reviewed journals, and reported his results in over 130 contributions and invitations to conferences and seminars at research institutions all over the world. He always prized scientific collaborations, and served as a Visiting Professor in Germany, Canada, and USA. He also prided himself on nurturing the next generation of scientists. For this reason, in 2006 he promoted the foundation of a European network for doctorates in the physics and chemistry of advanced materials—a network that currently includes fifteen universities from nine different countries and promotes internationalization through the exchange of students and teachers.

Gian Paolo took pleasure in organizing thematic conferences and workshops, paying tremendous attention to scientific, cultural, and artistic details that made the events memorable for all participants. The Editors of this Handbook fondly remember the 4th Vibration and Surfaces Meeting in Santa Margherita that Gian Paolo organized with Mario Rocca in 1992, the Summer School in Erice that he organized with Luca Vattuone in 2008, and the 17th Workshop on Dynamical Phenomena at Surfaces that he organized with Talat Rahman in Milan in 2016. In his true form as a scientist, a scholar, and a man of art, Gian Paolo also served as the external evaluator for the doctorate thesis of Luca Vattuone in 1995. Gian Paolo's passion for science, his warm personality, his thoughtful nature, and his desire to touch the lives of others made moments with him memorable.

We will miss his enlightened way of thinking and his humanity.

Summer 2020

About the Editors

Mario Rocca is an experimental physicist, working on the experimental measurement of surface phonon spectra, conventional and acoustic surface plasmon dispersion, and gas surface interaction. He graduated in Physics from the University of Genova. He received his PhD from RWTH Aachen. He was a research staff member at the University of Genoa from 1984 to 1992. In 2001, he became a Full Professor for Condensed Matter Physics. Mario Rocca is Vice Chair of the Surface Science Division of the International Union for Vacuum Science, Techniques, and Application (IUVSTA) and a member of the scientific board of the Italian Union of Scientists for Disarmament. He was Editor of the journal Surface Science Reports until 2018 and is currently Editor of Applied Surface Science and of the Springer Series in Surface Science.

Talat S. Rahman is Pegasus Professor at the Department of Physics at the University of Central Florida. She received her PhD from the University of Rochester and has held various academic positions, among which were positions at UC Irvine and Kansas State University, where she was the first female faculty member in the Physics Department. Her impressive list of visiting appointments includes stays at the MPI for Solid-State Research in Stuttgart, Germany, EPFL Lausanne, Switzerland, and the Brook Haven National Laboratory, USA. Talat Rahman has received numerous fellowships, including an Alexander von Humboldt Research Fellowship. Her research focus is multiscale modeling of chemical reactions and related phenomena at surfaces. She contributes actively to reforming STEM education, supporting women and minorities in STEM. She serves on the editorial board of Journal of Physics Condensed Matter.

Luca Vattuone has been Associate Professor of Condensed Matter Physics at the University of Genova since 2012. After graduating in physics from the University of Genoa, he received his PhD in Physics for his work on the sticking probability of oxygen on silver surfaces employing a molecular beam and for the EEL spectrometer he designed. He was a researcher in the group of D.A. King at the University of Cambridge, as well as the University of Genoa and INFM. His research activity focussed on the investigation of gas-surface interaction by high-resolution electron energy loss spectroscopy, supersonic molecular beams, and single-crystal calorimetry. He is currently Coordinator for the Material Science Courses of the University of Genova.

Part F Lattice Dynamics

Part G Gas Surface Interaction

List of Abbreviations

2-DBZ	2-D Brillouin zone
2DEG	two-dimensional electron gas

A

ADF	annular dark-field
AES	Auger electron spectroscopy
AFM	atomic force microscopy
AIMD	ab-initio molecular dynamics
ALDA	adiabatic local density approximation
ARPES	angle-resolved photoemission spectroscopy
ASP	acoustic surface plasmon

B

bcc	body-centered cubic
BCCF	bond-counting contribution factor
BCM	bond charge model
BCSOS	body-centered solid-on-solid
BEP	beam equivalent pressure
BNN	bulk nearest neighbor
BOA	Born–Oppenheimer approximation
BZ	Brillouin zone

C

CAGR	compounded average growth rate
CAICISS	coaxial-impact-collision ion scattering spectroscopy
CARS	coherent anti-Stokes Raman scattering
ccp	cubic close packed
CDW	charge-density wave
CMOS	complementary metal–oxide–semiconductor
CMSA	corrugation-mediated selective adsorption
CNT	carbon nanotube
CPM	Car–Parrinello method
CPO	catalytic partial oxidation
CTF	contrast transfer function
CVD	chemical vapor deposition

D

DEF	disordered even flat
DEMS	differential electrochemical mass spectrometry
DFT	density functional theory
DLC	diamond-like carbon
DOS	density of states
DRRS	double-resonance Raman scattering
DRS	differential reflectance spectroscopy
DW	Debye–Waller

E

EAM	embedded-atom method
ED-GIXRD	energy-dispersive grazing incidence x-ray diffraction
EDX	energy-dispersive x-ray analysis
EELS	electron energy-loss spectroscopy
ELS-LEED	electron energy-loss-low-energy electron diffraction
EMT	effective medium theory
EPI	electron–phonon interaction
EPR	electron paramagnetic resonance
ERDA	elastic recoil detection analysis
ESR	electron spin resonance
EXAFS	x-ray absorption fine structure

F

FBZ	first Brillouin zone
fcc	face-centered cubic
FESEM	field-emission scanning electron microscopy
FET	field-effect transistor
FFT	fast Fourier transform
FLAPW	full-potential linearized augmented plane wave
FM	ferromagnetic
FMR	ferromagnetic resonance
FTIR	Fourier transform infrared
FWHM	full width at half maximum

G

GGA	generalized gradient approximation
GIXD	grazing incidence x-ray diffraction
GNR	graphene nanoribbon

H

h-BN	hexagonal boron nitride
HAS	helium atom scattering
hcp	hexagonal close-packed
HF	Hartree–Fock
HOMO	highest occupied molecular orbital
HOPG	highly oriented pyrolytic graphite
HREELS	high-resolution electron energy-loss spectroscopy
HRLEED	high-resolution low-energy electron diffraction
HRSEM	high-resolution secondary-electron microscopy
HRTEM	high-resolution transmission electron microscopy

I

ICISS	impact-collision ion scattering spectroscopy
ICP	inductively coupled plasma
IETS	inelastic electron tunneling spectroscopy
IMFP	inelastic mean free path
IPES	inverse photoemission spectroscopy
IRAS	infrared reflection absorption spectroscopy
ISS	ion scattering spectroscopy
IXS	inelastic x-ray spectroscopy

J

JDOS	joint density of states

K

KS	Kohn–Sham

L

LDA	local density approximation
LDOS	local density of states
LEED	low-energy electron diffraction
LEEM	low-energy electron microscopy
LEIS	low-energy ion scattering
LSDA	local spin density approximation
LUMO	lowest unoccupied molecular orbital

M

MAS NMR	magic-angle spinning nuclear magnetic resonance
MBE	molecular beam epitaxy
MCA	magnetocrystalline anisotropy
MCD	magnetic circular dichroism
MD	molecular dynamics
MDC	momentum distribution curve
MEIS	medium-energy ion scattering
MEMS	microelectromechanical system
MFA	mean-field approximation
MFM	magnetic force microscopy
ML	monolayer
MOF	metal–organic framework
MOKE	magneto-optic Kerr effect
MOSFET	metal–oxide–semiconductor field-effect transistor
MPA	magnetic prism array
MSHD	mean square height difference
MSHG	magnetic second harmonic generation
MTJ	magnetic tunnel junction

N

NAP	near-ambient pressure
NC-AFM	noncontact atomic force microscopy
NEXAFS	near-edge x-ray absorption fine structure spectroscopy
NIS	neutron inelastic scattering
NP	nanoparticle
NRA	nuclear reaction analysis
NW	nanowire

O

OLED	organic light-emitting diode
ORR	oxygen reduction reaction
OSA	order-sorting aperture

P

PAW	projector-augmented wave
PBE	Perdew–Burke–Ernzerhof
PCM	phase-change material
PDOS	projected density of states
PED	photoelectron diffraction
PEEM	photoelectron emission microscopy
PES	photoemission spectroscopy
PES	potential energy surface
PIXE	particle-induced x-ray emission
PLD	pulsed laser deposition
PMCS	pulsed microplasma cluster source
PPP	pseudopotential perturbation
PSD	position-sensitive detector
PSF	point spread function
PVD	physical vapor deposition

Q

Q2-D	quasi two-dimensional
QAH	quantum anomalous Hall
QC	quasiclassical
QENS	quasielastic neutron scattering

Part A Kinetics a

Part A Kinetics and Thermodynamics at Surfaces

Part A deals with surface thermodynamics and kinetics. These are the phenomena that lead to the equilibrium configuration of the surface and imply additional degrees of freedom as compared to bulk thermodynamics; e.g., the surface area may vary, affecting the crystal shape, and the broken symmetry in the direction normal to the surface may lead to new excitations and surface-localized phenomena. Indeed, the structure of a real surface, as imaged by scanning tunneling microscopy or inferred from diffraction experiments, can be quite different from that expected from the ideal truncation of the solid. These features may not be surprising if the system is out of equilibrium, but could be unexpected under equilibrium conditions.

If we want a faithful and not oversimplified picture, we must think of the surface as a dynamic entity in which the positions of the atoms are neither constant in time nor perfectly periodic in space, even under equilibrium conditions. The former phenomenon may be due to the diffusion of atoms, while the latter corresponds to the formation of a rough surface (atoms at the lattice positions parallel to the surface plane but displaced randomly in height) or surface melting (atoms at random positions with respect to all directions), which are frequent phenomena at temperatures close to the melting point of the solid. The surface is also home to a variety of localized excitations that have their own manifestations in the physical and chemical properties of surfaces, as will be seen.

The theoretical framework is provided by equilibrium surface thermodynamics. The surface free energy is therefore the main thermodynamic potential to consider when seeking deeper insights into the overall phenomenology.

Chapter 1 describes the roughening transition from both theoretical and experimental points of view. Although solid surfaces often seem to be rougher at low than at high temperatures, this observation corresponds to nonequilibrium situations in which the surface atoms did not have sufficient time to reach the minimum energy configuration. The opposite holds true under equilibrium conditions, and surfaces may undergo a roughening transition at high temperatures that is characterized by the onset of divergence in the height-height correlation of the lattice positions. The same happens for steps: above the roughening transition they will not be straight but wavy, and they appear frizzy to scanning tunneling microscopy inspections. The first part of the chapter provides a theoretical description of the roughening phase transition, while the second part exploits the sensitivity of diffraction to disorder and provides examples of such transitions for low and high Miller index surfaces.

Chapter 2 is devoted to diffusion and the latest theoretical as well as experimental techniques that are used to study it. The chapter first describes elementary diffusion processes on flat and stepped surfaces, and then discusses the long-term behavior resulting from the combination of elementary steps. Two main approaches are used: those based on single particle motion and collective diffusion. The former approach concentrates on the motions of single adatoms or adsorbates, while the latter focuses on the decay of long-wavelength density fluctuations over time. An overview of available experimental techniques for surface diffusion measurements is also provided; in particular, the recently developed helium spin-echo technique is described.

Chapter 3 provides an overview of surface thermodynamics. First, a summary of bulk thermodynamics is provided and the main surface thermodynamic functions are introduced. Then the chapter anticipates the surface nomenclature and reviews some of the most widely used theoretical approaches. The key quantity here is the surface free energy, which includes the contributions from vibrational and configurational entropy. In the second part of the chapter, many examples of the vibrational density of states and the thermodynamic functions for both low and high Miller index surfaces are provided.

1. Roughening Transition: Theories and Experiments

Gianangelo Bracco, Andrea Claudio Levi

This chapter deals with the thermal phenomenon of equilibrium roughening, which is a genuine phase transition, with no counterpart in the bulk. Although the transition is a weak (infinite order) transition, it affects the growth of crystals and their equilibrium shape: a facet disappears above T_R.

The first part of the chapter is devoted to the description of the theories of roughening, starting with the BCF article and reviewing the work of many research groups that contributed to the foundation of the theory, and refering the reader to recent review articles for more advanced contributions. The second part of the chapter contains a review of the experimental investigations showing results that support the existence of a roughening transition and introducing the reader to the experimental problems of these studies.

1.1 Overview

Thermal roughening is a phase transition occurring on the surface of a crystal. Usually, the surface considered separates the solid from a gas (or vacuum) phase. An exception is helium, where the solid exists only at elevated pressures and the surface separates it from a liquid phase (we will briefly deal with the helium case in Sect. 1.10.1). As was shown already in 1951 by *Burton*, *Cabrera*, and *Frank* in their famous article (BCF) [1.1], a clean surface can exist in two different states: smooth and rough. At low temperatures the surface is smooth, and goes over to the rough state at a well-defined roughening temperature T_R. There is immediately here an apparent paradox. Experimentally, solid surfaces very often seem to be rougher at low T than at high T; but this is a nonequilibrium effect: disorder is frozen at low T. In equilibrium the opposite happens, and roughening occurs with rising temperature. The present chapter deals only with the latter phenomenon, equilibrium roughening, which is a genuine phase transition, with no counterpart in the bulk. Recently, an interesting theoretical overview of roughening was presented by *Akutsu* and *Yamamoto* [1.2]. For the somehow related subject of the equilibrium shape of crystals we refer the reader to the exhaustive review article by *T. Einstein* [1.3]. Many interesting contributions to the theory of roughening were presented at the Erice School in 1990 and are contained in the book by *Taub* et al. [1.4]. An up-to-date, advanced theoretical review of surfaces, both in equilibrium and out of equilibrium, was recently published by *Misbah* et al. [1.5]. This goes, however, beyond the limited scope of the present chapter, and many interesting topics presented there will not be discussed here.

1.2 Theoretical Considerations

Probably the most famous article on the theory of crystal growth was the above-mentioned BCF, recently reanalyzed by *Woodruff* [1.6]. But BCF's paper has an unusual structure: it is composed, actually, of two different articles. The first part, written by Frank, and known as a Bible to the students of crystal growth (as much as BCS's paper to those of superconductivity), contains the model of spiral growth around a screw dislocation, which solved the paradox, then quite puzzling, of layer-by-layer growth (which takes place even under such low disequilibria that the growth rate would be impossibly slow in terms of classical nucleation theories). The second part, written by Burton and Cabrera, discusses in detail the hypothesis of a roughening transition. Burton and Cabrera's starting point is a fundamental difference between two $(1+1)$ and three $(2+1)$ dimensions. In two dimensions, the separation element between two phases is a line. At $T=0$ it would be a straight line; but as the temperature increases point defects accumulate along the line, in the form of kinks, so that at any $T>0$ the line wanders away from the straight line and has a rough appearance. Not so in three dimensions. Here the separation element between two phases is a surface, reducing to a plane for $T=0$. But the defects that might roughen the surface are not point defects like the kinks along a line; they are steps, essentially infinitely long steps. And step creation is an energetically costly process, virtually impossible at low T, where, indeed, the most likely defects are point defects (adatoms, vacancies), irrelevant from the point of view of roughness. Thus, the surface remains smooth until T becomes so high that dangerous defects (i.e., steps) can form. At a certain point the steps multiply and the surface roughens, but this can only happen at a well-defined transition temperature T_{R}, the roughening temperature.

Roughening can be seen in the perspective of the γ-plot, i.e., of the orientational dependence of the surface free energy. The γ-plot is a polar representation of that dependence, where a surface is constructed in an abstract space by drawing vectors from the origin such that the length of a vector is proportional to the surface free energy γ per unit area for a surface perpendicular to that vector. The γ-plot is a highly singular object, since it is in principle nowhere differentiable; it has an inward cusp at every orientation characterized by a set of integer Miller indices: such orientations are dense on the solid angle. The strength of the cusp, however, decreases rapidly with increasing Miller indices (according to a fourth-power law), so that the only relevant cusps are those corresponding to low Miller indices (singular surfaces). Thus, the γ-plot resembles a raspberry, with inward cusps at the high-symmetry directions (Frank's raspberry) [1.6, 7]. In the equilibrium shape of a little crystal, corresponding to the strong inward cusps of the γ-plot, plane facets appear, whose angular extension is a monotonically increasing function of the strength of the cusps. As the temperature is increased, the inward cusps become less pronounced, until they disappear altogether and are replaced by rounded minima. The disappearance of a cusp in the γ-plot implies the disappearance of the corresponding face in the equilibrium shape of a little crystal. It also implies roughening of the corresponding surface of a large crystal. It should be mentioned that, for many purposes, the important quantity is not γ, but the *stiffness* $\tilde{\gamma}$, where

$$\tilde{\gamma} = \gamma + \frac{\mathrm{d}^2\gamma}{\mathrm{d}\phi^2}\,, \tag{1.1}$$

with ϕ being the azimuth [1.8]. In fact, the surface curvature is determined by the local stiffness, as was shown in 1951 by *Herring* [1.9]. Important contributions to the physics of roughening were presented by *Bienfait* [1.10], *Wortis* [1.11], *van Beijeren* and *Nolden* [1.12], *Lapujoulade* and *Salanon* [1.13], and others.

Burton and Cabrera's theory was convincing as a matter of principle, but in detail was not correct. They assumed a finite number of surface levels (in the case of two levels, they could use the well-known results of the two-dimensional Ising model), while in fact for a correct theory an infinite number of levels is essential. This advancement was obtained in the 1970s. Even before the formulation of an exact model, a number of mathematical theorems clarified the situation:

1. Dobrushin's theorem proved Burton and Cabrera's basic assumption for the Ising model in 3 $(2+1)$ dimensions: there exists a temperature $\hat{T}$ such that the surface is smooth for $T<\hat{T}$ [1.14].
2. Gallavotti's theorem proved the contrary in 2 $(1+1)$ dimensions: the separation line between two phases of the Ising model is always rough for any $T>0$ [1.15].
3. Van Beijeren's theorem showed that Dobrushin's temperature $\hat{T}$ is not less than the transition temperature of the corresponding two-dimensional Ising model [1.16].

Then a decisive step forward was made by *van Beijeren* himself in 1977 [1.17]. He succeeded in mapping a surface model (the body-centered solid-on-solid or BCSOS model) onto a special, antiferroelectric case of

the 6-vertex model, whose phase diagram was known. This proved explicitly the existence of the roughening transition in an exactly solvable statistical-mechanical model and, moreover, gave the mathematical properties of the transition. These properties are very interesting. Roughening, indeed, belongs to the class (studied by *Kosterlitz* and *Thouless* [1.18], who have just received the Nobel prize, to a large extent for this discovery) of topological, two-dimensional transitions whose free energy, although nonanalytical, is continuous at the transition with all its derivatives. Kosterlitz and Thouless discuss a number of extremely weak, infinite-order phase transitions in two dimensions (the Coulomb gas, a system of dislocations, the magnetic XY model, the two-dimensional crystal, the neutral superfluid). In most of these cases (notwithstanding the differences among the different systems) there is a transition from an ordered state below T_c to a disordered situation above; but the ordering below T_c is very different and weaker than the conventional ordering typically occurring in three dimensions. The two-dimensional, topological ordering is related, not to a two-point correlation function, but to the behavior at long distances. A general review of statistical mechanics involving Kosterlitz–Thouless (KT) transitions has recently been presented in an illuminating article by *Kosterlitz* himself [1.19]. Roughening belongs to this class of transitions.

For a general surface, it is not very easy to give a rigorous definition of roughness. Indeed, when a solid is in equilibrium with its vapor, an atom may belong to either phase, and the surface is not perfectly sharp. A simple approximation, where the surface is perfectly sharp and where the roughness may be easily defined, is the so-called solid-on-solid (SOS) model. This model in (x, y, z) space is such that the atoms are arranged in columns defined by x and y coordinates: in each column atoms belong to the solid up to a maximum $z = \zeta(x, y)$, while for $z > \zeta$ they belong to the vapor (solid-on-solid, indeed, means that below every solid atom there are only solid atoms, thus the model neglects vacancies in the crystal, as well as overhangs in the surface and flying atoms in the vapor). The difference between smooth and rough can be written in terms of $\zeta(x, y)$.

Considering two points with coordinates (x_1, y_1) and (x_2, y_2), the mean square height difference (MSHD) $\langle[\zeta(x_2, y_2) - \zeta(x_1, y_1)]^2\rangle = g(x_1, y_1, x_2, y_2) > 0$ depends on the difference of coordinates between the two points (in particular on their distance R on the surface). Now, when R tends to infinity, two cases are possible: either g tends to a finite limit g^* (it is easy to see that $g^* = 2\sigma^2$, where σ is the root mean square fluctuation of surface levels) in which case the surface is smooth and characterized by moderate oscillations around a mean plane; or g tends to infinity, and the surface is rough: for a rough surface no mean plane can be defined. It is thus clear that the distinction between smooth and rough is an asymptotic property.

For a surface or an interface which does not possess the SOS property, the concepts of smooth and rough may still be defined, but more caution is necessary. Let S be an infinite set (the solid) whose points fill most of the half-space $z < 0$, but are present sporadically also for $z > 0$. Let P_0 be a point in the plane $z = 0$, with coordinates $(x_0, y_0, 0)$; then for any radius R and level h the number of points of S, with coordinates (x, y, z), such that $(x - x_0)^2 + (y - y_0)^2 < R^2$ and $z > h$, will be a finite number $N(R, h)$, tending to 0 as h tends to infinity. Then for any small number ϵ and for any R there will be a level $\hat{h}$ such that, if $h > \hat{h}$, $N(R, h) < \pi R^2 \epsilon$. If this behavior is uniform (i.e., if $\hat{h}$ may be chosen to depend only on ϵ but not on R) the surface or the set S will be called smooth (at least at P_0). Otherwise we will be forced to allow $\hat{h}$ to increase and to diverge with R: then we will say that the surface is rough, and the nature of the roughness will be characterized mathematically by the diverging behavior of $\hat{h}$.

These geometrical definitions of roughness and roughening have an energetic counterpart. The creation of a step is energetically costly. This is true at $T = 0$, and remains true as long as the steps are few. But when they become really numerous (i.e., when the surface roughens), adding one more step makes no difference, so that the step free energy per unit length (i.e., the work necessary to nucleate it) vanishes at T_R. It is energetically favorable for a vicinal surface (i.e., for a surface forming a small angle θ with a high-symmetry surface) to form terraces of the high-symmetry surface, separated by regularly spaced steps. Then, if the surface free energy (per unit area) of the high-symmetry surface is γ_0, that of the vicinal surface is given by $\gamma = \gamma_0 \cos\theta + (\beta/a)|\sin\theta|$ where a is the step height and $a/|\sin\theta|$ the spacing between steps, and where β is the step free energy per unit length. The presence of the absolute value $|\sin\theta|$ determines a slope discontinuity in the γ-plot. At T_R, β vanishes and the slope becomes continuous. This determines both a continuity of the free energy derivative (actually, also of all higher order derivatives), and the disappearance of the corresponding facet in the equilibrium shape of a little crystal.

Much theoretical work on roughening has been done for the SOS surface models. *Chui* and *Weeks* introduced in 1976 [1.20] an important (and partly solvable) model, the DGSOS model and showed that the DGSOS partition function is a version of the SOS Hamiltonian in the form

$$H = J \sum_j \sum_\delta [m_{(j+\delta)} - m_j]^2 + J' \sum_j [m_j]^2 \qquad (1.2)$$

(this version, because of the Gaussian dependence of the Boltzmann factor, is called the Discrete Gaussian SOS model, or DGSOS), where the integer m_j defines the height of the SOS column j. The first term describes the interaction between the columns (i.e., the cost of steps), while the second term has merely the effect of anchoring the surface in the neighborhood of $m = 0$. In the DGSOS model, of course, the levels m are discrete, corresponding to crystallographic positions. If all real values of m were allowed and the sums were replaced by integrals, the so-called Continuous Gaussian (CG) would be obtained: the CG model had been solved by *Berlin* and *Kac* [1.21] as early as 1952, but the CG model is always rough at any positive T and has no transition. Now Chui and Weeks were able to prove that the DGSOS partition function is the product of the CG partition function (which has no singularities) times the partition function of the two-dimensional Coulomb gas, studied, e.g., by Kosterlitz and Thouless, so that the roughening transition of the DG model turns out to be isomorphic to the dielectric-plasma transition of the latter (with, however, a reversal of temperatures: the low-T dielectric corresponds to the high-T rough surface and the high-T plasma to the low-T smooth state). Then the critical properties of the Coulomb gas carry over to the surface case: the transition is extremely weak (infinite order); the maximum in the specific heat, which for the Coulomb gas took place after the transition, while the system was already a plasma, now takes place before the transition, while the surface is still smooth. But probably the most relevant result that Chui and Weeks drew from their mapping on the Coulomb gas refers to the asymptotic behavior of the correlations. The MSHD (bounded in the smooth state) diverges in the rough state, but only logarithmically: this very weak divergence, basically due to topology, is characteristic of two dimensions and contrasts sharply with the linear (Markovian) divergence of the mean square displacement in one dimension.

Chui and Weeks' roughening theory was a major step forward. But, since the two-dimensional Coulomb gas had not been solved completely, so neither was their DGSOS model: in particular, T_R was not known. Therefore van Beijeren's achievement, who (as mentioned above) mapped a somewhat similar roughening model, which he called the body-centered solid-on-solid (BCSOS) model, onto a completely solved model of statistical mechanics, the 6-vertex model [1.22], was important. Van Beijeren considered the (100) surface of a body-centered cubic lattice, where two sets of atoms forming two sublattices, corner atoms and center atoms, appear. By construction the projection of every corner atom onto the surface plane has only projections of center atoms as two-dimensional nearest neighbors, and vice versa. Thus the (100) surface is identified as

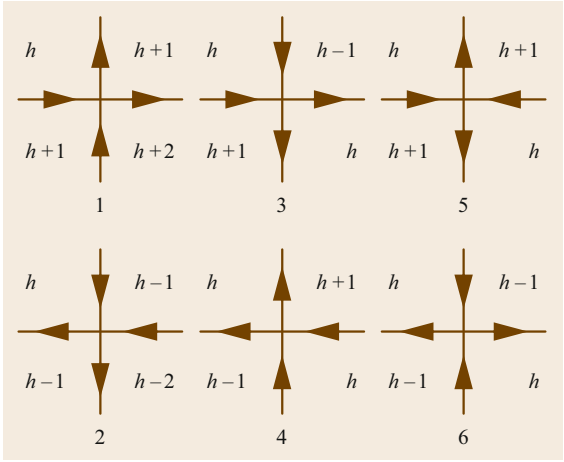

Fig. 1.1 The six vertices. For each vertex the corresponding height configuration that obeys van Beijeren's mapping is indicated

a square lattice, turned 45° with respect to the cube sides. Moreover, the level difference between two nearest neighbors is always exactly half a cube side (this can be used as height unit). Then it is possible to apply van Beijeren's mapping, where across the bond connecting the projections onto the surface plane of two surface nearest neighbors an arrow is drawn such that the higher atom lies, e.g., to the right of the arrow. At each point of the dual lattice four arrows meet, obeying the so-called *ice rule* that two arrows are pointing in and two out. But these are exactly the conditions defining the 6-vertex model of statistical mechanics (describing *two-dimensional ice* and two-dimensional ferroelectrics; this electrostatic interpretation has nothing to do with the Coulomb gas).

About the latter model, solved in the 1960s by the *Yangs* [1.23–25], *Lieb* [1.26–28], *Wu* [1.29] and *Sutherland* [1.30], nearly everything is known [1.22]. The six vertices, shown in Fig. 1.1, describe the six possible arrangements at the meeting of four arrows obeying the *ice rule*. To the arrows energies ϵ_j are associated, where j varies from 1−6. The simplest and most important situation is that of the symmetric 6-vertex model, where $\epsilon_2 = \epsilon_1, \epsilon_4 = \epsilon_3, \epsilon_6 = \epsilon_5$; in this case three Boltzmann factors $a_j = \exp(-\epsilon_j/(kT))$ suffice and, in fact, all physical properties are determined by the parameter

$$\Delta = \frac{a_1^2 + a_3^2 - a_5^2}{2a_1a_3} \,. \tag{1.3}$$

In the surface interpretation a smooth surface corresponds to Δ strongly negative (in the electrostatic interpretation, to antiferroelectricity); the ideal situation at $T = 0$ implies that all vertices are 5 and 6, hence Δ is $-\infty$; increasing T Δ increases, and roughening cor-

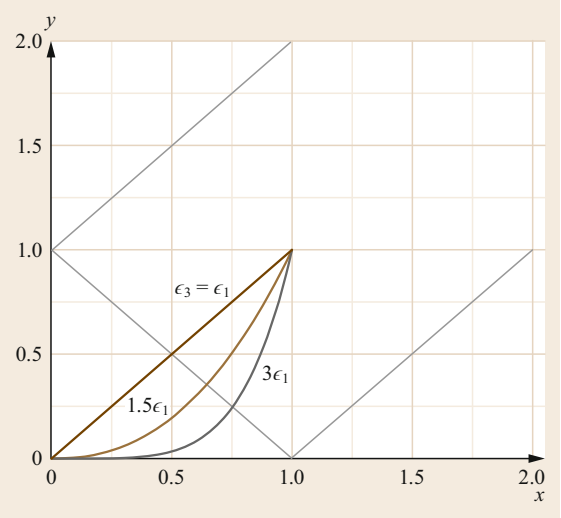

Fig. 1.2 The phase diagram of the six-vertex model, as interpreted for the smooth and rough phases, in the (x, y)-plane, where $x = a_1/a_5$ and $y = a_3/a_5$. The area for $x + y < 1$ corresponds to the smooth phase, the area for $x - 1 < y < x + 1$ to the rough phase. The areas for $y < x - 1$ and for $y > x + 1$ have no meaning for surfaces (although they are important in the ferroelectric interpretation). Roughening takes place on the line $x + y = 1$. Three temperature trajectories are drawn (for $\epsilon_3 = \epsilon_1$, for $\epsilon_3 = 1.5\epsilon_1$, and for $\epsilon_3 = 3\epsilon_1$). The point $(0, 0)$ corresponds to zero temperature, the point $(1, 1)$ to infinite temperature, and the straight line $(x + y = 1)$ to roughening

responds to

$$\Delta = -1 \tag{1.4}$$

(in the electrostatic interpretation, to the transition from the antiferroelectric to the paraelectric state). The BCSOS model is isomorphic to the special case where $\epsilon_1 = \epsilon_3 = \epsilon$, $\epsilon_5 = 0$, for which the very simple result $kT_R = \epsilon / \ln 2$ holds.

Other important results of the 6-vertex model (written of course in surface language) are:

1. *Sutherland*'s result [1.31] for the correlation of steps at the high temperature $2T_R$ (at this temperature the solution is particularly simple). If the correlations are sought in the direction perpendicular to the steps, the correlation at the distance l vanishes if l is even and is given by $-4/(\pi l)^2$ if l is odd: this correlation thus decays very slowly, hence it extends to large distances between steps.
2. *Forrester*'s result [1.32] giving the probability P_m of being at level m in the smooth phase. In such phase $\Delta < -1$, and defining λ from $\Delta = -\cosh\lambda$ the probability is $P_m = A \exp[-\lambda(m - 1/2)^2]$. From Forrester's result *Levi* et al. [1.33] obtained the probability B_m of stepping down from level m to level $m-1$ (if $m > 0$): $B_m = \sum_n (-1)^n \exp[-\lambda n(n + 2m - 1)]$.

The roughness is asymptotically described in terms of the logarithmic behavior of the mean square height difference

$$g = \langle |m(L) - m(0)|^2 \rangle \approx 2K \ln |L| \,. \tag{1.5}$$

Here $K(T)$ is a function of temperature (defined above T_R), which was calculated by *Youngblood* et al. [1.34] as

$$K(T) = (\pi \arccos \Delta)^{-1} \,, \tag{1.6}$$

for $T = 2T_R$, $K = 2/\pi^2$, which agrees with the above result of Sutherland. The phase diagram of the six-vertex model, in the form appropriate for surface roughening, is shown in Fig. 1.2.

1.3 Renormalization Group Analysis

These results of the 6-vertex model, although interesting, are rather model specific. Conversely, the most important properties of the roughening transition are universal and depend only on what happens at very long distances. As such, they can be expected to be obtainable from renormalization procedures, where the short distance behavior, depending on the details of the interaction, disappears from the picture. This is in fact the case, as was shown first by *Ohta* and *Kawasaki* [1.35]. We sketch briefly here such renormalization group analysis (which turns out to be essentially that of *Kosterlitz* [1.36]). We follow here the treatment of *Lapujoulade* and *Salanon* [1.13].

1.3.1 Continuous Solid

If layering is neglected, the surface is always rough, and the fluctuations have a logarithmic behavior. Indeed, if such fluctuations are small, the surface free energy can be written to first order

$$F = \gamma_0 S + W = \gamma_0 S + \frac{1}{2} \int_S \bar{\gamma} (\nabla z)^2 \mathrm{d}^2 \boldsymbol{R} \,, \tag{1.7}$$

where $S = L^2$ and $\tilde{\gamma}$ is the surface stiffness, i.e., for a slope θ, $\tilde{\gamma} = \gamma + \mathrm{d}^2\gamma/\mathrm{d}\theta^2$, and where W is the adiabatic work needed to create the fluctuations.

Going over to $\boldsymbol{q}$-space, $z = \sum_{\boldsymbol{Q}} z_{\boldsymbol{Q}} \exp(\mathrm{i}\boldsymbol{Q}\cdot\boldsymbol{R})$ and

$$W = \sum_{\boldsymbol{Q}} \frac{1}{2}\tilde{\gamma}L^2Q^2\langle z_{\boldsymbol{Q}}\rangle \,. \tag{1.8}$$

In the free fluctuating regime the modes are not coupled and each of them contributes $(1/2)k_\mathrm{B}T$ (there is no kinetic energy!) to the surface energy. The work W can be identified with the fluctuation contribution to the surface energy, so that

$$\langle z_{\boldsymbol{Q}}\rangle = \frac{k_\mathrm{B}T}{L^2\tilde{\gamma}Q^2} \,, \tag{1.9}$$

and the mean square deviation is

$$\langle(\Delta h)^2\rangle = \sum_{\boldsymbol{Q}}\langle z_{\boldsymbol{Q}}^2\rangle \tag{1.10}$$

$$= \frac{k_\mathrm{B}T}{L^2\tilde{\gamma}}\sum_{\boldsymbol{Q}} Q^{-2} \tag{1.11}$$

$$= \frac{k_\mathrm{B}T}{4\pi^2\tilde{\gamma}}\int_{\pi/L}^{\pi/a}\frac{2\pi Q}{Q^{-2}}\mathrm{d}Q \tag{1.12}$$

$$= \frac{k_\mathrm{B}T}{2\pi\tilde{\gamma}}\ln\left(\frac{L}{a}\right), \tag{1.13}$$

where a is an appropriate atomic scale.

Similarly, it is easy to show that the MSHD behaves asymptotically as

$$g(R) = \langle[z(R) - z(0)]^2\rangle = \frac{k_\mathrm{B}T}{\pi\tilde{\gamma}}\ln\left(\frac{R}{a}\right). \tag{1.14}$$

The fact that the coefficient of the logarithm in $g(R)$ is twice that in $\langle(\Delta h)^2\rangle$ is rather obvious, since if $\boldsymbol{R} = \boldsymbol{R}_2 - \boldsymbol{R}_1$, then

$$\begin{aligned} g(R) &= \langle[z(\boldsymbol{R}_2) - z(\boldsymbol{R}_1)]^2\rangle \\ &= \langle[z(\boldsymbol{R}_2) - z(\boldsymbol{R}_0) - z(\boldsymbol{R}_1) + z(\boldsymbol{R}_0)]^2\rangle \end{aligned}$$

(where $\boldsymbol{R}_0$ is an arbitrary point on the surface)

$$\begin{aligned} &= \langle[z(\boldsymbol{R}_2) - z(\boldsymbol{R}_0)]^2\rangle + \langle[z(\boldsymbol{R}_1) - z(\boldsymbol{R}_0)]^2\rangle \\ &\quad - 2\langle[z(\boldsymbol{R}_2) - z(\boldsymbol{R}_0)][z(\boldsymbol{R}_1) - z(\boldsymbol{R}_0)]\rangle \\ &\approx \langle[z(\boldsymbol{R}_2) - z(\boldsymbol{R}_0)]^2\rangle + \langle[z(\boldsymbol{R}_1) - z(\boldsymbol{R}_0)]^2\rangle \end{aligned}$$

(because of the asymptotic decay of correlations) and, since $\boldsymbol{R}_0$ is arbitrary, each of the two terms equals $(\Delta h)^2$.

1.3.2 Crystal

In order to simulate the crystallographic structure a periodic potential $V(z)$, forcing the surface to be preferentially located on equidistant parallel planes, is introduced.

The surface free energy becomes

$$F = \int_S \left(\gamma + \frac{1}{2}\tilde{\gamma}(\nabla z)^2 + V(z)\right)\mathrm{d}^2\boldsymbol{R} \,. \tag{1.15}$$

$V(z)$ may be taken to be

$$V(z) = V_0\left[l\cos\left(2\pi\frac{z}{a_z}\right)\right]. \tag{1.16}$$

In $\boldsymbol{q}$-space the energy E still depends on the set of the $z_{\boldsymbol{Q}}$'s; the potential, however, introduces a coupling between the modes. In the calculation of the partition function Z, integrals have to be performed over the variables

$$Z = \int\cdots\int_{\pi/L<Q<\pi/a} \mathrm{d}z_{\boldsymbol{Q}}\mathrm{e}^{E[z_{\boldsymbol{Q}}]/(k_\mathrm{B}T)} \,. \tag{1.17}$$

Since the interesting things happen asymptotically (i.e., at small Q), a new (smaller) cut-off $\bar{Q}$ is introduced, such that $\pi/L << \bar{Q} < \pi/a$. The *short-wavelength modes* (with $\bar{Q} < q < \pi/a$) are integrated away, and Z becomes a functional integral over the long-wavelength modes only

$$\int\cdots\int_{\pi/L<Q<\bar{Q}} \mathrm{d}z_{\boldsymbol{Q}}\mathrm{e}^{\bar{E}[z_{\boldsymbol{Q}}]/(k_\mathrm{B}T)} \,, \tag{1.18}$$

where $\bar{E}$ is a new functional of the $z_{\boldsymbol{Q}}$'s. It can be shown, by an expansion in powers of V up to second order, that $\bar{E}$ retains the same functional form as E provided that $\tilde{\gamma}$ and V are replaced by new, *renormalized* parameters $\bar{\gamma}$ and $\bar{V}$. The renormalization procedure can be iterated, and, in fact, can be made *differential* by varying the cut-off infinitesimally from $\bar{Q}$ to $\bar{Q} - \mathrm{d}\bar{Q}$.

Letting

$$\lambda = \ln\frac{\pi}{a\bar{Q}} \qquad x = \frac{2a^2\tilde{\gamma}}{\pi k_\mathrm{B}T} \qquad y = \frac{4\pi\bar{V}}{k_\mathrm{B}T\bar{Q}^2} \tag{1.19}$$

the dimensionless renormalized parameters x and y are seen to evolve as the renormalization variable, λ, changes from 0 to ∞, according to the following system of differential equations, first obtained by *Kosterlitz* and

Thouless [1.18, 36]

$$\frac{\mathrm{d}x}{\mathrm{d}\lambda} = \frac{y^2}{2x} A\left(\frac{2}{x}\right) \tag{1.20}$$

$$\frac{\mathrm{d}y}{\mathrm{d}\lambda} = 2y\left(1 - \frac{1}{x}\right), \tag{1.21}$$

$A(\xi)$ being a slowly varying function calculated exactly by *Nozières* and *Gallet* [1.37].

It is often sufficient, ignoring λ, to study the *renormalization trajectories* in the (x, y)-plane. The pair of equations (1.20) and (1.21) are then replaced by a single differential equation for $y(x)$

$$\frac{\mathrm{d}y}{\mathrm{d}x} = 4\frac{1 - \frac{1}{x}}{a(x)y}, \tag{1.22}$$

where $a(x) = A(2/x)$.

This differential equation is easy to solve (it is a separate variables equation), but it is interesting to approximate it further by replacing $A(x)$ by its maximum, which is the number of Nozières and Gallet $A(2) = 4\exp(-4\gamma) = 0.3975$ (where γ is Euler's constant 0.5772).

In this case the solution is represented by the hyperbolas shown in Fig. 1.3. The most important point about these equations is that $\mathrm{d}y/\mathrm{d}\lambda$ (and $\mathrm{d}y/\mathrm{d}x$) vanish for $x = 1$. Moreover $\mathrm{d}x/\mathrm{d}\lambda > 0$ always, and, for small λ (i.e., at the initial stages of the renormalization), $\mathrm{d}y/\mathrm{d}\lambda < 0$, $\mathrm{d}y/\mathrm{d}x < 0$. Hence two cases are possible:

a) If the initial value of y is large (i.e., at low temperatures), a minimum of y is reached for $x = 1$. Subsequently y increases and *diverges* as $\lambda \to \infty$. This divergence of the effective potential $\bar{V}/\bar{Q}^2$ implies that the surface is *pinned* at some crystallographic level:, i.e., it is *smooth*.
b) At high T the initial value of y is small. Then the renormalization trajectory bends down and meets the x-axis at some point $x^* \leq 1$. The effective potential becomes infinitely weak and is unable to hold the surface at a given level. The surface is then *rough*, and resembles closely the surface of a continuous solid, with, however, a renormalized value

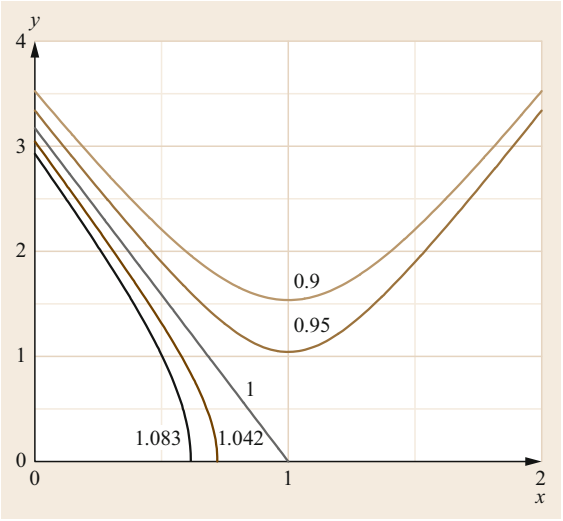

Fig. 1.3 Hyperbolas solving (1.22) for different temperatures. Curve 1: $T/T_\mathrm{R} = 0.9$; curve 2: $T/T_\mathrm{R} = 0.95$; curve 3: $T = T_\mathrm{R}$ (roughening); curve 4: $T/T_\mathrm{R} = 25/24$; curve 5: $T/T_\mathrm{R} = 13/12$

γ^* for the stiffness. Thus, the MSHD behaves again as

$$g(R) = 2a^2 K \ln R \tag{1.23}$$

with

$$K = K(T) = \frac{k_\mathrm{B} T}{2\pi a^2 \gamma^*}. \tag{1.24}$$

Of special interest is the limiting case, where y vanishes *exactly* at $x^* = 1$: this case corresponds to the roughening temperature. Then we have

$$\gamma^* = \frac{\pi k_\mathrm{B} T_\mathrm{R}}{2a^2} \tag{1.25}$$

and substituting into (1.24) the important result

$$K(T_\mathrm{R}) = \pi^{-2} \tag{1.26}$$

is obtained. This is again in agreement with the results obtained above by *Sutherland* [1.31] and by *Youngblood* et al. [1.34].

1.4 (110) Surfaces

As can be seen, the theoretical activity on roughening has been quite extensive. Conversely, the first experiments involved rather unusual systems, such as organic crystals [1.38, 39] or the helium solid–superfluid interface [1.40–43]. In the following, after a few words on the more classical roughening of *singular* surfaces, we shall discuss *missing-row roughening*.

For a long time not much was known about the roughening transition of low-Miller-index metal surfaces (except for the beautiful experiments of *Heyraud* and *Métois* on small Pb [1.44] and In clusters [1.45]).

Outside the realm of metals, the most interesting case is of course ^{4}He (Sect. 1.10.1), where the melting line is nearly horizontal in the (p versus T)-plot (rather than nearly vertical as for all other substances). As a consequence, the roughening of the different faces in the equilibrium shape (starting from the less stable) can be studied by simply increasing the temperature along the solid–superfluid coexistence curve [1.40–43]. From the theoretical point of view, an interesting study was presented by *Touzani* and *Wortis* [1.46].

The Trieste group proposed, however [1.47], that a notable exception to the relative lack of realizations of the roughening phenomenon on low-index metal surfaces may be the (110) faces of nonreconstructed noble (Cu, Ag) or near-noble (Ni, Rh, Pd) metals. For these surfaces, we expect roughening to occur well below T_M, where surface melting plays no role, and this is experimentally confirmed as we shall show in the experimental part. Such surfaces are good candidates for roughening because of the nondirectional nature of the cohesive forces in these metals. For a filled or nearly filled d-shell a large contribution to the cohesive energy can be obtained simply with a high coordination, irrespective of bond angles. In first approximation the cohesive energy may be written as the sum of a conventional two-body contribution, plus a many-body *glue* term [1.48, 49] $V_{\text{glue}} = \sum_i U(n_i)$. Here n_i, the number of neighbors of atom i, is given by $n_i = \sum_{j\neq i} \rho(\boldsymbol{r}_j - \boldsymbol{r}_i)$; $U(n)$ can be so chosen as to be minimal for $n = 12$, the number of nearest neighbors in the ideal fcc lattice, while $\rho(\boldsymbol{r})$ is some decreasing function of distance. For a surface, the effect of the glue at $T = 0$ is to reduce all surface energies, but more drastically so the energy of well-packed faces, in particular the (111) face. When the ratio $\gamma_{(111)}/\gamma_{(110)}$ decreases below the critical value $\sqrt{2/3} = 0.8165$, the (110) surface spontaneously reconstructs missing-rows, forming grooves whose flanks are (111) microfacets: this is what happens to gold and platinum (iridium appears to show more complex reconstructions). Noble metals (Cu, Ag, and Au) have a filled d-band; near-noble metals (Ni, Rh, Pd, Ir, Pt) are fcc transition metals with a nearly filled d-band (however, Co, although belonging to the same column in Mendeleev's table as Rh and Ir, has a different crystal structure). In the lighter noble (Cu, Ag) and near-noble metals (Ni, Rh, Pd) the above ratio remains slightly higher than the critical value, so that they do not reconstruct at $T = 0$; they are, however, on the verge of reconstruction (as shown, e.g., by the fact that Cu, Ag, and Pd do reconstruct in the presence of a small coverage of alkali atoms [1.50–53]) and, therefore, the missing rows are dominant defects at $T > 0$. When such defects proliferate, *missing-row roughening* ensues [1.47]. As first shown by *Jayaprakash* and *Saam* [1.54], van Beijeren's BCSOS model can also describe the (110) surface of the fcc lattice (the case of the (100) surface had been considered earlier by *Shugard* et al. [1.55]). It suffices to expand the lattice along the $\langle 1\bar{1}0\rangle$ rows by a factor $\sqrt{2}$, and then turn by 45°. The resulting surface becomes then very similar to the (100) surface of a bcc lattice. The only difference is that in the case of an (ideal) fcc lattice it is not really appropriate to consider as nearest neighbors of a surface atom only atoms in the second layer, since there are nearest neighbors in the surface itself. For noble and near-noble metals, however, a considerable inward relaxation takes place, so that the use of the BCSOS model is more justified [1.47].

An important characteristic of the (110) surface of fcc crystals is its anisotropy. The unit cell is a rectangle with sides a in the $\langle 001\rangle$ direction, but only $a/\sqrt{2}$ in the $\langle 1\bar{1}0\rangle$ direction (a being the cube side), so that *rows* of atoms are formed in the $\langle 1\bar{1}0\rangle$ direction: the forces keeping the atoms together within a row are much stronger than the forces between different rows. The (110) surface is rather open and has a high surface energy in comparison to the much stabler (111) surface. The missing-row reconstruction is a (2×1) reconstruction where alternate rows are suppressed, thereby uncovering atoms of the *third* layer. This reconstruction (and, for the unreconstructed metals, missing-row roughening at high temperatures [1.56]) is favored because the flanks of the grooves thus generated are rather stable (111) microfacets while, at the same time, very little energy is spent in the reconstruction because of the loose nature of the surface in the $\langle 001\rangle$ direction.

The missing-row reconstruction is destroyed by extended defects at high temperature, by a *deconstruction transition*. The interplay between deconstruction and roughening in Au and Pt is a very interesting and complicated problem, to which a wealth of experimental and theoretical work was devoted. We will discuss briefly some of the relevant concepts and results here

(relying heavily on *Mazzeo* et al. and *Bernasconi*'s work [1.57–61]). Similar, although less evident, phenomena occur in the unreconstructed case, where a *preroughening transition* is expected.

First of all, it is convenient to consider the (110) surface as a rectangular chequerboard composed of two two-dimensional sublattices, whose sites, following *Mazzeo* et al. [1.57], will be called here *white* and *black* sites. White and black sites not only alternate in the plane, but also in level, the height difference between a white and a black layer being one unit (i.e., $a/2\sqrt{2}$): white layers are at odd levels, black layers at even levels. At $T = 0$ the top layer is formed solely by white atoms (at level $m = 1$), while the second layer (at level $m = 0$) is black. But at higher temperatures there will be patches of black atoms on the top layer (formed either by adding atoms ($m = 2$) or by taking atoms away ($m = 0$)). It is then possible to define an *order parameter* P_{BW}, equal to the fraction of the surface top layer occupied by white atoms minus the fraction occupied by black atoms. $P_{BW} = 1$ at $T = 0$, but at a certain temperature T_{BW} a phase transition is expected where the sublattice ordering is destroyed and P_{BW} vanishes.

It may happen that T_{BW} coincides with T_R (this is the case, e.g., of the simple BCSOS model [1.58]), but it may also happen that $T_{BW} < T_R$. In the latter case, in the temperature range $T_{BW} < T < T_R$, the surface is still smooth but is inherently disordered. Such situations were first considered by *Rommelse* and *den Nijs* [1.62, 63], who introduced the concept of a disordered flat (DOF) phase. In their model the sign of a step is taken into account, and it is shown that, mostly for entropic reasons, two steps of the same sign repel while two steps of opposite sign attract each other. As a consequence, the steps tend to organize themselves in pairs of opposite sign, and although they become numerous at relatively high T, their cumulative effect on the level difference between two distant points is still negligible, i.e., the surface finds itself in a DOF phase. This can be represented as a backbone of steps, whose signs alternate, reproducing an antiferroelectric 6-vertex model on a *mesoscopic* scale. At still higher temperatures the backbone (or at least its antiferroelectric ordering) is destroyed by thermal fluctuations, and roughening ensues.

Rommelse and den Nijs' model, however, is only one of many models that have been proposed for the high-T behavior of (110) surfaces. Most of these models were aimed at describing the intriguing situation of the reconstructed gold and platinum surfaces, where the simple (but anisotropic) 6-vertex model, which was sufficient, at least in first approximation, for the unreconstructed surfaces of Ni, Cu, Pd and Ag, did not work. The point is that the (110) surface of the latter is mapped by *van Beijeren*'s construction [1.17], onto an

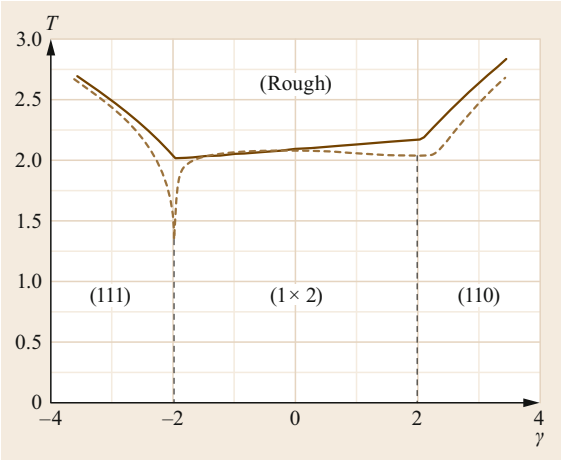

Fig. 1.4 Phase diagram of one of the models computed by Levi and Touzani with the ribbon transfer matrix method, as a function of the parameter $\gamma = (\epsilon_1 - \epsilon_3)/\epsilon_{56}$, where ϵ_1 and ϵ_3 are the energies of vertices 1 and 3 and ϵ_{56} is the repulsive energy involving adjacent vertices 5 and 6 (van Beijeren's mapping is used). (111) and (110) indicate faceting, while (1×2) indicates the missing-row reconstruction. Redrawn from data of [1.64]

antiferroelectric version of the 6-vertex model, where $\epsilon_5 < \epsilon_1 < \epsilon_3$. Since, in the reconstructed case, the flanks of the missing-row grooves are (111) microfacets corresponding to vertices 1 and 2, one might be tempted to try to mimic the reconstructs by lowering ϵ_1, going over to a 6-vertex model where $\epsilon_1 < \epsilon_5 < \epsilon_3$. Unfortunately this version of the model is *ferroelectric*, which, in the surface case, means not (2×1)-reconstruction but rather *faceting*, with the formation of macroscopic grooves whose flanks are extended (111) facets. In order to obtain a (2×1), missing-row reconstructed ground state the model has to be modified.

The simplest modification was proposed by *Levi* and *Touzani* [1.64] who introduced a 6-vertex model with nearest-neighbor interactions *between vertices*. Such interactions prevent the formation of extended areas occupied by vertices of type 1 (or 2) only, i.e., prevent faceting. The model cannot be solved exactly in the thermodynamic limit, but can be solved easily in the case where the system is a *ribbon* whose width is kept finite (and rather small) and whose length goes to ∞, by the *ribbon transfer matrix method*, well known in statistical mechanics (see, e.g., [1.65]), provided the interactions act only *across* the ribbon. The Levi–Touzani model leads to a simple phase diagram for (110) surfaces (including both the reconstructed and the unreconstructed case), reproduced in Fig. 1.4.

A model very similar to that of Levi and Touzani was proposed by *Kohanoff* et al. [1.66, 67] and studied,

by Monte Carlo simulations, by *Mazzeo* et al. [1.57]. The only difference is that the model of Kohanoff et al. is written in SOS language instead of in vertex language. In the most elementary case there is complete isomorphism. Introducing vertex–vertex interactions, however, corresponds, in SOS language, to introducing interactions between more distant neighboring atoms on the surface, but the correspondence is not perfect: there are small differences, so that the two models are not perfectly equivalent. More importantly, the model of Kohanoff et al. has been studied in complete detail by simulation, and this has yielded very interesting results [1.57] that the ribbon transfer matrix could not give. The most important result is that there are *two* distinct phase transitions, not one. In the reconstructed case the first transition is a *deconstruction transition*, while in the unreconstructed case it can be described as *preroughening*. In both cases, the second transition (at a temperature about 10% higher than the first) is the roughening transition. Deconstruction has critical exponents very near those of the 2-D Ising model. Conversely, preroughening has a new set of critical exponents (e.g., α is negative, about -0.23, i.e., the specific heat remains finite). Finally, roughening seems to be a transition of the *Kosterlitz–Thouless* type [1.18], but this is less certain.

The models proposed by *Villain* and *Vilfan* [1.68–74] are somewhat different. They compare two kinds of defects: domain walls and steps. A domain wall can be thought of as a bound pair of steps of opposite signs. If the binding energy is large enough, the domain walls are so energetically cheap in comparison to steps that a phase transition occurs, ahead of roughening, by proliferation of domain walls. The phase present between this kind of preroughening and roughening, however, is rather different from den Nijs' DOF phase: P_{BW} indeed, does not vanish in this phase, since a domain wall of the above kind does not invert the sublattice ordering. Such a phase was called by *Bernasconi* disordered even flat (DEF) [1.61, 75].

Then several *scenarios* are possible (Fig. 1.5) for the deconstruction and roughening of surfaces such as Au(110) and Pt(110) (the present classification is slightly modified with respect to [1.61, 75]):

a) First deconstruction takes place (by proliferation of domain walls) at some temperature T_D and the surface goes over from a low-temperature reconstructed phase to a DEF phase. At some higher temperature T_{BW} the steps proliferate, but their backbone preserves an antiferroelectric ordering: P_{BW} vanishes and the surface goes over from a DEF phase to a DOF phase. Finally, at a still higher temperature T_R, roughening takes place.

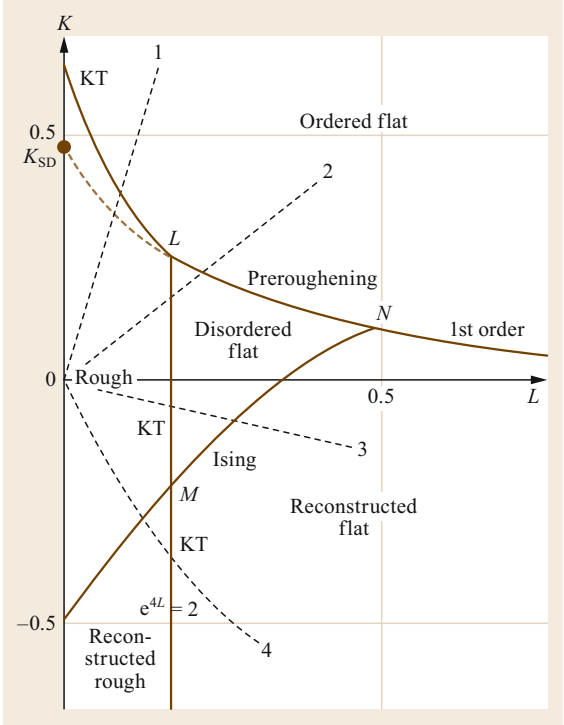

Fig. 1.5 Schematic phase diagram of the RSOS model. K and L are the nearest and next-nearest neighbor interactions. Both are in units of k_BT. Infinite temperature corresponds to $(K, L) = (0, 0)$. The *dashed lines* represent characteristic experimental paths. Reproduced from data of [1.76]

b) Deconstruction takes place by proliferation of domain walls at T_D. A DEF phase is formed and persists up to T_R.
c) Deconstruction takes place by step proliferation. The surface goes directly from the low-temperature reconstructed phase to den Nijs' DOF phase: T_{BW} coincides with T_D, but T_R is higher.
d) $T_D = T_{BW} = T_R$: there is only one transition, i.e., deconstruction and roughening occur together.

Scenario c) is one of the possibilities in *den Nijs*' theory [1.77–79], while scenario b) corresponds to the description of *Villain* and *Vilfan* [1.68–70] (both theories predict the possibility of scenario d)). The more complex scenario a), with three transitions, has been considered for the first time by *Bernasconi* [1.61]. *Mazzeo*'s thorough study [1.60], based on the Hamiltonian of Kohanoff et al., shows two transitions, between which the surface is in a state well described by den Nijs' DOF phase (scenario c)). Experiments on gold (Sect. 1.10.3) clearly showed two transitions. The intermediate phase cannot be DOF, since there is no broadening of the spec-

ular peak in antiphase, which would be a hallmark of the DOF phase [1.61]. Thus, the scenario for gold appears to be b). The case of platinum may be different. At first it seemed that there was only one transition (scenario d)) [1.80, 81], but more recent experiments showed two transitions, indicating scenarios b) or c) as described in the experimental section of this chapter.

An illuminating study of the competition between reconstruction and roughening was presented by *den Nijs* ([1.77], also on p. 247 of [1.4]), who considered deconstruction transitions (*preroughening*) which behave according to some typical properties of the Ising model, together with true roughening, which is, as we have seen, a transition belonging to the Kosterlitz–Thouless class. All this in the Reduced (RSOS) model. In this model, the level difference between two neighboring atoms is restricted to be 1, 0, or −1: the model is thus, by construction, smoother than DGSOS or ASOS, where in ASOS (absolute SOS) the squares appearing in (1.2) are replaced by absolute values.

1.5 Vicinal Surfaces

A vicinal surface is a crystal surface near to a high-symmetry, or *singular* surface. The singular surfaces correspond to the minima of free energy, i.e., to the inward singularities in the shape of Frank's raspberry. The vicinals show a first-order singularity (i.e., a first-order increase of free energy with respect to the singular surface, whatever is the sign of the deviation angle). But when analyzed in more detail the free energy increase usually contains a third-order term, as shown by *Gruber* and *Mullins* [1.82] while the second-order term is usually absent for high-symmetry surfaces. (A notable exception is the work by *Carlon* and *van Beijeren* [1.83], describing a model in which crossing steps form a network: in this model the second-order term is present and, for small deviation angles, is much more relevant than the usual third-order term.) This is the situation at low-temperatures.

Very different is the situation at roughening. Here there is no discontinuity in the derivative, i.e., no first-order term. On the contrary, the second-order term is present and dominant. Just above T_R, the vicinal surface free energy per unit area [1.2] is given by

$$f(p) = f(0) + \frac{\pi k_B T_R}{4a_z^2}|p|^2 + \dots , \qquad (1.27)$$

where a_z is the appropriate step height and p is the appropriate deviation angle.

Vicinal surfaces are liable to show roughening, very often at temperatures much lower than those appropriate to singular surfaces and farther down from melting. A general discussion of the roughening transition of high-index crystal faces was given by *Villain* et al. [1.84]. In more detail, vicinal surfaces can be conveniently (although not exactly) described in terms of the traditional TSK picture: the surface is characterized by terraces alternating with steps; there is a statistical distribution of steps; such steps are not straight, but are rather perturbed by atomistic irregularities (kinks). Hence the Terrace–Step–Kink (TSK) description. Such description is old, going back to *Kossel* and *Stranski* [1.85, 86], but is still very useful nowadays. Steps repel each other, and this allows the stability of terraces at low temperatures, until some sort of roughening occurs. It is clear, therefore, that the step–step interactions are essential; but, at the same time, there may be kink–kink interactions, which are also relevant for the properties of a vicinal surface at different temperatures. The statistical-mechanical problem of the roughening of vicinals depends thus on step–step and kink–kink interactions, and defines the nature of the phase corresponding to the different temperatures. Since the melting temperature T_M is typically much higher than the temperatures considered, the atomic positions can safely be assumed to remain the discrete positions dictated by crystallography, and only the occupation of the different crystal positions need be studied. Below the roughening temperature T_R, the steps remain sufficiently ordered; above T_R, the steps meander freely and kinks abound, giving rise to divergent fluctuations in the surface height profile. However, even below T_R there may in principle be disorder, related to the repulsion of parallel kinks. If such repulsion is strong enough, it could be possible to stabilize a disordered flat (DOF) phase: this would be disordered, because kinks are present in large amount along the steps, but flat, because of the limited step lateral excursion. A new phase transition, preroughening (PR) would occur in this case, whereas true roughening would be shifted to a higher temperature. Preroughening had been proposed (in a somewhat different context) by den Nijs and Rommelse who showed that long-range interactions favor the formation of a DOF phase, while a thorough discussion of the present problem has been given by *Prestipino* and *Tosatti* [1.63, 87]. Previously, a simpler theory had been given by Villain et al., in their discussion of the roughening transition of vicinals, where only the interaction among steps had been taken into

account: and the work of Prestipino and Tosatti is a modification of the theory of Villain et al. Such modification was necessary, because of the refined experimental work of *Hoogeman* et al. [1.88], who studied in depth, by scanning tunneling microscopy, the behavior of the (115) surface of silver. There had been indications of roughening at 490 K, and also indications of a previous roughening at a lower temperature, 440 K, with an average value of 465 K. One possibility, however, was that between 440 K and 490 K the surface is DOF. The very detailed and complex analysis by Prestipino and Tosatti affords much information, but some of the main doubts remain unsettled.

In parallel to their experiment, *Hoogeman* and *Frenken* performed a numerical simulation of the roughening of the (115) surface of silver [1.89]. Their Monte Carlo simulation was based on the TSK (also called TLK: Terrace–Ledge–Kink) model. The relevant energies are the kink formation energy and the interaction between steps: such parameters are extracted from previous experimental work by the authors [1.88]. The height correlation function diverges logarithmically with a prefactor $K(T)$ at high temperatures; $K(T_R)$ must equal π^{-2}, and this allows them to determine $T_R = 423 \pm 6$ K, in reasonable agreement with their experimental value of 465 ± 25 K.

1.6 Kinetic Roughening

An important issue is that of kinetic roughening, related to the process of surface growth under smooth or respectively rough conditions. For a discussion of the basic concepts of the theory of crystal growth we refer to *Weeks* and *Gilmer* [1.90] and also partly to *Levi* et al. [1.91], and *Levi* and *Kotrla* [1.92].

The process is usefully described by stochastic, partial differential equations such as *Edwards–Wilkinson* (EW) [1.93], *Chui–Weeks* (CW) [1.94], and *Kardar–Parisi–Zhang* (KPZ) [1.95].

Actually, kinetic roughness is an enormously vast subject, described in the excellent review by *Halpin-Healy* and *Zhang* [1.96]. In the present chapter, we limit ourselves to the most elementary aspects, which not only are simplest, but also are physically most relevant for the roughening transition of crystals.

The simplest time-dependent description of a stochastic surface is afforded by the EW equation [1.93]

$$\frac{\partial h}{\partial t} = \nu \nabla^2 h + \eta \tag{1.28}$$

where ν has the dimensions of a diffusion coefficient, and η is a noise term. This Edwards–Wilkinson equation was originally proposed for sedimentation, but can also describe a growing surface. In the present form, it is considered as written in the comoving frame. In $2+1$ dimensions the solutions of the EW equation give rise to a mean square height (h) difference

$$g(r) = \langle [h(r) - h(0)]^2 \rangle \tag{1.29}$$

behaving asymptotically as $\ln r$. This logarithmic roughness is quite similar to that of a surface in equilibrium (above T_R).

If the crystal structure is taken into account, the equation is modified by a periodic force favoring the integer levels, e.g.,

$$\frac{\partial h}{\partial t} = \nu \nabla^2 h + \frac{y \sin 2\pi h}{a + \eta} \,. \tag{1.30}$$

This is the *Chui–Weeks* equation [1.94]. The additional term tends to make the surface smoother: a surface obeying the CW equation either is smooth, or if it is rough cannot be more than logarithmically rough.

Another nonlinear modification of the EW equation was introduced by *Kardar*, *Parisi*, and *Zhang* [1.95]

$$\frac{\partial h}{\partial t} = \nu \nabla^2 h + \lambda (\nabla h)^2 + \eta \,. \tag{1.31}$$

This KPZ equation generates surfaces whose roughness may be stronger than logarithmic, i.e., power-law. Situations where such power-law roughness occurs are relevant in many situations [1.96] (the microbic growth on a substrate is a well-known example in biophysics: see for example the experiment by *Matsushita* and *Fujikawa* [1.97]. Conversely, in the present solid-state problem the same happens when the disequilibrium is very strong [1.98]).

Crystal growth modes vary widely, ranging from the fast *Wilson–Frenkel* mode (WF) (upper velocity limit) [1.99, 100] to slow nucleation, described in particular by *Becker* and *Döring* [1.101]. The EW equation describes a situation belonging to the most elementary mode of growth [1.102] often called the Volmer–Weber mode in the literature and similar to Wilson–Frenkel. Conversely, the CW equation at low temperatures is related to Becker and Döring (BD).

This discussion has a strong bearing on the roughening transition. In fact a smooth surface grows ac-

cording to something similar to the CW equation (with parameters determined by the physical details, e.g., by two-dimensional nucleation, see below), but after roughening the mode of growth degenerates to a simple EW behavior (actually, however, this change occurs already at a temperature somewhat lower than T_R, by an effect discovered by *Nozières* and *Gallet* [1.37]; we shall discuss this Nozières–Gallet effect below).

An interesting feature of growth conditions is a nontrivial scaling behavior. We have already mentioned the power-law roughness that may arise from the KPZ equation. More generally, the width w of the surface (i.e., the mean square height difference, given by $w^2 = \langle\langle h^2\rangle - \langle h\rangle^2\rangle$), very often obeys, as numerical simulations of simple models of crystal growth show, a scaling law with increasing time t and system size N [1.96, 103]

$$w(t,N) = N^{\zeta} f\frac{t}{N^z}\,, \tag{1.32}$$

i.e., a power-law roughness. Notice the very different (logarithmic) behavior occurring in equilibrium (in the rough phase)

$$w^2 = K(T)\ln N\,, \tag{1.33}$$

where, e.g., in the BCSOS model

$$K(T) = \frac{1}{\pi \arccos \Delta} \tag{1.34}$$

while in the smooth phase w remains finite. Simulations show that such logarithmic roughness still holds under growth conditions, provided the disequilibrium $\Delta\mu$ is small; there is a progressive change from logarithmic to power-law roughness with increasing disequilibrium [1.98].

The CW equation lends itself to a renormalization procedure similar to that used in the equilibrium case (Sect. 1.3). Both in equilibrium and off equilibrium the form of the surface is sharply different (at small q, i.e., at large distances) between a smooth and a rough surface.

This is characteristically related to the mode of growth. Typically, a smooth surface grows via nucleation of two-dimensional clusters on the surface: the classical theory of *Becker* and *Döring* [1.101] holds, and the growth velocity is proportional to the exponential

$$\exp\left(\frac{-\epsilon^2}{3kT\Delta\mu}\right) \tag{1.35}$$

(where $\Delta\mu$ is the chemical potential difference between fluid and solid, measuring the disequilibrium, and ϵ is the energy needed to increase the length of the border of a two-dimensional cluster by an atom): such velocity can be extremely slow if $\Delta\mu$ is small. Conversely, a rough surface, where steps and two-dimensional clusters are already present, grows at a much faster rate. Measuring the growth velocity in the smooth regime a measure of ϵ is obtained: this is the energetic cost of island border per atom, decreases steadily when roughening is approached (following the characteristic KT behavior), and vanishes at roughening. As an example, in the experimental part of the chapter we will show the data obtained by *Gallet* et al. [1.104] on the solid–superfluid interface of ^{4}He, where ϵ, the nucleation energy per atom, decreases, following precisely the KT law, in the range 1.13−1.22 K (above 1.22 K, however, the Nozières–Gallet effect takes over, see below, and the growth resembles closely that of a rough surface).

1.7 Nozières–Gallet Effect

In their important article of 1987, *Nozières* and *Gallet* [1.37] introduced an interesting effect, which refers to the behavior of a surface just below the roughening transition, under growth conditions.

In the nonequilibrium case Nozières and Gallet discovered that the rough behavior manifests itself already at a temperature a little less than T_R. They showed that, under growth conditions, the roughening transition becomes gradual and no longer sharp. Just below roughening the growth mode becomes Volmer–Weber and everything happens as if the surface were already rough. Moreover, the phenomena described become progressively stronger as the disequilibrium is increased.

Nozières and Gallet obtained their effect as a consequence of renormalization, stopping it in a similar way, for a growing surface (just below T_R) and for an equilibrium rough surface. Here, we give a more physical interpretation of the effect.

As discussed by *Levi* and *Kotrla*, this effect can be described as follows [1.105]. The (equilibrium) correlation length ξ diverges at roughening. For example, for the 6-vertex model characterized by the parameter Δ

(which is negative and less than -1 in the smooth phase and equal to -1 at T_R), ξ behaves as

$$\xi \approx a \exp\left[\frac{\pi^2}{2\sqrt{-2(\Delta+1)}}\right], \qquad (1.36)$$

another function with a typical KT behavior. As soon as ξ becomes larger than the size λ of the average terrace, everything happens as if ξ was infinite, i.e., as if the surface was rough, and the mode of growth appears as a simple Edwards–Wilkinson behavior, even though we are still below T_R.

A more detailed physical interpretation of this effect was given by *Levi* and *Kotrla* [1.92] (Fig. 1.6).

Let us briefly describe the physical situation near the roughening transition. In the Chui–Weeks equation the term $\nu\nabla^2 h$ describes the propagation over the surface of the information concerning the local level h. A new layer is completed in the time $\tau = a/v$ (where a is the vertical lattice spacing and v is the growth velocity), and in this time the information is propagated to a distance $L = \sqrt{2\nu\tau}$. As long as this distance is large enough—in fact, as long as it is larger than ξ, the equilibrium correlation length on the surface—, the surface grows layer-by-layer, in the nucleation mode, according to the same Becker–Döring laws as hold at lower temperatures. But near roughening ξ diverges and, as soon as it is larger than L, the information can no longer travel as far as ξ before a new layer is created. Everything occurs as if ξ were infinite: the surface roughens and the growth law becomes trivial: in particular, the growth velocity becomes linear in the disequilibrium $\Delta\mu$. The result is an effective lowering of the roughening temperature with increasing $\Delta\mu$.

Following [1.92], it is possible to attempt a more detailed discussion. According to classical nucleation theory (as applied to crystal growth by *Becker* and *Döring* [1.101]), a growth island of N atoms has a Gibbs free energy G made up of two terms: a negative term $-N\Delta\mu$ and a positive term, related to the energy cost of building the step that serves as island boundary, given by $B\epsilon$, where B is the number of boundary atoms and ϵ is the step free energy per atom.

If the island is convex, B is given by $B = b\sqrt{N}$, where, e.g., $b = 4$ for a square island. G is maximal for the critical nucleus, i.e., for $N = N^* = b^2\epsilon^2/(4\Delta\mu)$. If, however, L is relatively small, the surface behaves as if it had a finite size L and, in particular, if L is less than the size of the critical nucleus, the latter does not form: the area of the largest islands is of the order of L^2, which also implies a lowering of the nucleation barrier.

This is irrelevant at low temperatures, where $\xi \ll L$, but becomes important just below T_R. It should be recalled that ξ and ϵ are inversely proportional to each other: ξ long corresponds to ϵ small. The relevant quantities in our problem are $x = \beta\epsilon$, $y = \beta\Delta\mu$. The growth velocity v may be written as the *rough* (or *Wilson–Frenkel*) growth velocity v_0 divided by a factor ω, related to the nucleation barrier, which is not fixed but depends, in turn, on the size of the effective critical nucleus, i.e., on the growth velocity: thus the problem is self-consistent. The characteristic length L (which may be identified with the size of the relevant islands) can be found from the Chui–Weeks equation as $L = \sqrt{2\nu\tau}$, where ν, the coefficient of the Laplacian term in the stochastic equation, is of the order of av_0, and τ is the time for growing one layer, i.e., a/v. Then $L = a\sqrt{2\omega}$.

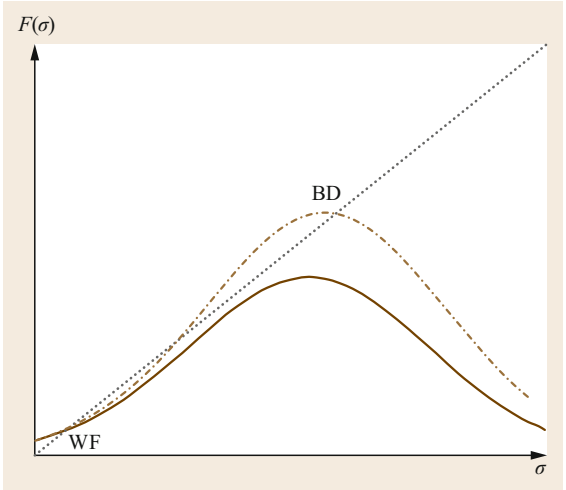

Fig. 1.6 Kinetic roughening as a first-order transition described by (1.37), for a dimensionless disequilibrium $y = 0.03$. *Dot-dashed curve* ($x = 0.36$): the equation has three solutions, of which the physical one, marked BD, corresponds to slow, Becker–Döring-like growth. *Solid curve* ($x = 0.34$): the slow solution has disappeared altogether and the growth takes place according to a small σ-value, i.e., to fast growth, corresponding to the point marked WF. Reproduced from data of [1.92]

Letting $\varpi = \sigma^2$, this leads to a self-consistency equation of the type

$$\sigma = \exp(px\sigma - qy\sigma^2)\,. \qquad (1.37)$$

In a simple description, the numbers p and q are given by $p = 2\sqrt{2}/3$, $q = 1/3$ (where the famous *Kolmogorov's cubic root* for two-dimensional nucleation has been used [1.90, 106]).

Let us consider the solutions of (1.37), and let us fix y (i.e., essentially the disequilibrium). Then for large x (i.e., far from roughening) there is only one, Becker–Döring-like, solution, but below a certain value of x (provided that y is less than a critical value $y_c =$

0.0747) there are two more solutions, corresponding to faster growth. Beyond another x-value, the slow mode disappears altogether and a jump is unavoidable to a faster growth mode. This appears as an indication that the Nozières–Gallet effect has set in. Conversely, if $y > y_c$, the growth should go to a faster regime smoothly, *supercritically*: this is understandable since at such strong disequilibria the critical nucleus is small anyway and even the Becker–Döring growth is fast anyway. The possibility of genuine critical phenomena in the neighborhood of such growth is an important point worth investigating (although *Tartaglino* and *Levi* did not find evidence for them in simulations [1.107]).

The relation between roughening and adsorption was first studied theoretically by *Suhl* and collaborators [1.108, 109]. More recently, the interesting problem of roughening on a surface covered with adsorbed molecules has been addressed by *Zhdanov* and *Kasemo* [1.110]. They showed that the adsorbate may lower the roughening temperature by several mechanisms:

a) Indirect next-nearest neighbor adsorbate–substrate repulsion
b) Attractive nearest-neighbor adsorbate–substrate lateral interaction
c) Repulsive adsorbate–adsorbate lateral interaction.

Vakarin and *Badiali* [1.111] showed, however, the situation to be more complicated: as a function of increasing coverage, T_R may first decrease, then increase again.

Finally, a possible relationship between roughening and surface melting was considered by *Levi* and *Tosatti* [1.112], who studied the roughening of molten surfaces. A step on the solid–liquid interface induces the formation, at the free liquid surface, of a corresponding feature whose shape and free energy cost are evaluated from the interplay between surface tension, attraction to the crystal, and layering. This cost prevents roughening until, just below bulk melting, the molten layer becomes so thick that the two interfaces decouple.

More recently, the relationship between roughening and surface melting has been studied in depth by Tosatti and coworkers, who have shown that surface melting may induce a sort of preroughening with a different mechanism from that considered by *den Nijs* and *Rommelse* [1.63]. From the point of view of the SOS model, assuming surface melting to be only incipient and therefore limited to a single layer, the surface may be covered by locally wet microareas in such a way that its symmetry plane is a half atom above the nominal level: this is indeed a description of a preroughened, or DOF, phase. To prove that this scenario is real, they use the Potts model of statistical mechanics. The latter involves a variable s_i, varying over N states, and is a generalization of the Ising model (reducing to the latter when $N = 2$). For $N > 2$ the Potts model has three different phases, which may be used to represent solid, liquid, and vapor [1.113]. In the present case the interesting values of N are very large. *Jagla* et al. show that for $N > 50$ the model shows a clear preroughening, which for $N > 80$ becomes first order [1.114–116].

Such a preroughening transition is confirmed by experiments concerning the high-temperature behavior of rare gas crystals [1.117] (we shall refer to such evidence in the experimental part), as well as, although not so easily, by Monte Carlo simulations of Lennard-Jones systems, describing with considerable precision the properties of such crystals [1.118].

These theories also afford a possible explanation of the surprising phenomenon of reentrant layering, where layering steps in adsorption isotherms first disappear, then reappear again [1.119].

1.8 Experimental Considerations

As shown in the above theoretical sections, the roughening transition is characterized at T_R by two related facts: the logarithmic divergence of the MSHD g and the disappearance of the corresponding facet from the equilibrium crystal shape. The occurrence of these two facts can be exploited to investigate experimentally the roughening transition: the observation of crystal shape in the macroscopic approach or the investigation of g in the microscopic approach. Other approaches based on the study of thermodynamic quantities are not feasible since the roughening transition, as we have shown, belongs to the Kosterlitz–Thouless universality class, hence is extremely weak (an infinite-order transition), and no discontinuities can be observed in thermodynamic functions that could provide the experimental evidence of the transition and could fix T_R.

The crystal shape can be observed on a crystal kept in equilibrium conditions at different increasing temperatures and the size of a facet can be followed up to its disappearance (or its appearance for decreasing temperatures starting above T_R). The crystal size must be visible (using an optical microscope or even an electron microscope), but big sizes hamper the possibility of a very uniform temperature of the sample and of a fast

response to approach equilibrium, while the behavior of too small crystals might be influenced by the interaction with the solid support underneath.

In the microscopic approach, the logarithmic behavior of g is asymptotic, therefore a large (on the atomic scale) exposed surface is required to average the experimentally determined g at long distances, and this poses several limitations both on experimental techniques and on samples. Real single crystals always present domains limiting the size of the perfect crystal under investigation and the exposed surface is cut within limited precision from the wanted crystal surface, involving the so-called miscut angle. Sensitivity to microscopic quantities on large atomic scale and at different temperatures can be obtained by using diffraction techniques sensitive to surface properties, i.e., diffraction techniques based on x-rays [1.120], electrons (low-energy electron diffraction, LEED) [1.121, 122]) or atom beams [1.123, 124], which perform the average of microscopic quantities on the size of the incident beam spot on the sample. In fact, measured diffraction patterns are analyzed in the reciprocal space and long distances are translated into small ranges of momentum exchange. Therefore a study of the shape of diffraction peaks, generally of the specular peak, contains information on g. Conversely, the experimental peak width is finite due to limitations of the experimental setup, such as divergence of the incident beam and acceptance angle of the detector, and all this is generally synthesized in the so-called transfer width on the sample [1.125, 126], i.e., the maximum size on the sample visible with the technique that corresponds to minimum peak width obtained by the setup. Hence the study of surface properties is limited to distances smaller than the transfer width, since larger distances are mapped within the minimum peak width. For an experimental setup, in particular for atomic beams, the presence of inelastic intensities means that also the energy resolution of the detector could be an important factor in order to reject inelastic contributions, accepting truly elastic (coherent or incoherent) intensities, such separation being important for the peak shape analysis. Moreover, a knowledge of defect density, in order to estimate the temperature where defect proliferation occurs, although not directly related to T_R, can be useful to understand the roughening mechanism and to correct the diffraction intensities: this can also be investigated with other techniques, sensitive to defects at short distances, to complement the diffraction ones, such as ion scattering techniques [1.127, 128] or scanning probe techniques [1.129, 130]. In fact structural information obtained in reciprocal space through diffraction is not unequivocally transformed into real space information at atomic level to distinguish the processes involved in a transition.

The microscopic approach could present a drawback for what concerns the equilibrium conditions. In fact the probe used in the experimental setup (e.g., in the case of electron or atom scattering) may require vacuum conditions, so that the crystal is not surrounded by its vapor at the proper equilibrium pressure. Instead this condition can be more easily obtained by working in a cell, which is generally the case for the macroscopic approach, and x-ray techniques could be suitable in this case.

Scanning probe techniques, e.g., scanning tunneling microscope (STM) in case of conductive samples, can reach atomic resolution; therefore the acquired images can show adatoms, vacancies and steps and a statistical analysis of their height distribution is feasible with the nuisance that many images are necessary to perform the necessary statistical average. The acquisition time is large compared to the diffusion at atomic scale, therefore mobile defects such as adatoms at high temperatures could contribute to some artifacts in images, the surface itself evolves during the acquisition time and the tip–surface interaction can modify the appearance of steps [1.131–134]. The development of high-speed instruments has partially mitigated all these problems [1.135].

Finally, another point is the presence of impurities in the crystal and their effect on the roughening transition. This point is usually neglected because the impurity density in crystals relevant for the present studies is generally low, but for solids with high melting temperature and high roughening temperatures, the necessity to keep the crystal at high temperature for long periods of time to perform measurements favors the segregation of impurities from the bulk. The contamination, even at very low coverage below the sensitive limit of conventional techniques to test surface cleaning such as Auger spectroscopy, has been shown to change the thermal behavior of surfaces, as will be described in the section about experimental results. As we have seen, the related topic of adsorbate effects on rough surfaces was theoretically investigated by *Resnyanskii* et al. [1.136], *Zhdanov* and *Kasemo* [1.110], and by *Vakarin* and *Badiali* [1.111]. For small coverage of the adsorbate, the results showed that T_R is a decreasing function of the coverage. Conversely, those studies were based on SOS models and Monte Carlo simulations or the lattice gas model and did not take into account the dynamics of the steps. Therefore, the pinning of steps due to contaminants is not treated, although pinning is probably very important for changing T_R and roughening mechanism (see for instance the case of Ag(110) or Au(110)).

1.9 Diffraction Techniques

As observed above, diffraction techniques are among the best options to study the roughening transition. In fact those techniques are sensitive to defects such as steps and the diffraction peak shape contains information about the distribution of those defects performing in real time the necessary statistical average on a macroscopic region corresponding to the beam spot size on the sample. In the following we will give a brief introduction, further information on diffraction techniques to study roughening can be found in reviews by *Conrad* [1.137], *Kern* [1.138], and *Lapujoulade* [1.139].

In general, diffraction requires the treatment of multiple scattering [1.140–145] and the analysis of a diffraction pattern can become very difficult. A single-scattering approximation greatly simplifies this analysis and this is generally a good approximation for x-rays [1.120], while electrons and atoms strongly interact with atoms in the crystal and this approximation is questionable, in particular for atoms [1.146]. Conversely, this so-called kinematical theory allows one to draw some general conclusions on the shape of diffraction peaks for all the probes useful to extract information on roughening.

In the single-scattering approximation, the intensity can be separated into two factors

$$I(\boldsymbol{Q}, q_z) = I_0(\boldsymbol{Q}) \sum_{\boldsymbol{R}} \exp(\mathrm{i}\boldsymbol{Q}\cdot\boldsymbol{R}) \times \langle \exp(\mathrm{i}q_z[h(\boldsymbol{R}) - h(\boldsymbol{0})]) \rangle \,, \tag{1.38}$$

where $\boldsymbol{q} = (\Delta\boldsymbol{K}, q_z)$ is the momentum exchange, $\Delta\boldsymbol{K}$ is its component parallel to the surface while the component perpendicular to the surface is q_z. We note that the experimental intensities contain also other contributions which are related to the atomic lattice vibrations: a brief discussion will be given below. The first factor, $I_0(\boldsymbol{Q})$, depends on the arrangement of atoms in the unit cell but does not depend on the roughness, it is related to the Bragg intensity for a perfect lattice. The second factor depends on the statistical properties of the surface. To further proceed, the so-called Gaussian approximation may be assumed in order to simplify this term

$$\begin{aligned} &\langle \exp(\mathrm{i}q_z[h(\boldsymbol{R}) - h(\boldsymbol{0})]) \rangle \\ &\quad \approx \exp(-p(q_z)\langle (h(\boldsymbol{R}) - h(\boldsymbol{0}))^2 \rangle) \\ &\quad = \exp(-p(q_z) g(\boldsymbol{R})) \,, \end{aligned} \tag{1.39}$$

where

$$p(q_z) = \frac{1}{2}\{q_z a_z \mod 2\pi\}^2 \,. \tag{1.40}$$

When p is an even multiple of π the scattering is in in-phase condition, i.e., constructive interference for scattered waves, the diffraction pattern is insensitive to surface defects, while for odd multiples of π the scattering is in out-of-phase condition, i.e., destructive interference, where the diffraction presents the highest sensitivity to surface defects.

In this approximation, the diffraction pattern is therefore related to the Fourier transform of the exponential of the MSHD. Below T_R, the MSHD asymptotically tends to a constant value so that its Fourier transform contains a Dirac δ-function, i.e., a diffraction peak which is the coherent part of the elastic intensity. At short distance, the MSHD will increase from a small value to the asymptotic value; assuming a linear increase, the Fourier transform is a Lorentzian function which is the incoherent part of the elastic intensity. Of course, the simple shape given by the δ function plus the Lorentzian function must be convoluted with the experimental resolution (transfer width) discussed in the previous section.

At and above T_R, the MSHD diverges in a logarithmical way. The lack of an asymptote means that the coherent part of the diffraction vanishes and only the incoherent part is present, and its shape is a power law

$$(a_x^2 Q_x^2 + \eta a_y^2 Q_y^2)^{(\tau/2-1)} \,, \tag{1.41}$$

where η accounts for the anisotropy, a_x and a_y are the lattice parameters of the surface cell, and the exponent τ depends on the temperature and the scattering conditions (p of (1.39)): in out-of-phase conditions for $T = T_R$

$$\tau(T_R, (2n+1)\pi) = 1 \,. \tag{1.42}$$

Moreover, this expression for the peak shape is valid when the roughening exponent is $\tau < 2$.

As shown in the theoretical part, steps are an important ingredient of roughening. They separate regions (terraces) with different height and the waves scattered by terraces interfere depending on the $p(q_z)$ value, therefore their presence can be inferred from the periodic oscillation in the peak profiles changing the scattering conditions from in-phase to out-of-phase [1.147–151].

To account for lattice vibrations that destroy the order of a lattice and in turn reduce elastic intensities, a Debye–Waller factor F_{DW} is introduced. For atom scattering, the related theory can be very complicated [1.152], but in the philosophy of the kinematical approximation, a simple expression valid for all the probes is an exponential decay $F_{DW} = \exp(-\langle(\boldsymbol{q}\cdot\boldsymbol{u})^2\rangle)$ where $\langle \ldots \rangle$ is a thermal average and $\langle \boldsymbol{u}^2 \rangle$ are the mean

square atomic displacements. For relatively small values of T, lattice vibrations can be treated in harmonic approximation and the mean square displacement increases linearly with T. Conversely, for higher temperatures the vibrations become anharmonic, therefore $\langle u^2 \rangle$ increases faster with T. Since T_R could be a sizable fraction of T_M, measurements can see anharmonic effects close to the transition.

Point defects, such as isolated adatoms and vacancies, produce a diffuse background: this further reduces the intensity I of those peaks but without a change of their shape [1.153]

$$I = I_0 \exp[-\langle (\boldsymbol{q} \cdot \boldsymbol{u})^2 \rangle](1-\theta)^{n_s \Sigma} \quad (1.43)$$

where Σ is the cross section for diffuse scattering of a single isolated defect, θ the point defect concentration, and n_s the number of lattice sites. We note that Σ for atom scattering can be larger than the surface unit cell. At low temperature, the concentration of single defects is generally small but increasing the temperature, especially when the vibrations become anharmonic, the excitation of adatoms/vacancies pair becomes more probable.

To set T_R, two criteria can be employed:

1. The vanishing of the coherent intensity
2. The peak shape analysis to get the exponent τ and measure the temperature for which $\tau = 1$.

The former approach is hampered by the finite acceptance angle of the detector that cannot distinguish between coherent and incoherent intensity at small Q and by the onset of anharmonic effects and point defect proliferation. The latter approach is more reliable although the peak shape requires a deconvolution to take into account the experimental resolution in particular for atom scattering. Examples are the results on Ag(110) and Cu(115).

1.10 Experimental Results

In this section, we will briefly describe the results of experimental investigations obtained on different systems and, in case also theoretical studies are available, the comparison with specific theoretical results. Other results will be included to describe also the onset of the transition with vibrational anharmonic effects and defect proliferation.

One of the first observations of roughening was obtained in 1977 by *Jackson* and *Miller* [1.38] who studied the growth from the vapor phase for both C_2Cl_6 and NH_4Cl which are crystals with cubic structures that sublime at atmospheric pressure rather than melting. The materials were sealed in a capsule and heated up in a two-zone furnace, the two capsule ends were kept with a temperature difference of about 10 K. The material at the hot end was the vapor source for the growth of crystals at the cold end. If the cold end is below the roughening temperature, the crystal grows with a faceted morphology, while its morphology is rounded for a temperature of the cold end higher than the roughening one as shown in Fig. 1.7. In this way the authors were able to set $T_R = 373$ K for C_2Cl_6 and $T_R = 638$ K for NH_4Cl.

Other pioneering studies on the equilibrium crystal shape at different temperatures, in particular on the morphology of included vapor in crystals (negative crystals) of tetrabromomethane, were performed by *Nenow* and coworkers who observed transitions from facets to rounded regions [1.154].

In the following review, we will present more detailed studies starting with the helium case and then passing to metal surfaces with an emphasis on the (110) surfaces of fcc metals.

1.10.1 Roughening in Helium

The study of roughening of helium surfaces is very important, in particular because helium shows surface phenomena in the cleanest form, without a number of perturbations that other systems have [1.155].

We shall discuss briefly here ^{4}He, by far the most important isotopic species (^{3}He of course is different in many ways). Helium differs from all other substances because it does not solidify at low temperatures, except at relatively high pressures. The solid and the liquid, in fact, are in equilibrium at a pressure p (for ^{4}He near to 25 bars and almost independent of temperature at low T). The helium surfaces are thus solid–liquid interfaces. The interesting temperature range is below 2.5 K: at such temperatures liquid ^{4}He is a superfluid. The most important roughening phenomenon takes place at 1.28 K, as can be seen in Fig. 1.8 [1.155]. Crystals of ^{4}He are hexagonal close-packed (except for a very small area of the (p, T) plane where bcc crystals form). For such an hcp crystal the most visible surface is the (0001) surface, in this case in equilibrium with the superfluid. The surface displays the properties predicted by theory, in particular it is smooth at low temperatures

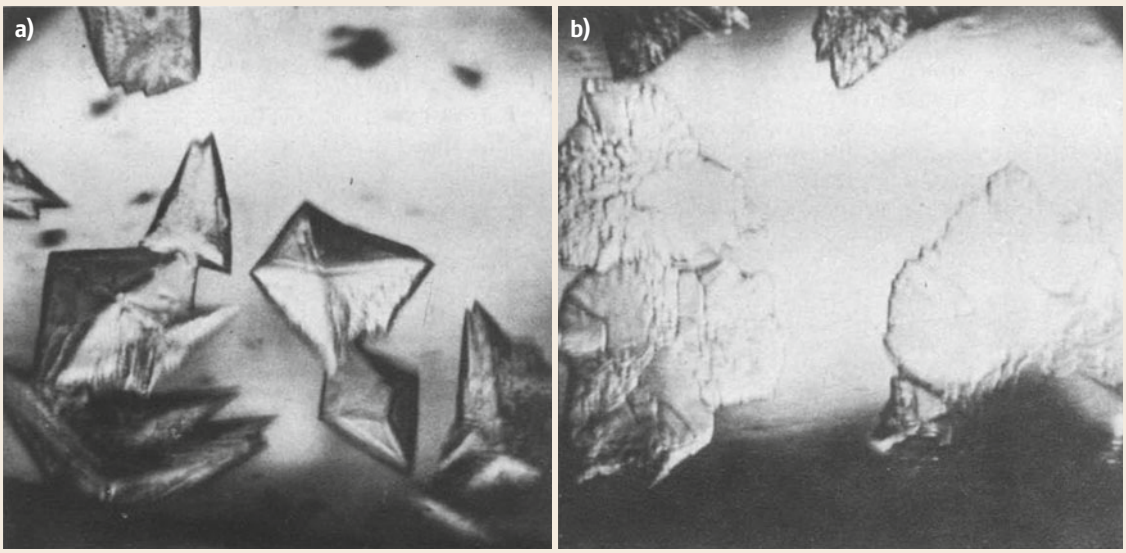

Fig. 1.7a,b Growth morphologies of vapor-transported C_2Cl_6, just below and just above the surface roughening transition. **(a)** Hot end 378 K, cold end 368 K; **(b)** Hot end 388 K, cold end 378 K. Reprinted from [1.38] with permission from Elsevier

and rough at higher temperatures. *Wolf* et al. [1.156] and *Gallet* et al. [1.104] measured the step free energy as a function of temperature: the step free energy decreases in the smooth situation, vanishes at roughening, and is zero in the rough situation as shown in Fig. 1.9. The step free energy is measured via the growth velocity, since, when a crystal grows by two-dimensional nucleation, the classical *Becker–Döring* theory holds [1.101] and gives the growth velocity in terms of an exponential dependence on the step free energy. The experimental results are shown in Fig. 1.9, where the step free energy is shown to decrease from $T = 1.15$ to $T = 1.23$ and to vanish at higher temperatures. This decrease is exponential, accordingly to a *Kosterlitz–Thouless* law [1.18] (in fact, this is presumably the case where the KT behavior is displayed most clearly). The roughening temperature can be evaluated to be $T_R = 1.28$ K. As expected for a KT transition, the step free energy vanishes at T_R with all its derivatives. But between 1.23 and 1.28 K the *Nozières–Gallet* effect [1.37] manifests itself: the step free energy is already effectively zero, although we are still below roughening.

1.10.2 Unreconstructed (110) Surfaces

In this part we will describe the results for the (110) surfaces of Cu, Ag, Ni, Pd, Pb, and Al. As mentioned in the theoretical part, the (110) surface of those fcc metals is unreconstructed but a missing-row reconstruction is observed upon deposition of a small amount of alkali metals. Hence the theory for (110) surfaces is suitable to describe their behavior.

Cu(110)

The first evidence of roughening on (110) surfaces was observed in 1976 by *Stock* and *Menzel* on crystals of 2 mm size of Cu supported on graphite stripes heated by direct current [1.157]. Photographs of those crystals close to melting showed only (111) and (100) facets. One year later, the study of photoemission data on Cu(110) showed an anomalous behavior with temperature [1.158]. The normal photoemission spectrum at a photon energy of $h\nu = 45$ eV was measured in the range between 300 and 1073 K. The spectrum significantly changes with temperature and, at high temperature, the d-band peak becomes asymmetric resembling that of polycrystalline copper. The authors ascribed this behavior to thermal disorder.

Several years later, *Gorse* and *Lapujoulade* using He atom scattering [1.159] obtained similar results. The authors carried out a comparative study on Cu(100) and Cu(110). They measured the specular peak for different kinematical conditions and, for the analysis, the peak was separated into two components: a Gaussian function, which fits the elastic coherent part of the signal, and a Lorentzian function, which could fit either the elastic incoherent or the inelastic contributions, since their apparatus did not perform energy analysis of the scattered beams. Up to 573 K the two copper surfaces behave in a similar way with a small Lorentzian compo-

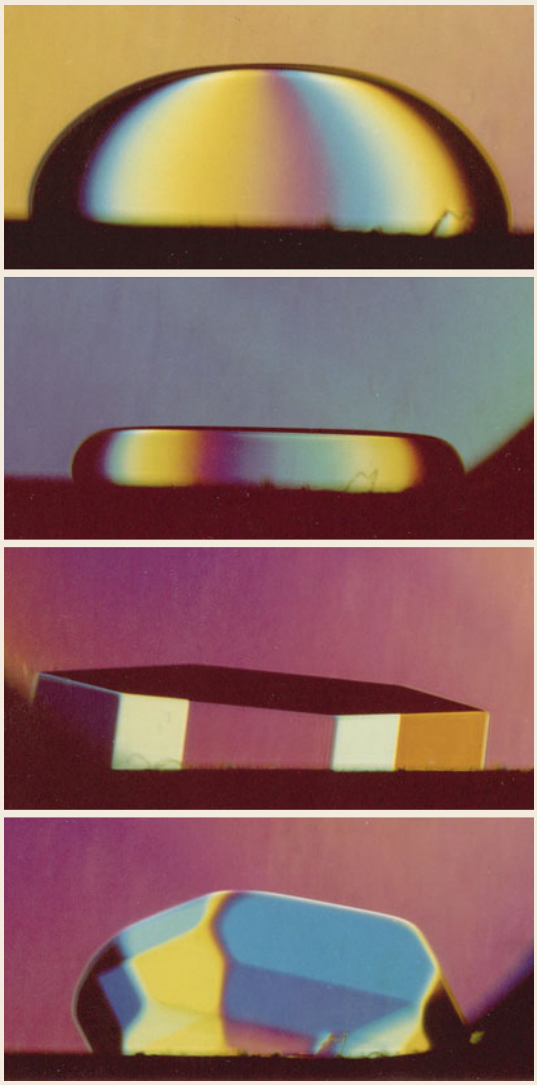

Fig. 1.8 Faceting of ^{4}He crystals during the cooling of the system. From *top* to *bottom panel*, the temperature is 1.4, 1, 0.4, and 0.1 K, respectively. The size of the facets is larger than on equilibrium shapes, because of the slow growth from the surrounding superfluid. Reprinted from [1.155]. Copyright 2005 by the American Physical Society

nent. Above this temperature, the Lorentzian intensity starts to increase but, for Cu(100), the Gaussian one is measurable up to 1273 K (melting temperature 1373 K) indicating that this surface retains some order up to temperatures close to melting. Instead, for Cu(110), the intensity starts to decrease faster than for Cu(100) and the authors were not able to perform measurements above 973 K since the signal dropped below the noise of the instrument. The strong decrease of the scattered

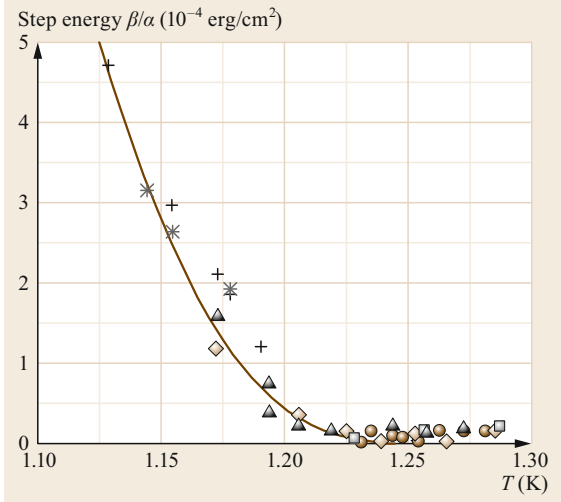

Fig. 1.9 Step free energy for ^{4}He. Drawn from data of [1.104]

intensity was ascribed to thermal excitation of point defects.

Two years later, the interpretation suggested by He atom scattering data was modified by *Fauster* et al. with ion scattering [1.160]. In fact the scattering at 50° of 500 eV Na^+ clearly showed that above 400 K there is a decrease of the scattered intensity and this can be related to huge vibration amplitudes and/or other atomic rearrangements. To gain further information, the authors also performed measurements on 5-keV Ne^+ in quasiback-scattering configuration (deflection angle 164°), i.e., they performed impact-collision ion scattering spectroscopy (ICISS). The angular position of the focusing peak depends on the nearest neighbors distance and its width is sensitive to atomic displacements from equilibrium positions, i.e., to vibration amplitudes. Moreover, a missing nearest neighbor means that the focusing peak shifts to the angular position corresponding to the next-nearest neighbor one, hence ICISS can discriminate between enhanced vibrational amplitude and point defect excitation. The analysis of ICISS data, although not completely conclusive, showed that point defects alone cannot explain all the features of the spectra, and large amplitudes of atomic vibrations in the surface were invoked without excluding the possibility of an atomic rearrangement for $T >$ 500 K.

In the meantime *Mochrie* [1.161] carried out an x-ray diffraction experiment which was consistent with an increase of the mean square roughness of the surface. He considered a reversible vanishing of the Bragg intensity and estimated a roughening temperature of $T_R = 873$ K, but he did not perform any peak shape

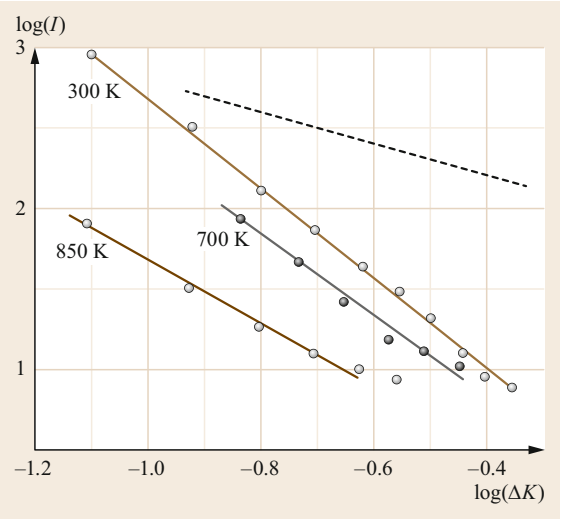

Fig. 1.10 Log–log plot of specular peak profiles in an extended region of the first Brillouin zone for different temperatures. The *dashed line* has a slope of 1 as expected for a peak measured from a surface at its roughening temperature while the experimental points show a much steeper slope. Redrawn from data of [1.163]

analysis to detect a power-law behavior. Conversely, experiments on slightly miscut Cu(110) surfaces performed by surface x-ray diffraction [1.162] showed that the surface can undergo a faceting transition, and some doubts were raised on conclusions about roughening obtained by previous x-ray data.

Zeppenfeld et al. [1.163], analyzing He scattering data obtained with time-of-flight detection, showed that above 550 K the decrease of the intensity is not accompanied by a substantial change of the specular profile, as shown in Fig. 1.10, so that steps are not thermally excited on Cu(110) up to 900 K. In this case, the increase of the mean square displacement measured by Mochrie was due to enhanced surface anharmonicity and not to roughening. In fact, this anharmonicity was directly measured later by *Baddorf* and *Plummer* [1.164] who studied phonon energies and lifetimes between 21 and 766 K by using high-resolution electron-energy-loss spectroscopy, observing a substantial change of the surface phonon lifetime above 450 K. Conversely, Zeppenfeld et al. also measured the diffuse (incoherent) elastic peak as a function of temperature and for various scattering geometries, observing that this intensity decreases with increasing temperature. Therefore, they also excluded the increase of point defect density as the main cause for the observed anomalous thermal behavior for $T > 550$ K. This second point is questionable, however, since both coherent and incoherent contributions decrease with temperature due to the increasing inelastic contributions. To reduce the inelastic effects, the ratio between coherent and incoherent intensity has to be considered; the ratio increases as can be inferred from their data, and this is a sign of defect formation. In fact, analysis of new Ne^+ ion scattering data in ICISS configuration in the energy range 4–5 keV [1.165] supports the enhanced surface anharmonicity for $T > 550$ K, but some observed features can only be explained by the presence of adatoms on top of flat terraces for $T > 455$ K. Moreover, above 1000 K an increase of the broadening of the spectra, not completely described by anharmonic atom vibrations, suggested a rearrangement of surface atoms which could be due to a roughening transition.

The data by *Kern* [1.138] obtained by means of He scattering with energy selection set the roughening temperature at $T_R = 1070$ K (about the value which was obtained by extrapolation of the data of [1.163]).

Comparing experiments with the results on the theoretical side, molecular dynamic simulations based on interaction potentials obtained from the embedded-atom method by *Yang* and *Rahman* [1.166] supported an enhancement of vibrations for surface atoms starting at 600 K (with the further indication that, around 900 K, adatoms and vacancies are created on the surface), but they excluded any roughening of the surface. *Häkkinen* et al. [1.167], using a combination of lattice-gas Monte Carlo and molecular dynamics methods based on the same many-atom interactions derived from the effective-medium theory, estimated the height–height correlation function, which presents a logarithmic divergence that sets the roughening temperature around 1000 K.

Further experimental evidence of the roughening transition for Cu(110) was found in measurements performed for instance by directional elastic peak electron spectroscopy [1.168] where the contrast in logarithmic scale shows a clear change of slope at about 1000 K, and more recently by reflection anisotropy spectroscopy (RAS) and scanning tunneling microscopy [1.169] which also set the transition around 1000 K.

Instead, other measurements performed by means of reflection anisotropy spectroscopy [1.170, 171] set the transition at a lower value around 900 K. The studies are based on the disappearance of the peak at 2.1 eV and on the observation of an energy shift of a feature of the spectrum from 4.2 to 4.3 eV. We can observe that previous results have shown that 900 K is the temperature at which adatoms and vacancies are created and it can be considered to be the onset of the process that will bring the surface to the transition: therefore, the claim of these RAS works on the roughening transition sets only a lower limit to the transition; they have demonstrated the sensitivity of the electronic transitions to surface disorder.

Finally, we would like to mention that in [1.169] the authors did not observe irreversible changes in the results treating the sample up to 850 K. Instead, with higher annealing temperatures, after cooling the sample to room temperature, they observed a permanent change and the previous situation was recovered by ion bombardment. No further analysis was done to relate this irreversible change to segregation of contaminants from bulk, but this effect might be a possible explanation.

Ag(110)

The (110) surface of Ag was the second metal surface extensively (and more successfully) studied to determine the presence and the mechanism of a roughening transition. The first study was performed by *Held* et al. with surface x-ray diffraction [1.172] on a surface having a miscut of 0.3° in the temperature range 373–823 K. The authors carried out radial and transverse scans that clearly showed the evolution of the shape of a bulk-forbidden diffracted peak with the temperature. At 373 K they observed a sharp peak; increasing the temperature to 648 K, the shape slightly changed and at higher temperatures it started to develop substantial tails with an appreciable decrease of the intensity. The radial peak shape was fitted by the sum of a Gaussian function and a Lorentzian one, which represent the coherent (Bragg) diffraction and diffuse scattering from steps, respectively. Above 723 K, the coherent part vanishes and even the tails showed a power-law shape with an exponent consistent with the roughening transition. Moreover, the observed transition was reversible with temperature, indicating that it is indeed an equilibrium phase transition and not a nonequilibrium microfaceting process. Instead, up to 773 K, the integrated intensity of the bulk Ag(111) peak decreases only by 20%, as expected by the Debye–Waller factor, without a change in line shape. The different behavior between surface and bulk peaks demonstrated that the observed changes are exclusively related to those in the surface morphology and T_R was estimated as (723 ± 25) K.

Several years later, *Robinson* et al. [1.173, 175] using x-ray diffraction investigated along the $\langle 1\bar{1}0 \rangle$ direction the peak shape as a function of the momentum exchange q_z perpendicular to the surface and found a behavior that did not agree with the prediction of the roughening theories. For temperatures well below T_R, the peak shape in out-of-phase condition, i.e., in the condition of *Held* et al. [1.172], could be described by a single component. However, when increasing q_z, the diffracted peaks showed an asymmetry and two scattering components were necessary to improve the fit. The authors interpreted this as the coexistence of two phases on the surface, i.e., a faceting. This faceting was explained by the authors as due to the existence

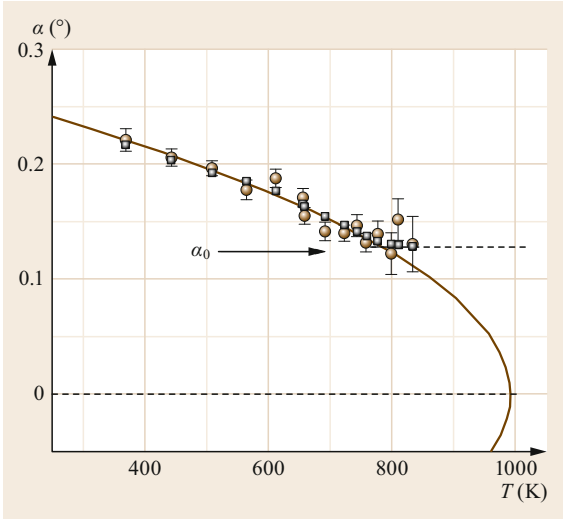

Fig. 1.11 Angle of tilt between the two surface phases, as measured from the separation of the two components of the peak (*brown circles*) or from their relative intensities (*black squares*) using (1.44). Redrawn from data of [1.173]

of forbidden directions in the equilibrium crystal shape around the (110) facet. Since real crystals are cut along the (110) plane within a miscut angle α_0, in the case this angle corresponds to a forbidden direction [1.176, 177], the surface free energy can be lowered separating the surface into regions corresponding to the (110) facet (A) and stepped (rough) regions (B), the so called hill-and-valley configuration. The angular separation between the two scattering components, related to the tilt angle between the (110) facet and rough regions, and their relative intensities, related to the surface area, supported this hypothesis. In fact, at room temperature, the data showed that the tilt angle α was greater than α_0 in order to preserve the macroscopic miscut and decreased until it leveled off at the value corresponding to α_0, as shown in Fig. 1.11. At the same temperature, the scattering intensity associated with the (110) facet vanished namely the (110) facet disappeared from the equilibrium crystal shape. The authors, by using the lever rule [1.178] made a second independent estimate of the tilt angle α' based on the surface areas of the A and B phases, and since the integrated intensities of the two fitting components, I_A and I_B, are proportional to areas, they obtained the following relationship

$$\alpha' = \frac{\alpha_0 (I_A + I_B)}{I_B} \qquad (1.44)$$

and the results are plotted in Fig. 1.11a. Cooling the sample, the surface phase separated once again into flat A and tilted rough B regions, but only a few points were measured for temperatures above 650 K.

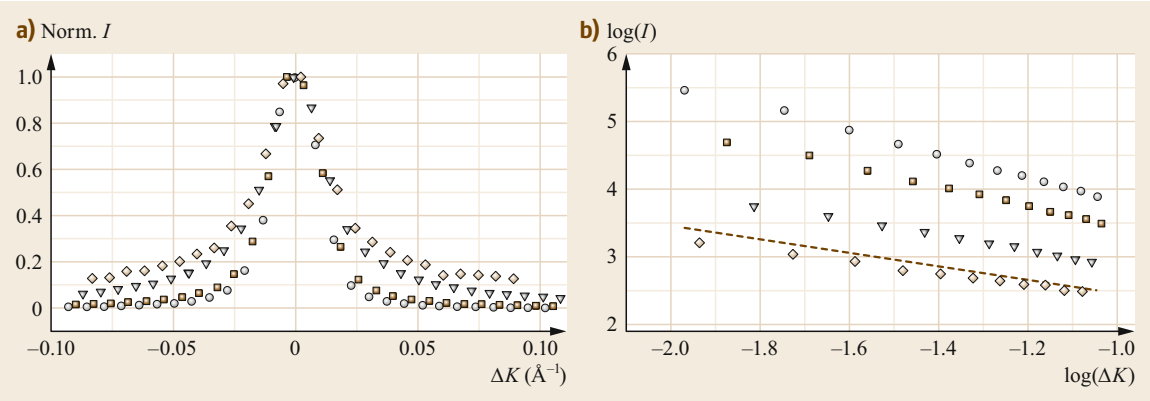

Fig. 1.12 **(a)** Normalized intensity of the specular peak measured from Ag(110) along ⟨001⟩ at 643 K (*circles*), 766 K (*squares*), 861 K (*triangles*), 951 K (*diamonds*). A constant background has been subtracted from all of the data shown. **(b)** Log–log plots of the tails of specular He profiles of **(a)**. Estimated values for the roughening exponent τ: 0.22 at 643 K, 0.49 at 766 K, 0.91 at 861 K, 1.17 at 951 K. The *dashed line* has the slope expected for a surface at its roughening temperature: $\tau = 1$. Redrawn from data of [1.174]

This behavior suggested a mechanism to roughen the surface different from that described in the theoretical part. On real surfaces (110) facets are coexistent with rough regions. Increasing the temperature results in new excited steps on the facets. These steps migrate toward the stepped regions which expand at the expense of the (110) facets. At the temperature T^*, which thus depends on the miscut angle, all the surface is covered by stepped regions and the surface becomes rough. Hence T^* corresponds to T_R and the roughening mechanism, which for classical theories is the proliferation of steps on a flat surface, must be replaced by the redistribution between flat and rough regions. In particular, Robinson et al. found $T^* = 790$ K for their crystal having $\alpha_0 \approx 0.14°$ and the discrepancy with the previous estimate of T_R [1.172] was ascribed to the large miscut angle, 0.3°, of the crystal used in the previous experiment. Moreover, they also extrapolated their results to estimate the roughening temperature of a perfect (110) surface ($\alpha_0 = 0°$) obtaining an approximate value of 990 K. These conclusions were drawn for the $\langle 1\bar{1}0 \rangle$ direction and Robinson et al. left open the possibility that the classical mechanism can act along ⟨001⟩.

The ⟨001⟩ direction was investigated by *Bracco* et al. [1.174] by means of He scattering with time-of-flight detection. There was no evidence, however, of a double component in the specular peak profile and all the data agreed with the classical picture of roughening. In fact, up to ≈ 700 K the intensity of the specular peak decreased following the prediction of the Debye–Waller factor and the incoherent to coherent ratio was almost constant, while for $T > 700$ K, the intensity decreased more rapidly along with the increase of the ratio, a clear sign of the proliferation of point defects. The analysis of the specular peak shape in out-of-phase scattering conditions showed that the onset of the transition happens for $T \approx 700$ K and a roughening temperature of 910 ± 15 K was estimated (Fig. 1.12). Moreover, the crystal used in the experiment had a miscut of $\approx 0.15°$ and this last estimate of the roughening temperature could not be explained by the hill-and-valley mechanism of *Robinson* et al. [1.175] without invoking two different roughening temperatures on the same surface. Other studies performed by means of STM and x-ray scattering [1.179, 180] showed that the faceting transition observed by Robinson is due to segregation of contaminants from the bulk, very probably sulfur. In fact, prolonged heating of the crystal at temperatures higher than 850 K determines the segregation of sulfur and even an estimated coverage of 0.001 of a monolayer was able to change the surface morphology. STM images showed clusters containing 10–20 sulfur atoms which act as pinning sites for steps. Studies performed with He scattering [1.181] showed the evolution of the surface morphology with prolonged Ar^+ sputtering. By using ions at low energies (100 eV), that are not effective to sputter Ag atoms but enough to remove low mass contaminants, and starting from a faceted surface the specular peak shape gradually lost the satellite peaks due to tilted areas. After 24 h the shape did not show additional components; therefore, the surface had recovered a morphology with uniformly distributed steps across the surface. The crystal treated in this way showed sufficient stability to allow the completion of experiments also at a temperature higher than 900 K before a new treatment was required. New x-ray results [1.182] on a sample, treated under ultra-high vacuum (UHV) conditions by several hours Ar^+-ion

sputtering at 500 eV and subsequent annealing up to 1000 K, gave an estimate of T_R of (900 ± 50) K. A few years later, another study carried out with He scattering [1.181, 183] performed a careful investigation of the effects that can affect the estimation of the roughening temperature through peak shape analysis. In fact, since He scattering is very sensitive to surface atomic vibrations, truly elastic intensities should be considered and collecting some inelastic intensities reduces the estimated values: for instance a deconvolution of the peak in elastic and inelastic phonon contribution increases T_R of 4% with respect to the case in which the intensity of each point of the peak profile is obtained by integrating the scattered signal within an energy window of 0.8 meV around the elastic intensity. Moreover, the short-range behavior of the MSHD can obscure the asymptotic evolution towards a power-law shape (see for instance the Cu(115) case) and taking into account that this effect increases T_R by about 10%. Including all these effects, the first estimated T_R at 910 ± 15 K increased up to 1000 ± 30 K.

Other experiments [1.184] showed that surface phonon anharmonicity is similar to Cu(110) and above 600 K frequency shifts increase due to proliferation of defects. A direct measurement of self-diffusion of Ag adatoms [1.185, 186] showed that silver adatoms migrate with a strong anisotropy. Diffusion limited to the $\langle 1\bar{1}0 \rangle$ direction started at a crystal temperature above 600 K, in agreement with theoretical simulations [1.187]. The analysis of an ion scattering investigation [1.188] showed that the $\langle 1\bar{1}0 \rangle$ atomic rows remain defect free up to 700 K while along $\langle 001 \rangle$ the defect percentage increases rapidly above 600 K. All the data indicated the presence of missing rows confirming the theoretical prediction about the proliferation of missing rows at the onset of the transition [1.47].

Molecular dynamic simulation on Ag(110) [1.189] showed that up to 700 K the mean square vibrational amplitudes of the surface atoms are very similar both in the surface plane and perpendicular to the plane, while above 700 K the amplitudes along the in-plane directions begin to become the larger ones, in particular along $\langle 001 \rangle$, and above 750 K, the surface begins to disorder due to the creation of adatom–vacancy pairs with adatoms that diffuse preferentially along the close-packed rows, i.e., along $\langle 1\bar{1}0 \rangle$. The roughening temperature was estimated to be 930 K with a statistical error of 20 K. More recent calculations [1.190] found a surface roughening at 950 K, essentially in agreement with previous simulations and with the experimental results.

Ni(110)

The roughening transition of Ni(110) was investigated by *Cao* and *Conrad* [1.191] using high-resolution low-energy electron diffraction. The sample was initially heated to 1120 K in O_2 at 10^{-6} Torr for 24 h to remove excess subsurface carbon. Then the sample was sputtered with 500 eV Ar^+ at a sample temperature of 1070 K to remove any remaining oxygen and sulfur contamination. Although the Auger signal showed no detectable contamination, the authors observed a non-reversible peak splitting of diffraction peaks when the sample was heated above 750 K. The sample was further treated with three weeks of repeated sputtering at 1070 K followed by annealing up to 1170 K and cooling down to 670 K with a slow rate of 0.4 K/s. After these prolonged treatments the splitting was no longer observed. On this clean sample, the measurements showed that, up to 900 K, the logarithm of the diffraction peak intensities linearly decayed; therefore the temperature dependence of specular and diffracted beams could be accounted for by a Debye–Waller factor. Instead, for temperatures up to 1200 K, the decay was faster with no change in the peak shape both for in-phase or for out-of-phase conditions so the anomalous decrease of the intensity was interpreted as due to anharmonic effects. This was also consistent with the trend of the background to peak intensity ratio which started to increase at 1150 K indicating vacancy formation at this temperature. For the analysis, the specular peak was fitted by a Gaussian central peak (G) and a Lorentzian function (L). Between 1200 and 1400 K the width of the L component in out-of-phase condition broadened and the ratio between G and L which was constant up to 1150 K started to decrease and before reaching 1400 K the ratio almost vanished. From these results, Cao and Conrad estimated a roughening temperature $T_R \geq 1300$ K.

Other experimental evidence of the roughening transition was found by *Mróz* studying the contrast in Auger signal versus sample temperature [1.192]. Above 740 K, the contrast showed a change of the slope with an increase in the decay followed by another increase for temperatures higher than 1300 K. The low temperature change was interpreted as due to anharmonic effects that set in above 740 K and the second change to a lateral disorder in the first atomic layers consistent with a roughening transition at 1300 K.

Molecular dynamics simulations performed by *Beaudet* et al. [1.193] and based on a semiempirical embedded-atom method gave results in substantial agreement with the Cao and Conrad results. In fact, Cao and Conrad estimated a vacancy density of the order of 4% at 1000 K, and between 5% and 15% at 1200 K to be compared with calculated values of 4% and 13%, respectively. The logarithmic divergence of the MSHD was not estimated to precisely set T_R due to the small scale of the simulations, however, at approximately 1300 K, the calculations showed that out-of-plane dis-

order reached the second layer. *Chen* et al. performed similar investigations [1.194] in which the embedded-atom theory is used to describe interatomic interactions. Although the main interest was the study of surface melting of Ni(110), they found that up to 1250 K the density profile showed a gradual change and, only at 1450 K, they observed the formation of an adlayer absent at lower temperatures. Since they did not perform simulations between 1250 and 1450 K, this temperature range is in agreement with the lower limit experimentally determined by Cao and Conrad for T_R at 1300 K.

The behavior for $T < T_R$ of the diffracted peaks, fitted by means of a broad Lorentzian plus a Gaussian central peak, was also consistent with the occurrence of a preroughening transition, even if no conclusive evidence for that was obtained [1.137].

Pd(110)

Hörnis et al. investigated the structure of Pd(110) with high-resolution low-energy electron diffraction [1.195]. The sample presented a miscut angle of 0.1° and was cleaned in situ by thousands of cycles of argon-ion sputtering at 500 eV for 10 min, followed by annealing at 1273 K for 10 min. After this cleaning procedure, Auger spectra did not show C, S, or O contaminations and it was possible to keep the sample at 1473 K for 30 min and then cool it to room temperature without a change in the diffraction intensity. The authors observed that a well-ordered (110) surface could only be obtained with slow cooling of the sample from 1273 to 673 K in no less than 3 min.

The width of the specular peak was measured for different scattering conditions and was found to oscillate with a period $2\pi/h$, where h is the height of a monatomic step on the Pd(110) surface ($h = 2.75$ Å) indicating that monatomic steps are present on the Pd(110) surface even at room temperature.

For temperatures below 1273 K, the authors observed the presence of satellite peaks near the specular peaks as shown in Fig. 1.13 along the direction perpendicular to the atomic rows, i.e., ⟨001⟩, as well as in the $\langle 1\bar{1}0\rangle$ parallel to the atomic rows. These satellite peaks were consistent with a large-scale 80×45 reconstruction of the Pd(110) surface [1.196]. This reconstruction was very stable since it was observed up to 1273 K.

We note that this long-range reconstruction for bare Pd(110) was not reproduced in subsequent investigations in real space with scanning tunneling microscopy carried out by *Niehus* and *Achete* [1.197], and long-range superstructures were observed only with oxygen adsorption.

Conversely, it is interesting to consider the results by *Hörnis* et al. [1.195] concerning the high-

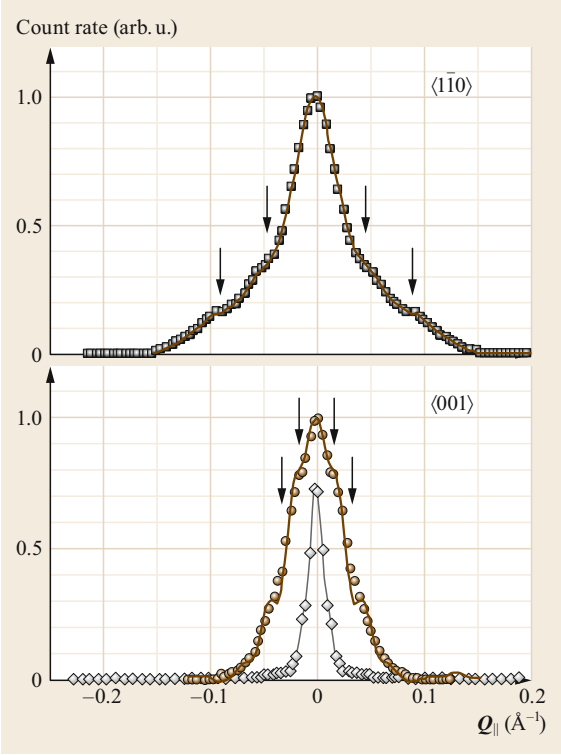

Fig. 1.13 Parallel momentum $Q_{||}$ scans through the (110) point taken both perpendicular to the atom rows, ⟨001⟩ (*circles*) and along the rows, $\langle 1\bar{1}0\rangle$ (*squares*). For comparison, the (220) in-phase peak is shown (*diamonds*). Measurements were carried out at 523 K with an electron energy of 307 eV, and an incident angle (relative to the sample normal) of 82.7°. *Arrows* indicate the positions of the satellite peaks. The *solid line* for the (001) azimuth is a fit assuming islands of 59 atoms, separated by 20 atomic spacings forming a system with periodicity of 79 atomic spacings. Reproduced with permission from [1.195]

temperature behavior of Pd(110). Their analysis showed that the width of the diffraction peaks shows three temperature regions as shown in Fig. 1.14. In fact, the line shapes were essentially constant up to 773 K. In the interval between 773 and 1173 K, the FWHM in the ⟨001⟩ direction, perpendicular to the atom rows, decreases, while in the $\langle 1\bar{1}0\rangle$ directions the FWHM increase is due mostly to an increase in the broad background component of the line shape. Since the separation distance between satellite peaks does not change in this interval the superlattice period remains constant. Therefore, the changes in the FWHM indicate a rearrangement of the structure of the superlattice cell.

Above 1373 K, the line shapes changed suggesting a transformation in the surface morphology since the satellite peaks disappear and the entire line shape be-

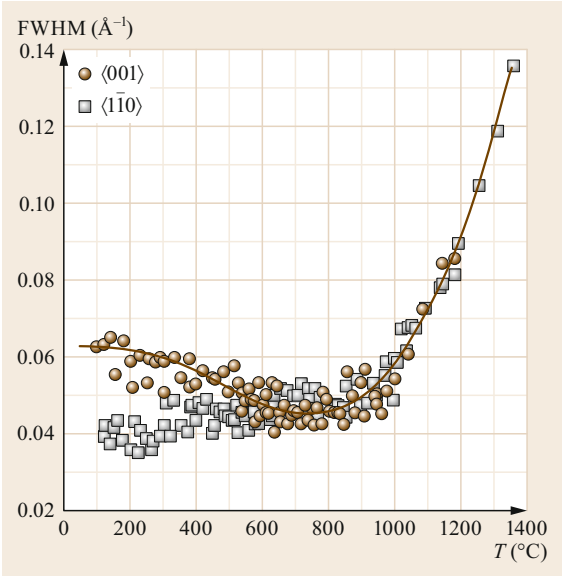

Fig. 1.14 FWHM of the (110) peak of Pd(110) versus temperature for scans along ⟨001⟩ (*circles*) and along ⟨1$\bar{1}$0⟩ (*squares*) directions. The *solid line* is a guide to the eye for the (001) data. Measurements performed at an electron energy of 307 eV, and with an incident angle (relative to the sample normal) of 82.7° for all scans. gins to broaden and the broadening was observed for peaks in out-of-phase scattering condition. This could be assigned to a roughening transition at a temperature of 1373 K. However, the authors took with caution this line-shape broadening as due entirely to a thermal roughening transition. In fact, Pd's vapor pressure between 1073 and 1273 K, increase from 1.2×10^{-9} to 8.4×10^{-7} Torr. At an even higher temperature of 1373 K, the evaporation rate from the surface is about one ML/s therefore the origin of this Pd(110) roughness cannot not be completely due to thermal equilibrium in the surface alone but even the kinetic of the evaporation, that could be considered as a negative growth process, can contribute to it.

Pb(110)

Heyraud and *Métois* studied the equilibrium shape of lead microcrystals lying on a graphite cleavage plane [1.44, 199]. In the first step, they condensed a 1000 Å-thick film on a cleaved graphite monocrystal in UHV, then, heating the film above the Pb melting temperature, the films broke in droplets of $\approx 5\,\mu$m size. The second step was the lowering of the temperature at the chosen value and a further Pb condensation of 1000 Å yielded the growth of flat crystallites. Finally, the sample, removed from the UHV preparation chamber, was observed by scanning electron microscopy. For growth temperatures above 393 K, only the (111) and (100) facets were observed. Below this temperature, the (110) was also observed.

Yang et al. measured the roughening transition of Pb(110) by means of high-resolution LEED (HRLEED) [1.198] on a sample whose miscut was estimated to be 0.1°. The authors measured the specular peak as well as another two diffracted peaks, (10) and (01). At low temperature, the peak profiles were smooth and without shoulders or peak splitting. Moreover, changing the incident energy, the FWHM of the peaks did not show any oscillatory behavior. However, an oscillatory behavior was observed upon raising the temperature, a clear sign that steps were generated on the surface, as shown in Fig. 1.15. From the

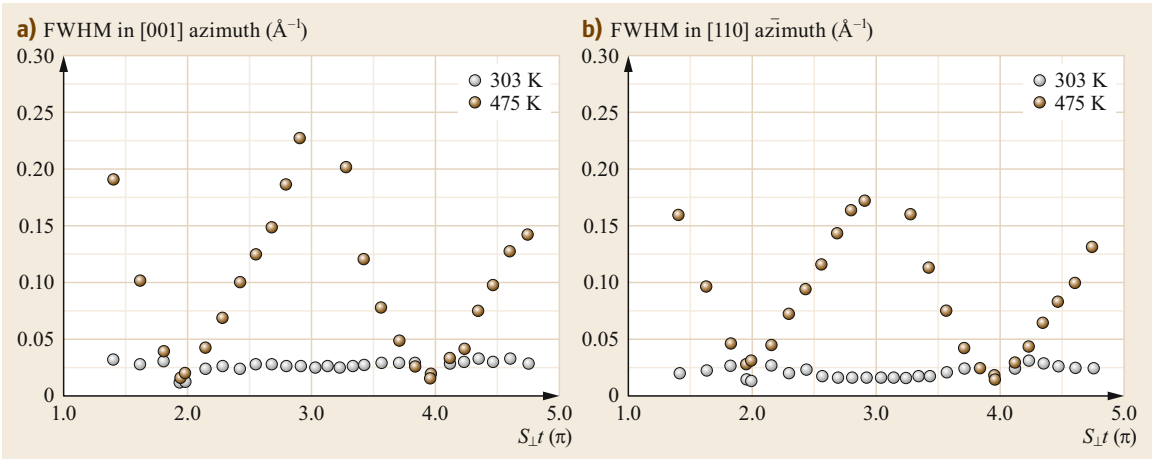

Fig. 1.15a,b FWHM of the (00) beam versus the perpendicular momentum exchange $S_\perp$ measured along **(a)** [001] and **(b)** [1$\bar{1}$0] directions. Measurements were performed at 303 and 475 K, t is the step height. Reproduced with permission from [1.198]

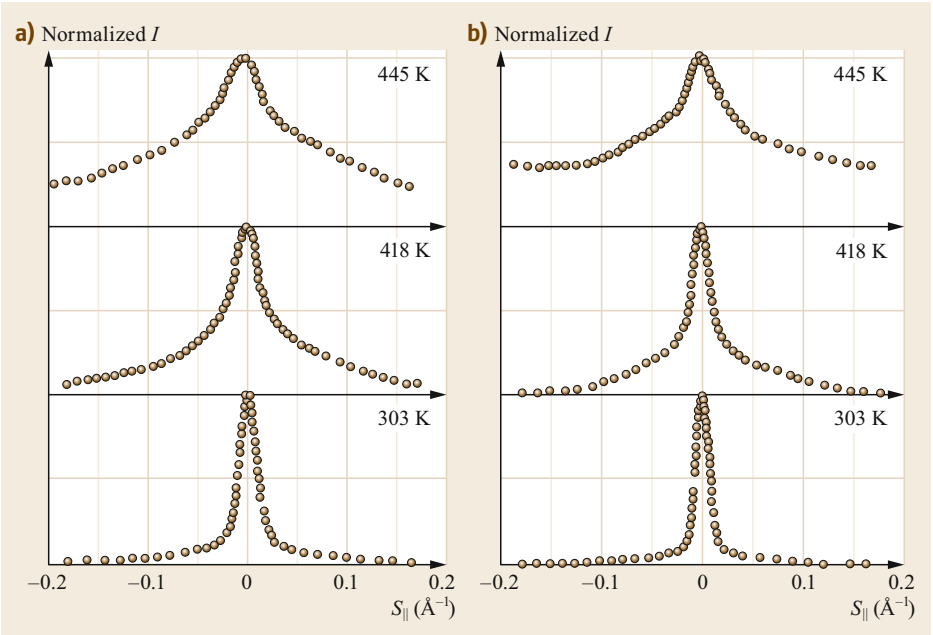

Fig. 1.16a,b Angular profiles of the (00) beam at 303, 418, and 445 K are plotted as a function of the parallel momentum transfer $S_{\|}$ and in out-of-phase condition ($S_{\perp}t = 3\pi$) at an incident energy $E = 27.0$ eV. **(a)** In [001] azimuth; **(b)** in $[1\bar{1}0]$ azimuth. Reproduced with permission from [1.198]

period of oscillation, the authors deduced that the surface contains single atomic steps with a step height of 1.75 ± 0.05 Å, a value consistent with the bulk value.

The authors also observed the evolution of the peak profiles measured along both the [001] and $[1\bar{1}0]$ directions at different temperatures in the out-of-phase condition shown in Fig. 1.16.

At low temperature the peak shape is sharp; substantial tails were instead observed at 418 K. Since close to the roughening transition, the peak shape is a power law due to the logarithmic behavior of the MSHD, the authors performed an analysis of tails as shown in Fig. 1.17 where the intensity is plotted as a function of the momentum exchange. The slope $\tau = -1$ is reached at about 415 K, hence they set $T_R \approx 415$ K.

Landa et al. performed a molecular dynamics simulation of Pb(110). They considered a semi-infinite system modeled by means of a slab of Pb atoms interacting through a many-body glue potential [1.48]. The simulations showed that the Pb(110) surface started to disorder through the excitation of adatom–vacancy pairs in the temperature range between 320 and 360 K. Up to 400 K, adatoms were isolated, but just above 400 K they formed small clusters of 2–3 atoms. With a further increase to 450 K, the authors observed clusters formed by 10–20 atoms and they identified this type of behavior with the roughening transition. With further increases in temperature, the Pb(110) surface disorders by step formation, first along the $[1\bar{1}0]$ direction and then along [001] direction. The exact transition temperature was estimated by the authors mapping their solid–gas interface model to an anisotropic 6-vertex solid-on-solid BCSOS model. As shown in Sect. 1.2, by using (1.4), the authors estimated $T_R = 436$ K, not far from the experimental value.

Al(110)

Schwarz et al. studied the dependence of Al(110) structure on the temperature by means of low-energy electron diffraction [1.200]. The study was performed between 100 and almost 900 K. The authors observed a sinusoidal variation of the FWHM at 300 K due to the presence of steps but this variation deviated from a sinusoid above 500 K. At the same temperature, the ratio of the background to the specular peak intensity showed a gradual increase. Analyzing the peak shape in out-of-phase condition, at low temperature it was well described by a Lorentzian function; instead, closer to the roughening transition, the shape was better represented by a power law whose exponent indicated a roughening temperature at about 550 K along $\langle 1\bar{1}0 \rangle$ and about 650 K along $\langle 001 \rangle$. On average a roughening transition at about 600 K was estimated.

A previous investigation by *Pavlovska* et al. [1.201], although not precisely fixing a value for T_R, concluded that in the range 420–750 K the surface is in a roughening state, accompanied by anharmonic vibrations not only parallel but also normal to the surface. An investigation carried out by *Pedemonte* et al. with ion scattering in backscattering mode provided another indication that supports the roughening transition for Al(110) at about 600 K [1.202].

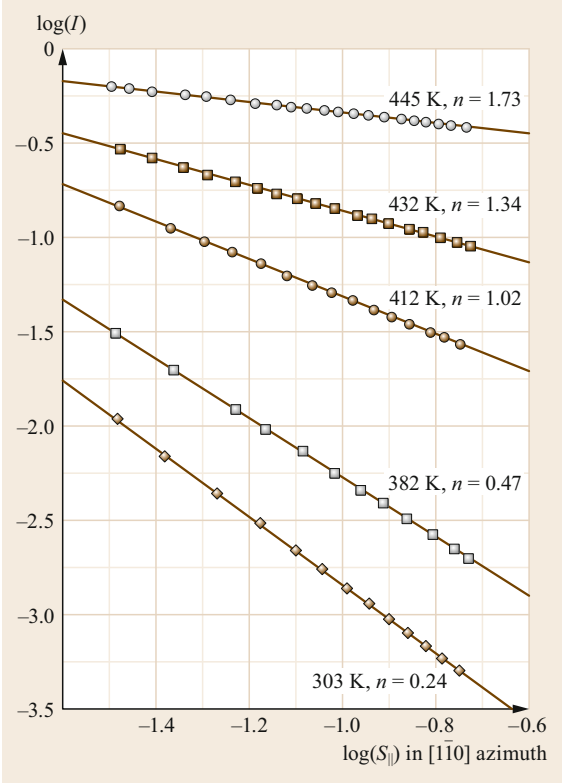

Fig. 1.17 The log–log plots of the tail part of the (00) beam profiles, measured in the $[1\bar{1}0]$ direction and in out-of-phase condition ($S_\perp t = 3\pi$), are shown at different temperatures. The data were taken from 2% to 10% of the Brillouin zone away from the center of the Bragg peak. The slope of the plots is equal to $(2-n)$ and, at roughening, $n = 1$. Similar plots were obtained for profiles measured in the [001] direction. Reproduced with permission from [1.198]

1.10.3 Reconstructed (110) Surfaces

As described in the theoretical part, in these systems two different transitions can be present, deconstruction and roughening, and it was interesting to study the coupling between them, to establish whether they occur at different temperatures, and to determine the universality class to which they belong.

Au(110)

Wolf et al. observed the deconstruction transition between the low-temperature missing-row reconstructed (1×2) to the unreconstructed (1×1) (110) surface of gold Au(110) with LEED at $T_D = 693 \pm 15$ K [1.203]. A few years later, *Campuzano* et al. carried out a detailed study of the deconstruction transition [1.204] investigating the dependence on the temperature half-order peaks related to the reconstructed phase. The sample presented a miscut angle of 0.5° and was carefully prepared. At room temperature the diffraction pattern presented the double periodicity but, for temperatures greater than 700 K, the half-order peaks disappeared and a diffraction pattern related to a primitive (1×1) structure was observed and the peak intensities did not show hysteresis as a function of temperature. Since near a second-order transition, the diffraction peak shape can be separated into two contributions [1.205]

$$I(\delta K, t) = \rho(t)^2 \delta\left(\Delta\boldsymbol{K} - \boldsymbol{G}_{\frac{1}{2}}\right) + \chi\left(\Delta\boldsymbol{K} - \boldsymbol{G}_{\frac{1}{2}}, t\right), \tag{1.45}$$

where $\boldsymbol{G}_{1/2}$ is the reciprocal vector of a half-order diffraction peak for the Au(110)(2×1) and $t = (T - T_D)/T_D$ is the reduced temperature. The first term, related to the long-range order parameter of the transition ρ, mainly contributes to the peak for $T < T_D$ and tends to zero at the transition as $|t|^{2\beta}$, the second term is the only term present above T_D and is related to the susceptibility χ which depends on the order parameter correlation function that diverges at T_D as $t^{-\gamma}$ and whose correlation length diverges as $|t|^{-\nu}$ contributing to the peak width above T_D as $|t|^{\nu}$: β, γ, and ν are the critical exponents of the transition and, through the investigation of the peak shape around T_D, their values can be estimated. In particular, for the two-dimensional Ising universality class of interest for the deconstruction transition, the exponents are $\beta = 1/8$, $\gamma = 7/4$, and $\nu = 1$. The analysis of the half-order peak shape based on (1.45) suggested that the transition indeed belonged to the 2-D Ising class with a deconstruction temperature $T_D = (649.2 \pm 1.5)$ K as shown in Fig. 1.18.

An ion scattering study was performed by *van de Riet* et al. [1.208] in the temperature range 300–900 K. They observed that single vacancy formation started at 530 K and up to 750 K double vacancy contribution was negligible. Above 650 K a background contribution due to the number of steps on the surface also started. The results of an x-ray study performed by *Keane* et al. [1.209] on the temperature dependence of the in-plane superlattice and integral-order surface peaks as well as on the specular reflectivity showed that the deconstruction transition happens at $T_D = 735$ K without an increase of step density and with estimated critical exponents close to 2-D Ising values. Above 784 K there was a significant increase in the density of surface steps that could be related to surface roughening and they estimated the onset in the range 752–784 K. They also observed a systematic shift in the deconstruction temperature: a decrease of 1 K for every four hours the sample temperature was above 700 K. This was interpreted as being caused by contaminants with

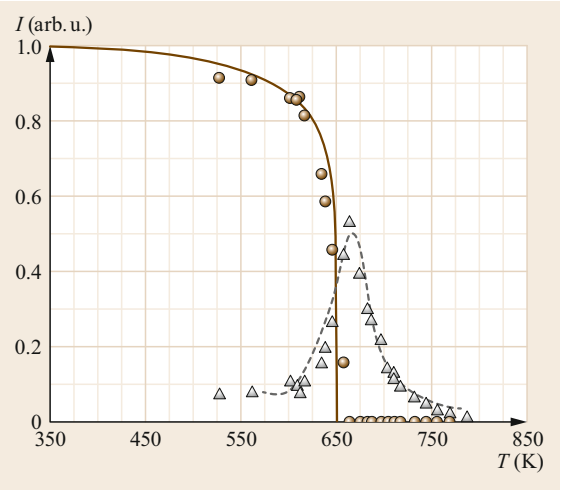

Fig. 1.18 Plot of the diffracted peak intensity measured from Au(110) (*circles*) related to long-range order and *Onsager*'s theoretical result [1.206] (*solid curve*); the fluctuations (*triangles*) and theoretical results by *Fisher* and *Burford* [1.207] (*dashed curve*) are also shown. Reproduced with permission from [1.204]

a coverage below the level of detectability of their Auger analyzer. Sprösser et al. investigated Au(110) with He atom diffraction. The deconstruction temperature was estimated at 650 K and, through a peak shape analysis and assuming the roughening exponent $\tau = 1$, T_R was estimated 740 K. Conversely, since the steps were observed not to be simply monatomic but instead presented a multiple-height distribution, and simulations performed by the authors [1.210] showed that T_R should be about 10% lower than the estimation obtained through the roughening exponent, they assigned T_R at 690 K, the onset temperature for specular broadening. An ion scattering investigation by *Hoss* et al. on the roughening and melting of Au(110) [1.211] reported an anomalous behavior at 680 K and a possible interpretation was the occurrence of a roughening transition. Another ion scattering study was carried out by *Höfner* and *Rabalais* [1.212] to investigate the deconstruction transition. Measurements were performed in the range of 298–720 K and the results of the data analysis showed that features related to the (1×2) reconstruction could still be observed at 720 K, reflecting the unusually high stability of the reconstruction. Another He beam scattering experiment was performed by *Cvetko* et al. [1.213]. The deconstruction was Ising-like and its temperature was estimated at 700 ± 5. An analysis of the peak shape was carried out up to 723 K where the power law shape showed a negative exponent -1.55. Unfortunately, the authors were not able to perform measurements at higher temperatures: in fact the segregation of Ca determined a relatively fast decay of the specular intensity; instead measurements below 725 K were reproducible. Since the exponent was smaller than the expected value at the roughening transition, the authors estimated $T_R > 723$ K.

A study on the specific heat anomalies by *Clark* et al. [1.214] showed that the critical exponents for the deconstruction were consistent with an Ising transition and the estimated critical temperature was $T_D = 695 \pm 3$ K.

Sturmat, *Koch*, and *Rieder* performed an STM investigation of Au(110) in the temperature range 300–700 K [1.215]. Since any real surface presents a miscut, terraces have a finite extension and are separated by steps and the authors observed that those steps became more jagged on increasing the temperature up to T_D. Instead the (1×2) reconstruction was stable above T_D as observed with ion scattering. Therefore, the authors proposed that the Ising transition observed with diffraction techniques was due to the 2-D roughening of the step edges, at higher temperature the (1×2) reconstruction is still present and only at the 3-D roughening transition (≈ 700 K) the surface deconstructs. These results confirmed that there are two transitions at different temperatures but the details of the step evolution involved in the deconstruction are in contrast with the theoretical models. Although some doubts were raised by *Rost* and *Frenken* [1.216] about possible artifacts due to the limited scan speed, the observation of jagged step edges was confirmed by *Koch* and *Schulz* [1.217].

It is interesting to consider the investigation by *McRae* et al. [1.218] on Sn segregation to the (110) surface of a nominally pure Au crystal. The authors carried out experiments with low-energy electron diffraction, Auger electron spectroscopy, and low-energy ion scattering and observed a change of the deconstruction temperature which depended on the Sn coverage. Sn segregated for $T > 675$ K and for a coverage of 0.002 ML T_D decreased by 15 K, while for 0.13 ML the decrease was 200 K. This sensitivity to contamination could be a possible explanation of the spread in the estimated transition temperatures among different experiments, since different samples can contain different amounts of contaminants.

Pt(110)

Robinson, *Vlieg*, and *Kern* investigated Pt(110) with x-ray diffraction [1.81]. The Pt crystal presented a miscut angle of 0.1° and was prepared with treatments in O_2 and annealing to 1200 K to remove C impurities. The peak shape analysis showed that the coherent intensity related to (1×2) reconstruction vanished at 1020 ± 1 K and within 5 K from this transition, the width and position of those peaks started to increase, as shown in

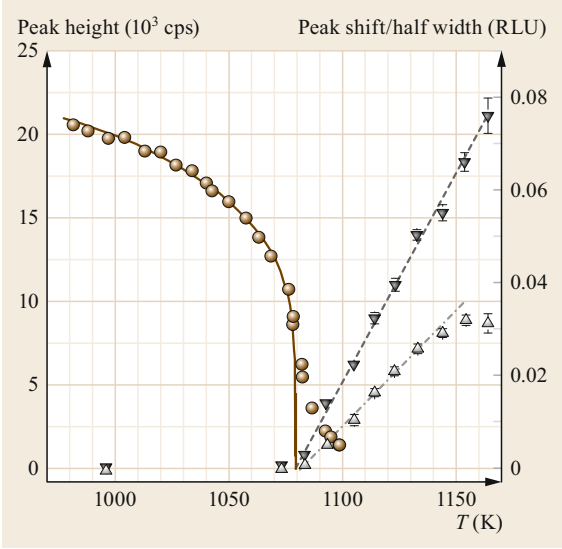

Fig. 1.19 Temperature dependence of the Lorentzian fitting parameters of the Pt(110) radial lineshape measured at $(1.5, 0, 0.06)$: peak height (*circles*) and fit (*solid line*) obtained with $T_D = 1080\,K$ and $\beta = 0.11$. Half-width (*black down triangles*) and its linear fit (*dashed line*); shift (*gray up triangles*) and its linear fit (*dot-dashed line*). Shifts and widths are in reciprocal lattice units (RLU). Drawn from data of [1.81]

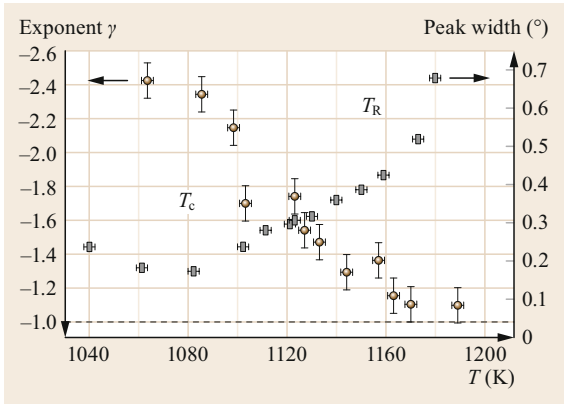

Fig. 1.21 Deconvoluted specular peak width (FWHM) (*gray rectangles*) versus temperature. *Brown circles*: exponent γ from the best fit of the specular tails to the power law, $|\Delta Q|^{-\gamma}$. T_c deconstruction temperature, T_R roughening temperature. Reproduced with permission from [1.219]

Fig. 1.19. Since the shift is in contrast with the expected behavior for an Ising system the authors interpreted this fact as due to spontaneous step formation above the deconstruction transition and hence assumed that the surface is in a rough phase, although they did not perform a fit for establishing that the peak shape is a power-law.

A He scattering study performed by *Cvetko* et al. [1.219] found a different behavior. The deconstruction temperature was estimated at $1087 \pm 5\,K$ and the behavior is consistent with an Ising transition. The broadening of half-integer order peaks (shown in Fig. 1.20) is similar to x-ray results. Conversely, above this temperature, the specular peak broadening is less pronounced than that of the half-integer order peaks and the authors interpreted this difference as due to a density of single steps that increased at a much slower rate than the density of domain walls, therefore single steps are only partially involved in the deconstruction. Moreover, a peak shape analysis up to 1250 K separating elastic from inelastic contributions showed that the specular peak in out-of-phase condition evolved to a power-law shape and the roughening exponent was close to -1 at $1160 \pm 10\,K$, as shown in Fig. 1.21. *Krzyzowski* et al. studied Pt(110)(1×2) with He scattering and electron diffraction [1.220]. They found that the deconstruction transition at $1025 \pm 10\,K$ is consistent with an Ising transition. At higher temperature the analysis of the peak evolution to a power-law shape allowed them to evaluate $T_R = 1095 \pm 20\,K$.

Koch et al. also performed a comparative study of Au(110) and Pt(110) with STM [1.221]. The two surfaces showed a similar behavior for what concerned the presence of the (2×1) reconstruction above the transition at lower temperature due to 2-D roughening of preexisting steps, but with the difference that for Pt there is also a simultaneous formation of islands and holes in the flat terraces.

1.10.4 Vicinal Surfaces

The roughening on metal singular-faces, as (110), requires step formation on a flat step-free surface and a lot of energy is involved in the process, therefore it is foreseen that singular faces roughen at high temperatures close to the melting one. Instead on vicinal metal surfaces a step array is already present and its disordering due to kink formation costs less in energy, therefore the roughening temperature is much lower than the melting temperature: for this reason, experimental studies on vicinal surfaces were in some way easier to perform, but if the temperatures are really low this can impede the attainment of equilibrium conditions.

Cu(113) was investigated by *Salanon* et al. with helium atom diffraction [1.222]. The authors performed a peak shape analysis and estimated $T_R = 720 \pm 50$ K. A previous x-ray study by *Liang* et al. [1.223] estimated a step-roughening transition temperature at (620 ± 10) K only analyzing the vanishing of diffraction peaks. The discrepancy between the two values was explained by the different analysis procedure.

Cu(113) was also investigated by *Wollschläger* et al. with electron diffraction [1.224]. They found a vanishing of the coherent scattering intensity at 750 K but the peak shape was consistent with a linear divergence of MSHD. This linear trend for the correlation function was found also by *Fabre* et al. studying Cu(1 1 11) with He atom diffraction [1.225].

Cu(115) was investigated by *Fabre* et al. with helium atom diffraction [1.226, 227] and through a peak shape analysis roughening was estimated to occur at $T_R = 380$ K. Several years later, *Ernst* et al. [1.228] investigated the thermal roughening with energy-resolved atom diffraction and questioned the previous results for the following points. The first is related to the energy window of the experiment, in fact without energy resolution they obtained results compatible with those of Fabre et al. with a $T_R = 420$ K, but reducing the inelastic contributions the estimated temperature became $T_R > 700$ K. The second point is related to the form of the MSHD, which is logarithmically divergent at long range, but at short range must present a lower cutoff to regularize its behavior, therefore two different lengths must be compared: the transfer width of the experiment and the length where there is the crossover between short- and long-range behavior. In order to observe the logarithmic behavior, the transfer width must be larger than the crossover position. Moreover, the position of the crossover poses also the requirement on a third length: the linear size of domains on the surface must be larger than the crossover position. A more recent study was carried out by *Le Goff* et al. with STM and x-ray diffraction on Cu(115) and copper alloys [1.229]. For bare Cu(115), through a comparison with Monte Carlo simulations a roughening temperature was estimated at 380 K, a value supported also by the analysis of x-ray data, confirming the first estimate.

Ni(113) was investigated by *Conrad* et al. with energy-resolved He scattering [1.230, 231] and through a lineshape analysis the estimated temperature value was $T_R = 750 \pm 50$ K. These results were also confirmed by *Robinson* et al. with x-ray diffraction [1.232]. The authors performed a detailed analysis of the peak shape and found $T_R = 770 \pm 30$ K.

Ni(115) was investigated by *Conrad* et al. and a roughening temperature of 450 ± 50 K was estimated [1.233].

Ni(117) was investigated by *Blanchard* et al. and they estimated $T_R = 400 \pm 50$ K [1.234].

Ag(115) was investigated by *Hoogeman* et al. with STM [1.88, 235, 236]. The authors performed a direct measurement of the height correlation function on the acquired images and initially found a linear behavior of MSHD which was in agreement with the results on other vicinal surfaces described above. Conversely, the authors observed that the MSHD did not rise monotonically with temperature. A detailed study showed that on a large scale the surface was not perfectly flat, therefore the supposed (115) surface had an orientation that varied around (115) and the authors estimated a temperature-independent root-mean-square deviation of 0.20°. These residual variations in surface orientation are the main contributions to the estimated MSHD masking the true temperature-dependent roughness involved in the roughening transition. They developed a pattern recognition procedure based on the crystallographic information of the possible step heights and step distances on Ag(115): the algorithm selected small regions of the full image and was demonstrated to be insensitive to statistical noise and to bad resolution of the STM tip. The procedure used one-dimensional windows, smaller than that of the full image, and accepted only positions where the scan line had the same height at the beginning and at the end of the window. By employing this procedure the expected logarithmic behavior was recovered. The authors also commented that the equal-height condition was similar to periodic boundary conditions in computer simulations. To further support their procedure, the authors performed Monte Carlo simulations to mimic the selection procedure [1.89] and the results showed that deviations of T_R were less than 2% from the prediction of the TLK model [1.88]. The estimate roughening temperature was $T_R = 465 \pm 25$ K from the analysis of STM images and 423 ± 6 K from the simulations.

1.10.5 Other Systems

The (111) surfaces of fcc metals are very stable [1.237]: calculations show that the roughening does not happen below the melting of the crystal [1.238] and in fact they have not been observed to roughen. An investigation performed by *Pluis* et al. on Pb with ion scattering showed that the (111) surface retains its order up to the melting [1.239]. The single exception is Al(111) for which calculations performed by *Trudu* et al. and based on embedded-atom interactions [1.240] set the roughening at 890 K, well below the bulk melting value of 933 K.

For the (100) surface of fcc metals the situation is not so clear and could depend on the system. For Cu(100), the observation on 2-mm size crystals supported on graphite stripes [1.157] suggests that in this case (100) is stable up to melting. Moreover, as noted before for the Cu(110) case, He diffraction experiments [1.159] showed that the specular peak from Cu(100) is measurable up to 1273 K ($\approx 0.93 T_M$) and the authors commented that the surface retains some order up to the highest temperature measured.

Yang et al. studied Pb(100) using high-resolution low-energy electron diffraction [1.241]. They observed an anomalous surface expansion below 480 K and a sudden proliferation of vacancies between 480 and 540 K, with an increase of $(20 \pm 5)\%$ from room temperature to 530 K. For both the out-of-phase and in-phase diffraction conditions, the peak shape analysis did not show changes or broadening due to steps up to 5 K from T_M. Hence Pb(100) was not observed to roughen.

Conversely, *Abernathy* et al. [1.242] performed an x-ray scattering study on Pt(001) which shows a hexagonal reconstruction. The sample was a Pt disk with a mosaic of 0.01° full-width at half-maximum (FWHM) and a miscut angle of 0.06° away from the crystallographic (001) plane. The sample was treated with procedures yielding a surface that remained clean at elevated temperatures for extended periods of time. The authors observed that the surface morphology below 1820 K is atomically smooth. However, above 1820 K, the Pt(001) surface is unreconstructed and rough. The coherent x-ray scattering experiments by *Pierce* et al. [1.243] on Pt(001) provide a further support to previous results and the analysis of the data showed that $T_R = 1834$ K similarly to the previous estimation.

Au(001) presents a reconstruction similar, but not identical, to Pt(001) [1.244, 245]. Even for what concerns roughening, the x-ray reflectivity investigation by *Gibbs* et al. [1.246] and coherent x-ray scattering study by *Pierce* et al. [1.243, 247] did not support the occurrence of a roughening transition on Au(001).

Roughening of In, which presents a face-centered tetragonal structure, i.e., a distorted fcc structure, was investigated by *Métois* and *Heyraud* [1.248] and by *Pavlovska* et al. [1.249]. Both groups observed microcrystals with electron microscopy and T_R was determined for a few faces. The temperature determined by the two groups agrees within a few K for {113} ($T_R = 373$ K [1.248], $T_R = 375$ K [1.249]), in reasonable agreement for {110} ($T_R = 283$ K [1.248], $T_R < 305$ K [1.249]), with a larger discrepancy for {311} ($T_R = 317$ K [1.248], $T_R = 355$ K [1.249]) and {011} ($T_R = 293$ K [1.248], $T_R = 345$ K [1.249]). One year later, *Georgiev* et al. [1.250] performed low-energy electron diffraction studies of In(100) and In(110) surfaces. For (100), as expected from the results on microcrystals, the specular peak shape did not change almost up to T_M. In the case of (110) the specular peak shape behaves in a way similar to (100); hence, in contrast with the results based on the macroscopic disappearance of (110), the results of microscopic observations of the (110) disordering show that this occurs without any evidence of roughening. The authors suggested that this behavior is due to anharmonic vibrations and a high density of adatoms and vacancies. In a study of In(111), *Lin* et al. [1.251] observed creation of vacancies and adatoms but no step roughness was detected up to 426 K.

Pavlovska et al. also investigated Sn microcrystals [1.249] and for several surfaces a roughening temperature was estimated below the melting temperature.

Roughening of Ta was investigated by *Vanselow* and *Li* [1.252] on vicinal areas of (110) and (100) surfaces with field-emission microscopy. They carried out growth studies on Ta crystallites at different temperatures and observed a transition with an increase in growth rate, as predicted by roughening theories.

Systems different from metals were also studied, including He and the systems mentioned in the introduction, C_2Cl_6, NH_4Cl, and tetrabromomethane.

Ohachi and *Taniguchi* investigated the roughening of bcc α-Ag_2S [1.253]. The observation of the sample in a transparent furnace allowed them to follow the evolution of the faceting of the crystal at different temperatures. For (110) surfaces T_R was estimated at 853 K and, for (100), at 753 K.

The roughening in rare gas crystals different from He was also investigated. *Maruyama* investigated Xe and Kr [1.254] by an apparatus that worked in a constant-temperature cryostat. A vacuum jacket surrounded the cell and this part was immersed in liquid nitrogen. The cell, inside the jacket, was made of two copper parts: an upper copper block and a lower copper substrate with the substrate thermally insulated by the copper block. At the beginning of the experiment, the cell was pumped and when the required temperature was reached, the cell was filled with the sample gas. The crystals were grown decreasing the temperature of the

substrate below the block temperature: crystals grown on the block sublimated behaving as a source of gas for those grown on the substrate, with a supersaturation given by $s = P_B(T_B)/P_S(T_S) - 1$, where P_B is the vapor pressure at the temperature of the block T_B and P_S is the vapor pressure at temperature of the substrate T_S. For Xe at 114 K and $s = 0.4°$, facet crystals grew and both the (111) and (100) facets were observed. At 125 K and $s = 0.7°$, both facets and curved surfaces appeared. At an estimated temperature of 129 K, all the crystals are bounded by curved surfaces. Since this shape could be related to supercooled liquid droplets, the author described some facts that indicated that those curved samples actually were solid. For Kr, the behavior was similar to that of Xe and the estimated temperature, at which the crystal was observed bounded by curved surfaces, was 93 K. Of course this investigation, although semiquantitative since it did not give an estimate of the roughening temperature for each facet separately, suggests that, on these rare gas systems, (111) facets do not survive up to the melting of crystal.

Pontikis and *Rosato* performed a molecular dynamics study of the (110) surface of Ar [1.255, 256]. They observed an increase of the vacancy-adatoms pairs above $0.7T_M$ and by using this value they estimated a roughening transition at about 58 K for Ar(110).

More recent experiments on multilayer films of Ar, Kr, and Xe on graphite [1.117, 119, 257] showed intriguing behaviors related to preroughening and its connections with surface melting (this will be briefly commented upon at the end of this section). The film growth proceeds layer-by-layer and a first-order transition is present as observed in adsorption isotherms, where at each completion of a layer steps appear: this layering transition terminates at a layering critical temperature $T_c(n)$ which depends on the number of layers n. Above this critical temperature, the film grows in a continuous way and atoms are present at layer $n+1$, $n+2$ etc. a situation similar to the rough phase, in fact it was suggested that the limit of $T_c(n)$ for increasing n is the roughening temperature of the exposed face of the 3-D crystal [1.258]. *Youn* and *Hess* [1.119] performed ellipsometric adsorption isotherm measurements to investigate the layering transitions of Ar films on graphite and found $T_c(2) = 69.4 \pm 0.2$ K, $T_c(3) = 67.6 \pm 0.2$ K while, at higher temperatures, the layering steps disappeared. This first part was consistent with results already present in the literature [1.259, 260] with an estimate for the roughening of Ar(111) at $T_R = 68$ K, but, for a further increase of the temperature, Youn and Hess observed that the steps reappeared for $T > 70$ K and persisted up to 77 K and they named this phenomenon *reentrant layering*. Moreover, the reentrant steps in isotherms were not aligned with the previous steps but happened in between, in a position corresponding to half of a layer. Of course this finding poses the question about the nature of the second transition. Other measurements by *Day* et al. [1.261] and by *Larese* and *Zhang* [1.262] confirmed these results. From the analysis of the phase diagram, on one hand the transition was interpreted as a signature of a preroughening transition with the surface layer in a disordered flat phase, while on the other hand it pointed to a possible relationship of this transition with a liquid phase at the outermost layer.

The growth of Ar thick films on single-crystal MgO was investigated with x-ray reflection by *Rieutord* et al. [1.263]. At 70 K, in a reproducible way, they observed a jump in the total thickness which corresponded to half a layer, consistent with Youn and Hess' results for films grown on graphite, therefore this is a property of the film. Moreover, the authors performed measurements of the peak shape and no evidence for a divergent MSHD was found therefore the transition was not a roughening transition. Finally, reflectivity data could not be fitted at every temperature with a one-layer description but with a two-layer description which the authors assigned to correspond to the liquid and solid parts of the film. These results therefore supported the idea that the surface melting starts with a preroughening transition.

Si(100) was investigated by *Bartelt* et al. with low-energy electron microscopy (LEEM) [1.264]. The authors studied in real-time equilibrium step fluctuations at different temperatures obtaining an estimate of the step free energy that vanishes at 1473 K. Since at 1443 K, the sublimation rate is about 0.12 ML/s, the transition could be a kinetic roughening but the authors observed an increase of step fluctuations already at 1373 K, where sublimation is very small, supporting a thermodynamic origin of the surface roughening observed at higher temperature.

The equilibrium crystal shape of silicon was investigated by *Bermond* et al. with electron microscopy [1.266]. The (111) surface was present up to $T = 1673$ K, 13 K lower than T_M. The roughening temperatures in equilibrium experiments were evaluated as 1643 K for (110) and 1613 K for (113). Similar studies were performed by *Suzuki* et al. [1.267] on high-index surfaces. A study of Si(331) was performed by *Noh* et al. with x-ray scattering experiments [1.268]. The analysis of diffraction peaks indicated the occurrence of roughening at (1075 ± 10) K in good agreement with the estimated value by *Suzuki* et al. [1.267], but these results were not completely confirmed by an STM study performed by *Hibino* and *Ogino* [1.269].

Roughening of H_2O ice was studied by *Elbaum* [1.270] who observed the transition on the prism facet $\{10\bar{1}0\}$ at 271 K while the basal facet {0001} per-

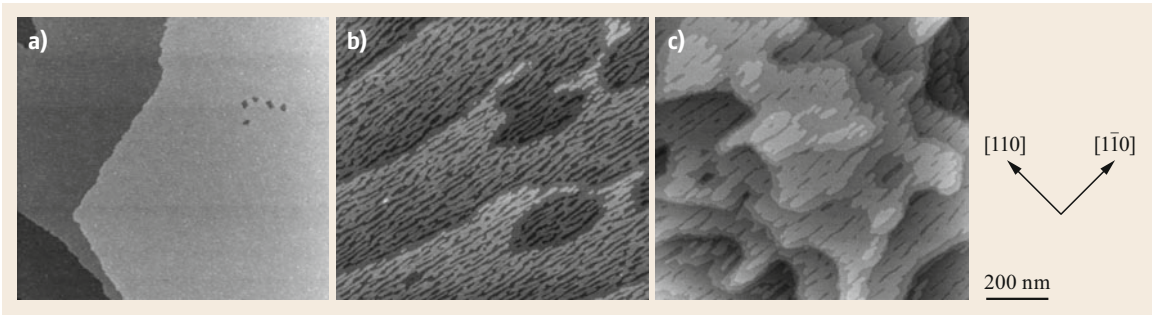

Fig. 1.22a–c Three 1 μm × 1 μm filled-state STM images of the GaAs(001) surface prepared under different annealing conditions. **(a)** Ordered flat (783 K and 0.03 μTorr As_4), **(b)** disordered flat (838 K and 0.03 μTorr As_4) showing single level islands, **(c)** rough (878 K and 0.03 μTorr As_4) showing multilevel islands. Fig. 1.23 Phase diagram of a GaAs(001) (2 × 4) reconstructed surface prepared under different annealing conditions and As_4 beam equivalent pressures (BEP). The *brown line* with *squares* is the boundary of ordered flat and disordered flat phases. To the left of this line, the coverage of islands is zero. The *brown line* with *circles* is the transition boundary between disordered flat and rough phases. For this line the data points are also labeled with the island coverage reached just prior to roughening. Notice that the coverage just before roughening varies from 80–40% as the substrate temperature is increased. Reproduced with permission from [1.265]

sisted until melting. *Maruyama* performed a study at high pressure [1.271] and measured the roughening of the prism facet at $T_R = 257$ K for H_2O at 160 MPa and $T_R = 259$ K for D_2O at 180 MPa; even in this case, the basal plane was stable up to 273 K.

Ionic crystals of NaCl were studied by *Lampert* and *Reichelt* [1.272] and a roughening temperature was estimated between 898 and 948 K. *Heyraud* and *Métois* [1.273] showed that for $T \leq 923$ K the NaCl crystal is bounded by sharp facets, while above 923 K the facets started to become rounded. *Arsic* et al. studied cesium halide crystals in saturated aqueous solution droplets and in the temperature range from 275 to 344 K [1.274]. For cesium bromide, a roughening temperature $T_R = 278 \pm 1$ K was estimated.

Finally, although outside the scope of the present chapter, we would also like to mention the roughening of grain boundaries which are important for technological applications. For example, roughening influences the mobility of grain boundaries in the process of their removal [1.275]. More information on this topic can be found in the review by *Straumal* et al. [1.276].

To conclude this experimental section, we briefly consider again the preroughening transition. A striking evidence of this transition was obtained in real space for GaAs(001) by *Ding* et al. with STM [1.265]. The samples were prepared by annealing at fixed temperature in the range 773–973 K for a time that assured equilibrium conditions and in a fixed As_4 flux. Then the samples were cooled to room temperature following by a procedure that froze-in the surface morphology present at higher temperatures and images acquired at three different annealing temperatures are shown in Fig. 1.22 where the different morphologies of the surface are clear. Modifying the annealing temperatures and the As_4 flux a phase diagram was determined and is shown in Fig. 1.23.

The surface at low temperature and high flux is in the flat phase, increasing the temperature (and/or decreasing the flux) the surface undergoes a preroughening transition to a disordered flat phase and, then, for higher temperatures, to a rough phase.

In the study of the various systems, a roughening transition was not always observed but sometimes there was only an increase of adatom–vacancy pairs. This

could be a signature of a preroughening transition as observed by *Tosatti* and coworkers [1.114, 115] who discussed a relationship between surface melting and preroughening, where initial melting phenomena determine a preroughening behavior, thus explaining the results of experiments on multilayer films of rare gases on graphite. They also suggested a similar interpretation for the behavior of Pb(100) and Au(100).

1.11 Conclusions: Growth

As we have discussed in the present chapter, roughening was an interesting application of statistical mechanics to solids. The roughening transition is an infinite-order phase transition, and is one of the most evident examples of a Kosterlitz–Thouless transition. Most of the theoretical predictions have been satisfactorily verified experimentally. An equally important point (and more relevant, even today, for practical applications) is the relation between roughening and the surface growth mode. Indeed, the bulk of the experimental work on the roughening transition to study mechanism and temperatures was done in the 1990s, but the results are still important today for the growth of bulk or nanostructured materials. For an extensive discussion of growth modes, see the classical work of *Weeks* and *Gilmer* [1.90]; see also *Levi* et al. [1.91, 92]. Although the distinction is not sharp, it is clear that a smooth surface tends preferentially to grow in the layer growth mode, where a layer is completed locally before a new layer is started above it, and there is a bottleneck: the nucleation of 2-D islands. Conversely, a rough surface tends to grow in the continuous, or 3-dimensional growth mode, where atoms may stick anywhere, forming hillocks. These two modes are completely different, with the consequence that the transition, which in equilibrium is an extremely weak, Kosterlitz–Thouless transition, dynamically involves a dramatic change. In Sect. 1.6 we have briefly discussed the problems of kinetic roughening, which appear to be very relevant from the present point of view and may give rise to the vast set of phenomena discussed in the reviews by *Halpin-Healy* and *Zhang* [1.96] and by *Misbah* et al. [1.5].

Andrea Claudio Levi graduated in physics in 1960 from Genoa University. Levi became a full professor and was called to Naples in 1981. In 1987, and again between 1989 and 1992, Levi stayed at the SISSA in Trieste. He has published 112 scientific papers and is the author of 3 books of collections of tales and essays.

2. Surface Diffusion

Riccardo Ferrando, Andrew P. Jardine

Surface diffusion is a key step in several phenomena occurring on crystal surfaces, for example in thin-film growth and in chemical reactions. Here, we review the basic concepts of surface diffusion. The elementary diffusion mechanisms on flat and stepped surfaces, such as jumps and exchanges are treated first. Then, the long-time result of the combination of such elementary diffusion moves is considered, both from the point of view of single-particle (or tracer) diffusion and of collective diffusion. Finally, an overview of the experimental techniques to measure surface diffusion is given, with special attention being paid to the helium spin-echo technique.

Adatom mobility is extremely important in a series of processes of technological relevance, such as thin-film growth and heterogeneous catalysis. In fact, smooth thin films can be grown only if the deposited atoms are able to move around on terraces and between different terraces. On the other hand, surface chemical reactions are possible only if the reactants, which usually impinge on the surface in random positions, can move around to meet each other. In this chapter, we review the basic aspects of adatom mobility on surfaces, first focusing on the elementary atomic moves and then on the combination of these moves in determining the long-time stochastic motion of the adatoms. Literature on this subject is vast, and, therefore, we refer to a narrower domain, metal-on-metal diffusion, as regards the specific examples. The interested reader may refer to books and review articles for more complete overviews [2.1–6]. Moreover, we focus on single-adatom mobility, recalling, however, that mobility on surfaces may involve also atomic aggregates [2.7–24].

2.1 Elementary Mechanism of Surface Diffusion

Let us consider an atom that is deposited on an otherwise empty crystal surface. The adsorbed atom can exchange energy with the substrate, which acts as a thermostat at temperature T. For simplicity, we assume now that the substrate does not participate actively in mass transport, i.e., that substrate atoms simply oscillate around their lattice positions. This assumption will be relaxed when dealing with exchange diffusion. After deposition, a series of different processes may take place in sequence for the adatom. These processes may be schematically described as follows:

- *Transient mobility*. When the incoming atom hits the surface, it may have a significant amount of kinetic energy, coming from the kinetic energy of the beam and from the condensation energy on the sub-

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-46906-1_2

strate (which is of the order of few eV for transition metals), or from the dissociation energy in the case in which molecules, such as O_2, are deposited. This excess energy may cause some transient mobility of the adatom before the initial nonthermal energy is dissipated to the substrate [2.25, 26]. Dissipation may take place either by exciting phonons or by creating electron–hole pairs in the substrate [2.27]. The former mechanism contributes to the phononic part of the friction, whereas the latter contributes to the electronic part of the friction. Recent estimates for diffusion of Na on Cu(111) [2.28] show that dissipation to phonons and to electron–hole pairs account for $\approx 80\%$ and 20% of the total friction, respectively.

- *Thermalization*. After the initial excess energy is dissipated, the atom equilibrates with the substrate in some adsorption site, where it stays for some time by making small oscillations of frequency ν_{osc} at the potential well bottom. This is possible if the potential energy well associated with the adsorption site is much deeper than $k_{\mathrm{B}}T$, where T is the temperature of the substrate. If adsorption sites are very shallow, the adatom equilibrates on the substrate but keeps on moving in a quasicontinuous way. This type of motion is, however, rather uncommon. An example is the case of adatom diffusion on fcc(111) surfaces, as discussed.
- *Activated escape*. Even if deeper than $k_{\mathrm{B}}T$, an adsorption site is not infinitely deep, so that the adatom can escape from it through a saddle point, by surmounting an energy barrier E_{b}. Here, we consider only diffusion by thermal activation, since quantum tunneling is relevant only at low temperatures (< 100 K for hydrogen and at even lower temperatures for other atoms [2.1, 29]). The escape rate ν_j is given by an expression known as the *Arrhenius law*

$$\nu_j = \nu_{0j} \mathrm{e}^{-\frac{E_{\mathrm{b}}}{k_{\mathrm{B}}T}} , \tag{2.1}$$

where ν_{0j} is the *rate prefactor*. Since $\nu_{0j} \approx \nu_{\mathrm{osc}}$ [2.5] one has

$$\nu_j \ll \nu_{\mathrm{osc}} . \tag{2.2}$$

Energy barriers for diffusion depend on many factors. For a given type of substrate and adatom, the barrier depends on the surface orientation. For example, for Au, Ag, and Cu adatom diffusion on the surfaces of these metals, the barrier for hopping diffusion is of a few tens of meV for diffusion on the (111) surface, and of a few hundred meV on the (100) surface [2.30–35]. The very low barriers on the (111) surface cause a quasicontinuous diffusive motion in the network on fcc and hcp adsorption sites, which can take place already at room temperature. As discussed in Sect. 2.1.2, E_{b} is different in the vicinity of steps and other defects than on the flat, perfect surface. For diffusion of metal atoms on insulating surfaces, E_{b} may also depend on the charge state of the adatom [2.36]. Diffusion barriers may depend on the direction on anisotropic surfaces, to the extent that diffusion may become essentially one-dimensional in some cases [2.37–41].

- *Jump diffusion*. After jumping out from an adsorption site, the adatom will finally thermalize in another adsorption site, which may be either a nearest/neighbor site or a more distant site [2.5, 42]. In the latter case, a *long jump* has taken place. For deep potential wells, the time of flight τ_{fl} between escaping from the first site and thermalizing in the new site is much shorter than the average residence time in the well τ_j

$$\tau_{\mathrm{fl}} \ll \tau_j = \frac{1}{\nu_j} . \tag{2.3}$$

The residence time is, therefore, sufficiently long to eliminate correlations between subsequent jumps, so that the overall adatom motion will be a sequence of uncorrelated events, which produces a random walk in the lattice of adsorption sites.

A schematic representation of the trajectory of a diffusion event of an adatom is given in Fig. 2.1. The adatom oscillates in an adsorption site, then it jumps to a nearest-neighbor site and, finally, thermalizes there and keeps on oscillating.

The occurrence of long jumps indicates a weak energy exchange between the adatom and the substrate. This can be qualitatively discussed in the framework of the Langevin model, in which the energy exchange between adatom and substrate is described in terms of friction and white noise. In the Langevin model, the motion of the adatom obeys a stochastic differential equation. For simplicity, we discuss the one-dimensional case, which is relevant, for example, in diffusion along channels or steps. Let us assume that the adatom is diffusing in a spatially periodic system of period a, which corresponds to the lattice distance between nearest-neighbor adsorption sites of our system. The displacement $x(t)$ of the adatom of mass m is ruled by

$$m\frac{\mathrm{d}^2x}{\mathrm{d}t^2} = -m\gamma v + F(x) + \Gamma(t) , \tag{2.4}$$

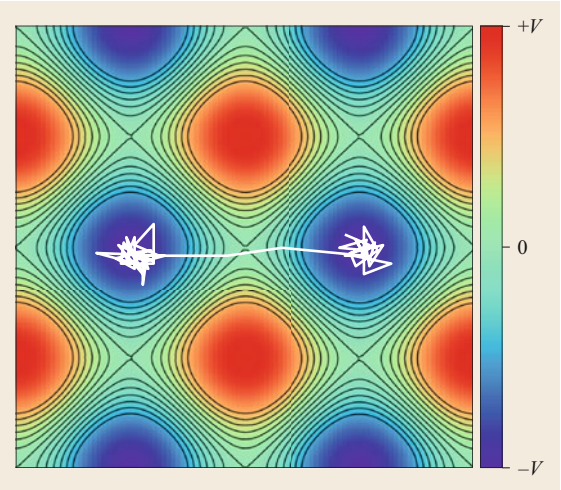

Fig. 2.1 Trajectory (projected in the surface plane) of an adatom jumping between two adsorption sites (of energy $-V$ at the well bottom) through a saddle point of energy 0 (the saddle point is at the *center*). The energy barrier E_b is given by the energy difference between the saddle point and the minimum, $E_b = V$

where v is the velocity of the adatom, $F(x) = -\mathrm{d}V/\mathrm{d}x$ is a spatially periodic force derived from the *adiabatic potential*, which describes the average interaction with the substrate, and γ is the friction per unit mass; $\Gamma(t)$ is a δ-correlated white noise, whose intensity is related to the friction by the fluctuation-dissipation theorem [2.43]. While the friction term can only subtract energy to the adatom, the noise term can give and subtract energy to insure thermal equilibrium with the substrate.

In order to discuss the occurrence of long jumps [2.44, 45], let us calculate the energy dissipated by the adatom that crosses a lattice cell assuming that the amplitude $A = E_b/2$ of $V(x)$ is much larger than $k_B T$. We can assume that the adatom starts from the top of the barrier with a kinetic energy of $k_B T$ and then dissipates the energy Δ while crossing the cell to reach the next barrier top

$$\Delta = \int_0^a m\gamma v(x)\mathrm{d}x \,. \tag{2.5}$$

Since long jumps can occur only when dissipation is small, we can estimate $v(x)$ as if the motion of the adatom would be conservative, i.e., assuming that

$$\frac{1}{2}mv^2(x) + V(x) = E_b + k_B T \,, \tag{2.6}$$

so that

$$\Delta = \gamma \int_0^a \sqrt{2m[E_b + k_B T - V(x)]}$$

$$\simeq \gamma \int_0^a \sqrt{2m[E_b - V(x)]} \,, \tag{2.7}$$

because $E_b \gg k_B T$. In this limit, the main contribution to the integral comes from x close to the well bottom, so that the integral itself can be approximated by E_b/ν_{osc}. The condition for the occurrence of long jumps thus becomes

$$\frac{\Delta}{k_B T} \ll 1 \quad \longrightarrow \quad \frac{\gamma}{\nu_{osc}} \ll \frac{k_B T}{E_b} \,. \tag{2.8}$$

Long jumps have been observed in different experiments [2.37, 38, 46–50] and in many simulations and calculations [2.16, 31, 32, 51–56].

Mass transport on surfaces can take place by several different mechanisms besides jumps. Below we describe the most important ones.

2.1.1 Exchange Diffusion

In exchange diffusion, an adatom enters the substrate taking the place of a substrate atom, which is pushed up on the surface and becomes the new adatom. Even though this mechanism implies an active role of the substrate, for homoepitaxial systems it can be treated by the same line of reasoning as the jumps, since the final result of the process is the same as in a jump between the appropriate initial and final sites. For heteroepitaxial systems, after the exchange process, the new diffusing adatom may, of course, be of a different species.

There are several systems in which the exchange mechanism is favored over the simple jump. The first example is the diffusion of adatoms on the (110) surface of fcc metals. This is a channeled surface, with atomic rows running along the $[1\bar{1}0]$ direction (Fig. 2.2). Diffusion across these channels, i.e., in the [001] direction, can hardly take place by jumps. In fact, in the adsorption site, the adatom has five nearest neighbors, which reduce to two at the saddle point for the jump process, with a corresponding huge amount of energy which is of the order of 1 eV and more for transition and noble metals. On the contrary, diffusion by exchange requires surmounting much smaller barriers, often well < 0.5 eV.

Exchange diffusion has been observed also on surfaces with square symmetry, such as the (100) surface of fcc crystals. As shown in Fig. 2.2b, the adatom enters the substrate taking the place of one of its four

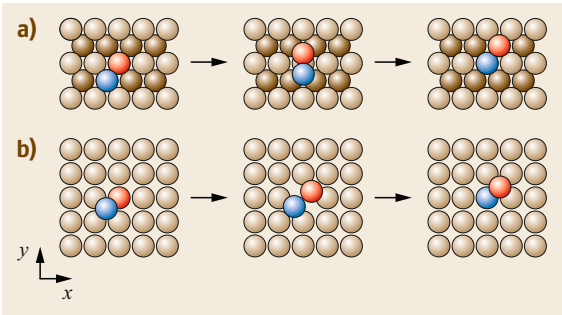

Fig. 2.2 **(a)** Exchange process on a (100) surface of an fcc metal. This channeled surface, with atom rows along the [1$\bar{1}$0] direction (*x*-direction) is shown in a top view. The atom rows are very difficult to surmount by a jump process to reach the adjacent channel. In the *middle panel* the typical symmetric *dumbbell configuration* is shown. This is either the saddle point or a short-lifetime metastable configuration corresponding to a very shallow local minimum. **(b)** Exchange process on a (100) surface of an fcc metal. The adatom enters the substrate and substitutes an atom that becomes the new adatom. The process causes mass transport along the diagonal, in the [011] direction. A single jump process would cause mass transport either along the *x* or the *y*-direction

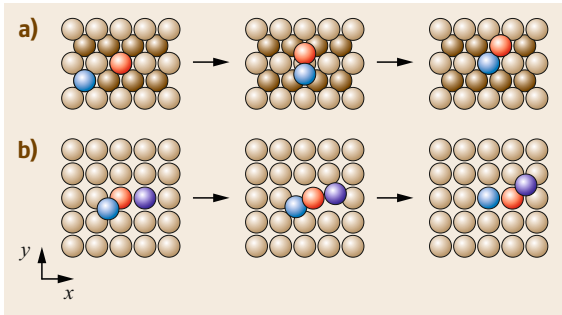

Fig. 2.3 **(a)** A correlated jump-exchange process [2.51] on an fcc(110) surface. The original adatom (*blue color*) makes a jump along the a channel in the [1$\bar{1}$0] direction, but, instead of stopping in the next well, it pushes a substrate atom of an adjacent row (*red color*) to the next channel and takes its place in the row. **(b)** A multiple exchange process on an fcc(100) surface [2.67] in which the adatom is incorporated into the substrate by pushing two atoms. One of them (*violet color*) becomes the new adatom

nearest neighbors. This process produces a net displacement in a diagonal direction (such as the [011] direction), i.e., the same displacement that would be obtained by a jump to a second-neighbor site. Therefore, if diffusion on this surface takes place exclusively by exchange, the adsorption sites of a single sublattice can be visited by a series of subsequent exchanges, while the other sublattice is never visited. This sublattice is rotated by 45°, like the network of white squares on a checkerboard. On the other hand, if diffusion takes place by jumps or by a combination of jumps and exchanges, all sites can be visited. This allows us to single out pure exchange diffusion in experiments [2.57, 58]. There are also systems in which both exchanges and jumps occur at comparable frequencies, for example, in W/W(100) [2.59].

In simulations, exchange diffusion has been observed for a large variety of metal-on-metal homoepitaxial and heteroepitaxial systems [2.31, 51, 60–66].

Exchange processes may also take complex pathways involving the displacement of more than two atoms. Evidence in favor of these multiatom processes essentially comes from simulations [2.51, 67–75]. In some cases, also correlated processes involving a jump and an exchange part have been seen [2.31, 51]. Schematic representations of a correlated jump-exchange process and of a three-atom exchange are given in Fig. 2.3.

2.1.2 Diffusion Across and Along Steps

Surface diffusion in the presence of defects is also an important research topic. Steps are the most common extended defects on a surface, and both diffusion along and across steps play an important role in the evolution of the surface during thin-film growth [2.76, 77].

Adatom diffusion across a step (Fig. 2.4) is an asymmetric process. In metal-on-metal diffusion, descending from the upper to the lower terrace is usually easier than the reverse process (upward diffusion). This happens because the site reached by the adatom on the lower terrace is more coordinated than sites on the upper terrace, so that there is an energy gain in the downward move. For other systems, the behavior may

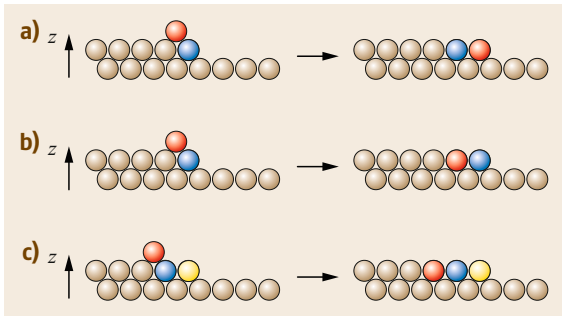

Fig. 2.4 **(a)** An adatom jumps down at a step. **(b)** The adatom is incorporated in the step riser after an exchange, whereas a former step atom is the new adatom that can diffuse either along the step or on the bottom terrace. **(c)** The adatom is incorporated in an inner position of the terrace by a multiple-exchange process

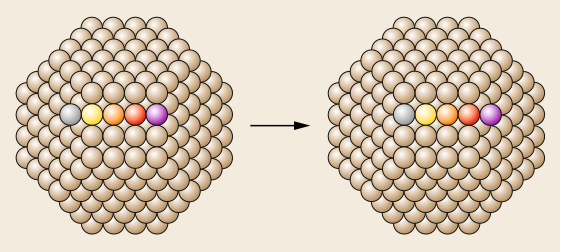

Fig. 2.5 An adatom on the border between a (111) and a (100) facet on an fcc truncated octahedral cluster pushes a row of atoms of the (100) facet, so that finally an adatom appears on the opposite (111) facet

be different—for example, simulations of the diffusion of oxygen on Cu(001) by reactive force fields [2.78] have shown that in this case, upward diffusion is easier than downward diffusion. In the following, we focus on metal-on-metal diffusion, in which downward diffusion between terraces is the easier process.

Diffusion across steps can take place by jumps and by exchange, the latter being possible also from sites that are not in the close vicinity of the terrace border, as is shown in Fig. 2.4. Even though there is a final energy gain in the downward diffusion processes, the intermediate configurations of these processes often contain severely undercoordinated atoms, as is schematically shown in Fig. 2.4. For this reason, the activation barrier for downward diffusion can be higher than the barrier for diffusion on the upper terrace. The additional barrier for crossing the step is known as the Ehrlich–Schwoebel (ES) barrier [2.79, 80]. In Fig. 2.6, we sketch a typical energy profile of the diffusion pathway across a step. If the diffusion on the upper terrace, far away from the step, has a barrier E_{ut}, and the downward diffusion across the step has a barrier $E^{\perp}_{\mathrm{step}}$, then the ES barrier is defined by $E^{\perp}_{\mathrm{step}} = E_{\mathrm{ut}} + E_{\mathrm{ES}}$. The ES barrier is a crucial factor in determining the thin-film growth mode. Small or nonexistent ES barriers favor layer-by-layer growth, while large ES barrier favor three-dimensional growth because they hinder the mobility between terraces at different levels [2.76]. There are even cases in which the barrier for downward step crossing may be lower than the barrier on the flat terrace, as was found in calculations for exchange crossing on Ag(100) [2.81]. In these cases, the ES barrier is negative. Zero or even negative ES barriers may be found also for downward crossing at step kinks [2.7, 82, 83].

Also the diffusion of adatoms between adjacent facets on a nanoparticle [2.84, 85] takes place by similar types of mechanisms to the diffusion between terraces of high-index crystal surfaces. Interfacet diffusion processes, therefore, have their own ES barriers [2.68, 86]. In nanoparticles, there is also the possibility of chain diffusion mechanisms that allow the displacement of atoms between opposite sides of the nanoparticle [2.68, 87], as shown in Fig. 2.5.

The diffusion of adatoms across steps has been studied in many cases, especially by simulations. For metal-on-metal diffusion, these studies considered both homoepitaxial [2.88–92] and heteroepitaxial systems [2.92–94]

Diffusion along steps may take place on the lower and on the upper side of the step. Since the sites on the lower side have higher coordination, they act as traps of adatoms. On the other hand, the adsorption energy in sites on the upper side of the step is usually very close to that of inner terrace sites. For these reasons, most studies have focused on diffusion along the lower sides of steps. Diffusion along steps is quite difficult to measure directly in experiments, but it has important experimental consequences as far as the shape of

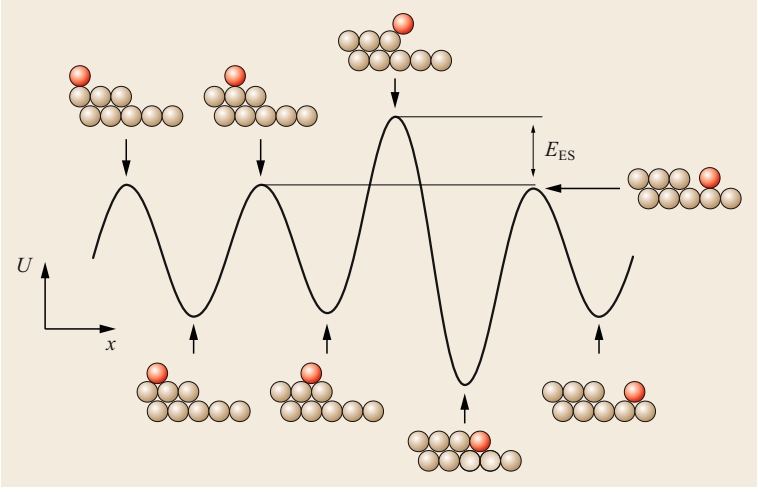

Fig. 2.6 Potential energy profile along the diffusion pathway of an atom crossing a step to descend to the lower terrace. The additional ES barrier E_{ES} for crossing the step is indicated

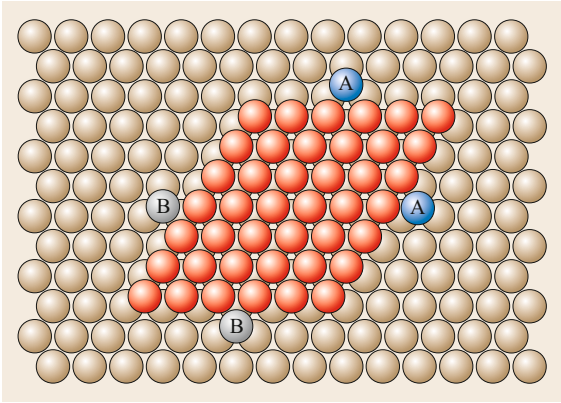

Fig. 2.7 An island on a (111) surface of an fcc crystal. The island is limited by straight steps, and there are four adatoms diffusing on the lower edges of the steps. There are two different types of steps. The steps of type A (those of the adatoms marked by A) have square facets on the step riser. The steps of type B (those of the adatoms marked by B) have triangular facets on the step riser

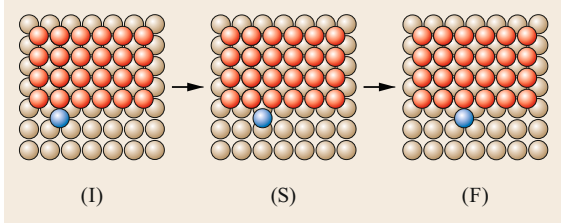

Fig. 2.8 Diffusion of an adatom along a straight step on an fcc(100) surface. From the initial position (I), the adatom passes through the saddle point (S) and then moves to the final site (F). In (I) and (F), the adatom has five first neighbors, while in (S) it has four first neighbors

growing islands is concerned [2.76, 95, 96], especially if diffusion around corners is also considered. The presence of steps is also important because it can alter the interaction between adsorbed molecules on the terraces, thus influencing their diffusion coefficient [2.97].

Due to the difficulty of measuring the diffusion of adatoms along steps, most studies in the literature are simulation studies. For metal-on-metal diffusion, one may refer to, for example, [2.93, 98–102].

The diffusion barriers for adatoms diffusing along steps strongly depend on the symmetry of the surface and on the type of step. This can be exemplified by considering straight steps on two high-index surfaces of fcc crystals, the (111) and the (100) surfaces.

Let us consider first the (111) surface. In Fig. 2.7, a schematic representation of an island on a (111) surface is shown. This island is limited by four straight steps, which, however, are not equivalent, because two of them present square facets on the step riser (steps of type A), and two of them present triangular facets on the step riser (steps of type B). If there is an A step on one side of the island, on the opposite side there will be a B step. Rhombic and hexagonal islands must, therefore, present both step types, while triangular islands (of orientations differing by 60°) present a single type of step [2.76]. Diffusion of adatoms along these steps may be characterized by different energy barriers [2.98]. Also the diffusion pathway along A and B steps may be somewhat different. In fact, calculations for Au(111) and Ag(111) showed that the preferential diffusion pathway is a straight line along step B, whereas it has a cosine-like shape along step A [2.98]. However, the most important point is that on this surface, diffusion along steps has much higher barriers than diffusion on the flat terrace. In Ag and Au(111), the former has barriers of a few tenths of eV, while the latter has barriers of ≤ 0.1 eV [2.30, 98]. This means that there is a temperature range in which terrace diffusion is activated while diffusion along steps is not, allowing the growth of fractal-like islands [2.76].

On the (100) surface, the situation is quite different. In fact, referring again to Ag and Au as examples, diffusion on the flat terrace is characterized by barriers of a few tenths of eV [2.31]. In the jump mechanism, terrace diffusion takes place by passing through a saddle point, where coordination is decreased from four to two. For diffusion along a straight step, the decrease in coordination at the saddle point is only from five to four, as shown in Fig. 2.8. This indicates that the barrier for diffusion along straight steps may be lower than that on the terrace, as is, indeed, verified by several calculations ([2.101] and references therein). Therefore, on these (100) surfaces, there is no temperature interval in which terrace diffusion is activated while diffusion along steps is not. This causes the growth of islands limited by straight steps, which are much more compact than the island grown on the on the (111) surface of the same metals.

2.2 Single-Particle and Collective Diffusion Coefficients

In the previous section, we focused on the elementary moves by which an adatom can displace from one site to another on a crystal surface. Now we focus on the long-time result of the combination of such elementary moves, assuming that they are statistically independent of each other. This amounts to assuming that each time the diffusing atom reaches a new adsorption site on the surface, it stays there for a sufficiently long time to equilibrate with the substrate.

As we will show in the following, the combination of statistically independent elementary moves leads to a long-time behavior in which the mean square displacement of the adatom increases (apart from a numerical constant related to the dimensionality of the system) linearly as $D_s t$, where D_s is the single-particle (or tracer) diffusion coefficient; D_s is, thus, related to the average behavior of each individual diffusing particle. However, this is not the only diffusion coefficient that can be defined. In fact, there is also the collective diffusion coefficient D_c, which describes how density gradients relax to equilibrium in the system; D_s and D_c may both depend on the density of the adsorbate, but, as we will see in the following, in quite different ways.

2.2.1 Single-Particle (Tracer) Diffusion

Let us consider an isotropic surface and a single diffusing adatom whose position as a function of time t is $\boldsymbol{r}(t)$. The diffusing adatom is in contact with the substrate, which exchanges energy with the adatom, thus acting as a thermostat at a temperature T. For sufficiently long times, the motion of the diffusing adatom can be described as a random walk. The net mean displacement of the adatom is

$$\langle \Delta \boldsymbol{r}(t) \rangle = \langle [\boldsymbol{r}(t) - \boldsymbol{r}(0)] \rangle = 0 \tag{2.9}$$

due to left-right symmetry. On the contrary, the mean square displacement

$$\langle \Delta \boldsymbol{r}^2(t) \rangle = \langle [\boldsymbol{r}(t) - \boldsymbol{r}(0)]^2 \rangle \tag{2.10}$$

is different from zero and tends to increase as t^α, with the exponent $\alpha > 0$, for sufficiently long times. This allows us to define the single-particle (or tracer) diffusion coefficient D_s

$$D_s = \lim_{t\to\infty} \frac{\langle \Delta \boldsymbol{r}^2(t) \rangle}{2dt} , \tag{2.11}$$

where d is the dimensionality of the system, $d = 2$. The limit in (2.11) converges to a finite value if asymptotically $\langle \Delta \boldsymbol{r}^2(t) \rangle \propto t$, i.e., $\alpha = 1$. If this does not happen, i.e., if the asymptotic behavior is proportional to t^α with $\alpha \neq 1$, one has the so-called *anomalous diffusion*, of which there are some examples also in the case of surfaces [2.103, 104]. It can be easily shown that (2.11) is equivalent to [2.43]

$$D_s = \frac{1}{d} \int_0^\infty \langle \boldsymbol{v}(t) \cdot \boldsymbol{v}(0) \rangle \mathrm{d}t , \tag{2.12}$$

where $\boldsymbol{v}$ is the velocity of the adatom.

In the general case, the surface can be anisotropic, so that one has to consider the diffusion tensor $\mathbf{D}_s$

$$\mathbf{D}_s = \begin{pmatrix} D_s^{xx} & D_s^{xy} \\ D_s^{yx} & D_s^{yy} \end{pmatrix} , \tag{2.13}$$

where

$$\begin{aligned} D_s^{xx} &= \lim_{t\to\infty} \frac{\langle [x(t) - x(0)]^2 \rangle}{2t} , \\ D_s^{yy} &= \lim_{t\to\infty} \frac{\langle [y(t) - y(0)]^2 \rangle}{2t} , \\ D_s^{xy} &= D_s^{yx} = \lim_{t\to\infty} \frac{\langle [x(t) - x(0)][y(t) - y(0)] \rangle}{2t} ; \end{aligned} \tag{2.14}$$

$\mathbf{D}_s$ is, thus, symmetric by definition, so that it can be diagonalized. This allows us to find two principal diffusion directions x_p and y_p for which

$$\begin{aligned} D_s^x &= \lim_{t\to\infty} \frac{\langle [x_p(t) - x_p(0)]^2 \rangle}{2t} , \\ D_s^y &= \lim_{t\to\infty} \frac{\langle [y_p(t) - y_p(0)]^2 \rangle}{2t} . \end{aligned} \tag{2.15}$$

If x_p and y_p are equivalent, one recovers the isotropic case, i.e., $D_s^x = D_s^y$.

Let us consider jump diffusion. We first restrict ourselves to the case of isotropic lattices in which only jumps to nearest neighbor sites are allowed. There are n_{pv} nearest neighbors ($n_{pv} = 4$, 6, and 3 for the square, the triangular, and the honeycomb lattices, respectively). The adatom starts from the origin of the coordinates and jumps on average at intervals δt, which means that its total jump rate (or frequency) is $\nu_j = 1/\delta t$. At the i-th jump, the adatom displacement from its previous position is

$$\delta \boldsymbol{r}_i = (\delta x_i, \delta y_i) , \tag{2.16}$$

while its total displacement after n jumps is

$$\boldsymbol{r}^{(n)}(t) = \sum_{i=1}^{n} \delta \boldsymbol{r}_i \,, \tag{2.17}$$

with $t = n\delta t$. Taking into account that for $i \neq j$ jumps are statistically independent and that all jumps are equivalent, the mean square displacement is given by

$$\begin{aligned} \langle \Delta \boldsymbol{r}^2(t) \rangle &= \langle \boldsymbol{r}^{(n)}(t) \cdot \boldsymbol{r}^{(n)}(t) \rangle \\ &= \left\langle \sum_{i=1}^{n} \delta \boldsymbol{r}_i \cdot \sum_{j=1}^{n} \delta \boldsymbol{r}_j \right\rangle \\ &= \left\langle \sum_{i=1}^{n} \delta \boldsymbol{r}_i \cdot \delta \boldsymbol{r}_i \right\rangle = n \langle \delta \boldsymbol{r}_1^2 \rangle \,. \end{aligned} \tag{2.18}$$

The tracer diffusion coefficient is, thus, given by

$$D_\mathrm{s} = \lim_{t\to\infty} \frac{\langle \Delta \boldsymbol{r}^2(t) \rangle}{4t} = \lim_{t\to\infty} \frac{n \langle \delta \boldsymbol{r}_1^2 \rangle}{4n\delta t} = \frac{1}{4} \nu_j \langle \delta \boldsymbol{r}_1^2 \rangle \,. \tag{2.19}$$

If the distance of first neighbors is a, whatever direction is taken for the jump, the square displacement is a^2, so that

$$\langle \delta \boldsymbol{r}_1^2 \rangle = a^2 \,, \tag{2.20}$$

which leads to the final expression of the tracer diffusion coefficient in a jump model with nearest-neighbor jumps

$$D_\mathrm{s} = \frac{1}{4} \nu_j a^2 \,. \tag{2.21}$$

For anisotropic lattices, we have

$$D_\mathrm{s}^x = \frac{1}{2} \nu_j^x a^2 \quad D_\mathrm{s}^y = \frac{1}{2} \nu_j^y b^2 \,, \tag{2.22}$$

where ν_j^x, ν_j^y are the total jump rates in x and y directions, respectively, and a, b are the nearest-neighbor distances in the directions x and y.

As we saw in the previous section, there are several examples of surface diffusion in which jumps to more distant neighbors than the first ones are possible. Let us consider the contribution of these long jumps to diffusion. We consider the isotropic case and calculate $\langle \delta \boldsymbol{r}_1^2 \rangle$. From the site of departure (in $\boldsymbol{r} = 0$ for simplicity), the adatom can jump to any other site $\boldsymbol{l}$ of the lattice with probability $\pi_{\boldsymbol{l}}$, with the normalization condition

$$\sum_{\boldsymbol{l}\neq 0} \pi_{\boldsymbol{l}} = 1 \,. \tag{2.23}$$

We have that $\langle \delta \boldsymbol{r}_1^2 \rangle$ equals the mean-square jump length $\langle l^2 \rangle$

$$\langle \delta \boldsymbol{r}_1^2 \rangle = \sum_{\boldsymbol{l}\neq 0} \pi_{\boldsymbol{l}} (\boldsymbol{l} \cdot \boldsymbol{l}) = \langle l^2 \rangle \,, \tag{2.24}$$

giving

$$D_\mathrm{s} = \frac{1}{4} \nu_j \langle l^2 \rangle \,. \tag{2.25}$$

If long jumps occur in one dimension, for example, on channeled surfaces such as the (1×2) missing-row reconstructed surface, the expression for $\langle l^2 \rangle$ is

$$\langle l^2 \rangle = \sum_{l\neq 0} \pi_l (la)^2 \,, \tag{2.26}$$

with l an integer. Since $\pi_l = \pi_{-l}$, we can define $p_l = 2\pi_l$ for $l > 0$ and write

$$\langle l^2 \rangle = \sum_{l=1}^{\infty} p_l l^2 a^2 \,. \tag{2.27}$$

The diffusion coefficient is

$$D_\mathrm{s} = \frac{1}{2} \nu_j a^2 \sum_{l=1}^{\infty} p_l l^2 \,. \tag{2.28}$$

Single-particle diffusion is not limited to isolated adatoms. In fact, in general, D_s can be defined for a dense adsorbate. For N diffusing adatoms (which are here assumed to be identical), D_s is defined exactly in the same way as for an isolated adatom, with the advantage (quite important in simulations) of averaging on all adatoms. The definition for the isotropic case is

$$D_\mathrm{s} = \lim_{t\to\infty} \frac{1}{2dt} \sum_{i=1}^{N} \langle \Delta \boldsymbol{r}_i^2(t) \rangle \,. \tag{2.29}$$

Lattice models are very often used to treat diffusion in dense adsorbates, because they allow a simplified treatment. Here, we consider a specific two-dimensional lattice model, which is known as the *Langmuir gas*. This model allows us to easily understand the main differences between tracer and collective diffusion. Our discrete lattice contains M equivalent adsorption sites, and it is filled by N adatoms. Each site can be occupied by no more than one adatom, so that the fraction of occupied sites, usually called coverage, is $\theta = N/M$; D_s will depend on θ, generally in a quite complex way. The adatoms diffuse by jumping between nearest-neighbor sites on the lattice and are assumed

to interact only by *site blocking*. Site blocking mimics the short-distance hard-sphere repulsion between the adatoms forbidding multiple occupancy of sites. Even for this simple model, the exact analytical expression for $D_s(\theta)$ is not known. In the limit $\theta \to 0$, D_s must tend to the expression of (2.21). Then, due to site blocking, $D_s(\theta)$ decreases with θ. As a first approximation, we note that, on average, the jump rate is decreased proportionally to the average fraction of occupied nearest-neighbor sites, which is given by θ is this simple model. Therefore, a mean-field expression for $D_s(\theta)$ is

$$D_s(\theta) = \frac{1}{4}\nu_j a^2(1-\theta)\,. \tag{2.30}$$

This expression is exact for both limits $\theta = 0$ and $\theta = 1$ (for $\theta = 1$, no adatom can move), but it overestimates the true D_s for intermediate θ. This is due to neglecting *memory effects*, which correlate sequences of subsequent jumps. To understand why memory effects lower D_s compared to the mean-field expression of (2.30), one may note that after a jump, the adatom leaves a free site behind, so that a jump back is more likely than a jump to another site, whose probability of being empty is $1-\theta$. In order to take into account memory effects, a *tracer correlation factor* $f_t(\theta)$ is introduced, so that

$$D_s(\theta) = \frac{1}{4}\nu_j a^2(1-\theta) f_t(\theta)\,. \tag{2.31}$$

Evaluating $f_t(\theta)$ by analytical means is quite complicated, so that numerical evaluations by Monte Carlo simulations are often used [2.105]. Anyway, very accurate analytical formulas have been produced [2.106–108], mostly by using projection-operator techniques. For example, for a square lattice, one may use

$$f_t(\theta) = 1 - \frac{2\theta}{6-\theta-\xi(2-\theta)}\,, \tag{2.32}$$

with $\xi = 10\,440/9443$. The behavior of $D_s(\theta)$ according to the different approximations is reported in Fig. 2.9.

Further interactions between the adatoms besides site blocking are usually called *lateral interactions*. In general, attractive lateral interactions slow down tracer diffusion, because each adatom has to break the bonds with its neighbors to make a jump. On the other hand, repulsive lateral interactions may enhance diffusion, unless they are so strong (compared to $k_B T$) as to cause the formation of ordered phases, whose rigid framework leads to a decrease in adatom mobility.

2.2.2 Collective Diffusion

While tracer diffusion describes the long-time motion of each adatom individually, collective diffusion describes the time decay of long-wavelength density fluctuations of the whole adsorbate [2.1, 2, 5, 109]. Let us consider an isotropic adsorbate with average density $\overline{\rho}$. At a given point $\boldsymbol{r}$ on the surface and time t, the density is $\rho(\boldsymbol{r}, t)$, so that the density fluctuation $\delta\rho$ is

$$\delta\rho(\boldsymbol{r}, t) = \rho(\boldsymbol{r}, t) - \overline{\rho}\,. \tag{2.33}$$

We assume that the flux of matter in the adsorbate is proportional to the density gradient according to Fick's law

$$\boldsymbol{J}(\boldsymbol{r}, t) = -D_c \nabla\rho(\boldsymbol{r}, t) = -D_c \nabla\delta\rho(\boldsymbol{r}, t)\,, \tag{2.34}$$

where $\boldsymbol{J}$ is the current density, and D_c is the collective diffusion coefficient. Combining this equation with the

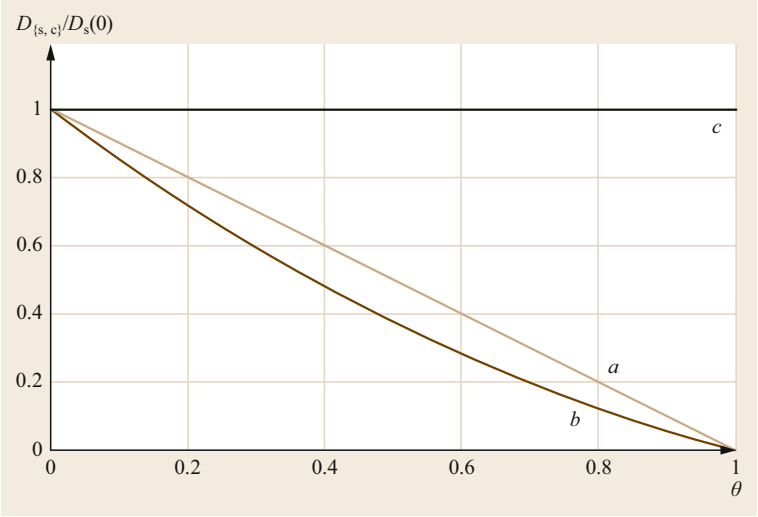

Fig. 2.9 Normalized diffusion coefficients $D_{\{s,c\}}/D_s(0)$ as functions of the coverage θ in a Langmuir gas: *a* mean-field approximation for D_s (2.30), *b* D_s with memory effects taken into account (2.31) and (2.32), *c* D_c (Sect. 2.2.2), which, in the Langmuir gas, does not depend on coverage

continuity equation we obtain the diffusion equation

$$\frac{\partial \delta\rho}{\partial t} = D_c \nabla^2 \delta\rho \,. \tag{2.35}$$

Let us consider a periodic density fluctuation and calculate how it decays with time according to (2.35). The fluctuation at time $t = 0$ is

$$\delta\rho(\boldsymbol{r}, 0) = \delta\rho_0 \cos(\boldsymbol{q}_0 \cdot \boldsymbol{r}) = \delta\rho_0 \frac{\mathrm{e}^{\mathrm{i}\boldsymbol{q}_0\cdot\boldsymbol{r}} + \mathrm{e}^{-\mathrm{i}\boldsymbol{q}_0\cdot\boldsymbol{r}}}{2} \,. \tag{2.36}$$

We define

$$S(\boldsymbol{q}, t) = \int \mathrm{d}\boldsymbol{r} \mathrm{e}^{\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{r}} \delta\rho(\boldsymbol{r}, t) \,, \tag{2.37}$$

with the inversion formula

$$\delta\rho(\boldsymbol{r}, t) = \frac{1}{(2\pi)^d} \int \mathrm{d}\boldsymbol{q} \mathrm{e}^{-\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{r}} S(\boldsymbol{q}, t) \,. \tag{2.38}$$

Substituting in (2.35) we find an equation for the evolution of S

$$\frac{\partial S}{\partial t} = -D_c q^2 S(\boldsymbol{q}, t) \,, \tag{2.39}$$

with solution

$$S(\boldsymbol{q}, t) = S(\boldsymbol{q}, 0) \mathrm{e}^{-D_c q^2 t} \,, \tag{2.40}$$

with

$$S(\boldsymbol{q}, 0) = (2\pi)^d \frac{\delta\rho_0}{2} \left[\delta(\boldsymbol{q} - \boldsymbol{q}_0) + \delta(\boldsymbol{q} + \boldsymbol{q}_0)\right] . \tag{2.41}$$

Substituting in (2.38)

$$\delta\rho(\boldsymbol{r}, t) = \delta\rho_0 \cos(\boldsymbol{q}_0 \cdot \boldsymbol{r}) \mathrm{e}^{-D_c q_0^2 t} \,, \tag{2.42}$$

which gives that the fluctuation decays exponentially with time constant

$$\tau_c(\boldsymbol{q}_0) = \frac{1}{D_c q_0^2} \,. \tag{2.43}$$

Now, we treat collective diffusion in a Langmuir gas. We consider fluctuations in the coverage, by considering the evolution of $\theta_{\boldsymbol{l}}(t)$, which represents the probability that at time t site $\boldsymbol{l}$ is occupied, from an initial periodic configuration. This evolution is described by a *master equation*

$$\frac{\mathrm{d}\theta_{\boldsymbol{l}}}{\mathrm{d}t} = \alpha \sum_{\boldsymbol{a}} (\theta_{\boldsymbol{l}+\boldsymbol{a}} - \theta_{\boldsymbol{l}}) \,, \tag{2.44}$$

where $\boldsymbol{l} + \boldsymbol{a}$ are the positions of the first neighbors of site $\boldsymbol{l}$ of the two-dimensional Bravais lattice (noting that the only isotropic two-dimensional Bravais lattices are the square and the hexagonal lattices). The coefficient $\alpha = \nu_j / n_{\mathrm{pv}}$ is the directional jump rate from $\boldsymbol{l}$ to $\boldsymbol{l} + \boldsymbol{a}$. The equilibrium probability is the average coverage θ, so that the fluctuation of the coverage is given by

$$\delta\theta_{\boldsymbol{l}}(t) = \theta_{\boldsymbol{l}}(t) - \theta \,. \tag{2.45}$$

The master equation for $\delta\theta_{\boldsymbol{l}}(t)$ is, thus,

$$\frac{\mathrm{d}\delta\theta_{\boldsymbol{l}}}{\mathrm{d}t} = \alpha \sum_{\boldsymbol{a}} (\delta\theta_{\boldsymbol{l}+\boldsymbol{a}} - \delta\theta_{\boldsymbol{l}}) \,. \tag{2.46}$$

which has to be solved with the initial condition

$$\delta\theta_{\boldsymbol{l}}(0) = \delta\theta_0 \cos(\boldsymbol{q}_0 \cdot \boldsymbol{l}) \,; \tag{2.47}$$

$S(\boldsymbol{q}, t)$, in this case, is defined as

$$S(\boldsymbol{q}, t) = \sum_{\boldsymbol{l}} \mathrm{e}^{\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{l}} \delta\theta_{\boldsymbol{l}}(t) \,, \tag{2.48}$$

with the inversion formula

$$\delta\theta_{\boldsymbol{l}}(t) = A_c \int \mathrm{d}\boldsymbol{q} \mathrm{e}^{-\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{l}} S(\boldsymbol{q}, t) \,, \tag{2.49}$$

where A_c is the area of the primitive unit cell of the Bravais lattice. Inserting (2.49) in (2.46), one obtains

$$\frac{\mathrm{d}S}{\mathrm{d}t} = -f(\boldsymbol{q}) S(\boldsymbol{q}, t) \,, \tag{2.50}$$

with

$$f(\boldsymbol{q}) = \alpha \sum_{\boldsymbol{a}} (1 - \mathrm{e}^{-\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{a}}) = \alpha \sum_{\boldsymbol{a}} [1 - \cos(\boldsymbol{q} \cdot \boldsymbol{a})] \,. \tag{2.51}$$

For long-wavelength fluctuations $q \ll 1/a$,

$$f(\boldsymbol{q}) = \alpha \sum_{\boldsymbol{a}} \frac{1}{2} (\boldsymbol{q} \cdot \boldsymbol{a})^2 = \frac{\nu_j}{4} a^2 q^2 \,, \tag{2.52}$$

recalling that $\alpha = \nu_j / n_{\mathrm{pv}}$ and verifying the equation for the square and hexagonal lattices. However, from (2.30) $\nu_j a^2 / 4 = D_s(0)$, so that

$$f(\boldsymbol{q}) = D_s(0) q^2 \,. \tag{2.53}$$

Therefore,

$$S(\boldsymbol{q}, t) = S(\boldsymbol{q}, 0) \mathrm{e}^{-D_s(0) q^2 t} \,, \tag{2.54}$$

with

$$S(\boldsymbol{q}, 0) = \frac{\delta\theta_0}{2A_c} [\delta(\boldsymbol{q} - \boldsymbol{q_0}) + \delta(\boldsymbol{q} + \boldsymbol{q_0})] \tag{2.55}$$

and, finally,

$$\delta\theta_{\boldsymbol{l}}(t) = \delta\theta_0 \cos(\boldsymbol{q}_0 \cdot \boldsymbol{l}) \mathrm{e}^{-D_s(0) q_0^2 t} \,, \tag{2.56}$$

which shows that the fluctuation decays with a time constant

$$\tau_c(\boldsymbol{q}_0) = \frac{1}{D_s(0)q_0^2} \,. \tag{2.57}$$

Comparing this with (2.43), one obtains

$$D_c(\theta) = D_s(0) \,, \tag{2.58}$$

which means that in a Langmuir gas, the collective diffusion coefficient does not depend on coverage, and its value is equal to the zero-coverage tracer diffusion coefficient, as shown in Fig. 2.9. Therefore, collective diffusion in the Langmuir gas is as fast in the limit of full coverage as in the limit of zero coverage. This seemingly counterintuitive result can be explained by recalling that D_c always measures the mobility of density fluctuations. In the limit of $\theta \to 1$, density fluctuations are a few isolated atomic vacancies in the adsorbate, which diffuse as fast as isolated adatoms in the limit $\theta \to 0$.

An equivalent definition of D_c can be given in terms of the asymptotic behavior of the displacement of the center of mass of the adsorbate $\boldsymbol{R} = \sum_{i=1}^{N} \boldsymbol{r}_i$

$$D_c = \lim_{t\to\infty} \frac{1}{2dNS_0 t} \langle [\boldsymbol{R}(t) - \boldsymbol{R}(0)]^2 \rangle \,, \tag{2.59}$$

where S_0 is the *static structure factor*, which can be related to the isothermal compressibility of the adsorbate χ_T by

$$S_0 = \overline{\rho} k_B T \chi_T \,, \tag{2.60}$$

where the average density $\overline{\rho}$ is given by $\overline{\rho} = \theta/a^2$. The equivalence of the definitions of D_c by (2.59) and by Fick's law can be demonstrated in a straightforward but lengthy way. The interested reader is referred to [2.111]. From the computational point of view, the comparison of (2.11) and (2.59) shows that D_s is much easier to calculate than D_c, because in a single simulation box, there are N independent samples for calculating D_s, while there is a single sample (the coordinate of the center of mass) for calculating D_c.

The calculation of D_c in interacting systems turns out to be quite difficult. However, at variance with D_s, we note that for D_c memory effects are absent in the Langmuir gas, so that we may assume that they are somewhat less important even in the presence of lateral interactions besides site blocking. If memory effects are neglected, D_c in a lattice gas of coverage θ turns out to be given by the following expression [2.112, 113]

$$D_c = \frac{a^2 \langle \nu_j \rangle}{4 k_B T \theta \chi_T} \,, \tag{2.61}$$

where $\langle \nu_j \rangle$ is the thermally averaged jump rate.

Results about the dependence of D_c in a triangular lattice gas with repulsive interactions are given in Fig. 2.10. These results [2.110] have been obtained

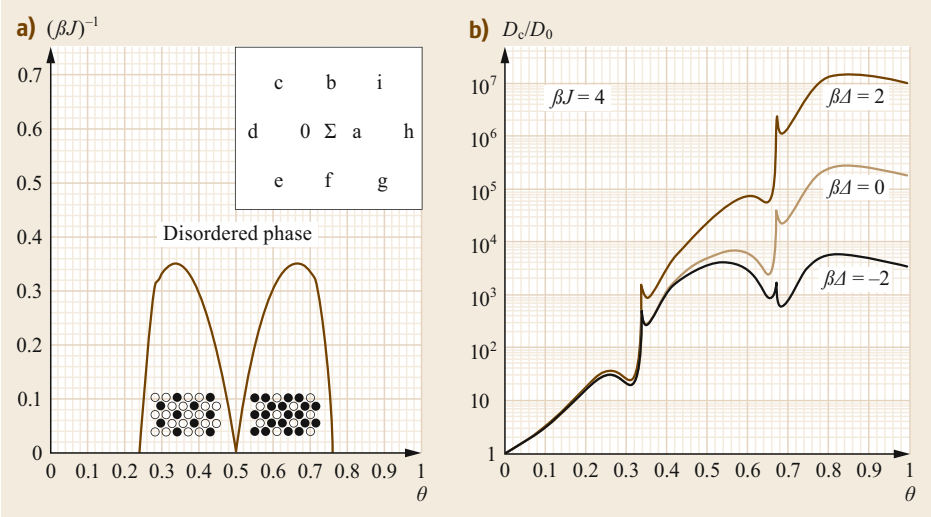

Fig. 2.10 **(a)** Phase diagram of the repulsive lattice gas on a triangular lattice. Nearest-neighbor interactions are assumed. The *inset* considers an adatom that jumps from the adsorption site 0 to the adsorption site a, passing through the saddle point Σ. In 0, the adatom feels the repulsion of other adatoms which may occupy sites b, c, d, e, and f. This repulsion has intensity $J > 0$. At the saddle point, the adatom feels the interaction with other adatoms in sites b and f, with intensity J_Σ, which may be either positive or negative. Putting $\Delta = J - J_\Sigma$, the energy barrier E_b for this jump is given by $E_b = E_0 - J(n_c + n_d + n_e) - \Delta(n_b + n_f)$, where E_0 is the energy barrier for an isolated adatom, and the variables n are either 0 or 1, depending on the corresponding site being free or occupied by an adatom. **(b)** Behavior of D_c depending on the coverage θ for $\beta J = 4$ and different values of $\beta\Delta$, with $\beta = 1/(k_B T)$ (adapted from [2.110])

by the approximation of (2.61), in which the thermally averaged quantities $\langle \nu_j \rangle$ and χ_T were calculated by the cluster variation method [2.114]. The results of Fig. 2.10 are representative of the complex dependence of D_c on coverage in systems in which there is the formation of ordered phases. This complex behavior results from the competition between the decrease of both $\langle \nu_j \rangle$ and of χ_T in the ordered phases. Outside the region of the phase diagram corresponding to the ordered phases, D_c shows a tendency to increase with θ because of the repulsive character of the interactions.

However, it must be noted that the approximation of (2.61) may be insufficient in the vicinity of phase transitions in the adsorbate, where memory effects may become important also for collective diffusion [2.115]. More sophisticated analytical approaches have been developed in more recent times [2.116, 117], also for heterogeneous and anisotropic lattices [2.118–120].

2.3 Experimental Measurements of Diffusion

Various techniques have been established to measure diffusion of atoms and molecules at surfaces experimentally. Again, the literature is vast, and there have been a number of comprehensive reviews on experimental progress [2.1, 4, 121–123]. There is a broad distinction between experimental techniques that either measure the evolution of an initially imposed concentration profile of a surface species, and those that follow the motion of individual particles moving in equilibrium. The former generally measures diffusion over relatively large length scales and interprets the motion within Fick's law and usually provides chemical diffusion constants and their temperature dependence. Once the concentration profile has been established, its evolution can be measured by various methods [2.1], including work function probes, photoelectron microscopy, and scanning Auger microscopy. Similarly, laser-induced thermal desorption has been used to repeatedly desorb species from a particular region of the surface and to subsequently monitor the rate of refilling by diffusion. All these methods rely on being able to generate a suitable initial configuration and, more fundamentally, are only indirectly related to the underlying microscopic characteristics of the system.

Equilibrium methods generally follow the motion of individual particles or fluctuations in the equilibrium configuration of an assembly of particles. Equilibrium methods, therefore, provide more direct microscopic information; specifically, local correlations in individual particle motion can be understood in detail, along with the transition between localized microscopic interactions and dynamics that follow Fick's law in the macroscopic limit. Equilibrium diffusion measurements can be routinely performed using time-lapse imaging, typically based on scanning tunneling microscopy (STM) or field ion microscopy (FIM) [2.121, 124]. However, because of the limited framing rate (interframe times are at least milliseconds [2.124]) they can only distinguish the *before* and *after* states associated with jumps between adsorption sites—the detail of, for example, long jumps cannot be captured. Similarly, to limit the extent of motion between frames, low temperatures are usually required (i.e., thermal energy, $k_B T \ll$ activation energy, E_a), which means such data is often from a different regime than to many physical processes of practical interest, such as catalysis or epitaxial growth. Fluctuation correlation methods such as fluorescence correlation spectroscopy (FCS) [2.125] and x-ray photon correlation spectroscopy (XPCS) [2.126] are equilibrium methods that provide more extensive information, as they yield correlation information on specific length scales, using optical and x-ray scattering, respectively. However, as they are sensitive to mesoscopic length scales and relatively long timescales, they still cannot provide a complete atomic-scale description of motion.

The technique of helium spin-echo (HeSE) [2.127–130] is a relatively recent equilibrium approach to measuring surface diffusion. The method provides perhaps the most comprehensive surface transport data available—giving access to both diffusion and other forms of surface motion. The technique is the surface analogue of quasielastic neutron scattering (QENS) [2.131] and involves scattering a beam of *neutral* thermal energy helium atoms from mobile species on a surface. The scattered atom distribution is directly related to a pair correlation function that provides a comprehensive statistical description of the motion, with information spanning timescales between picoseconds and nanoseconds and length scales from ångströms up to tens of nanometers. Since HeSE provides such comprehensive data, we will focus on that method here and provide a series of examples.

2.3.1 Helium Scattering and the Spin–Echo Technique

The broad technique of helium atom scattering has been used routinely in a number of specialist laboratories around the world since the 1970s. The method involves producing a nearly monochromatic, collimated,

beam of thermal energy helium atoms (typically 10 to 100 meV), then scattering the atomic beam from a surface in order to study the surface properties [2.132–135]. Since the incident energy of helium is so low, the atoms scatter from the outermost valence electrons at the surface. Through that interaction, the helium atoms can, in general, exchange momentum, $\hbar\Delta\boldsymbol{k}$, and energy, $\hbar\omega$, with the surface, where $\boldsymbol{k}$ and ω relate to wavevector and frequency, respectively. Both elastic and inelastic scattering are possible, enabling surface structure and dynamical processes to be studied, respectively.

In the case of elastic scattering, when the helium atoms experience no energy exchange with the surface, the main processes are diffraction and diffuse scattering. These have been used to study surface structure and growth, often in relation to thin films and delicate adsorbed species [2.133, 134]. During inelastic scattering, helium atoms generally interact with surface phonons or adsorbate vibrations. If the interaction is with a single mode, the well-defined energy transfer condition corresponding to the vibrational frequency of the mode means surface dispersion curves can be mapped out [2.135]. Multiphonon interactions are also possible.

If helium atoms interact with an aperiodically moving species (i.e., a diffusing atom), energy changes are still possible, but are now centered around zero energy transfer, i.e., around the elastic peak. These *quasielastic* energy changes are characteristic of that aperiodic diffusive motion and, hence, enable the motion to be studied—the phenomenon is known as *quasielastic helium atom scattering* (QHAS) and underpins the HeSE method. Note that these quasielastic energy changes are very small, usually in the μeV range, or even smaller.

In general, quantitative interpretation of helium scattering data can be complex, and various approximations have been developed [2.132]. Fortunately, for helium atoms scattered from mobile adsorbates on a surface, the kinematic approximation can be used to simplify analysis by decomposing the overall scattered intensity, $A(\Delta\boldsymbol{K},\omega)$, into the product of an intensity structure factor, S, and an amplitude form factor, F,

$$A(\Delta\boldsymbol{K},\omega) = S(\Delta\boldsymbol{K},\omega)\cdot|F(\Delta\boldsymbol{K},\omega)|^2 \ ; \qquad (2.62)$$

$S(\Delta\boldsymbol{K},\omega)$ is determined by the position of the scatterers on the surface, and $F(\Delta\boldsymbol{K},\omega)$ is a result of the shape of each scatterer. For analysis of adsorbate dynamics, the approximation works very well [2.136]; $\Delta\boldsymbol{K}$ represents the change in wavevector of the helium atoms during scattering, projected into the surface plane and is given by the scattering geometry according to

$$\Delta K = k_\mathrm{f}\sin(\theta_\mathrm{SD}-\theta_\mathrm{i}) - k_\mathrm{i}\sin(\theta_\mathrm{i}); \qquad (2.63)$$

k_i and k_f are the incident and final helium wavevectors, and θ_SD and θ_i are the total scattering angle and incident angles, respectively; $S(\Delta\boldsymbol{K},\omega)$ is known as the dynamic structure factor, a quantity used extensively in neutron scattering [2.131], and which was shown by *Van Hove* [2.137] to be related to a pair correlation function, $G(\boldsymbol{R},t)$, by a double Fourier transform in both space and time, through the intermediate scattering function, $I(\Delta\boldsymbol{K},t)$,

$$S(\Delta\boldsymbol{K},\omega) \overset{\text{Temporal FT}}{\rightleftharpoons} I(\Delta\boldsymbol{K},t) \overset{\text{Spatial FT}}{\rightleftharpoons} G(\boldsymbol{R},t). \qquad (2.64)$$

The pair correlation function $G(\boldsymbol{R},t)$ provides a complete statistical description of the motion of the scatterers.

In most energy-resolved helium scattering experiments, the scattering angles are controlled by the experimental setup, and the *absolute* energy distribution of the scattered beam is measured using time-of-flight methods [2.134]. Hence, providing F can be accounted for or ignored, $S(\Delta\boldsymbol{K},\omega)$ is obtained directly from the experiment, which then provides information about diffusion and vibration through the relationship with $G(\boldsymbol{R},t)$. For QHAS experiments of surface diffusion, the finite velocity spread in the initial helium beam is a serious limit on time-of-flight measurements. The velocity spread masks the tiny quasielastic energy changes that relate to surface diffusion in all but a very few physical systems [2.138, 139]. In contrast, HeSE experiments only measure the energy *changes* during scattering, and so are not limited by the spread of energies in the incident helium beam, and, thus, the HeSE method can be applied much more widely. As we will describe below, HeSE experiments obtain the intermediate scattering function, $I(\Delta\boldsymbol{K},t)$, directly, hence providing a more direct link to the information about diffusion that is encoded in $G(\boldsymbol{R},t)$. By measuring $I(\Delta\boldsymbol{K},t)$ under a sufficiently wide range of conditions, analysis can reveal the full detail of surface transport, including diffusion, vibration, energy exchange, and collective motion, in a regime that is not accessible to any other experimental technique.

2.3.2 Measuring the Intermediate Scattering Function with HeSE

Before proceeding to discuss HeSE measurements of diffusion, we give a brief overview of the technique, following the semiclassical description by *Gähler* et al. [2.140]; for more details, the reader is directed to [2.130]. The basic principle of HeSE is shown schematically in Fig. 2.11. An HeSE instrument con-

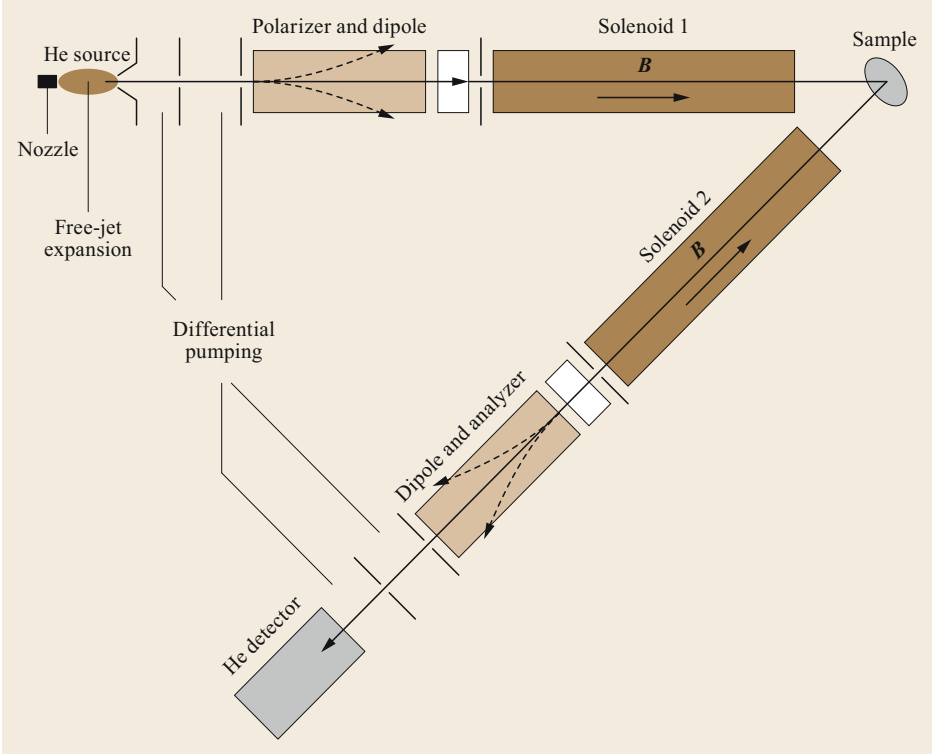

Fig. 2.11 The HeSE technique. Atoms produced in the helium source are polarized in a hexapole magnet, spin-aligned in a dipole field, and then passed through a solenoid magnet. The solenoid splits the helium wavepacket into two spin components, which reach the sample separated by a short time delay t_{SE}. Along the second arm of the instrument, the spin components are recombined and passed through a further dipole and hexapole to spin-analyze the beam. The beam-averaged polarization is proportional to the intermediate scattering function $I(\Delta \boldsymbol{K}, t)$.

sists of an extended series of vacuum chambers to convey a beam of helium atoms from the beam source to the sample and then to transfer atoms scattered in a particular direction, to the detector. Along the two beamlines, a series of magnetic components are used to measure the intermediate scattering function, by making use of the nuclear spin of ^{3}He.

Working along the beamlines shown in Fig. 2.11, the beam of ^{3}He atoms is first produced in a standard free-jet supersonic expansion, followed by several stages of differential pumping to reduce the background helium pressure diffusing along the beamline from the source chamber. Next, the beam is passed through an intense hexapole magnetic field, where the ^{3}He nuclear spins must align either parallel or antiparallel to the local-field direction. The hexapole field is highly inhomogeneous and has a magnitude B_h, which varies quadratically with the radius. Consequently, the field applies a force to each spin, given by $\boldsymbol{F} = \pm\mu\nabla B_h$, which focusses one polarization of atoms onto the sample, while the other is defocused and removed for recycling. The focused component of the beam is then passed through a dipole field, which aligns the spins in a particular direction perpendicular to the beamline, which we denote as the state $|+\rangle_x$. The focused atoms then continue into a solenoidal field B_s oriented along the beamline. Inside the solenoid, the helium wavepacket can be represented as a superposition of two spin eigenstates, aligned either parallel or antiparallel to the field,

$$|+\rangle_x = \frac{1}{\sqrt{2}}(|+\rangle_z + |-\rangle_z), \tag{2.65}$$

whose energies are split by $\pm\mu B_s$, respectively. Since the energies are split, the two spin components, $|\pm\rangle_z$, travel at different velocities and so separate as they travel towards the sample. It can be shown [2.130] that the two components reach the sample with a time delay, t_{SE}, given by

$$t_{SE} = \frac{\gamma\hbar}{mv^3}\int_0^L B_s \mathrm{d}l\,, \tag{2.66}$$

where γ, m and v are the gyromagnetic ratio, mass, and velocity of the ^{3}He atoms, respectively, and the integral is through the solenoid field of length L. In practice, t_{SE} is controlled by adjusting the current in the solenoid windings, and can range from a fraction of a picosecond to the nanosecond range.

After interacting with the surface, atoms scattered in a particular outgoing direction pass along the second beamline, through an identical but reversed solenoid field, where the separated components, $|\pm\rangle_z$, are recombined. If the surface remains unchanged over t_{SE}, both spin components will scatter from the surface in exactly the same way, so the original polarized form, $|+\rangle_x$, will be recovered. However, if the surface has changed, for example, if an atom has jumped between adsorption sites, the recovered spin direction will be changed, and, on average, there will be a reduction in the overall polarization of the beam.

The recovered spins then pass through an analyzer dipole and hexapole, which selects the x component of the polarization, and focuses that proportion of atoms into a mass-spectrometer detector. Quadrature methods, which involve adding an extra $\pi/4$, $\pi/2$, and $3\pi/2$ of spin rotation near the first dipole field, enable the full polarization to be determined [2.141]. The measured polarization, $P(\Delta\boldsymbol{K}, t_{SE})$, is usually a good approximation to the normalized intermediate scattering function, $I(\Delta\boldsymbol{K}, t)$, given by

$$P(\Delta\boldsymbol{K}, t_{SE}) = \frac{I(\Delta\boldsymbol{K}, t_{SE})}{I(\Delta\boldsymbol{K}, 0)} \,. \tag{2.67}$$

In other words, by measuring polarization, we make a direct measurement of the surface correlation over time t_{SE} and on the length scale and in the direction determined by the wavevector $\Delta\boldsymbol{K}$. Note that to measure certain properties, such as phonon linewidths, a more sophisticated *wavelength transfer matrix* approach is helpful [2.130, 142, 143], but this is beyond the scope of the present chapter.

The HeSE measurement principle is very general and thus can be applied to a wide variety of experiments, including measuring surface diffusion, surface and adsorbate vibrations, and for probing energy exchange rates. To date, experiments have usually been carried out on single crystal samples under ultra-high vacuum conditions. Samples are mounted on a six axis manipulator to enable $\Delta\boldsymbol{K}$ to be aligned along any surface direction. The vacuum systems include standard surface preparation and characterization tools, as well as sample transfer for rapid-exchange into the measurement facility.

2.3.3 Measuring Diffusion with HeSE

Studying diffusion, or other surface properties, with HeSE involves interpreting the measured intermediate scattering function. Although, in principle, $G(\boldsymbol{R}, t)$ contains a complete description of all the surface dynamics and is related to $I(\Delta\boldsymbol{K}, t_{SE})$ by a spatial Fourier transform, it is usually not possible to obtain sufficient data to perform an inverse transform directly. Hence, HeSE analysis is generally based on examining changes in the shape of $I(\Delta\boldsymbol{K}, t_{SE})$ across a range of values of $\Delta\boldsymbol{K}$.

Figure 2.12 shows a cartoon of the typical form of $I(\Delta\boldsymbol{K}, t_{SE})$ for a measurement of an adsorbed species on a surface. The function takes a decaying form as the surface correlation, as seen by the helium beam over the length scale and direction determined by $\Delta\boldsymbol{K}$, reduces with time. Oscillations in $I(\Delta\boldsymbol{K}, t_{SE})$ relate to surface vibrations, such as phonons, and generally die away quickly at a rate that is characteristic of energy exchange with the substrate. The overall decay relates to aperiodic processes such as the dephasing of vibrations [2.144], where the characteristic time is usually less than a few picoseconds, or surface diffusion, where the characteristic time can be much longer. Surface dif-

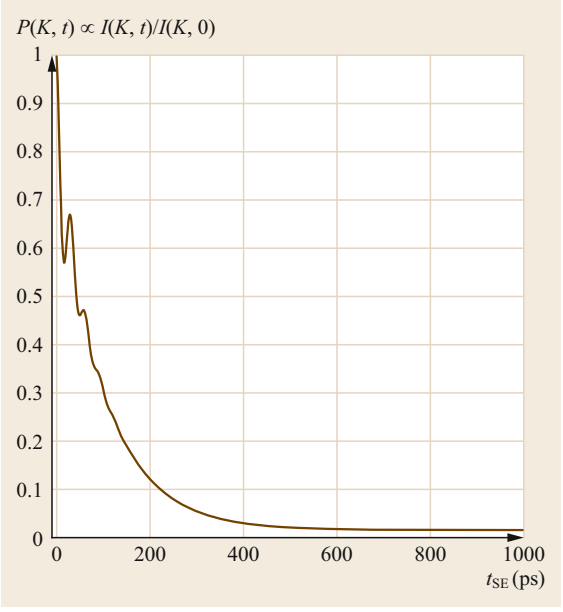

Fig. 2.12 The typical form of $I(\Delta\boldsymbol{K}, t_{SE})$ as measured by HeSE. The general form is a decaying function, as the surface correlation, as seen by the helium beam over the length scale and direction determined by $\Delta\boldsymbol{K}$ reduces with spin echo time t_{SE}. Periodic surface processes, such as phonons, result in oscillations, while aperiodic processes such as diffusion generally result in an exponential decay

fusion generally results in an exponentially decaying form

$$I(\Delta \boldsymbol{K}, t_{\mathrm{SE}}) = A \exp(-\alpha t) \,, \tag{2.68}$$

as correlations in the surface configuration, measured at a particular value of $\Delta \boldsymbol{K}$, decay with a well-defined rate $\alpha(\Delta \boldsymbol{K})$, known as the *dephasing rate*. Different analytic models for surface transport, such as simple hopping, long jumping, or continuous Brownian motion, each give rise to a characteristic variation of α with $\Delta \boldsymbol{K}$. Hence, by measuring $\alpha(\Delta \boldsymbol{K})$, the microscopic mechanism of motion can be determined. Once the mechanism is understood, parameters describing that motion can be obtained by fitting a suitable model to the empirical data, and from those model parameters, macroscopic quantities, such as diffusion constants or energy barriers, can be determined [2.130].

Jump Diffusion

Jump diffusion was first analyzed by *Chudley* and *Elliott* [2.145] in order to interpret quasielastic neutron scattering data. The same principles were applied to HeSE [2.146] and resulted in $I(\Delta \boldsymbol{K}, t_{\mathrm{SE}})$ taking the general form in (2.68), with $\alpha(\Delta \boldsymbol{K})$ varying sinusoidally,

$$\alpha(\Delta \boldsymbol{K}) = 2 \sum_j \nu_j \sin^2 \left(\frac{\Delta \boldsymbol{K} \cdot \boldsymbol{j}}{2} \right) . \tag{2.69}$$

The summation is over all the possible adsorbate jumps $\boldsymbol{j}$ within the unit cell, and ν_j are the associated jump frequencies—in other words, each possible jump type contributes a sinusoidal component to the overall dependence. The tracer diffusion constant may then be estimated using [2.147]

$$D_{\Delta K} = \frac{1}{2} \nu \left\langle j^2_{\Delta K} \right\rangle \,,$$

where the parameters are projected along a particular $\Delta \boldsymbol{K}$ direction.

As an example, Fig. 2.13 shows measured HeSE data for the jump diffusion of H and D atoms on a Pt(111) surface, from [2.148]. Here, the mechanism of motion almost conforms perfectly to a single jump model, in excellent agreement with the form in (2.69). More widely, measurements have established that show that most systems exhibit jump characteristics, although the precise mechanism often contains a distribution of different jump lengths, elements of continuous motion (e.g., intracell diffusive motion [2.144]), and more complex processes (see later). In the case of different jump lengths, these can be distinguished by fitting a series of Fourier components to the measured $\alpha(\Delta \boldsymbol{K})$ dependence, one for each type of jump, using (2.69).

Other examples where good approximations to jump diffusion have been observed include alkali metals atoms on transition metals [2.149–152] (although in many situations the motion can be further complicated by lateral interactions, leading to correlated motion) and many small molecules [2.153–160]. Note that (2.69) applies to jumps between adsorption sites that form a Bravais lattice directly. For other networks of adsorption sites, such as the hexagonal lattice that can be formed from the two types of hollow sites on a (111) surface, a more complex model applies [2.161].

Continuous Brownian Motion

If the lateral variation in the potential between adsorbates and substrate is weak, or if the coupling between adsorbate and substrate is very strong, then rather than hopping, continuous Brownian motion can result, even on the atomic scale. Analysis of such motion [2.147] also results in $I(\Delta \boldsymbol{K}, t_{\mathrm{SE}})$ decaying exponentially with t_{SE}, but this time, α varies quadratically with $\Delta \boldsymbol{K}$,

$$\alpha(\Delta \boldsymbol{K}) = D \Delta \boldsymbol{K}^2 \,, \tag{2.70}$$

scaled by the diffusion constant. Note that in the limit of large length scales (small $\Delta \boldsymbol{K}$), all microscopic mechanisms approach this form, including the limiting case of the previous jump model. An example of perfect Brownian motion at an atomic level is the case of benzene adsorbed on graphite [2.162], as shown in Fig. 2.14. The behavior is a result of the extended nature of the molecule averaging over multiple atomic interactions, combined with a high rate of energy exchange between the molecule and the substrate.

Activation Energies

At a particular $\Delta \boldsymbol{K}$, the dephasing rate, α, usually varies with temperature T according to the well-known Arrhenius law

$$\alpha = \alpha_0 \exp \left(-\frac{E_{\mathrm{a}}}{k_{\mathrm{B}} T} \right) , \tag{2.71}$$

where E_{a} is an activation energy for motion, and k_{B} is the Boltzmann constant. Hence, activation energies can be routinely determined from measurements of $I(\Delta \boldsymbol{K}, t_{\mathrm{SE}})$ at different temperatures. However, it is important to approach such analysis with care. Depending on the mechanism of motion, values of $I(\Delta \boldsymbol{K}, t_{\mathrm{SE}})$ at a particular value of ΔK may contain contributions from multiple processes, each with different temperature dependencies. For example, at the sinusoidal minima in Fig. 2.13, at $\Delta \boldsymbol{K} \approx 2.5\,\text{Å}^{-1}$, measurements of $I(\Delta \boldsymbol{K}, t_{\mathrm{SE}})$ contain a vanishing amount of information about the jump mechanism. Similarly, it is also

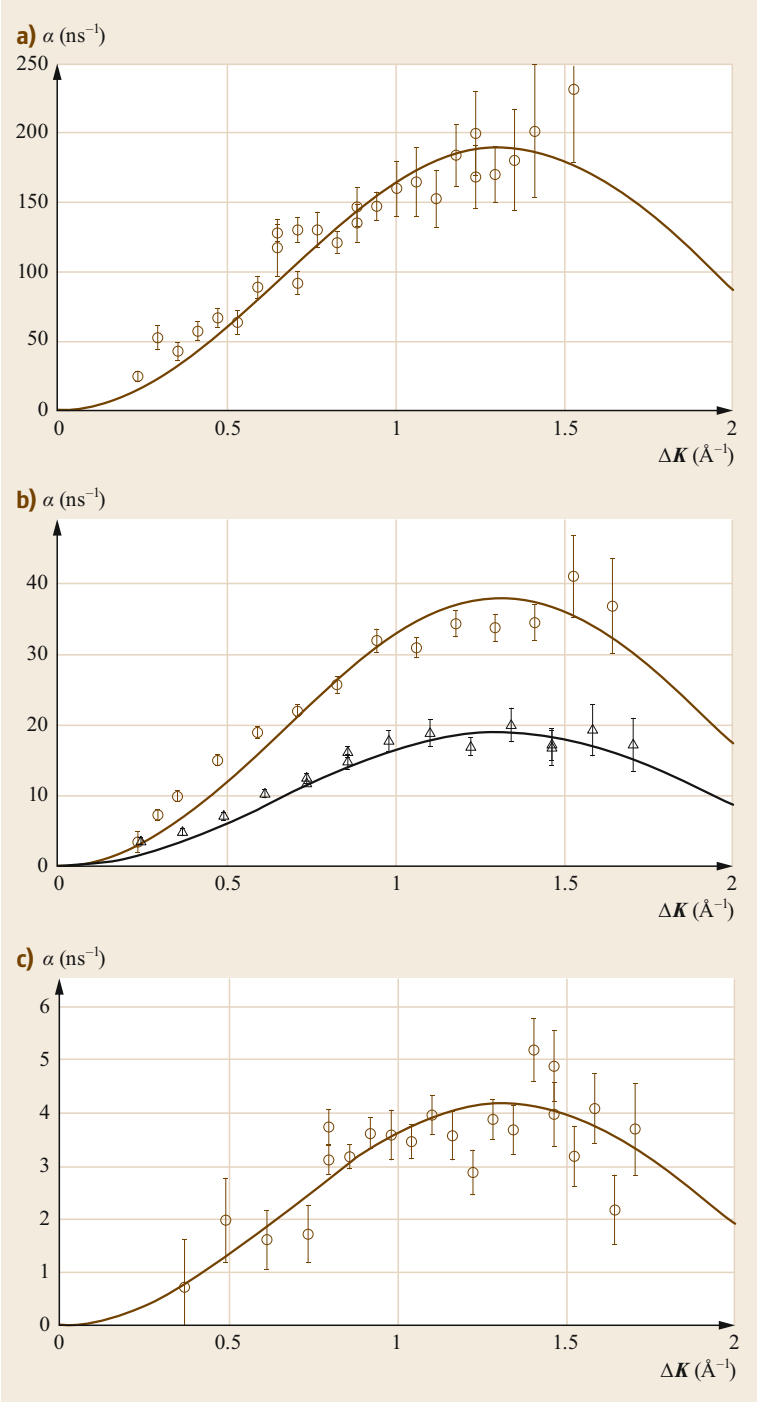

Fig. 2.13a–c HeSE measurements (dephasing angle α versus momentum transfer $\Delta\boldsymbol{K}$) of H (*brown circles*) and D (*black triangles*) diffusion on a Pt(111) surface at three temperatures: **(a)** 220 K, **(b)** 140 K, and **(c)** 90 K. The measurements are in excellent agreement with a single jump model for hopping between adjacent fcc hollow sites (adapted with permission from [2.148], Copyright 2012 by the American Physical Society)

possible for the mechanism of motion to change with temperature, further affecting the analysis. Figure 2.15 illustrates Arrhenius plots for ethanethiol adsorbed on Cu(111) [2.163]; at low temperatures the data is dominated by localized rotation of the molecule (see below), whereas as higher temperatures it is overtaken by translation. The mechanism in each regime was determined from the form of $\alpha(\Delta\boldsymbol{K})$, which subsequently enabled the Arrhenius behavior to be understood and accurate activation energies to be extracted.

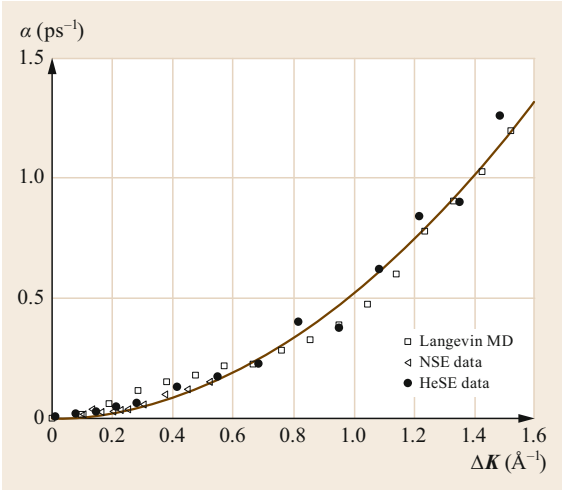

Fig. 2.14 HeSE measurements of the diffusion of benzene molecules on a graphite surface, showing continuous Brownian motion on the atomic scale. The *solid line* is a quadratic fit, as per (2.70), resulting in a diffusion constant of $D = 5.39 \pm 0.13 \times 10^{-9}$ m^2 s^{-1}. HeSE experiments (*circles*) were also shown to be in good agreement with neutron spin-echo measurements (*triangles*) performed at low coverages and Langevin MD simulations described in [2.162]

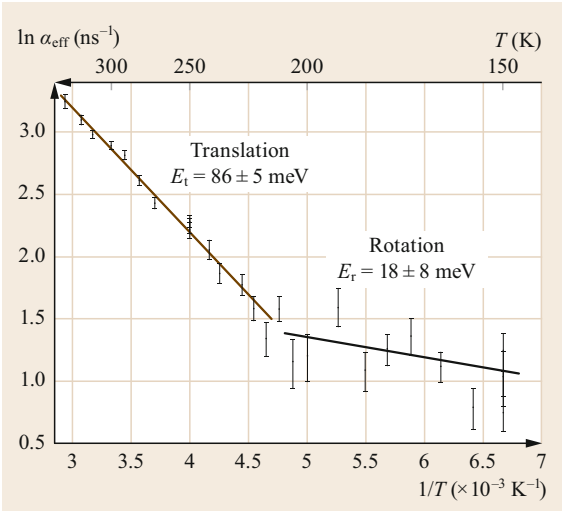

Fig. 2.15 Arrhenius plots of the dephasing rate, α, extracted from the rotational and translationally dominated measurement regimes for ethanethiol on Cu(111) (adapted with permission from [2.163], Copyright 2012 by the American Physical Society)

Diffusion measurements are often used to estimate the adiabatic potential energy barrier to diffusion, and it is possible to use HeSE data to estimate these barriers. The activation energy obtained from Arrhenius analysis alone usually underestimates the adiabatic barrier, and currently, the most accurate way to obtain the true barrier is to use Langevin molecular dynamics simulations to refine a trial potential, including adjustment of the adiabatic barrier heights, to best fit the experimental data (see below).

2.3.4 Beyond Diffusion Constants

Most real systems do not conform fully to the simple analytic models of diffusion discussed so far. For example, when alkali metals are adsorbed onto metal surfaces, electron transfer sets up a strong dipole. Consequently, there is strong dipole–dipole repulsion between adsorbed atoms and, thus, strong correlations in the motion result [2.149–152]. In order to interpret such systems, more sophisticated methods are required and, in general, analytic expressions are insufficient. Simulations are routinely used to predict adsorbate motion given a specific model, from which simulated HeSE data can be produced and subsequently compared with experiment. Free parameters within the model can then be refined to best fit the experimental data. Molecular dynamics simulations that treat all the atoms in the substrate individually can be used but are computationally intensive. For computational speed, the Langevin framework has been used widely, within which only the adsorbed atoms are treated explicitly. The adsorbate–substrate interaction is described by a *frozen* adiabatic potential, $V(\boldsymbol{R})$, and a frictional coupling parameter, η, is used to describe energy exchange. The equation of motion for the i-th adsorbate atom then becomes

$$m\ddot{\boldsymbol{R}}_i = -\nabla V(\boldsymbol{R}_i) - \eta m\dot{\boldsymbol{R}}_i + \xi_i(t) + \sum_{j\neq i} F(|\boldsymbol{R}_j - \boldsymbol{R}_i|), \tag{2.72}$$

where the second and third terms are drag and stochastic excitation, respectively, describing interaction with the substrate heat bath in terms of η, which is scaled according to the fluctuation dissipation theorem [2.164]. The final term can be added to include pairwise interaction forces F between adsorbed atoms. The Langevin framework thus provides a much more sophisticated and general description of the dynamical adsorbate–substrate interaction than is possible using diffusion constants alone.

Interaction Potentials

In general, since adsorbate motion explores the entire surface, HeSE data enables the complete shape of the potential energy surface for diffusion to be determined, not just the rate-limiting adiabatic barri-

ers. The Langevin molecular dynamics approach has thus been used to determine many experimental potentials [2.149–152, 154–160, 165]. Usually such a determination can be performed to a level of better than 10 meV, depending on the complexity of the system and the quantity of HeSE data available.

Figure 2.16a shows a typical experimental potential energy surface, in this case determined for CO molecules on Cu(111) [2.156]. The cross section in Fig. 2.16b shows the potential along the high-symmetry directions within the unit cell. Various features are clearly evident, including the adsorption minima (top site), the overall maximum (hollow site), as well as intermediate minima and maxima, the latter which forms the principal rate-limiting barrier for diffusion. In this case, as the coverage of CO is increased, CO interactions were not found to be described by pairwise interactions, but to result in *nonpairwise* changes in the form of the potential, as shown by the dashed brown line in the figure. Despite being clearly observed, at present, the theoretical origin of this effect is not well understood.

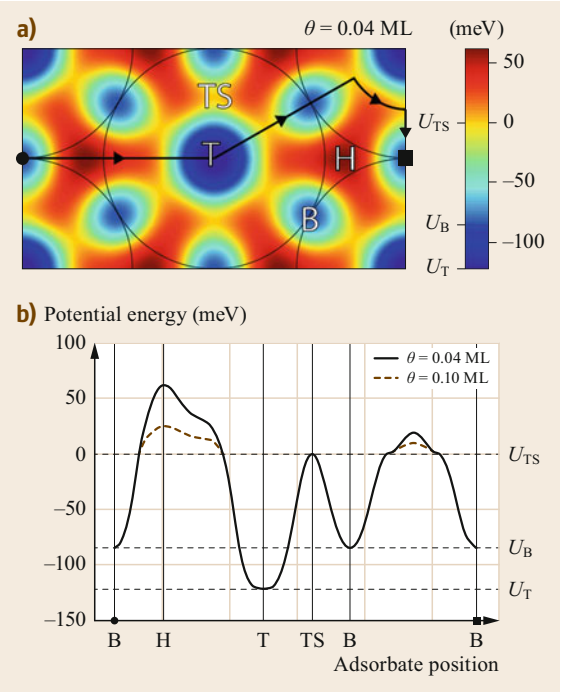

Fig. 2.16a,b Experimental adsorbate–substrate potential energy surface determined for the center of mass motion of CO molecules on a Cu(111) surface (adapted from [2.156]). T, H, B, and TS represent the top site (adsorption site), hollow site (potential maximum), bridge site (local minimum), and the transition state (rate limiting maximum), respectively. **(a)** shows the lateral variation, while **(b)** shows cross sections along the directions indicated in **(a)**. Increasing the CO coverage results in changes to the potential energy surface rather than localized interaction effects (adapted from [2.156], © IOP Publishing. Reproduced with permission. All rights reserved)

As well as providing a detailed fundamental description of the surface interaction, such interaction potentials have been used as a sensitive test of the validity of first-principles theory for predicting potentials—recent advances in dispersion-corrected density functional theory have been tested [2.160]. Similarly, as more complex molecular systems are beginning to be studied using HeSE, it is becoming possible to explore how higher degrees of freedom can be included in the potential. For example, the coupling between diffusion and molecular orientation has been examined for pentacene molecules [2.166].

Energy Transfer and Rate Theory

Transition state theory (TST) can be used to estimate transition rates across a barrier (i.e., hopping, in the present context), by using the energy barrier and partition functions in both the transition and well states [2.5]. More sophisticated rate theory models [2.167] also take account of the rate of energy exchange between the substrate and adsorbate, parameterized by the friction, η. Friction has a significant effect on both the mechanism and rate of diffusion. At a simple level, if the friction is weak, the rate of activation to jumping is low, as it takes a long time for fluctuations to provide sufficient energy to overcome the limiting barrier. However, once activated, it also takes a long time for motion to deactivate, so adsorbates subsequently take long jumps over the surface. Conversely, if the friction is very high, adsorbates are turned around before they actually cross the barrier, and so the rate of jumping is also low, but with well-defined single jumps. In the intermediate regime, the highest rates of transport are achieved.

Through these effects on adsorbate dynamics the different frictional regimes can be identified clearly in HeSE data—using the combined effect on the mechanism and the absolute rate of motion. In general, low-friction regimes can be identified by the presence of long jumps, evident through flattened sinusoidal $\alpha(\Delta \boldsymbol{K})$ curves containing many Fourier components (2.69), such as in the case of Cs/Cu(111) [2.150]. High-friction regimes result in single jumps on a corrugated surface, as is the case for H on Pt(111) [2.148], or Brownian motion on an uncorrugated surface, which is the situation seen for benzene on graphite [2.162]. Langevin molecular dynamics simulations are, again, used to obtain quantitative values of η, and, thus, most

systems where HeSE data has been analyzed in detail have provided precise values of the frictional energy exchange rate.

Adsorbate Interactions and Correlated Motion

Repulsive adsorbate interactions have been studied extensively using HeSE [2.149, 152, 154, 156]. In general, pairwise repulsion between adsorbates leads to the formation of a quasihexagonal overstructure to maximize their separation. These repulsive interactions are superimposed upon the usual adsorbate–substrate interaction potential and can at low coverages lead to a series of larger-scale structures forming. Thermal excitation still leads to motion, which is then determined by both the substrate potential and interactions between adsorbates. The effect on HeSE measurements is the introduction of a *peak and dip* structure superimposed on the $\alpha(\Delta \boldsymbol{K})$ curve. The peak corresponds to jumping within the preferred hexagonal structure, as in (2.69). The dip corresponds to the *preferred* length scale of greatest stability, i.e., at the momentum transfer of the diffraction ring associated with the quasihexagonal structure.

In general, the form of such interactions can be tested by adjusting the form of the pairwise interaction, $F(R)$ in (2.72), and comparing simulations with experiment as usual. For alkali metal atoms moving on transition metal substrates, good agreement has been found with a dipole–dipole repulsion model based on the Topping model for the coverage dependence of the dipole moment [2.149–152]. Conversely, in other systems, it has been possible to rule out the presence of pairwise forces altogether, such as in the case of CO on Pt(111) [2.154]. Here, the signatures for pairwise repulsion between adsorbates were found to be completely absent from the experimental HeSE data. In the existing literature, pairwise forces have been widely invoked to explain changes in the heat of adsorption. The HeSE dynamics data leads to the conclusion that changes in the CO dynamics must be due to more complex longer-scale mean-field changes in the CO/substrate interaction, which cannot be described in a pairwise manner. Such effects cannot be observed with simpler techniques and require direct observation of the dynamical correlations in order to be distinguished.

2.4 Perspectives—Towards Complex Surface Motion

The examples above have illustrated the rich variety of diffusion information that can be accessed experimentally, which motivate new theory. We can clearly see that real systems exhibit complex diffusive behavior, which is related to both the substrate and to the mobile species. Looking forwards, we can highlight a few representative examples of areas where HeSE methods are just beginning to be applied and where further new and interesting phenomena can be expected.

One of the most obvious issues is the fact that real surfaces are much more complex than the flat surfaces generally studied so far. Complex surface structure can modulate and confine diffusion, fundamentally altering the nature of transport at the atomic scale. Signatures of confined diffusion in HeSE measurements have been established [2.130] and essentially involve $I(\Delta \boldsymbol{K}, t_{\mathrm{SE}})$ decaying to a finite level at large t_{SE}—since confinement means the adsorbate always retains some correlation in its position. However, to date, there have been few studies of any form of confined diffusion. Existing work either relates to motion perpendicular to the surface during lateral diffusion [2.149] or diffusion that is confined to narrow stepped terraces of atoms [2.152], where highly anisotropic motion has been observed. In the latter case, anisotropy in the correlations between atoms has also been seen, indicating effective screening of interactions between adsorbates on different terraces.

As molecules become more structurally complex, it becomes crucial to distinguish between many possible dynamical processes. These could include, for example, changes in conformation or motion of a side chain, as well as center of mass motion. To date, HeSE has generally been applied to point particles or rigid molecules with rotation. Specifically, analytic forms of the HeSE signatures for rotational motion have been identified [2.168] and used to distinguish ongoing rotational motion of adsorbed thiols from the onset of translational motion [2.163]. Similarly, jumping, rotating, and flapping motion has been distinguished for thiophene on Cu(111) [2.158], and the contribution of rotational modes in boosting the overall rate of diffusion has been established [2.159]. The next steps are likely to involve decoupling and, thus, an understanding of nonrigid species.

So far, we have only discussed classical mechanisms of diffusion. However, for sufficiently small species and low temperatures, quantum processes can be dominant. The transition towards a quantum diffusion-dominated regime has been observed for H and D atoms on Pt(111) [2.148] and more extensively on Ru(0001) [2.169]. As well as the direct technological relevance of such results to the *hydrogen economy*, HeSE also provides an ideal opportunity for fundamental testing of quantum-rate theory models, and in

particular models for the transition between coherent and incoherent modes of propagation.

All of these areas suggest that a much greater wealth of fundamental information on diffusion is available, which can be accessed experimentally through HeSE, given the method's unique sensitivity to dynamics on the combination of picosecond time and nanometer length scales. Further development of HeSE instrumentation will be important in measuring these increasingly complex forms of motion—for example, to enable better separation of processes by timescales. Fortunately, further increases in resolution and signal level are both realistic prospects [2.170]. We look forward to a next generation of spin-echo measurement facility, and subsequent uptake by the user community, to take forward our scientific understanding in this exciting and unique regime.

ferrando@fisica.unige.it

Riccardo Ferrando is currently Professor of Theoretical Condensed Matter Physics at the University of Genoa, Italy. He is the author of about 230 articles in peer-reviewed international journals. His research activity lies in the field of computational modeling of nanosystems, interfaces, and colloids.

Andrew Jardine

Cavendish Laboratory
University of Cambridge
Cambridge, UK
apj24@cam.ac.uk

Dr Andrew Jardine is University Lecturer in Physics at the Cavendish Laboratory, University of Cambridge, and a Fellow and Director of Studies at Fitzwilliam College within the University. He received his PhD from the University of Cambridge (2002). His research interests include developing new experimental techniques and instrumentation for condensed matter research, studying picosecond dynamics of atoms and molecules on surfaces, and understanding the mechanical and constitutive properties of materials.

3. Surface Thermodynamics and Vibrational Entropy

Talat S. Rahman

As with bulk material, a few thermodynamic variables determine the stability and equilibrium properties of solid surfaces. Since the environment at the surface is typically very different from that in the bulk, as a result of the lack of symmetry created by the presence of the surface, thermodynamics plays an important role in determining surface structure and dynamics. The quantity of interest here is the surface free energy, which inherently includes the contribution of vibrational (and configurational) entropy. Given the existence of surfaces vibrational modes whose features are distinct from those in the bulk, and dependent on local surface geometry and electronic structure, the emphasis in this chapter is on the characteristics of vibrational entropy, which, in turn, affect surface thermodynamical quantities that are in excess of values in the bulk. Special attention is paid to characteristics of vibrational density of states of low and high Miller index surfaces and their contribution to vibrational entropy, and, hence, to thermodynamical functions. In fact, it is argued that the distinguishing features in the vibrational density of states, namely enhancement of the number of modes at low frequencies and appearance of modes above the bulk band, highlight the impact of the undercoordinated atoms at surfaces, steps, and kink sites and lead to variations in the local surface electronic structure. The characteristics found on high Miller index surfaces in particular pave the way for understanding vibrational dynamics of nanoparticles. Contact is made with experimental data where available.

In this chapter, after presenting a summary of bulk thermodynamics in Sect. 3.1, the stage is set for summarizing the essentials of surface thermodynamical functions in Sect. 3.2. Surface nomenclature is discussed in Sect. 3.3 and details of theoretical techniques are presented in Sect. 3.4. A sampling of results obtained on a few surfaces is provided in Sect. 3.5 and a summary is presented in Sect. 3.6.

Over four decades of experimental and theoretical research in surface science has brought us to the point where we can probe the subtle role played by thermodynamics in determining unique features of solid surfaces and nanostructures. The lack of symmetry created by removal of the top half-atoms to create a surface inherently leads to a heterogeneous environment with nonuniform local geometric and modified electronic structure that can promote a plethora of surface phenomena, which continue to be revealed at length scales ranging from the microscopic (localized surface states and vibrational modes), to the macroscopic (surface tension, surface acoustic wave) and at time scales going down to femtoseconds. In this Handbook, a number of chapters address the experimental and theoretical findings of a multitude of surface phenomena, allowing this chapter to concentrate only on the peculiarities of surface thermodynamics that make the surface an interesting playground for realization of physical and chemical properties than that in the bulk.

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-46906-1_3

In considerations of relative stability of surfaces, nanostructures, as well as bulk phases of different crystallographic orientations, the quantity of interest is the free energy, which includes contributions from the structural potential energy and the system's vibrational and configurational entropy. Assuming the structural potential energy to be insensitive to temperature variations, it is the entropic contributions that control the surface phase diagram and structural stability. In this regard, configurational entropy is an important constituent for any system containing more than one type of element (for example, alloys), but for surfaces and nanostructures of single elements, it is vibrational entropy that accounts for the temperature dependencies of surface free energy, mean-square vibrational amplitudes of surface atoms, the surface Debye temperature, and the surface heat capacity, albeit within the harmonic and quasiharmonic approximation of lattice dynamics. It is also the quantity that may determine the equilibrium shape of crystal surfaces and its possible structural phase transitions and surface reconstructions. These comments are not to disregard the role of configurational entropy for single-element surfaces at temperatures that accompany structural disorder. Such considerations are beyond the scope of this chapter. Knowledge of surface free energy, together with that of the step and kink free energy, is also essential for considerations of surface faceting, bunching, and roughening. The extraction of free energy from experimental data is, however, nontrivial [3.1]. The lattice contribution, which can be critical for determining structural transitions, is nonzero, albeit a small fraction of the structural energy. It is, thus, encouraging to see the flurry of activity in analyzing the contribution of vibrational entropy [3.2] to the thermodynamic functions for several surface systems [3.3–5]. These calculations have already provided a qualitative measure of the effect of vibrational entropy on surface stability and structure and have set the stage for a systematic evaluation of the local vibrational contribution to the free energy. Since these calculations were based on the usage of many-body interaction potentials [3.6], questions have been asked about their accuracy, particularly for 5d metals Pt, Ir, and Au, for which these potentials are not expected to work as well as they do for Ag, Cu, and Ni. With the availability of ab-initio electronic structure methods based on the density functional perturbation theory [3.7, 8], surface phonon dispersion curves can be calculated with remarkable accuracy [3.9]. These dispersion curves further lend themselves to the extraction of vibrational density of states and, thus, of the vibrational contribution to surface free energy and entropy. Efforts have thus been made to analyze surface thermodynamic properties of the several metals using ab-initio methods and to compare the findings with those obtained using semiempirical approaches [3.10].

3.1 Some Essentials of Bulk Thermodynamics

In this section, some background information is provided on thermodynamic functions to provide context and facilitate discussion, greater details of which can be found in textbooks [3.11, 12]. With the entropy already mentioned above, two extensive thermodynamic variables need to be introduced: the Helmholtz free energy F equivalent to the maximum amount of work a system can do at constant volume and temperature and the Gibbs free energy G, which is the maximum amount of work a system can do at constant pressure and temperature; G is a minimum for closed systems at equilibrium with a well-defined temperature and pressure. Both Helmholtz and Gibbs free energies are known as thermodynamic potential. Furthermore, the first law of thermodynamics states that the increase in energy $\mathrm{d}U$ of a system is equal to the difference of the heat absorbed by the system δQ and the amount of work done by the system δW as quantified by

$$\mathrm{d}U = \delta Q - \delta W \,. \tag{3.1}$$

Equation (3.1) implies that there is a quantity U called the internal energy which is a function of the state of the system (temperature and pressure) and that the difference between two values of U is independent of the path of getting from one state to the other. In other words, U is the integral of an exact differential $\mathrm{d}U$. If the energy of the system can be described by the thermodynamic variables' pressure, temperature, and volume, then for an infinitesimal quasistatic reversible process, the work done by the system is $P\mathrm{d}V$, and the heat absorbed is $T\mathrm{d}S$. Thus,

$$\mathrm{d}U = T\mathrm{d}S - P\mathrm{d}V \,, \tag{3.2}$$

from which temperature and pressure follow as respective derivatives of the internal energy U. Since S and V are often inconvenient independent variables [3.13], it is more usual to work with T and P. The thermodynamic potentials, F and G introduced before and the enthalpy H are then defined by

$$F = U - TS = U - S\left(\frac{\delta U}{\delta S}\right)_v \,, \tag{3.3}$$

$$H = U + PV \,, \tag{3.4}$$

$$G = U - TS + PV = H - TS \,. \tag{3.5}$$

While the quantities form the basis of thermodynamical description of bulk material with an infinite sea of particles, Gibbs' introduction [3.14] of the explicit dependence of U on the number of particles N and their related chemical potential μ allows us to extend these thermodynamic concepts to solid surfaces. There is, thus, a consensus that in equilibrium, a one-component system can be fully defined by its internal energy (U), which is a unique function of the entropy (S), volume (V), and number of particles (N), such that

$$U = U(S, V, N) \,, \tag{3.6}$$

$$\mathrm{d}U = T\mathrm{d}S - P\mathrm{d}V + \mu\mathrm{d}N \,. \tag{3.7}$$

The reader is referred to more detailed analysis in *Zangwill* [3.11] from where some of the description has been extracted.

3.2 Surface Thermodynamic Functions

When it comes to surfaces, in addition to volume V, area (A) should also play a role, since we need energy to create a surface with a particular *surface energy*. The creation of a surface should inherently involve an increase in the total internal energy proportional to the area. Thus, the internal energy equation should include an additional term

$$U = TS - PV + \mu N + \gamma A \,, \tag{3.8}$$

where γ is the surface tension. Of course, the introduction of the surface brings in an ambiguity, as the boundary of the surface is not well defined. For example, the density of the electrons in a one-component system will not fall off sharply at the surface. Rather, it would tail off as one moves away from the surface, in a manner characteristic of the material. Additionally, surface thermodynamical quantities would follow from those calculated for the bulk with the inclusion of one term that accounts for excesses from the bulk value needed to create the surface. Equation (3.8) has also introduced another observable, surface tension, which is a macroscopic property of a material.

Surface internal energy may, thus, be defined as an excess over the bulk value in the manner described very nicely by *Somorjai* and *Li* [3.12], assuming that a crystalline solid is bound by two surfaces and denoting the energy and entropy of each bulk atom by U^{b} and S^{b}, respectively, and the surface energy per unit area as U^{s}. The total internal energy of the solid is then

$$U = NU^{\mathrm{b}} + AU^{\mathrm{s}} \,. \tag{3.9}$$

Here, AU^{s} is the excess from the bulk. In the same way, the total entropy of the system can be written as

$$S = NS^{\mathrm{b}} + AS^{\mathrm{s}} \,. \tag{3.10}$$

Note that the surface term (with the suffix s) is with respect to per unit surface area. Bearing in mind that the surface terms are excess over the bulk value in the manner described above, we can write the expressions for the surface Helmholtz and Gibbs free energies (per unit area) and the enthalpy (per unit area) in terms of the corresponding expressions for the bulk

$$F^{\mathrm{s}} = U^{\mathrm{s}} - TS^{\mathrm{s}} \,, \tag{3.11}$$

$$G^{\mathrm{s}} = H^{\mathrm{s}} - TS^{\mathrm{s}} \,. \tag{3.12}$$

Here, H^{s} is the specific surface enthalpy, which is the excess heat absorbed by the system per unit surface area created under constant external force, i.e., pressure. By the same token, the total Gibbs free energy of the system can be written in terms of G^{b}, the Gibbs free energy per bulk atom and G^{s}, and the Gibbs free energy per unit surface area

$$G = NG^{\mathrm{b}} + AG^{\mathrm{s}} \,. \tag{3.13}$$

We next move on to considerations of some of the thermodynamic functions for surfaces and other reduced dimensional materials. However, before we do so we need to establish the nomenclature, the calculation methodology, and provide some background information.

3.3 Surface Nomenclature and Geometry

Bulk solids exist in a number of crystallographic structures, details of which can be found in standard textbooks [3.15]. The fundamental property of a solid is its inherent periodic structure, which is defined by a lattice containing an infinite array of points generated by a primitive lattice translation vector

$$\boldsymbol{T}_m = m_1\boldsymbol{a} + m_2\boldsymbol{b} + m_3\boldsymbol{c} \,, \tag{3.14}$$

where m_i is an integer (positive, negative, or zero) and $\boldsymbol{a}$, $\boldsymbol{b}$, and $\boldsymbol{c}$ are three mutually perpendicular vectors,

generally taken to be along the Cartesian x, y, and z coordinates. A lattice point $m_1\boldsymbol{a} + m_2\boldsymbol{b} + m_3\boldsymbol{c}$ lies in the direction $[m_1, m_2, m_3]$. Generally, the values of m_i are divided by their greatest common divisor, so as to have the smallest integer set. For example, the body diagonal of a unit cell is denoted by the direction [111] (rather than [333], etc.). Furthermore, a set of directions, such as [100], [010], [001], $[\bar{1}00]$, $[0\bar{1}0]$, $[00\bar{1}]$, which may be related by symmetry, are denoted by the bracket $\langle 100\rangle$.

The planes containing the lattice point define the crystal structure and the ensuing symmetry and other geometrical characteristics of the surface. These planes are usually defined in terms of Miller indices (hkl), where the values of h, k, and l follow from the following. If a plane intersects the axes ($m_1\boldsymbol{a}$, $m_2\boldsymbol{b}$, and $m_3\boldsymbol{c}$), the Miller indices of the plane are the set of integers, without a common multiple, that are inversely proportional to the intercept of the axes with the plane. That is, $h : k : l = 1/m_1 : 1/m_2 : 1/m_3$. Thus, in a cubic lattice, the direction $\langle hkl\rangle$ is perpendicular to the plane (hkl). Here, too, a family of planes that are equivalent by symmetry are denoted by curly brackets { }. These Miller indices provide a convenient way to classify surfaces with respect to the extent of their terraces and regularly present steps and kinks. As will be seen below and was already presented in [3.5], the low and high Miller index surfaces provide two sets of surfaces with distinct crystallography.

3.3.1 Low Miller Index Surfaces

The low Miller index surfaces are those for which h, k, and l have the values 0 or 1. These are extended surfaces without any step or kink [3.16]. A simple example is that of a cube with its six faces $\langle 100\rangle$, $\langle 010\rangle$, etc., represented collectively by {100}. The low Miller index surfaces (100), (110), and (111) of both fcc and bcc cubic crystals are shown in Fig. 3.1. Note that the (111) surface is the most close-packed, while the least so is the (110) surface. In the early days of surface science, the majority of investigations were carried out on the three low Miller index surfaces for obvious reasons. They were relatively easy to characterize experimentally with techniques such as low-energy electron diffraction (LEED) and were amenable to theoretical calculations, both analytical and numerical with the then available computational power. However, the larger number of low-coordinated sites offered by surfaces containing steps and kinks compared to those without them, led both experimentalists and theorists to venture into the more complex, and intriguing, local environment offered by the high-Miller index surfaces, also called vicinal surfaces. These surfaces can now be created and characterized with a variety of techniques, as summarized in several other chapters in this Springer Handbook. Their well-defined periodic arrangement of steps and kinks provides regions of low coordination with interesting implications for their physics and chemistry, as we shall see in this book. They also serve as benchmarks for understanding properties of nanoparticles while offering sites with a range of low coordination that lack the periodicity of vicinal surfaces.

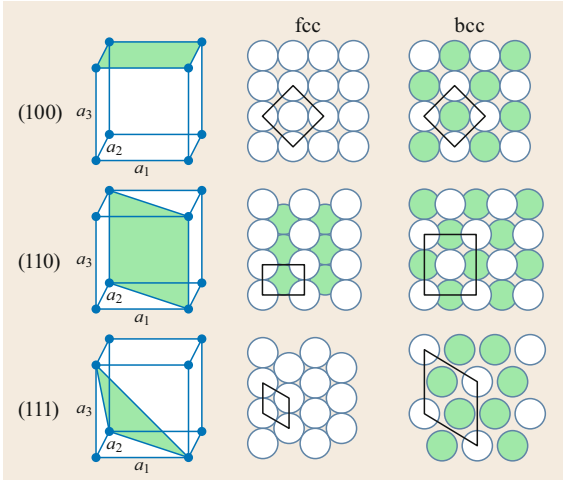

Fig. 3.1 Low Miller index surfaces

3.3.2 High Miller Index Surfaces

The simplest vicinal surfaces consist of regularly-spaced low Miller index terraces separated by monatomic steps. A slight miscut of the crystal at an angle slightly off the low Miller index ((100), (111), and (110)) planes will give rise to a vicinal surface. In Fig. 3.2, we depict a hard sphere diagram of an fcc(977) surface showing the geometry of the terrace and the step face. On this surface, the terrace has fcc(111) orientation and is eight-atom wide, while the step face has a (100) microfacet. This vicinal is created by cutting the crystal at 7° away from the (111) plane towards the $[2\bar{1}\bar{1}]$ direction, which results in monatomic steps along the $[0\bar{1}1]$ direction. Note that on the fcc(111) surface, the $\langle 110\rangle$ direction is not parallel to any plane of symmetry, and there exist two different ways of generating monatomic stepped surfaces: by directing the miscut angle towards either the $[2\bar{1}\bar{1}]$ or the $[\bar{2}11]$ direction. In the case of the former, as we can see in Fig. 3.1, the step face has a (100) microfacet (the so-called A type), while in the case of the latter, it would yield a (111) microfacet (the so-called B type). Such a surface with an eight-atom wide fcc(111) terrace and a (111) microfacet is the fcc(997) surface for which

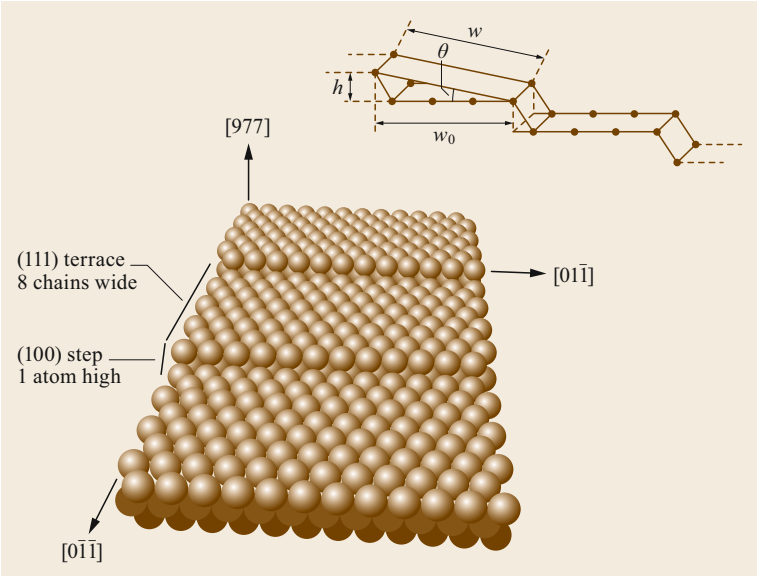

Fig. 3.2 Hard sphere model of the fcc(977) surface that is a vicinal of fcc(111) with an eight-atom wide terrace and a monatomic (100) microfaceted step face. The miscut angle θ and the terrace width w are shown in the *inset*. (Adapted from [3.17], © IOP Publishing. Reproduced with permission. All rights reserved)

the miscut angle is 6.5°. It is complementary to the fcc(977) surface shown in Fig. 3.2. Since a monoatomic stepped surface may have a (100) or (111) microfacet, a more self-contained notation for the surface structure was introduced by *Lang* et al. [3.18] in the general form $S(h_t k_t l_t) \times (n_s k_s l_s)$, where $(h_t k_t l_t)$ represents the Miller indices of the terrace plane and $(n_s k_s l_s)$ that of the step face, and S is the atomic width of the terrace. In Table 3.1, we summarize the notation for the various vicinal surfaces that are discussed in this chapter, together with their miscut angles θ and the interatomic separations for ideal (bulk terminated) geometry. Here, w is the width of the terrace (Fig. 3.2) and $f..r$ is the registry (Fig. 3.5).

This relationship of the vicinal surface to the low Miller index mother surface is also nicely captured in Fig. 3.3, which presents a stereographic view of stepped surfaces of varying terrace widths and geometries, drawn around the pole at fcc(100) and converging on the other two low Miller index surfaces (111) and (100). As already mentioned, the two equal terrace-width vicinals of fcc(111), fcc(997), and fcc(977) fall on the two sides of the graph around (111) separated by 60°. Similar to the (997) surface, the (331) and (551) surfaces have a B-type step face but only three-atom wide terraces.

For fcc(100) surfaces, the stereograph map neatly separates the two types of step face of its vicinals: those with a close-packed (111) microfacet lie along the line joining the (100) pole to (111) and those with the (110) microfacet along the other line. An angle of 45° separates the in-plane orientation of these steps. Similarly, the set of loosely and close-packed step faces of vicinals of fcc(110) flank the location of (110) on the stere-

Table 3.1 Structural notation and geometric features for several fcc vicinals. Here, d_b is the bulk interlayer separation, Δr is the surface registry and w is the terrace width (all in units of a, the lattice constant). (Adapted from [3.17], © 2003 IOP Publishing)

Miller index *hkl*	Compact step notation $S(h_t k_t l_t) \times (n_s k_s l_s)$	Miscut angle (deg)	d_b (a)	Δr (a)	w (a)

ograph with a separation of 90° between them. Thus, along each side of the stereograph the terrace geometry and width change logically while maintaining the same geometry for the step face. In the Miller index notation, vicinals lying along the (100)–(110) side of the stereograph have indices ($hk0$), while those along (110)–(111) have (hhk) and those along (111)–(100) are denoted by (hkk).

To examine the finer details of the local atomic environment, we take the example of a set of vicinal surfaces whose terraces are approximately three-atom wide with either (100), (111), or (110) crystallographic orientation and two types of step microfacets. These six surfaces are shown in Fig. 3.4.

Here, (511) and (310) are vicinals of fcc(100), with (111) and (100) microfaceted step faces, respectively. As is noticeable in Fig. 3.4, the (310) surface has an open-step arrangement, akin to a regularly kinked step edge. The coordination of the step atoms on the fcc(310) is also 6, which is typical of atoms at a kink site. Similarly, the (211) and (331) surfaces in Fig. 3.4 are corresponding vicinals of the fcc(111) surfaces with the A and B types of step microfacet, respectively. Finally, the corresponding vicinals of the fcc(110) surface are the (551) and (320) surfaces, the former with a close-packed (111) step face and the latter with a kinked (100) microfacet. The structural parameters of the above six surfaces, given in terms of the lattice

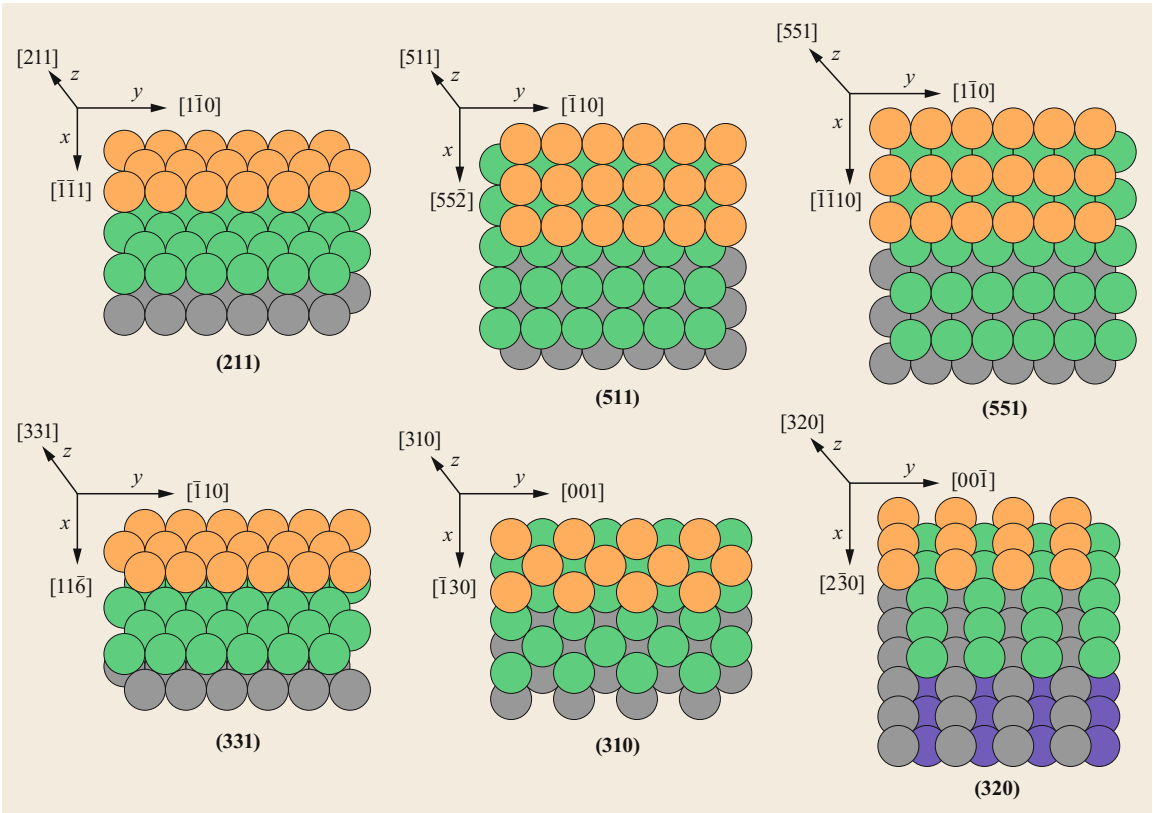

Fig. 3.4 A top view of six vicinals of three-atom wide terraces. (Adapted from [3.17], © IOP Publishing. Reproduced with permission. All rights reserved)

constant, in Table 3.1, together with those of few other related vicinal surfaces, show that the fcc(977) surface is just a broader terrace version of the fcc(211) surface, while the fcc(410) surface is related to the fcc(310) surface, except for the difference in terrace width.

As in several previous studies [3.4, 11, 12, 14] we will use the following notation for the surface atoms, as illustrated in Fig. 3.5: SC for atoms in the step chain; TC for atoms in the terrace chain (if there are more than one, we label them as TC1, TC2, etc.), and CC for atoms in the corner chain. For the three surfaces (310), (320), and (551), there are actually five undercoordinated sites—three in the top terrace and two underneath. On the other hand, on the (511), (211), and (331) surfaces, there are only three undercoordinated sites. Together, these six surfaces provide atoms with the range of coordination extending from 6 to 11. As we shall see the atom labeled BNN in Fig. 3.5, a bulk nearest neighbor of the corner atom contributes interestingly to the vibrational density of states of these surfaces. Note that in the calculations, the x and y-axes are taken to lie in the surface plane, the x-axis being perpendicular to the step and the y-axis along the step. The z-axis is along the normal to the surface.

3.4 Theoretical Techniques

The goal in this section is to provide the reader with some details of theoretical techniques that have been used to calculate the ingredients mentioned above that are needed to determine surface thermodynamical functions such as vibrational entropy, heat capacity, mean-square vibrational amplitudes, and, subsequently, the *Debye* temperature for the surface in question. We put Debye in italics here as the concept of Debye temperature, which is based on the Debye model for the vibrational density of states, is not valid for surfaces and nanostructures for which, as we shall see, the vibrational density of states does not follow the same dependence on energy as the atoms in the bulk [3.19]. Of course, the quantity of prime importance is the vibrational density of states to calculate which one needs to first evaluate the system minimum energy configuration, followed by a calculation of the system vibrational dynamics and, thence, that of the thermodynamical functions. Calculations for details of the electronic structure, charge redistributions, and local electronic densities of states are also of interest, but as they are included in other chapters in this book, they will not be discussed here in any detail. In this section, we provide some of the essentials for the calculations of:

a) Geometrical structure
b) Vibrational dynamics
c) Vibrational free energy.

3.4.1 Determination of Surface Structure and Energetics

Once the coordinates of atoms for the system with the surface geometry discussed in Table 3.1 are generated, it is necessary to allow the system to relax so that atoms find their equilibrium positions in their undercoordinated sites. As is well known, atoms in the surface layers of a solid relax away from their bulk terminated positions, as a result of the bonds that were severed in the creation of the surface. These relaxations can be inwards or outwards with respect to the surface plane. To obtain the relaxed position standard algorithms, such as simulated annealing, steepest descent, and conjugate gradient methods, are used for minimizing the total energy of the system [3.20]. A critical input for all such calculations is the form of the interaction between the atoms/ion cores/electrons, which, not surprisingly, has been the subject of decades of research.

A simple way to proceed is to assume an analytical form of the interaction, such as a Lennard-Jones or Morse potential. However, extensive studies have shown that pair potentials fail to capture some of the main features of solids and their surfaces. A very practical alternative was introduced some years ago in the form of semiempirical many-body potentials, such as those from the embedded atom method (EAM) [3.6, 21] and effective medium theory (EMT) [3.22], which

continue to be widely applied. Although based on fitting of parameters from experiments (and sometimes from more sophisticated theoretical methods) these interaction potentials have had tremendous success in predicting/explaining the characteristics of surfaces and nanostructures of six transition metals (Ni, Cu, Ag, Pd, Pt, Au). Of course, their reliability needs to be checked by comparison with more accurate methods, such as those based on ab-initio density functional theory. Below, we give some general details of ab-initio electronic structure calculations that we and others have used. We follow this up with a short description of the EAM potentials that have been used to calculate structural properties of vicinal surfaces.

Ab-initio Electronic Structure Calculations

Since this topic is covered in detail in several other chapters, only a summary of calculational details is provided here. Ab-initio electronic structure calculations based on density functional theory (DFT) are performed either within a pseudopotential or an all-electron approach using either the local-density approximation (LDA) [3.23] or the generalized gradient approximation (GGA) [3.24]. Of the variety of DFT based codes that are available, two that are frequently used here are the Vienna ab-initio simulation package (VASP) [3.25] and the Quantum ESPRESSO [3.26]. For example, to model the charge density distribution and structural relaxation of nanoparticles, *Shafai* et al. [3.27] adopted the pseudopotential approach [3.25] to describe the interaction of the electrons and the nucleus employing projector-augmented wave (PAW) [3.28, 29] pseudopotentials. For systems in which relativistic effects are significant, as in gold, scalar relativistic pseudopotentials are used [3.30–33]. The Kohn–Sham orbitals are expanded as plane waves with a reasonable kinetic energy cutoff (for example, 720 eV for Au). The exchange-correlation functional proposed by *Perdew*, *Burke*, and *Ernzerhof* (PBE) [3.34] was used. The ion cores in the system are allowed to relax using a conjugate gradient algorithm until the Hellman–Feynman forces acting on each atom are less than 1×10^{-3} eV/Å. Similarly, the total energy is taken to be converged if the changes in the energy in the self-consistent loop are below 10^{-6} eV. Since we use periodic boundary conditions, the supercell for the system of interest is taken to be large enough such that the interactions between the model system and its periodic images are negligible. That is in addition to a specific number of layers of atoms, the model system contains about 12−15 Å of vacuum. The resulting supercells, thus, have dimensions that depend on the size/shape of the system under study. Further details of these calculations may be found elsewhere [3.10].

Many-Body Interaction Potentials

To describe the interactions between the atoms in model systems, several types of many-body, semiempirical potentials [3.6, 21, 22, 35, 36] have been proposed. Without doing justice to others, some details of the semiempirical, many-body potential, EAM, developed by *Foiles*, *Baskes*, and *Daw* [3.6, 21] are presented. Although the EAM potentials neglect the large gradient in the charge density near the surface and use atomic (elemental) charge densities to describe those for the corresponding solid, for the six fcc metals Ag, Au, Cu, Ni, Pd, and Pt, and their alloys, these interatomic potentials have done a good job of reproducing many of the characteristics of bulk and surface systems [3.6, 21]. We have also found EAM potentials to be reliable for examining the temperature-dependent structure and dynamics of the low Miller index surfaces of Ag and Cu [3.37–41] and also for describing the energetics of vicinal surfaces of Cu and self-diffusion processes on the (100) surfaces of Ag, Cu, and Ni [3.42]. This method exploits the findings that the ground state of an interacting electron gas is a unique functional of the total electron charge density [3.23]. It further assumes that the energy of an impurity in a host is a functional of the electron density of the unperturbed host electron density [3.43].

The many-body term in the total energy has the form $E = F_{Z,R}(\rho_{\mathrm{h}}(r))$, where $\rho_{\mathrm{h}}(r)$ is the electron density of the host without impurity at R, the position at which the impurity is to be replaced, and Z is the type of impurity. Each atom in a solid is, thus, viewed as an impurity embedded in a host consisting of all other atoms, and its energy is given by

$$E_{\mathrm{tot}} = \sum_i F_{i,j}(\rho_{\mathrm{h},i}) + \frac{1}{2}\sum_{\substack{i,j \\ (i\neq j)}} \varnothing_{i,j}(R_{i,j}) \,, \tag{3.15}$$

where $\varnothing_{i,j}$ is the short-range pair potential ($\varnothing_{i,j} = Z_i(r)Z_j(r)/r$) and $R_{i,j}$ is the distance between atoms i and j. Further simplification is introduced by assuming that the host density ($\rho_{\mathrm{h},i}$) is a sum of the atomic densities (ρ_j^{a}) and given by

$$\rho_{\mathrm{h},i} = \sum_{j(\neq i)} \rho_j^{\mathrm{a}}(R_{ij}) \,, \tag{3.16}$$

where ρ_j^{a} is the contribution to the electron density from atom j. Connection to the atomic densities makes the total energy to be a function of the atomic positions in electron density ρ_i, and $\varnothing$ is a short-range electrostatic pair potential between atoms i and j.

It is further assumed that the electron density ρ_i is given by a linear superposition of the electron densities of the constituent atoms, which is taken to be spherically symmetric. The EAM functions for the six fcc metals, Ag, Au, Cu, Ni, Pd, and Pt, and their alloys were developed by numerically fitting the functions to the bulk lattice constants, cohesive energy, elastic constants, vacancy formation energy, and alloy heats of mixing. Using these interactions for a model system constructed in its bulk terminated positions, the conjugate gradient method is used to relax the system to 0 K equilibrium configuration. The dynamical matrix needed to calculate the vibrational (or phonon) density of states for a system of interest is then obtained from analytical expressions for the partial second derivatives of the EAM potentials [3.6, 21].

3.4.2 Determination of the Vibrational Density of States

There are several theoretical techniques for calculations for surface and bulk phonons in crystals, ranging from those based on DFT to those that rely on some form of interatomic potentials. Ab-initio methods based on density functional perturbation theory and their applications are covered elsewhere in this Handbook and, hence, will not be covered here. Instead, we will focus here on methods that typically employ semiempirical interaction potentials. In these cases, the most commonly used is the slab method in which one needs to diagonalize the dynamical matrix portraying the interactions between the particles in N layers of the slab [3.44]. In the case of high Miller index surfaces, in particular those with large terraces, representative of large surface periodicities, slab calculations are hampered by the need for model systems with an extraordinarily large number of layers to describe the inhomogeneities of the surface structure. Furthermore, our interest is in calculating the phonon density of states, rather than phonon dispersion curves, of systems that lack long-range order, because of the presence of steps, kinks, etc. For such purposes, the continued fraction method [3.45] using a real space Green's function developed by *Wu* and coworkers [3.46] is especially suitable, since it determines the local densities of states (LDOS) directly. In fact, the total phonon density of states is calculated as a sum of the contributions from the individual regions of interest. For example, the regions of interest could be the surface layer, the second layer, and so on. Or it could be the kink sites, the steps, the terraces, and so forth. The approach is based on constructing the resolvent matrix of an infinite block-tridiagonal matrix [3.45]. Green's function is defined as the matrix representation of the resolvent operator that yields the LDOS via its matrix elements. Such a matrix must be constructed in a block-tridiagonal form, and the range of the interactions must be finite, which is fortunately the case for the transition metals named above. The system Hamiltonian is then written in a block-tridiagonal matrix as

$$\mathbf{H} = \begin{pmatrix} \ddots & & & \\ \boldsymbol{v}_{i,i-1} & \mathbf{h}_i & \boldsymbol{v}_{i,i+1} & \\ & \boldsymbol{v}_{i+1,i} & \mathbf{h}_{i+1} & \boldsymbol{v}_{i+1,i+2} \\ & & & \ddots \end{pmatrix} , \quad (3.17)$$

where $\mathbf{h}_i$ submatrices along the diagonal are $3n_i \times 3n_{i+1}$ square matrices, $\boldsymbol{v}_{i,i+1}$ matrices along the off-diagonals have dimension $3n_i \times 3n_{i+1}$, and n_i is the number of particles in the chosen locality. Figure 3.6 shows such a system divided into three regions (localities labeled L_1 to L_3). For each locality, there is a submatrix ($\mathbf{h}_1$, $\mathbf{h}_2$ and $\mathbf{h}_3$) describing the interactions within the associated locality. The submatrices ($\boldsymbol{v}_{12}$ and $\boldsymbol{v}_{23}$) describe the interactions between localities. The interactions beyond these localities are assumed to be bulk-like.

Note that in our calculations, the system Hamiltonian is described by the force constant matrix, which is obtained from the second derivative of the interaction potential. The eigenvalue can be derived by means of the Green's function that is associated with the matrix $\mathbf{H}$ and is given by

$$\mathbf{G}(z) = (z\mathbf{I} - \mathbf{H})^{-1} , \quad (3.18)$$

where $z = \omega^2 + \mathrm{i}\varepsilon$, ε is the width of the Lorentzian representing the delta function at ω^2, and $\mathbf{I}$ is a unit matrix

of the same dimension as that of **H**. The diagonal element of the Green's function matrix corresponding to a chosen locality is expressed as

$$\mathbf{G}_{ii} = [(z\mathbf{I} - \mathbf{h}_i) - \boldsymbol{v}_{i,i+1}\Delta_{i+1}^{+}\boldsymbol{v}_{i+1,i} - \boldsymbol{v}_{i,i-1}\Delta_{i-1}^{-}\boldsymbol{v}_{i-1,i}]^{-1} . \quad (3.19)$$

Δ_i^+ and Δ_i^- are defined as forward and backward partial Green's functions and described by

$$\Delta_i^{+} = (z\mathbf{I} - \mathbf{h}_i - \boldsymbol{v}_{i,i+1}\Delta_{i+1}^{+}\boldsymbol{v}_{i+1,i})^{-1} , \quad (3.20)$$

$$\Delta_i^{-} = (z\mathbf{I} - \mathbf{h}_i - \boldsymbol{v}_{i,i-1}\Delta_{i-1}^{-}\boldsymbol{v}_{i-1,i})^{-1} . \quad (3.21)$$

The relation between the successive diagonal elements of the Green's function matrix **G** is obtained by

$$\mathbf{G}_{ii} = \Delta_i^{\pm} + \Delta_i^{\pm}\boldsymbol{v}_{i,i\pm1}\mathbf{G}_{i\pm1,i\pm1}\boldsymbol{v}_{i\pm1,i}\Delta_i^{\pm} . \quad (3.22)$$

As can be seen the calculation of Green's function mainly depends on the forward and backward Green's functions ($\Delta_i^{\pm}$), which are the inverses of matrices with the dimensions same as that of $\mathbf{h}_i$. The convergence procedure for the calculation of $\Delta_i^{\pm}$ for an infinite system starts with the condition as

$$\Delta_1^{+(1)} = \lim_{\substack{m\to\infty,\\ \varepsilon\to 0}} \Delta_1^{+(m)}(z) , \quad (3.23)$$

where

$$\Delta_1^{+(m)} = \{(zI_1 - h_1) - v_{12}[(zI_2 - h_2) - \ldots[v_{m-1,m} \times (zI_m - h_m)^{-1}v_{m,m-1}]^{-1}\ldots]^{-1}v_{21}\}^{-1} . \quad (3.24)$$

From this equation, one can define the forward Green's function for any chosen regime as

$$\Delta_1^{+(1)} = (zI_1 - h_1)^{-1} , \quad (3.25)$$

$$\Delta_1^{+(2)} = [(zI_1 - h_1) - v_{12}(zI_2 - h_2)^{-1}v_{21}]^{-1} , \quad (3.26)$$

$$\Delta_1^{+(3)} = \{zI_1 - h_1 - v_{12}[(zI_2 - h_2) - v_{23}(zI_3 - h_3)^{-1}v_{32}]^{-1}v_{21}\}^{-1} , \quad (3.27)$$

$$\vdots$$

$$\Delta_1^{+(m)} . \quad (3.28)$$

The convergence procedure shows that the information obtained in previous steps cannot be used to calculate $\Delta_1^{+(m)}$ for the current step; hence, for each step, the sequence must be repeated independently. This requires excessive computing time. In order to make use of the information obtained at the previous step ($\Delta_1^{+(m-1)}$) and the current one ($\Delta_1^{+(m)}$), a recursive method is introduced that defines the forward Green's function for the localities ($\Delta_1^{+(1)}$, $\Delta_1^{+(2)}$, $\Delta_1^{+(3)}$, …, $\Delta_1^{+(m)}$) for a finite system as

$$\begin{aligned}
\Delta_1^{+(1)} &= (zI_1 - h_1)^{-1} \equiv \Delta_1^{-} , \\
\Delta_1^{+(2)} &\equiv G_{11}^{(2)} , \\
\Delta_1^{+(3)} &\equiv G_{11}^{(3)} , \\
&\vdots , \\
&\vdots , \\
\Delta_1^{+(m)} &\equiv G_{11}^{(m)} ,
\end{aligned} \quad (3.29)$$

where $G_{11}^{(m)}$ is the (1, 1) diagonal block of Green's function corresponding to the matrix $H^{(m)}$. Using (3.22), $\Delta_1^{+(2)}$ and $G_{22}^{(2)}$ are given by

$$\Delta_1^{+(2)} = G_{11}^{(2)} = \Delta_1^{-} + \Delta_1^{-}v_{12}G_{22}^{(2)}v_{21}\Delta_1^{-} , \quad (3.30)$$

$$G_{22}^{(2)} = \Delta_2^{-} = [(zI_2 - h_2) - v_{12}\Delta_1^{-}v_{21}]^{-1} . \quad (3.31)$$

So, the relation between the successive forward Green's functions is obtained as

$$\Delta_1^{+(2)} = \Delta_1^{+(1)} + A_1\Delta_2^{-}B_1 , \quad (3.32)$$

where $A_1 = \Delta_1^{-}v_{12}$ and $B_1 = v_{12}\Delta_1^{-}$. Repeating the same steps, general recursive relation can be obtained

$$\Delta_1^{+(m)} = \Delta_1^{+(m-1)} + A_{m-1}\Delta_m^{-}B_{m-1} , \quad (3.33)$$

$$A_{m-1} = A_{m-2}\Delta_{m-1}^{-}v_{m-1,m} , \quad (3.34)$$

$$B_{m-1} = v_{m,m-1}\Delta_{m-1}^{-}B_{m-2} . \quad (3.35)$$

This method, thus, simplifies the calculation of Green's functions to inversion and multiplication of matrices whose dimensions are much smaller than the total number of degrees of freedom of the system. The diagonal element of Green's function represents the entire system. The method ensures that Green's function associated with a particular locality in the system can be reasonably calculated. Further details may be found in [3.46–49].

In calculating the LDOS for the surfaces of interest, we take each system to consist of an infinite number of layers with in-plane periodicity and specify a certain number of layers to constitute a locality. The submatrix elements of the block-tridiagonal matrix represent the

force constants between the atoms, within and between the chosen localities. We then determine the normalized LDOS from the trace of Green's function by employing

$$g(\nu^2) = \frac{-1}{3n\pi} \lim_{\varepsilon \to 0} \mathrm{Im}\{\mathrm{tr}[G(\nu^2 + \mathrm{i}\varepsilon)]\} , \tag{3.36}$$

$$N(\nu) = 2\nu g(\nu^2) , \tag{3.37}$$

where ε is the width of the Gaussian and frequency-dependent LDOS ($N(\nu)$) is related to the normalized local LDOS ($g(\nu^2)$).

The method has been applied successfully to both high and low-symmetry systems [3.47–52] such as bulk, low and high Miller index surfaces, and single-element [3.53, 54] and bimetallic NPs [3.55]. These studies have proved that it can accurately reveal the vibrational properties, especially for low-symmetric systems. Applications of the method have provided insights into the effect of coordination and alloying on vibrational and thermodynamical properties of such low-symmetry systems [3.49].

3.4.3 Determination of Surface Thermodynamics

Having calculated the vibrational density of states, as described above, the task is to determine the surface thermodynamical functions, which includes vibrational entropy. Since the harmonic approximation of lattice dynamics was invoked in the above section, in what follows, the same approximation will be implicit. We expect the results summarized here to be valid for low temperatures. Molecular dynamics simulations for Cu and Ag surfaces [3.37, 39, 40], using EAM potentials, show the atomic mean-square displacements to vary linearly with temperature even beyond half the melting temperature, implying the validity of the harmonic approximation for that temperature range. Below, we provide some details of the calculations of the local and excess vibrational free energy for surfaces. The main quantity of interest here is the vibrational contribution to surface free energy. While details may be found in [3.17], we include the main points here.

As discussed before, the free energy of a system is given by the standard definition $F = U - TS$, where U is the internal energy, S is the entropy, and T is the temperature. Both U and S have contributions from atomic configurations and vibrations, such that $F = F_{\mathrm{conf}} + F_{\mathrm{vib}}$. That is, for each atomic configuration of the system, there is a specific vibrational contribution, which can be further written as $F_{\mathrm{vib}} = U_{\mathrm{vib}} - TS_{\mathrm{vib}}$. It is this latter quantity that we calculate here for the surface systems of interest for their relaxed atomic configurations (of minimum energy) at 0 K. In the harmonic approximation, the vibrational free energy, the vibrational internal energy, and the vibrational entropy are given by

$$F^{\mathrm{vib}} = k_{\mathrm{B}}T \int_0^\infty N(\nu) \ln\left[2 \sinh\left(\frac{x}{2}\right)\right] \mathrm{d}\nu , \tag{3.38}$$

$$U_{\mathrm{vib}} = k_{\mathrm{B}}T \int_0^\infty N(\nu) \left(\frac{1}{2}x + \frac{x}{\mathrm{e}^x - 1}\right) \mathrm{d}\nu , \tag{3.39}$$

$$S_{\mathrm{vib}} = k_{\mathrm{B}} \int_0^\infty N(\nu) \left[-\ln(1 - \mathrm{e}^{-x}) + \frac{x}{\mathrm{e}^x - 1}\right] \mathrm{d}\nu , \tag{3.40}$$

where k_{B} is the Boltzmann constant, T is the temperature, $x = h\nu/(k_{\mathrm{B}}T)$, and h is the Planck constant. The vibrational density of states can, in turn, be written as $N(\nu) = \sum_l n_l(\upsilon)$, where $n_l(\upsilon)$ is the local density of states of the region of interest, the layer, the step, the kink, or any other locality.

To calculate the vibrational contribution to the free energy of a surface (flat, stepped, kinked, ...) we consider a slab of N atoms, arranged such that the top and bottom surfaces consist of the Miller index planes. The surface free energy, which is defined as the excess over the values associated with the bulk system, is evaluated using the expression

$$F^{\mathrm{vib}}_{\mathrm{SURF}} = \frac{F^{\mathrm{vib}}_{\mathrm{SLAB}} - NF^{\mathrm{vib}}_{\mathrm{BULK}}}{2A} . \tag{3.41}$$

In (3.41), $F^{\mathrm{vib}}_{\mathrm{SLAB}}$ and $F^{\mathrm{vib}}_{\mathrm{BULK}}$ are, respectively, the vibrational free energy calculated for a finite slab representing the surface system and a single bulk atom, and A is the surface area of the system. The factor 2 arises from the fact that the system contains two free surfaces. In the same vein, the step vibrational free energy is defined as the excess energy over that for a low Miller index surface of the same geometry as the terrace. The vibrational contribution to the step free energy is then calculated using [3.3]

$$F^{\mathrm{vib}}_{\mathrm{STEP}} = F^{\mathrm{vib}}_{\mathrm{S}}(\theta) - (p - 1 + f)F^{\mathrm{vib}}_{\mathrm{S}}(\infty) , \tag{3.42}$$

where $F^{\mathrm{vib}}_{\mathrm{STEP}}$ is the vibrational step free energy, $F^{\mathrm{vib}}_{\mathrm{S}}(\theta)$ and $F^{\mathrm{vib}}_{\mathrm{S}}(\infty)$ are the vibrational surface energies of the corresponding high and low Miller index surfaces forming the terraces of the vicinal surface, p is the number of atomic chains on the terrace, and f is a geometrical factor determined by the projection of the ledge on the terrace. According to this definition f is 2/3 for (211), 1/3 for (331), and 1/2 for (511).

3.5 Results

In this section, we present examples of vibrational density of states for some prototype low and high Miller index surfaces. For the former, we consider the (100) surfaces of Pd, Pt, and Au, for which an extensive study was carried out in [3.10] to compare the results obtained from application of the EAM potentials with those from DFT, while for the latter we focus on Ni(977).

3.5.1 Local Vibrational Density of States

The layer-resolved vibrational density of states for the first four layers of Pd(100), Pt(100), and Au(100) are presented in Fig. 3.7. We note from the figure that the LDOS for the atoms in the first layer is remarkably different from that for the atoms in the second, third, and fourth layers. It, thus, suffices to focus our analysis of the LDOS only for atoms in the first layer. The reader is reminded that the first-layer atoms on the fcc(100) surface have coordination 8, since they have lost four neighbors. As a result, there is a loosening of bonds and a softening of the in-plane force constants in the first layer. The softening of the force constants, in turn, yields a shift towards lower frequencies that is reflected in Fig. 3.7. Note that this red shift in the density of states is a characteristic of all the five elements discussed in this chapter. This is not a global red shift of the density of states, which would have had drastic consequences for the stability of the surfaces. Rather, it is depletion of the high-frequency band accompanying an enhancement of the low-frequency band. We can also conclude from Fig. 3.7 that these effects are marginal for the second-layer atoms and are absent for the third and fourth layers. Though not presented in Fig. 3.7, the LDOS for Cu(100) and Ag(100) show the same trend as the three surfaces shown therein.

Turning next to high Miller index surfaces, we present the calculated local density of states for the step and the terrace atoms of Ni(977) and compare them with those for the Ni(111) surface atoms in Fig. 3.8. We have chosen here Ni(977), since this surface displays a step localized vibrational mode at a frequency [3.52] that is close to that of one that was observed experimentally using the He-atom surface scattering method [3.56, 57]. Note that the terrace of Ni(977) contains eight atoms, seven of which have the same coordination (9) as that of the atoms in the top layer of Ni(111), and the eighth is at the step with coordination 7. Because of the reasonably large terrace width, the LDOS of the Ni(977) terrace atoms is similar to that of the atoms in the top layer of Ni(111).

This result suggests that in studies of phonons of vicinal surfaces with relatively large terraces, as in (977), or on realistic surfaces with nonregularly distributed steps, it is feasible to use a local approach to determine the phonons of the step and its surrounding atoms, while resorting to standard techniques (diagonalizing a force constant-based dynamical matrix for a slab with a large number of layers) for calculating phonons of the close-packed flat surface for the terrace. Another interesting feature in Fig. 3.8 is that the low-frequency modes associated with the step atoms display a global shift to lower frequencies, to the modes associated with the terrace (and Ni(111) surface atoms), thereby pointing to an extra softening of relevant force constants, in agreement with suggestions of *Niu* et al. [3.56, 57]. As shown in Table 3.2, the force constants between the surface atoms, calculated using EAM interaction potentials, undergo both softening and stiffening.

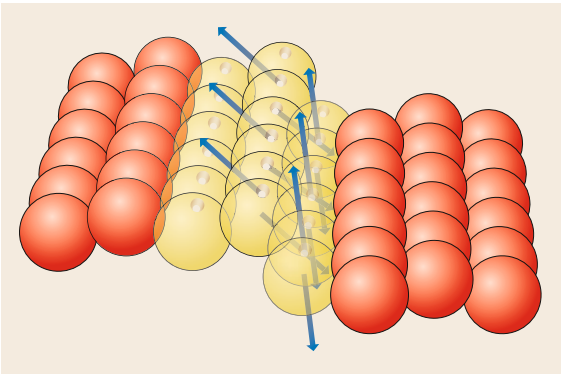

Fig. 3.9 The displacement pattern of the step-localized vibrational mode on Ni(977). (Adapted from [3.18], © IOP Publishing. Reproduced with permission. All rights reserved)

A detailed examination of the LDOS of Ni(977) [3.52] shows that the most prominent low-frequency mode is at 3.3 THz with maximum displacement along the x-direction. The displacement vectors of the atoms contributing to this mode, found from the imaginary part of the Green function, is shown in Fig. 3.9. Note that this mode is quasi-one dimensional: it involves only the concerted motion of the SC and CC atoms in conjunction with that of the TC atoms. The step atoms alternate with displacement vectors $(+1, 0, -0.67)$ and $(-1, 0, +0.67)$, the corner atoms with vectors $(+0.27, 0, -1)$ and $(-0.27, 0, +1)$, and the TC atoms with vectors $(0, +0.24, 0)$ and $(0, -0.24, 0)$. Thus, the step and the corner atoms move in the xz-plane, while the TC atoms move along the y-direction to accommodate the propagation of this mode along the direction parallel to the step. The rest of the atoms are at rest. The wavelength of the mode is $2\times$ *nearest-neighbor distance* or 4.978 Å, and its wavevector $q = (0.0, 1.262\,\text{Å}^{-1}, 0.0)$. This is a *super*localized mode, since the motion is restricted to the step atoms and their immediate neighbors on the

surface. Modes such as the one displayed in Fig. 3.9 exist on a number of vicinal surfaces. Similarly, along the y and z-directions there are noticeable peaks, at low frequencies, at 3.9, and 4.9 THz, respectively. There is also a prominent high-frequency peak at 9.1 THz, close to the top of the bulk band. In Table 3.3, we present a summary of the frequencies of the observed modes and refer the reader to discussions in related publications.

3.5.2 Surface Vibrational Free Energies

An important conclusion from the calculated LDOS of the (100) surfaces of Pd, Pt, and Au presented in Fig. 3.7 is that we should expect deviations in surface thermodynamics from the bulk values, and that this difference will be mainly for the top-layer atoms. This inference (obtained using DFT) is in accord with what was reported in earlier publications on the vibrational dynamics and thermodynamics of vicinal and kinked fcc metal surfaces using EAM potentials [3.6, 21]. The quantities of interest here are the lattice heat capacity (local and excess), the contribution of the vibrational dynamics to the free energy (local and excess), and the atomic mean-square displacements. As shown in Figs. 3.10a, 3.11a and 3.12a, the local lattice heat capacity (C_V) of the first-layer atoms of Pd(100), Pt(100), and Au(100) differs from that of the other atoms in the system, and that this difference is temperature dependent. These deviations from the bulk values are better described by the local excess from the bulk as illustrated in Figs. 3.10b, 3.11b, and 3.12b. Indeed, for Pd and Pt(100), the maximum deviation was found to be 3.4 and 2.8 J/(K mol), respectively, both occurring at a temperature of 50 K. However, the first-layer atoms of Au(100) behave differently; with a maximum deviation of only 2.2 J/(K mol) occurring at a lower temperature (30 K).

Let us now turn our attention to the local and excess vibrational free energy. The results are presented in Figs. 3.10, 3.11, and 3.12, for Pd, Pt, and Au(100), respectively. Here again, only the first-layer atoms show differences from the atoms in the other layers. As shown in the figures, the local contributions to the vibrational free energies for the layers beyond the second converge to the corresponding bulk values. For the atoms in the first layer, the local contribution to the vibrational free energy decreases with temperature and reaches −48, −64, and −79 meV/atom for Pd, Pt, and Au(100), respectively, at 300 K. The excess vibrational free energies are significantly different for the first-layer atoms, as can be seen in Figs. 3.10d, 3.11d, and 3.12d, with the contribution amounting to 19, 17, and 14 meV/atom at 300 K. Our DFT calculations for Cu and Ag(100) show 15 meV/atom, which is in good agreement with the EAM results (about 18 meV/atom for both surfaces at 300 K).

In the harmonic approximation, the mean-square vibrational amplitude (MSVA) is expected to vary linearly with temperature. Note that at 0 K, the MSVA does not go to zero due to the zero-point motion. In Figs. 3.10e, 3.11e, and 3.12e, we present our DFT results for the MSVA of Pd, Pt, and Au(100), respectively. The MSVA of the atoms in the third and fourth layers are bulk-like (0.008, 0.0075, and 0.0130 Å^2 at 300 K for Pd, Pt, and Au(100), respectively). Though MSVA of the second-layer atoms is close to the bulk values, that corresponding to the first-layer atoms shows large deviations. The ratio between the first-layer and the bulk MSVA is 2.06, 1.73, and 1.73 for Pd, Pt, and Au(100), respectively. This deviation is due to the decrease of coordination at the surface as compared to the bulk. Note that the ratio is the same for Pt and Au(100) and the highest for Pd(100), reflecting the mass effect.

We now turn to a summary of the impact of further undercoordination on the vibrational contribution to the thermodynamic properties as presented by vicinal surfaces with a few specific examples. In Fig. 3.13, we show the vibrational LDOS for the step (SC), terrace (TC), and corner (CC) atoms of Cu(511), Cu(211), and Cu(331). The shift towards low frequencies, in each

case, reflects the lower coordination of these atoms. There are some differences in LDOS between the sets of atoms on the three surfaces. On Cu(331), for example, the corner atom is almost bulk-like, while the other two atoms contribute more to the lower-frequency modes than the atoms in the bulk. As noted in previous publications [3.3, 11], the LDOS of the (211) and the (511) surfaces are similar to each other and different from those of the (331). These similarities and differences are related to trends in the multilayer relaxation patterns on these surfaces, as discussed above. Furthermore, the plots in Fig. 3.13 suggest complexity in the way the different surface localities differ from those of the atoms in the bulk. We also find that the LDOS of the BNN atoms (in the layer adjacent to the corner atoms) show an enhancement in the *high*-frequency region over bulk values [3.3]. This enhancement at the high-frequency end is very prominent in the LDOS of the surface atoms on Cu(532), which has a regular array of kinks, as can be seen in Fig. 3.14.

The effect of new features in the vibrational dynamics is reflected in the calculated local vibrational free energy illustrated in Fig. 3.15 for the top layers of (511), (211), and (331). On Cu(511) and Cu(211), the local contribution to vibrational entropy from atoms in the three surface chains (SC, TC, CC) is distinct from that of the atoms in the bulk. On Cu(331), however, layer 3, which corresponds to CC atoms on the terrace, shows characteristics more akin to those of atoms in the bulk than those on the surface. This interesting behavior can, again, be traced to the effective coordination number. As we know from Table 3.2, the coordination number for a CC atom of (511) and (211) is 10, while that of a (331) surface is 11, close to the value 12 for a bulk atom. In the equilibrium configuration obtained after ionic relaxation of the model system [3.3, 11], while the CC atom of (211) and (511) moves upward, away from the bulk, that of (331) moves toward the rest of the bulk, increasing its effective coordination number. Note that the difference in coordination between the terrace atoms on (511) and (211) (8 and 9, respectively) is also displayed in the local free energies in Fig. 3.15. The terrace atoms on (511) have contributions closer to those of their step atoms, while on (211), they are closer to those of the corner atoms. The reader is referred to [3.3] for details of the effects of varying coordination and complex relaxation patterns on the vibrational thermodynamic properties of the vicinal surfaces. We summarize the essential points below.

For convenience, we focus the discussion on local thermodynamical quantities calculated at 300 K. Interestingly, the contributions of the step atoms (SC) are about the same on all three vicinal surfaces. On the Cu surfaces, it is almost 41 meV/atom, while on

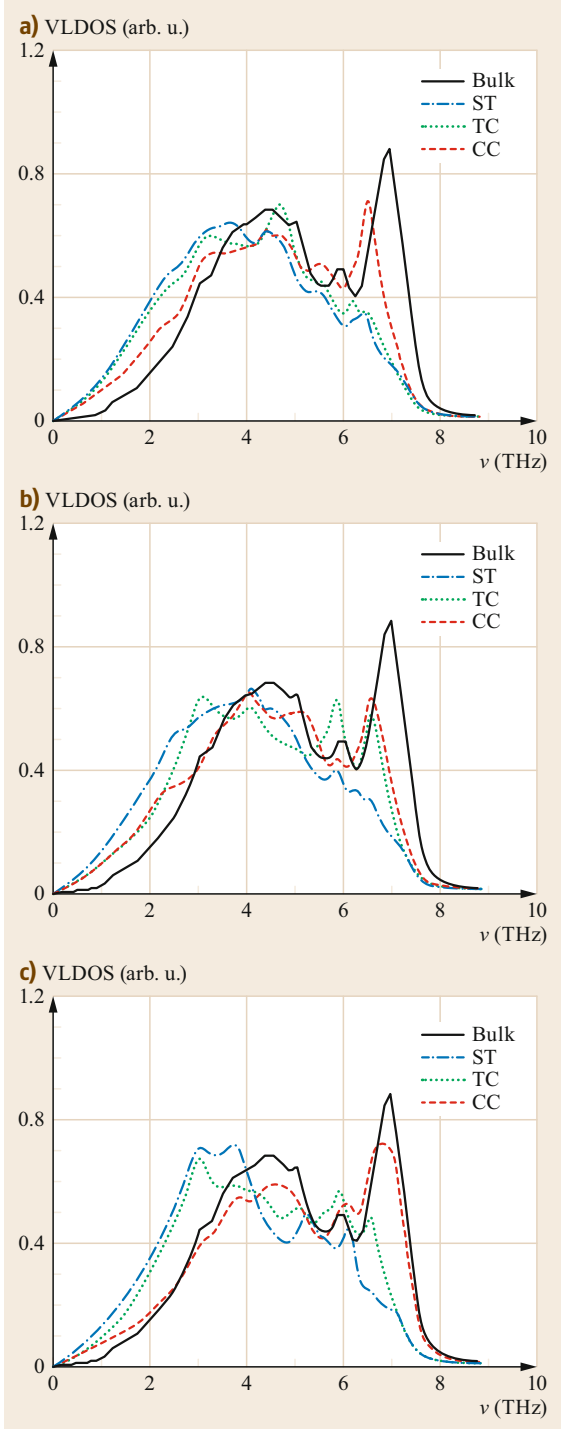

Fig. 3.13a–c Projected vibrational densities of states of the step (SC), terrace (TC), and corner (CC) atoms on **(a)** Cu(511), **(b)** Cu(211), and **(c)** Cu(311) compared to that of a bulk atom. (Adapted from [3.17], © IOP Publishing. Reproduced with permission. All rights reserved)

the Ag surfaces, it is about 68 meV/atom. Although the percentage enhancement over the bulk value is larger on Cu surfaces than on Ag, in each case, it is in excess of about 19 meV/atom over that in the bulk. Turning to the contributions of the TC atoms, we find a good correspondence with their respective coordination number. On (511), on which their coordination is 8, they contribute about 17 meV/atom more than the bulk atoms, similarly to the value for the atoms on (100) surface with the same coordination. On (211) and (331), their contribution over the bulk is about 13–11 meV/atom, resembling that of the surface atoms on (111), which also have a coordination of 9. The largest difference in contribution for the atoms on the three types of vicinal surface comes from the corner atoms, which contribute only 2–3 meV/atom more than the atoms in the bulk on Cu(331), while on Cu(511) and Cu(211) the corresponding amount is 9 meV/atom. This is, again, understandable from previous arguments based on atomic coordination. The atoms in the other layers in the tables have similar contributions to the bulk, and small variations can, again, be linked to their ionic relaxation and nonbulk-like contribution to the vibrational DOS. The above findings regarding the differential, local vibrational free energy contribution of atoms in undercoordinated sites show that the vibrational free energy does not scale with the coordination number in a simple manner, although its dependence on atomic coordination is remarkable. This is not surprising, as other factors also impact the characteristics of the surface atoms. Ionic relaxations of the individual atoms and their bond lengths with the surrounding atoms are also expected to play

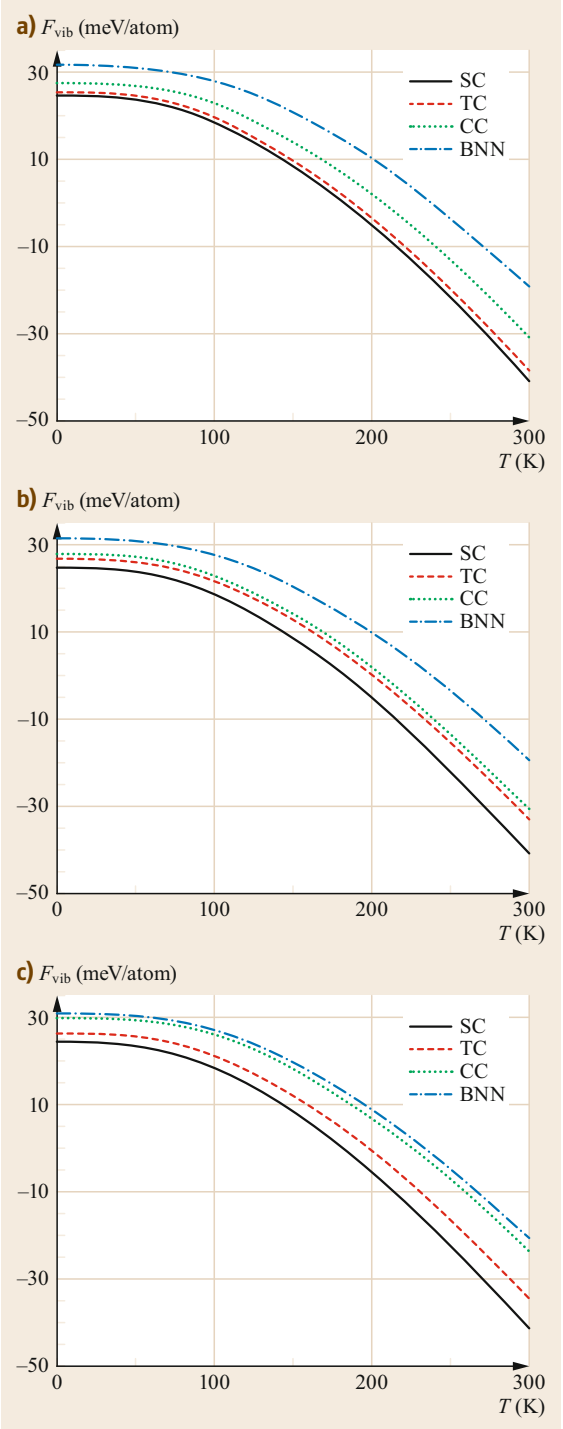

Fig. 3.15a–c The dependence of the local contribution on the vibrational free energy F_{vib} of vicinal surfaces on the local coordination for **(a)** Cu(511), **(b)** Cu(211), and **(c)** Cu(331). (Adapted from [3.17], © IOP Publishing. Reproduced with permission. All rights reserved)

a role in defining the local characteristics of a surface. While atoms on low Miller index surfaces lose symmetry in the direction perpendicular to the surface, the atoms forming the terraces of vicinal surfaces experience a lack of symmetry along the direction perpendicular to the step edge, in the terrace plane, in addition to the direction normal to it. This, in turn, leads to complex relaxation patterns and bond lengths for the surface atoms, as shown in previous studies [3.11, 22], resulting in distinctive characteristics of the local regions on the surface. Note that in this chapter, relaxation patterns of the surfaces considered are not presented, to keep the focus on vibrational contributions. However, there is a direct link between frequencies of surface (and step) localized modes, the changes in force constants from the values in the bulk, and the manner in which atoms in undercoordinated sites relax to configurations away from their bulk terminated positions. The reader is encouraged to refer to previous studies that summarize these interesting and complex relaxation patterns.

Using the local contributions to the vibrational entropy we can calculate the surface and step excess free energies, following the procedure discussed earlier; we find the calculated surface excess vibrational free energies for Cu and Ag vicinals at 0, 100, and 300 K to be quite small. The calculation of the excess step free energies, however, shows a remarkable effect of the vibrational component. The temperature variation of the step vibrational free energy for the three surface geometries is plotted in Fig. 3.16. It is remarkable that the excess vibrational contribution is almost nonexistent for both Ag(511) and Cu(511). From 0 to 300 K, it shows a variation of only about 1 meV/atom. On the other hand, the contribution is remarkable for both Ag(211) and Cu(211) and constitutes about 10% of the total free energy [3.3, 58] in the case of Cu. The case of the (331) surfaces lies in between the other two geometries. Since the step free energy is relevant to the roughening temperature of a surface, we expect vibrational contributions to play an important role, particularly for Cu(211) and Ag(211).

3.6 Summary

This chapter contains some details of the calculation of local vibrational contributions of surface atoms to selected dynamical properties and thermodynamic quantities. Already published results obtained by the author and her coworkers (A. Kara, S. Durkanoglu, M. Alcantara Ortigoza, and H. Yildirim) are used as examples of the novel vibrational characteristics that impact the thermodynamical properties of a set of low and high Miller index surfaces of several transition metals. Calculations were performed using either ab-initio electronic structure calculations or many-body interaction potentials. Comparisons of results are made with experimental data where available. The main conclusion to be drawn is that of the important role of the local coordination and geometry in determining the structural, dynamical, and, ultimately, thermodynamical proper-

ties of these surface nanostructures. Of the large list of vicinals of varying surface geometry, terrace width, step-face orientation, and elemental metal summarized here, the striking feature in the multilayer relaxation is the large outward relaxation of the corner atom (actually, the least undercoordinated atom) coupled with the inward relaxation of its neighboring surface atom. At least for Cu, Pd, Al, and selected vicinals of Ni, Ag, and Pt, the trends in the calculated multilayer relaxations point to this enhanced local effect at the step and near the corner site, in accordance with principles of charge smoothing. The reduced coordination of the surface atoms leads to electronic densities of states that are narrower and shifted towards the Fermi level. Furthermore, changes in the bond lengths of the surface atoms from their neighbors are reflected in corresponding softening and stiffening of force constants with respect to those in the bulk. As a result, localized modes appear on stepped surfaces whose existence has been verified experimentally. Moreover, projected vibrational densities of states of surface atoms show enhancements of modes at the low-frequency end, as well as near (and sometimes above) the top of the bulk modes. The vibrational entropies of these surfaces are thereby impacted on by their local geometry and coordination. The local contributions scale with coordination in a complex manner. While the surface free energies of a set of vicinals of Ag and Cu show very little sensitivity to the vibrational contribution, the excess step free energy could have a vibrational contribution of about 25%.

In considerations of growth and surface stability, vibrational contributions cannot be ignored. Needless to say, surface relaxations are an inherent component of the novel features of vicinal surfaces and should not be ignored in any serious examination of these surfaces. Last but not least, the modifications in the structural, dynamical, and subsequently thermodynamical, properties introduced by the presence of steps on surfaces are local in nature, thereby allowing an extension of the knowledge gained from systematic studies of stepped surfaces to more complex environments such as those on nanocrystals.

Talat S. Rahman is a Pegasus Professor of Physics at University of Central Florida. Her research interests are in computational design of functional nanomaterials through microscopic understanding of their physical and chemical properties. A related interest is in multiscale modeling of chemical reactions and thin film growth processes. She is engaged in implementing evidence-based teaching strategies and in efforts that enhance the participation of women and underrepresented minority groups in physics.

Surface C Part B

Part B Surface Crystallography

Part B deals with surface crystallography. When the solid—which ideally fills the entire space—is cut to create a surface, translational invariance in the direction perpendicular to the surface plane is lost. This generates unsaturated chemical bonds (also called dangling bonds), affecting not only the structure but potentially all properties of the material in the surface region—in particular the vibrational spectrum, the electronic and magnetic structure, and the chemical reactivity. Minimization of the free energy of the system may then lead to relaxation (i.e., a change in the distance between the outermost atomic planes) and/or potentially extensive and complex surface reconstruction (i.e., the rearrangement of atoms in the surface plane). Possibly the most famous reconstruction is the (7×7) rearrangement of Si(111), which involves three atomic planes and 49 surface unit cells. Interestingly, since the number of dangling bonds (one per atom) is odd, the resulting surface is metallic, albeit with a very low density of states at the Fermi energy. Work to determine the atomic positions took decades and involved dozens of laboratories worldwide. Determining the structures of other materials can be as challenging (e.g., the many phases of SiC surfaces). The presence of supported adsorbate layers, ultrathin films, and two-dimensional (2-D) materials at surfaces makes surface systems even more complex, but they are important since they have properties that are not present in 3-D systems. An example is provided by Dirac fermions in graphene: their effective mass of zero gives electrons an extremely high mobility that is not attained in graphite.

Chapter 4 provides a brief but general introduction to surface crystallography. Starting from an overview of bulk crystallography, the chapter presents point and space group symmetries in 2-D. The concept of a reciprocal lattice is introduced and Bloch's theorem is formulated. The chapter also addresses low-energy electron diffraction and Ewald sphere construction to describe the scattering process. In its final part, stereographic projection is introduced and several examples are given. The chapter also provides a useful compilation of the different notations used in surface crystallography.

Chapter 5 addresses the theoretical ab initio methods that are used to determine the surface structures of semiconductors. Such methods have advanced tremendously in recent years and now have the ability to make reliable predictions, especially for low-dimensional systems. The chapter first introduces the theoretical framework and the most suitable protocols for solving problems ranging from the microscopic characterization of interfaces (mandatory when, for example, designing contacts) to functionalization and sensing. The chapter also covers recent developments in contacts and heterojunctions, with an emphasis on ohmic versus Schottky barriers, core–shell nanowires, and alternative plasmonic systems. Finally, it explores the semiconductor/water interface and compares the characteristics of this interface with those of a metal/water interface.

Chapter 6 first briefly reviews the structures of the surfaces of a variety of oxides and then focuses on rock salt oxides and perovskites. For ionic solids, surface relaxation involves the rumpling of anions and cations, which undergo significant displacements. Rock salt oxide surfaces are therefore particularly intriguing since they form a series of compounds with identical structures in which only the cations change. Ternary oxides are used for applications in which the exact surface structure must be known. As an example, the surface terminations and reconstructions of $SrTiO_3(100)$ are discussed in detail, with special attention paid to the roles of Sr stoichiometry and defects that make it challenging to prepare a single-phase terminated surface.

Chapter 7 is devoted to the crystallography of metallic surfaces that are clean and covered with adsorbates. In the first part, details of the main experimental techniques used to determine surface structures are presented (LEED, XPD, SXRD, and XSW) and critically compared. Further analysis is presented to show that these techniques allow the determination of atomic positions with an accuracy of up to 0.01 Å. In the second part of the chapter, common trends in the surface structures of metals are presented, and the chemisorption characteristics of several inorganic and organic adsorbate layers are enumerated and compared.

Chapter 8 deals with the imaging, spectroscopy, and manipulation performed in scanning tunneling microscopy. This technique is shown to provide not only images of the surface at the subnanoscale, but also spectroscopic information on the local density of states. A large part of the chapter is devoted to the use of the tip to manipulate adatoms and admolecules, thus establishing a bridge to nanotechnology in a bottom-up approach. Lateral manipulation as well as the use of electric fields and the inelastic tunneling of electrons are explored. Possible directions for future research include single-molecule motors and ultraminiaturized circuits, and the factors limiting such fascinating developments are discussed in the final part of the chapter.

Chapter 9 presents an overall summary of the synthesis and growth of 2-D materials of the 'ene' family (graphene, silicene, germanene, stanene, hafnene) on transition metal surfaces in a controlled ultrahigh-vacuum environment. Calculations based on density functional theory are provided to explain the observed structures, in particular their Moiré patterns. Recent progress in device building suggests that these materi-

als will begin to be used in applications in the very near future. Given their importance, some of these materials will also be addressed in greater detail in the last section of this Handbook.

Chapter 10 reviews the properties of ultrathin oxide thin films. These systems were initially investigated to simulate bulk oxide surfaces as they allow the application of electron-based techniques, but they were soon recognized to offer their own exotic phases and to exhibit intriguing chemical and physical properties that differ from those of the surfaces of the corresponding bulk oxides, with the additional advantage of tunability. These differences ultimately arise from their intrinsic reduced dimensionality and, at the monolayer limit, the influence of the substrate. The first part of the chapter describes the structures of various films, including those of MgO, CaO, silica, iron oxide, and other transition metal oxides. In the second part, the effects of charge transfer and doping with impurities and adatoms are discussed. In the final part of the chapter, practical applications of thin oxide films are described, with particular attention paid to catalysis, since these films can be used as active supports for metal nanoparticles (e.g., Pt deposited on FeO is used to catalyze CO oxidation) or directly as catalysts themselves (e.g., the partial oxidation of methanol on vanadium oxide).

4. Crystallography of Surfaces

Stephen J. Jenkins

In no aspect is the two-dimensional nature of the surface more readily apparent than in its crystallography. Concepts familiar from the three-dimensional crystallography of bulk materials must be modified to suit the surface subspace, with important consequences for the symmetries and structural forms that may occur. The lowering of symmetry at the surface affords scope for relaxations and reconstructions that are not seen in the parent material, and these phenomena can be of crucial importance in dictating the physical and chemical properties of the surface region. Here, we shall review the basics of three-dimensional crystallography (lattices, unit cells, reciprocal space, etc.) and demonstrate how they carry over into the two-dimensional realm of the surface. We shall also focus upon consequences for point and space symmetries, relating these to surface structural features (e.g., steps, kinks, etc.) via a stereographic representation developed to place vicinal surfaces within a unified conceptual framework. Finally, we introduce and comment upon standard notational schemes for referencing symmetry-breaking reconstruction and/or adsorbate superstructure.

4.1 Context

The application of crystallographic techniques to three-dimensional materials has a long and illustrious history, dating back at least to early experiments by pioneers such as the Braggs in the first decades of the twentieth century. Investigation of the two-dimensional crystallography of surfaces followed somewhat later, but by now is no less developed, albeit the practical difficulties faced by its proponents unavoidably limits the information that may be gleaned. Nevertheless, the parallels between three- and two-dimensional crystallography are sufficiently strong that both may usefully be presented side-by-side, the former shedding light upon the latter (or vice versa, depending upon one's viewpoint). Let us begin our discussion, therefore, by defining some fundamental terms that are common to both situations.

4.2 Bravais Lattices and Crystal Structure

We shall take as our definition of a crystalline material one in possession of long-range spatial periodicity. That is, a crystal must have a structure in which the same local arrangement of atoms recurs repetitively across large length scales. Within this definition, amorphous materials are clearly excluded, since any short-range

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-46906-1_4

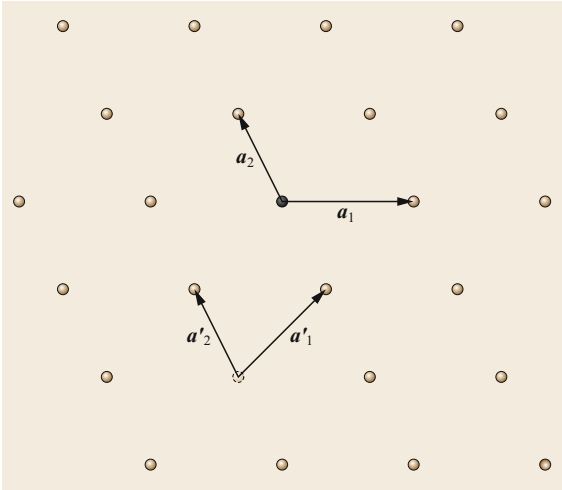

Fig. 4.1 A two-dimensional Bravais lattice, generated by the primitive lattice vectors $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$. General lattice points are small light-brown balls; the dark-gray ball represents the origin. Note that vectors $\boldsymbol{a}'_1$ and $\boldsymbol{a}'_2$, together with a different origin, would define precisely the same lattice equally well

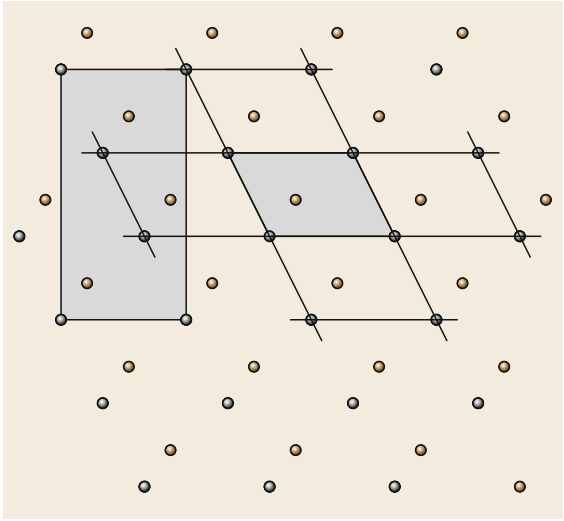

Fig. 4.2 A two-dimensional crystal generated by adding a two-atom motif to the Bravais lattice depicted in Fig. 4.1. The primitive unit cell corresponding to vectors $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$ in that figure is *shaded*, and its tessellation indicated with *construction lines*; an alternative, nonprimitive, unit cell of higher symmetry is also *shaded*

structures that *may* recur throughout the material do not do so according to a repetitive pattern. Furthermore, quasicrystalline materials are also excluded, since the recurrence of short-range structures in these cases, whilst conforming to a well-defined pattern, is again not truly periodic.

From a mathematical standpoint, perhaps the simplest way to define a prototypical crystal is by specifying a set of so-called primitive lattice vectors, which we shall denote $\boldsymbol{a}_i$. In the three-dimensional case, this allows us to write a general lattice vector as

$$\boldsymbol{R} = \alpha_1\boldsymbol{a}_1 + \alpha_2\boldsymbol{a}_2 + \alpha_3\boldsymbol{a}_3 \tag{4.1}$$

in which α_1, α_2 and α_3 are integer coefficients (of either sign). In two dimensions, the linear combination is, of course, restricted to the form

$$\boldsymbol{R} = \alpha_1\boldsymbol{a}_1 + \alpha_2\boldsymbol{a}_2 \tag{4.2}$$

but the cases are otherwise analogous. Each lattice vector may be viewed as terminating at a well-defined location in either three- or two-dimensional space, which we shall describe as a lattice point, with the case corresponding to $\alpha_1 = \alpha_2(= \alpha_3) = 0$ constituting the origin of our system. Three-dimensional crystallography is, of course, covered in far greater detail within many textbooks, for example the classic work of *Ashcroft* and *Mermin* [4.1]; our intent in briefly summarizing it here is merely to highlight the similarities between three- and two-dimensional situations.

Taking the complete (infinite) set of lattice points obtained by essaying all possible combinations of α_1, α_2 and (if appropriate) α_3, one obtains the mathematical entity known as a Bravais lattice (Fig. 4.1). Placing a single atom (of some particular species) at each and every lattice point will necessarily generate a crystalline material, whose structure conforms identically to that of its parent Bravais lattice. Evidently, such a structure exhibits long-range spatial periodicity by construction, satisfying that definition of a crystal introduced above. Note, however, that the same Bravais lattice may be defined in terms of infinitely many sets of primitive lattice vectors, each of which is equally satisfactory. In contrast, as we shall shortly quantify, the number of symmetrically distinct crystalline structures that may be described simply by placing an atom at each lattice point within a Bravais lattice is rather limited. For a start, no crystalline structure containing more than a single element could be thus described, and even many common single-element crystal structures (diamond, for example) would remain out of reach. Fortunately, of course, one may retain the long-range periodicity whilst introducing considerable structural flexibility by placing a well-defined atomic motif at each lattice point (Fig. 4.2) rather than a single atom (such motifs are sometimes described as the atomic basis). In this manner, the number of symmetrically distinct crystalline structures expands to encompass *all* possible cases within our working definition.

Conveniently, one may now consider the region spanned by the primitive lattice vectors (an area in the two-dimensional case, but a volume in the three-dimensional case) to constitute the primitive unit cell of the crystal. It contains precisely one lattice point, and correspondingly just one repeat of the atomic motif; moreover, it tessellates (by translation through the primitive lattice vectors) to fill space and reproduce the entire crystal structure. On occasion, it may prove convenient to eschew the primitive unit cell in favor of a larger cell of higher symmetry, which may be termed (if it is frequently employed) the conventional unit cell. There is much to be said for working with the highest-symmetry unit cell possible for any given structure, although the advantage of the primitive unit cell in containing the fewest atoms is also compelling. Certainly, when making use of a primitive unit cell, one should prefer (out of the many possible choices) that which exhibits maximum symmetry. Let us, therefore, proceed by considering the symmetry properties of atomic systems in general, and of two- and three-dimensional cases in particular.

4.3 Point and Space Group Symmetries

It is evident that two crystalline structures differing only by a uniform scaling are only trivially distinct from one another. Similarly, changing the elemental identity of atoms within a structure does not fundamentally imply an entirely distinct structure, so long as spatial arrangements remain generically the same. Diamond and silicon, for example, may both be said to share the same crystal structure, despite the obvious substitution of carbon atoms for silicon, and the consequent difference in lattice spacing. Gallium arsenide, on the other hand, is generally held to adopt a distinctly different structure, because atoms of its two constituent elements alternate (albeit their positions match those of diamond and silicon, to within a trivial scaling). In order to classify crystal structures, therefore, it will be desirable to focus only upon nontrivial differences, and it has become standard to do so by prioritizing intrinsic symmetry properties over contingent details.

To be clear, we should first state what is meant by a symmetry of the system. In essence, a symmetry operation may be considered to be any operation that, when enacted upon an entity, leaves that entity indistinguishable from its original state. The simplest symmetry operation is merely that of identity, which consists of doing nothing whatsoever; clearly this must, by definition, leave the entity unchanged. Other symmetry operations, however, include reflection (across a plane), rotation (around an axis) and inversion (through a point). The planes, axes and/or points associated with these symmetry operations are known generically as symmetry elements, which a particular entity may or may not possess. All such symmetry elements imply at least one point that remains literally unmoved under the corresponding symmetry operation, and collectively they are known as the point symmetry elements and point symmetry operations.

For any entity, whether localized (e.g., an atom or molecule) or extended (e.g., a solid or surface), it is possible to collate the set of all point symmetry operations that it exhibits. This set is known as the point group of that entity, and in the case of a localized entity this fully describes the entirety of its spatial symmetry. Point groups in localized cases are typically labeled within either the Schönflies or the Hermann–Mauguin convention. For reasons of brevity, we shall merely summarize the main features of these two conventions here; the reader is referred to standard texts on symmetry for a more complete explanation.

In the Schönflies notation, point groups are assigned labels comprising a capital letter and a subscript: the letters C, S, D, T, O and I indicate symmetries of cyclic, spiegel, dihedral, tetrahedral, octahedral and icosahedral type, respectively. The *cyclic* symmetry groups feature only an n-fold rotational axis. The term *spiegel* is taken from the German, literally meaning mirror, but here noting the existence of a so-called rotoreflection axis—the symmetry element combining both rotation and reflection. The *dihedral* symmetry groups contain not only an n-fold rotational axis, but also n two-fold axes at right angles to it. The *tetrahedral*, *octahedral* and *icosahedral* symmetry groups are characterized by the rotational axes pertaining to the corresponding platonic solids. In the Schönflies notation, subscripts may be numeric and/or include the lowercase letters v, h or d, indicating the nature of any special axes and/or the orientation of any special planes. Thus, by way of example, the water, methane and benzene molecules display C_{2v}, T_d and D_{6h} symmetries, respectively, each symbol fully specifying the symmetry elements that are present.

Turning to the Hermann–Mauguin notation, in contrast, the defining symmetries of the point group (i.e., those symmetries that collectively serve to distinguish the point group from all other point groups) are simply listed, employing an italic letter m to indicate the presence of a mirror plane and/or a number to indi-

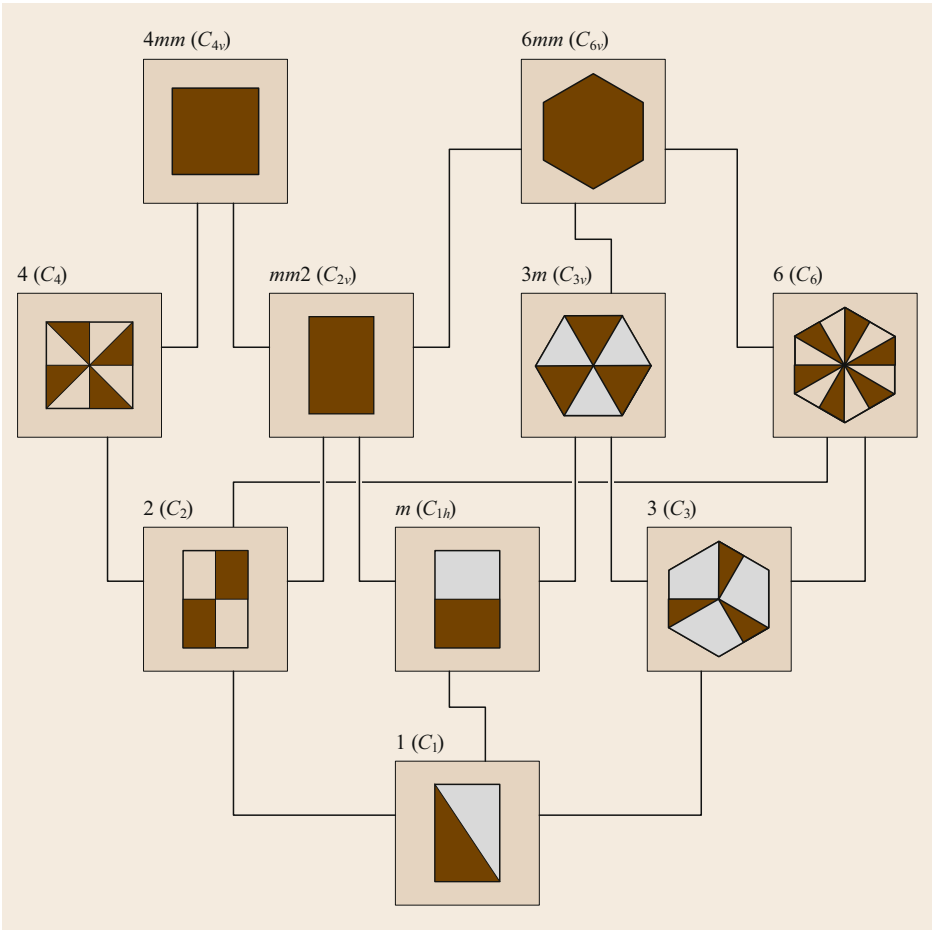

Fig. 4.3 The ten point groups compatible with two-dimensional translational periodicity. Illustrative shapes in each case should be understood as lacking any symmetry operations involving the dimension perpendicular to the page. Connections between different point groups indicate when those lower down the page are subgroups of those higher up the page

cate the presence of a rotational axis (a number with an overline indicates a rotoinversion axis, combining both rotation and inversion). Thus, the point groups C_{2v}, T_d and D_{6h} mentioned above are represented as *mm*2, $\overline{4}3m$ and 6/*mmm*, respectively; the way in which the individual components of these symbols are combined provides information about the geometric relationship of the various symmetry elements, but the details of this need not concern us unduly here.

In the case of extended systems, matters are a little more complicated, since the possibility of translation as a symmetry operation now arises; displacement of a crystalline entity through any of the primitive lattice vectors (and, by extension, through any integer linear combination of them) results in a crystal indistinguishable from the original. There is no corresponding symmetry element (unless one considers the relevant lattice vector to play this role) and the operation is certainly not a point one. Moreover, the translation operation may be combined with either reflection (yielding the operation known as glide) or rotation (giving rise to the screw operation); the former is associated with the symmetry element known as the glide plane, and the latter with a so-called screw axis. The complete set of symmetry operations displayed by such an extended system, including pure translation, together with glide and screw operations if present, is then known as the space group.

In light of the foregoing discussion, it is clear that we need to take some care in describing the symmetry of crystalline materials. We may, for instance, wish to describe the point group of the lattice, or the point group of the crystal; equally, one may speak of the space group of the lattice, as distinct from the space group of the crystal. To make matters yet more complicated, we must also recognize the existence of the so-called point group of the space group, which is obtained from the space group of the crystal by converting all glide operations to reflection operations and all screw operations to rotation operations; it is *this* point group that determines the symmetry of macroscopically observable crystalline phenomena, including morphological, electronic, magnetic and optical properties. Note that the point group of

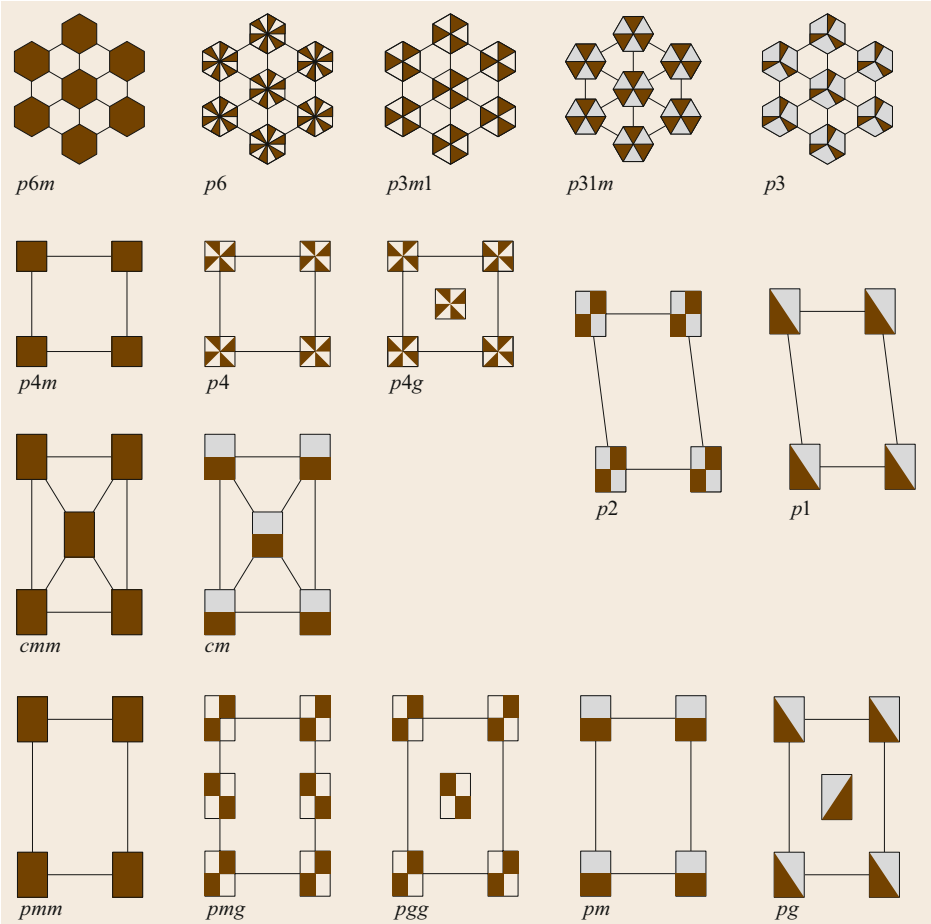

Fig. 4.4 The 17 space groups compatible with two-dimensional translational periodicity. Illustrative shapes in each case should be understood as repeating ad infinitum within the plane of the page, whilst lacking any symmetry operations involving the dimension perpendicular to that plane

the space group is *not* generally synonymous with the point group of the crystal, although it is quite common for the latter term to be used when strictly the former would be more accurate.

In three dimensions, it turns out that only 32 point groups are compatible with translational periodicity, and these are known as the crystallographic point groups. The point group of a crystalline space group must fall within this set, and accordingly there exist only 230 possible space groups that may be adopted by three-dimensional crystals. As for the parent Bravais lattices, only 14 different types may be envisioned, once categorized in terms of the their space groups, consisting of four within the orthorhombic system, three within the cubic system, two each within the tetragonal and monoclinic systems, and one each within the hexagonal, rhombohedral and triclinic systems. Note that the seven lattice systems mentioned here differ from the seven crystal systems or six crystal families whose definitions are based on the space group of the crystal rather than that of the lattice. Confusingly, whilst the three different categorization schemes conform to one another in most cases, the hexagonal and rhombohedral lattice systems are conjoined to form the hexagonal crystal family, and jumbled to form the hexagonal and trigonal crystal systems.

Moving to two dimensions, matters are drastically simplified. Now, only ten crystallographic point groups are compatible with translational periodicity (Fig. 4.3) giving rise to a total of only 17 distinct space groups for two-dimensional crystals (Fig. 4.4). Moreover, only five distinct Bravais lattice types exist, categorized according to *their* space groups; two of these fall within the rectangular two-dimensional lattice system, with one each in the oblique, triangular and square two-dimensional lattice systems; examples are shown in Fig. 4.5. It follows from this discussion that the symmetries exhibited by surfaces are strictly limited, and the two-dimensional lattices upon which their structures are based even more so. The diversity of surface structure (as opposed to the paucity of surface symmetry) derives from the range of observed motifs rather than of lattices.

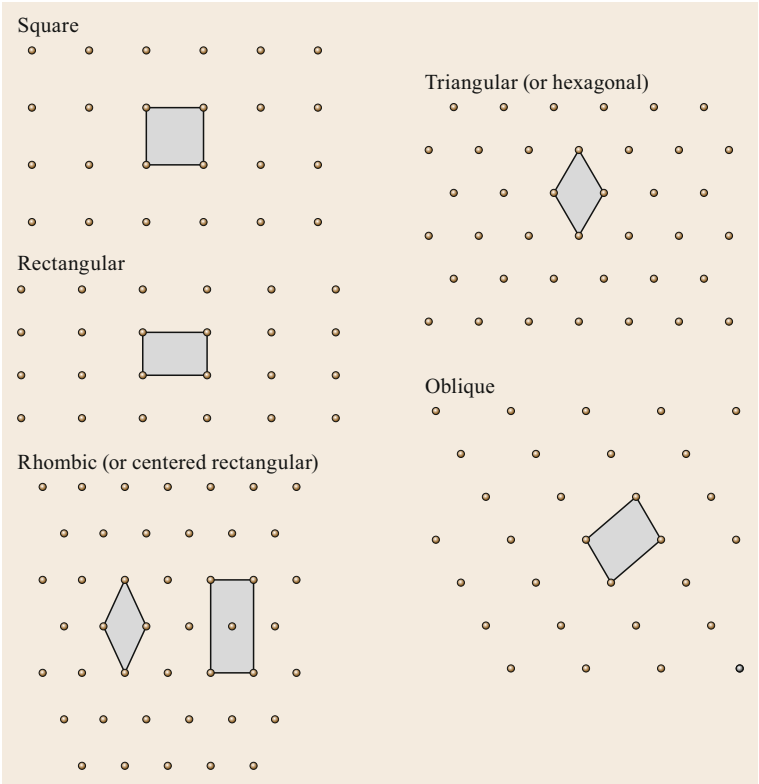

Fig. 4.5 Two-dimensional Bravais lattices of square, triangular, rectangular, rhombic and oblique symmetry. In each case, the primitive unit cell of maximum symmetry is *shaded*; in the rhombic case, a conventional (nonprimitive) rectangular unit cell is also depicted, justifying the alternative name of centered rectangular. Internal angles for the square and rectangular cells are, of course, right angles; those for the cell in the triangular (or hexagonal) case are 60° and 120°

Considering the surface to be a semi-infinite object, the motif attached to each two-dimensional lattice point consists of an infinite stack of atoms descending into the bulk from the uppermost atomic layer. The nature of both the two-dimensional lattice and the associated motif will depend upon both the three-dimensional crystalline structure of the bulk material and the relative orientation of the surface plane.

4.4 The Reciprocal Lattice and Its Implications

Whenever wavelike phenomena occur within crystalline materials, instances that are commensurate with the periodicity of the parent Bravais lattice (i.e., repeat precisely from one primitive unit cell to the next) take on a special significance. Writing the general mathematical form of a sinusoidal wave as

$$f(\boldsymbol{r}) = F\mathrm{e}^{\mathrm{i}(\boldsymbol{k}\cdot\boldsymbol{r}-\omega t)} \tag{4.3}$$

with amplitude F, wavevector $\boldsymbol{k}$ and frequency ω, the property we seek may be captured in the constraint that

$$f(\boldsymbol{r}) = f(\boldsymbol{r}+\boldsymbol{R}) \tag{4.4}$$

with $\boldsymbol{R}$ being any lattice vector of the crystal's parent Bravais lattice. Clearly this implies

$$\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}} = \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot(\boldsymbol{r}+\boldsymbol{R})} \tag{4.5}$$

from which we may infer that commensurate waves are simply those for which $\boldsymbol{k}\cdot\boldsymbol{R} = 2\pi n$, with integer n. Given that there exist infinitely many lattice vectors, $\boldsymbol{R}$, it follows that there must be infinitely many wavevectors satisfying this condition, collectively forming a mathematical entity that we may describe as the reciprocal lattice (in recognition that the spacing of its points scales inversely with the spacing of points within what we shall henceforth call the real-space lattice).

Specifying general points within the reciprocal lattice (i.e., reciprocal lattice points) by means of reciprocal lattice vectors, denoted $\boldsymbol{G}$, we may write

$$\boldsymbol{G} = \beta_1\boldsymbol{b}_1 + \beta_2\boldsymbol{b}_2 + \beta_3\boldsymbol{b}_3 \tag{4.6}$$

in three dimensions, or

$$\boldsymbol{G} = \beta_1\boldsymbol{b}_1 + \beta_2\boldsymbol{b}_2 \tag{4.7}$$

in two, where β_1, β_2 and (if appropriate) β_3 are integer coefficients (of either sign) and the vectors $\boldsymbol{b}_i$ are primitive reciprocal lattice vectors.

Furthermore, given a set of primitive lattice vectors, $\boldsymbol{a}_i$, for a particular three-dimensional crystal, the corresponding set of primitive reciprocal lattice vectors, $\boldsymbol{b}_i$, may readily be obtained as

$$\boldsymbol{b}_1 = 2\pi \frac{\boldsymbol{a}_2 \times \boldsymbol{a}_3}{\boldsymbol{a}_1 \cdot (\boldsymbol{a}_2 \times \boldsymbol{a}_3)} \tag{4.8}$$

$$\boldsymbol{b}_2 = 2\pi \frac{\boldsymbol{a}_3 \times \boldsymbol{a}_1}{\boldsymbol{a}_2 \cdot (\boldsymbol{a}_3 \times \boldsymbol{a}_1)} \tag{4.9}$$

$$\boldsymbol{b}_3 = 2\pi \frac{\boldsymbol{a}_1 \times \boldsymbol{a}_2}{\boldsymbol{a}_3 \cdot (\boldsymbol{a}_1 \times \boldsymbol{a}_2)} \tag{4.10}$$

in which a cyclic pattern is clearly discernible. That this construction ensures conformity with the necessary condition $\boldsymbol{G} \cdot \boldsymbol{R} = 2\pi n$ should be similarly evident, from the fact that we have engineered a situation where $\boldsymbol{a}_i \cdot \boldsymbol{b}_j = 2\pi\delta_{ij}$ (with δ_{ij} the Kronecker delta).

The same convenient construction may be retained in the two-dimensional case by the simple expedient of supplementing the two *real* primitive lattice vectors, $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$, with a third *dummy* primitive lattice vector of arbitrary length pointing in the surface normal direction; that is, we set $\boldsymbol{a}_3 = |\boldsymbol{a}_3|\hat{\boldsymbol{n}}$ with $\hat{\boldsymbol{n}}$ the surface normal unit vector. We then obtain

$$\boldsymbol{b}_1 = 2\pi \frac{\boldsymbol{a}_2 \times \hat{\boldsymbol{n}}}{\boldsymbol{a}_1 \cdot (\boldsymbol{a}_2 \times \hat{\boldsymbol{n}})} \tag{4.11}$$

$$\boldsymbol{b}_2 = 2\pi \frac{\hat{\boldsymbol{n}} \times \boldsymbol{a}_1}{\boldsymbol{a}_1 \cdot (\hat{\boldsymbol{n}} \times \boldsymbol{a}_1)} \tag{4.12}$$

$$\boldsymbol{b}_3 = \frac{2\pi\hat{\boldsymbol{n}}}{|\boldsymbol{a}_3|} \tag{4.13}$$

in which the third primitive reciprocal lattice vector may itself be taken as a *dummy* vector. Alternatively, we can think of our two-dimensional system as a pseudo-three-dimensional system, by allowing the magnitude of $\boldsymbol{a}_3$ to tend towards infinity, implying that the two-dimensional reciprocal lattice points become pseudo-three-dimensional reciprocal lattice rods (i.e., the two-dimensional points are extruded in the surface-normal direction).

Whether in two or three dimensions, the significance of the reciprocal lattice lies in its utility in representing arbitrary sinusoidal waves, not only those that happen to be commensurate with the parent Bravais lattice. This role can, perhaps, be seen most clearly in the description of electronic wavefunctions by means of Bloch's theorem. Here, we note that an electron within a crystal may possess a wavefunction, $\psi(\boldsymbol{r})$, whose periodicity need not correspond to that of the crystal itself. Nevertheless, this wavefunction may always be written (following Bloch) in the form

$$\psi_{n,\boldsymbol{k}}(\boldsymbol{r}) = \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}} u_{n,\boldsymbol{k}}(\boldsymbol{r}) \tag{4.14}$$

where the function $u_{n,\boldsymbol{k}}(\boldsymbol{r})$ (the Bloch function) *does* exhibit identical periodicity to the crystalline structure. The subscript $\boldsymbol{k}$ is introduced to keep track of which Bloch function goes with which exponential function, whereas the subscript n recognizes that, in general, many different wavefunctions may be possible for each value of $\boldsymbol{k}$. Clearly, the implication is that electronic wavefunctions in crystalline materials may be conceived of as the product of a simple plane wave (of wavevector $\boldsymbol{k}$) with a commensurately periodic function (tied to that same wavevector $\boldsymbol{k}$). Moreover, it turns out that one may restrict the values of $\boldsymbol{k}$ to extend only within that region of reciprocal space lying closer to the origin than to any other reciprocal lattice point, without loss of generality. In some sense, this region, known as the Brillouin zone, may be viewed as fulfilling an equivalent function to the primitive unit cell in real-space lattices (Fig. 4.6).

A corollary of applying this (voluntary) restriction is that one may think of the plane wave factor as controlling the long-range behavior of the wavefunction (repeating at length scales beyond that of the primitive unit cell) whilst the Bloch function controls its short-range behavior (showing structure within each primitive unit cell, but simply repeating that structure from one to the next).

One further consequence of Bloch's theorem, which will be of particular interest to us, is most readily seen by defining Bloch functions associated with wavevectors lying *outside* the Brillouin zone in terms of those lying *within* it. There being no constraint upon their functional form other than the requirement of lattice periodicity, we are free to do this in the following manner

$$u_{n,\boldsymbol{k}+\boldsymbol{G}}(\boldsymbol{r}) = \mathrm{e}^{-\mathrm{i}\boldsymbol{G}\cdot\boldsymbol{r}} u_{n,\boldsymbol{k}}(\boldsymbol{r}) \tag{4.15}$$

whereupon one finds

$$\psi_{n,\boldsymbol{k}+\boldsymbol{G}}(\boldsymbol{r}) = \mathrm{e}^{\mathrm{i}(\boldsymbol{k}+\boldsymbol{G})\cdot\boldsymbol{r}} u_{n,\boldsymbol{k}+\boldsymbol{G}}(\boldsymbol{r}) \tag{4.16}$$

$$= \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}} u_{n,\boldsymbol{k}}(\boldsymbol{r}) = \psi_{n,\boldsymbol{k}}(\boldsymbol{r})\,, \tag{4.17}$$

which is to say that the wavefunctions associated with two wavevectors differing by a reciprocal lattice vector are identical with one another, or equivalently that the wavevector associated with a particular wavefunction is well defined only to within the addition or subtraction of an arbitrary reciprocal lattice vector. Identifying $\hbar\boldsymbol{k}$ with the linear momentum of a quantum particle, we hence conclude that the electron's crystal momentum (i.e., the momentum associated with the plane wave factor in its Bloch form) is well defined only to within the

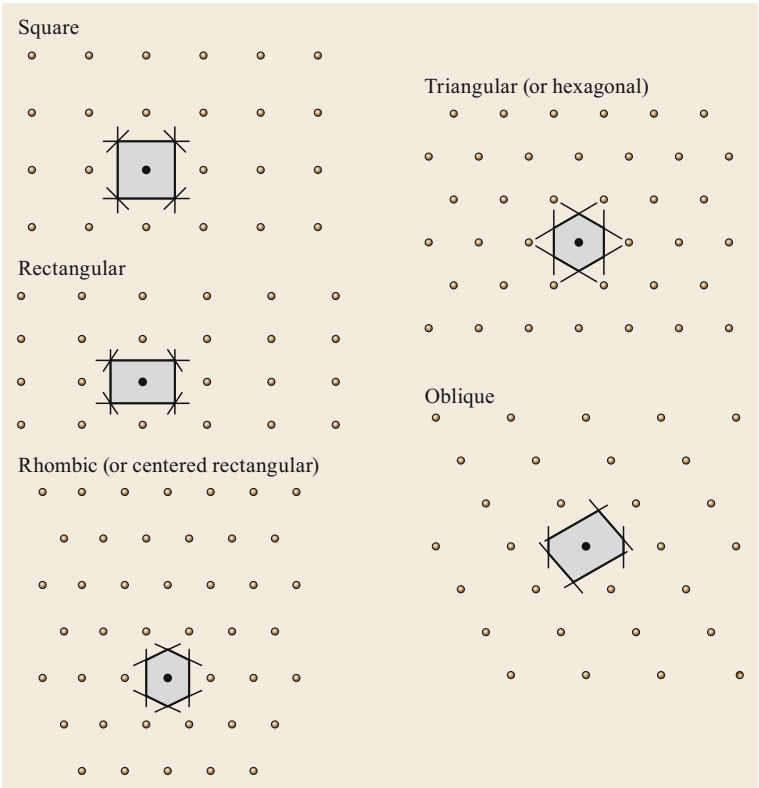

Fig. 4.6 Two-dimensional reciprocal lattices, with the origin *marked* and the first Brillouin zone *shaded* in each case; *construction lines* are perpendicular bisectors of reciprocal lattice vectors, included to demonstrate that these regions lie closer to the origin than to any other reciprocal lattice point

addition or subtraction of a discrete (but essentially arbitrary) offset, $\hbar \boldsymbol{G}$. In the context of electrons scattering from a crystalline surface, we must therefore anticipate that linear momentum within the plane of the surface must be conserved only to within a similarly defined offset, and it is this fact that accounts for the observed diffraction patterns that typically result, as we shall shortly see.

4.5 Low-Energy Electron Diffraction (LEED)

The ubiquity of x-ray diffraction in *bulk* crystallographic studies rests upon two important (and related) factors: firstly, that the relatively weak interaction of such short-wavelength light with matter ensures a penetration depth sufficient that surface effects may largely be ignored in the subsequent analysis; and secondly that the same weak interaction allows that analysis to be conducted on the assumption that each photon scatters only once. In efforts to elucidate the structure and symmetry of the *surface*, in contrast, it is natural to turn for one's probe to wavelike phenomena whose strong interaction with matter restricts the penetration depth to the selvedge region, even though this typically implies that multiple scattering will complicate the process of data analysis. One candidate for this role is the helium atom, whose light mass is consistent with a quantum wavelength comparable with the spacing of atoms in solids. In view of the dominance of electron-based techniques over helium scattering, however, we shall eschew any further discussion of detail in this chapter; from a mathematical perspective, the helium scattering problem differs little from the brief treatment of electron scattering offered below, despite obvious divergence in terms of the practical experimental details. Here, then, we shall focus upon the diffraction of low-energy electrons, whose quantum wavelength is again comparable with interatomic spacings in solids, and whose penetration depth rarely exceeds a few nanometres. An excellent dedicated textbook on this subject, covering experimental details and methods of analysis, is the work by *Van Hove*, *Weinberg* and *Chan* [4.2], so for our present purposes we merely summarize the basic principles of the technique and its relationship with the concept of the reciprocal lattice.

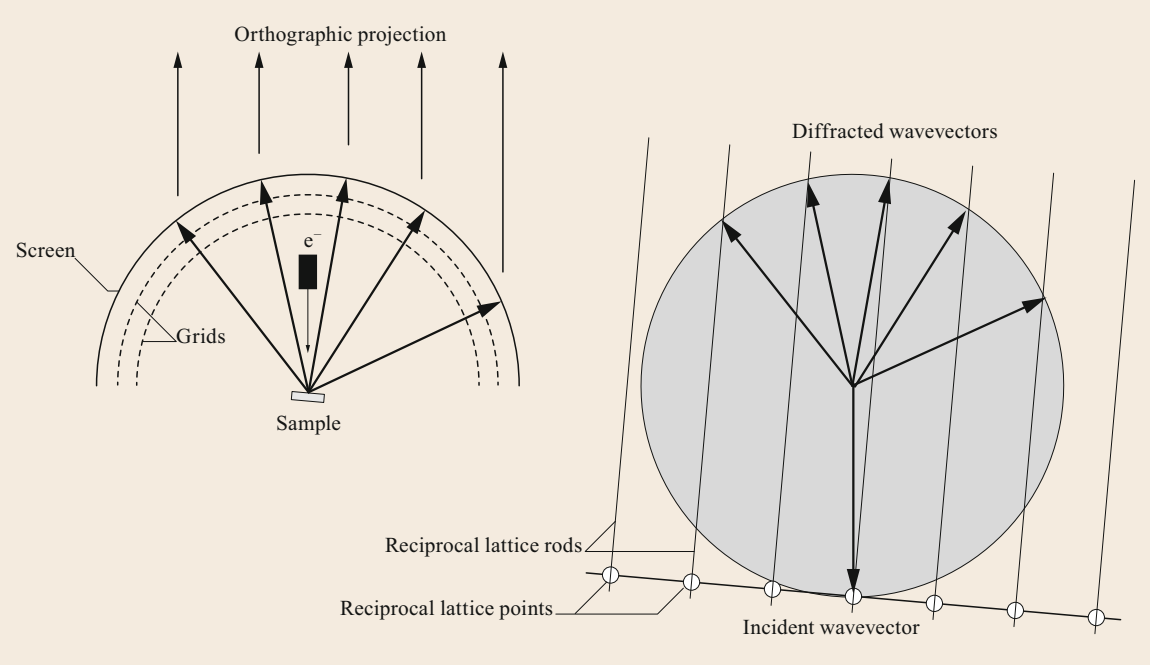

Fig. 4.7 LEED geometry and the Ewald sphere construction; reciprocal lattice rods are oriented perpendicular to the sample surface, and pass through reciprocal lattice points whose two-dimensional wavevectors differ from the surface-parallel component of the incident wavevector by surface reciprocal lattice vectors

At the simplest level, a prototypical LEED experiment involves the impingement of a monoenergetic electron beam upon a crystalline surface, and the collection of scattered electrons by means of some position-sensitive detector. In the vast majority of cases, this detector comprises little more than a phosphor-coated hemispherical screen that glows in response to the impact of electrons. It is usual to interpose two or three fine wire grids between the screen and the sample, which is situated at the focal point of the screen; the role of these grids, which are held at carefully chosen potentials during the experiment, is first to screen out any inelastically scattered electrons that may confuse the interpretation of elastic scattering events, and then to accelerate the remaining electrons towards the screen in order to maximize the electron-induced glow and hence the sensitivity. The diffraction pattern may then be observed upon the screen, from either the same or the opposite side as the sample (the latter option requiring a transparent screen, of course). The incident beam is generated by an electron gun, situated either between the sample and the screen, or more usually on the far side of the screen (the latter option requiring a small hole to be present in the center of the screen). Although normal incidence of electrons onto the sample is by no means an absolute necessity, it is nevertheless the norm.

Considering the general case of nonnormal incidence, we can predict the diffraction pattern due to electron scattering by means of a simple geometric construction known as the Ewald sphere (Fig. 4.7). We start with a vector in reciprocal space, representing the wavevector of the incident electron, and imagine a sphere of radius equal to the magnitude of this vector and centered on the origin. Conservation of energy implies that elastically scattered electrons must leave the surface with wavevectors whose tips lie somewhere on this sphere. Conservation of linear momentum, on the other hand, implies that the surface-parallel component of any outgoing wavevector must equal that of the incoming wavevector, to within an offsetting reciprocal lattice vector $\boldsymbol{G}$. We can include this in the construction by adding reciprocal lattice rods, positioned so that one rod passes through the tip of the incident wavevector and the orientation is perpendicular to the surface. Points where these rods intersect the sphere become, therefore, the only points at which outgoing wavevectors may terminate. The complete set of outgoing wavevectors satisfying the demands of the Ewald construction thus defines the pattern of outgoing electron beams constituting the diffraction pattern. In the standard geometry, with the sample lying at the focal point of a hemispherical screen and electrons imping-

ing at normal incidence, the orthographic projection of the bright spots in the pattern corresponds perfectly to the reciprocal lattice of the sample. Varying the energy of the incoming electron beam (by varying the accelerating voltage in the electron gun) causes a scaling of the observed pattern, due to a change in the incident wavevector, but no change in its qualitative features. The intensity of different outgoing beams does change with incoming beam energy, however, so that some LEED spots may become imperceptible under certain circumstances. Scanning the incoming beam energy is advisable, therefore, to ensure that patterns are correctly identified. Moreover, the intensity of individual LEED spots may be plotted as a function of the accelerating voltage, yielding so-called *I–V* curves. In just the same way that intensity variation with wavelength carries detailed structural information in x-ray diffraction experiments, here too the *I–V* curves carry similar detail embedded in their peaks and troughs. Analysis of LEED *I–V* curves is considerably more difficult than the comparatively simple extraction of structural detail by direct inversion of x-ray diffraction data, due to the multiple scattering of electrons, but nevertheless a trial and error approach works well.

4.6 Stereographic Representation of Surface Symmetry and Structure

Surfaces may be considered high-energy defects, relative to an idealized defect-free bulk material. Indeed, we can assign a specific surface energy (i.e., excess energy per unit area of surface) to any exposed facet, and one should expect the system as a whole to adopt a morphology that minimizes the total surface energy (i.e., the summed product of specific surface energies for different facets with the corresponding surface areas of those facets). To a first approximation, the specific surface energy may be expected to be roughly proportional to the number of nearest-neighbor interatomic bonds that are severed in creating the surface by cleavage of the bulk material, and hence it is no surprise that the lowest specific surface energies are typically found for the most close-packed structures. In crystals of face-centered cubic structure (Fig. 4.8) the most stable surface facet is of {111} type (coordination number of nine in the outermost layer) while the second most stable is of {100} type (coordination number of eight in the outermost layer). In crystals of body-centered cubic structure, on the other hand, the most stable surface is of {110} type (coordination number of six in the outermost layer), whereas this combination of Miller indices yields only the third most stable surface of face-centered cubic materials (coordination number of seven in the outermost layer). It is worth bearing in mind that the bulk coordination number in the body-centered cubic structure is only eight, compared to 12 in the face-centered cubic case. Notwithstanding this viewpoint, however, it is certainly the case that real surfaces will themselves play host to a variety of defects. The most stable (and hence most prolific) defective structure on an otherwise close-packed surface may most simply be described as a step, separating two terraces of nondefective material. Next, in order of stability, comes the kink, in which an otherwise straight-edged step suffers a lateral dislocation. Isolated adatoms and/or vacancies are also possible, of course, but these are typically so much higher in energy that their existence may be ignored at first blush. Accordingly, the TSK (terrace-step-kink) model of surface structure (Fig. 4.9) is widely taken as the basis for morphological discussions.

We should stress, at this point, that the occurrence of steps and kinks on close-packed surfaces is essentially random, depending in its precise detail upon the (unknown and unknowable) microscopic history of our sample's preparation. Granted, a systematic miscut of the sample may bias its surface towards a particular type and/or frequency of steps and/or kinks, but other preparational aspects (e.g., polishing, sputtering, etc.)

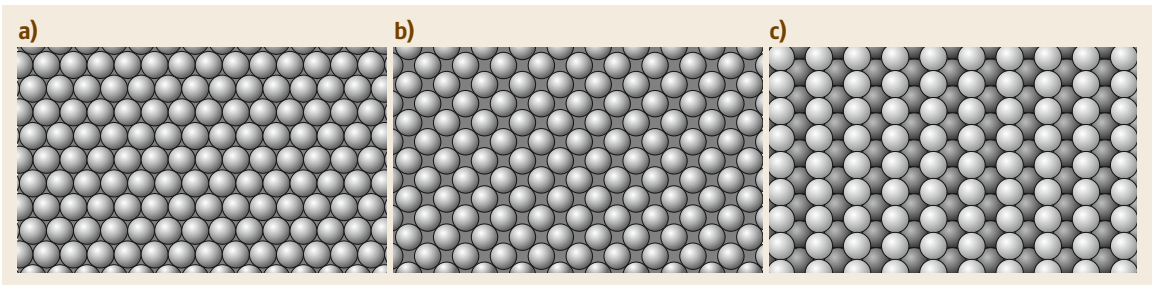

Fig. 4.8a–c Models of the (**a**) {111}, (**b**) {100} and (**c**) {110} surfaces of the face-centered cubic crystal structure

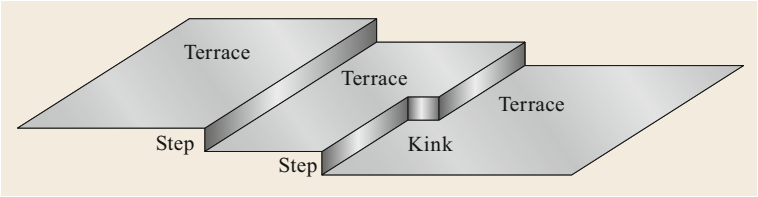

Fig. 4.9 Schematic view of the terrace-step-kink (TSK) model of surface morphology

will typically ensure that considerable heterogeneity and contingency characterizes their actual manifestation. Moving away from the close-packed surfaces, however, increasing attention is now paid to surfaces cut at some considerable angle from the low-index {111}, {100} and {110} planes. These high-index (sometimes described as vicinal) surfaces are distinguished in displaying more-or-less regular arrays of steps and/or kinks, presenting an opportunity to study what can be rather important low-coordination sites in a controlled manner. It is, therefore, to the classification of symmetry and structure in high-index surfaces that we now turn. Note the etymology of the word vicinal implies a degree of proximity (vicar, vicarious, etc.) and indeed the correct usage ought to describe certain high-index surfaces as *vicinal to* {111} or *vicinal to* {100} and so forth. That is, the term should indicate the low-index surface to which the high-index surface most closely approximates. Perhaps unfortunately, however, there is a tendency in modern usage to employ the word vicinal without qualification, simply as a synonym for *not low-index*.

4.6.1 The Surface Symmetry Stereogram

Let us begin with a focus on symmetry, taking the face-centered and body-centered cubic crystal structures as our case studies. Together, these two structures account for nearly all of the transition and coinage metals commonly used in catalytic applications. The concepts outlined here may readily be extended to other, more complicated, crystal structures; for a full introduction to the philosophy behind this approach, and an application to the hexagonal close-packed crystal structure, see the work by *Jenkins* and *Pratt* [4.3]. Our first task will be to represent graphically those surfaces possessing mirror symmetry, and we shall achieve this by means of either a spherical or a stereographic representation. Here, one must first imagine a vast single crystal in the shape of a sphere, the significance of which is that a microscopic examination of any sufficiently small region of its surface would reveal atoms arranged in accordance with a tiny patch of planar surface. Different points on the sphere necessarily correspond to different surface orientations, with eight points giving rise to patches of {111} type, six yielding patches of {100} type, and 12 revealing patches of {110} type; elsewhere on the sphere, one would find all possible high-index surface orientations represented at well-defined locations.

In order to highlight *surfaces* possessing mirror symmetry, it will prove helpful first to consider the mirror symmetries of the parent *bulk* material. In both face-centered *and* body-centered cubic crystals, mirror planes exist in the orientations perpendicular to the ⟨100⟩ and ⟨110⟩ crystallographic directions. Imagining the complete set of these mirror planes converging at the center of the sphere, one can confirm that all surface orientations corresponding to points on the surface of the sphere cut by one of these planes must necessarily exhibit that particular mirror symmetry. Marking the great circles of intersection between sphere and mirror planes with lines (which we shall henceforth describe as zones) one obtains the construction shown in Fig. 4.10a. More commonly, this spherical representation is subjected to a stereographic projection in order to render it onto a flat plane, as in Fig. 4.10b. Here, we can state immediately that any surface orientation corresponding to a point on the sphere lying at the junction between four of the marked zones must possess four distinct mirror symmetries; only the surfaces of {100} type satisfy this condition, and indeed they *are* the only surfaces of face- or body-centered cubic crystals that support so many mirror planes. Similarly, any surface orientation corresponding to a point on the sphere lying at the junction between three of the marked zones must possess three distinct mirror symmetries, and this time it is the surfaces of {111} type that uniquely exhibit this property. Likewise, the surfaces of {110} type are the only ones that lie at the junction between two of the marked zones, implying that they are the only examples that possess precisely two mirror planes. The low-index surfaces we have discussed above in the context of the TSK model, without ever presenting a firm dividing line between the epithets *low* and *high*, thus turn out to correspond precisely to the subset of face- or body-centered cubic surfaces possessing multiple mirror symmetries. On the other hand, an infinite number of surfaces may be envisioned that lie upon just a single marked zone, and *all* of these possess just one mirror plane within their space group.

Turning now to those surfaces whose orientations correspond to a point on the sphere that does *not* co-

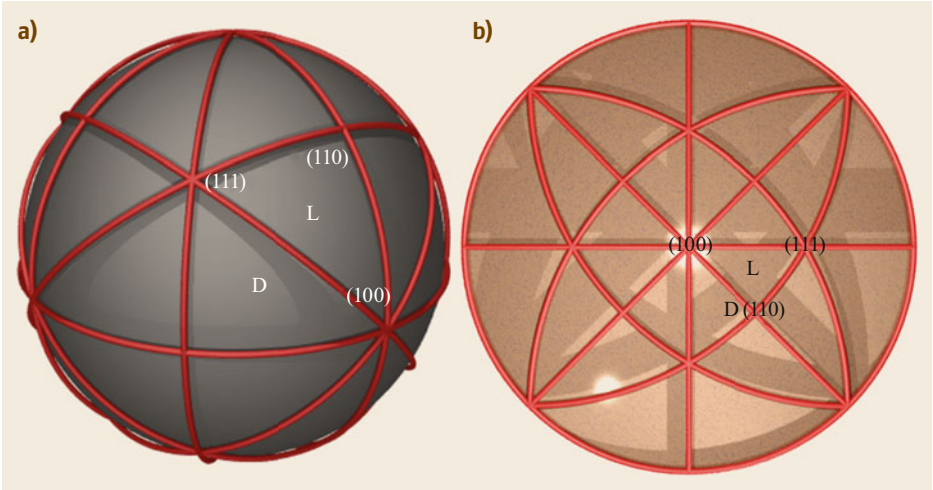

Fig. 4.10a,b Representation of surface symmetry for face-centered and body-centered cubic materials, with highlighted zones indicating surfaces displaying at least one mirror symmetry. In **(a)** these mirror zones are shown on the surface of a notional single-crystalline sphere, while in **(b)** the same information is stereographically projected onto a two-dimensional plane. Selected high-symmetry surfaces are indicated in each case, and two stereographic triangles in which chiral surfaces (lying off the mirror zones) labeled D or L are marked

incide with any of the marked zones, it follows that these must necessarily be devoid of any mirror symmetry. In the absence of any possible inversion symmetry (incompatible with all surface geometries) it further follows that all such surfaces are actually chiral—that is to say, the mirror image of such a surface would not be superimposable upon the original surface itself. The consequences of such a state of affairs for asymmetric synthesis, separation or sensing applications are, needless to say, potentially profound, and these surfaces have drawn quite a bit of attention in this regard over the last couple of decades.

Just as chiral molecules are typically labeled to distinguish their two nonsuperimposable mirror images (or, more properly, their enantiomers) so too it has proved useful to agree upon a convention for labeling the two nonsuperimposable mirror images of a chiral surface (which we shall call its enantiomorphs). Certainly the most popular scheme (proposed originally by *Attard* [4.4]) is one based upon the Cahn–Ingold–Prelog rules, whereby groups attached to a central carbon atom within a chiral molecule are assigned (arbitrary, but well-defined) priorities and the chiral label *R* or *S* is determined by the sense of rotation in going from high to low priority when viewed from a particular direction. (The labels *R* and *S* derive from the Latin words *rectus* and *sinister*, meaning right and left; there is, however, nothing objectively right-handed about one structure and left-handed about the other, even though they are often colloquially described in these terms once their labels have been assigned.) In the surface-modified version, one first examines the surface structure and identifies microfacets of {111}, {100} and {110} type in the vicinity of a kink, assigning them priority in order of their degree of close packing. If, when viewed from above the surface and visited in this order, these microfacets are arranged in the clockwise sense, the surface is labeled *R*, but if the arrangement is anticlockwise the label must be *S*. The method is simple, requiring nothing more than a structural model of the surface for its application, and has been adopted by most authors in this field. It does, however, suffer from a serious drawback when dealing with chiral surfaces that do not display kinks and hence do not possess microfacets of all three types. Fortunately, in the case of face-centered cubic crystals, all chiral surfaces *do* possess kinks (as we shall confirm in the next subsection) and so this problem does not arise. For surfaces of body-centered cubic crystals, however, the issue is very real and an alternative approach to labeling enantiomorphs is required.

Amongst the surfaces of face-centered cubic materials, the Attard convention may, in fact be simplified thus: a surface whose Miller indices are all positive and arranged in descending order of magnitude (e.g., the (531) surface) will acquire the label *S*, as will any surface whose Miller indices may be obtained from this instance via cyclic permutation and/or change of sign in any two indices. If the Miller indices are all positive but arranged in ascending order of magnitude (e.g., the (135) surface) or may be obtained from *this* instance by cyclic permutation and/or change of sign in any two indices, the appropriate label will be *R*. Finally, we note

that noncyclic permutations, or a change of sign in any one or all three indices will swap chirality labels between *S* and *R*.

One alternative approach (proposed by *Pratt et al.* [4.5]) emerges directly from the stereographic philosophy. Here, one first identifies the stereographic triangle within which a particular surface orientation lies, and then visits the vertices of this triangle in order of increasing symmetry (i.e., {110} followed by {111} followed by {100}); if, in so doing, the itinerary proceeds in a clockwise sense, one assigns the chirality label D, but if it proceeds anticlockwise then L must be the correct label. (The labels D and L once again derive from Latin, but in this case the words *dexter* and *laevo* are used as synonyms for right and left. In molecular chemistry, the assignment of D and L as chiral labels is made on the basis of similarities in structure with the compound glyceraldehyde, for which labeling is essentially arbitrary.) When applied to the surfaces of face-centered cubic crystals, the equivalences $R \equiv$ D and $S \equiv$ L hold true in all cases; for body-centered cubic crystals, the same is true where both labeling systems apply, but the D/L system continues to hold even when the *R*/*S* system fails.

4.6.2 The Surface Structure Stereogram

Having rendered the mirror symmetries of crystalline surfaces in stereographic form, it is an interesting and illuminating exercise to perform the same trick with aspects of their structure. One might, in principle, achieve this in various ways, but for the face- and body-centered cubic systems discussed above, the most natural approach is arguably to focus upon the crystallographic directions within the bulk material that correspond with atomic close-packing. In face-centered crystals, close packing of atoms occurs only along the ⟨110⟩ axes, whereas in body-centered crystals the same role is played by the ⟨111⟩ axes. Highlighting, on a sphere or stereogram, those surfaces for which one or other of these axes lies parallel to the surface plane, one arrives at the constructions shown in Fig. 4.11.

The significance of the newly marked zones in these diagrams is that they tell us specifically about the disposition of steps and kinks on the surface. A surface orientation corresponding to a point lying on precisely one of these zones necessarily features one, and only one, in-plane direction in which close-packed chains of atoms can be found; this state of affairs may be most reasonably described as indicating a regularly stepped surface (as opposed to one that merely happens to possess a low concentration of randomly distributed steps). Surface orientations corresponding to points that do not lie on any of these zones do not feature close-packed atomic chains at all, and are best described as regularly kinked (as distinct from merely possessing a low concentration of randomly distributed kinks). Finally, surface orientations corresponding to points lying at the junction of two or more of these zones necessarily feature the appropriate number of distinct directions within which close-packed chains of atoms are found, and hence must be considered atomically flat (in the sense of possessing neither regular steps nor regular kinks). In the case of face-centered cubic crystals, flat surfaces comprise those of {111} and {100} type, with three or two distinct close-packed directions respec-

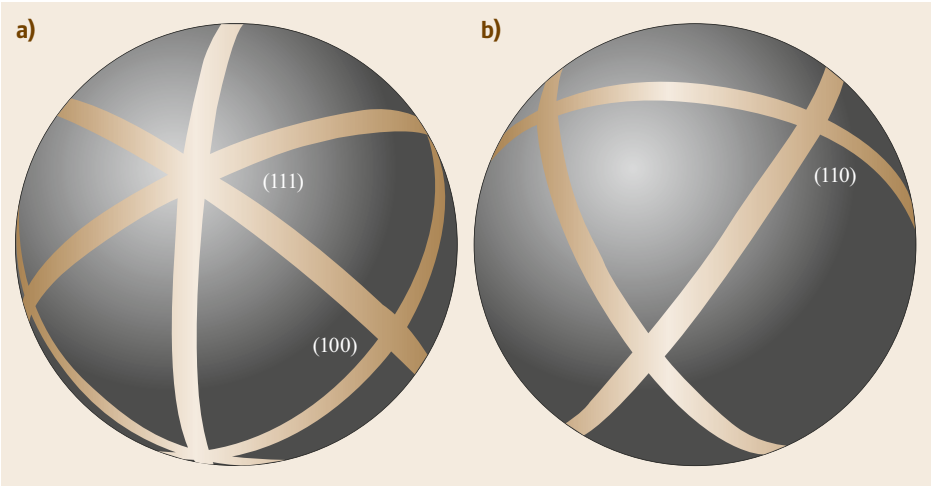

Fig. 4.11a,b Representation of surface structure for **(a)** face-centered cubic and **(b)** body-centered cubic materials. The highlighted zones indicate surfaces displaying close-packed atoms in at least one surface-parallel direction, described as regularly stepped; intersections correspond to atomically flat surfaces, while off-zone surfaces are regularly kinked

tively, whereas in the case of body-centered crystals only the surfaces of {110} type, with two distinct close-packed directions, may be considered to be flat within this scheme.

Importantly, the definitions of flat, stepped and kinked surfaces described here do actually correspond to physically measurable and significant features. Indeed, strong support for the meaningfulness of these categories is provided by a series of experiments from the *Gellman* group, in which propylene oxide and 3-methylcyclohexanone have been used as probe molecules to gauge the strength of binding at different surface sites on a variety of flat, stepped and kinked surfaces [4.6–12]. Results conform very closely to expectations based on the model described here. Specifically, it may be noted that the presently discussed definitions relate especially closely to the coordination number of atoms in the outermost layer, with consequences in turn for surface energy and stability against roughening. In the case of face-centered cubic crystals, the flat surfaces have the highest coordination number in the outermost layer (nine for the {111} type and eight for the {100} type), while the stepped surfaces all have the same slightly lower coordination number (seven) and the kinked surfaces all share the lowest coordination number (six). Unsurprisingly, the specific surface energies of the kinked surfaces are always higher than those of the stepped surfaces, which in turn are higher than those of the flat surfaces. Moreover, one may also make secure statements about the propensity for roughening based upon the concept of creating an adatom/vacancy pair by removing an atom from the outermost layer and redepositing it elsewhere on an otherwise pristine region of the surface. For the {111} surface, this process would involve first breaking nine nearest-neighbor bonds, and then making just three; the overall cost of six bonds implies that adatom/vacancy pair creation is enthalpically unfavorable, and that roughening would only occur at sufficiently elevated temperature so that entropic effects dominate. Similarly, for the {100} surface the formation of a vacancy would require the breaking of eight nearest-neighbor bonds, while the redeposition of an adatom would make only four; the overall cost of four bonds, whilst less than in the previous case, would still prohibit roughening at moderate temperatures. Turning to the stepped surfaces, however, removal of an atom from the step itself involves the breaking of only seven nearest-neighbor bonds, while redeposition would involve making five, for an overall cost of just two bonds; accordingly, roughening of stepped surfaces is expected to occur at lower temperature than for otherwise similar flat surfaces, and indeed this is generally found to be true. On kinked surfaces, in contrast, the removal of an atom to form a vacancy requires only six nearest-neighbor bonds to be broken, while redeposition elsewhere to form an adatom would create precisely the same number of new bonds; as a consequence, there will be very little enthalpic cost involved in adatom/vacancy pair creation, meaning that it can happen repeatedly at low temperature, implying that kinked surfaces will always be atomically rough. Very similar arguments apply to surfaces of body-centered cubic crystals, where the cost of adatom/vacancy pair creation amounts to four nearest-neighbor bonds on flat {110} surfaces, two such bonds on stepped surfaces, and zero on kinked surfaces; once again the flat surfaces are most stable against roughening, the stepped surfaces slightly less so, and the kinked surfaces not at all. It is worth mentioning, at this juncture, that simplistic energetic arguments based upon nearest-neighbour bonds work reasonably well for close-packed metals (i.e., face-centered cubic or hexagonal close-packed) but rather less well for more open structures (e.g., body-centered cubic). In large part, this is because interactions between next-nearest neighbors play a much larger role in the latter cases. Nevertheless, to a first approximation, conclusions drawn from these arguments do serve to frame the results of more detailed examination (e.g., through density functional calculations), which tend to concur in their essentials with the simpler picture.

4.6.3 Synthesis of Symmetry and Structure

Whilst the analysis presented above provides a framework for discussion of flat, stepped and kinked surfaces, it is possible to extend the idea based upon structural features of the parent bulk material other than just close-packed chains of atoms. One might, for example, seek out other extended motifs like zig-zag chains of atoms, plotting the zones corresponding to these onto stereograms to define additional families of surface orientations. A roadmap summarizing the structural connections between different surfaces, as revealed by this kind of approach, has been presented by *Jenkins* and *Pratt* [4.3] and the interested reader is directed to that work. For the present purpose, we shall focus on structure only at the most basic level. Nevertheless, important observations may be made by combining the spherical or stereographic representation of surface structure with that of surface symmetry. The resulting constructions for face-centered and body-centered cubic materials are presented in Fig. 4.12, with permissible combinations of symmetry and structure derived from these summarized in Fig. 4.13.

Considering first the representation for the face-centered cubic structure, we see immediately that whilst the zones indicating stepped surfaces all coincide with

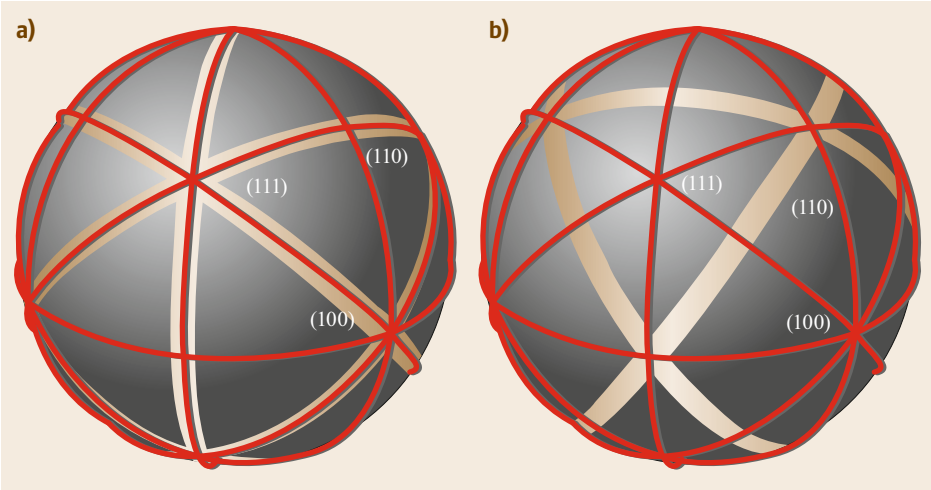

Fig. 4.12a,b Representation of surface symmetry and structure for **(a)** face-centered cubic and **(b)** body-centered cubic materials, showing mirror zones *and* structural zones together

zones indicating mirror symmetries, the reverse is not the case. Not only, therefore, does the diagram confirm that only the flat surfaces (those of {111} and {100} type) are of high symmetry (exhibiting three or four mirror planes) but it also reveals that *all* stepped surfaces of face-centered cubic structure necessarily display mirror symmetry, although not all mirror-symmetric surfaces are stepped. Specifically, we can see that surfaces with precisely two Miller indices of the same magnitude generally possess both a stepped structure and a single mirror plane; the only exceptions are surfaces of {110} type, which are the most highly symmetric stepped surfaces, having two mirror planes. At the same time, we can observe that all chiral surfaces are kinked, though not all kinked surfaces are chiral. That is, surfaces with three nonzero Miller indices of inequivalent magnitude possess no mirror symmetry and display no surface-parallel chains of close-packed atoms; surfaces with a single zero Miller index, other than the {110} surface, are also kinked in their structure, but do possess a single mirror plane. It follows, from the the discussion of surface stability offered in the preceding subsection, that the intrinsically chiral surfaces of face-centered cubic materials are necessarily always going to be prone to significant surface roughening. This propensity has indeed been observed in the

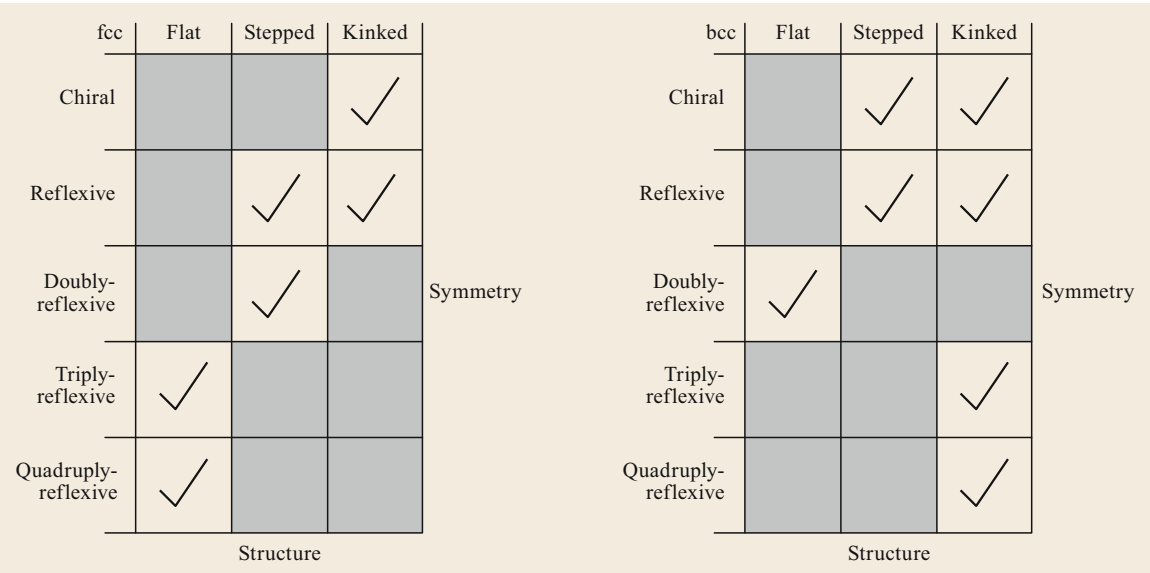

Fig. 4.13 Permitted combinations of symmetry and structure categories for face-centered and body-centered cubic materials

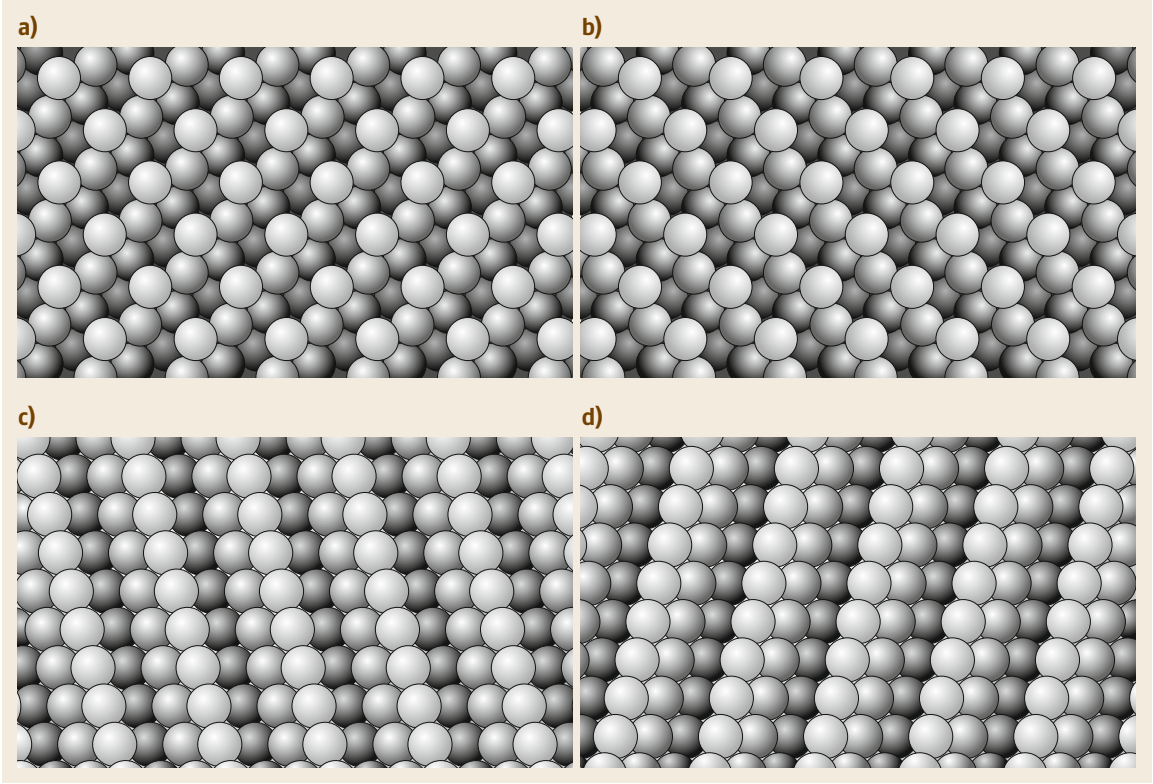

Fig. 4.14a–d Examples of chiral surfaces. As with all chiral surfaces of face-centered cubic materials, those of {531} type are kinked **(a)** fcc-{531}-L; **(b)** fcc-{531}-D. Materials taking the body-centered cubic crystal structure, in contrast, have not only kinked chiral surfaces, but also stepped chiral surfaces, as illustrated here by the examples of {321} type: **(c)** fcc-{321}-L; **(d)** fcc-{321}-D

case of Cu{531} [4.13] and is likely to be generally true, although it seems also that some degree of ordering may be imposed by the action of certain adsorbates.

In the body-centered cubic case, the picture is radically altered. Here, we immediately see that the zones indicating stepped surfaces do not, in general, coincide with those indicating mirror symmetries. Once again, the only flat surfaces (those of {110} type) are confirmed to display relatively high symmetry (exhibiting two mirror planes) but the very highest symmetry surfaces are, in fact, of the kinked variety (those of {100} and {111} type, with four or three mirror planes respectively). Surfaces having either two Miller indices of the same magnitude, or one zero Miller index, display a single mirror plane and are generally also kinked; the only exceptions are surfaces of {211} type, which are merely stepped. Indeed, the {211} surfaces are the most highly symmetric of the stepped surfaces for body-centered cubic materials (occupying a similar role to that of the {110} surfaces in the face-centered cubic case) and *all* other stepped surfaces are found to be chiral; these stepped surfaces may be identified from their Miller indices by the fact that two of the index magnitudes can be summed to give the magnitude of the remaining index (Fig. 4.14). There are, of course, as the spherical/stereographic representation also makes clear, many chiral kinked surfaces in addition to the stepped ones, but these will suffer a similar degree of instability against roughening as is expected of their face-centered cubic counterparts. The stepped chiral surfaces, on the other hand, are anticipated to be significantly more stable against roughening, and hence eminently suitable for studies of asymmetric surface phenomena.

4.7 Notational Conventions for Surface Superstructure

Our discussion thus far has focused upon idealized clean surfaces, whose structure is simply that of a bulk crystal terminated on a two-dimensional plane. In reality, of course, any such termination lowers the symmetry at the surface, implying unbalanced forces on the selvedge atoms, and opens the possibility of surface relaxation and potentially surface reconstruction. Here, we define surface reconstruction as any change in atomic positions resulting in a surface structure that either (a) is of lower symmetry than the ideal bulk-terminated surface, or (b) cannot be obtained through a continuous deformation of the bulk-terminated surface without passing through a lower-symmetry intermediate state. The first situation may be described as a *real* lowering of symmetry, and the second as a *virtual* one. Any displacement of atoms that falls short of this definition will be described as a surface relaxation. In general, one or other of these phenomena must occur at all surfaces, although in the absence of surface reconstruction the atomic displacements associated with surface relaxation may range from significant to barely perceptible. The change in symmetry involved in surface reconstruction (whether real or virtual) may occur within the point group of the surface, but equally may be limited only to translational symmetry elements; either way, it is convenient to define a notational standard to specify how the periodicity of a reconstructed surface relates to that of the ideal bulk-terminated surface. Similarly, when surface adsorption occurs, the adsorbed atoms and/or molecules may arrange themselves in an orderly periodic fashion, and the same notational convention will serve to keep track of this phenomenon equally well.

4.7.1 Wood's Notation

Since we aim to describe surface adsorption *and* surface reconstruction by means of the same notation, we shall refrain from drawing figures showing either type of situation explicitly. Instead, we will simply indicate, on a diagram of the ideal bulk-terminated surface, a unit cell (usually primitive) corresponding to the reconstructed and/or adsorbate-covered surface. We also depict an appropriate primitive unit cell of the clean unreconstructed surface for reference. The essence of our notational approach will be to define the former in terms of the latter.

In what is known as Wood's notation, the primitive unit cell of the surface superstructure is indicated by means of two multiplying factors to be applied to the primitive lattice vectors spanning the ideal surface's primitive unit cell. Wood's notation $(m \times n)$ is therefore to be interpreted as referring to a unit cell spanned by the vectors $m\boldsymbol{a}_1$ and $n\boldsymbol{a}_2$ (where $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$ are primitive lattice vectors for the clean unreconstructed surface). The primitive unit cell of the ideal surface is, in this notation, simply the (1×1) cell, and the area of any general unit cell is precisely mn times greater than this. In certain cases, it may be necessary not only to scale the (1×1) cell in order to represent the superstructure, but also to rotate it, in which circumstance the notation may be augmented to read $(m \times n)\mathrm{R}\theta$, where θ is the necessary rotation (anticlockwise) about the surface normal. Examples are depicted in Fig. 4.15.

A special case arises where the primitive unit cell of the surface superstructure cannot simply be represented as a scaled and rotated version of the (1×1) cell, but where the addition of an additional lattice point at the center of each $(m \times n)$ will suffice to achieve the desired mapping. In such circumstances, the proper notation takes the form $\mathrm{c}(m \times n)$, where the prefix indicates a *centered* cell; on occasion, ordinary *noncentered* cells may be written in the form $\mathrm{p}(m \times n)$, where the prefix indicates *primitive*, but this is essentially redundant and not a universal practice. Centered cells may, of course, be rotated relative to the (1×1) cell, if necessary, and again a postfixed $\mathrm{R}\theta$ serves to indicate such an eventuality. An example of such a centered cell is again provided in Fig. 4.15.

Alert readers will, by now, have spotted two critical flaws in an otherwise convenient and concise notational scheme: firstly, that there can certainly exist superstructures whose periodicity does not happen to conform to

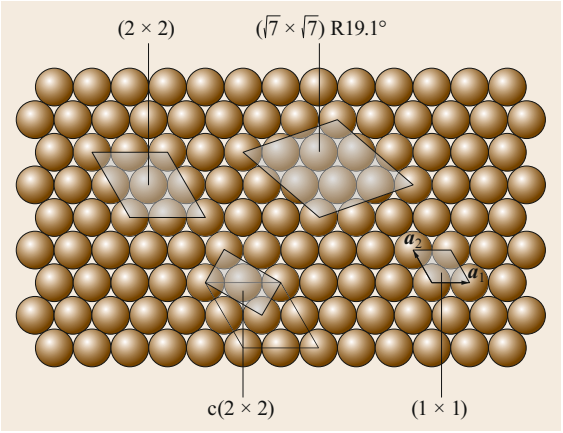

Fig. 4.15 Examples of Wood's notation at the {111} surface of a face-centered cubic material, with the relevant primitive lattice vectors (and corresponding primitive unit cell) of the unreconstructed clean surface shown for reference

a simple scaling and/or rotation of the ideal surface's primitive unit cell; and secondly, that the definition of the ideal surface's primitive unit cell is, in itself, not well defined. The first problem may be addressed by adopting the so-called matrix notation described in the next subsection, but the second is fundamentally an issue for *both* notational approaches. Unfortunately, although some attempts have been made to standardize the choice of primitive unit cells, none of these have yet been universally adopted within the surface science community. We shall discuss the matter further below, but for the moment it is worth emphasizing that neither notational scheme is adequate to describe the periodicity of surface superstructures unless the choice of primitive lattice vectors for the ideal surface is first explicitly defined.

4.7.2 Matrix Notation

As alluded to above, one can readily conceive of surface superstructures whose periodicity cannot be represented as a simple scaling and/or rotation of the ideal surface's lattice. In these cases, Wood's notation proves inadequate, and the more general matrix notation must be adopted. Here, the primitive lattice vectors of the superstructure, which we shall denote $\boldsymbol{a}'_1$ and $\boldsymbol{a}'_2$, are written in terms of those defining the ideal surface lattice, denoted $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$, by means of a matrix multiplication. Thus,

$$\begin{pmatrix} \boldsymbol{a}'_1 \\ \boldsymbol{a}'_2 \end{pmatrix} = \begin{pmatrix} m_{11} & m_{12} \\ m_{21} & m_{22} \end{pmatrix} \begin{pmatrix} \boldsymbol{a}_1 \\ \boldsymbol{a}_2 \end{pmatrix} \tag{4.18}$$

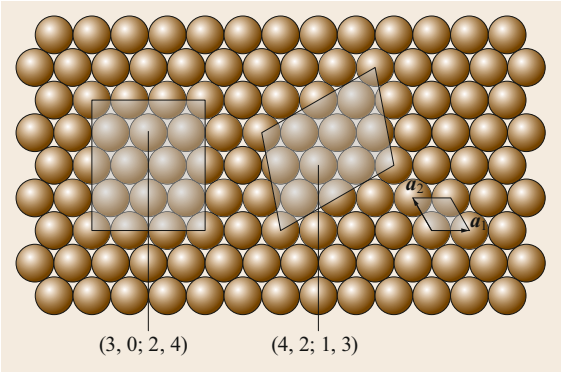

Fig. 4.16 Examples of matrix notation at the {111} surface of a face-centered cubic material, with the relevant primitive lattice vectors (and corresponding primitive unit cell) of the unreconstructed clean surface shown for reference

with integer matrix coefficients. The superstructure may then conveniently be referred to by the in-line form of the matrix, i.e., $(m_{11}, m_{12}; m_{21}, m_{22})$. Examples are shown in Fig. 4.16.

Just as Wood's notation provided a simple check on the area of the superstructure's primitive unit cell, relative to that of the unreconstructed clean surface, so the determinant of the matrix (i.e., $m_{11}m_{22} - m_{12}m_{21}$) performs the same function here, or rather its magnitude does; the *sign* of the determinant indicates whether the trio of vectors $\boldsymbol{a}'_1$, $\boldsymbol{a}'_2$ and $\hat{\boldsymbol{n}}$ form a coordinate system whose handedness matches (positive) or opposes (negative) that adopted for the $\boldsymbol{a}_1$, $\boldsymbol{a}_2$ and $\hat{\boldsymbol{n}}$ vectors.

4.8 On the Choice of the (1×1) Cell

Since both notational schemes discussed above define superstructure periodicity relative to that of the unreconstructed clean surface, it is clear that they each become meaningless when there remains any doubt as to how that reference periodicity is defined. Specifically, different choices for the primitive (1×1) unit cell of the unreconstructed clean surface will, in general, yield different notations for the same superstructure periodicity, and indeed different superstructure periodicities for the same notation. Figure 4.17, for example, shows three different potential choices for the (1×1) cell of a surface having a rectangular two-dimensional Brillouin zone, each of which yields differently shaped cells corresponding to (1×2) periodicity in Wood's notation. Similar ambiguity also arises in matrix notation, for precisely the same reason.

Unsurprisingly, surface scientists have adopted a number of (largely unspoken) conventions when choosing the (1×1) cell, in order that some degree of agreement between different workers may generally be anticipated. In cases with square, triangular and rectangular lattices, for example, such cells are almost invariably chosen to reflect the maximum possible symmetry, as per Fig. 4.5 and the associated discussion. Sadly the same cannot always be said of cases with rhombic lattices, where symmetry is often ignored in choosing the reference cell. For rectangular cells, the standard choice is that $\boldsymbol{a}_1$ should be shorter than $\boldsymbol{a}_2$, while for nonorthogonal cells (of the triangular, rhombic or oblique lattices) the angle between $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$ is chosen to be obtuse. Finally, the trio of vectors $\boldsymbol{a}_1$, $\boldsymbol{a}_2$ and $\hat{\boldsymbol{n}}$ is most often chosen to form a right-handed set of axes. Widespread adherence to these conventions eliminates much confusion, but it should be stressed that it is certainly best practice to explicitly state the choice of reference cell and the disposition of the

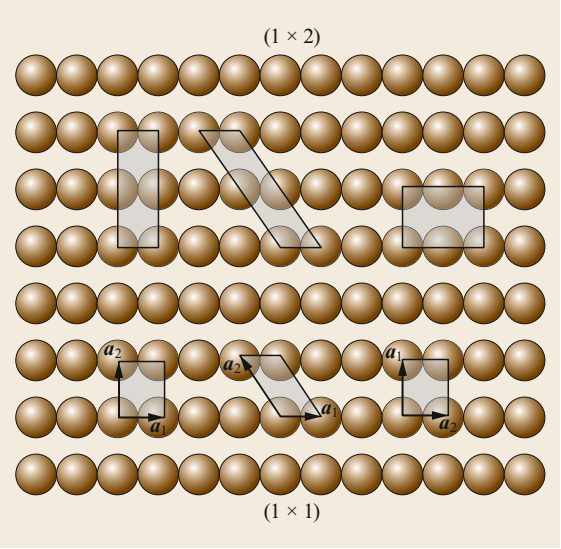

Fig. 4.17 Illustrating the ambiguity of notation when different choices are made for the (1×1) unit cell, in the case of a face-centered cubic {110} surface (only top-layer atoms depicted, for clarity). Each of the superstructure cells can be described as having (2×1) periodicity, relative to the (1×1) cells shown beneath

associated primitive lattices vectors whenever any doubt may arise.

It is worth mentioning, at this point, that these conventions do break down somewhat when dealing with chiral surfaces. Here, it is not always possible to satisfy the requirements pertaining to the length of, and angle between, the primitive lattice vectors, whilst also retaining a right-handed coordinate system with the surface normal vector. It seems to the present author that adoption of a left-handed coordinate system for surfaces bearing the chirality label *S* (or L) would avoid this problem, with a right-handed system used for those bearing the chirality label *R* (or D) and as a default for those surfaces that are achiral. This is not, however, standard practice. Nevertheless, it is true that attempts have been made to promote standard conventions to deal with these problematic cases and to resolve any possible ambiguities that may remain. One proposal, originating with *Barlow* and *Raval* [4.14], turned out not to resolve fully all possible ambiguous situations, but a more recent scheme, proposed by *Merz* and *Ernst* [4.15], does appear to be watertight; nonetheless, neither proposal has garnered sufficient support to be considered settled, and scope for proposal of alternative conventions remains.

Stephen J. Jenkins is Professor of Physical & Computational Surface Chemistry at the University of Cambridge, where he conducts research within the Department of Chemistry. His core interests include the dynamics of surface processes, hydrogen- and/or halogen-bonded overlayers, and the manifestation of chirality at surfaces. His book on the latter topic was published by Wiley in 2018.

5. Ab Initio Simulations of Semiconductor Surfaces and Interfaces

Arrigo Calzolari, Giancarlo Cicero, Alessandra Catellani

Calculations of the electronic properties of solids and surfaces span years of research activity and have produced an enormous amount of publications over the last decades. However, only recently have quantum simulations reached the degree of accuracy to be predictable against experimental data, and this is particularly true for systems with reduced periodicity, such as surfaces, interfaces, and nanostructures. In this review, we present a survey about the characterization of low-dimensional semiconductor-based systems by ab initio density functional methods and compare them with the experimental data available.

Several computational issues afflict the description of the different systems; we will not enter into the details of the theoretical approach and of the very many refinements, which cover a broad chapter by themselves. Rather, a discriminating analysis of the single computational protocols to describe and complement specific experimental problems is presented. Prototypical examples that can be considered as templates for the specific problem, with particular emphasis on surface and interface effects, will be addressed.

5.1 Overview

The ability to manipulate semiconductor surfaces and interfaces has gained significant attention in the past few years, in particular to design novel routes for the development of sensors and new materials, like smart tissues for biophysics applications, but also nanostructures with tailored electronic and optical properties that can be used for enhanced data control and communications or optical filters and intelligent (meta)materials. Most efforts could be avoided if predictive tools in the design were available. We are, thus, interested in a predictive theory of solids. Although no single theory exists that gives all observables for every material or issue, a suitable combination of different approximations and approaches allows us to characterize the electronic properties of solids and related phenomena, such as surface reconstruction, surface reactivity, chemisorption, polarization, etc.

Here, we stick to simulations based on ab initio density functional theory (DFT) [5.1, 2] and we emphasize the essential approximations and point out successes and failures with the aid of selected prototypical examples. DFT is the most popular, robust, and successful theory for the description of the ground-state properties of solids, including surfaces and nanostructures; it provides a solid methodology that can be rather simply implemented, with controlled accuracy, and the codes can be usually sophisticatedly tuned and optimized for the specific hardware parallel architecture, so as to de-

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-46906-1_5

scribe complex problems with hundreds of atoms and thousands of electrons. Furthermore, implementations of hybrid functionals [5.3] or Hubbard corrections [5.4–6] allow us to study the effects of a strongly correlated electron gas, which are difficult to describe in the pure, in principle exact, DFT formulation, based on a nearly homogeneous electron-gas treatment of the electron density, without severe trade-offs in computational cost.

In this review, by capitalizing on our experience in this field, we will show the capabilities of first principles approaches in studying complex physical effects (e.g., reconstruction, molecular adsorption, chemical and optical sensitization, wettability, mechanical response, etc.) that take place at the surface and interfaces of semiconductors. To this aim, we present a few selected examples—taken from our own group's results, with no presumption of completeness—with an eye to the final application. Besides the description of the physical aspects of the single presented scientific cases, we will focus on the main advantages and challenges of ab initio techniques in treating such realistic systems and how the simulated results can be compared with experimental data.

The work is organized as follows: In Sect. 5.2 we briefly revise the main computational approach that is generally adopted as the standard frame for these sorts of simulations; Sections 5.3 and 5.4 are devoted to the study of surface functionalization, with particular emphasis on the description of photovoltaic, bio, and gas sensing applications; a route to engineering nanocantilevers via a suitable control of the surface chemistry of the substrate is provided. Section 5.5 is devoted to the study of bulk interfaces between semiconductors, or metals and semiconductors, such as those required to obtain contacts; here we stick to a wide-gap metal oxide, zinc oxide (ZnO), whose popularity is rapidly increasing as its optoelectronic properties can be suitably modified to find applications in a wide frequency range of operation, from IR plasmonics (with metal doping) up to UV devices. Water being ubiquitous, one may wonder how the interaction with liquid or molecular water can alter the surface properties, and how these effects can be theoretically described; we conclude this review by describing in Sect. 5.6 the water/surface interaction in two specific cases: a semiconductor, namely silicon carbide (SiC) and a metal (gold) substrate.

5.2 Theoretical Framework

This paper is devoted to the ab initio study of semiconductor surfaces and interfaces.

In general, solid-state DFT codes take advantage of periodic boundary conditions. The loss of translational symmetry perpendicular to the surface/interface can be accounted for within the supercell approach, i.e., by a periodic repetition of supercells along the surface perpendicular direction. The supercell contains a sufficiently thick slab of substrate layers and a thick vacuum spacer that separates the material slabs in neighboring supercells to electronically decouple them from one another. Indeed, although creating a surface generally involves local changes that vanish within few layers, recovery of bulk behavior in the inner part of the slab is mandatory, both from a numerical point of view, as a test, and also to prevent interaction of surfaces across the slab itself. We describe this situation in Fig. 5.1, where we schematize the oscillating behavior of dipoles in a polar compound, ZnO: at least three bilayers (L1) are required to damp oscillations and recover the bulk dipole value. Similarly, a reconstructed surface, with reduced two-dimensional (2-D) periodicity (Fig. 5.2), or impinging molecules on the surface, impose the minimum value of lateral cell size (L2, Fig. 5.1c). This means that the bulk and vacuum depths are chosen as at least twice a specific decay length, which is characteristic of the property to be analyzed. This length, in turn, defines the number of layers to be included to regain bulk behavior (L1 in Fig. 5.1) and/or the number of unit cell replicas in the surface plane to have noninteracting adsorbates in the surface plane (L2 in Fig. 5.1). In order to improve efficiency and convergence, symmetric slabs are generally preferred [5.7]. This is, however, not a strong requirement, and sometimes asymmetric slabs are considered, with one surface possibly *passivated* by hydrogen atoms.

Depending on the actual code, special k-points [5.9] are eventually used for Brillouin zone summations. If this is not possible, as in the case of ab-initio molecular dynamics (AIMD) [5.10–12], where better performances are obtained by sampling only the Γ point of the supercell, a large enough number of atoms per layer should be considered, in order to sample the surface unit cell; in this latter case, typical calculations are done with few (e.g., four) replicas of the number of atoms/layer necessary to describe the surface reconstruction [5.13–15]. This is, thus, equivalent to considering a set of some (accordingly $\simeq 4$ for the example above) symmetry points sampling.

Although not an explicit requirement, in general the interaction between electrons and ionic cores is evaluated via pseudopotentials [5.16], which allow us to use a reduced number of basis functions than that which would be required to describe the rapidly oscillating atomic-like core wavefunctions. Generally,

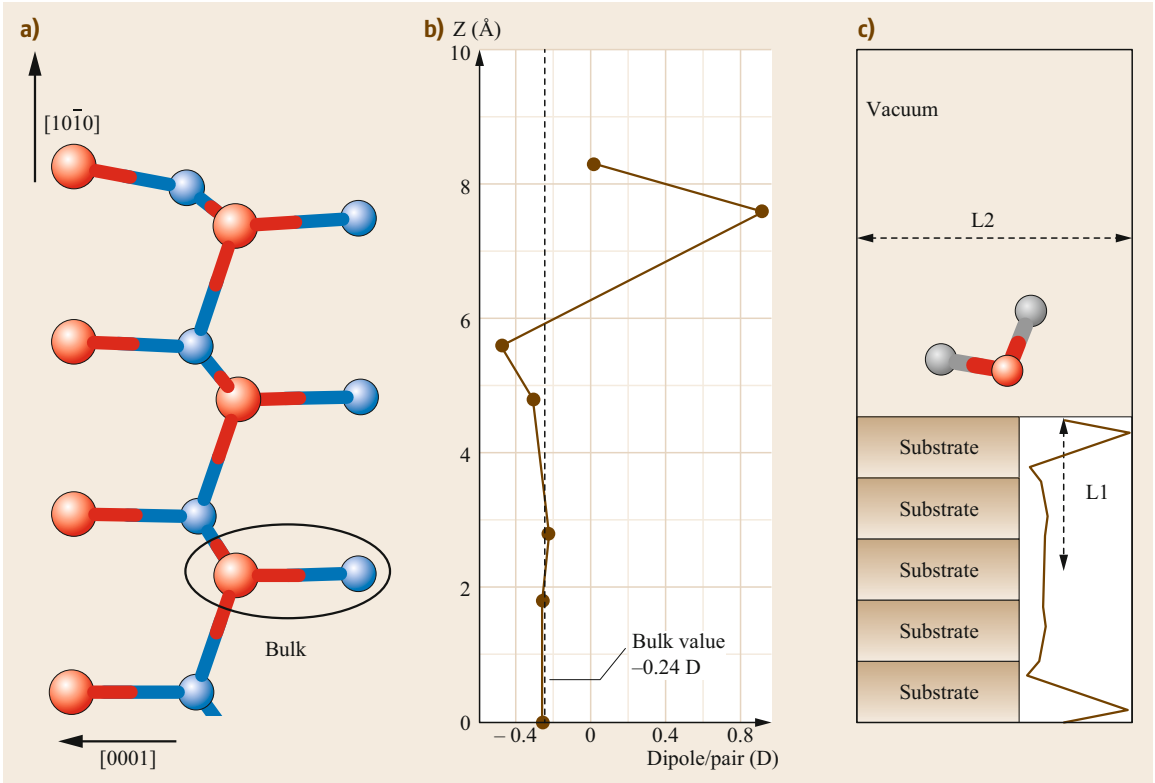

Fig. 5.1a–c Defining the optimal lengths for a supercell. **(a,b)** The size of the slab portion must be large enough to reproduce bulk values: here the local dipole values at the surface and underlayer are remarkably different from the bulk one and several (at least 3–4) bilayers are required to reproduce the bulk value and allow defining the polarization of a ZnO surface [5.8]. **(c)** A sketch of the final supercell, namely the minimal unit that will be used. A different example useful to define lengths in the surface plane is offered instead, e.g., in Fig. 5.2. (Adapted with permission from [5.8]. Copyright (2009) by the American Physical Society)

a plane wave expansion of the electronic wavefunctions and charge density is implemented. Accurate state-of-the-art calculations have also been performed, however, with Gaussian basis sets [5.17]. Alternatively, all-electron description are sometimes used [5.18]; in this case, however, the system size (i.e., number of atoms) that can be numerically treated is much smaller. Whenever possible, we adopt ultrasoft pseudopotentials [5.19], which may contain computational costs, further reducing the cutoff energy of plane waves in the charge density and wavefunction expansion, without a severe compromise in the description of the electronic properties of the system. In most cases, we describe the electronic structure at the PBE-GGA (Perdew–Burke–Ernzerhof generalized gradient approximation) [5.20] level of approximation for the exchange and correlation functional, V_{xc}. This parametrization was proved to be an accurate tool, more suited to describe broken bonds and rehybridization [5.21–23].

Being a ground-state theory, DFT will, in general, fail in describing energy gaps, optical transitions, but also weakly bonded or strongly correlated systems. While band gap underestimation is usually recovered by merely applying a scissor operator for simple systems, different approximations have been developed to cure more complex problems (e.g., hybrid functionals, *GW*, etc.). Various semiempirical schemes have been implemented to include weak van der Waals forces, dispersive interactions relevant in physisorption and closed shell systems [5.26]; here, a few examples of this sort of approximation are discussed to describe the wettability of a gold surface [5.27] and the functionalization of a SiC surface with benzene and porphyrin [5.28]. A different problem where DFT will eventually fail is the description of strongly correlated electron systems, where both delocalized s and p states must be treated along with highly localized atomic-like d/f states, such as in the cases presented here for Zn compounds. Among the different schemes imple-

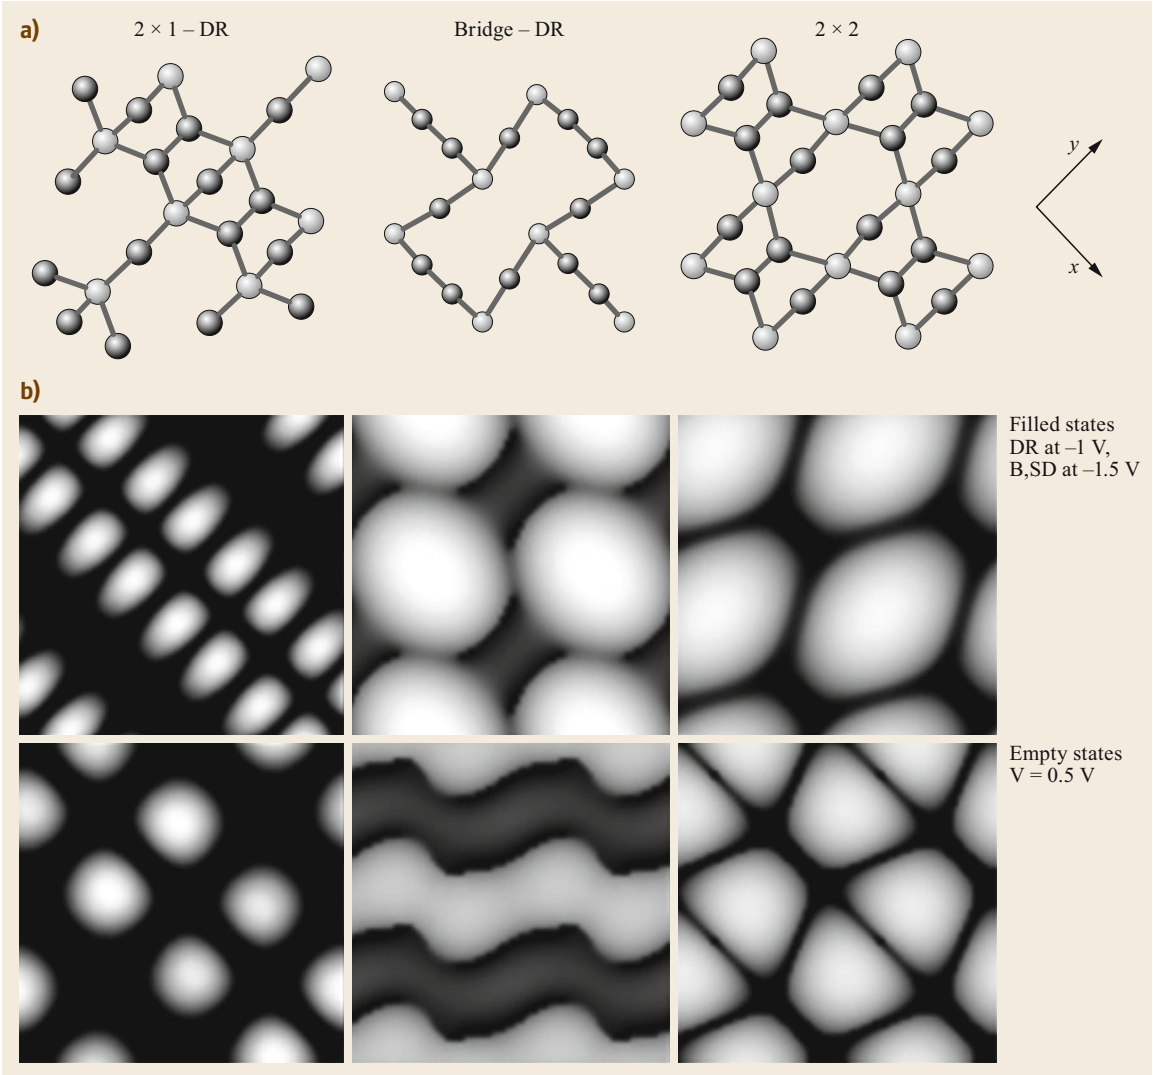

Fig. 5.2a,b An example of different predicted surface reconstructions for the carbon-terminated (001) stoichiometric surface of cubic SiC [5.14]. **(a)** Panels reproduce the atomic geometry of the two outermost layers: *black* (*gray*) *dots* represent C (Si) atoms. The strong atomic rearrangement for each different reconstruction is evident and reveals the reduced two-dimensional periodicity associated with the reconstruction, with respect to the original bulk face centered cubic (fcc) plane. Below each panel, the corresponding predicted STM images [5.24] for filled and empty states are reproduced **(b)**, which allow us to recognize at a glance the original surface reconstruction. Note that different preparation methods can lead to one or the other configuration, as well as different choices of the exchange-correlation functional (V_{xc}) will stabilize a different reconstruction [5.14]. However, extremely clean experimental conditions and refined V_{xc} will lead to the same optimal Bridge geometry, in agreement with [5.25]. Results are in agreement with a number of experimental investigations on both C and Si-terminated surfaces ([5.14] and references therein). (Reprinted with permission from [5.14]. Copyright (1996) by the American Physical Society)

mented, we choose to correct the DFT band structure including a Coulomb repulsion term U as a Hubbard-like correction, as described in [5.5, 29, 30]. This approach is relatively simple to implement and computationally cheap.

Upon relaxation of all the degrees of freedom, namely all ionic and electronics coordinates, up to a desired convergence level (on Hellman–Feynman forces and total energy) a ground-state electronic and geometrical structure is obtained. This rather simple protocol

allows us to obtain the correct crystal structure as the lowest energy configuration, bond lengths, bulk moduli, and so on, are accurate within a few percent with respect to experiments. This leads to information such as:

- Surface reconstruction or relaxation
- Presence of surface states, as induced by broken/wrong bonds at variance with the bulk ones
- Energetics, electronics, and structural properties of different adsorbates in the case of surface functionalization
- Schottky barriers and band offsets in the case of heterojunctions

More refined information that requires higher convergence levels can lead to phonon dispersions, elastic constants for the surface, and polarization decay, to quote only few examples. This frame, as implemented in the Quantum ESPRESSO package [5.31], is the standard along which we obtain our results, as described below.

Some definitions that are generally used when dealing with simulations of surfaces and interfaces will be given in the sections where they are addressed.

5.2.1 Surface Relaxation and Reconstruction

Creating a surface by truncating a bulk is accompanied by formation of highly energetic, charged, and unstable dangling bonds. In order to reduce the free energy, atoms in the outermost layers will be subjected to rearrangements, which are more relevant the higher the number of dangling bonds created per atom, the polarity and directionality of the bond in the compound and the surface direction. Metals and nonpolar surfaces of semiconductors generally present a simple relaxation, that is, a tiny rearrangement of surface layers, with small adjustments in the coordinates perpendicular to the surface plane, with no change in surface periodicity. This is what occurs for the nonpolar surface of SiC and ZnO, which will be subject of the following sections. On the other hand, a cut along polar directions of directional bonds promotes large geometric rearrangements and bond rehybridization possibly accompanied by the presence of surface states in the pristine bulk band gap of the material; this is the case for cubic and hexagonal SiC, as described below. An example of surface reconstruction of cubic SiC to create a (001) surface is presented in Fig. 5.2.

Among several possible choices to illustrate the methodology described above and the role of surface reconstruction, we choose as an example the first principles simulation of cubic silicon carbide (β-SiC) growth [5.15, 32].

Silicon carbide (SiC) is a unique compound semiconductor, with appealing properties for high-power electronics and biological sensors. The material appears in nature in a number of tetrahedral polytypes [5.32–35], thus the potential energy surface which determines the relative stability of these different bulk phases has several almost degenerate local minima; the largest difference of only few meV occurs between the zincblende 3C (*ABC* stacking sequence) and the wurtzite lattice 2H (*AB* stacking sequence), which is characterized by a reduced symmetry compatible with a spontaneous polarization field that lowers the formation energy with respect to the more symmetric zincblende phase [5.35, 36], optimizing the internal atomic coordinates in the unit cell. The two crystal structures are identical up to third neighbors. The polytypes, however, sensibly differ in (opto)electronic properties, e.g., the electron mobility of the 6H polytype is less than half the cubic one [5.33]. Thus, particular attention must be paid to convergence tests, k-point sampling, and the accuracy of the pseudopotential and exchange correlation functional adopted [5.7, 21, 32].

SiC Growth

In order to provide some basic understanding of experimental studies about homoepitaxy of SiC [5.37], we proposed an ab initio simulation of the initial stages of β-SiC(111) growth which highlights the role of surface reconstruction of the underlying SiC substrate [5.38]. The SiC(111) surface presents a hexagonal lattice, with C_{3v} symmetry, and is thus fully compatible with the surfaces of both zincblende and wurtzite lattices, along the polar direction. Furthermore, experimental results [5.39] revealed that a cubic phase is grown by homoepitaxy on the Si-terminated $(\sqrt{3}\times\sqrt{3})$ SiC(0001) polar surface, despite the hexagonal topology of the underlying substrate. If this were to be confirmed by independent theoretical or experimental analysis, it could be argued that a surface-controlled growth procedure may affect the stacking sequence of the grown material, favoring one polytype among all the others when performing homoepitaxy of SiC. This information would be relevant from the technological point of view, since it would open the possibility to determine the stacking of newly attached bilayers, and thus the optoelectronic properties of the compound. From the fundamental point of view it would also assign a leading role to the surface properties, like order, stoichiometry, energetics to control formation, and order of adlayers. With this in mind, our simulation was performed in a rather large simulation supercell, includ-

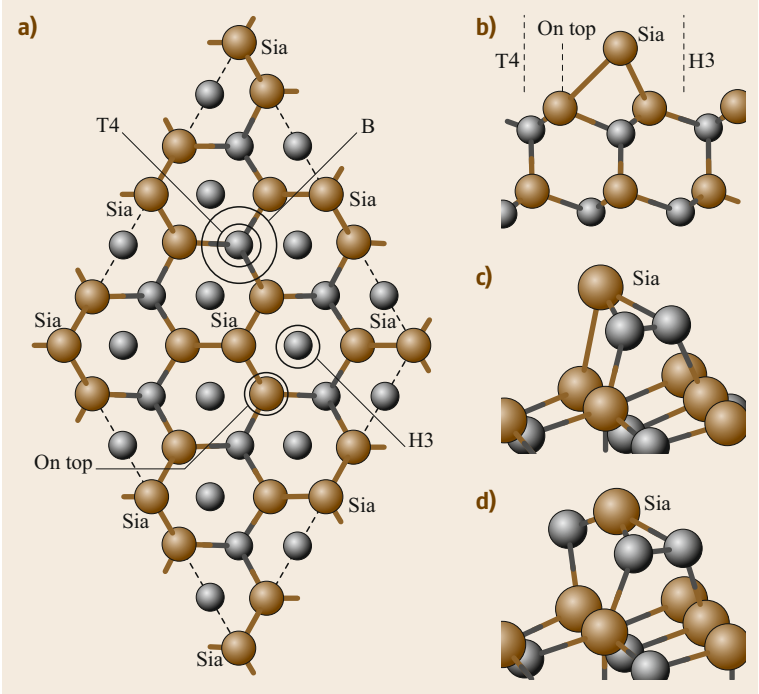

Fig. 5.3a–d The role played by the surface reconstruction. Here we utilize our theoretical prediction to describe the initial stages of a layer-by-layer growth of SiC(111) and predict the diffusion coefficient for C adatoms on the silicon terminated SiC surface. In the theoretical experiment, a C adatom is positioned at the most likely sites upon the Si−SiC(111) surface, and then the whole system is relaxed. The surface reconstruction shapes a multilevel potential energy surface that favors the occupation of the correct sites (on top) for bulk continuation, along with the formation of strong C−Si bonds at the expenses of weaker Si−Si bonds breaking, which restores the local order and layer stoichiometry. (Adapted with permission from [5.15] Copyright (2003) by the American Physical Society)

ing four replicas of the atoms required to describe the surface reconstruction, leading to a $(2\sqrt{3}\times 2\sqrt{3})$ 2-D periodicity; this means 12 atoms per layer, and 4 SiC bilayers (Fig. 5.3). The large in-plane size was chosen with two purposes: (i) At low coverages, it allows for the study of isolated adatoms, avoiding the interaction of an adatom with its periodic replicas; (ii) it provides a reasonable sampling of the $(\sqrt{3}\times\sqrt{3})$ surfaces, when the sole Γ point is included in the Brillouin zone summations. Tests on the cutoff energy of the plane-waves expansion, but also on different choices of V_{xc} were considered [5.32]. First, a fine description of the adsorption sites on the surface was obtained by evaluating the potential energy surface (PES). Then, a nudged elastic band method [5.40] was adopted to compute energy barriers for adatom diffusion, which were then employed in a kinetic Monte Carlo simulation of the growth [5.38]. This allows us to follow the adatom diffusion at realistic growth temperatures and mesoscopic time scales.

Our results showed that the specific stoichiometry of the surface outermost layer and its reconstruction are responsible for the attainment of high-quality films, when suitable growth conditions are selected; the reconstruction geometry is associated with a multivalley PES that models the adatom kinetics and incorporation. The surface reconstruction along with the most favorable adsorption sites for C adatoms, as result from the simulation process, are depicted in Fig. 5.3.

We also identified a further important role played by the surface reconstruction in reducing the adatom mobility on the surface; Si adatoms in the substrate act as nucleation centers for the newly deposited impinging C atoms (Fig. 5.3). This may favor layer-by-layer growth, as observed, e.g., for metallic surfaces. The strong energy gain upon surface stabilization is responsible for the reorganization of disordered atoms into the ordered crystal structure. Our results provide some understanding of processes, such as atomic layer epitaxy, that allow for surface superstructures to be stabilized during growth and for the formation of defect-free layers in SiC homoepitaxy.

Hydrogen at SiC

Another relevant example where a proper description of surface details is mandatory for comparison with the experiment is the study of SiC surface metallization induced by hydrogen adsorption under extremely controlled and clean conditions [5.41, 42]. Recent studies performed both on the theoretical [5.42–45] and the experimental [5.41, 42] side have surprisingly revealed that adsorption of atomic H on one of the possible reconstructions of cubic SiC surfaces (namely the SiC(100)-(3×2)) actually promotes the appearance of surface states (Fig. 5.4), in dramatic contrast with the common experience that surface states are removed (*quenched*) by chemisorbed atoms or molecules. These H-induced dangling bonds result in a nanotunnel open-

ing at the semiconductor subsurface that offer a promising template to capturing atoms or molecules promoting novel nanofunctionalization approaches. Furthermore, depending on H coverage and surface treatment, this can lead to surface metallicity, an important result for the nanofabrication of conducting channels. Such nanotunnels have also been recently predicted for the C-terminated 3C-SiC(001)-c(2×2) surface [5.46].

5.3 Surface/Molecule Interaction

Low-dimensional electronic systems have attracted much interest, because of fundamental problems as well as for technological reasons. Modifying the electronic properties of a material by modifying its surface, either chemically, via adsorption and functionalization reactions, or via geometric patterning, is a possible route to enhance its sensitivity and reactivity to environmental agents. Depending on the specific field of applications, ranging from plasmonics, to photovoltaics, catalysis and (bio)sensors, experimental and theoretical studies of different systems were presented, including self-organized arrays of atomic metal chains [5.47, 48], covalent binding of organic molecules [5.28, 30, 49, 50], and protein docking [5.51–53]. In the following, we discuss some examples devoted to surface functionalization for understanding the role of surface states in charge transfer processes towards photovoltaic (PV) applications in dye-sensitized solar cell (DSSC) design [5.30, 54, 55] and in biosensors [5.28, 56]. Similar concepts, and the same computational frame, help to shed light on other sensing mechanisms, which are described in the subsequent specific sections.

5.3.1 Surface Functionalization

The adsorption of organic molecules on solid substrates is a fundamental step in many important processes and is also becoming an increasingly significant aspect of surface modification in microelectronics and sensing technology. A precise control of the electronic properties of the new system thus obtained could improve versatility and widen applicability in (opto)electronics and sensing [5.57, 58]. Computer simulations based on a quantum-mechanical description of the interactions between adsorbates and the substrate are a fundamental tool to shed light on the intimate nature of the functionalized system; in recent years, these have gained an increasingly important impact on solid-state physics and chemistry and on material science, promoting a deeper understanding, and thus offering a relevant contribution to material design for future technologies.

In particular, a refined description of the electronic properties of the semiconductor substrate in the band gap region, with respect to the distribution of the states of the molecule, provides a rigorous instrument to tailor the optoelectronic properties of the functionalized hybrid system and select suitable ligands.

Catechol at Semiconductor Surfaces

Among the wide-gap semiconductors, oxides are experiencing a renewed interest in different fields because of their stability, high quality, and low production costs [5.30, 59]. ZnO in particular has a wide range of applications, including optoelectronics, plasmonics, nanowire lasers, gas and bio-sensing, catalysis, advanced material for solar cells, and transparent conductors (TC). Indeed, adsorption of molecular dyes can tailor the optical response of the metal oxide, making it photoactive in the visible range and thus useful as photoanodes in dye-sensitized solar cells or contaminant detectors in photocatalytic sensors. The catechol unit (1,2-dihydroxybenzene) has emerged as a very attractive ligand for the functionalization of a wide range of substrates by providing effective, stable, and versatile surface modification, also in wet conditions [5.60]. In particular, catechol is a prototype sensitizer and molecular binder for solar cells. In this sense, catechol on a ZnO surface can be considered as a paradigmatic example.

As both ZnO and catechol exhibit the fundamental transition between edge states in the UV range, in order to understand the sensitization process that enables operation in the visible energy range for the hybrid catechol/ZnO interface, as required for PV cells, the study of the energy level alignment of the functionalized system is mandatory. Indeed, upon adsorption the establishment of molecular levels in the substrate energy gap and the formation of a staggered *type-II* interface are necessary (for a thorough description of band offset and band alignment, see Fig. 5.11). Only this specific band distribution allows for absorption of visible light and separation of electrons and holes across the interface and fast injecting photoelectrons from dye to metal oxide. The formation of a *type-I* interface, could, in principle, be possible, as it happens in the case of similar small molecules (e.g., water, formic acidic) on metal oxide surfaces (e.g., TiO_2, ZnO, MgO) or organic molecules (e.g., benzene, styrene) on Si surfaces. However, only favoring splitting and quick

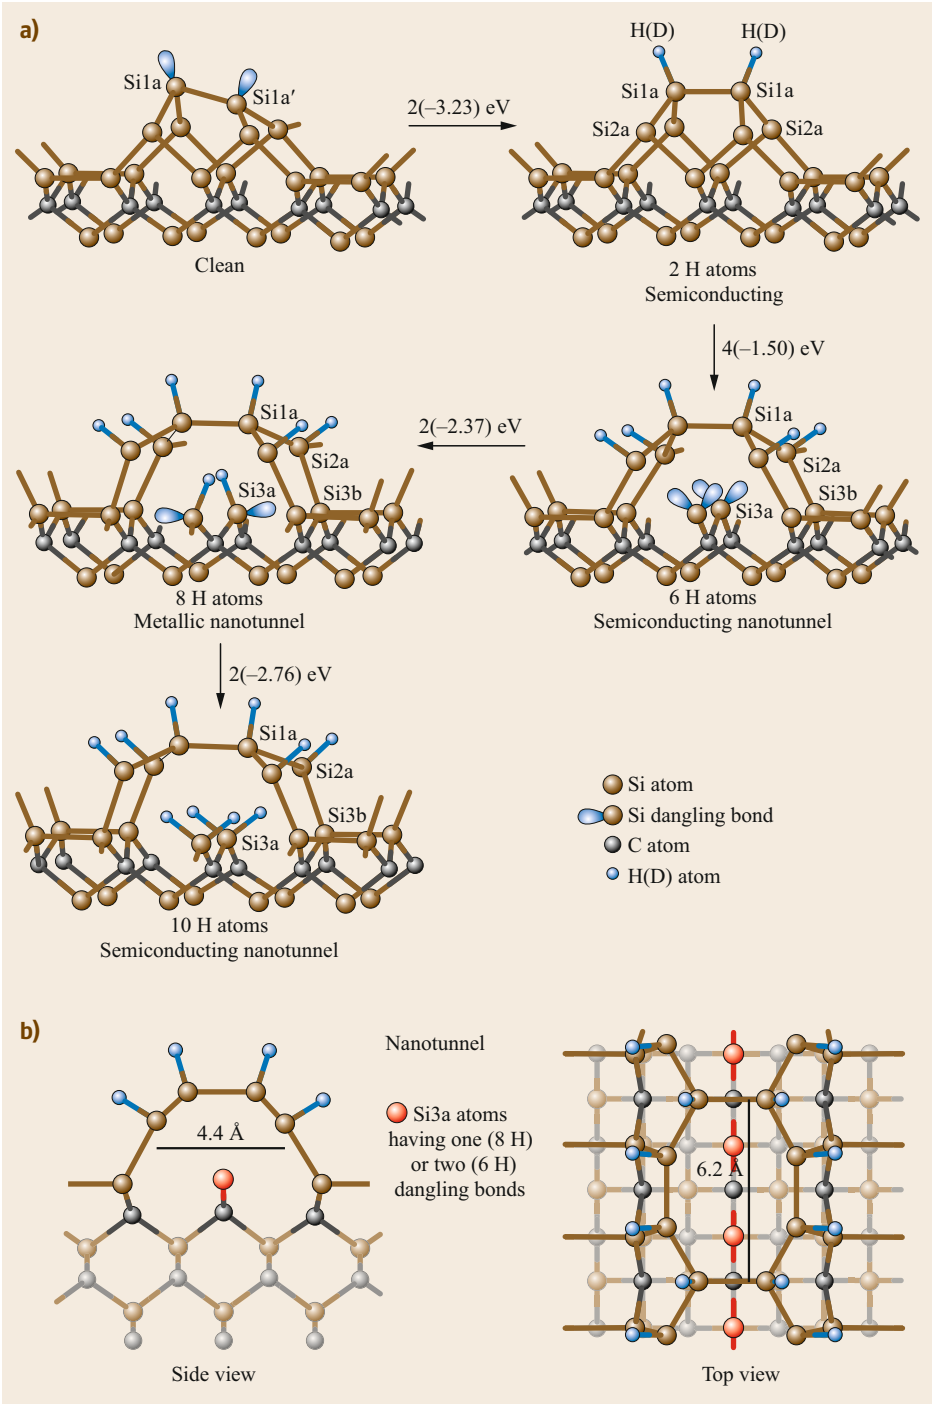

Fig. 5.4a,b Structures of the clean and H/3C-SiC(100)-(3×2) surfaces and views of a nanotunnel. **(a)** The 2H, 6H, 8H, and 10H structures refer to the number of H atoms per surface unit cell. Nanotunnel opening is seen for 6H, 8H and 10H. The energy release per H atom for each step is indicated. Si1a(b), Si2a, and Si3a(b) refer to Si atoms in the first, second, and third plane, respectively. Si dangling bonds are depicted in *blue*. **(b)** The nanotunnel has a size of 6.2 × 4.4 Å (at the level of the second layer). The *red* atoms within the nanotunnel mark Si atoms with one or two dangling bonds corresponding to the 8H (metallic) and 6H (insulating) structures, respectively. (Adapted from [5.42])

charge separation can lead to obtaining charge flow and open-circuit conditions, as required for PV cells.

We have thus studied catechol adsorption on the nonpolar $(10\bar{1}0)$ ZnO surface via ab initio DFT simulations. As it happens for most compound semiconductors [5.59], the acknowledged description of the clean ZnO surface presents ordered rows of buckled dimers lying along the polar (0001) direction, with a net electron accumulation on the exposed oxygen atoms, and no reconstruction but a mere relaxation of the outermost

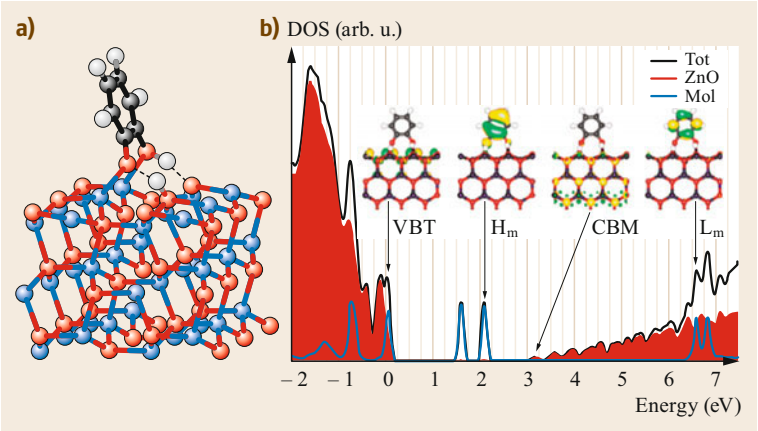

Fig. 5.5a,b Catechol at ZnO. **(a)** Side view of the relaxed atomic structure of catechol adsorbed on ZnO($10\bar{1}0$). **(b)** Portion around the pristine ZnO bandgap of the total DOS (*black line*) and projected contributions on ZnO substrate (*shaded area*) and catechol (*blue line*) for the molecule/surface interface. *Inner panels* show representative single-particle states, at the DFT+U level. The zero of the energy scale is aligned to the top of the valence band (VBT) of the clean ZnO surface. Here, CBM stands for the substrate conduction band minimum, and H_m (L_m) for the catechol highest occupied (lowest unoccupied) molecular orbital. (Reprinted with permission from [5.30]. Copyright 2011 American Chemical Society)

layers [5.30, 61, 62]. On the electronic side, surface relaxation introduces a surface state per dimer at the top of the valence band (VB) in the 2-D band structure, which reduces the gap to 2.9 eV. The bottom of the conduction band (CB) instead maintains its sp bulk-like behavior. It is here relevant to note that to obtain this correct description, in particular of the system band structure around the bandgap, the introduction of specific corrections to V_{xc} are mandatory to cure the fictitiously large hybridization between Zn-3d and O-2p states, induced by the incorrect treatment of correlated d states within DFT. We here chose to use ad hoc Hubbard correction both on d orbitals of Zn ($U = 12.0$ eV) and 2p orbitals of O ($U = 6.5$ eV) [5.63]. This strategy recovers correct bandgap and energy position of d levels (Sect. 5.2).

Our results show that catechol adsorbs on the nonpolar ($10\bar{1}0$)ZnO surface, forming two chemical bonds with the substrate through the hydroxyl terminations of the molecule; namely we observe partial dissociation of these terminations with formation of two Zn−O bonds and two H bonds to the substrate (an H-donating and an accepting one, see Fig. 5.5a). Bond formation induces molecular states in the ZnO bandgap that efficiently reduce the optical gap and allow for an ultrafast dye-to-substrate electron injection (Fig. 5.5). We demonstrate that the origin of this staggered band alignment is due to the specific lone pair interaction between the oxygen atoms along with the aromatic nature of the phenyl ring. Furthermore, taking catechol as the reference structure, we studied how it is possible to modify the interface properties varying the band alignment by inserting different end groups or aromatic rings in the adsorbing molecule [5.30].

This study led us to compare different semiconductor substrates, namely SiC, GaN, InN, CdS, and CdSe [5.59]. We selected wurtzite substrates presenting different ionicities, reactivities, and band properties and concentrated on flat periodic nonpolar ($10\bar{1}0$) surfaces, which are among the most frequently exposed faces in hexagonal nanostructures [5.64]. We demonstrated how the geometrical and electrostatic modifications in the substrate surfaces affect the catechol adsorption and the bonding path; surface effects, such as bond distortion, surface stress and surface states in the bandgap, must be fully taken into account, especially for the most reactive substrates. In particular, for the case of SiC, and only in this case in view of the peculiar indirect gap and bond lengths, we observe a full deprotonation of the impinging catechol, which dissociates when approaching the SiC surface to form tight Si−O bonds with the substrate, while the dissociated H atoms bind to the C atoms of the broken SiC surface dimer, revealing charge transfer and structural reorganization at the interface.

Biosensors: Porphyrin at SiC

A different application that we have considered in view of possible routes for the design of biosensors is the functionalization of SiC surfaces via deposition of aromatic fragments, up to a full porphyrin molecule [5.28].

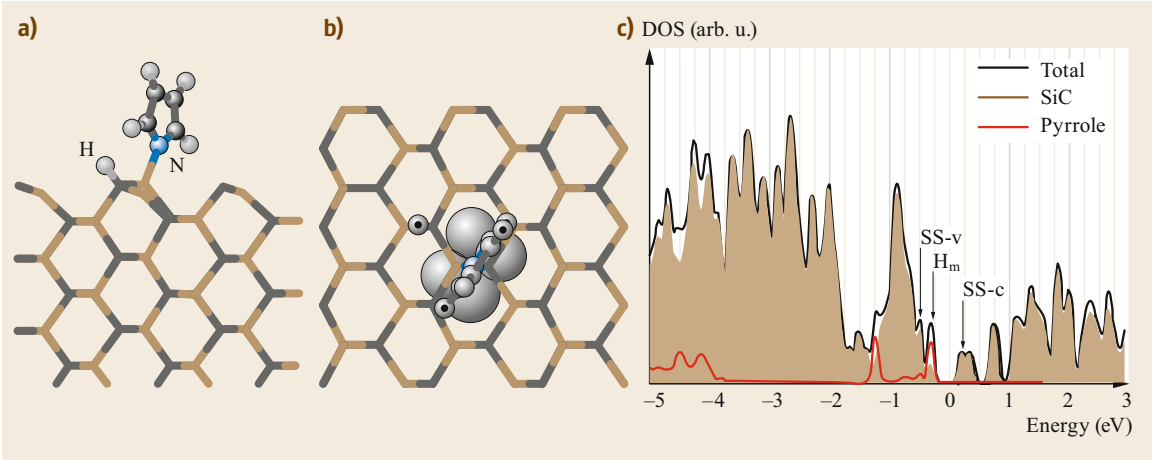

Fig. 5.6a–c Pyrrole on SiC(110) clean surface. **(a)** Side view of functionalized surface. **(b)** Simulated STM image of filled states ($V_{tip} = 0.5\,eV$); here the structural pattern is superimposed to help reading. **(c)** Total and projected density of state. Zero energy is referred to the Fermi level. SS-v and SS-c are, respectively, occupied and empty surface states in the energy gap. (Reprinted with permission from [5.28]. Copyright 2011 American Chemical Society)

The functionalization of SiC surfaces by means of specific organic molecules is strategic for the realization of biosensors based on molecular recognition. However, although they are extensively used, operating devices that adopt macrocycles as functional groups are not easily achievable, mainly because of a poor control on chemical/physical processes occurring at the interface between molecule and substrate. The porphyrin macrocycle itself, beyond offering the interesting characteristic coordination properties of the carbon rings, does not allow for the formation of strong chemical bonds but rather leads to π–π interaction.

Also in this case we studied a nonpolar surface, namely SiC(110) of the cubic polytype. Again, as described before (Sect. 5.2) this can also be representative of hexagonal nonpolar surfaces, since the two crystal structures are equivalent up to third neighbors. Moreover, β-SiC is expected to present better electronic properties than the most common and stable hexagonal phases [5.33]; it is expected to present better biocompatibility [5.56] and it is fully compatible with Si technology. As discussed above, the surface simply relaxes, with Si moving inward, which gives rise to modest ($\simeq 9^\circ$) buckling; correspondingly, the electronic distribution presents one dangling bond per Si and C atoms, respectively [5.7, 17]. The surface can be easily hydroxylated via dissociative adsorption of water molecules, with H atoms bonding to C and −OH groups to Si atoms [5.65].

We demonstrated that among the various fragments considered, only pyrrole can form covalent bonds to the clean β-SiC substrate, with strong modifications of its electronic properties around the Fermi level. This is illustrated in Fig. 5.6, where we report the structural details of the functionalized surface (Fig. 5.6a), along with the corresponding density of states in the bandgap region that presents several charge transfer states induced by molecular dissociation and bonding to the surface (Fig. 5.6c). A simulated STM image for the filled state is also reproduced [5.13, 24].

Benzene, fluorinated-benzene and the full porphyrin do not chemically bind to SiC, even including London corrections [5.26] in the exchange correlation potential to account for van der Waals interactions. Furthermore, a comparative study of absorption on the hydroxylated SiC surface reveals minor modifications to the present picture, in view of the increased inertness of the surface that impedes bond formation. Similarly, first principles molecular dynamics at finite temperature reveals that the impinging molecules float over the surface, without drastic inter-unit bending distortions that would allow to expose reactive units to the substrate and favor bonding. Our results thus rule out the possibility of forming stable hybrids obtained via porphyrin adsorption on the clean SiC(110), as observed for other wide-gap materials such as TiO_2 [5.66]. Modification of the surface may, however, take advantage of grafting through pyrrole groups, as linker for further functionalization.

5.4 DFT for Sensing

A deep understanding of the sensing mechanism is often required to improve the sensor efficiency in terms of sensitivity and selectivity and to further engineer the sensing element for tailored applications. Surfaces of materials are often involved in the sensing mechanism, although the actual role played by the surfaces is not always known in detail. DFT studies have been employed to unravel the role of surfaces in determining the sensing mechanism of different types of sensors. In the following, we will comment on two theoretical key studies based on DFT calculations that were recently reported in the literature. The first study is related to understanding the effect of surface functionalization on the mechanical properties of vibrating cantilevers, often employed as mechanical sensors. The second study regards the study of the mechanism leading to gas sensing in ZnO nanostructures and, in particular, focuses on understanding the origin of the changes in the electrical properties of the nanostructures upon interaction with gases.

5.4.1 Mechanical Properties of Functionalized Silicon Surfaces

Introduction to Cantilever-Based Detection Mechanism

The ability to realize micro and nanoelectronics with controlled dimensions and tailored surface chemistry has opened up the opportunity to create hybrid devices exploiting the properties and features of both organic and inorganic materials. One of the most promising approaches consists of combining organic materials with more conventional semiconductors, like silicon, with the aim of engineering semiconductor surfaces to induce specific properties useful for a given sensing application. In particular, in the last decades, microcantilever-based sensors have gained large attention since they can be employed to detect specific molecules with a very high sensitivity. When the surface of a beam comes into contact with an analyte, it responds with a mechanical transduction signal directly related to the concentration of the molecule in the environment. The mechanism on which these kinds of sensors are based is the following: upon interaction of the analyte with the surface of the cantilever that has been chemically modified, the surface stress varies and, as a consequence, the cantilever bends; correspondingly, the resonance frequency of the beam changes. The amount of bending (static detection mode) and the change in resonance frequency (dynamical detection mode) following molecule/surface interaction can be measured with high accuracy and can be related to the amount of the adsorbed species (Fig. 5.7).

Although many cantilever sensors exploit adsorption induced bending, the transduction detection based on resonance frequency shifts can potentially provide ultimate sensitivity for unravelling the presence of a single molecule on the cantilever surface [5.67]. The resonance frequency of a beam depends on the effective spring constant, K, and on the effective mass, m^*, of the cantilever as follows: $f = 1/(2\pi)\sqrt{K/m^*}$. Upon attachment of an analyte to the cantilever surface the observed frequency shift, Δf, depends both on change of the adsorbed mass (variation of m^*) and on variations of the surface elastic constants (variation of K). As such, performing an accurate quantitative analysis of the analyte concentration would require knowledge of the amount of the shift which can be ascribed to the change in m^* and which to the change in K. Unfortunately, this estimate is not easily achieved and, during experimental analysis, the frequency shift is usually fully ascribed to absorbed mass leading to an overestimation of the detected amount of analyte. Ab initio atomistic simulations provide a powerful predictive tool to access these quantities as detailed in the following.

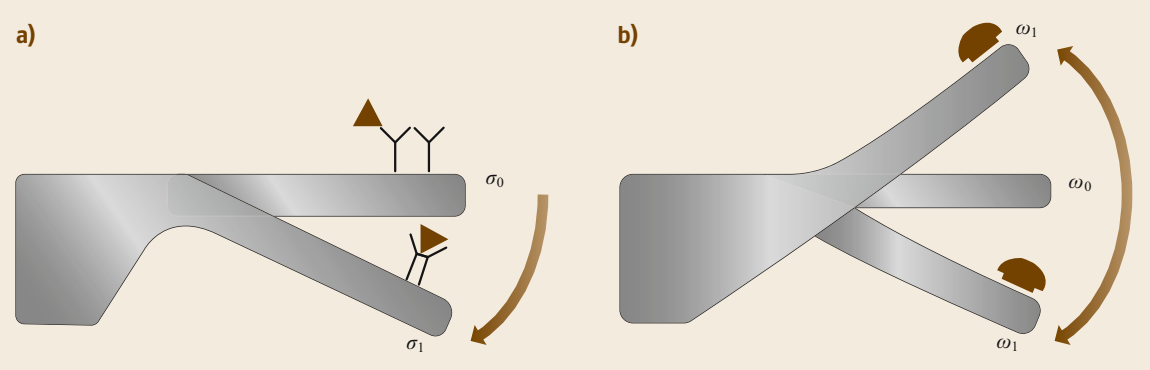

Fig. 5.7a,b Cantilever sensor operation in the static deflection mode **(a)** and in the dynamic resonant frequency mode **(b)**

Calculations of Surface Strain and Surface Elastic Constants

Both surface stress and surface elastic constants can be calculated with high accuracy by employing first principles simulations. For a given material surface, simulated with a finite slab of atomic layers, surface stresses, σ_i^{surf}, can be estimated by computing the stress tensor of the simulation supercell, σ_i^{bulk}. This is done, within ab initio calculations by applying the Nielson–Martin stress theorem [5.68], according to which the stress can be expressed as a functional of the ground-state density. In particular, the above-mentioned two quantities are linked through the equation

$$\sigma_i^{\text{surf}} = \frac{1}{2}\sigma_i^{\text{bulk}} c \,, \tag{5.1}$$

where c is the length of the supercell along the surface normal, and the coefficient $1/2$ takes into account the presence of two equivalent surfaces in a slab calculation. As pointed out in [5.69], the stress values estimated at a given plane waves' energy cutoff have to be corrected because of a fictitious stress contribution arising from the use of a finite basis set.

The surface elastic constants of a given material can, instead, be calculated by exploiting the relationship between the second-order derivative of the energy of the system (E^{Tot}) and the strain, ϵ_i, imposed on the slab

$$\left.\frac{\partial^2 E^{\text{Tot}}}{\partial\epsilon_i \partial\epsilon_j}\right|_{\epsilon=0} = V_0 D_{ij} \,. \tag{5.2}$$

In this equation, D_{ij} represents the plate (slab) elastic response when an axial strain is applied along one of the surface primitive cell directions, while V_0 is the slab equilibrium volume. The elastic response is usually divided in two contributions [5.70]: one arises from the inner atomic layers and is related to the *bulk-like* response of the system, and the other is associated to the two identical surfaces corresponding to the outer atomic layers. Within this approach, (5.2) can be rewritten as

$$V_0 D_{ij} = 2A_0 S_{ij} + V_0 C'_{ij} \,, \tag{5.3}$$

where the above-mentioned contributions are explicitly represented by the surface elastic constants, S_{ij}, and the bulk elastic constants C'_{ij}; A_0 is the equilibrium surface area. The bulk term also takes into account that, once strained along a surface direction, a material plate is free to contract in the direction perpendicular to the surface. We recall that, if S_{ii} (with $i = j$) yields positive values, the surface layer is mechanically stiffer than the inner bulk layers, while negative values would indicate that surface bond breaking gives rise to local bond weakening and, correspondingly, to softer surfaces. On the other hand, negative S_{ij} (with $i \neq j$) values correspond to a softening of the surface and imply that the surface stress in the i direction has an opposite behavior with respect to the j surface stress component, similarly to a negative Poisson's ratio in the case of a bulk system; positive S_{ij} can be thought as the equivalent of a positive Poisson's ratio in a bulk material.

Mechanical Properties of Propyl–Urea Functionalized Silicon Surfaces

The method described above has been employed to predict the mechanical properties on Si(111) surface functionalized with propyl-urea molecules [5.71]. Such molecules have been chosen because they are able to form intermolecular hydrogen bonds and thus give rise to stiffer and more stable self-assembled monolayers (SAM). This feature would not only render a device more durable in time but would also increase the performance of a sensor. Indeed, in micro and nanomechanical resonators with surfaces functionalizated able to respond to specific chemical stimuli, larger values of the surface elastic constant imply larger resonance frequencies and, thus, larger sensitivity [5.72]. Moreover, the study of a propyl-urea SAM was proposed as a test case to tailor surface properties by changing the lateral intermolecular interactions.

The structure of the propyl-urea SAM on the Si(111) was predicted by employing DFT calculations by taking into account the ability of propyl-urea to form periodic H-bonded chains and considering the periodicity of the silicon(111) surface [5.73]. Several SAM configurations were initially built trying to maximize the intermolecular H-bond interaction by at the same time keeping the periodicity constraints imposed by the surface binding sites. It was found that propyl-urea can form stable SAM at the Si surface at a maximum coverage of half of a monolayer. Larger coverage would give rise to endothermic hydrosilation reaction. Indeed, at high coverages, the molecules in the SAM would be too densely packed and would repel each other, yielding positive formation and cohesive (about 1 eV) energies. The most favorable Si(111)/propyl-urea structure is represented in Fig. 5.8. In this configuration, H-bonded molecular chains form at the surface, as indicated by the dashed lines. The H bonds are optimized along the molecular chains and, consequently, the molecules are folded with respect to the axis perpendicular to the surface. In particular, each propyl-urea molecule forms two kinds of H bonds (2.06 and 2.22 Å long) responsible for a quite large SAM cohesive energy of $-0.44\,\text{eV/molecule}$.

The surface stress of the functionalized surface has one tensile component, $\sigma_1 = 0.89\,\text{J/m}^2$, along the

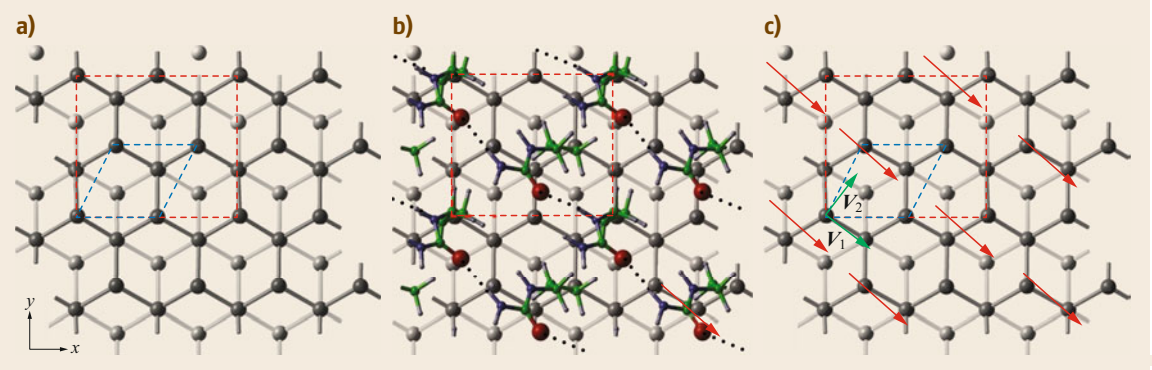

Fig. 5.8a–c Ball and stick representation (*top view*) of the clean **(a)** and propyl-urea functionalized **(b,c)** Si(111) surfaces. The *darker gray balls* correspond to Si atoms of the outermost layer, the *lighter gray* to Si atoms of the inner layers. *Red balls* represent O atoms, *green ones* C atoms, *blue ones* N atoms, and *smaller gray ones* H atoms. The *dashed lines* correspond to the surface supercells; the *blue* (*red*) *line* indicates the primitive cell of the clean (functionalized) Si(111). The *black dotted lines* in **(b)** show the hydrogen bonds between the molecules of the SAM. Reprinted from [5.71] with permission from Elsevier

molecular chain direction, and one compressive, $\sigma_2 = -0.04\,\mathrm{J/m^2}$ in the perpendicular direction, as indicated by the green arrows in Fig. 5.8. The tensile stress component is due to the H-bond interaction between propyl-urea molecules that would pull the molecules and shorten the intermolecular distance, whereas the weak compressive stress can be associated with the repulsion between dipoles of parallel molecular chains. The surface elastic constants of the functionalized surface were found to be larger than those of the clean and hydrogenated Si(111) surfaces, indicating an increase of surface stiffness due to H-bond network formation (Tab. 5.1). Although propyl-urea attachment renders the surface structurally anisotropic, the two surface elastic constants, S_{11} and S_{22}, are similar. This is due to the fact that the H bonds are oriented along the diagonal of the surface cell, as a consequence $S_{12} \simeq S_{21}$. H-bond network optimization is also responsible for the change in sign of the S_{12} elastic constant.

The values of surface elastic constants estimated via ab initio simulations have been used as input parameters to a finite element (FE) model that allows us to assign mechanical constitutive relations to the surfaces of a three-dimensional (3-D) object [5.74] representing a microcantilever. The latter has been modeled as a rectangular-shaped silicon beam with typical micrometric dimensions $l = 100\,\mu\mathrm{m}$ (length), $w = 20\,\mu\mathrm{m}$ (width), and $t = 0.9\,\mu\mathrm{m}$ (depth) [5.75]. It was found that the frequency shift due to the functionalization with a propyl-urea SAM is mainly due to the inertial effect rather than to changes of surface elastic constants. On the other hand, if all the shift is erroneously ascribed to the inertial contribution, the mass of the SAM is overestimated by more than two times.

In conclusion, for the model systems of Si(111)/propyl-urea it was proved that both the change in surface elastic constants and the amount of loaded mass at the cantilever surfaces are important contributions to the resonance frequency shift. In particular, ignoring the change in surface elastic constants would lead to a large overestimation of the attached mass, invalidating the analysis of the adsorbed mass.

Table 5.1 Surface stress and surface elastic constants for the clean Si(111), hydrogenated Si(111)-H and functionalized silicon surfaces. σ_i^{surf} corresponds to the surface stress along the principal axis of the stress tensor and $\bar{\sigma}^{\mathrm{surf}}$ is the trace of the same tensor. In the clean and hydrogenated Si(111), the principal axis coincides with the Cartesian directions of the supercell surface ($i = x, y$, see the red dashed line of Fig. 5.8), whereas in the functionalized surface, the principal axes are indicated by the vectors v_1 and v_2 reported as green arrows in Fig. 5.8c

Surface	σ_1^{surf} (J/m^2)	σ_2^{surf} (J/m^2)	$\bar{\sigma}^{\mathrm{surf}}$ (J/m^2)	S_{11} (eV/Å^2)	S_{22} (eV/Å^2)	S_{12} (eV/Å^2)
Clean-Si(111)	−0.41	−0.41	−0.41	0.151	0.151	−0.138
H-Si(111)	−0.10	−0.10	−0.10	0.258	0.258	−0.104
SAM-Si(111)	0.89	−0.04	0.42	0.305	0.306	2.441

5.4.2 Understanding the Gas Sensing Mechanism of Oxide Nanostructures

ZnO Nanowire–Based Chemoresistors

Due to their large surface to volume ratio, metal oxide nanostructures have showed great potential in chemical sensing applications [5.76]. The mechanism leading to detection of specific chemical species was discussed in recent publications [5.77, 78]. Among the type of sensors employing nanowires proposed in literature, chemoresistors are the most easily realized. These are based on the measurement of changes in conductance of the sensing element (i.e., single or collection of NWs) upon interaction with target molecules. Typically, resistance versus time plots of the sensor are recorded, and increases or drops in resistance values are directly related to the concentration of target molecules. The response of a chemoresistor can be defined as follows

$$\text{Response} = \frac{R_a - R_b}{R_a} \times 100\,, \tag{5.4}$$

where R_a and R_b are the electric resistance of the sensor measured in air and in the presence of the target molecule, respectively. Ideal gas sensors should show a high response and should be characterized by complete recovery of the electric conductance when back in air. For example, a response of 1850% was obtained for 0.5 ppm of NO_2 concentration at 200 °C in [5.78]. Typically, gas species are divided in two classes: reducing and oxidizing species. When a reducing gas (such as ethanol) is introduced to a chemical sensor, the interaction of the molecules with the nanowire surface results in an overall increase of the electrical conductance of metal oxide nanowires; on the other hand, if a chemical sensor is exposed to an oxidant gas (such as NO_2), the gas molecules serve as charge acceptor, withdrawing electrons from the nanowire and inducing a reduction of the electrical conductance.

Among the nanostructured oxides that have recently been proposed for the realization of chemoresistors with excellent properties, ZnO nanowires have attracted a lot of attention in the literature because they can be used for detection of a wide class of chemicals. ZnO gas sensing capabilities have been exploited both for reducing and oxidizing species, thanks also to the superior properties of this material, such as enhanced sensitivity, stability, and low cost [5.79]. DFT calculations have been recently employed to understand the mechanism leading to sensing phase in ZnO for two gas species, ethanol and NO_2 [5.77, 78], which are prototype molecules for reducing and oxidant gases, respectively. In particular, the studies presented in the literature highlight the role played by oxygen molecules pre-adsorbed over the ZnO surfaces. We now present the results on the modification of a ZnO surface when gas molecules are adsorbed on it and discuss how sensing is achieved.

Ethanol and the NO_2 Gas Sensing Mechanism

Chemical sensors based on oxide structure usually work in ambient atmosphere and, as such, it is expected that the ZnO surfaces will already be covered with gas species before being exposed to an analyte. In particular, one of the most reactive and abundant gases known to be adsorbed on the surface of metal oxides [5.80, 81] is molecular oxygen. For this reason, when analyzing gas sensing mechanisms, before studying the interaction of ZnO with the gas that is to be sensed, it is mandatory to understand whether oxygen has effects on the electronic features of the pristine ZnO nanostructures. Experimental evidence shows that ZnO presents intrinsic n-type conductivity, both in the form of bulk and nanostructures. Although the origin of this behavior has been the subject of debate in the literature, it was recently ruled out that neutral oxygen vacancies are responsible for the unintentional n-type character of the compound, which is rather ascribed to hydrogen interstitial impurities [5.82–84] and/or to Zn vacancies [5.85]. While the clean surface is semiconducting (Sect. 5.3), the presence of hydrogen impurities shifts the Fermi level (E_F) in the conduction band of ZnO, in an otherwise barely modified DOS. Hence, the ZnO surface becomes conductive (Fig. 5.9).

DFT calculations have shown that O_2 absorbs at the clean ZnO surface in two stable configurations which are characterized by an elongation of the O=O bond that appears to be weakened by the interaction with the surface. The most stable adsorption geometry corresponds to a bridging configuration in which both the oxygen atoms of O_2 bind to two neighboring Zn atoms on the surface (Zn_{surf}–O distance of 2.13 Å) and, correspondingly, the oxygen molecule bond length increases by about 5% (Fig. 5.10a); the adsorption energy (E_b) is −0.35 eV per molecule.

Oxygen adsorption at the H-doped ZnO $(10\bar{1}0)$ face induces a shift of the Fermi level from the CB into the pristine energy gap of the oxide. In particular, O_2 generates both occupied and empty states in the gap, which are responsible for a shift of the E_F position that is brought to coincide with one of these states (Fig. 5.9b). The state at the Fermi level derives from the lowest unoccupied state of the oxygen molecule, which becomes filled upon oxygen/surface interaction, due to an electron transfer from the H-ZnO conduction band to the adsorbed O_2. This electron trapping pins the Fermi level of the system within the ZnO energy gap. These results show that when n-type ZnO is exposed to ambient atmosphere, the concentrations of free carri-

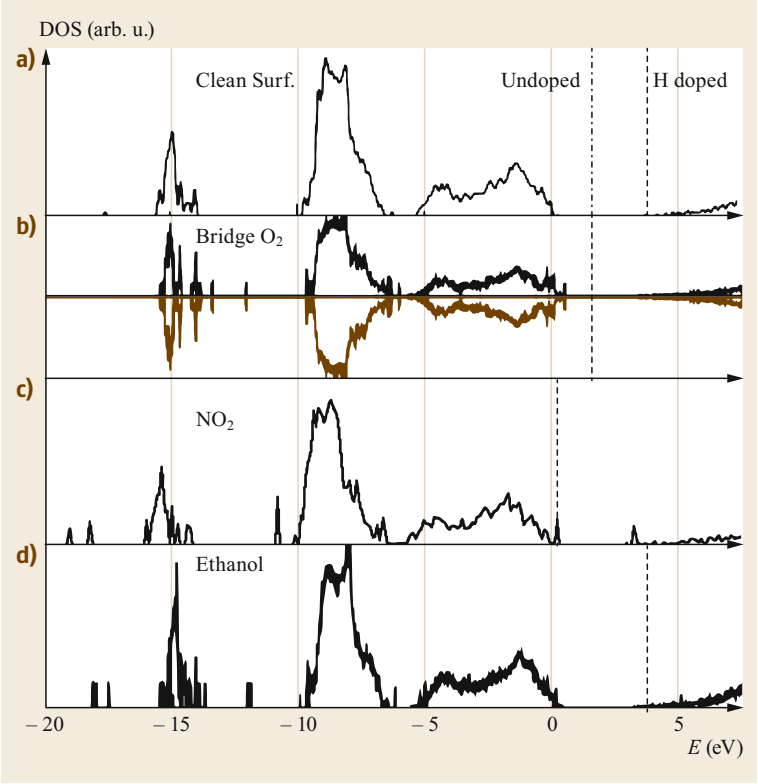

Fig. 5.9a–c Density of state (DOS) for the ZnO($10\bar{1}0$) surface **(a)**, oxygen molecule **(b)**, NO_2 molecule **(c)**, and ethanol molecule **(d)** adsorbed on the H-doped ZnO($10\bar{1}0$) surfaces. In **(a)** the Fermi level is indicated by the *dotted* (*dotted-dashed line*) for the H-doped (undoped) system. In **(b)** the spin-up and spin-down DOS are represented by the *black* and *brown curves*, respectively. The presence of hydrogen was accounted for by introducing an isolated hydrogen atom in the vacuum buffer of the supercell. The H-interstitial impurity was located in a deep inner (the fifth) layer away from the outermost surface plane with concentration of about 0.70 at.%. in the simulation supercell representing the ZnO surface. This way, we could avoid possible structural deformations induced by the impurity on the ZnO surface structure. When located in an interstitial ZnO site, H forms a strong O–H bond 0.98 Å long with one of the closest oxygen atoms of the crystal, consequently a local distortion of the lattice network occurs characterized by an out of plane shift ($\simeq 1$ Å) of the Zn atom initially bonded to the H-bonded oxygen. The presence of hydrogen below the surface does not alter the structural properties of the outer layer (the one exposed to air during gas sensing experiments), but it strongly modifies the electronic properties of the surface. Figure adapted with permission from [5.77, 78]. Copyright 2014 and 2016 American Chemical Society

ers in the conduction band of the oxide decreases and, consequently, the conductivity of the nanowire sample decreases, due to oxygen adsorption at surfaces.

The above condition is the one presented by the ZnO sensing elements before being exposed to gas species. We now analyze the changes induced at the surface when NWs are exposed to ethanol and NO_2, the first representing a reducing species and the second an oxidant one. In particular, DFT calculations have been used to predict the adsorption geometries and energies of these gases and to understand the modification in the electronic properties of oxygen covered H-ZnO when sensing is achieved [5.77, 78].

Results of the interaction of ethanol with the ZnO($10\bar{1}0$) surface show that adsorption of this species occurs in a geometry in which the hydroxyl group (–OH) binds to the two surface atoms in a bridge configuration (Fig. 5.10b). In particular, ethanol forms a Zn_{surf}–O bond 2.05 Å long and an O_{surf}–H bond 1.56 Å long, with an energy gain of –0.96 eV, which is much larger than that occurring for O_2. As for the electronic properties of the ZnO/ethanol adsorbed system, an analysis of the DOS highlights features that are very similar to those of the clean n-doped surface. In particular, at variance with the case of oxygen adsorption, the position of E_F is very close to that of the pristine

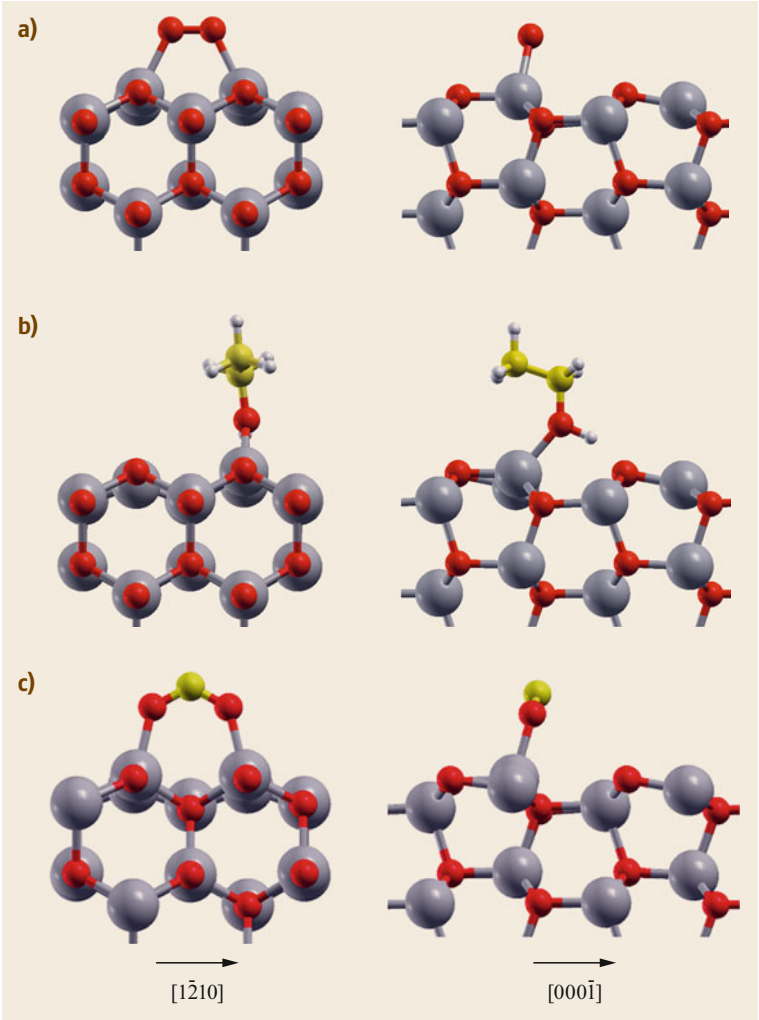

Fig. 5.10a–c Side view of the optimized O_2/ZnO(10$\bar{1}$0) interface **(a)** ethanol/ZnO(10$\bar{1}$0) interface **(b)** and NO_2/ZnO(10$\bar{1}$0) interface **(c)** represented along the [1$\bar{2}$10] (*left structures*) and [000$\bar{1}$] (*right structures*) directions. n-type clean surface (Fig. 5.9d). Thus, when ZnO wires are covered with ethanol, they are found in a low resistance state, and conductivity is due to the free electrons in the CB due to intrinsic doping.

Similarly to the oxygen and ethanol molecules, NO_2 chemisorbs to the ZnO nonpolar surface. The lowest energy configurationcorresponds to a bidentate geometry in which the oxygen atoms of NO_2 bind to two neighboring Zn surface ions, while the nitrogen atom points outwards (Fig. 5.10c). In this adsorption configuration the N–O bond elongated by 0.05 Å and the bond angle contracted by 12°, correspondingly; the adsorption energy is –0.59 eV. As in the case of ethanol, it is predicted that NO_2 binds to the ZnO(10$\bar{1}$0) surface more strongly than O_2. When a chemical sensor based on ZnO NWs is exposed to NO_2, the nanostructure surfaces would be readily covered with NO_2 molecules that may either occupy free binding sites or may displace some of the chemisorbed oxygen molecules. The DOS for the H-doped ZnO surface after adsorption of NO_2 is reported in Fig. 5.9c. This figure shows that when NO_2 interacts with the H-ZnO(10$\bar{1}$0) surface the Fermi level shifts down in energy with respect to the condition in which the NWs are found in air, and it is found right at the top of the valence band. This occurs because NO_2 generates surface levels deeper than those generated by O_2, which trap free electrons from the H-ZnO conduction band more strongly. Such trapping induces an increase in sensor resistance as has been found experimentally [5.78].

From the results obtained for the interaction of O_2, ethanol, and NO_2 with H-ZnO (10$\bar{1}$0), the sensing mechanism of ZnO NWs has been drawn. When n-type conducting ZnO NWs are exposed to an ambient condition, which is normally rich in oxygen gas, their surfaces will immediately be covered by O_2 species

($E_b = -0.35$ eV). The adsorbed oxygen captures electrons from CB, hence the substrate will be forced back to the semiconducting configuration. When ethanol or NO_2 are introduced into the atmosphere, increases and decreases in conductivity are observed, respectively. This effect is attributed to phenomena occurring at the surface: (i) since both ethanol and NO_2 have a higher adsorption energy compared to oxygen, they are able to remove oxygen from the surface; (ii) this is accompanied by a change in the surface conductivity of the ZnO NWs. In particular, when ethanol replaces adsorbed O_2, electrons trapped in mid gap states are injected back to CB and conductivity increases. For each ethanol molecule that replaces an oxygen molecule on the ZnO surface, one electron is restored to CB. Therefore, surface carrier density will be closely linked to the concentration of ethanol in the atmosphere, and higher conductivities should be attained when O_2 molecules are completely removed from the surface. In the case of NO_2 adsorption, deep acceptor levels are generated close to the top of the ZnO valence band, which are responsible for further electron trapping and for the resistance increase observed experimentally.

In conclusion, for simple gas molecules such as ethanol and NO_2, ab initio simulations revealed that it is the competitive adsorption between the pre-adsorbed oxygen molecules and the target molecules on the surface of n-type ZnO that is responsible for sensing. These findings give insights on the detection mechanism of ZnO NWs, which may provide crucial details essential for improving the performance of ZnO-based devices for gas detection and other related applications.

5.5 DFT for Interfaces

5.5.1 Contact and Heterojunctions

One of the most studied problems with respect to semiconductors is the optoelectronic characterization of interfaces and heterojunctions, when paired with other semiconductors or with metals [5.86]. Semiconductor/semiconductor interfaces are at the basis of most electronic (e.g., diodes, field effect transistors (FETs), rectifiers, etc.) and optical (e.g., LEDs, lasers, etc.) devices, while metal/semiconductor systems are the building blocks of most electrical contacts. The specific operation of such different devices is mainly related to the peculiar electronic properties of the semiconductor in the bandgap region. Hence, control of gap states is fundamental for the final application, since their presence can produce disruptive effects or be of primary importance in devices that involve light coupling for very different purposes (e.g., absorption, emission, photochemical reactions, plasmon excitations).

In the case of semiconductor/semiconductor interfaces three kinds of possible band alignments may exist (Fig. 5.11), depending on the relative energy position of the valence band top (VBT) and the conduction band minimum (CBM) of the two systems [5.87]. In straddling interfaces (*type-I*, left panel) both VBT and CBM of the materials with the smaller bandgap lie in the bandgap region of the other semiconductor. The discontinuities of the bands are such that both types of carriers, electrons (el) and holes (h), need energy to change from the material with the smaller bandgap to the one with the larger gap; vice versa, carriers from the other side gain the same energy. *Type-I* interfaces favor energy transfer, and fluorescence decays are thus used for biological tagging [5.88] and in light-emitting diodes [5.89, 90]. In staggered interfaces (namely *type-II*), the bandgaps of the two sides partially overlap with the VBT of one semiconductor that lies in the bandgap of the other. The interface is energetically asymmetric, thus carriers gain energy moving in opposite directions. Following Fig. 5.11a (central panel), electrons (holes) gain energy moving from left (right) to right (left), respectively. This specific band distribution is particularly suited for absorption of light and separation of el–h pairs across the interface (i.e., exciton splitting), and thus it is useful for devices that produce photocurrent and/or voltage drop, such as photovoltaic solar cells [5.91–94]. Furthermore, once a *type-II* interface is formed, the energy position of VBT inside the other bandgap, i.e., closer to the valence rather than to the conduction band, affects some characteristic properties of the final device, such as the direct/inverse polarization offset of photodiodes or the open-circuit voltage in excitonic solar cells. The broken-gap heterojunction (*type-III*) is a special case of type-II, where the CBM of one side is lower than the VBT of the other. Thus, the conduction band of the former overlaps the valence band of the latter, while the bandgaps do not overlap at all. The situation for carrier transfer is like *type-II*, just more pronounced. These band alignments may be also realized in hybrid organic/inorganic interfaces, where semiconductor surfaces are coupled to molecular adsorbates. For example, the catechol/ZnO interface shown in Sect. 5.3 realizes a *type-II* junction that has been proposed for excitonic light harvesting applications [5.30, 59], as described above (Sect. 5.3).

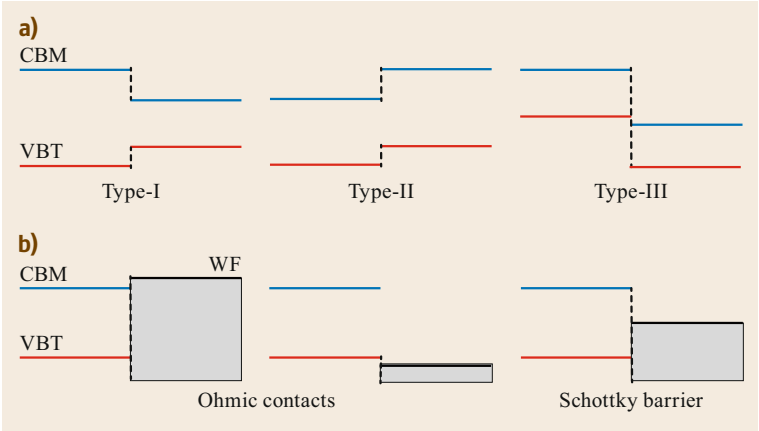

Fig. 5.11a,b Semiconductor heterojunctions organized by band alignments: **(a)** semiconductor/semiconductor interface; **(b)** semiconductor/metal interface. Here, VBT (CBM) is the valence band top (conduction band minimum) and WF the work function

In the presence of a metal-semiconductor interface, the electrical character of the heterojunction is dictated by the position of the metal Fermi level and work function (WF) value, with respect to the semiconductor bandgap (Fig. 5.11b). If metal E_F is degenerate with the conduction (left panel) or valence band (central panel) of the semiconductor, an Ohmic (non-rectifying) junction is established. This causes a free charge transfer (electrons in the left, holes in the central scheme) across the interface, until the charge neutrality is achieved. Ohmic junctions are the archetype of the optimal low-loss electrical contacts, necessary to drive the current from the active part of the device to the external circuitry. When, instead, the metal E_F lies in the semiconductor gap, a Schottky barrier (right panel) is formed. In the case of n-type semiconductors, an electron can be freely injected from the conduction band of the semiconductor into the metal contact, while an energy barrier has to be overcome to excite an electron from the metal contact into the semiconductor. The opposite holds for p-type systems. A Schottky barrier acts as a rectifier and typically results in both a low forward voltage drop and very fast switching. Schottky diodes are useful in voltage clamping applications and prevention of transistor saturation due to the higher current density in the Schottky diode. Also, because of the low forward voltage drop, less energy is wasted as heat, therefore making them a good choice for applications that are sensitive to efficiency [5.87]. Other relevant physical effects can take place at the metal/semiconductor interface in the presence of an external electromagnetic field. This is the case, for instance, of the excitation of surface plasmon polaritons (SPP). SPPs are mixed oscillatory modes, generated by the coupling between the incident light radiation and the surface charge fluctuations that can propagate on the metal/dielectric interfaces that are exploited as waveguides and telecommunication applications [5.95].

The electrical and optical character of both semiconductor/semiconductors and metal/semiconductor interfaces results from the balance between different effects; a few (such as the bandgap, the work function, the energy level distribution) are intrinsic to the materials that compose the junction, others derive from the details of the specific interface that is formed (such as surface states, surface reconstruction, defects, traps etc.). In this light, a rationale to predict lineups between the two materials, starting from local properties of the isolated systems, and the comparison with the properties of the actual heterojunction is of paramount importance for the improvement of the final application.

In the following, we present three prototypical examples based on ZnO interfaces that clearly show the large capability of first principles techniques in predicting both electrical and optical and plasmonic properties of heterojunctions, giving deep insights about the microscopic mechanisms that regulate the charge transfer and the band alignment at the interface.

Since the optoelectronic properties mostly depend on the region around the Fermi level, a proper treatment of the bandgap is an unavoidable point that must be carefully taken into account. As mentioned above, standard DFT fails in the quantitative description of the bandgap. In all the examples, a pseudohybrid implementation of DFT+U approach (namely ACBN0 [5.5]) is adopted in order to correct the severe DFT gap underestimation. As described in Sect. 5.2, this approach profitably corrects also the dielectric [5.63] and vibrational [5.96] properties of semiconductors. The band alignment resulting from the formation of semiconductor heterostructures has an important effect also on the optical properties of the system. The direct evaluation of the absorption spectrum of surfaces and interfaces, also at the single-particle level, is usually computationally very expensive for systems as large as the ones proposed in the next sections. In the following

examples, a novel first principles tight-binding (TB) approach [5.97] was used to simulate the optical properties of bulks and interfaces through the solution of the generalized Drude–Lorentz expression of the macroscopic complex dielectric function $\hat{\epsilon} = \epsilon_1 + i\epsilon_2$, where both intraband (Drude-like) and interband (Lorentz-like) contributions are explicitly taken into account. This procedure combines the accuracy and the predictive value of first principles approaches with the low computational cost of TB techniques. Furthermore, it is particularly useful for the evaluation of properties such as the optical absorption spectra that require a precise and ultrafine reciprocal space integration, which is too computationally expensive.

Ohmic Versus Schottky Barrier: The Al/ZnO Interface

In its simplest approximation, the barrier Φ between a metal (m) and a semiconductor (s) is predicted to be proportional to the difference of the metal-vacuum work function (WF) and the semiconductor-vacuum electron affinity (EA) in the case of n-doped semiconductors [5.86]. For p-doped materials, a similar expression holds, with the ionization potential (IP) in place of the electron affinity. However, in principle, the quantities WF, AE, and IP are ill defined in supercell approaches where the absolute value of the vacuum level is not univocally defined, due to the periodic boundary conditions. In order to overcome this problem, it is useful to adopt an approach originally proposed by M. Peressi and coworkers [5.98], which consists in the evaluation of Φ as the sum of two separate contributions

$$\Phi = \Delta\epsilon + \Delta\bar{\bar{V}}\,, \tag{5.5}$$

where the first term

$$\Delta\epsilon = (E_F - \bar{\bar{V}}_m) - (\mathrm{VBT} - \bar{\bar{V}}_s) \tag{5.6}$$

derives from bulk calculations and gives the difference between the Fermi energy (E_F) of the metal and the VBT of the semiconductor, each measured with respect to the *macroscopic average* of the electrostatic potential of the corresponding crystal $\bar{\bar{V}}_{m,s}$. The macroscopic average of the electrostatic potential $\bar{\bar{V}}(z)$ is related to the charge distribution by a one-dimensional Poisson equation, and it is defined as [5.98, 99]

$$\bar{\bar{V}}(z) = \frac{1}{a}\int_{-a/2}^{+a/2} \bar{V}(z')\mathrm{d}z'\,, \tag{5.7}$$

where a is the characteristic length along the direction (z) perpendicular to the surface, and $\bar{V}$ is the planar average of the electrostatic potential over the xy plane. The second term in (5.5) ($\Delta\bar{\bar{V}}$) is an interface-specific property and must be extracted from supercell calculations by using the same macroscopic average technique; $\Delta\bar{\bar{V}}$ is related through the Poisson equation to dipole formation at the interface, and it is strictly dependent on the atomic details of the surface reconstruction at the interface. The intermediate step of referring E_F and VBT to the bulk average potential $\bar{\bar{V}}$, allows for the definition of an accessible energy reference, alternatively to the vacuum level; provided that the supercell calculation includes a metal and a semiconductor layer thick enough to reproduce the corresponding bulk in their central section (see also Sect. 5.2). The energy level scheme for a generic semiconductor/metal is described in Fig. 5.12a.

The formation of good contacts with external metals is a necessary step for the realization of efficient electronic devices. Due to its low work function [5.100, 101], aluminum has been used in the formation of Ohmic contacts with n-doped ZnO. Furthermore, it has been proposed that the Al/ZnO contact witnesses out-diffusion of oxygen atoms from ZnO to participate in the formation of Al_2O_3 at the interface, with accumulation of oxygen vacancies close to the ZnO surface. In spite of its strategic relevance in view of applications, the Al/ZnO junction is a debated system; a number of different metallization schemes have been proposed, ranging from the deposition of the single metal to alloys and sandwiches of different metal layers to optimize the electrical characteristics and block inter/outer diffusion and degradation of the contact ([5.102] and references therein), and eventually the possibility to obtain a Schottky-like electric behavior was reported [5.103]. Here, we characterize the formation of the electrical contact at the Al/ZnO interface built along the polar ZnO(0001) axis, which is the most common direction of growth. The interface (Fig. 5.12b) is composed of a layer of Al(111) metal and a layer of ZnO semiconductor, exposing the polar (0001)-Zn terminated face. Further details on the (000$\bar{1}$)-O terminated surface are reported in the original paper [5.104]. From the computational point of view, particular attention must be devoted to the potential drop inside the slab, which stems from the internal polarization field along the polar c-axis of the wurtzite structure and the surface charge rearrangement [5.105]. Depending on the growth techniques, the ZnO(0001) surface is stabilized by either surface vacancies (as in the present case) or by surfactants (such as −OH groups), which compensate the internal polarization field.

Upon exposing the vacancy-reconstructed ZnO (0001) [5.105] surface to Al deposition, we observe intermixing at the interface layer (Fig. 5.12b). The formation of the contact causes an aluminum atom

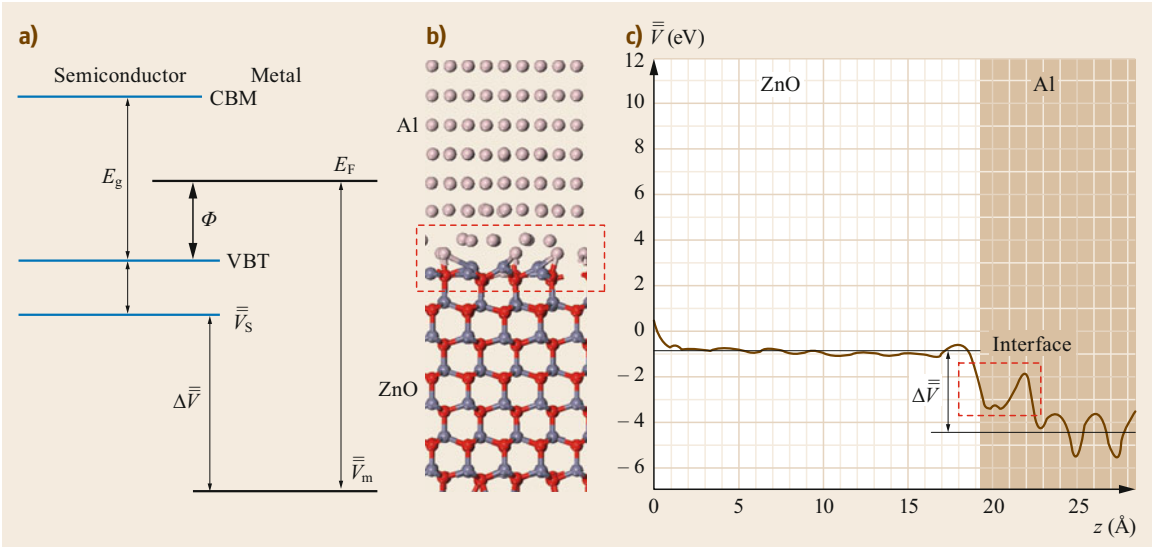

Fig. 5.12a–c **(a)** Energy level scheme corresponding to Φ as defined in (5.5). **(b)** Side view of the Al/ZnO(0001) relaxed heterojunction. The *dashed line* marks the atomic readjustment at the interface. **(c)** Average potential profile for the simulated Al/ZnO interface

to penetrate into the site that was left empty by one of the (three) Zn vacancies and became involved in bonding with the surrounding oxygen atoms. This result is also in agreement with the observation of the Zn-substitutional behavior of Al dopants in formation of Al-doped ZnO (AZO) [5.106, 107]. The complex surface relaxation imparts a net charge dipole at the interface, which can be quantified in terms of $\Delta\bar{\bar{V}}$, as shown in Fig. 5.12c.

The application of the potential-dipole model mentioned above would give a negative Φ barrier, with the Fermi level of the metal higher in energy than the conduction band minimum of the semiconductor [5.102]. Clearly, such band alignment would correspond to a thermodynamically unstable system; the equilibrium condition is restored upon a metal-to-semiconductor charge transfer that zeroes the barrier. This is the fingerprint of an Ohmic contact. The analysis of the electronic structure (e.g., DOS) reveals that the Fermi level of the interface is located within the ZnO conduction band, which is consistent with an occupation of bulk-like ZnO states. Further, the energy region close to the Fermi level is occupied by Al-ZnO states. These interface states, which lie in the pristine bandgap of ZnO, derive from the natural charge spilling from the Al surface. The charge piles up at the interface and decays within the very first ZnO interface layers. The charge transfer that accompanies the Fermi level realignment is the dominant effect, and it is related to the Ohmic character of the Al/ZnO junction, in agreement with most experimental results.

On the other hand, the intercalation of a single gold monolayer between ZnO and Al compounds is sufficient to change the electrical behavior of the barrier, moving from an Ohmic to a Schottky contact, as for the ZnO/Au interface [5.108]. This remarkable difference reflects the fact that the Schottky barrier is very sensitive to interfacial details, in agreement with the experimental observation. In this case, the Fermi level of the interface lies in the projected ZnO bandgap and a bunch of Au-derived states, responsible for interface dipoles, fills the forbidden energy region also in this case, while the CBM of ZnO remains empty.

We further note that this kind of analysis is possible only because the atomistic details of the interfaces (and the corresponding charge transfer) are treated explicitly from first principles. The pivotal role of charge redistribution at the interface is often neglected in simplified models, such as the Schottky–Mott rule, where the Schottky barrier is evaluated as the difference between the metal work function and the semiconductor electron affinity of the separated bulk systems. Despite the crude approximations, the present approach has been proved to give realistic results on both the electrical character (i.e., Ohmic versus Schottky) and the barrier heights in most metal/semiconductor junctions. The results are usually accurate enough to be directly compared with the experiment. On the other hand, other effects such as the quantification of band-bending and of the charge depletion region, which have a mesoscopic spatial extent, are not caught by atomistic approaches that have access

only to a restricted region (a few nanometers) around the interface.

One Dimensional Type-II Alignment: ZnO/ZnS Core/Shell Nanowires

As seen before, semiconductor nanostructures have received much attention for their potential use in a wide range of technological applications, including solar cells [5.54], UV detectors [5.109], light emitters and lasers [5.110], bioimaging [5.111], and gas sensors [5.112]. In particular, the use of quasi-one-dimensional (1-D), vertically aligned nanostructures to construct three-dimensional architectures as building blocks for optoelectronic (e.g., photovoltaic, LEDs) devices, boosting charge transport and collection, and/or enhancing light absorption, has demonstrated advantages over conventional planar devices [5.113, 114].

However, intrinsic problems in 1-D nanowires, such as the high number of defects and surface states, due to the presence of surface atoms with reduced coordination, along with the high electron–hole recombination rate upon light absorption, reduce the device performances and limit their large-scale commercial application for optoelectronic devices. For example, to facilitate efficient charge separation, great efforts have been made to impart a p-n junction functionality to nanowires [5.115], through selective doping [5.116]. However, doping small nanosystems is a tremendous experimental challenge, and if such p-n junctions can be formed, due to the small size of the system the junction can have a large device-to-device fluctuation.

The optoelectronic properties of 1-D wires can be adjusted as desired not only by impurity doping but also through surface modification [5.117–120]. Beyond the functionalization processes of semiconductor surfaces addressed in the previous Sect. 5.3, further modification with inorganic adlayers can be a suitable tool to passivate surface defects and design novel nanocomposites with different properties. By changing the band alignment at the interface, it is possible to tailor the bandgap of the resulting material [5.64]. Previous attempts in the formation of fully inorganic heterostructures dealt mainly with quantum dots or extended superlattices, while the synthesis of one-dimensional heterostructures is a much more recent achievement. In general, two types of one-dimensional heterostructures can be formed: stacked longitudinal (SL) and coaxial core-shell (CCS) heterostructures.

Here, we focus on the latter [5.121, 122], which are nanowires with different core and shell compositions. In contrast to the bulk situation, the carrier localization profile relies on the core diameter and the shell thickness. Because of quantum confinement, the growth of a shell of a higher bandgap material on a core of another lower bandgap material is expected to form a *type-II* heterostructure, while the opposite would realize a *type-I* interface. Despite the fact that, in principle, the formation of 1-D nanoscale heterostructures is conceptually simple, their synthesis, control, and characterization are a formidable task for both experiments and theory. Indeed, the first unambiguous experimental reports on such 1-D component-modulated materials appeared mainly in the last years.

On the theoretical side, the simulation of CCS heterostructures is a tremendous challenge, as it requires the explicit treatment of very large systems that are hardly accessible even with the parallel supercomputers that are available nowadays. Here, we present the prototypical case of a CCS nanowire of ZnO (core) and ZnS (shell), which was experimentally synthesized [5.123–127]. The system has 588 atoms and ≈ 5300 electrons. The core is made of ZnO, and it has an internal radius $r_c = 1.1\,\text{nm}$, which is large enough to correctly reproduce a realistic ZnO wire [5.8, 128]. The shell is made of ZnS, the total radius of the heterostructure is $r_s = 1.9\,\text{nm}$, close to that of experimental samples [5.123]. The wire is aligned along the polar c-axis of the wurtzite ZnO crystal. The CCS structure has a hexagonal symmetry and exposes only nonpolar $(10\bar{1}0)$ faces. Due to the huge dimension of the system, only two bilayers of ZnS-ZnO wurtzite material are included along the wire direction, i.e., the minimum to obtain a periodic wire.

In the optimized structure (Fig. 5.13a) the inner ZnO core almost maintains its ideal geometry, while the external ZnS shell undergoes remarkable distortion due to the relaxation of the mismatch at the interface. Nonetheless, the outermost layer exhibits a buckled dimer arrangement, typical of the ZnS$(10\bar{1}0)$ surface. The resulting electronic structure is summarized in Fig. 5.13b. Albeit ZnO and ZnS have similar bandgap $\left(E_g^{\text{ZnO}} = 3.1\,\text{eV} \text{ and } E_g^{\text{ZnS}} = 2.8\,\text{eV}\right)$, the different ionization potential causes the formation of a staggered *type-II* band alignment at the interface, with the top of ZnS valence band lying in the pristine gap of ZnO. This implies a reduction of the bandgap of the overall structure $E_g = 1.2\,\text{eV}$ that lies in the near-IR range (NIR). Accordingly, the highest occupied molecular orbital (HOMO) state is localized in the ZnO core, while lowest unoccupied molecular orbital (LUMO) is confined in the external ZnS shell. This also gives information on the charge transport mechanisms along the wire; hole carriers flow in the external ZnS crown, while electrons move in the internal ZnO core, confirming the intrinsic charge separation observed experimentally [5.127].

Simulated optical properties are summarized in Fig. 5.13c. The peaks in the imaginary part of the dielectric function ϵ_2 correspond to single-particle valence-to-conduction transitions. As expected, it is

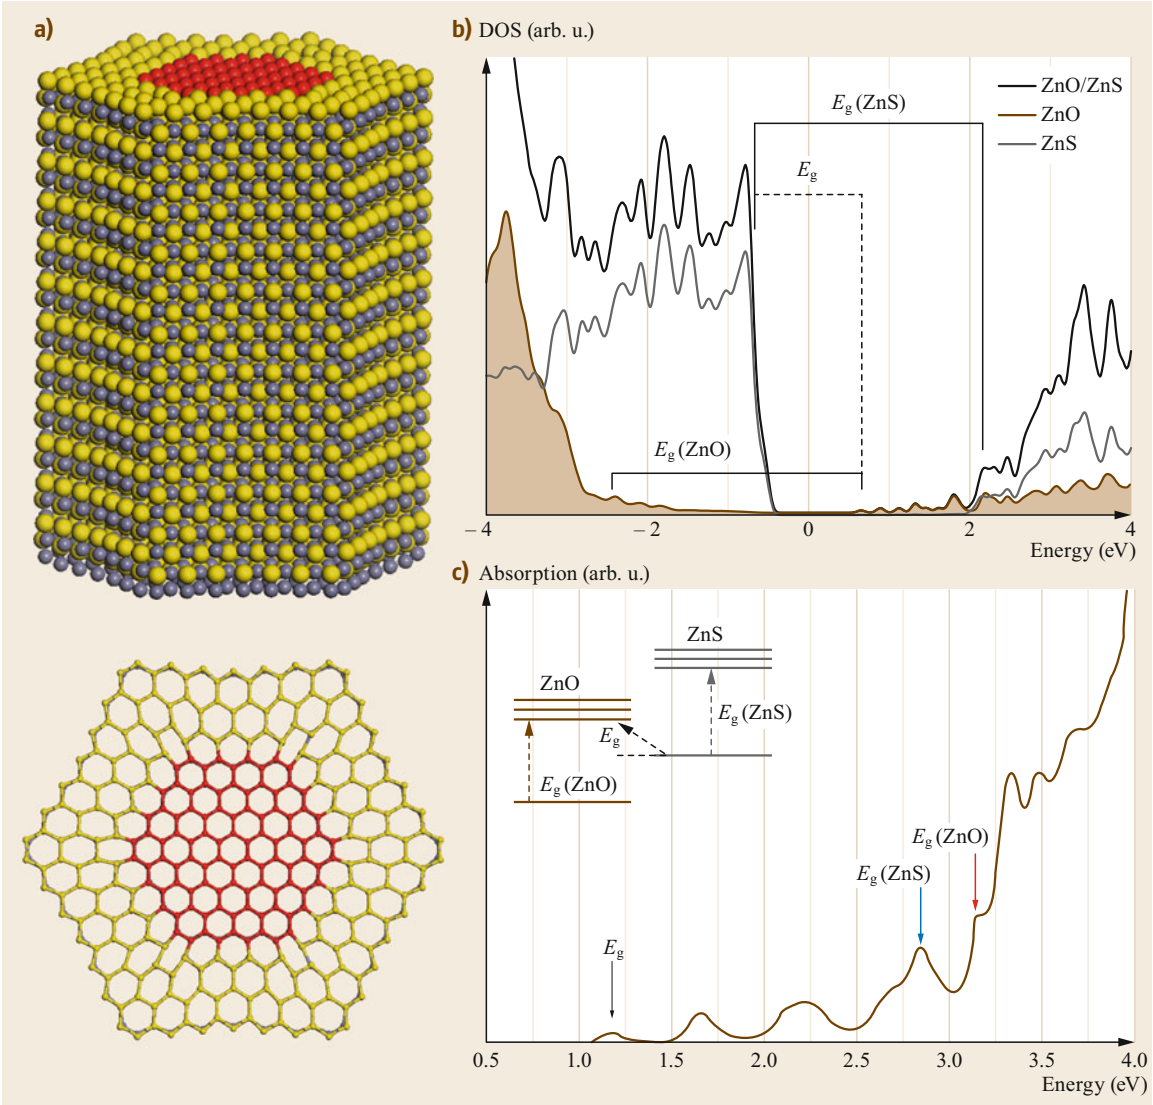

Fig. 5.13a–c **(a)** Side and top view of the CCS ZnO/ZnS nanowire. **(b)** Total and material-projected DOS plot. **(c)** Imaginary part of dielectric function of ZnS/ZnO nanowires. easy to recognize the valence-to-conduction absorption edges in the external ZnS shell (2.8 eV, blue arrow) and in the inner ZnO (3.1 eV, red arrow), which correspond to the E_g values of each material. However, other lower-energy transitions are present in the range 1.2–2.8 eV, which correspond to intermaterial ZnO-to-ZnS transitions, as depicted in the inset of the figure. Although the frontier's orbitals are mostly localized in the core (electrons) and in the shell (hole), the overlap and the symmetry of the wave functions give low but not negligible oscillator strength to the first four transitions. This agrees well with the dramatic red shift of the absorption edge (i.e., from UV to near-IR) observed experimentally [5.125, 126].

Alternative Plasmonic Systems: AZO/ZnO Interface

Surface plasmons are the normal modes of charge fluctuation at a metallic surface that govern the long-range interaction between the metal and the external environment [5.129]. Surface plasmons may be induced on both nanoparticles and planar surfaces. In the former

case, they are referred to as *localized surface plasmons* (LSP), in the latter case as *surface plasmon polariton* (SPP) modes [5.130]. SPPs, in particular, involve the excitation of an electric field which propagates a metal/dielectric interface and provide the opportunity of confining light in very small dimensions (Fig. 5.14a). This allows one to conjugate the compactness of electronic devices and the speed of photonic systems, opening up a wide range of applications from energy conversion [5.131, 132] to telecommunications [5.133, 134].

The polarization induced by an electromagnetic radiation on a sample can be described by the material's complex dielectric function, denoted by $\hat{\epsilon} = \epsilon_1 + i\epsilon_2$. While the real part of the dielectric function (ϵ_1) describes the strength of the polarization induced by an external electric field; the imaginary part (ϵ_2) describes the losses encountered in polarizing the material. Following Drude theory, it is easy to demonstrate that efficient plasmonic materials present negative ϵ_1 for energy lower than the plasma frequency $\omega_p^2 = ne^2/(\epsilon_0 m^*)$, which must be higher than the desired frequency of application. Because noble metals (e.g., Au, Ag) tend to have large plasma frequencies and high electrical conductivity, they have traditionally been the materials of choice for plasmonics [5.136]. However, they are plagued by large losses (i.e., large ϵ_2), especially in the visible and UV spectral ranges, arising in part from interband electronic transitions and in part from dissipative scattering events (e.g., el-el, el-ph). These losses are detrimental to the performance of plasmonic devices, seriously limiting the feasibility of many plasmonic applications.

Because these losses are inherent to the constituent materials, the research/design of alternative plasmonic materials with lower losses are required to develop robust plasmonic devices [5.137]. As an alternative to metals, semiconductors are conventionally regarded as dielectric materials for frequencies above several hundred THz. However, semiconductors can actually exhibit a negative real permittivity in this spectral region when heavily doped. Due to the ease of fabrication and flexibility in tuning their properties, such as carrier concentration, semiconductors are also potential materials for plasmonics. In order to qualify as a low-loss plasmonic material, both the bandgap and plasma frequency of the semiconductor must be larger than the frequency range of interest. While a large plasma frequency ensures a negative real part of dielectric function, a large bandgap ensures almost no interband transition losses.

Heavy doping ($\approx 10^{21}\,\mathrm{cm}^{-3}$) with Al and Ga elements is possible in oxide semiconductors such as zinc oxide and indium oxide. These semiconductors have wide bandgaps, and their ϵ_2 values are moderately low. In addition, relatively high mobilities of charge carriers can be achieved with polycrystalline microstructures and very high mobilities are typically observed in single crystals. In particular, AZO can have losses as low as four times smaller than that of silver in the NIR. Together with indium tin oxide (ITO) these compounds were recently proposed also as low-loss plasmonic materials in the NIR/visible range [5.133, 135, 138–140]. Furthermore, they are qualified as transparent conductive oxide (TCO) materials [5.141], i.e., they show an unusual coexistence of high conductivity and high transparency in the visible region. This makes these materials very appealing for optoelectronic applications, such as solar cells and liquid crystal displays, and opens new alternatives for plasmonic applications in the optical spectrum, with the further advantage of a relatively low production cost, with respect to noble metals. In the following, we will focus on the characteristics of SPP at the AZO/ZnO interfaces, where AZO is the metal part and ZnO the dielectric component of the system.

The properties of SPP derive from the combination of the dielectric properties of the two components. In general, SSP can propagate along a metal/dielectric interface when the condition

$$\hat{\boldsymbol{k}}_{\parallel} = \frac{\omega}{c}\left(\sqrt{\frac{\hat{\epsilon}_m \hat{\epsilon}_d}{\hat{\epsilon}_m + \hat{\epsilon}_d}}\right), \tag{5.8}$$

is satisfied; $\hat{\boldsymbol{k}}_{\parallel}$ is the complex wavevector parallel to metal surface, along the propagation direction, $\hat{\epsilon}_{m,d}$ are the complex dielectric functions of the metal and the dielectric bulks, and c is the light velocity in vacuum. The real part of $\hat{\boldsymbol{k}}_{\parallel}(\omega)$ completely defines the dispersion relation of the excitation. For a pure Drude-like metal it exhibits a divergence for $\omega = \omega_p$, giving rise to high and low-energy branches, separated by a forbidden gap for $\omega_{sp} \le \omega \le \omega_p$, where ω_{sp} is the surface plasmon frequency, which for simple Drude metals is $\omega_{sp} = \omega_p/\sqrt{2}$. Within the forbidden gap, $\hat{\boldsymbol{k}}_{\parallel}(\omega)$ is a purely imaginary number, prohibiting wave propagation. The high-energy branch ($\omega > \omega_p$) does not describe a surface wave (Fig. 5.14). This corresponds to the fact that for $\omega > \omega_p$ the metal is no longer reflecting, becoming transparent to the incoming radiation. The nonradiative character of SPP in the low-energy branch ($\omega < \omega_{sp}$) follows from the fact that the surface plasmon polariton propagates with a momentum larger than that of an electromagnetic wave traveling in the dielectric part with the same angular frequency. As a consequence, SSP cannot couple with light in the de-excitation process, and only nonradiative inelastic scattering effects (e.g., el-ph) can take place. At large wavevectors SPP approaches the nonpropagating surface plasmon limit (ω_{sp}).

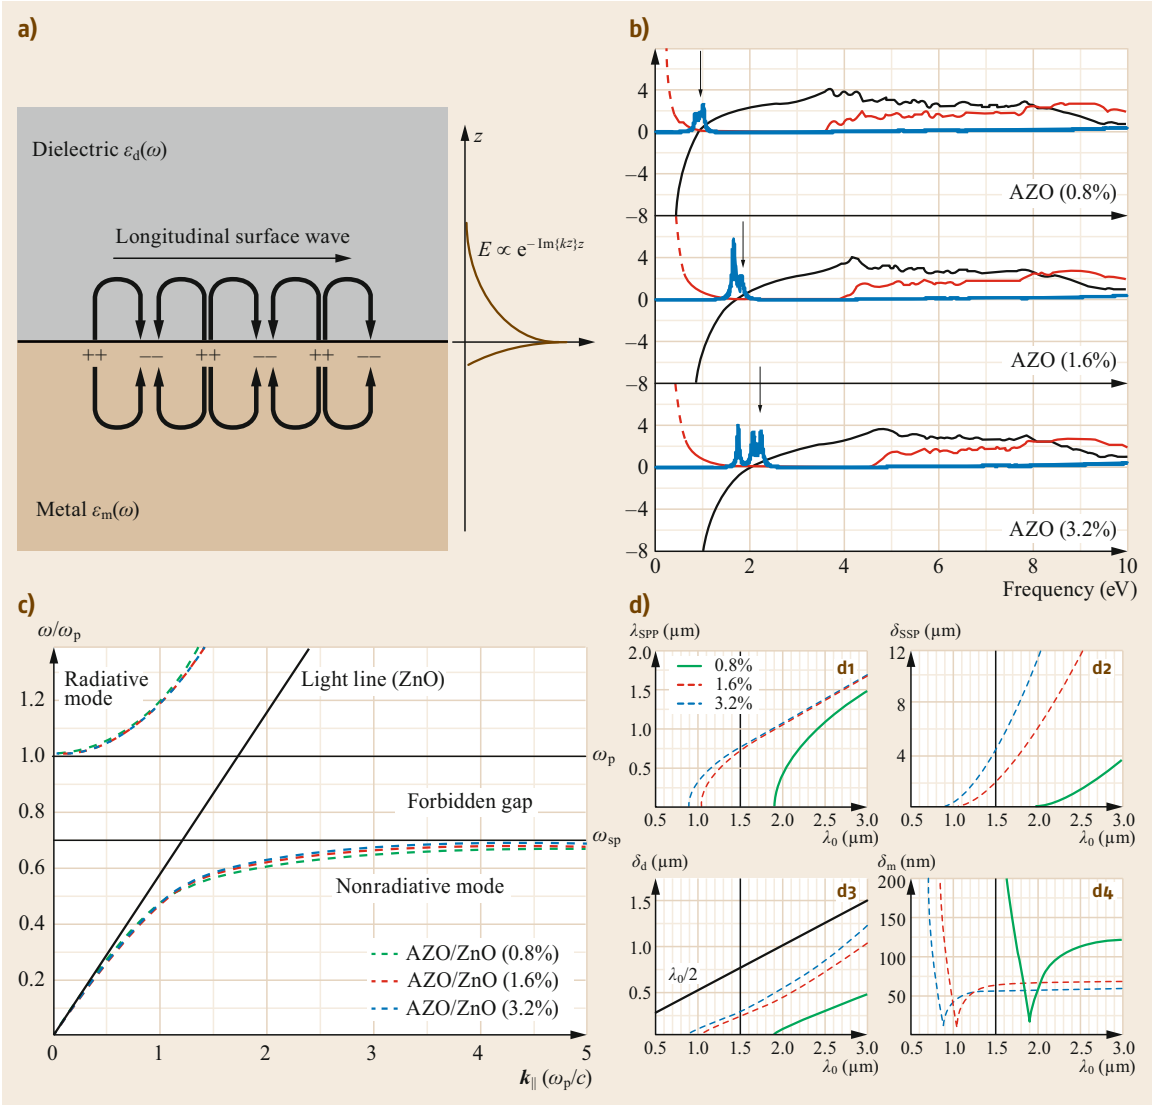

Fig. 5.14a–d **(a)** Localized SPP propagating on the metal surface at the metal/dielectric interface. **(b)** Real (*black line*) and imaginary (*red line*) parts of the complex dielectric function and the electron energy-loss function (*blue line*) of AZO at different Al concentrations. *Vertical arrows* mark the plasma frequency. **(c)** Dispersion relation of the real part of the SPP wavevector $\boldsymbol{k}_\parallel$ of AZO/ZnO interfaces at different Al concentrations. The *thick black line* marks the dispersion relation for light in the ZnO region. *Horizontal gray lines* define the forbidden gap. **(d)** Characteristic lengths of SPP (λ_{SPP}) in AZO/ZnO interfaces at different Al concentrations. *Vertical black lines* mark the characteristic wavelength for telecommunications. The *dashed line* in *panel* (d_3) corresponds to the upper compactness limit $\delta_d = \lambda/2$. Figure adapted with permission from [5.135]. Copyright 2014 American Chemical Society

In order to apply the matching condition of (5.8), it is necessary to know the dielectric function of the two separate materials over the frequency range of interest. However, while for noble metals the plasma frequency and the other plasmonic properties can be extracted once and for all from experimental data, in the case of TCOs this is not possible because of the doping-induced modifications in the optoelectronic properties of the host material. First principles simulations provide a very useful tool for the evaluation of the optical and electronic properties of materials and their interfaces, also in the case of dopants and impurities as in AZO, where semiempirical values for the dielectric function are not univocally defined. Here, for the description of

the optical properties of bulk-like systems, we adopted the TB approach described above [5.97], which has its foundation on the DFT characterization of the ground-state electronic structure. Once the complete dielectric function is known, the electron energy-loss function can also be easily obtained as $L(\omega) = \mathrm{Im}\{-1/\hat{\epsilon}\}$.

As doping may change the optoelectronic properties of AZO, we investigated different doped systems, as obtained by varying the number of substitutional Al atoms in the range 0–3.2%, in the virtual crystal approximation [5.84, 106]. Within the solubility limit (3.5%), Al dopants mostly assume Zn-substitutional sites, and the crystalline order of the ZnO host is only slightly perturbed, as results from complete relaxation of the atomic structure. This has two main effects on the electronic structure of AZO: (i) Al does not induce the formation of defect states in the ZnO bandgap, and (ii) Al donates its 3p electron to the ZnO conduction band, without remarkably changing the shape and the curvature of the conduction band minimum. This is the typical fingerprint of an intrinsic n-type conductor. Increasing the doping percentage forces an upward energy shift of the Fermi energy in the pristine ZnO conduction band. The simultaneous presence of point defects (e.g., Zn or O vacancies) or other impurities (e.g., H) may change the details of the resulting electronic structure, introducing further charge-compensation effects [5.85, 142]. However, this does not change the general picture described above. In virtue of the single quasi-parabolic band at the ZnO bottom of the conduction band, the effect of Al doping is the formation of a free electron gas in the metal oxide. This is the fundamental prerequisite for a plasmonic material. The results of the optical properties are summarized in Fig. 5.14b. For all the dopant ratios, we distinguish two energy regions. In the UV range, the imaginary part of the dielectric function has a net peak, whose energy position depends on the doping level. This corresponds to the interband valence-to-conduction absorption edge. In all cases, there is a blue shift of the absorption edge, which may be explained in terms of the Burnstein–Moss effect [5.143]. At lower frequencies, the optical properties of AZO completely differ from the original ZnO ones, being similar to an ideal simple metal. The rapid decay of ϵ_2 (red line) expresses viscous electron damping due to scattering processes associated with the electrical resistivity. The real part of the dielectric function (black line) is negative and diverges for $\omega \to 0$, in agreement with the formation of a free electron gas upon Al doping. Where $\epsilon_1 = 0$ and $\epsilon_2 \ll 1$, the loss function (blue line) has a peak corresponding to the plasma frequency ω_p of the system. The presence of Al dopants imparts a drastic shift of the plasma frequency that moves from the far-UV ($\approx 17\,\mathrm{eV}$, not shown) in the case of ZnO to the NIR and the visible range in the case of AZO, in agreement with recent experimental results [5.138]. This proves that in the case of TCOs ω_p can be tuned by controlling the electron density, i.e., by changing doping content. Even in the heavy doping regime (e.g., 3.2%), the plasma frequency does not overlap with the interband transition energy region. This assures low losses in the NIR-VIS range, reducing one of the most challenging problems that plagues standard metallic materials. This, along with the agreement with the experimental results, confirms the validity of the Drude model for this compound, which actually acts a low-loss plasmonic metal.

Once the dielectric functions of AZO and ZnO are known, the SPP properties can be investigated. The dispersion relations (5.8) for the AZO/ZnO interface at different Al concentrations are shown in Fig. 5.14c. At low frequencies, the surface mode asymptotically approaches the light line for ZnO (black line). As the frequency increases, the SPP mode separates from the light line and approaches the surface plasmon frequency (ω_sp) of the conductor (AZO). From $\hat{\boldsymbol{k}}_\parallel(\omega)$ we can derive the length scales that characterize the spatial profile of the SPP mode for the AZO/ZnO ideal interface as a function of the incoming radiation (λ_0) and of Al doping, as is shown in Fig. 5.14d. For the potential application of these materials in telecommunication devices, we mark the corresponding characteristic wavelength ($1.5\,\mu\mathrm{m}$) with a vertical line. The SPP profile can be described in terms of wavelength (λ_SPP), propagation length (δ_SPP), and dielectric (δ_d) and metal (δ_m) penetration depths. In the case of the AZO/ZnO interface, λ_SPP (panel d_1) is of the order of $1.0\,\mu\mathrm{m}$. Since λ_SPP defines the periodicity of the SPP wave, it also defines the scale of optical structures (e.g., Bragg scatterers) typically used to control the SPP. The propagation length (δ_SPP) is the distance over which the intensity of the SPP mode falls to $1/\mathrm{e}$ of its initial value. For any real application, it is necessary that $\delta_\mathrm{SPP} > \lambda_\mathrm{SPP}$; i.e., SPP should propagate as a straight ray in geometrical optics. This is the case for the AZO/ZnO interface, where the SPP can propagate up to a few microns also at the telecom wavelength (panel d_2), if the doping level is sufficiently high. The penetration lengths into the dielectric and metallic layers determine the compactness of the SPP, giving a measure of the minimum thickness required for the dielectric and metal layers. The need for high localization at interfaces imposes that the penetration depths be as small as possible. The penetration length inside the ZnO layer δ_d (panel d_3) is very short ($\approx 200\,\mathrm{nm}$ depending on the Al content) at $\lambda = 1.5\,\mu\mathrm{m}$, giving rise to a high compact optical system. In order to highlight this feature, we reported (black dashed line, panel d_3) the so-called *upper compactness* limit

$\delta_d = \lambda_0/2$, which corresponds to the minimal diameter spot of a dielectric photonic device. The fact that for the AZO/ZnO interface δ_d is always below the $\lambda_0/2$ line indicates that the SPP mode has electromagnetic field enhancement properties typical of photonic systems and the subwavelength confinement of electronic devices. Notably, standard plasmonic materials such as Au and Ag do not fulfill this requirement, crossing the compactness limit in the range 300–500 nm. The skin-depth properties of the metallic layer are quantified in terms of the penetration length inside the metal δ_m (panel d_4). In the present case, δ_m is at least two orders of magnitude smaller than the corresponding δ_d for each doping considered.

The good agreement with the experimental results confirms, on the one hand, the validity of the Drude–Lorentz model in the description of this class of materials, and on the other hand, the capability of DFT approaches to characterize and predict the optoelectronic properties of complex materials and interfaces.

5.6 Exploring Water/Solid Interfaces via DFT Simulations

One of the most compelling tasks when dealing with atomistic ab initio approaches is the description of the physical properties of solid/water interfaces. Understanding at an atomistic level how liquid water wets a solid surface is of fundamental relevance both at a basic and an applied research level. On the one hand, it would be desirable to understand how concepts such as hydrophobicity/hydrophilicity are revealed at the molecular level and to identify the fingerprints of the resulting wetting layer; whereas, from a macroscopic point of view, it would be important to predict how the presence of the hydration layer influences the physical properties of the material when employed in devices or applications occurring in liquid environment. In the following, we summarize the results of two of the few examples reported in the literature dealing with the microscopic description of the interface between liquid water and a solid surface obtained by ab initio molecular dynamics simulations. In particular, we will focus on the hydroxylated Si-SiC(001) surface [5.144] and the gold(111) surface [5.27]; we will give an insight into the perturbation induced in water at the surface layer both under the structural and electronic point of view. A detailed analysis of the interaction of water molecules with the atoms at the surface reveals the hydrophilic character of these two surfaces, but the mechanism leading to such behavior is different when comparing a clean metal surface like gold and a hydroxylated semiconductor surface such as that of Si-SiC(001).

5.6.1 How to Build a Solid/Liquid Interface?

Contrary to all the previously presented cases, here we cannot assume a single static configuration for the solid/liquid interface. In fact, at room temperature the molecules that form the liquid continuously fluctuate, changing their position in space and the bonding path with both the other molecules of the solvent and the solid surface. Therefore, a molecular dynamics (MD) approach is needed. Before presenting the results on the wetting behavior of water obtained by means of ab initio molecular dynamics, we first discuss an important step along the computational strategy for the simulation of a solid/liquid interface: the preparation of the initial MD configuration. Performing an ab initio molecular dynamic simulation of a solid/liquid interface requires a good initial starting configuration, which is not straightforward to achieve. The main difficulty derives from the fact that the majority of computer codes employed to perform ab initio molecular dynamics use plane waves to expand the system wavefunction and, as such, are coded to deal with simulation cells that are periodic in three directions, as discussed in Sect. 5.2. In the case of simulations involving a disordered system, and in particular a polar solvent like water, this poses a further difficulty. When placing the liquid slab on top of the surface, one has to select the number of molecules needed to represent the correct density of the liquid phase, and, in this respect, some attention must be paid due to the existence of an exclusion volume at a solid surface that is due to steric effects. Neglecting the exclusion volume present at the surface would lead to an overestimation of the volume occupied by the liquid and, consequently, to studying an interface with a less dense liquid.

Typically, two alternative methods have been used to cope with this problem and to prepare a realistic interface. In the first approach, the starting configuration for the first principles simulations is obtained by performing preliminary classical MD simulations employing a classical force field for water–water and water–surface interaction, if available. In the water/solid system the supercell dimensions in the (x, y) plane are fixed and determined by the size of a solid surface periodicity. To obtain an estimate of the surface exclusion volume, which is connected to the supercell lattice

parameter in the direction perpendicular to the interface (z), the cell dimension is varied, until the stress along this direction yields a pressure equal to the atmospheric one. Alternatively, one can fix the supercell size in the z-direction and change (increase or decrease) the number of water molecules in the supercell until the stress on the simulation cell corresponds to atmospheric pressure.

The second approach consists in a short (few ps) ab initio molecular dynamics of the solid/liquid interface at low coverage regime (for example, one monolayer of molecules). The result of this simulation allows estimating the average distance between the interfacial water molecules and the surface, and thus the thickness of the exclusion volume. In the two solid/water interface examples described below both approaches were used and, in particular, a preliminary classical molecular dynamics run has been used for the gold/water surface. Once the initial configuration is obtained, the first principles calculation typically starts with an initial thermalization of the system at $T = 400$ K for a few picoseconds, employing a thermostat to keep the temperature constant. The equilibration is then followed by 10–20 ps of production run (microcanonical ensemble, NVE) and, finally, the trajectories are analyzed. The ab initio molecular dynamics that we present here are performed at the temperature (400 K) at which DFT using PBE and Car–Parrinello dynamics yields results in good agreement with experiments for structural and diffusion properties of liquid water at ambient conditions [5.145, 146]. This thus allows us to compare bulk and interface water properties, to enhance the effect of interfaces.

5.6.2 The Cases of Si-SiC/Water and Gold/Water Interfaces

The interface between water and two hydrophilic interfaces, namely hydroxylated Si-SiC(001) and clean gold(111) surfaces, as discussed in [5.27, 144] are represented in Fig. 5.15. For both systems, the structural properties of interfacial water was first investigated by analyzing how the average water density and the number of hydrogen bonds change as a function of the distance from the interface. As shown in Fig. 5.16, at both Si-SiC and gold surfaces, water density presents a high peak when in contact with the solid surface. This enhanced density at the interface was observed in other simulations of solid/water interfaces [5.147, 148], and it is determined by packing forces, and by the tendency of water to maximize hydrogen bonds. The observed interfacial peak is expected to be at a closer distance to the outermost atomic layer in the case of hydrophilic surfaces if compared to hydrophobic surfaces. In particular, in the case of the hydroxylated Si-SiC surface, the water density presents a single intense peak at 2.2 Å from the surface hydroxyl groups (Fig. 5.16b), while in the case of gold, the first high-density maximum is a structured peak that has a maximum at 3.2 Å from the surface atoms and presents a prominent shoulder (the red arrow and the inset in Fig. 5.16a) at a shorter distance of about 2.6 Å. A detailed analysis of the restructuring of the water network occurring at this interfacial water layer reveals that the mechanism leading to the hydrophilic behavior is different for these two surfaces.

Large golden spheres represent Au atoms, while red and white sticks represent oxygen and hydrogen atoms, respectively. **(b)** Ball-and-stick rendering of a representative configuration for the interface between the hydroxylated Si-SiC surface and liquid water. *Inset* Top view of the hydroxylated Si-SiC surface. *Red*, *white*, *gray*, and *light blue spheres* represent oxygen, hydrogen, carbon, and silicon atoms, respectively. Figure adapted with permission from [5.27, 144]. Copyright 2005 and 2011 American Chemical Society

In the case of Si-SiC, water molecules at the surface form a smaller number of hydrogen bonds than in the bulk; at a distance of about 3 Å from the surface atoms, the bulk value of 3.6 H bond/water is recovered; see Fig. 5.16d, where the H bonds connecting water molecules to the surface hydroxyl groups were not included. As shown by the blue and red curves in Fig. 5.16d, the water molecules at the surface do not show any preference in accepting or donating H bonds. A deeper structural analysis also shows that the water molecules close to the surface do not adopt a tetrahedral-like coordination but rather are arranged so as to optimize their H-bonding network in a manner compatible with the orientation and periodicity of the surface hydroxyl groups. In particular, a study of the spatial distribution of the interfacial water molecules proves that water molecules do not wet the surface uniformly, preferring the direction parallel to the hydroxylated surface dimer rows. In other words, in such a hydroxylated surface, it is the geometry of the surface −OH groups [5.65] that plays a determinant role in the restructuring of the interfacial water layer. These induce a directionality in the filling space properties of water and ultimately determine the presence of chains of hydrogen bonded molecules bridging over hydrophilic surface groups. To assess more specifically the nature of the water/surface interaction in this case, the total electron density of the interface, ρ_{int}, was compared to that of the isolated hydroxylated surface, ρ_{SiC} and water, ρ_{water}, for a given snapshot of the molecular dynamics run. The changes in electronic charge induced by the water surface interaction is expressed as: $\rho_{diff} = \rho_{int} - [\rho_{SiC} + \rho_{water}]$. The quantity ρ_{diff} is positive when there is an addition of charge to the system with respect to the isolated fragments, and negative in the opposite case. In Fig. 5.17a ρ_{diff} is represented for a particular snapshot of the simulation run. The depletion and accumulation of charge, with respect to the isolated water and surface systems, are represented by blue and yellow iso-surfaces, respectively. The main changes in the charge density are localized directly at the interface, and in particular they are located along the directions of the hydrogen bonds established between the surface −OH groups and water molecules. The projection of ρ_{diff} on two clip planes containing two different surface −OH groups is represented in Fig. 5.17b, which shows one −OH group donating (left panel) and the other accepting (right panel) a hydrogen bond. In both cases, it is

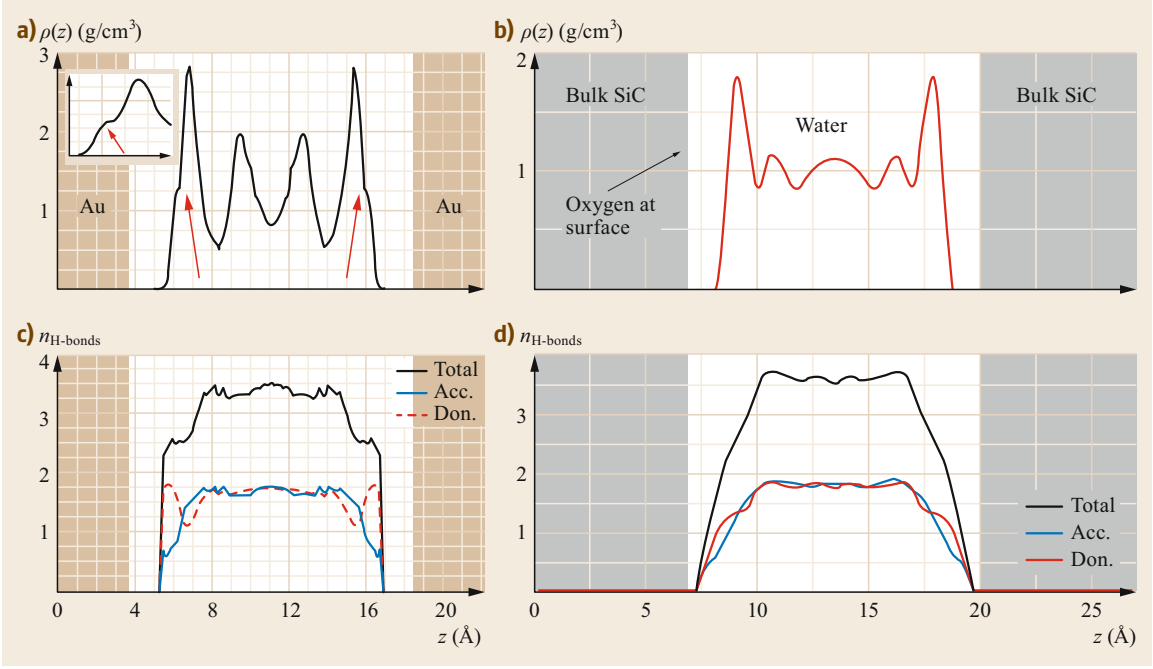

Fig. 5.16a–d Average oxygen density (**a**,**b**) and average number of water–water H bonds (**c**,**d**) as a function of the distance from the interface between liquid water and the Au(111) surface (**a**,**c**) and the hydroxylated Si-SiC(001) surface (**b**,**d**). The curves in (**c**) and (**d**) were obtained by counting the number of H-bond donors (*red curve*) or acceptors (*blue curve*) for each water molecule; the sum of the two curves is also reported (*black line*). The following geometric criterion to define a H bond was chosen: O−O distance < 3.5 Å and O−HO angle > 140°. Figure adapted with permission from [5.27, 144]. Copyright 2005 and 2011 American Chemical Society

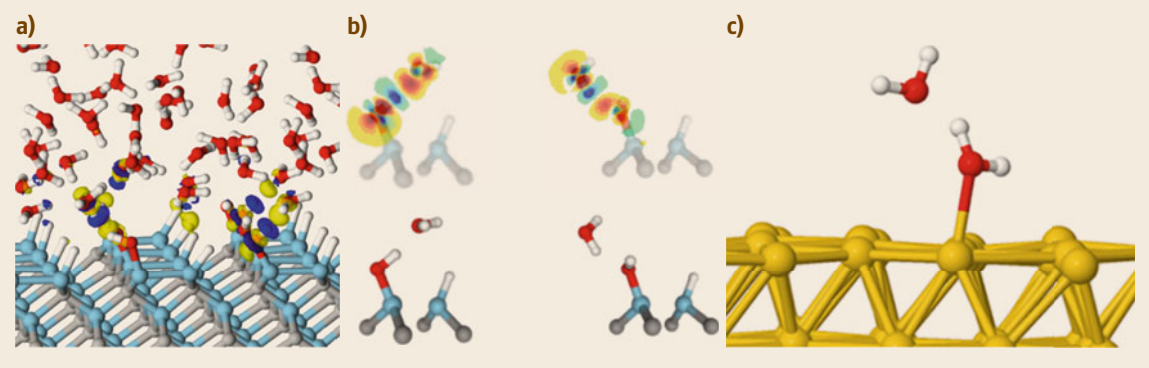

Fig. 5.17 **(a)** Isosurfaces of the electron density difference, ρ_{diff}, at the interface between the hydroxylated surface and liquid water. *Yellow* (*blue*) isosurfaces represent charge density increase (decrease) with respect to isolated surfaces. *Red*, *white*, *gray*, and *light blue spheres* represent oxygen, hydrogen, carbon, and silicon atoms, respectively. **(b)** Projection of the isosurface of the electron density difference onto a clip plane passing through an −OH surface group acting as a H-bond donor (*left panel*) and acceptor (*right panel*). **(c)** Representative snapshot (side view) along the molecular dynamics simulation run for the Au(111) surface exposed to 1 ML of water molecules. One water molecule interacts through its lone pair with a surface gold atom (Au−O = 2.5 Å) and at the same time it is involved in a hydrogen bond interaction with a water molecule in the gas phase (O−O = 2.6 Å). The other water molecules have been removed for a clearer rendering. Figure adapted with permission from [5.27, 144]. Copyright 2005 and 2001 American Chemical Society

found that upon H-bond formation the −OH group polarity is enhanced, and the H atom resides in a positive charge basin (blue spot). At the same time, the electron density in the region of the lone pair of the oxygen accepting the hydrogen bond increases. These results confirm that most of the surface/water interaction is local and strongly related to the capability of the hydroxyl groups at the surface to establish H bonds.

In the case of gold, the surface atoms are not able to directly form strong hydrogen bonds with surrounding water molecules, yet the interaction with the first liquid layer with the exposed gold atoms strongly affects the ability of these water molecules to establish hydrogen bonds. This is evidenced by an analysis of Fig. 5.16c, where the average number of hydrogen bonds per water molecule is reported as a function of the distance from the surface. Although, similarly to Si-SiC(001) far from the surface (beyond 4 Å) the average number of H bonds is the one observed for water in the liquid phase (with an equivalent number of H-bond acceptors and donors), the situation is different for the molecules of the surface hydration layer. These molecules have only one half of their hydration shell and, for this reason, form a smaller number of H bonds, yet, it is surprising to notice that at distances < 2.8 Å from the surface water molecules persistently behave as H-bond donors; their average number of donated H bonds is even slightly larger than that found far from the surface (i.e., for liquid water). This feature has not been observed for the hydroxylated SiC. By inspection of the spatial distribution of the water molecules in contact with the gold surface, i.e., the molecules of the density shoulder located at the 2.6 Å distance, it is revealed that the oxygen atoms preferentially reside at on-top Au(111) sites while the hydrogen atoms are uniformly distributed around them. This orientation is due to the formation of a dative-like bond between the lone pair at the oxygen atom of water and the gold atoms at the surface (Fig. 5.17c). This type of interaction is responsible for an oxygen-to-gold charge transfer, which favors a dynamical attractive coupling between the metal and the first wetting layer. Moreover, this interaction is responsible for the enhanced H-bond formation of the interfacial water. In fact, a detailed analysis of the hydrogen bond strength of interfacial water indicates that the intermolecular H bond is stronger in the presence of the gold surface by about 0.2 eV. In other words, interfacial water molecules, due to their interaction with the gold surface, appear more acidic and keener on donating H and forming H bonds that are stronger than those in the liquid phase, rendering the surface "hydrophilic-like."

The hydrophilic behavior of both gold and Si-SiC surfaces has also been addressed by calculating the average water dipole moment in the liquid sample in contact with the two surfaces. The dipole of a water molecule is strongly influenced by the number of hydrogen bonds that the molecule forms. In particular, the dipole increases passing from the gas phase 1.87 D (no H bonds) to the liquid 2.88 D (about 3.6 H bonds) and to the solid phase 3.00 D (4 H bonds). Interfacial water molecules would present different dipole values depending on the

hydrophobicity/hydrophilicity of the surface. In particular, at hydrophobic surfaces molecules have a number of H bonds typically smaller than in liquid and, for this reason, have smaller dipoles, while in the case of a hydrophilic surface, the molecules have dipoles similar to those found in liquid water [5.148]. Both in the case of the hydroxylated Si-SiC and in the case of the Au surface, it was found that the average dipole moments of the interfacial water molecules are unchanged with respect to the liquid value, and it is thus consistent with a surface of hydrophilic character.

In conclusion, the results presented above show for two sample surfaces how it is possible to achieve detailed atomistic models for solid/liquid interfaces together with insight into the electronic and bonding properties, by using predictive and accurate ab initio simulations. A detailed analysis of water restructuring at the surface shows that only the molecules in the first water layer are perturbed by the surface and that the interaction is local. The local nature of the water/solid interaction is confirmed by electronic structure analyses, indicating that all major changes in the charge density of the isolated liquid and the material slabs are localized at the interface. While in the case of Si-SiC, the hydrophilic character of the surface and the water rearrangements are guided by the presence of −OH groups at the surface, in the case of gold, it is rather the surface together with its hydration layer that has a hydrophilic character. This latter conclusion can be drawn based on the observation that the water molecules interacting with the gold atoms form H bonds that are stronger than the average hydrogen bond strength in liquid water.

5.7 Conclusions

In this short review, without presumption of completeness, we have presented a number of test cases where ab initio DFT simulations are found to be fundamental in the understanding and predictivity of specific issues relevant to parallel experiments in surface science. We chose to describe the protocols most suited to complement some experimental problems that range from the microscopic characterization of interfaces, mandatory for, e.g., the design of contacts, to functionalization and sensing. This has been done at the expense of a detailed formal description of the advances in theory, which are beyond the present scope. Yet, the field is continuously evolving, with the inclusions of many different approximations that allow us to study more complex systems, and eventually at the expense of simplicity, efficacy, and speed. For these issues we refer the reader to specific reviews, such as [5.149].

Giancarlo Cicero received his PhD in Physics in 2003 from the University of Torino. He is currently at the Politecnico di Torino as Associate Professor in the Materials Science and Chemical Engineering Department. His main expertise is the atomistic simulations of surfaces and nanostructures to be employed in nanoscale devices and, in particular, third generation solar cells.

Alessandra Catellani

CNR-Istituto Nanoscienze
Modena, Italy
alessandra.catellani@nano.cnr.it

Alessandra Catellani is Senior Researcher at the Istituto Nanoscienze of the National Research Council of Italy (CNR-NANO). Her main research interests are related to the ab-initio simulation of structural and electronic properties of low-dimensional systems, such as nanostructures and interfaces, for energy conversion and (nano)sensor applications.

6. Surfaces of Bulk Oxides

Jacques Jupille

Following a brief overview that illustrates the strong research activity dealing with the surface structures of binary oxide, two issues are addressed herein: the relaxation at oxide surfaces and the surface structure of ternary oxides. As a quite general phenomenon, the compensation of the stress generated by the creation of a surface results in relaxation of interlayer spacings and, in the case of ionic solids, in difference in displacement between anions and cations, the so-called rumpling. Rocksalt oxides are of particular interest in this context because they form a series of compounds of identical structure of which only the cations change. Due to the gradual variation they present over the series, they offer a unique playground for the critical analysis of relaxation and rumpling at ionic surfaces.

The many applications of the oxides of perovskite structure require the control of terminations at the atomic scale. Despite puzzling discrepancies in preparation conditions, many $SrTiO_3$(100) surface reconstructions—c(4 × 2), c(6 × 2), ($\sqrt{5} \times \sqrt{5}$)-R26.6°, ($\sqrt{13} \times \sqrt{13}$)-R33.7°—are reproducibly obtained, leading to a set of structural models. However, the demonstration that strontium and stoichiometry defects play a direct role in reconstructions questions the present models and challenges the goal of preparation of single-terminated $SrTiO_3$(100) surfaces of uniform structure.

6.1 Overview

Oxides are ubiquitous in natural and industrial environments, whether in the form of bulk compounds or corrosion layers covering metals and alloys. In the many circumstances in which oxides or oxidized objects come into chemical or mechanical contact with foreign media, the knowledge of surface structures is essential to understanding surface chemistry [6.1, 2]. Surface structures are key ingredients of the behavior of oxides in catalysis [6.3, 4], photochemistry [6.5–7], gas sensing [6.8, 9], microelectronics [6.10], and adhesion [6.11]. They are also central in geochemistry, in the context of minerals in the environment [6.12–16]. In surface science of oxides, the study of thin films fruitfully completes the analysis of single crystals [6.17–22]. The primary incentive for synthesis of thin films was to escape the limitations imposed by the insulating character of most oxide substrates and to enable imaging of surfaces at the atomic scale by scanning tunneling microscopy (STM). However, the field quickly turned out to be a prodigious source of original structures that do not exist in bulk [6.17–21]. Synthesis of thin films offered a versatile approach for the study of oxide nanostructures in reduced dimensions [6.18, 19] and microscopic characterization of interfaces [6.18, 22]. The important role played by defects is another aspect specific to oxide surfaces. As detailed in a book dedicated to defects on oxide surfaces [6.23] and in a number of review articles, defects are strongly involved in the chemistry and physics of metal oxide surfaces. Defects can be classified according to topological features that include terraces, steps, kinks and corners [6.24–26], and point defects, which

involve vacancies, adatoms, and interstitial and substitutional atoms. Many efforts have been devoted to the formation of these at the surface of metal oxides, either reducible [6.28, 29] or irreducible [6.28], and of rare earth oxides [6.29]. The main related issues are the identification of defects [6.30–34] and the localization of defective states [6.35–37], the impact of the defects created on the crystallographic [6.38, 39] and electronic structure [6.9], and their role in surface chemistry and photochemistry [6.5, 6] and electronic transport [6.40]. The omnipresence of thin films, nanoparticles, and extended or point defects explains the growing role of near-field microscopy in the study of the surface crystallography of oxides, since the flexibility of the method allows for the combination of structural and spectroscopic analysis at different scales. In support of the experiment or in parallel with it, numerical simulations have increasing importance. To better describe localized states, density functional theory approaches are complemented by hybrid functionals, which involve Fock and DFT (density functional theory) exchange energy, and the so-called DFT + U method in which the Coulomb interaction is partially screened.

Oxide surfaces are made very complex by changes in stoichiometry, reconstructions, stabilization processes required by polar terminations [6.41–43], and

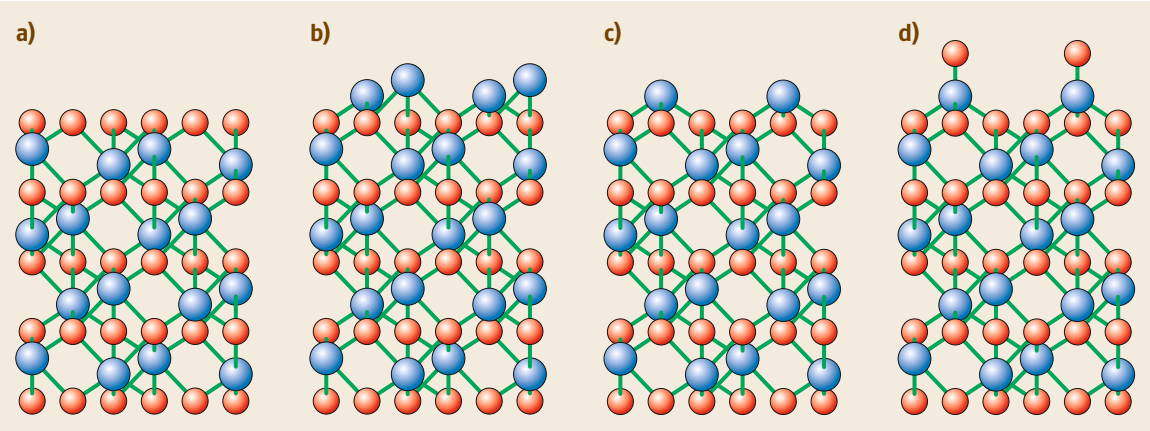

Fig. 6.2a–d Side view of the four possible (0001) terminations of the corundum structure (see text) **(a)** O_3; **(b)** full-metal; **(c)** half-metal; **(d)** Me=O (Reprinted with permission from [6.44]. Copyright 2013 American Chemical Society)

the sometimes uncontrolled reactivity with hydrogen or water. As a result, since the 2000s, where structures of oxide surfaces have been reviewed extensively, most of the dedicated articles focus on a limited selection of compounds, often only one. In this introductory part of the chapter, we discuss recent advances regarding the main oxide families—titanium oxide, SnO_2 and transparent conductive oxides, corundum-phase oxides, oxides of rocksalt structure, vanadium oxides, iron oxides, ceria, and zinc oxide—and the reasons that prompted us to focus the present review on oxides of rocksalt and perovskite structure.

TiO_2 surfaces have attracted much attention due to their direct involvement in many applications, such as solar energy conversion, self-cleaning coatings, biocompatible materials, photochemistry, and (photo)catalysis, as highlighted in the seminal review by *Diebold* [6.45]. Recent experimental and theoretical reviews have been dedicated to low-index rutile [6.46] and anatase [6.47] surfaces. A comprehensive issue of *Chemical Reviews* dedicated to titanium dioxide nanomaterials [6.48, 49] includes in particular papers on structure–property relationships [6.47] and on the synthesis of titania nanocrystals (anatase, rutile, and brookite) with tailored facets [6.50]. Finally, through surface science, approaches for TiO_2 photocatalysis provide molecular-level insights into photon-initiated events occurring at TiO_2 surfaces [6.5, 6]. The low activity relative to thin films of titanium oxide is likely explained by the availability of high-quality single crystals of that compound and the ease with which they are made conductive by reduction [6.46].

Among the several polymorphs of SnO_2, the most important naturally occurring form is cassiterite, a phase with a tetragonal rutile structure [6.8, 27, 51]. The hierarchy of the surface energies of the crystallographic orientations shown in Fig. 6.1 ((110) < (100) < (101) < (001) [6.27]) drives the growth and shape of the nanoparticles and controls the physicochemical activity. SnO_2 is widely used as oxidation catalyst, gas sensor, and transparent conductor. Those properties rely on the natural nonstoichiometry of the oxide that results from the low formation energies of tin interstitials and oxygen vacancies and on the multivalence of tin that easily switches from Sn(IV) as in SnO_2 and Sn(II) as in SnO. In particular, electrons donated by defects to the conduction band without increasing optical interband absorption explain the coexistence of conductivity and transparency, a unique property among the column-IV oxides [6.52]. However, the market for transparent conductive oxides is dominated by the tin-doped indium oxide (labeled ITO), as the material offers a better combination of conductivity and transparency than doped ZnO or SnO_2 [6.9]. This property was a strong motivation for the study of the structure of In_2O_3 surfaces. Under ambient conditions, In_2O_3 adopts a body-centered cubic bixbyite structure which is close to the parent fluorite structure, while alternative rhombohedral (corundum-like) and orthorhombic phases have been identified [6.9].

Besides the popular α-Al_2O_3, the corundum-phase oxides currently studied are V_2O_3, Cr_2O_3, and hematite α-Fe_2O_3 [6.44]. With respect to the most studied basal (0001) orientation, the rhombohedral structure can be represented by flat oxygen layers in hexagonal arrangement that sandwich double planes of aluminum atoms occupying two of three octahedral oxygen sites. By cleaving the bulk lattice, the obtained termination can be oxygen O_3−Me−Me, full-metal Me−Me−O_3, or half-metal Me−O_3−Me (Fig. 6.2). The latter is the expected nonpolar termination for that orientation which belongs to Tasker's type II classification. However, in

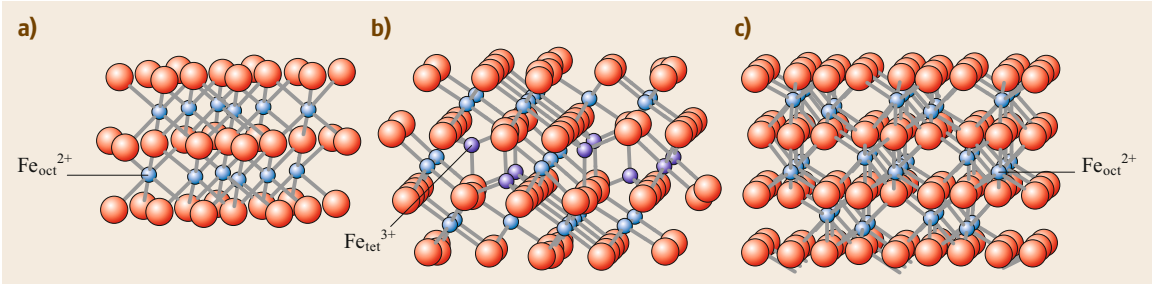

Fig. 6.3a–c The close-packed O^{2-} anion sublattice (*red spheres*) that is common to **(a)** wüstite, $Fe_{1-x}O$ (fcc oxygen lattice), **(b)** magnetite, Fe_3O_4 (fcc oxygen lattice), **(c)** hematite, α-Fe_2O_3 (hcp oxygen lattice), and maghemite (not shown) is clearly observed. The Fe cations in octahedral (*light blue*) and tetrahedral (*dark blue*) sites are indicated (Reprinted from [6.53], with permission from Elsevier)

all four cases, the issue is debated. Although the existence of the Al-terminated α-$Al_2O_3(0001)$ surface is postulated on the basis of measurements supported by atomistic simulations, some experiments suggest a partial termination of the surface by hydroxyl groups, even after annealing in ultrahigh vacuum. The presence of these groups could explain the discrepancy between the relaxation calculated by DFT for the Al-terminated surface and experimental measurements. Both experimental and theoretical approaches for $V_2O_3(0001)$, $Cr_2O_3(0001)$, and α-$Fe_2O_3(0001)$ suggest terminations in which the half-metal surface atoms are capped with oxygen atoms to give rise to Me=O termination (Fig. 6.2). Those terminations, which are not derived from bulk structure, are labeled vanadyl, chromyl, and ferryl, respectively. The O_3 and vanadyl terminations are alternatively suggested for $V_2O_3(0001)$ thin films [6.21]. Fe-, O_3-, and Fe=O terminations are identified on both α-$Fe_2O_3(0001)$ films and single crystals. However, the surface phase diagram remains controversial, in part because, since the conditions required to prepare stoichiometric surfaces are far different from those of common surface science studies, well-identified monophase surface terminations are lacking [6.21, 53]. Different Cr-terminations $Cr_2O_3(0001)$ are evidenced at low oxygen chemical potential, while chromyl groups are formed upon exposure to oxygen.

The vanadium–oxygen system is characterized by different oxidation states from V^{2+} to V^{5+} and various oxygen coordination geometries that are at the origin of the unique catalytic performance. Vanadium is the most important metal used in supported metal oxide catalysis [6.54]. Vanadium oxides involve binary compounds from VO (V^{2+}) to V_2O_5 (V^{5+}), and mixed-valence compounds such as Magnéli phases V_nO_{2n-1} and Wadsley phases $V_{2n}O_{5n-1}$ [6.21, 55]. Beyond studies dedicated to single crystals such as $V_2O_5(001)$, $VO_2(011)$, $V_2O_3(0001)$, and $V_2O_3(10\bar{1}2)$ [6.55], investigations of films supported on either oxides or metals became dominant because they offer a much wider choice of orientations and composition and are easily analyzed by electronic probes [6.17–19, 21, 55].

Iron oxides can be considered as a class since they have in common a close-packed layer of oxygen atoms (Fig. 6.3) [6.21, 53]. Wüstite FeO crystallizes in the rocksalt structure. Fe^{2+} ions are in octahedral positions. Wüstite is often nonstoichiometric because of cation deficiency. Magnetite Fe_3O_4 has an inverse spinel structure with tetrahedrally coordinated Fe^{3+} and a 50 : 50 mixture of Fe^{2+} and Fe^{3+} in octahedral position. (Spinels have the general formula AB_2O_4. In so-called normal spinels, such as $MgAl_2O_4$, the A^{2+} and B^{3+} cations occupy tetrahedral and octahedral positions, respectively. However, if A^{2+} cations have a large crystal field stabilization energy [6.53], as in the case of Fe_3O_4, they occupy half of the octahedral sites, while the displaced B^{3+} cations are in tetrahedral sites; such materials are known as *inverse spinel*.) Magnetite is the most studied iron oxide because at 125 K it undergoes the so-called Verwey transition from a monoclinic to an inverse spinel structure that leads to profound changes in conductivity and magnetic properties. In hematite α-Fe_2O_3, the most stable phase, Fe^{3+} ions occupy octahedral sites. Direct oxidation of Fe_3O_4 leads to maghemite γ-Fe_2O_3, in which Fe^{2+} is converted into Fe^{3+}, while the spinel structure, with Fe vacancies in octahedral positions, is preserved. Although the spinel structure is metastable with respect to the corundum structure, the transformation requires the difficult transition of the O^{2-} lattice from fcc to hcp. Conversely, transitions from wüstite to magnetite to maghemite are easy because they only require cation rearrangement while keeping the fcc oxygen lattice.

Ceria CeO_2 has the fluorite (CaF_2) crystal structure, with a face-centered cubic sublattice of Ce cations and a simple cubic arrangement of O anions. Although ceria single crystal surfaces are used, surface science studies of ceria are generally performed on thin films that

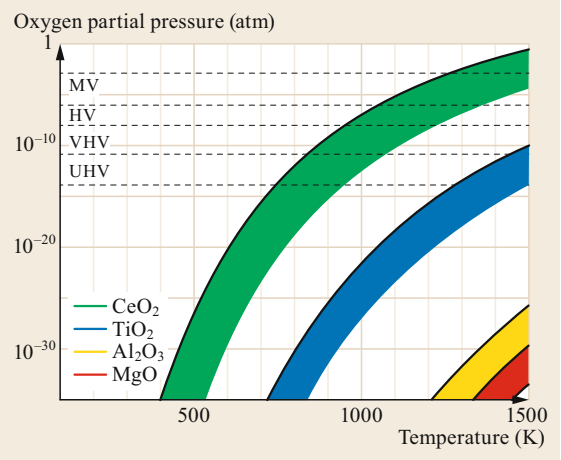

Fig. 6.4 Comparison of so-called reducible (here, CeO_2 and TiO_2) and irreducible oxides (Al_2O_3 and MgO): A $P(O_2)$ versus T phase diagram, as determined by density functional theory approaches, shows transition curves from pristine to defective surfaces in thermodynamic equilibrium. *Colored areas* give estimates of errors. *Dashed horizontal lines* indicate residual pressures encountered in various vacuum regimes. The reducible character of ceria is highlighted (Reprinted with permission from [6.20]. Copyright 2013 American Chemical Society)

are prepared either by direct deposition of the oxide or via precursors or, most often, by oxidation of cerium films [6.56]. The catalytic applications of ceria, a material of which a particular property is the ability to pass rapidly through redox cycles (Fig. 6.4) [6.20], are the focus of much attention [6.3, 20, 29, 56, 57].

Zinc oxide is commonly used as catalyst, especially in the industrially important production of methanol, and as pigment. ZnO powders of wurtzite structure reveal nonpolar facets, $(10\bar{1}0)$ and $(11\bar{2}0)$, and polar zinc- and oxygen-terminated facets, $(000\bar{1})$-Zn and $(000\bar{1})$-O [6.58, 59]. As regards the $(10\bar{1}0)$ surface, overall consistency is observed between experimental approaches and between these approaches and the theoretical modeling. Conversely, little is known about the polar $(000\bar{1})$-O surface that is stressed as being the most catalytically active ZnO termination. Neither the compensation of the electrostatic instability of that surface nor its hydrogen termination is understood [6.58].

This brief overview illustrates the strong research activity relating to the surface structures of binary oxides. I propose herein to address two important issues from angles that seem to avoid redundancies: (i) the quite general question of surface relaxation, and (ii) the surface of strontium titanate, whose structure/property relations are strongly debated [6.10, 60–67].

In the first part, special attention is paid to rumpling, an issue common to all ionic surfaces [6.68, 69]. The rocksalt oxide surfaces, recently reviewed by *Woodruff* [6.44], are chosen in this context because, given the gradual variation they present over the series, they offer a unique playground for the critical analysis of relaxation and rumpling mechanisms. Whatever the material, the creation of a surface generates a stress that is compensated by atomic rearrangements whose energetically dominant contribution is the relaxation of the surface and subsurface interlayer spacings [6.70–75]. Within a given atomic layer, cations and anions show different displacements in the direction normal to the surface because of their specific polarizability and bonding. The difference between these displacements is the so-called rumpling. With an energy of two orders of magnitude lower than relaxation [6.70], rumpling has, however, attracted continual interest because its mechanism relies on the nature of the atomic interactions in the surface region. In this context, oxides of rocksalt structure are of particular interest because they form a series of compounds of identical structure, of which only the cations change. After the examination of MgO(100), one of the oxide surfaces having accumulated the greatest number of studies, the data related to the series of the (100) nonpolar orientation of the alkaline earth oxides (CaO, SrO, BaO) and the oxides of the transition metals of Group III (MnO, FeO, CoO, NiO) are considered, respectively.

The second part of the review turns toward a reflection on ternary oxides. Many applications require surfaces with precisely defined structures [6.10, 60–67], although their composition reflects the bulk complexity. In the global movement that has focused on oxide surfaces and interfaces over the past few decades, the early discovery of catalytic [6.76], sensing [6.77], ferroelectric [6.78], and dielectric [6.79] properties of oxides of perovskite structure has prompted intense investigations, with particular interest in the crystallographic orientation (100) of strontium titanate $SrTiO_3$, which is the subject of this review. The surface structures of $SrTiO_3(110)$ and $SrTiO_3(111)$ (polar) and those of the other oxides of perovskite structure have been much less investigated [6.10, 80–82]. The story began with the early use of $SrTiO_3$ for growing epitaxial high-temperature superconducting oxide films [6.83]. The need for atomically defined substrate prompted *Kawasaki* et al. to prepare single-terminated $SrTiO_3(100)$ surfaces [6.84] that subsequently inspired many other studies. Epitaxial growth on $SrTiO_3(001)$ depends intimately on the surface structure. The $(\sqrt{13} \times \sqrt{13})$-R33.7° reconstruction favors homoepitaxy [6.85], while heteroepitaxy is easier on

the $(\sqrt{13}\times\sqrt{13})$-R33.7° [6.86] and (2×1) [6.87] structures. The nucleation of perovskite is forbidden on $SrTiO_3(001)$-c(6×2) [6.87] but allows pseudomorphic CdTe(211) growth [6.88]. High-quality epitaxy [6.89] and lower critical temperature [6.90] are obtained for $YBa_2Cu_3O_{7-x}$ on smooth single-terminated terminations. Unusual transport properties are observed on $SrTiO_3(106)$ stepped surfaces [6.91]. Such a close matching of many oxides and semiconductors on $SrTiO_3(100)$ surfaces was the source of an impressive series of new findings. Examples are provided by the crystalline gate dielectric in silicon-based devices [6.92], channels for field-effect transistors [6.93, 94], two-dimensional electron gases (2DEGs) [6.61]—later observed at cleaved STO surfaces [6.66]—ferroelectric superlattices [6.62], and superconducting and magnetic interfaces [6.65], which have paved the way for atomically fabricated innovative heterostructures. Referred to as the "gold standard" [6.95] for its ability to act as a photocatalyst in promoting water splitting without bias [6.76], strontium titanate became a workhorse [6.10, 67] for the emerging oxide nanoelectronics, similar to what silicon is for the field of semiconductors [6.10, 64, 66, 67]. In relation to these developments, the control of the structure and composition of the $SrTiO_3(100)$ surface is of crucial importance. The second part of the review examines the TiO_2 and SrO terminations of $SrTiO_3(100)$ and describes the reconstructions of that surface, before discussing the limits of the current state of the art.

6.2 Oxides of Rocksalt Structure

MgO(100) is a reference for the surface science of oxides. The simple rocksalt cubic structure of the oxide is tractable for calculations, while the easy cleavage along the low-energy (100) face allows for the preparation of well-defined surfaces in a reproducible manner. Magnesium oxide is also obtained in the form of cubic nanoparticles closed by (100) facets by various methods ranging from decomposition of hydroxides or carbonates in vacuum [6.96, 97], burning metallic magnesium in oxygen [6.98], or gas-phase reaction of magnesium with oxygen [6.99]. Those nanocrystalline powders exhibit a variety of low-coordinated ions that were used as a model for catalytic reactions [6.96] and water [6.97, 100] or hydrogen [6.99] dissociation. CaO and BaO powders contribute many applications such as bioactive glass ceramics [6.101, 102] and dye-sensitized core–shell nanocrystals [6.103]. BaO allows the storage of NO_x emissions in three-way catalysts [6.104]. MgO is the basic component of catalysts for the activation of methane [6.105]. Single-crystalline Fe/MgO/Fe magnetic tunnel junctions show giant tunneling magnetoresistance [6.106]. Although CaO has attracted fewer experimental surface studies than MgO, and SrO and BaO none, the numerous applications, especially those related to catalysis, have stimulated the development of theoretical approaches [6.107–110]. The (100) surfaces of the transition-metal oxide series MnO, CoO, FeO, and NiO also became quite popular because they are cleavage planes of oxides that are antiferromagnets below Néel temperatures of 116, 198, 291, and 525 K, respectively [6.111], used as catalysts [6.112–114] and commonly encountered as corrosion products [6.115].

6.2.1 Surface Geometry

Relaxation and rumpling are currently defined in two different ways. A first approach is based on the relative position of the atoms of the i-th layer compared with those of the $(i+1)$-th layer. Another description uses the absolute positions of the atomic layers with respect to the first undistorted deep layer, which is more appropriate when the relaxation involves more than one surface layer [6.72, 73]. If the first undistorted atomic layer is the third one, the distances d_O and d_{Me} of the oxygen and metallic ions, respectively, are defined with respect to this layer (Fig. 6.5). Relaxation δ_{rel} and rumpling δ_{rump} are expressed as a percentage of the bulk interlayer spacing d_{bulk} [6.72]

$$\delta_{rel} = \frac{d_O + d_{Me} - 4d_{bulk}}{2d_{bulk}} , \tag{6.1}$$

$$\delta_{rump} = \frac{d_O - d_{Me}}{d_{bulk}} . \tag{6.2}$$

A positive (negative) value of the relaxation means that the first interlayer spacing is expanded (contracted). A positive (negative) value of the rumpling indicates that the anion (cation) shifts outward with respect to the cation (anion).

6.2.2 MgO(100)

MgO is the first in the series of alkaline earth oxides classified by increasing molecular weight. The crystallographic structures of MgO, CaO, SrO, and BaO all belong to the $Fm\bar{3}m$ space group. The lattice param-

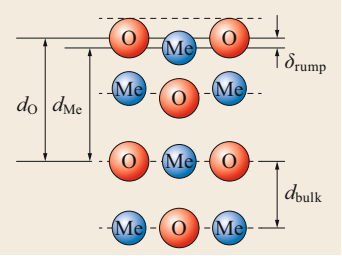

Fig. 6.5 Schematic representation of a nonpolar oxide surface with an inward relaxation and a positive rumpling in which anions shift outward with respect to cations. *Dashed lines* represent the position of layers separated by the bulk interlayer distance d_{bulk} (After [6.72])

eters are 4.21, 4.81, 5.16, and 5.52 Å for MgO, CaO, SrO, and BaO, respectively [6.116]. Similarly to the decrease in the bulk modulus, the surface energy decrease along the MgO–BaO series indicates a weakening of the interatomic interactions [6.71–75]. The trend in ionic character is a decrease from MgO to BaO [6.73, 74, 117–119].

Many experimental and theoretical studies have been dedicated to the determination of relaxation and rumpling at the MgO(100) surface. Data are summarized in Fig. 6.6 [6.71–75, 120–153]. The experimental methods used by the cited authors include low-energy electron diffraction (LEED), impact-collision ion scattering spectroscopy (ICISS), electron energy loss fine structure (EELFS), medium-energy ion scattering (MEIS), grazing incidence x-ray scattering (GIXS), fast-atom diffraction (FAD), transmission electron microscopy (TEM), and helium diffraction. The calculations quoted were performed by shell methods, density functional theory (DFT) by calculating exchange–correlation density and potential within both the local density approximation (LDA) and the generalized gradient approximation (GGA), Hartree–Fock (HF) approaches, and hybrid functional (B3LYP). Overall, the MgO(100) surface is close to bulk-terminated, with surface relaxation and rumpling which essentially go from −1 to +3% and 0 to 6%, respectively. Rumpling appears systematically positive, while the sign of the relaxation seems indeterminate, since positive and negative values are found by both theory and experiment (Fig. 6.6). Before analyzing the data set in more detail, it is worth examining the surface preparation methods.

Surface Preparation

The strong hydrophilicity of MgO [6.97, 98, 100] prompted the preparation of clean surfaces dedicated to ultrahigh vacuum (UHV) analysis via vacuum cleavage, as in most of the structural studies of MgO(100) by electron diffraction [6.120–123, 125]. Indeed, very large relaxations observed on air-cleaved or polished surfaces [6.126, 127] could be suspected to come from adsorbates [6.127, 154], although nothing systematic can be proven [6.121]. The drawback of cleavage is the generation of rather rough surfaces involving steps, slip lines, adstuctures, and holes, as shown by atomic force microscopy (AFM) [6.155] and noncontact atomic force microscopy (NC-AFM) [6.156] (Fig. 6.7a,b). Next to fairly flat areas where terraces are separated by monatomic steps (Fig. 6.7b, left), the cleaved surfaces present very chaotic zones with series of multiatomic steps (Fig. 6.7b, right) whose distribution, which is beyond control, can lead to unreproducible measurements. Moreover, defects generate complex relaxations. For example, relaxations tend to smoothen steps by shifting footstep atoms outward and terrace atoms away from step edges, as nicely shown by TEM [6.128] (Fig. 6.7c), in agreement with simulations [6.129, 130, 157, 158]. Therefore, cleaved surfaces are poor candidates for diffraction studies requiring large coherence length [6.131]. To solve this issue, several groups have combined annealing at high temperature and ion bombardment [6.131, 132]. Ion bombardment alone leads to disordered surfaces [6.124], but annealing to 1640−1870 K in UHV enables surface diffusion that restores the crystallinity [6.124, 126, 131, 132]. Appropriate combinations of bombardment by ions or atoms, annealing, and exposure to oxygen lead to flat defect-free MgO surfaces with wide (100) terraces, as demonstrated by x-ray diffraction (XRD) [6.132] and FAD [6.131].

Relaxation and Rumpling

Measurements performed on those defect-free surfaces [6.131, 132] lead to values of $(-0.56 \pm 0.35)\%$ [6.132] for relaxation and $(1.07 \pm 0.5)\%$ [6.132] or $(1.6 \pm 1.5)\%$ [6.131] for rumpling, which can be considered the most reliable experimental data. The mostly negative experimental estimates of relaxation (Fig. 6.6) support the inward relaxation evidenced by XRD measurement. Conversely, the outward relaxation of $(3 \pm 4)\%$ determined by TEM [6.128] deviates significantly from all other measurements. This singular value is probably due to the very defective nature of the surfaces on which the measurements have been made, as shown by the fact that in TEM images, the displacements of the surface atoms are all influenced by the vicinity of the steps (Fig. 6.7c, middle). Unlike experiments, calculations favor an expansion of the first interlayer spacing. In particular, the DFT calculations performed on the thicker slabs [6.72–75, 133], which are expected to be the most reliable, lead systematically to positive values of the relaxation (Fig. 6.6).

Rumpling data show much clearer trends. The systematically positive values of the rumpling (Fig. 6.6) demonstrate that the oxygen ions protrude above the magnesium ions at the MgO(100) surface. Theoretical estimates from shell models that are based on empirical parameters and LEED measurements are somewhat scattered (Fig. 6.6). It is logical to compare the values measured on surfaces with large and well-defined

terraces by XRD ($1.07 \pm 0.5\%$ [6.132]) and FAD ($1.6 \pm 1.5\%$ [6.131]) to DFT calculations performed on the thicker slabs (≥ 6 layers), i.e., 2.31% [6.133], 2.2% [6.72], 2.22% [6.73], 2.08% [6.74], and 2.2% [6.75], the latter value corresponding to four averaged values from [6.75]. (In the case of the rumpling determined by FAD [6.131], the value of the atomic displacement of oxygen with respect to magnesium (0.033 ± 0.03 Å) is sometimes confused with the percentage of the bulk interlayer spacing—$\delta_{\mathrm{rump}}(1)$ in Fig. 6.6—that defines the rumpling [6.44, 75].) The DFT values of the rumpling are remarkably similar. The scatter due to the difference between the exchange–correlation functionals that are used in the various calculations appears quite marginal [6.75, 131].

The average values obtained by the calculations performed on the thickest slabs [6.72–75, 133] (taking only average values from the four values calculated in [6.75]) are $+0.16\%$ for relaxation and 2.1% for rumpling. Therefore, theoretical estimates for relaxation and rumpling are a little less than 1% above the XRD and FAD experimental values (Fig. 6.6). These discrepancies are comparable to those observed on metal surfaces, although metals are believed to involve a simpler approach than oxide surfaces. For example, theoretical and experimental relaxation values differ significantly for low-index Al, Pd, Pt, Au, and Ti surfaces [6.159].

6.2.3 Alkaline Earth Metal Oxides

The calculated values of surface relaxation and rumpling in the CaO(100), SrO(100), and BaO(100) series are summarized in Fig. 6.8 [6.71–75, 149, 151]. Trends are comparable, but numbers differ widely. The surface relaxation of the (100) orientation, which is close to zero in the case of MgO, is predicted by calculations to be increasingly negative along the series of alkaline earth metal oxides from CaO to BaO [6.71–75, 149]. (It should be noted, however, that the rather low relaxation values found by *Skorodumova* et al. [6.72] (Fig. 6.8) with respect to the other groups comes in part from the use of (6.1). According to these authors, the subsurface layer relaxes outward. Therefore, a relaxation defined as the variation in the distance between the first and second layers leads to higher values than a calculation that considers the absolute positions [6.72].) In parallel, the rumpling which is positive on MgO(100) is the opposite for the rest of the series. It is increasingly negative for CaO(100), SrO(100), and BaO(100), which means that cations are expected to protrude from the surface. Measurements were performed on CaO(100) [6.160, 161]. The relaxation of -1% found by LEED agrees with the simulation, but the value of 2% found for the rumpling is at odds with the theoretical predictions. The authors have suggested that a negative rumpling could lead to a better fit of the data, but did not explore this possibility [6.160]. A standing wave analysis concluded that the relaxation was too small to be observed [6.161].

Most studies report negative electron affinity for MgO(100) [6.73, 162–164] and also for CaO(100) and SrO(100), but not for BaO [6.73]. Conversely, *Logsdail* et al. find positive electron affinity along the MgO–BaO series [6.75], in agreement with thermionic measurements performed on MgO [6.165]. However, a confirmation would be required [6.166], since those measurements were conducted under conditions that do not totally exclude the presence of adsorbates, especially given the very hydrophilic nature of MgO (Sect 6.2.1).

Surface Relaxation

In fully covalent systems, surface relaxation results from the competition between band energy and short-range repulsion terms that in simple models vary as $\sqrt{Z}$ and Z, respectively, if Z is the coordination number [6.69, 70]. Surfaces are therefore expected to relax inward. In fully ionic systems, atomistic approaches relying on electrostatic and short-range interactions result in interatomic distances that vary as Z/α (where α is the Madelung constant), which again leads to inward relaxation [6.69, 70]. Iono-covalent systems are shown to behave in a way which depends on the variations in the three terms (covalent, electrostatic, and repulsion) as a function of environment [6.69, 70]. Beyond the debate on the relative importance of the ionic [6.73] or covalent [6.69, 70] character of the alkaline earth metal oxide surfaces, it appears that the delocalization of the electrons plays an important role in the surface relaxation of these oxides [6.70–73, 149].

Cleavage results in a downward shift of the semicore p-state of surface cations [6.72, 73]. This has little effect on MgO, since the Mg p-state lies very low in energy. At CaO, SrO, and BaO(100) surfaces, the upward shift of the cation p-state would result in wider p-O bands in the absence of relaxation. The effect of relaxation is to narrow those bands. The electron localization around oxygen atoms then increases the Coulomb interaction between cations and anions, which causes a contraction of the surface and subsurface interlayer spacings. *Skorodumova et al.* divide the relaxation energy into a band energy term that represents the occupied one-electron states and a term corresponding to the sum of electron–electron Coulomb interaction (Hartree term), electron–core interaction, electronic exchange and correlation, and core–core Coulomb energy [6.72]. The MgO(100) relaxation mostly stems from the first contribution, while SrO(100) and BaO(100) relaxations are dominated by electrostatic interactions. CaO(100) is a border case [6.72].

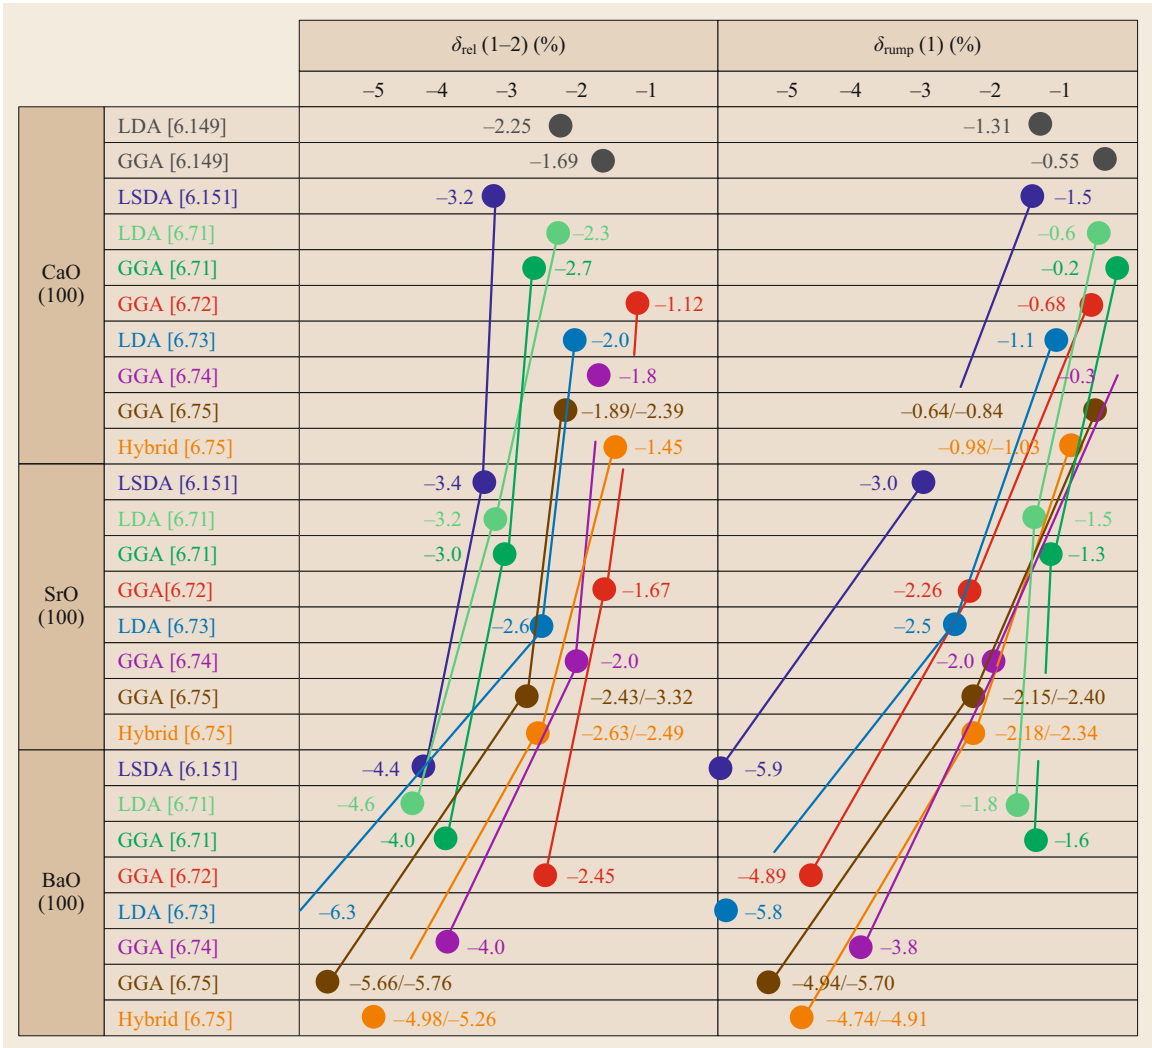

Fig. 6.8 Calculated values of the relaxation δ_{rel} (1−2) of the topmost interplanar spacing and of the surface rumpling δ_{rump} (1) for CaO(100), SrO(100), and BaO(100)

Role of Electron Delocalization

Rumpling is due to an asymmetric response of cations and anions to bulk cleavage that can originate from differences in either polarizability or bond characteristics [6.70, 71]. In the earlier model of *Verwey* [6.167], the rumpling stems from the difference in anion and cation polarizabilities. Having the highest polarizability, the oxygen ion protrudes outward, as observed on MgO(100) (Sect. 6.2.2). However, if the difference in polarizability were the only driving force for rumpling, all oxides in the alkaline earth metal oxide series should exhibit a positive rumpling [6.71, 149], since the Pauling polarizabilities of Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, and O^{2-} are 0.094, 0.47, 0.86, 1.55, and 3.88, respectively [6.71]. In addition to the Verwey model, which still holds even if it is not dominant, driving forces that stem from atomic bonds were suggested [6.71–74, 149]. On the basis of contracted and expanded unit cells in which ionicity is preserved, the opposite rumpling of MgO(100) and CaO(100) was suggested by *Alfonso* et al. to come from valence repulsion effects, or in other words, steric effects [6.149]. *Broqvist* et al. [6.71] distinguished two types of differences in bond characteristics: metal–oxygen covalence, and bonds between oxygen next-nearest neighbors that rely on electron delocalization. The authors observed that the O(2p)–O(2p) overlap decreases from MgO to BaO. At the MgO(100) surface, they suggest that the positive rumpling results from next-nearest-neighbor interaction via the strong

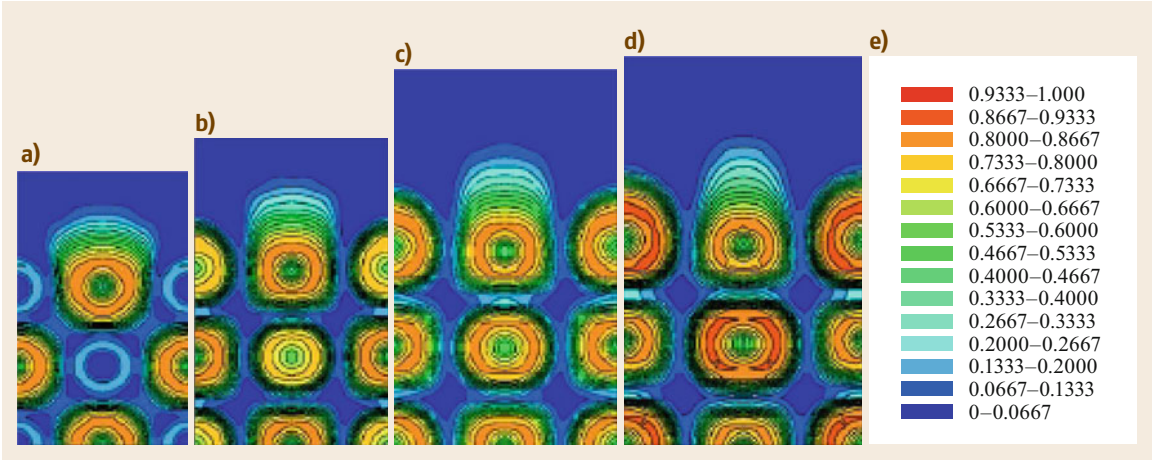

Fig. 6.9a–e Electron localization function for the (100) surfaces of **(a)** MgO, **(b)** CaO, **(c)** SrO, and **(d)** BaO. The values 0.5 and 1 **(e)** correspond to complete delocalization and localization, respectively. The delocalized oxygen electrons that protrude in vacuum appear to noticeably shrink from MgO(100) to BaO(100). The increasing electron localization around oxygen accompanies the band narrowing (Reprinted with permission from [6.72]. Copyright 2005 by the American Physical Society)

O(2p)–O(2p) overlap. Conversely, the electron delocalization progressively reduces along the CaO, SrO, and BaO series, while the contribution of the nearest-neighbor interactions (Me−O bond) increases [6.71]. To increase cohesion, the surface ions tend to relax toward the subsurface layer. However, because of differences in polarizability, the covalence of the bonds between surface anions and subsurface cations is higher than that of the bonds between surface cations and subsurface anions. This effect favors a negative rumpling. Therefore, the increasingly negative values of rumpling that are predicted in the CaO, SrO, and BaO series for both (100) and (110) orientations have been attributed to a balance between the effect of electron delocalization (anion–anion repulsion) and the metal–oxygen bond [6.71].

At cleaved oxide surfaces, *Skorodumova* et al. [6.72] and *Baumeier* et al. [6.73] observed a downward shift of the semicore p-states of surface cations which they link to the surface and subsurface relaxation and rumpling. (As noted in [6.72], the interaction between the metal p-M and oxygen states has already been shown to stabilize ABO_3 perovskite structures [6.168].) The electronic structure of the oxides is characterized by a narrowing of the valence band, consisting mostly of the p-O states, along the alkaline earth metal oxide series: 4.44 eV (MgO), 2.57 eV (CaO), 2.08 eV (SrO), and 1.83 eV (BaO) [6.71, 72]). The spill-out of the oxygen electrons is predicted to narrow that surface p-O band and to cause semicore s oxygen states to shift outward [6.72] (Fig. 6.9). The low-lying p-Mg state hardly affects the oxygen p band at the MgO(100) surface. In contrast, the width of the semicore p-O states associated with CaO, SrO, and BaO surfaces correlates strongly with the energy position of p-M [6.71, 72]. It becomes wider than in bulk as the p-M states shift toward lower energy. The increasing localization of oxygen electrons increases Coulomb interactions. The anions are pushed downward by the surrounding cations, which leads to negative rumpling on the (100) surfaces of CaO, SrO, and BaO. The role of the semicore states is highlighted by calculation of slabs involving artificially expanded or contracted surface in-plane lattices [6.72]. Relaxations change in amplitude but keep their sign, except in the border case of CaO. Upon lattice expansion, the neighboring cations of the surface anions move away, which causes the p-M band to shift downward and the oxygen electron to delocalize. Therefore, the expansion of the in-plane lattice parameter promotes positive rumpling. Compression has the opposite effect [6.72].

Rumpling is suggested to be of local origin [6.71], since the change in rumpling between MgO and the CaO, SrO, and BaO series has been previously reported for small $(MeO)_{12}$ clusters [6.169, 170]. In the case of MgO(100), the local origin of the rumpling might explain the relevance of TEM measurements made on highly defective samples [6.128] (Fig. 6.7c). They lead to a value of rumpling of $(1 \pm 3)\%$, in fair agreement with values determined by diffraction on high-quality surfaces [6.131, 132], while the relaxation analyzed in the context of the same TEM measurements strongly deviates from the bulk of the other data (Fig. 6.6).

6.2.4 Transition-Metal Oxides

The transition-metal oxides (TMOs) MnO, FeO, CoO, and NiO crystallize in the rocksalt structure in the paramagnetic phase with lattice parameters of 4.44, 4.30, 4.27, and 4.17 Å, respectively. They become antiferromagnetically ordered below Néel temperatures of 116 K (MnO), 198 K (FeO), 291 K (CoO), and 525 K (NiO) [6.171] with rhombohedral (MnO and NiO) or monoclinic (FeO and CoO) distortions. Not observed by STM [6.172, 173] (Fig. 6.10a), the (2×1) ferromagnetic surface over-structure is evidenced by LEED on Ni(100) in normal conditions [6.174]. By DFT approaches, *Schrön* et al. predict the observation of pronounced spin contrasts by spin-polarized STM (using ferromagnetic tips) in the (2×1) structure along the MnO(100), FeO(100), CoO(100), and NiO(100) series [6.175] (Fig. 6.10b).

As in the case with alkaline earth metal oxide surfaces, the relaxations of the (100) faces of the paramagnetic phases of the TMOs are bulk-like terminated with interlayer spacing relaxation and intra-layer rumpling that minimize the surface energy. The related results are summarized in Fig. 6.11. From the reported data, the superficial relaxation of NiO(100) is the only case which appears indisputable. The eight values obtained by measurement or calculation, which range from −1.4 to −2%, are in fair agreement in indicating an outward displacement of surface oxygen atoms with respect to surface nickel atoms. Data on the other, most studied TMO surface, MnO(100), are inconclusive. DFT and MD predict a contraction of the first interlayer spacing. Conversely, measurements favor an expansion, although with large error bars (Fig. 6.11).

As a trend, the values found for rumpling are positive for the four surfaces, except for two DFT calculations [6.151] and two MEIS measurements [6.180, 181] on MnO(100) and NiO(100) surfaces (Fig. 6.11). Data on thin films are presented in Fig. 6.11 [6.179, 183, 185, 187]. Are they meaningful with respect to bulk samples? Supported films may offer better crystalline surface quality than cleaved crystals, and are often preferred for structural studies [6.183, 185], as highlighted in the introduction for oxide surfaces in general. In the case of FeO, the disproportionation of the bulk oxide into Fe and Fe_3O_4 below 840 K [6.53] encourages the preparation of thin films, although care must be taken to avoid mixtures of $Fe_{1-x}O$, Fe, and Fe_3O_4 [6.53, 185]. Surface interlayer relaxations of supported films partly compensate the in-plane interface

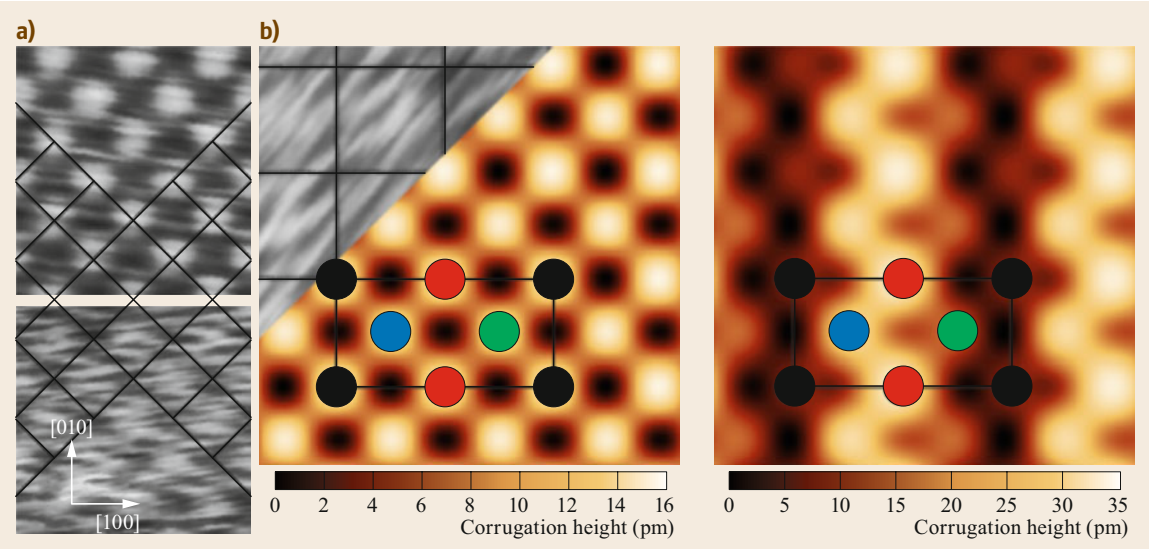

Fig. 6.10a,b The NiO(100) surface **(a)** (1×1) structure seen by STM: Images of empty states, where bright spots correspond to Ni sites (*top*) and filled states (*bottom*) where oxygen dominates (Reprinted with permission from [6.172]. Copyright 1997 by the American Physical Society); **(b)** simulation of the (1×1) STM image (*left*) and of the (2×1) SP-STM (*right*) of the filled states with an integration up to −1.5 eV below the VBM; *black* (*red*) *spheres* indicate TM↑ (TM↓) ions, and *blue* (*green*) *spheres* indicate O↑ (O↓); the simulated (1×1) STM image that shows O and Ni as bright spots is compared with the experimental image (*bottom* **(a)** [6.172] in *inset*). On the simulated (2×1) SP-STM image, the Ni^{2+} ions with magnetic moments aligned antiparallel to the tip magnetization become brighter due to tunneling from the minority-spin t_{2g} states, which increases the contrast between Ni^{2+} (Reprinted with permission from [6.175]. Fig. 6.11 Experimental and theoretical values of the relaxation of the topmost interplanar spacing δ_{rel} (1−2) and surface rumpling δ_{rump} (1) for MnO(100), FeO(100), CoO(100), and NiO(100). Methods and preparation are indicated (VC, AC, N_2-C for vacuum-, air-, and N_2-cleaved)

strain [6.187], which likely results in an expansion of the 4 ML CoO(100) film [6.187] with respect to bulk, while the 48 ML MnO(100) film [6.183] and the 22 ML FeO(100) film [6.185] are contracted. Therefore, the comparison of the relaxation of thin films with that of bulk samples is not straightforward. The case of rumpling is different. The rumpling at the surface of metal-supported films depends on the interface oxide–metal bond [6.189, 190]. An estimate of the film thickness for which the surface geometry escapes the influence of the substrate is given by DFT calculations relative to three-layer MgO(100) and BaO(100) films deposited on Al, Mo, Ag, Au (MgO) and on Pt, Pd, Ag, Au (BaO) [6.189]. Positive surface rumpling of 2.3−2.8% (MgO) and 3.3−5.8% (BaO) is reported [6.189], in agreement with predictions related to the (100) surface of bulk oxides (Fig. 6.8). This validates the values of rumpling determined on the MnO(100) (48 ML) [6.183], FeO(100) (22 ML) [6.185], CoO(100) (4 ML) [6.187], and NiO(100) (2 ML) [6.179] films (Fig. 6.11). All those values support the above suggestion that, as a trend, rumpling is positive along the series MnO(100)–NiO(100). Surprisingly, both surface relaxation (-1.7 ± 1.7)% and rumpling (-2.4 ± 2.4)% of the 2 ML-thick NiO(100)/Ag(100) film [6.179] agree with the other results obtained on NiO(100) surfaces

(Fig. 6.11). Finally, the rumpling at the (100) surface of oxides of rocksalt structure was suggested to be proportional to the lattice spacing, with an increase through the series NiO, MgO, CoO, FeO, MnO [6.185]. However, the absence of a clear trend through the whole MnO–NiO data set reported in Fig. 6.11 questions the suggested rule. Moreover, it does not apply to the negative CaO–BaO rumpling (Fig. 6.8).

In Fig. 6.11, the extreme experimental values are separated by significant differences ($\approx 9\%$ and $\approx 7\%$ for the rumpling of MnO(100) and NiO(100), respectively) that are far beyond the estimated errors. They can have different origins: (i) DFT calculations were carried out on the ferromagnetic phase, whereas, except in the case of NiO(100), measurements were performed on the paramagnetic phase. Indeed, a series of MEIS measurements shows a strong increase in the interlayer spacing and an inversion of the rumpling in the 300–600 K temperature range, i.e., through the antiferromagnetic–ferromagnetic transition [6.182]; (ii) in a manner comparable to that observed on MgO surfaces (Sect. 6.2.2, Fig. 6.7a,b [6.155, 156]), the NiO(100) surfaces obtained by cleavage exhibit very disturbed areas [6.191, 192].

6.3 The $SrTiO_3$(100) Surface

The mineral of $CaTiO_3$ composition was named perovskite by the geologist Gustav Rose in the 1830s, after the Russian mineralogist Lev Aleksevich von Perovski [6.193]. The ideal perovskite has an ABO_3 stoichiometry and a cubic crystal structure (space group $Pm\bar{3}m$) in which the A ion is often an alkaline earth or rare earth element and the B ion is a transition-metal element. The cell consists of a height corner-sharing network of BO_6 octahedra with, at its center, the A ion that is coordinated to 12 oxygen atoms (Fig. 6.12). However, in the real ABO_3 perovskites, the difference in radii between cations causes lattice distortions that tilt BO_6 octahedra in a way which is predicted by the Goldschmidt tolerance factor. The resulting changes in lattice symmetry lead to orthogonal, rhombohedral, tetragonal, monoclinic, and triclinic phases that are at the origin of the immense diversity of the physical and chemical properties of perovskite-type oxides [6.80, 193–196].

6.3.1 Single Terminations

Along ⟨100⟩ directions, as all the ABO_3 oxides of perovskite structure, $SrTiO_3$ consists of alternating stacks of AO and BO_2 atomic layers that can be terminated by either of these. Because those mixed terminations are unsuited to most applications, an early concern was the preparation of atomically smooth single-terminated crystals of either composition.

Coexistence of TiO_2 and SrO Terminations

As first evidenced by electron diffraction [6.197] and consistently confirmed since, SrO and TiO_2 domains coexist systematically on as-received $SrTiO_3$(100) surfaces. The $SrTiO_3$(100) surface was first modeled with this double termination [6.198, 199]. Reliable estimates of the relative Sr/Ti surface coverage are given by ion scattering techniques, including low-energy ion scattering (LEIS) [6.84, 200, 201], medium-energy ion scattering (MEIS) [6.202, 203], and coaxial-impact-collision ion scattering spectroscopy (CAICISS) [6.204–206]. Although electron spectroscopies are quite flexible probes, they hardly characterize the composition of the extreme surface in an unambiguous way. By using ion scattering, the SrO coverage was found to range from ≈ 5 to 25% at the (100) surface of commercial $SrTiO_3$ crystals [6.84, 204], to $\approx 66\%$ on a fractured surface [6.207].

The coexistence of terraces of different chemical composition is also evidenced by the observation of non-integer unit-cell-high steps by STM or atomic force microscopy (AFM) [6.10, 89, 207–211]. These techniques motivated the search for methods to characterize the nature of the terminations. Direct imaging of the two types of termination is provided by friction force microscopy [6.205, 212–215] and phase-lag analysis [6.216], which can be used to distinguish

the different domains on a local scale. The chemical composition profoundly influences the morphology of the steps. It has been suggested that TiO_2-terminated terrace edges meander along the [100] and [010] directions, while the SrO-terminated terrace edges are curved [6.212], this under the assumption—which has since been questioned [6.213]—that the friction forces are lower on TiO_2 than on SrO [6.205, 212]. However, the geometry of the step edges of the SrO and TiO_2 terraces is sometimes the opposite of that suggested by [6.212], with the former following a broken line and the latter being rounded [6.216]. The dependence of the friction force on tip termination [6.215] and on the environment may explain these discrepancies. The friction force in particular is greatly increased on SrO terminations (not on TiO_2 terminations) by exposure to water vapor [6.217].

TiO_2 Termination

Kawasaki et al. took advantage of the opposite acid–base character of the two terminations to develop a method that eliminates one of the two [6.84]. Buffered NH_4F-HF (BHF) solutions with a pH at a critical value of 4.5 allowed full dissolution of the basic SrO surface domains. Ion scattering spectroscopy measurements demonstrated the uniformity of the BHF-etched TiO_2 termination [6.84]. The preparation leads to flat surfaces that involve wide single-terminated terraces with one-bulk-unit-cell-high steps that are suitable for film growth [6.84, 89, 209, 211, 213], as shown by the AFM image presented in Fig. 6.13. Nevertheless, the etching process does not completely eliminate the SrO domains, which still cover around 10% of the surface, as shown by MEIS analysis [6.202, 203].

The risk of hole formation during acid treatment [6.218] has inspired an evolution of the preparation method—the addition of a water immersion step to the process—based on the propensity of SrO to form hydroxides that are more prone to dissolution in acid and make the preparation less sensitive to the pH of the solution [6.89, 213] (Fig. 6.13). The treatment proved to be quite reproducible [6.219]. CAICISS analysis showed that annealing in vacuum above 570 K results in segregation of Sr, which forms SrO microclusters that cover between 15 and 20% of the surface [6.206]. The observation was confirmed by high-resolution synchrotron photoemission spectroscopy [6.220]. After removal of Sr by re-etching treatments, the TiO_2 termination is stable up to 970 K [6.206]. The segregated Sr can also be eliminated in vacuum [6.221]. In line with this, the BHF-prepared $SrTiO_3(100)$ surface was made smoother by sonication in deionized water [6.222]. Subsequently, the etching by water was rationalized to avoid the use of acids, which raises a safety issue [6.210]. In addition, the contact with the BHF solution results in unintentional F-doping of the $SrTiO_3(100)$ surface [6.223]. Motivated by those concerns, two groups have developed acid-free etchant methods [6.210, 223]. Processes combining only rinsing in deionized water and annealing at 1220–1270 K in air were shown to be effective in preparing TiO_2-terminated flat $SrTiO_3(100)$ surfaces [6.210, 223].

SrO Terminations

So far, it has been shown that the $SrTiO_3(100)$ surfaces are almost always partially covered with SrO. However, obtaining single SrO-terminated surfaces is not easy. A first strategy relies on the deposition of an SrO monolayer on TiO_2-terminated $SrTiO_3(100)$ [6.84, 224] or on other substrates [6.225]. Oxygen plasma was also used to prepare SrO-terminated surfaces to enable the deposition of high-quality YBaCuO films [6.226]. However, the treatment could not be reproduced [6.219], possibly because of the role of adventitious fluorine in the etching of strontium titanate [6.226]. Annealing $SrTiO_3(100)$ surfaces in oxygen has long been observed to activate the diffusion of strontium toward the surface, although the SrO surface coverage obtained remains fractional [6.202, 205, 206, 227–233]. High-temperature treatments can even lead the oxide to dismantle to form Ruddlesden–Popper phases [6.228]. Nevertheless, *Bachelet* et al. succeeded in controlling the enrichment in SrO of the surface at high temperature [6.216]. By annealing an initially TiO_2-terminated

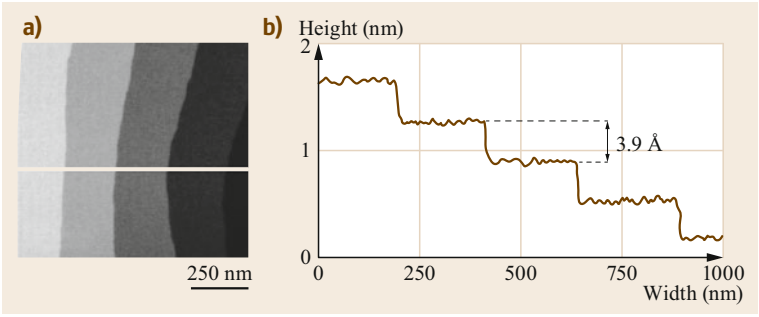

Fig. 6.13a,b TiO_2-terminated $SrTiO_3(100)$ surface **(a)** AFM image with flat terraces; **(b)** height profile along the *line* drawn in **(a)**, with 0.39 nm-high steps which correspond to a single bulk unit cell (Reprinted from [6.213], with the permission of AIP Publishing)

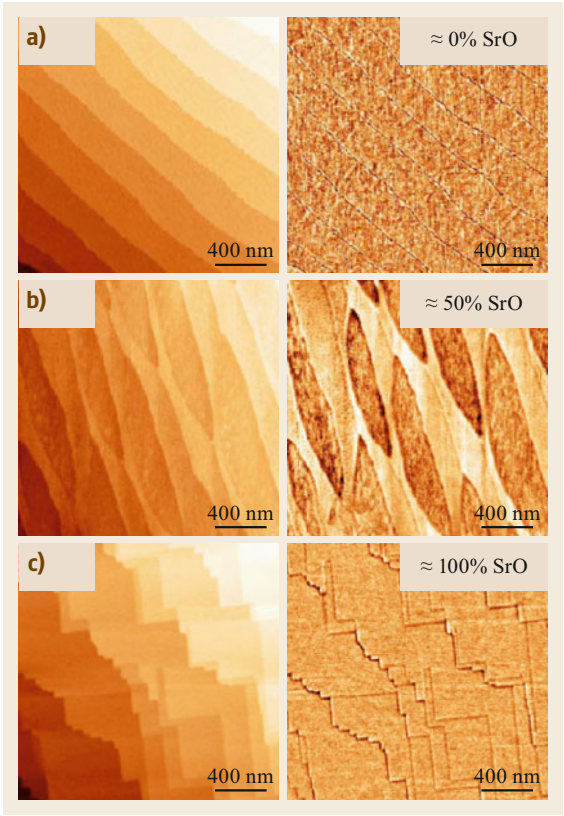

Fig. 6.14a–c Formation of an SrO-terminated surface from a TiO_2-terminated $SrTiO_3$(100) surface, as evidenced by comparing AFM topographic (*left*) to phase-lag AFM (*right*) after annealing at 1570 K in air for: **(a)** 2 h: Atomically flat surface with sharp steps of one unit cell in height and smooth step edges. The absence of contrast in the phase-lag image characterizes a single TiO_2 termination; **(b)** 12 h: Narrow terraces edging with oval regions separated by half-unit-cell-high steps indicate the appearance of a second type of chemical termination (SrO); **(c)** 72 h: The uniformity of the phase-lag image supports the formation of a single SrO-terminated surface (Reprinted from [6.216], with the permission of AIP Publishing)

$SrTiO_3$(100) crystal in air at 1570 K for 72 h, they obtained a fully SrO-terminated surface while avoiding the formation of Ruddlesden–Popper phases. Surface terminations were also characterized by combining [6.216] amplitude-modulation AFM with phase-lag analysis [6.234] (Fig. 6.14) and x-ray photoelectron spectroscopy (XPS). *Ogawa* et al. obtained an SrO-terminated surface that shows a $(\sqrt{2}\times\sqrt{2})$-R45° structure, which was assigned to a periodically SrO-deficient surface on the basis of first-principles calculations [6.235]. This structure is suggested to correspond to the c(2×2) reconstruction that was described by other groups [6.225, 236] on the SrO-terminated $SrTiO_3$(100) surface [6.235]. The ability to prepare terminations comprising simultaneous SrO and TiO_2 terminations in the form of nanostructured domains [6.216] was subsequently monitored using chemically nanopatterned substrates [6.237].

Fractured and Vicinal Surfaces

As mixed-terminated surfaces, fractured and vicinal surfaces deserve particular attention since they are required for specific applications. In particular, it is at cleaved $SrTiO_3$(100) surfaces that 2DEGs are observed [6.66]. Vicinal $SrTiO_3$(106) surfaces show an "astonishing degree of long-range order" [6.238]. Straight steps arranged in a perfectly regular way are shown to involve alternating SrO and TiO_2 rows (Fig. 6.15a). By fracturing $SrTiO_3$ crystals [6.207, 239], in the absence of a natural cleavage plane, rather smooth steps were obtained at the nanometer scale at room temperature, by scribing the sample by means of a high-precision dicing saw prior to fracturing it [6.207]. Conductance maps recorded by scanning tunneling spectroscopy reveal two types of striped domains with characteristic widths ranging from 10 to 30 nm. Comparison of the conductance maps with the topography analyzed by STM shows that the long-range order of the stripes is independent of the directions of the step edges (Fig. 6.15b). TiO_2 domains are narrower (≈ 12 nm) than SrO (≈ 24 nm) domains. The rough appearance of SrO stripes was judged to be consistent with the lower stability of SrO surfaces (Fig. 6.15b) [6.207]. Similar to layered oxides [6.240], less defective surfaces with larger terraces were obtained by fracturing at lower temperature [6.241]. Significantly, 2DEGs are only observed on surfaces fractured at low temperature [6.66].

Surface Structures

The strong dependence of the $SrTiO_3$(100) surface structure on the preparation conditions was noted [6.197, 227, 242–244] prior to the development in the mid-1990s of surface preparations that reproducibly lead to well-defined terminations [6.84]. The control of the chemical termination of $SrTiO_3$(100) was the starting point for the systematic exploration of its surface structure, with a main focus on TiO_2-terminated surfaces. After a few years, in the early 2000s, a number of $SrTiO_3$(100) surface structures were identified: (1 × 1), (2 × 1), (2 × 2), c(4 × 2), (4 × 4), c(4 × 4), c(6 × 2), (6 × 2), $(\sqrt{5}\times\sqrt{5})$-R26.6°, and $(\sqrt{13}\times\sqrt{13})$-R33.7° (the latter two are hereafter referred to as $(\sqrt{5}\times\sqrt{5})$ and $(\sqrt{13}\times\sqrt{13})$ for simplicity). The reconstruction of $SrTiO_3$(100) were first attributed to ordered □−Ti−O vacancy complexes (□ stands for an oxygen vacancy) [6.245–247] before two models were proposed, one based on a double-

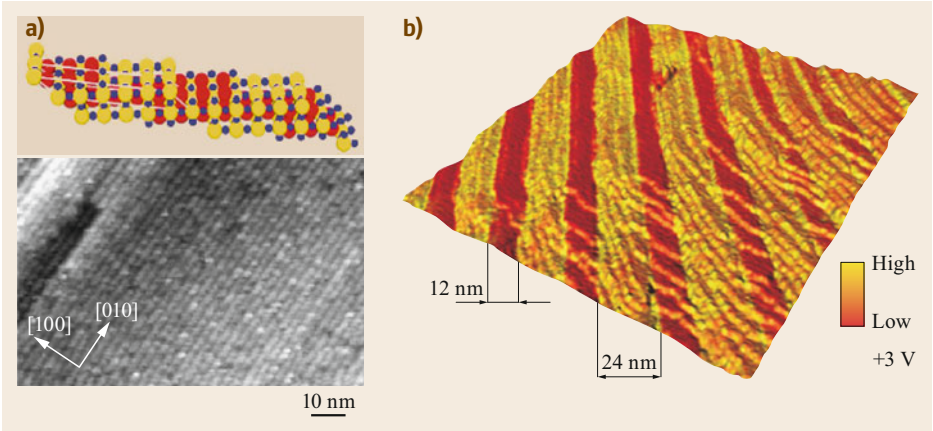

Fig. 6.15a,b Vicinal and fractured $SrTiO_3$ surfaces: **(a)** *Bottom*: $SrTiO_3(106)$ recorded by scanning tunneling microscopy (STM)—*Top*: Model of the surface as determined by grazing incidence x-ray diffraction: Sr, Ti, and O atoms are represented by *red*, *yellow*, and *blue spheres*, respectively (Reprinted with permission from [6.238]. Copyright 2005 Elsevier); **(b)** Conductance map of a fractured $SrTiO_3$ surface overlaid with the topographic AFM image. *Dark* (12 nm) and *bright* (24 nm) *areas*, assigned to SrO and TiO_2 terminations, respectively, reveal a long-range order of the local density of states that escapes the surface geometry (Reprinted with permission from [6.207]. Copyright 2009 American Chemical Society)

layer TiO_2-terminated surface [6.248] and the other on the enrichment of the TiO_2 surface layer by segregating strontium atoms [6.249]. In the following description of the $SrTiO_3(100)$ reconstructions, the (1×1) termination and the associated structures, (2×1) and (2×2), are presented first, because they give rise to a particular problem [6.200, 250]. Figure 6.16 summarizes the preparation conditions for the various reconstructions and the experimental observations by LEED, reflection high-energy electron diffraction (RHEED), STM, HRTEM, XRD, MEIS, and NC-AFM [6.85–87, 197, 200, 202, 203, 208, 221, 244, 245, 248–277].

6.3.2 $SrTiO_3(100)$-(1×1) Surfaces

Sharp (1×1) diffraction patterns have long been observed on $SrTiO_3(100)$, independent of the control of the surface termination [6.84]. They were obtained early by ion bombardment followed by annealing either in UHV (1100–1200 K [6.251, 252] or 870–1070 K [6.208, 245, 253]) or in oxygen (1020–1170 K [6.208, 253, 254] or 1100–1200 K [6.255]), or successively in oxygen, hydrogen, and UHV at 1300–1400 K [6.78]. A sharp (1×1) LEED pattern allowed the first structural study of $SrTiO_3(100)$ that was shown to combine SrO and TiO_2 domains [6.78]. The two domains then proved to coexist quite systematically on pristine surfaces. The same structure was observed on fractured surfaces, although the LEED pattern was slightly diffuse [6.251]. RHEED patterns were obtained after annealing in vacuum at 1020–1070 K [6.244]. Most importantly, similar (1×1) patterns were observed on smooth $SrTiO_3(100)$ substrates pretreated in buffered NH_4-HF solution [6.84], after annealing in vacuum or under oxygen partial pressure [6.86, 200, 202, 250, 256, 266], either by LEED [6.86, 256, 266], RHEED [6.86, 202, 203, 279], or XRD [6.200, 250].

However, the occurrence of extremely sharp (1×1) diffraction patterns contrasts astonishingly with the absence of structurally ordered surfaces at the atomic scale in STM analysis [6.86, 211, 245, 256, 266, 278]. A way to tackle the contradiction is to invoke a carbon contamination that blurs the surface imaging by STM of an otherwise well-defined structure. The (1×1) LEED pattern is suggested to originate from the ordered $SrTiO_3$ layers beneath the carbon adlayer [6.256]. Another suggestion is the occurrence of randomly distributed charges that perturb the imaging process. The NC-AFM reveals that well-defined surface structures can involve localized defect charges [6.266], thus leading to both fairly sharp diffraction patterns and blurred imaging by near-field microscopies operated at the atomic level.

An alternative explanation came from the x-ray diffraction study of *Herger* et al. [6.200, 250], who combined the XRD analysis of the $SrTiO_3(100)$ surface performed at room temperature with measurements at 1023 K under 10^{-5} mbar O_2, in typical conditions for growth of perovskite films. At 300 K, the (2×2), (2×1), and (1×1) domains are stable, at least over the measurement time. Conversely, at 1023 K, the (2×2) and (2×1) rapidly vanish, and the (1×1) structure dom-

inates. It is necessary [6.200, 250] to understand the (2×2) and (2×1) reconstructions before examining the (1×1) structure, hence the order of the following paragraphs.

(2×1) Reconstruction

The $SrTiO_3(100)$-(2×1) structure is commonly observed by annealing in UHV [6.208, 244, 253, 256, 266] or moderate oxygen pressure (10^{-5} mbar [6.200, 250]) at temperatures ranging from 1020 to 1220 K.

Erdman et al. [6.248] examined the $SrTiO_3(100)$-(2×1) by high-resolution transmission electron microscopy (HRTEM) on an electron-transparent $SrTiO_3$ (100) sample prepared by ion milling and then annealed at 1220–1270 K in oxygen. The treatment proved efficient to both cure the damage caused by ion bombardment and promote the (2×1) surface reconstruction. The resulting model is a double-layer TiO_2-terminated surface (Fig. 6.17). The z position of atoms was determined by plane-wave pseudo-potential DFT calculations. The top layer has a TiO_2 stoichiometry. It involves zigzag rows of 5-coordinated TiO_5 units (giving rise to $p2mg$ symmetry) that share edges between them as well as with the layer underneath, which is made of slightly tilted bulk-like TiO_6 octahedra. In the surface layer, oxygen atoms that belong to shared edges (O1, O2) are bulk-like. In contrast, those not shared by neighboring octahedra bear a significantly reduced charge. More covalent Ti–O bonding compensates for the lower coordination number, particularly in the case of the surface oxygen atom O4 which is double-bonded to the surface titanium atom Ti1. The edge-shared TiO_5 units yield a charge-neutral reconstructed surface with the stoichiometry TiO_2. The authors suggest that edge-shared assembly of TiO_x units, analogous to creation of a *block structure* in Nb_2O_{5-x} and ReO_3-type bulk-like structures, controls the surface structure of $SrTiO_3(100)$ [6.248].

The (2×1) structure of the $SrTiO_3(100)$ surface was also studied by surface x-ray diffraction (SXRD) measurements by *Herger* et al. [6.200, 250]. The analysis was performed on a BHF-treated $SrTiO_3(100)$ substrate annealed eventually to 1220 K in UHV [6.84, 213]. Three different domain types were identified. At room temperature, the best fit of the SXRD data led to a combination of (2×2) (43%) and (2×1) (37%) reconstructions and a contribution of (1×1) termination (20%). The fit procedure included R-factor but also the physical reasonableness of the models. Surface energies determined by DFT calculations were also considered [6.200, 250]. As regards the (2×1) structure, test models included terminations previously proposed by other groups, i.e., oxygen-deficient surfaces [6.256] and Sr- or SrO-rich substrates [6.206, 259]. The obtained model, terminated by a double TiO_2 layer [6.200, 250], is in perfect agreement with that proposed by *Erdman* et al. [6.248].

(2×2) Reconstruction

p2mg Symmetry. Two different symmetries were observed for the $SrTiO_3(100)$-(2×2) surface structure (Fig. 6.16). *Herger* et al. assigned the (2×2) reconstruction that they observed to a double-layer TiO_2-terminated structure of *p2mg* symmetry [6.200, 250] (Fig. 6.18) which had been found to be energetically favorable by *Warschkow* et al. (the (2×2)A structure in [6.279]). The (2×2) structure can be viewed as a juxtaposition of the (2×1) structure with its mirror image (Fig. 6.18) [6.250].

p4mm Symmetry. Another (2×2) reconstruction of the $SrTiO_3(100)$ surface, but this time of fourfold *p4mm* symmetry, was observed by annealing in UHV at 1220–1270 K [6.259, 260, 280]. It was obtained on a BHF-etched $SrTiO_3(100)$ by repeated annealing at 870 K [6.261]. Several models were tested, including an Sr-terminated surface [6.259], by comparing experimental STM images to DFT simulations [6.261]. The TiO_{2-x} terminated surfaces were modeled using a repeated slab configuration. The proposed (2×2) model corresponds to the (2×2) C structure of *p4mm* space symmetry previously suggested by *Warschkow* et al. [6.279]. It does not correspond to a reduced configuration. The structural model includes two types of surface oxygen atoms represented in Fig. 6.19 by light blue and dark blue spheres, respectively. The former correspond to bulk-like oxygen atoms. The

latter correspond to atoms bound to two surface Ti atoms but to none of the subsurface Ti atoms. Similar *floating* oxygen atoms were found in structural models related to the (2×1) [6.248] (Sect. 6.3.2 and Fig. 6.17) and the $c(4 \times 2)$ (Sect. 6.3.1) [6.263] reconstructions. In addition, there are onefold-coordinated surface oxygen atoms at the corners of the surface unit cell (O(1) in Fig. 6.19) that are only bonded to the subsurface Ti atoms lying underneath. They form Ti=O double bonds whose bond length is about 0.3 Å less than that of the typical Ti−O single bond in $SrTiO_3$ bulk [6.263]. The $SrTiO_3(100)$-(2×1) structural model involves a similar Ti=O bond, but in this case, both titanium and oxygen are surface atoms [6.248] (Sect. 6.3.2 and Fig. 6.17). Onefold-coordinated oxygen atoms are also found at the surface of the (2×1)-reconstructed rutile $TiO_2(011)$ surface [6.281] and are rather commonly encountered at surfaces of oxides of corundum structure. Chromyl (Cr=O), ferryl (Fe=O), and vanadyl (V=O) species have been revealed at the surface of α-$Cr_2O_3(0001)$ [6.282] and α-$Fe_2O_3(0001)$ [6.283] single crystals and $V_2O_3(0001)$ thin films [6.284], respectively. Lin et al. observed that shifting every second reconstructed cell row in the (2×2) structure (Fig. 6.19) by one bulk lattice constant results in the $c(4 \times 2)$ configuration (Sect. 6.3.3). The geometrical similarity led them to suggest that the (2×2) surface is transformed from the $c(4 \times 2)$ surface by using different sample preparation conditions [6.261].

(1×1) Termination

Herger et al. noted that the double-layer (1×1) termination seems to be unlikely for its much too high surface energy, while poor fits discard the *ideal* bulk (1×1) termination [6.200, 250], in line with the suggestion that this termination does not exist [6.285]. In the same way as for the (2×1) and (2×2) reconstructions, fits of (1×1) data significantly favored the configurations involving a double-layer TiO_2 termination and a zigzag motif of the top Ti atoms [6.200, 250]. Surface energy considerations suggested that the (1×1) structure results from a mixture of (2×1) and (2×2) reconstructions with a disordered combination of the zigzag motifs. Such origin is consistent with the unique occurrence of the (1×1) structure at high temperature. The surface vibrational energy might exceed the difference in surface energy between the (2×1) and (2×2) domains, resulting in their complete mixing [6.200, 250] in an order–disorder transition [6.286] similar to what was observed for the W(100) clean surface phase transition [6.287]. The best fit of the *hot* (1×1) leads to a structure similar to the (1×1) found at room temperature [6.200, 250], but with more puckering of the top TiO_2 surface layer via protruding surface Ti atoms (Fig. 6.20).

Comparison Between Models

The (1×1) [6.200, 250, 279, 285, 288], (2×1) [6.200, 250, 279, 285, 288], (2×2) [6.200, 250, 279], and $c(4 \times 2)$ [6.279] reconstructions of the $SrTiO_3(100)$ surface

have been studied using ab initio approaches. Many tests have been carried out for each structure, by removing atomic rows, changing the surface terminations, or creating vacancies [6.200, 250, 285], or using different symmetry groups [6.279]. Overall, the results of the calculations support the experimental results, in particular the double-layer (DL) TiO_2-terminated (1×1) [6.200, 250], (2×1) [6.200, 248, 250], and *p2mg* (2×2) [6.200, 250] models. DFT calculations predict the (1×1) DL to be unstable [6.250, 288]. They confirm the very low surface energies of the (2×1)-DL and (2×2)-DL reconstructions, the latter having the lowest energy [6.250, 279]. However, the (2×1)-DL is not clearly favored with respect to the bulk-terminated (1×1) [6.250, 285].

Calculations relative to the geometry of the $SrTiO_3$ (001)-(2×1) structure are in good agreement [6.200, 248, 250, 279, 285, 288]. In all models, the predicted reconstruction extends over three atomic layers, and the featured trends appear very similar. A puckering [6.200, 250] of the surface Ti atoms is evidenced [6.248, 285]. However, the out-of-plane relaxation of a surface oxygen atom (O4 in Fig. 6.17 [6.248]), which is modeled in [6.248, 285], does not appear in the model proposed in [6.200, 250] (Figs. 6.18 and 6.20).

Finally, in the absence of assignment to a defined structure, the measurements performed on the surface relaxation of $SrTiO_3$ by LEED, RHEED, and MEIS [6.78, 197, 203, 229] can hardly be reconciled with an atomistic description of the surface. As a trend, however, they indicate systematically a small positive rumpling [6.78, 197, 203, 229], which might correspond to the protrusion of some surface oxygen atoms in the (2×1) [6.248, 279, 285] and (2×2) [6.200, 250] structures which are the dominant contributions of the $SrTiO_3$(001)-(1×1) termination [6.200, 250].

6.3.3 $SrTiO_3$(100) Reconstructions

c(4 × 2)

Observed by annealing at 1220 K under hydrogen at a partial pressure of 5×10^{-5} mbar [6.208], the c(4 × 2) structure can be obtained after sputtering with Ar^+ ions and annealing either to 1470 K in UHV [6.256, 264] or to 1120 K under oxygen at 1×10^{-6} mbar [6.265]. However, *Dagdeviren* et al. prepared it by annealing the (1×1) at 1270 K under flowing oxygen for 30 min, which evidences a totally different origin of the reconstruction [6.266]. The reconstructed c(4 × 2) surface involves domains rotated by 90° with respect to each other, as analyzed by LEED [6.208, 256, 266]. STM images show straight step edges aligned with the [001] and [010] directions [6.208, 256, 257, 265]. The reproducible observation that steps are one bulk unit cell high implies a unique termination which is assumed to be TiO_2 [6.208, 256, 266]. Auger electron spectroscopy (AES) analysis rules out the possibility that impurities could be the driving force for the reconstruction [6.208].

Erdman et al. [6.263] analyzed the c(4 × 2) reconstruction by the same HRTEM technique as the (2×1) structure [6.248]. Samples are prepared by ion milling and then annealing under flowing oxygen (Fig. 6.16). Measurements made by HRTEM on the electron-transparent samples were complemented by plane-wave pseudo-potential DFT calculations to determine z positions. The surface structure consists of a periodic pattern of clustered quartets of edge-sharing TiO_5 polyhedra. The subsurface is a bulk-like TiO_2 layer (Fig. 6.21) [6.263, 264]. The c(4 × 2) and (2×1) models are close to each other. However, the c(4 × 2) termination is more stable than the (2×1) reconstruction, as determined by DFT. Consistently, the c(4 × 2) is obtained by annealing in flowing oxygen at a lower

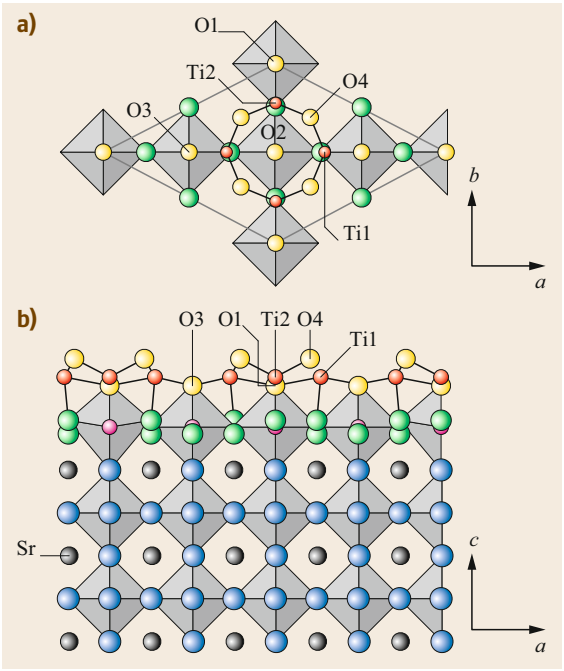

Fig. 6.21 **(a)** Top and **(b)** side view of the $SrTiO_3$(100)-c(4 × 2) reconstruction. Note the oxygen atoms (O4) in flexible positions (not bonded to subsurface Ti atoms). The Ti, Sr, surface O, and subsurface O atoms are represented by *red*, *black*, *yellow*, and *green spheres*, respectively. Bulk TiO_6 octahedra are shown in *blue*. Floating oxygen O4 are similar to those found in the $SrTiO_3$(100)-(2×1) (Fig. 6.17) [6.248] and in $SrTiO_3$(100)-(2 × 2) of *p4mm* symmetry (Fig. 6.19) [6.261] (Reprinted with permission from [6.263]. Copyright 2003 American Chemical Society)

temperature than the (2 × 1) structure (1100–1200 and 1220–1270 K, for the c(4 × 2) [6.262] and the (2 × 1) [6.248], respectively). In the proposed c(4 × 2) structure [6.263], half of the surface oxygen atoms occupy a flexible position (oxygen atoms with no Ti atom positioned directly underneath, O4 in Fig. 6.21), while there are only one-quarter of such atoms in the (2 × 1) structure proposed by the same group [6.248].

c(6 × 2)

After annealing an $SrTiO_3$(100) crystal at 1270 K in flowing oxygen, faint spots assigned to the c(6 × 2) structure were observed to coexist with the ($\sqrt{13} \times \sqrt{13}$) RHEED pattern [6.244]. *Jiang* and *Zegenhagen* observed the c(6 × 2) reconstruction by heating the crystal to 1220–1370 K for 4–5 h in pure oxygen at atmospheric pressure and then at 1220 K for 2 h in the UHV system [6.208, 254]. LEED and STM characterize a (6 × 2) surface structure whose twofold symmetry is at odds with the fourfold symmetry of the $SrTiO_3$(100) surface. The accommodation of the reconstruction by the substrate explains that the surface is tiled randomly by equivalent (6 × 2) domains rotated by 90° with respect to each other and aligned in ⟨100⟩ directions. However, a slight miscut favors a single-domain superstructure [6.254]. The unit-cell-high steps indicate a unique termination, assumed to be Ti-rich on the basis of AES analysis. As in the case of the c(4 × 2), the possibility that the reconstruction is induced by impurities is discarded. Interestingly, the c(6 × 2) reconstruction, which is always obtained upon annealing in flowing oxygen, proves to be extremely stable. It is even hardly affected by exposure to oxygen or ambient air [6.208, 254].

A first model for the atomic structure for the c(6 × 2) was proposed by combining transmission electron diffraction, surface x-ray diffraction, and density functional theory [6.268]. Samples were prepared in conditions similar to those used previously [6.208, 244, 254]. The TEM and x-ray analyses were performed on electron-transparent samples and $SrTiO_3$(001) crystals, respectively, annealed for 2–5 h at 1320–1370 K under a flow of high-purity oxygen at atmospheric pressure. The surface was suggested to involve four related structures, either stoichiometric or slightly reduced, and nonperiodic surface TiO_2 units [6.268]. However, a recent study by the same group questioned this view [6.269, 270]. High-resolution secondary-electron microscopy (HRSEM) coupled with annular dark-field (ADF) TEM allowed for simultaneous measurement of both the atomically resolved bulk (ADF) and surface crystal structure (HRSEM) [6.269, 270]. The analysis revealed that the previous model [6.268] involves a shift of the surface $SrTiO_3$ layers with respect to the bulk. The DFT approach used to reconcile the complete data set led to a c(6 × 2) structure (also belonging to the *c2mm* space group) consisting of a triple TiO_2 overlayer terminated by TiO_5 octahedrally coordinated titanium similar to those found on (2 × 1) [6.248] and c(4 × 2) [6.262, 263] surfaces. In addition, in each c(6 × 2) unit, two Sr atoms with sevenfold coordination to oxygen are substitutionally exchanged for Ti in the uppermost surface layer (Fig. 6.22) [6.269, 270].

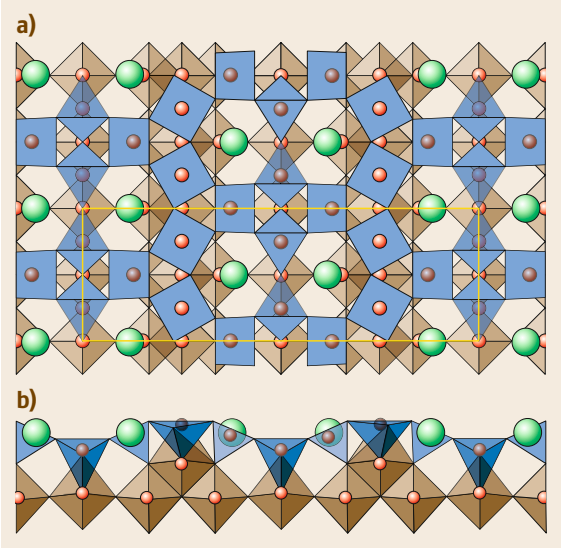

Fig. 6.22 **(a)** Top and **(b)** side view of the $SrTiO_3$(001)-c(6 × 2) reconstruction as suggested by *Ciston* et al. [6.269]. Ti atoms, Sr atoms, surface TiO_5 truncated octahedra, and bulk-like subsurface TiO_6 octahedra are in *red*, *green*, *blue*, and *brown*, respectively. The unit cell is shown in *yellow* (Adapted with permission from [6.269])

($\sqrt{13} \times \sqrt{13}$)-R33.7°

The air-stable [6.276] $SrTiO_3$(100)-($\sqrt{13} \times \sqrt{13}$) reconstruction has been observed by RHEED [6.244], TEM [6.276], and LEED [6.266] after annealing at 1070–1370 K in flowing oxygen for 5–15 h [6.244, 266, 276] (Fig. 6.16). The ($\sqrt{13} \times \sqrt{13}$) RHEED pattern was also observed following a treatment at similar temperatures under much lower oxygen partial pressure (Fig. 6.16), either at 1120–1270 K under (i) 3×10^{-5} mbar O_2 for 40 min [6.85, 221, 277], or (ii) at 900 K under 1×10^{-6} mbar O_2 for 16 h [6.266]. In the latter case, however, the ($\sqrt{13} \times \sqrt{13}$) phase was mixed to traces of the initial c(4 × 2) structure [6.266]. What distinguishes the formation conditions of c(6 × 2) from those of ($\sqrt{13} \times \sqrt{13}$) is unclear. Both are obtained under flowing oxygen at similar temperature, to the point that they can coexist [6.244] (Fig. 6.16). However, they differ strongly. In particular, the c(6 × 2)

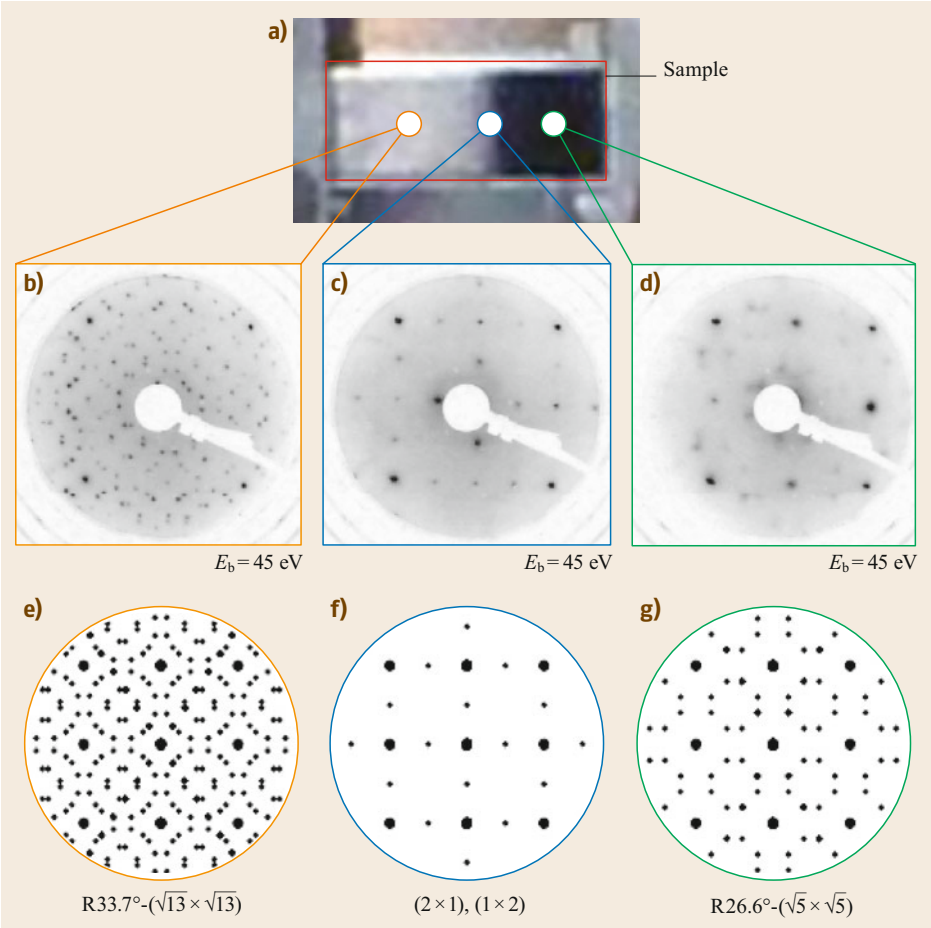

Fig. 6.23a–g $SrTiO_3$(100) structural surface reconstruction versus the reduction state of the crystal. **(a)** Photograph of the crystal annealed at 1070 K for 24 h while being subjected to a dc voltage; **(b–d)** LEED patterns from $(\sqrt{13} \times \sqrt{13})$, (2×1)-(1×2), and $(\sqrt{5} \times \sqrt{5})$ reconstructions that are unambiguously associated with **(b)** the transparent zone (positive electrode), **(c)** the intermediate zone, and **(d)** the dark zone (negative electrode), respectively; **(e–g)** schematic representation of the LEED patterns (Reprinted from [6.289], with the permission of AIP Publishing)

structure includes surface Sr atoms [6.269], while the $(\sqrt{13} \times \sqrt{13})$ reconstruction is TiO_2-terminated [6.276, 277], with a marginal Sr segregation at steps [6.221] (see later in chapter).

A Reconstruction of Highly Oxidized $SrTiO_3$(100) Surfaces. The diversity of the preparation conditions for the $(\sqrt{13} \times \sqrt{13})$ structure makes it impossible to determine whether it is associated with a precise oxidation state of the substrate. The experiments of *Shimizu* et al. [6.289] help remove the ambiguity. These authors resistively annealed an $SrTiO_3$(100) crystal to $\approx$ 970–1070 K in UHV by a dc current via a thick Pt film deposited on the back of the sample. Upon annealing, defective sites migrate close to the negative electrode, as shown by the spatial color gradation of the $SrTiO_3$ crystal from transparent to black (Fig. 6.23a). LEED patterns associated with the $(\sqrt{13} \times \sqrt{13})$, (2×1), and $(\sqrt{5} \times \sqrt{5})$ reconstructions appear in the transparent area, the intermediate blue part, and the strongly reduced black zone, respectively (Fig. 6.23b–g). In accordance with the colors, the Ti 2p levels shift from Ti^{4+} to Ti^{3+} states. STM images of the three reconstructions were recorded in preparation conditions similar to those of the LEED. The oxidized and reduced zones are generated by the diffusion of the species under the effects of the electric field, but are not generated by either the gaseous environment or the elevation in temperature. Therefore, the spontaneous $(\sqrt{13} \times \sqrt{13})$ reconstruction of the transparent part of the crystal indicates that $(\sqrt{13} \times \sqrt{13})$ is the stable structure of the fully oxidized $SrTiO_3$(100) surface [6.289]. This is in

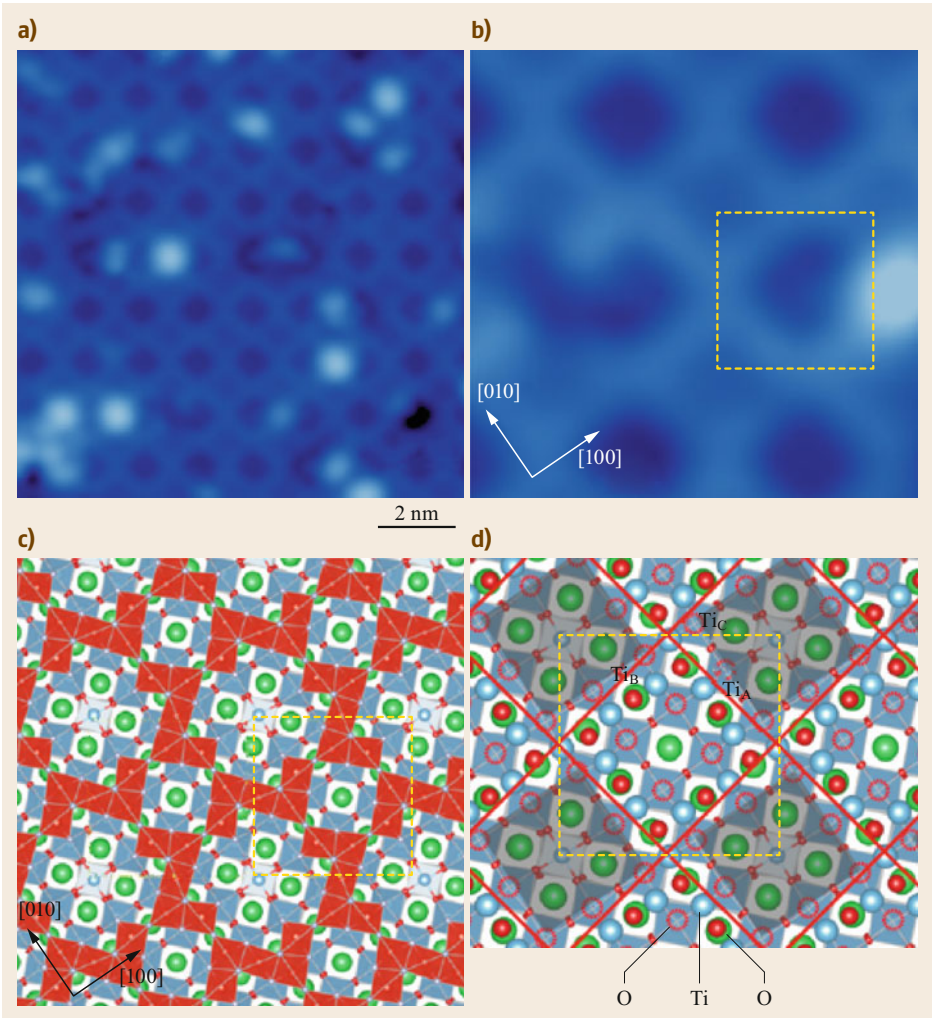

Fig. 6.24a–d STM analysis of the $(\sqrt{13}\times\sqrt{13})$ reconstruction of the $SrTiO_3(100)$ surface. **(a)** Topographic image; **(b)** $3.7\times3.7\,nm^2$ topographic image; the *dashed squares* correspond to the $(\sqrt{13}\times\sqrt{13})$ unit cell; **(c)** $(\sqrt{13}\times\sqrt{13})$ surface structure: Sr, Ti, and O atoms correspond to *green*, *blue*, and *red spheres*, respectively; *blue* and *red polyhedra* indicate TiO_6 octahedra in bulk and truncated octahedra TiO_5 at the surface, respectively. **(d)** Other representation of the $(\sqrt{13}\times\sqrt{13})$ structure on the bulk-like TiO_2-terminated surface (Sr, Ti, and O atoms correspond to *green*, *blue*, and *red* (*filled* or *empty*) *spheres*, respectively); dark and faint-dark zones seen in STM images **(a)** and **(b)** are indicated, as well as the three inequivalent surface Ti atoms (Ti_A, Ti_B, Ti_C) (Adapted with permission from [6.277]. Copyright 2014 American Chemical Society)

line with the formation of the structure upon annealing at 1070–1370 K in flowing oxygen for 5–15 h [6.244, 266, 276], under conditions of time and pressure that likely bring the system close to equilibrium. This does not contradict the formation of the $(\sqrt{13}\times\sqrt{13})$ structure at 1120 K under lower O_2 pressures [6.85, 221, 277], since it has been shown that the reconstructed surface obtained in such conditions is almost perfectly stoichiometric, with no detectable contribution of Ti^{3+} [6.221]. The puzzling $(\sqrt{13}\times\sqrt{13})$ structure obtained by annealing an $SrTiO_3(100)$-$(\sqrt{5}\times\sqrt{5})$ surface at 1520 K for a few seconds [6.259] likely stems from kinetic effects.

The TiO_2 Termination. The topographic STM image of the $(\sqrt{13}\times\sqrt{13})$ exhibits dark and faint-dark tiles separated by a bright lattice [6.221, 259, 277, 289] (Fig. 6.24a,b). Two very close geometries have been proposed. One is based on HRTEM [6.276]. The other, which is derived from STM imaging [6.277], is pre-

sented here because it also accounts for the distribution of the surface d states. To model the reconstruction from the STM data, dark and faint-dark tiles were assigned to vacant sites in the TiO_x adlayer. This adlayer was then arranged to fulfill the periodicity and the fourfold symmetry of the $(\sqrt{13}\times\sqrt{13})$ reconstruction. The stoichiometric surface TiO_2 layer consists of Z-shaped units involving five edge-sharing TiO_5 truncated octahedra that form a two-dimensional network with small and large vacant sites. The model derived from the STM analysis is shown in Fig. 6.24c. Its relevance was tested by DFT calculation [6.277]. The geometry is very close to that determined by HRTEM [6.276]. The model also accounts for marked changes in the differential conductance dI/dV obtained from differentiation of the tunneling current (I) at each point, as a function of the sample bias voltage (V) [6.277]. It is assumed that the degeneracy of the t_{2g} levels (d_{xy}, d_{yz}, d_{zx}) is lifted upon reconstruction. However, the energy levels and localizations of the orbitals differ for each of the three types of Ti atoms that belong to the surface TiO_2 lattice: Ti_A and Ti_B have corner sharing in addition to edge sharing, while Ti_C has only edge sharing (Fig. 6.24d). The marked energy dependence of the spectroscopic image is attributed to changes in the d orbitals probed with STS, which are suggested to be d_{xy} at lower bias (≤ 1.2 eV) and $d_\pi(d_{yz} + d_{zx})$ at higher bias (≥ 1.3 eV). The proposed structural model satisfactorily accounts for the observed dI/dV profile [6.277].

Therefore, the atomistic description of the double-layer TiO_2-terminated model of the $SrTiO_3$(100)-$(\sqrt{13}\times\sqrt{13})$ reconstruction [6.276, 277] is consistent with the macroscopic analysis. The structure appears on a highly oxidized surface close to stoichiometry [6.221, 289], on which one-unit-cell-high steps are indicative of a single-terminated surface [6.85]. The Sr coverage at the $(\sqrt{13}\times\sqrt{13})$ surface was estimated at only 1% and was attributed to segregation at steps [6.221]. The apparent contradiction of this situation with the constant observation that Sr segregates upon annealing in vacuum of BHF-treated $SrTiO_3$(100) substrate [6.202, 205, 206, 230–233] is not explained.

$(\sqrt{5}\times\sqrt{5})$-R26.6°

All preparations of the $SrTiO_3$(100)-$(\sqrt{5}\times\sqrt{5})$ reconstruction consist in annealing the $SrTiO_3$ crystal to 1455−1670 K in UHV [6.242, 245, 249, 259, 267, 271–273, 275, 290] (Fig. 6.16). The $(\sqrt{5}\times\sqrt{5})$ reconstruction was first obtained by annealing an $SrTiO_3$(100) crystal to 1470 K for 2 min in UHV, possibly after degassing at 1070−1170 K, and initially attributed to reducing conditions [6.242, 245, 249, 259, 271–273]. The c(4 × 4)-dot and $(\sqrt{5}\times\sqrt{5})$ reconstructions both result from annealing in UHV. However, the former shows up at slightly lower temperature. It actually coexists with the $(\sqrt{5}\times\sqrt{5})$ structure [6.259] which covers the whole surface after further annealing [6.259, 267]. In greater reducing conditions, by heating an $SrTiO_3$ crystal to 1470−1680 K for many hours, a crystal conductivity jump was observed to parallel the $(\sqrt{5}\times\sqrt{5})$ reconstruction, which means that the reconstruction is due to a significant reduction of the crystal [6.267, 275]. On the annealed $SrTiO_3$ crystal under polarization (Fig. 6.23), the structure $(\sqrt{5}\times\sqrt{5})$ is formed at the strongly reduced end, on the side opposite the one where the structure $(\sqrt{13}\times\sqrt{13})$ is seen [6.289]. Therefore, the preparations which rest on prolonged heating times that tend probably to equilibrium [6.267, 275, 289] all indicate that the $(\sqrt{5}\times\sqrt{5})$ structure is the reconstruction of reduced $SrTiO_3$(100) surfaces.

The STM image corresponding to the $SrTiO_3$(100)-$(\sqrt{5}\times\sqrt{5})$ reconstruction was initially described as a (2 × 2) structure [6.242] before being properly assigned [6.245, 271, 272]. The bright spots on the STM images were first assigned to oxygen vacancies, and the reconstruction was assumed to be a $\square-Ti^{3+}-O$ complex [6.245, 271, 272], as supported by simulations [6.246, 291]. The model was later questioned by the prediction that the bright spots should be split into two spots [6.247].

Kubo and *Nozoye* investigated the $SrTiO_3$(100)-$(\sqrt{5}\times\sqrt{5})$ structure by means of STM (Fig. 6.25a) and NC-AFM (Fig. 6.25b) imaging, supported by ab initio calculations [6.249, 259, 290]. In particular, images at the atomic scale of the $(\sqrt{5}\times\sqrt{5})$ lattice cell recorded by NC-AFM were assumed to reflect a surface corrugation (Fig. 6.25b). The bright spots at the corner of the lattice were assigned to Sr atoms, and the dark spots aligned along the [001] and [010] directions (inset of Fig. 6.25b) were suggested to be related to the oxygen atoms of the TiO_2 plane. In this way, the $(\sqrt{5}\times\sqrt{5})$ structure was viewed as an ordered array of Sr adatoms sitting at oxygen fourfold hollow sites on a TiO_2-terminated surface [6.249, 259, 290] (Fig. 6.25d). The interpretation of the STM and NC-AFM images was supported by first-principles total energy calculations. Subsequent studies confirmed these results. A cross-shaped protrusion observed by STM at the center of the $(\sqrt{5}\times\sqrt{5})$ unit cell was attributed to Ti−O−Ti bridges [6.275] by comparison with [6.199]. The $(\sqrt{5}\times\sqrt{5})$ was shown by Auger spectroscopy [6.267] and photoemission [6.292] to correspond to a Ti enrichment, a strong O depletion, and a clear reduction of Sr [6.292] over the UHV cleaved sample taken as representative of the bulk composition [6.267]. The lack of sensitivity of STM to sample bias (from $+3.5$ to -3.5 eV) was judged to be indicative of the metallicity of the reconstructed

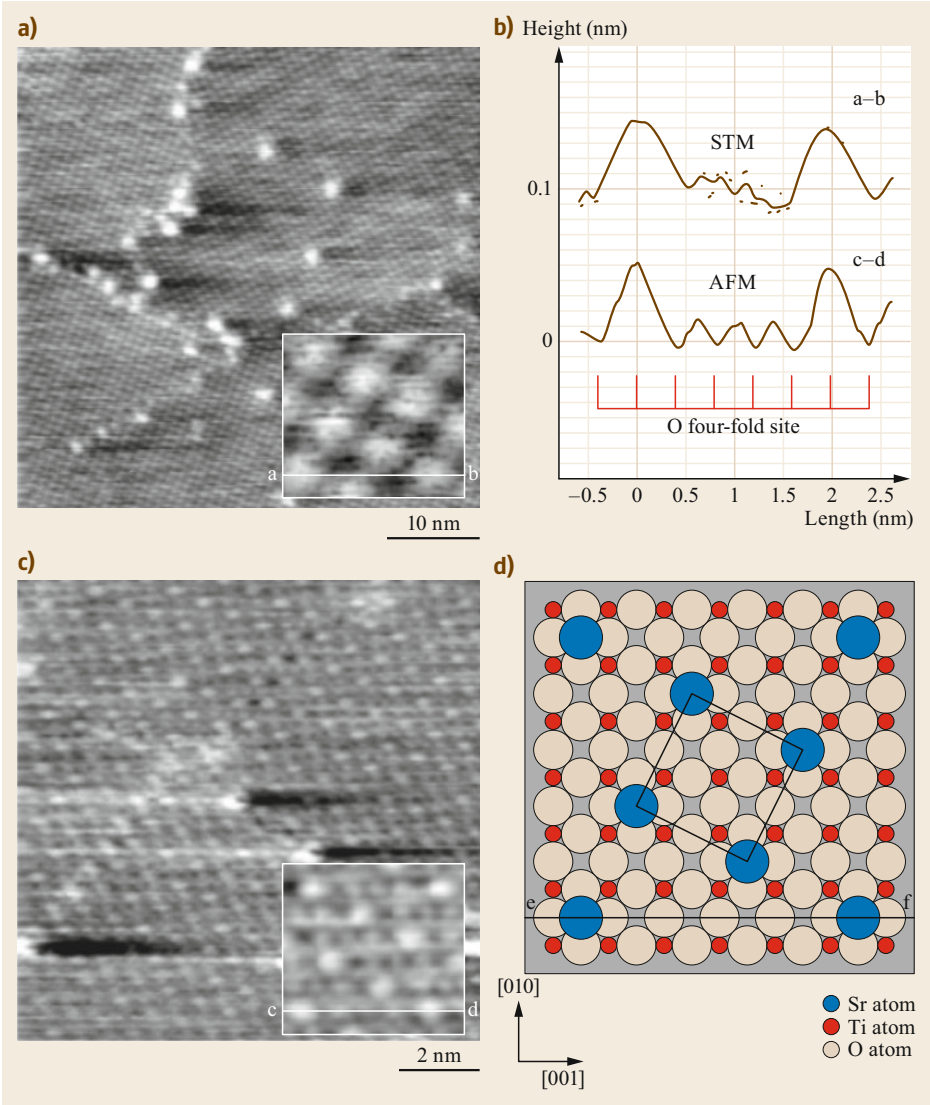

Fig. 6.25a–d Analysis of the $SrTiO_3(100)$-$(\sqrt{5}\times\sqrt{5})$ reconstruction. **(a)** STM image 50×50 nm^2 and **(c)** NC-AFM image 12×12 nm^2; **(b)** vertical profiles along the *lines* a–b and c–d drawn in *insets* in **(a)** and **(c)**; **(d)** suggested model for the $(\sqrt{5}\times\sqrt{5})$ structure; the *line* e–f corresponds to both the *lines* a–b and c–d in **(a)** and **(c)**, respectively (Reprinted with permission from [6.249]. surface [6.267]. A phase separation occurring on the strongly reduced surface was suggested by *Newell* et al. to give rise, on the one hand, to the Sr adatoms of the $(\sqrt{5}\times\sqrt{5})$ structure and, on the other hand, to islands whose composition was assumed to be TiO [6.293] (corresponding to Ti^{2+}) on the basis of the Ti LMV Auger line shape [6.267]. (The observation that the shape of the Ti LMV line reflects the stoichiometry in compounds containing reduced titanium [6.251, 294, 295] was substantiated by the identification of the components of the Ti LMV transition [6.296, 297].) Despite the relatively poor overall Sr content of the surface region of the $(\sqrt{5}\times\sqrt{5})$ reconstruction, *Newell* et al. support the Sr-terminated model [6.267]. Interestingly, doping affects the $(\sqrt{5}\times\sqrt{5})$ reconstruction in a way that seems compatible with that model. The structure is observed on Nb-doped but not La-doped STO(100). Nb^{5+} ions that are located substitutionally on Ti sites do not segregate, while La^{3+} ions located on Sr sites do segregate and presumably prevent the segregation of Sr and the formation of the $(\sqrt{5}\times\sqrt{5})$ reconstruction [6.298].

Kubo et al. further extended the Sr-terminated model [6.249] to the c(2 × 2), c(4 × 4), (2 × 2), (4 × 4), $(\sqrt{5}\times\sqrt{5})$, and $(\sqrt{13}\times\sqrt{13})$ reconstructions that they achieved by a succession of short annealing cycles (a few seconds) separated by small temperature increments, from 1270 to 1520 K [6.249, 259]. They assumed that the reconstructions so obtained consist of phase transitions rather than composition changes [6.259,

290]. However, first-principles total energy calculations of Sr-terminated $SrTiO_3$(100) reconstructions [6.299] led to the conclusion that the only stable structures for the temperature and pressure ranges indicated by *Kubo* and *Nozoye* and *Kubo* et al. [6.249, 259, 290] are the (2×2) and $(\sqrt{5}\times\sqrt{5})$ reconstructions.

A different model came from an STM study supported by DFT calculations of the $BaTiO_3$(001)-$(\sqrt{5}\times\sqrt{5})$-R26.6° surface reconstruction [6.300]. By comparing the surface phase diagram of $BaTiO_3$(001) determined by DFT calculations to STM and STS investigations, Martirez et al. favored TiO_2-$Ti_{3/5}$ or TiO_2-$Ti_{4/5}$ terminations in which Ti adatoms occupy hollow sites of the TiO_2 surface. These atoms, whose density of states strongly contributes to the conduction band, are expected to be observed mostly in empty-state images. Conversely, Ti atoms belonging to the TiO_2 layer, of which the density of states involves bandgap states, are predicted to appear in filled-state images. The model includes three different Ti atoms. *Martirez* et al. suggested that it could apply to the $(\sqrt{5}\times\sqrt{5})$ reconstruction of the $SrTiO_3$(001) surface [6.300]. Leaving aside that suggestion, which is not supported by any $SrTiO_3$ modeling, the Sr-terminated model of the $SrTiO_3$(001)-$(\sqrt{5}\times\sqrt{5})$ from Kubo and Nozoye is concordant [6.267, 275, 292], but its extension to other surfaces is not recognized.

(4×4) and $c(4\times4)$ Reconstructions

Other structures—(4×4) and $c(4\times4)$—have been observed on $SrTiO_3$(100) surfaces. Also, nanostructured $SrTiO_3$(100) surfaces and defective structures can be obtained by annealing in UHV, as recently reviewed by *Marshall* et al. [6.38]. Annealing a (2×1) structure at 1170−1670 K in UHV after BHF etching gave rise to a $c(4\times4)$ reconstruction that consists of broken lines running in the [100] direction [6.256]. The periodicity of the breaks (four bulk unit cells) and the offset of the line result in a $c(4\times4)$ structure suggested to evolve from the (2×1) areas through ordering of defects. The two reconstructions coexist even after annealing at 1670 K [6.256].

A different $c(4\times4)$ reconstruction was obtained by annealing an $SrTiO_3$(100)-(2×2) surface at 1300 K in UHV [6.260] or, alternatively, by annealing a BHF-etched $SrTiO_3$(001) surface in UHV at 1270 K [6.267]. The structure now consists of ordered bright spots oriented in ⟨110⟩ directions (for that reason, it is labeled $c(4\times4)$ dots in Fig. 6.16). Eventually, after 80 min at 1350 °C, the formation of the $(\sqrt{5}\times\sqrt{5})$ reconstruction follows a significant increase in conductivity of the crystal [6.267]. *Kubo* and *Nozoye* [6.259] observed small (2×2) and $c(4\times4)$ domains after annealing at 1270 K for 20 min. By successive annealing for several seconds at 1370, 1420, 1450, and 1470 K, they observed a series of reconstructed surfaces, i.e., $c(4\times4)$, (4×4), a mixture of (4×4) and $(\sqrt{5}\times\sqrt{5})$, and $(\sqrt{5}\times\sqrt{5})$, that were all assigned to ordered arrays of surface Sr atoms [6.259]. The $c(4\times4)$ structures obtained in [6.259, 267] are apparently similar. Both result from heating an $SrTiO_3$(100)-(2×2) surface in UHV. Both lead by further annealing to the $(\sqrt{5}\times\sqrt{5})$ reconstruction, but with extremely different annealing times, a few seconds in one case [6.259] and 80 min in the other investigation [6.267].

6.3.4 Open Issues

A vast corpus of experiments shows that the chemistry of the bulk, near-surface, and surface of an $SrTiO_3$(100) crystal depends on its temperature and environment. Upon annealing in vacuum, the $SrTiO_3$(100) surface loses oxygen while the Sr content increases relative to titanium [6.202, 208, 227, 266]. But it is unclear [6.266, 267] whether such enrichment is proof of the surface segregation of strontium [6.249, 259, 290]. The oxygen deficiencies induced by annealing in UHV leave two electrons behind that reduce the transition-metal cations [6.267]. However, it is not easy to distinguish the effects of annealing from those resulting from the presence of vacancies [6.289]. Although the complex formed by oxygen vacancies and reduced titanium was suggested in early works [6.242, 245, 246, 271, 291] to drive the $(\sqrt{5}\times\sqrt{5})$ reconstruction prior to being discarded [6.247, 249], little attention has since been paid to the influence of the degree of reduction of the solid on the surface reconstruction [6.289]. Defective sites and charge transfers complicate the configurations formed by the three elements involved in the oxide, to the point that the analysis is hardly tractable.

Stoichiometry-Driven Reconstructions

From this point of view, insights can be gained by experiments that favor one particular parameter, all other parameters being unaffected. The above-described experiment by *Shimizu* et al. (Sect. 6.3.3 and Fig. 6.23) follows such an approach [6.289]. Three structures appear in the UHV-annealed and polarized $SrTiO_3$ crystal: $(\sqrt{13}\times\sqrt{13})$, (2×1), and $(\sqrt{5}\times\sqrt{5})$. They clearly rely on the oxidation state of the substrate lying underneath, either fully oxidized, partially reduced, or fully reduced. Similar ideas come from *Newell* et al.'s observation on annealed $SrTiO_3$ crystal that the onset of the formation of the $(\sqrt{5}\times\sqrt{5})$ LEED pattern correlates with a jump in conductivity, i.e., a sudden increase in bulk concentration of reduced species [6.267]. However, while the colors of the polarized $SrTiO_3$ crystal could be reversibly reversed by switching the polarity of the bias

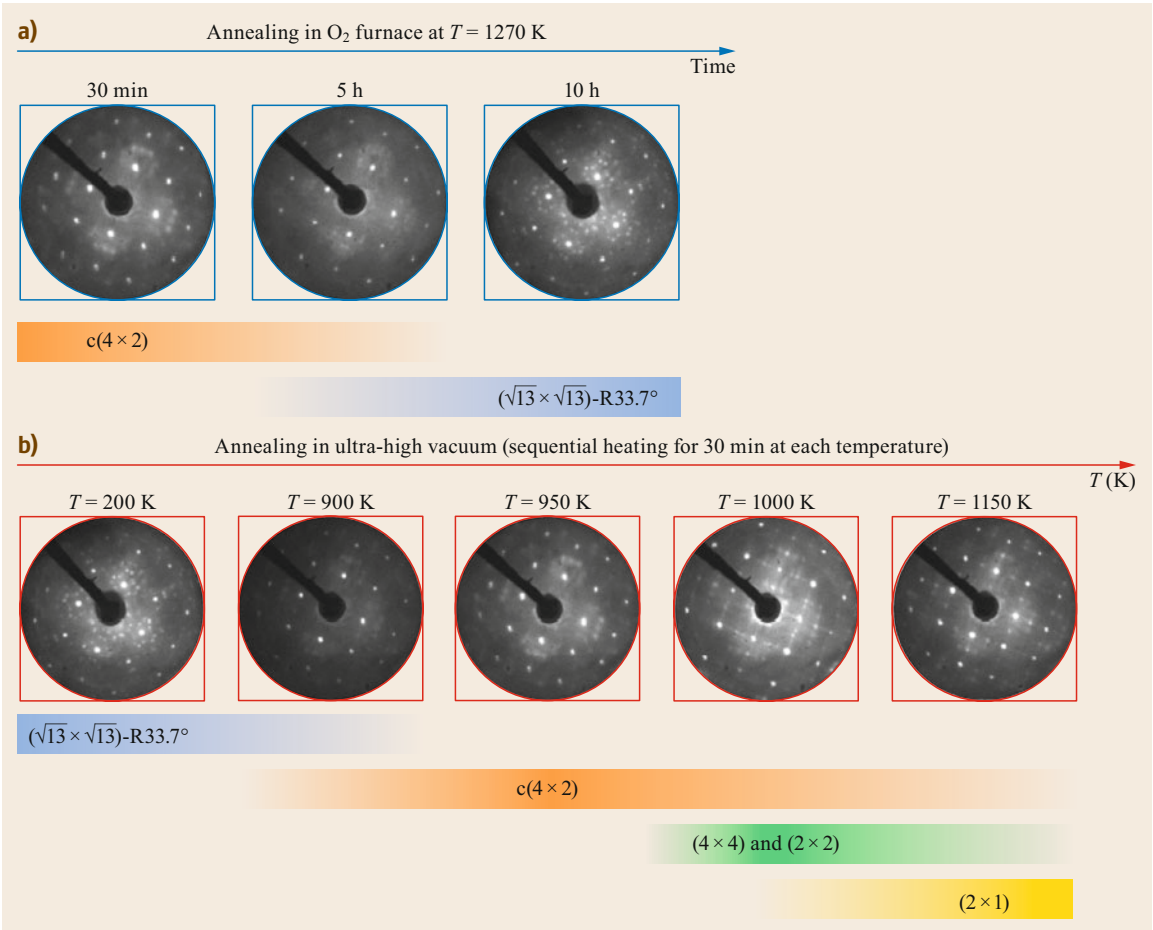

Fig. 6.26a,b Structural transition on $SrTiO_3(100)$ as a function of temperature and environment. **(a)** Annealing of $SrTiO_3(100)$-(1×1) at 1270 K in flowing oxygen; the $c(4 \times 2)$ structure that first appears is progressively replaced by the $(\sqrt{13} \times \sqrt{13})$ reconstruction; **(b)** annealing the $(\sqrt{13} \times \sqrt{13})$ termination in UHV, the reverse transformation results in the recovery of the $c(4 \times 2)$ structure and then in combinations of (4×4), (2×2), and (2×1) structure (Reprinted with permission from [6.266]. Copyright 2016 by the American Physical Society)

voltage, it was not possible to modify the reconstructions by this means [6.289]. Such behavior is indicative of a reconstruction process that does not stem from the bulk defect concentration alone. It likely involves more complex correlations between Sr, Ti, O, and vacancies that depend on the redox status of the $SrTiO_3$ substrate. In particular, for thermodynamic reasons, the concentration of defective sites at reducible oxide surfaces can strongly differ from that in bulk, as observed in the case of the rutile TiO_2 (110) [6.301, 302].

Dagdeviren et al. reported a series of $SrTiO_3(100)$ reconstructions obtained by varying the temperature and/or the annealing time under given environments, including oxygen at normal pressure (Fig. 6.26) [6.266]. They pay particular attention to transitions and reverse transitions between reconstructions. Annealed in a furnace at 1270 K under flowing oxygen, the original (1×1) surface structure transforms first into a $c(4 \times 2)$ reconstruction and then, after 10 h, into a $(\sqrt{13} \times \sqrt{13})$ structure. A similar transformation is observed when the sample is removed from the O_2 furnace after 30 min and then annealed at 900 K in a UHV chamber in 10^{-6} mbar O_2, although traces of the $c(4 \times 2)$ phase are still visible after 16 h. Conversely, the $(\sqrt{13} \times \sqrt{13})$ structure could be switched into the $c(4 \times 2)$ reconstruction by annealing the crystal at 950 K in UHV. Further annealing at 1000 and 1150 K gives rise to (4×4), (2×2), and (2×1) reconstructions. As discussed earlier, the $(\sqrt{13} \times \sqrt{13})$ reconstruction appears as the favored surface structure under oxidizing conditions. The $c(4 \times 2)$, (4×4), (2×2), and (2×1) are likely comparatively increasingly oxygen-deficient [6.266].

On the $SrTiO_3(100)$-c(4 × 2) substrate, the systematic observation of terraces separated by unit-cell step height [6.266] proves the uniform coverage of the surface by a single termination. Upon annealing the c(4 × 2) surface in UHV at increasing temperatures, AES analysis shows that Sr and Ti segregate at the $SrTiO_3(100)$ surface while the Sr/Ti ratio increases, in agreement with the commonly accepted behavior. A chemical surface and subsurface disorder is evidenced by temperature- and bias-induced changes in surface roughness. In parallel, steps and holes of fractional unit-cell step heights (770−1170 K) evidenced by NC-AFM reveal the progressive emergence of surface terminations of various natures (Sect. 6.3.1 *Coexistence of TiO_2 and SrO*). Therefore, the transition from the $SrTiO_3(100)$-c(4 × 2) to (4 × 4), (2 × 2), and (2 × 1) by annealing in UHV is accompanied by changes in chemical composition and appearance of various terminations, although the c(4 × 2) [6.263], (2 × 2) [6.200, 250, 261], and (2 × 1) [6.200, 248, 250, 261] reconstructions are modeled by similar double-layer TiO_2 structures.

Surface Chemistry

The changes in the surface structure of $SrTiO_3(100)$ that are caused by deposition of strontium and titanium [6.265] follow the same direction as the above findings. In a similar way as on the $SrTiO_3(110)$ [6.303] and $SrTiO_3(111)$ [6.304] surfaces, *Gerhold* et al. transformed the surface reconstructions of the $SrTiO_3(100)$ surface by Sr and Ti deposition [6.265]. A two-domain c(4 × 2) reconstruction was transformed into a (2 × 2) structure by deposition of strontium and annealing to 1120 K in 10^{-6} mbar O_2. The inverse transformation can be performed by titanium deposition and annealing in oxygen. The operation can be repeated more than ten times without visible degradation. For the two structures, unit-cell step heights characterize a single-terminated surface, and the Ti core-level profiles are indicative of fully oxidized surfaces. However, the steps aligned with ⟨100⟩ directions observed on the c(4 × 2) reconstructed surface and the curved steps seen on the (2 × 2) surface [6.265] are reminiscent of the TiO_2 and SrO terrace edges [6.212], respectively. This and the higher Sr/Ti ratio found by LEIS on the (2 × 2) surface question the prediction of a similar double-layer TiO_2 termination for the two reconstructions. *Gerhold* et al. suggest that the building blocks of the two surfaces should be different and that the surface stoichiometry is at the origin of the formation of the different reconstructions of the $SrTiO_3(100)$ surface [6.265]. This conclusion is in line with the suggestion by *Dagdeviren* et al. that the c(4 × 2) and (2 × 2) terminations exhibit different terminations [6.266].

6.4 Outlook

The always positive values of the rumpling at MgO(100), as determined by both experiment and theory, demonstrate that the oxygen ions protrude above the magnesium ions at that surface. As a trend, rumpling is also positive along the series of (100) surfaces of transition-metal oxides MnO, FeO, CoO, and NiO. Conversely, the rumpling is predicted to switch from positive on MgO(100) to increasingly negative along the CaO(100), SrO(100), and BaO(100) series, with cations protruding outward. Because the earlier model of Verwey, which relies on differences in ion polarizability, cannot account for that trend, these predictions suggest a relaxation mechanism that includes the metal and oxygen semicore state interactions and the overlap O(2p)−O(2p) between next-nearest neighbors. As regards relaxation, x-ray diffraction performed on high-quality MgO(100) single crystal shows that the first interlayer spacing is slightly contracted, while atomistic simulations predict a weak expansion, leading to the qualitative conclusion that the MgO(100) surface relaxation is close to zero. An increasing negative relaxation is predicted along the CaO(100)–BaO(100) series, in agreement with the only existing measurement, which was carried out on CaO(100). There is complete consensus on the contraction of the first interlayer spacing of NiO(100), but nothing is clear about the MnO, FeO, CoO series. Overall, the support of experimental data by numerical simulations reinforces the reliability of the conclusions. However, in the case of the much-studied relaxation and rumpling of MgO(100), the theory puts forward estimates that are about 1% higher than experimental values. These small but systematic discrepancies indicate that the issue escapes complete understanding.

The c(4 × 2), c(6 × 2), $(\sqrt{5} \times \sqrt{5})$, and $(\sqrt{13} \times \sqrt{13})$ surface reconstructions of $SrTiO_3(100)$ are reproducibly prepared. However, the temperature and pressure conditions observed from one group to another for the formation of given reconstructions often escape rationality and sometimes seem contradictory. A crucial concern is the preparation of single-terminated surfaces with unambiguous surface composition. As shown by the formation of specific reconstructions as a function of the degree of reduction of the material, species associated with the reduction of the oxide, oxy-

gen vacancies, or reduced cations are definitely active in driving reconstructions. In addition, the involvement of surface strontium in reconstructions is underestimated. Nevertheless, the existing structural models of $SrTiO_3(100)$ reconstructions hardly take those species into account.

jacques.jupille@insp.jussieu.fr

Jacques Jupille is an Emeritus CNRS Senior Scientist at the Institute of Nanosciences of Paris (INSP). He received his PhD from the University of Nancy. In 1990, he moved to the joint CNRS–Saint-Gobain laboratory Glass Surfaces and Interfaces. In 2002, he moved to INSP to create the Low-Dimensional Oxides group. His research activity focuses on the physical chemistry of oxide surfaces and interfaces, from ultra-high vacuum to ambient conditions. In 2019, he has been awarded the "Grande Médaille" of the French Society of Metallurgy and Materials (SF2M).

7. Crystallography of Metal Surfaces and Adsorbed Layers

Georg Held

Crystallography involves the determination of atom positions with accuracy better than a few percent of interatomic bond lengths. The first part of this chapter describes the main experimental techniques that are used for surface crystallography on metal surfaces: low-energy electron diffraction, photoelectron diffraction, surface x-ray diffraction, and the x-ray standing wave technique. The second part discusses common features and trends found in the structures of metal surfaces with and without adsorbates, and presents representative examples of experimentally determined surface structures. These examples illustrate how the interplay between vertical (adsorbate–substrate) and lateral (adsorbate–adsorbate) interactions of different strengths determines the arrangement of atoms at the surface.

7.1 Experimental Surface Crystallographic Techniques

Since the 1960s, single-crystal surfaces have been used routinely for surface science studies, which has also enabled the development of techniques for characterizing these crystals. The availability of reliable laboratory instruments and synchrotron radiation and a massive increase in computer power over the past five decades have made a number of surface crystallographic techniques readily available today. The choice of technique depends on the type of surface under investigation and the type of information that is required. The most accurate structural information is obtained from diffraction techniques, such as low-energy electron diffraction (LEED), surface x-ray diffraction (SXRD), x-ray photoelectron diffraction (XPD), photoelectron diffraction (PhD), or the x-ray standing wave technique (XSW). These techniques yield the positions of surface atoms with an accuracy of typically 0.01–0.1 Å, depending on their contribution to the overall diffraction signal. They do, however, rely on a homogeneous surface, with either long-range order (LEED, SXRD) or at least identical adsorption sites (XPD, PhD, XSW). We will concentrate on these techniques in the following section. Scanning probe microscopy techniques such as scanning tunneling microscopy (STM) or atomic force microscopy (AFM) (discussed in Chap. 8) do not have the same restriction in terms of surface homogeneity, but their lateral resolution in terms of atomic positions is typically poor at the atomic level (≈ 0.5 Å). Spectroscopic techniques, such as x-ray photoelectron spectroscopy (XPS), near-edge x-ray absorption fine structure spectroscopy (NEXAFS), or vibrational spectroscopy (high-resolution electron energy loss spectroscopy HREELS, reflection-absorption infrared spectroscopy RAIRS) (discussed in Chap. 25), require identical adsorption sites but no long-range order. They will only yield a subset of structural parameters, such as coordination of atoms or bond angles, which can be very useful in cases where the full crystallographic data set cannot be acquired. For further details on surface characterization methods, we refer to recent general

textbooks [7.1, 2] and review articles on specific techniques, as cited below.

7.1.1 Basic Concepts of Surface Diffraction Techniques

As a surface breaks the translational symmetry of a crystal in the direction perpendicular to the surface plane, there is only two-dimensional periodicity within this plane. The surface sensitivity or penetration depth of the probe used in an experiment (e.g., electrons, x-rays) determines to what extent the periodicity perpendicular to the surface affects the diffraction pattern.

Surface Lattice

The two-dimensional periodicity is described by two lattice vectors, $\boldsymbol{a}_1, \boldsymbol{a}_2$, and reciprocal lattice vectors $\boldsymbol{b}_1, \boldsymbol{b}_2$, which are parallel to the surface plane, as discussed in Chap. 4. The vector $\boldsymbol{R}$ between two equivalent lattice points of a periodic surface is an integer multiple of these lattice vectors

$$\boldsymbol{R} = n_1\boldsymbol{a}_1 + n_2\boldsymbol{a}_2 \,. \tag{7.1}$$

The two-dimensional Laue condition leads to the following relationship between $\boldsymbol{a}_1, \boldsymbol{a}_2$ and the reciprocal lattice vectors $\boldsymbol{b}_1, \boldsymbol{b}_2$

$$\begin{aligned} \boldsymbol{a}_1\boldsymbol{b}_1 &= \boldsymbol{a}_2\boldsymbol{b}_2 = 2\pi \,, \\ \boldsymbol{a}_1\boldsymbol{b}_2 &= \boldsymbol{a}_2\boldsymbol{b}_1 = 0 \,, \end{aligned} \tag{7.2}$$

and explicit expressions

$$\boldsymbol{b_1} = \frac{2\pi}{a_{1x}a_{2y} - a_{1y}a_{2x}} \begin{pmatrix} a_{2y} \\ -a_{2x} \end{pmatrix}, \tag{7.3}$$

$$\boldsymbol{b_2} = \frac{2\pi}{a_{1x}a_{2y} - a_{1y}a_{2x}} \begin{pmatrix} -a_{1y} \\ a_{1x} \end{pmatrix}, \tag{7.4}$$

where $a_{1x}, a_{1y}, a_{2x}, a_{2y}$ are the coordinates of the real-space lattice vectors. The reciprocal lattice vectors have units of Å^{-1} and are also parallel to the surface, as mentioned earlier. In analogy to the real lattice vectors, they define the diffraction pattern in reciprocal space. Each diffraction spot corresponds to the sum of integer multiples of $\boldsymbol{b}_1$ and $\boldsymbol{b}_2$,

$$\boldsymbol{g}(n_1, n_2) = n_1\boldsymbol{b}_1 + n_2\boldsymbol{b}_2 \,. \tag{7.5}$$

The pair of integer numbers (n_1, n_2) are used as indices to label the respective spots. Examples of real-space and reciprocal-space lattices are shown in Fig. 7.1.

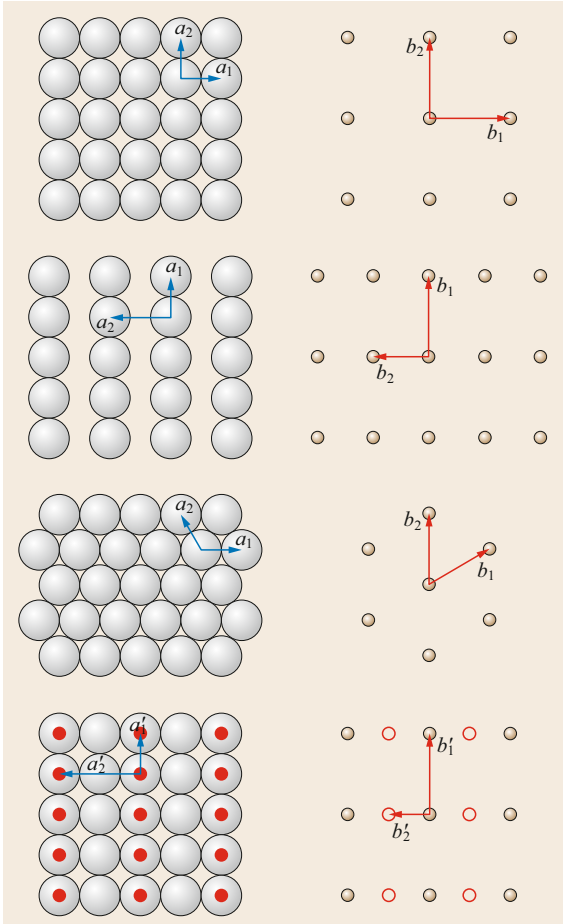

Fig. 7.1 Examples of diffraction patterns for common surfaces: fcc{100}, fcc{110}, fcc{111}, fcc{100}-p(2 × 1)

Superstructures

In many cases, the periodicity of the surface lattice is larger than expected for the bulk-truncated surface of a given crystal due to adsorption or reconstruction. This leads to additional (superstructure) spots in the diffraction pattern, for which fractional indices are used. There are two nomenclatures commonly used to describe such superstructures, the matrix notation [7.3] and the Wood notation [7.4], which are also described in Chap. 4. Here we concentrate on the matrix notation, as this is the most general way of describing a superstructure.

The lattice vectors $\boldsymbol{a}_1'$ and $\boldsymbol{a}_2'$ of such superstructures can be expressed as multiples of the (1 × 1) lattice vectors $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$

$$\begin{aligned} \boldsymbol{a}_1' &= m_{11}\boldsymbol{a}_1 + m_{12}\boldsymbol{a}_2 \,, \\ \boldsymbol{a}_2' &= m_{21}\boldsymbol{a}_1 + m_{22}\boldsymbol{a}_2 \,, \end{aligned} \tag{7.6}$$

where the numbers m_{ij} are the coefficients of the superstructure matrix $\mathbf{M}$

$$\mathbf{M} = \begin{pmatrix} m_{11} & m_{12} \\ m_{21} & m_{22} \end{pmatrix} = (m_{11}\, m_{12}; m_{21}\, m_{22})\,. \tag{7.7}$$

The area of the superstructure unit cell, A', is given by

$$A' = \det \mathbf{M}\, A\,, \tag{7.8}$$

where A is the area of the (1×1) unit cell and $\det \mathbf{M} = m_{11}m_{22} - m_{12}m_{21}$.

Also, the positions and indices of the additional diffraction spots can be calculated directly from the superstructure matrix. The reciprocal lattice vectors $\boldsymbol{b}'_1, \boldsymbol{b}'_2$ which correspond to the superstructure vectors $\boldsymbol{a}'_1$ and $\boldsymbol{a}'_2$ are given by

$$\begin{aligned} \boldsymbol{b}'_1 &= +\frac{m_{22}}{\det \mathbf{M}}\boldsymbol{b}_1 - \frac{m_{21}}{\det \mathbf{M}}\boldsymbol{b}_2\,, \\ \boldsymbol{b}'_2 &= -\frac{m_{12}}{\det \mathbf{M}}\boldsymbol{b}_1 - \frac{m_{11}}{\det \mathbf{M}}\boldsymbol{b}_2\,. \end{aligned} \tag{7.9}$$

The reciprocal lattice, and hence the diffraction pattern of the superstructure, can be constructed by integer multiples of $\boldsymbol{b}'_1$ and $\boldsymbol{b}'_2$ in the same way as in (7.5),

$$\begin{aligned} \boldsymbol{g}(n'_1, n'_2) &= n'_1\boldsymbol{b}'_1 + n'_2\boldsymbol{b}'_2 \\ &= \frac{n'_1 m_{22} - n'_2 m_{12}}{\det \mathbf{M}}\,\boldsymbol{b}_1 \\ &\quad + \frac{-n'_1 m_{21} - n'_2 m_{11}}{\det \mathbf{M}}\,\boldsymbol{b}_2\,. \end{aligned} \tag{7.10}$$

As $\det \mathbf{M}$ is greater than 1, the prefactors of $\boldsymbol{b}_1$ and $\boldsymbol{b}_2$ in (7.10) are fractions, and therefore the superstructure spots have fractional indices.

Often, the actual diffraction pattern contains more superstructure spots than one would get from constructing the reciprocal lattice according to (7.10). This is the case when the symmetry of the superstructure lattice is lower than the symmetry of the substrate and the adsorption complex. In this case, the domains of all symmetry-equivalent superstructure orientations are present at the surface covering equal areas. These orientations are found by applying the missing symmetry operations to the superstructure lattice.

As the diameter of an electron or x-ray beam in a conventional diffraction experiment is orders of magnitude larger than the typical domain size (100–1000 Å), the observed diffraction pattern is normally a superposition of all rotational and/or mirror domains. Hence, the diffraction pattern usually shows the same symmetry as the substrate, even if the superlattice symmetry is lower. Important exceptions are the superstructures of enantiopure chiral molecules, which themselves do not have any mirror symmetry. For these structures, mirror domains are not observed, since applying a mirror operation would turn the molecule into the opposite enantiomer. For the same enantiomer, applying a mirror operation to the lattice would alter the adsorption site geometry of the molecule [7.5].

The left-hand column of Fig. 7.2 shows three examples of LEED patterns observed for different amounts of CO adsorbed on Ni{111} [7.6], $\mathrm{p}(\sqrt{3}\times\sqrt{3})\mathrm{R30°}/(1\,2;-1\,1)$ at 0.33 ML; $\mathrm{c}(2\times4)/(2\,0;1\,2)$ at 0.33 ML, and $\mathrm{p}(\sqrt{7}\times\sqrt{7})\mathrm{R19°}/(3\,1;-1\,2)$ at 0.57 ML. The white arrows indicate the reciprocal lattice vectors for one domain. The column on the right shows the superstructure unit cells of all domains observed in the patterns. The Ni{111} surface has a $p3m1$ symmetry, i.e., threefold rotation symmetry and three mirror planes. The $\mathrm{p}(\sqrt{3}\times\sqrt{3})\mathrm{R30°}$ superstructure has the same symmetry; therefore, only one domain is observed. The $\mathrm{c}(2\times4)$ superstructure has a rectangular unit cell with pm symmetry, which shares a mirror plane with the substrate, but not the rotational symmetry; therefore, three domains, rotated by 120° and 240° with respect to each other, are observed in the LEED pattern. The $\mathrm{p}(\sqrt{7}\times\sqrt{7})\mathrm{R19°}$ unit cell has a threefold $p3$ symmetry without the mirror plane; therefore, two domains are observed, which are related by a mirror operation.

7.1.2 Low-Energy Electron Diffraction (LEED)

Low-energy electron diffraction (LEED) is the diffraction technique most commonly used to study surfaces. A number of textbooks describe the technique in great detail [7.1, 7–9]. As shown in Fig. 7.3, the surface is exposed to a monoenergetic collimated beam of electrons, and the diffraction pattern of the backscattered electrons is detected on a transparent fluorescent screen. Between the screen and sample there is an assembly of suppressor grids, which filter out inelastically scattered electrons and only allow electrons with the same energy as the incoming beam to be detected. The de Broglie wavelength of an electron of kinetic energy E_{kin} is

$$\lambda_{\mathrm{e}} = \sqrt{\frac{h^2}{2m_{\mathrm{e}}E_{\mathrm{kin}}}} = \sqrt{\frac{150.41\,\mathrm{eV}}{E_{\mathrm{kin}}}}\,\text{Å}\,, \tag{7.11}$$

where h is Planck's constant and m_{e} the electron mass. The corresponding wave vector is

$$k_{\mathrm{e}} = \frac{2\pi}{\lambda_{\mathrm{e}}} = \sqrt{\frac{E_{\mathrm{kin}}}{3.8099\,\mathrm{eV}}}\,\text{Å}^{-1}\,. \tag{7.12}$$

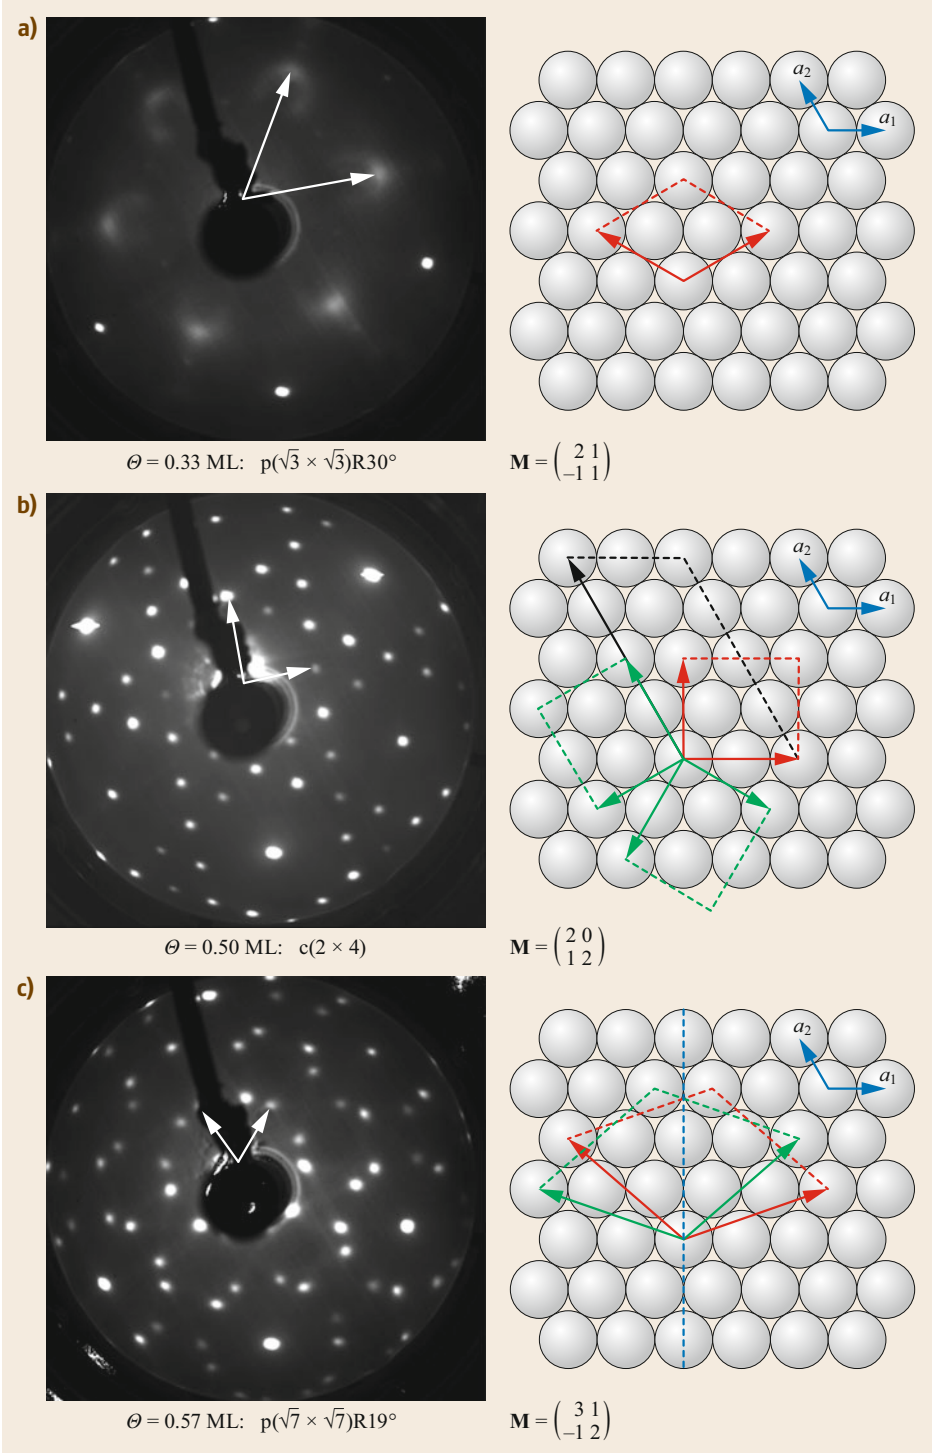

Fig. 7.2a–c Experimental LEED patterns for CO adsorbed on Ni{111} (*left*) and corresponding real-space unit cells (*right*): p($\sqrt{3} \times \sqrt{3}$)R30° (**(a)**, only one domain), c(2 × 4) (**(b)**, 3 rotational domains), and p($\sqrt{7} \times \sqrt{7}$)R19° (**(c)**, 2 mirror domains) [7.6]. Note that real-space diagrams are rotated by about 30° with respect to the crystal orientation of the experiment

For low kinetic energies between 40 and 600 eV, the electron wavelength ranges from 2 to 0.5 Å, which is the same range as the wavelengths used in x-ray crystallography. *Davisson* and *Germer* were the first to observe diffraction patterns for low-energy electrons in 1927 [7.10], and realized already then that the

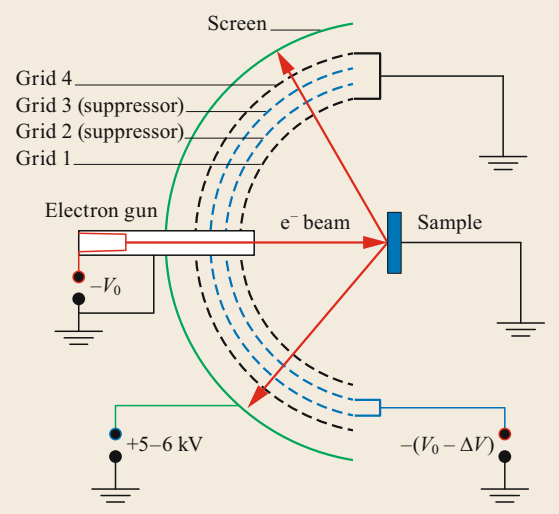

Fig. 7.3 Schematic of a typical LEED experiment. The incident electron beam, accelerated by the potential V_0, is emitted from a small electron gun behind a transparent hemispherical fluorescent screen and hits the sample through a hole in the screen. The surface is in the center of the hemisphere, so that all back-diffracted electrons travel toward the LEED screen on radial trajectories. Before the electrons hit the screen, they have to pass a retarding field energy analyzer (RFA). It consists of four (sometimes three) hemispherical grids concentric with the screen. The first grid (nearest the sample) is connected to earth, as is the sample, in order to provide a field-free region between the sample and this grid. A negative potential $-(V_0 - \Delta V)$ is applied to the second and third grid, the so-called suppressor grids. These repel all electrons that have undergone inelastic scattering processes and have lost more than $e\Delta V$ (typically $\approx 5\,\mathrm{eV}$) of their original kinetic energy. Thus, only elastically scattered electrons and those with small energy losses can pass through to the fluorescent screen. The fourth grid is usually on ground potential in order to reduce field penetration of the screen voltage to the suppressor grids. The screen is at a potential of around 5–6 kV; it provides the electrons with enough energy to cause bright fluorescence on the screen. The pattern can be observed through a viewport from behind the screen

diffraction of low-energy electrons (LEED) could be used to determine the structure of single-crystal surfaces. Because of their small inelastic mean free path (IMFP) of typically $< 10\,\text{Å}$, electrons in this energy range probe only the topmost atomic layers of a surface and are, therefore, better suited for the analysis of surface geometries than x-rays which have a much larger mean free path (typically a few micrometers). As a consequence, low-energy electrons do not sample the periodicity perpendicular to the surface plane, and only a two-dimensional Laue condition must be satisfied for a diffraction spot to be observed

$$\boldsymbol{k}(n_1, n_2) = \boldsymbol{k}_{\text{in}} + \boldsymbol{g}(n_1, n_2)\,, \tag{7.13}$$

where $\boldsymbol{k}_{\text{in}}$ and $\boldsymbol{k}(n_1, n_2)$ are the wave vectors of the incoming and outgoing electron beams, $\boldsymbol{g}(n_1, n_2)$ is a reciprocal lattice vector, as defined by (7.5), and n_1, n_2 are the spot indices. The parallel component of the outgoing wave vector is

$$\boldsymbol{k}_{\parallel}(n_1, n_2) = \boldsymbol{k}_{\parallel,in} + \boldsymbol{g}(n_1, n_2)\,. \tag{7.14}$$

Diffraction is only observed for elastically scattered electrons. Therefore, the lengths of the incoming and outgoing wave vectors are the same, $|\boldsymbol{k}| = \sqrt{2m_{\text{e}}E_{\text{kin}}/\hbar^2}$. The vertical component, $k_{\perp}$, of the electrons back-diffracted into spot (n_1, n_2) is defined by energy conservation

$$k_{\perp}(n_1, n_2) = \sqrt{\frac{2m_{\text{e}}E_{\text{kin}}}{\hbar^2} - |\boldsymbol{k}_{\parallel}(n_1, n_2)|^2}\,. \tag{7.15}$$

Equation (7.15) also limits the number of observable LEED spots, since the expression under the square root must be greater than zero. With increasing electron energy, the number of LEED spots increases, while the polar emission angle with respect to the specular spot $(0, 0)$ decreases for each spot. The specular spot does not change its position if the angle of incidence is kept constant. This is often visualized in terms of an Ewald construction, as illustrated in Fig. 7.4. The incoming and outgoing wave vectors start from the center of the Ewald sphere. Unlike for x-rays, for electrons only the incoming vector needs to point to a reciprocal lattice point. The two-dimensional Laue condition is already fulfilled when the outgoing vector points at the intersect of the Ewald sphere and a reciprocal lattice rod. These reciprocal lattice rods pass through a reciprocal lattice point and are perpendicular to the surface plane. Figure 7.4 shows Ewald constructions for the same angle of incidence but two different energies. The specular $(0, 0)$ vectors emerge at the same angle in both cases, but the angles of the other vectors are different: the higher the energy, the smaller the angles between the vectors. As a result, the diffraction pattern is more compressed at higher energies (i.e., shorter wavelengths). There are also more rods intersecting the larger Ewald sphere at the higher energy; hence more diffraction spots are observed.

Multiple scattering plays an important role in the diffraction process of electrons at solid surfaces. This does not affect the positions of diffraction spots; hence the surface periodicity (size and orientation of the surface lattice) can be determined using the equations

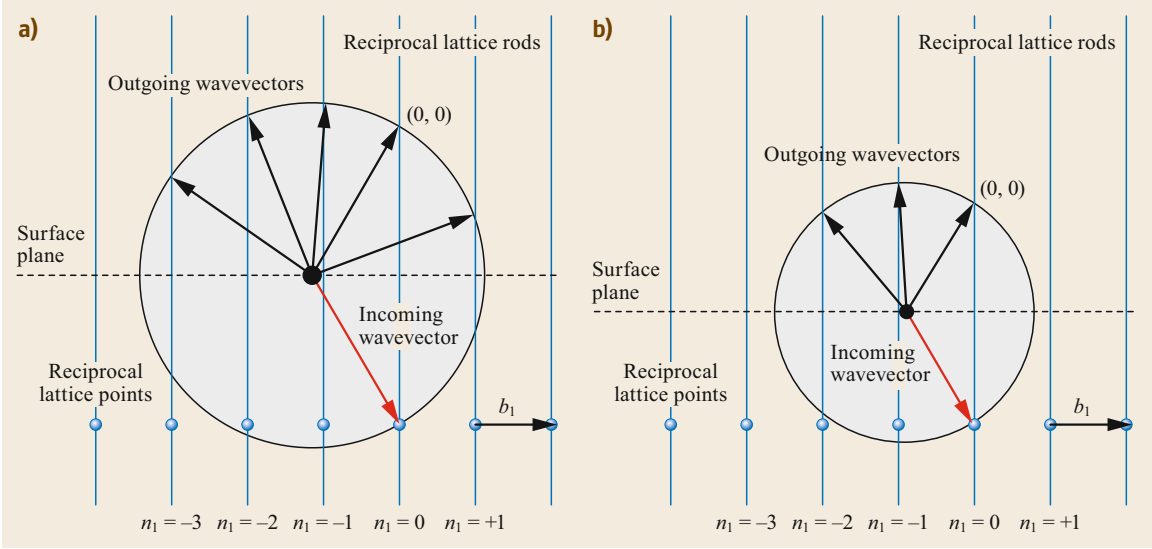

Fig. 7.4a,b Ewald sphere for LEED. **(a)** High energy; **(b)** low energy

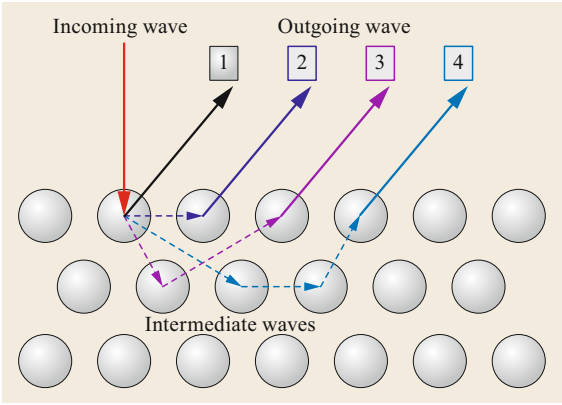

Fig. 7.5 Schematic illustration of single- and multiple-scattering events. The numbers indicate the number of atoms involved in each scattering path

above. The intensities of the diffraction spots, however, are determined by the interference of electron partial waves scattered from the different surface atoms within the unit cell. Figure 7.5 schematically illustrates single- and multiple-scattering events. In the latter, the electron wave interacts with more than one atom before it leaves the surface toward the detector. As a consequence, the phase differences between partial waves depend on the relative positions of all the atoms along the scattering paths and the phase shifts imposed onto the electron wave due to the interaction with the potential of the atoms. The amplitude, and hence the intensity, of the outgoing wave in the direction of a diffraction spot is determined by the superposition of an infinite number of partial waves from all possible (single and multiple) scattering paths, which contain information about the relative positions of atoms within the surface. The amplitudes of each partial electron wave Ψ_k decay exponentially while propagating through the solid, with an energy-dependent decay length, $l(E)$, typically of a few angstroms

$$|\Psi(\boldsymbol{r}+\boldsymbol{s})| = \mathrm{e}^{-\frac{|\boldsymbol{s}|}{2l(E)}}|\Psi(\boldsymbol{r})|\,, \tag{7.16}$$

($|\boldsymbol{s}|$ is the path length of travel). Therefore, the number of multiple scattering paths that need to be considered in practice is limited.

The positions of the atoms can be extracted from the energy dependence of the spot intensities, the so-called LEED I–V, or $I(E)$, curves. Examples are shown in Fig. 7.6. By comparing experimental I–V curves with calculated curves for different test geometries the surface geometry can be identified and refined. The agreement between experimental and theoretical data is quantified using so-called reliability factors (R factors), of which Pendry's R factor is the most common [7.11]. This way, the process of optimizing the atom positions reduces to a minimization problem which can be automated easily. The relative importance of multiple scattering requires fully dynamical quantum mechanical calculations in order to produce I–V curves for the test geometries. A standard approach for calculating LEED I–V curves has been developed in the 1970s through the 1990s by *Pendry*, *Tong*, *Van Hove*, and others [7.7, 9, 12, 13].

To date, structure analysis by LEED I–V is the most accurate and reliable means of determining the atomic positions at surfaces. In particular, the fact that

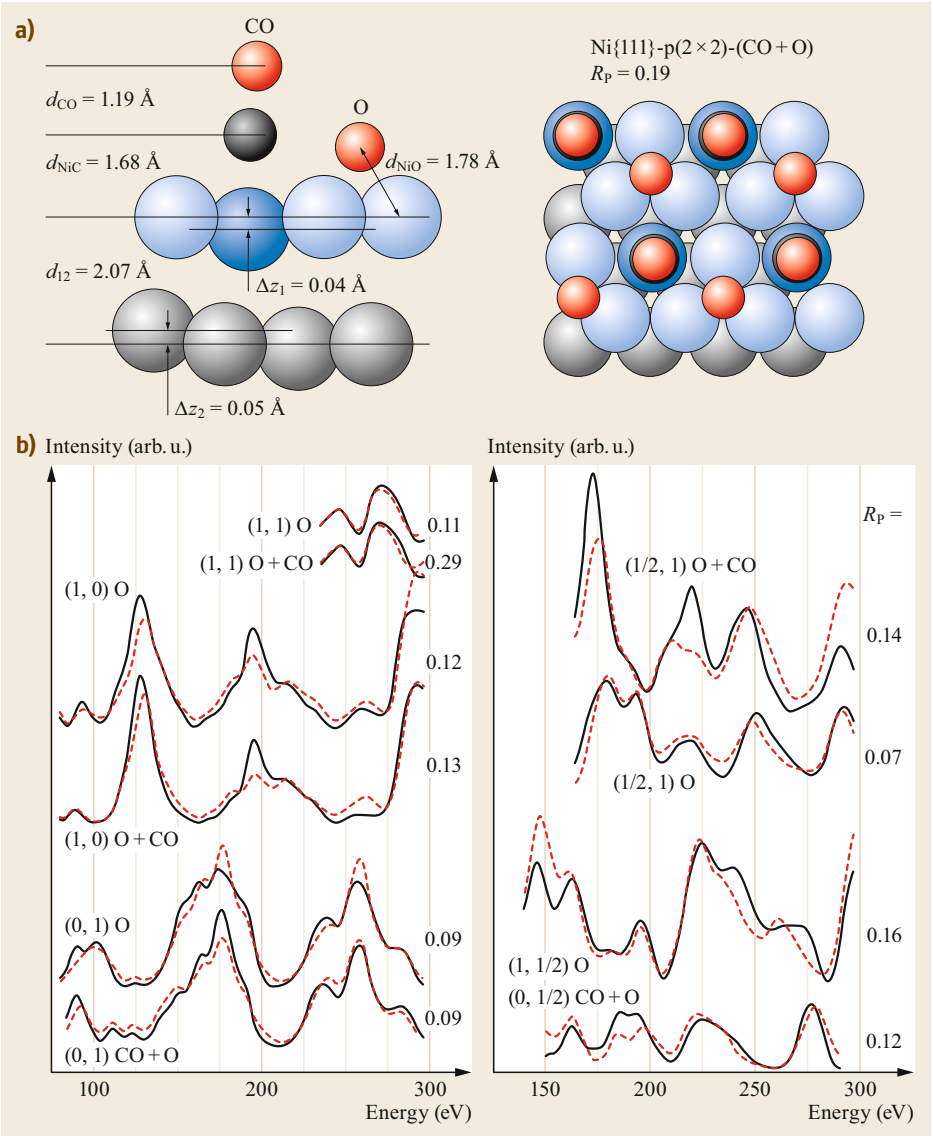

Fig. 7.6
(a) Adsorption geometry for the p(2 × 2) superstructure of co-adsorbed CO and O on Ni{111} according to [7.14] and **(b)** selected LEED *I–V* curves for this structure (CO + O) and the p(2 × 2) superstructure of oxygen only (O). The *black solid lines* are experimental; the *red dashed lines* are calculated *I–V* curves

LEED is sensitive to the atomic positions not only in the topmost layer but down to several layers below the surface makes it an ideal tool for studying intrinsic or adsorbate-induced surface reconstructions. General restrictions are that LEED usually requires ordered and conducting surfaces; otherwise charging would distort the LEED pattern. The time needed for calculating the *I–V* curves and the number of trial geometries are factors limiting the complexity of accessible surface structures on the computational side; the density of LEED spots on the fluorescent screen is an experimental factor limiting the size of unit cells that can be studied.

Since LEED theory was initially developed for close-packed clean metal surfaces, these are the most reliably determined surface structures with theory–experiment agreement comparable to that between two experimental sets of *I–V* curves and error bars for the atomic coordinates as small as 0.01 Å. A good overview of state-of-the-art LEED structure determinations of clean metal surfaces and further references are found in a series of articles by *Heinz* et al. [7.13, 15, 16]. For more open adsorbate-covered and/or reconstructed surfaces, certain approximations used in the standard programs are less accurate, which leads to higher R_P factor values. For simple superstructures of monatomic adsorbates or small molecules on metal, the agreement is usually not as good, and is worse for large molecules, which often adsorb in complex super-

structures and semiconductor surfaces. Since the error margins scale with the agreement between experimental data and theoretical calculations, the accuracy of atomic coordinates in these latter cases is smaller, with error bars up to 0.1 Å. A review of structure determinations of molecular adsorbates was published by *Over* [7.17]; the structure determination of semiconductor surfaces was reviewed by *Kahn* [7.18]. In general, the accuracy is higher for coordinates perpendicular to the surface than for lateral coordinates. For further details about the history, experimental setup, and theoretical approaches of LEED, refer to the books by *Pendry* [7.7], *Van Hove* and *Tong* [7.12], *Van Hove* et al. [7.9], and *Clarke* [7.8].

7.1.3 X-ray Photoelectron Diffraction (PhD, XPD)

Diffraction effects are also observed when an electron is emitted from an atom due to the photoelectric effect. In this case, the energy of a photon, $h\nu$, is transferred onto a valence or core electron, which leaves the emitter atom with a kinetic energy of

$$E_{\mathrm{el}} = h\nu - E_{\mathrm{B}} - \Phi \,, \tag{7.17}$$

where E_{B} is the binding energy of the emitted electron, and Φ the work function of the sample. For x-rays in the energy range from a few hundred to a few thousand electron volts (*soft x-rays*) and binding energies in a similar range, the kinetic energies of the photoelectrons are similar to those in LEED with de Broglie wavelengths of the order of 1 Å. Therefore, the propagation of photoelectrons from an atom which is embedded in a solid is governed by very similar effects as the propagation of LEED electrons. The part of the photoelectron wave function that is scattered by atoms surrounding the emitter atom interferes with the directly emitted electron wave, which leads to significant intensity variations as a function of the detection angle and kinetic (photon) energy. These photoelectron diffraction effects strongly depend on the position of the scattering atoms with respect to the emitter, and can thus be used as a tool to determine the surface structure [7.19–21]. As with LEED, the fact that electrons of relatively low energies are detected makes photoelectron diffraction a surface-sensitive technique. However, there are several important differences between LEED and photoelectron diffraction:

- The wave function of the primary photoelectron is described by a spherical wave, whereas in LEED the incoming electron is described as a plane wave.
- The primary, unscattered part of the photoelectron wave function is always detected alongside the diffracted part, which leads to smaller variations in the recorded intensities compared with LEED.
- The emitter atom is a specific element, and only the environment of this atom is probed. The type of emitter atom can be selected by choosing the kinetic/binding energy of the photoelectron, according to (7.17). In practice, of course, the signal measured is the superposition of signals from all atoms emitting electrons with the respective energy.
- Only the immediate vicinity of the emitter atom contributes to the photoelectron scattering. Therefore, the long-range arrangement of atoms (beyond the inelastic mean free path) does not affect the signal, and no sharp diffraction spots are observed.

In order to measure a photoelectron diffraction signal, one needs a monochromatic photon source and an energy-resolving electron detector. Photon sources are either an x-ray anode with fixed photon energy (typically Al K_α with $h\nu = 1486.7\,\mathrm{eV}$ or Mg K_α with $h\nu = 1253.6\,\mathrm{eV}$) or a synchrotron radiation source, which provides tunable photon energy. The most common detectors are hemispherical electron energy analyzers. For a more detailed description of the experimental setup see [7.19–22]. The current state of the technique and its applications were recently reviewed by *Woodruff* [7.23]. The particular advantage of photoelectron diffraction over other surface-sensitive diffraction methods, such as LEED and surface x-ray diffraction (SXRD), is that it is element-specific and does not require long-range order; the only condition is that the local environment be the same for all atoms that emit electrons of the same binding energy.

Figure 7.7 shows the angular dependence of the scattering factor for electrons of different kinetic energies on a Cu atom, which is representative of most atoms. The scattering factor is proportional to the probability of the electron being scattered in the a direction of polar angle θ. From Fig. 7.7 it is clear that the highest probability is always for scattering in the forward direction ($\theta = 0°$), but at low energies, about 300 eV and below, scattering sideways ($40° < \theta < 120°$) and backward ($\theta \approx 180°$) is also strong, whereas $> 500\,\mathrm{eV}$ the scattering factor is strongly peaked in the forward direction. Therefore, the crystallographic information extracted from photoelectron diffraction is strongly dependent on the kinetic energy of the electrons detected. At high kinetic energies, the signal is affected predominantly by atoms which are between the emitter atom and the detector (*forward focusing*); at low energies, the signal has strong contributions from all atoms surrounding the emitter (*backscattering*).

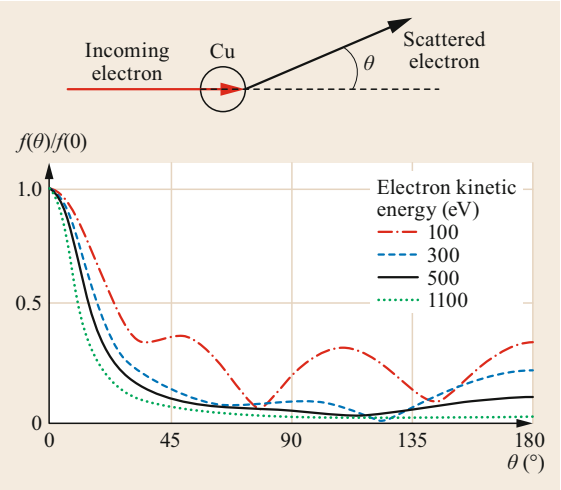

Fig. 7.7 Angular dependence of the modulus of the atomic scattering factor for electrons by a copper atom at several different electron energies (Reprinted with permission from [7.23] with permission from Elsevier)

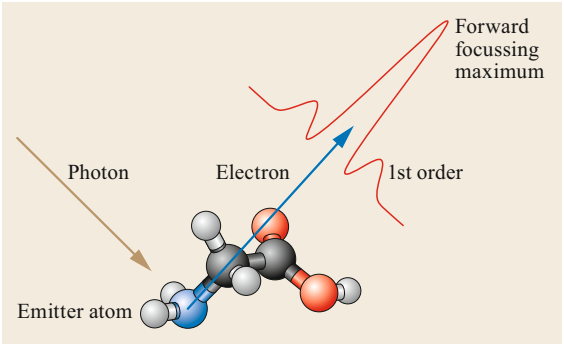

Fig. 7.8 Basic principle of forward focusing. A maximum of the photoelectron signal is observed when a *focusing atom* is between the emitter atom and detector. In this example, the N 1s signal from the N atom in glycine is focused by the neighboring C atom

Forward Focusing (XPD)

For kinetic energies above $\approx 500\,\text{eV}$, electrons are predominantly scattered in the forward direction [7.20, 24]. This leads to the so-called *forward-focusing effect* when another atom is between the emitter and the detector. In this direction, the intensity is amplified; in addition, small-intensity minima are observed at angles 10°–20° from this direction, as indicated in Fig. 7.8. The magnitude of these x-ray photoelectron diffraction (XPD) intensity variations decreases with increasing distance between emitter and scatterer such that effectively only atoms within the same molecule or close neighbors in solids need to be considered. The maxima in the angular distribution of the photoelectron intensity, therefore, correspond directly to the connecting lines between the emitter and neighboring atoms. This makes the data analysis straightforward such that even the adsorption geometry of molecules as large as C_{60} can be determined [7.25]. XPD studies have most commonly been carried out using conventional x-ray sources, often equipped with purpose-built automated in-vacuum goniometers to scan the entire hemisphere above the surface [7.26, 27]. Until recently, synchrotron beamlines did not offer great advantages, since high-energy resolution is usually not required, and the total photon flux at the high end of the soft x-ray range which is required for these measurements is often comparable with un-monochromated Al K_α sources. The higher stability of laboratory sources in terms of flux is an additional advantage over synchrotron radiation, since scanning the entire hemisphere requires long data acquisition times. Recently, however, synchrotron radiation has been used very successfully for this type of experiment [7.28, 29]. Tunable photon energies and polarization enable contrast enhancement by exploiting resonance effects [7.30]. XPD has been applied mostly to studying the structures of thin films and adsorption geometries of molecules, including enantiomeric differences in the adsorption geometries of chiral molecules [7.28, 29].

Backscattering (PhD)

For kinetic energies $< 300\,\text{eV}$, elastic scattering away from the forward direction is very significant, whereby backscattering is a particularly important scattering path. The photoelectron signal emitted from adsorbate atoms is therefore the superposition of the direct wave and the electron wave backscattered from the substrate atoms. The interference of these two waves carries information about the registry between adsorbate and substrate, i.e., adsorption sites and adsorbate–substrate bond lengths, which is not accessible through XPD. In order to make a distinction between the forward and backward scattering regimes in photoelectron diffraction, crystallographic studies using the low kinetic energy range have been termed *PhD* (for *photoelectron diffraction*). Scanning the photon energy with the detector recording the photoemission signal at a fixed angle has become the standard means of data acquisition for this technique. This procedure is repeated for several angles [7.23]. The photon energy range is chosen such that the kinetic energy of the photoelectrons typically varies between 20 and 300 eV. Therefore, these measurements can only be performed at synchrotron beamlines with tunable monochromators. Both hard ($> 2\,\text{keV}$) and soft x-ray ($< 2\,\text{keV}$) beamlines have been used to access core levels of different adsorbates, depending on the binding energies of the relevant core

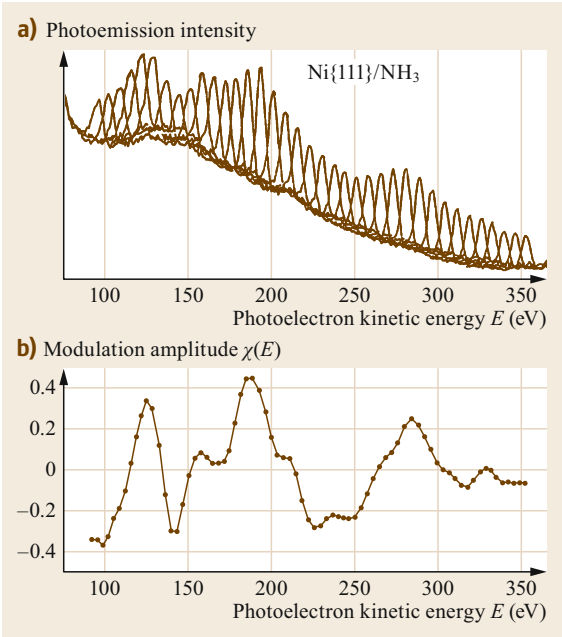

Fig. 7.9a,b Experimental PhD data for NH_3 adsorption on Ni{111} [7.31]. **(a)** Individual N 1s photoelectron spectra as a function of kinetic energy. **(b)** PhD modulation spectrum (relative deviation of the integrated N 1s peak intensities from the sliding average) as a function of the kinetic energy. See text for details (Reprinted with permission from [7.23] with permission from Elsevier)

levels. For most molecular adsorbates, soft x-rays are required to access the core levels of C (1s ≈ 285 eV), N (1s ≈ 400 eV), and O atoms (1s ≈ 530 eV).

As the electron wavelength changes when the kinetic energy is varied, the interference conditions between the direct and the backscattered electron wave change, and intensity variations are observed as a function of photon/kinetic energy, which is illustrated in Fig. 7.9 for the N 1s photoelectrons emitted from NH_3 on Ni{111} [7.31]. The data analysis is not as straightforward as in XPD, and involves multiple-electron scattering theory, similar to LEED. The intensity variations (relative deviation from the unperturbed intensity, see lower panel of Fig. 7.9) are calculated for model geometries and compared with the experimental data. Optimization of the model geometries to improve the agreement eventually leads to the adsorption geometry. A large number of adsorption geometries have been determined to date using PhD, mostly for atomic adsorbates and small molecules adsorbed on metal or metal oxide surfaces (see [7.23] for a complete review up to 2007).

The high energy resolution of third-generation synchrotron beamlines makes it possible to separate the intensity variations for different chemical shifts, i.e., different chemical environments of emitter atoms of the same element. Their positions with respect to the substrate can thus be determined separately, which is particularly important for oxide surfaces, when the signal of molecular oxygen atoms needs to be separated from the substrate [7.32, 33].

7.1.4 Surface X-ray Diffraction (SXRD)

The principle of surface x-ray diffraction (SXRD) is very similar to that of low-energy electron diffraction (LEED). The wavelength of x-rays is related to the photon energy E_{ph} as

$$\lambda_X = \frac{hc}{E_{ph}} = \frac{12\,398\,\text{eV}}{E_{ph}}\text{Å}\,, \tag{7.18}$$

the wave vector of a photon is

$$k_X = \frac{2\pi}{\lambda_X} = \frac{E_{ph}}{1974.2\,\text{eV}}\text{Å}^{-1}\,. \tag{7.19}$$

Therefore, *hard x-rays* of energies ≈ 12 keV (i.e., 1 Å) are best suited for probing atomic positions. Since the groundbreaking work of *Bragg* and *Bragg*, *von Laue*, and others [7.34–36], x-ray diffraction has been successfully used to determine countless crystal structures, from simple atomic solids to complex biomolecules, by analyzing the intensities of Bragg reflections. The relatively low scattering cross section and large penetration depth of x-rays, which is about three to four orders of magnitude larger than that of low-energy electrons, means that the signal recorded from x-ray diffraction is usually dominated by bulk contributions. Intense x-ray sources, such as synchrotrons, and grazing scattering geometries make it possible, however, to extract crystallographic information about the surface geometry as well [7.37–40].

Because of the large penetration depth of x-rays, they, unlike electrons, probe the periodicity of a single crystal normal to the surface, which leads to sharp Laue conditions not only in the surface plane but also in the perpendicular direction. However, the fact that the periodic stacking of layers abruptly ends at the surface causes a relaxation of the Laue condition normal to the surface. As a consequence, some intensity is scattered into the momentum space between the Bragg spots along lines perpendicular to the surface, as indicated in Fig. 7.10. These lines are referred to as *crystal truncation rods*, or *CTRs*. The intensity along the CTRs can be measured by varying the angles of the incident x-ray beam and/or the detector with respect to the surface. This signal contains very useful information about the surface geometry due to the interference between bulk and surface scattering. By convention, in surface x-ray crystallography, two of the real-space lattice vectors, $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$, are chosen as described in (7.1). The

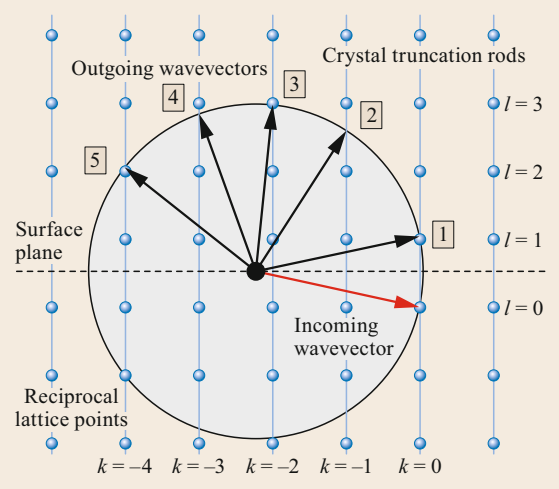

Fig. 7.10 Ewald construction for SXRD

third lattice vector, $\boldsymbol{a}_3$, is perpendicular to the surface. Consequently, the corresponding reciprocal lattice vectors are also parallel ($\boldsymbol{b}_1, \boldsymbol{b}_2$) and perpendicular ($\boldsymbol{b}_3$) to the surface plane. For details regarding the choice of lattice vectors see [7.38, 41].

In general, the intensity diffracted from a single crystal into a Bragg peak is proportional to the square of the structure factor $|F|^2$

$$I(h\boldsymbol{b}_1, k\boldsymbol{b}_2, l\boldsymbol{b}_3) = I_0 \frac{e^4}{m^2 c^4 R^2} P |F(h\boldsymbol{b}_1, k\boldsymbol{b}_2, l\boldsymbol{b}_3)|^2 , \tag{7.20}$$

where I_0 is a constant depending on material properties (e.g., scattering cross section), e the charge and m the mass of an electron, and R the distance between sample and detector. The polarization factor P is unity if the polarization of the incoming wave is normal to the scattering plane (i.e., the plane containing the incoming and diffracted beams), and $P = \cos^2(2\theta)$ if it is within this plane, whereby 2θ is the angle between the incoming and diffracted beams.

For a finite bulk-terminated crystal, the structure factor can be calculated using single-scattering theory [7.37]

$$\begin{aligned} &|F(\boldsymbol{q}_1, \boldsymbol{q}_2, \boldsymbol{q}_3)|^2 \\ &= \left| \sum_{n_1=0}^{N_1-1} \sum_{n_2=0}^{N_2-1} \sum_{n_3=0}^{N_3-1} \exp[\mathrm{i}(n_1 \boldsymbol{q}_1 \boldsymbol{a}_1 + n_2 \boldsymbol{q}_2 \boldsymbol{a}_2 + n_3 \boldsymbol{q}_3 \boldsymbol{a}_3)] \right|^2 \\ &= \frac{\sin^2(\frac{1}{2} N_1 \boldsymbol{q}_1 \boldsymbol{a}_1)}{\sin^2(\frac{1}{2} \boldsymbol{q}_1 \boldsymbol{a}_1)} \frac{\sin^2(\frac{1}{2} N_2 \boldsymbol{q}_2 \boldsymbol{a}_2)}{\sin^2(\frac{1}{2} \boldsymbol{q}_2 \boldsymbol{a}_2)} \frac{\sin^2(\frac{1}{2} N_3 \boldsymbol{q}_3 \boldsymbol{a}_3)}{\sin^2(\frac{1}{2} \boldsymbol{q}_3 \boldsymbol{a}_3)} , \end{aligned} \tag{7.21}$$

where N_1, N_2, N_3 are the (large) numbers of unit cells along the directions of the three real lattice vectors, and $\boldsymbol{q}_1, \boldsymbol{q}_2, \boldsymbol{q}_3$ are vectors in reciprocal space pointing in the directions of the reciprocal lattice vectors. If $\boldsymbol{q}_1$ and $\boldsymbol{q}_2$ are integer multiples of $\boldsymbol{b}_1$ and $\boldsymbol{b}_2$, respectively, such that $\boldsymbol{q}_1 \boldsymbol{a}_1 = 2\pi h; \boldsymbol{q}_2 \boldsymbol{a}_2 = 2\pi k$, the respective terms in (7.21) reduce to $N_1^2 N_2^2$. Hence, the intensity along the truncation rods (i.e., along the continuous variable $\boldsymbol{q}_3$ perpendicular to the surface) is proportional to

$$|F(h\boldsymbol{b}_1, k\boldsymbol{b}_2, \boldsymbol{q}_3)|^2 = N_1^2 N_2^2 \frac{\sin^2(\frac{1}{2} N_3 \boldsymbol{q}_3 \boldsymbol{a}_3)}{\sin^2(\frac{1}{2} \boldsymbol{q}_3 \boldsymbol{a}_3)} . \tag{7.22}$$

For $N_3 \to \infty$ and $\boldsymbol{q}_3 \boldsymbol{a}_3 \neq 2\pi l$ we get

$$|F(h\boldsymbol{b}_1, k\boldsymbol{b}_2, \boldsymbol{q}_3)|^2 \to N_1^2 N_2^2 \frac{1}{\sin^2(\frac{1}{2} \boldsymbol{q}_3 \boldsymbol{a}_3)} . \tag{7.23}$$

The shape of this function for a perfectly flat surface is plotted as a solid black line in Fig. 7.11. The intensity distribution along the crystal truncation rods is strongly dependent on the arrangement of atoms near the surface. Surface roughness at the atomic level, i.e., partial occupation of the layer or several of the layers nearest the surface, leads to deeper minima between the Bragg peaks. This is described by the structure factor

$$\begin{aligned} &|F(h\boldsymbol{b}_1, k\boldsymbol{b}_2, \boldsymbol{q}_3)|^2 \\ &= N_1^2 N_2^2 \frac{(1-\beta)^2}{[1 + \beta^2 - 2\beta \cos(\boldsymbol{q}_3 \boldsymbol{a}_3)]} \frac{1}{4 \sin^2(\frac{1}{2} \boldsymbol{q}_3 \boldsymbol{a}_3)} , \\ &\text{for } \boldsymbol{q}_3 \boldsymbol{a}_3 \neq 2\pi l , \end{aligned} \tag{7.24}$$

where the parameter β describes the partial occupation of the surface layers (for details see [7.37]). The corresponding intensity distribution along the truncation rod is plotted as a dashed line in Fig. 7.11.

Expansion or compression of interlayer distances near the surface leads to asymmetric intensity distributions, as in the red curve plotted in Fig. 7.11. In this case, the distance between the first and the second layer is expanded by 10% with respect to the bulk interlayer distance $|\boldsymbol{a}_3|$. If (7.21) is modified accordingly, this leads to a structure factor

$$\begin{aligned} &|F(h\boldsymbol{b}_1, k\boldsymbol{b}_2, \boldsymbol{q}_3)|^2 \\ &= N_1^2 N_2^2 \left(\frac{\left\{ 2 \sin\left(\frac{1}{2} \boldsymbol{q}_3 \boldsymbol{a}_3\right) - \sin\left[\frac{1}{2} \boldsymbol{q}_3 (2\boldsymbol{d} - \boldsymbol{a}_3)\right] \right\}^2}{4 \sin^2\left(\frac{1}{2} \boldsymbol{q}_3 \boldsymbol{a}_3\right)} \right. \\ &\qquad \left. + \frac{\cos^2\left[\frac{1}{2} \boldsymbol{q}_3 (2\boldsymbol{d} - \boldsymbol{a}_3)\right]}{4 \sin^2\left(\frac{1}{2} \boldsymbol{q}_3 \boldsymbol{a}_3\right)} \right) \\ &\text{for } \boldsymbol{q}_3 \boldsymbol{a}_3 \neq 2\pi l , \end{aligned} \tag{7.25}$$

where $\boldsymbol{d}$ is the vector pointing from the second to the first layer.

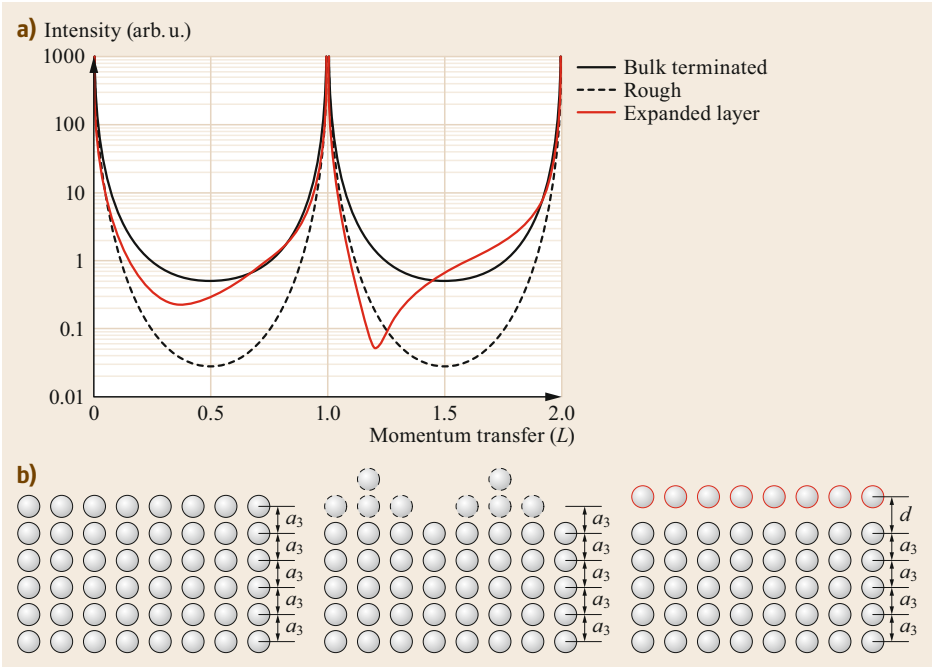

Fig. 7.11
(a) Calculated crystal truncation rods for a bulk-terminated surface (*solid black line*), a rough surface (*dashed black line*), and a surface where the interlayer distance of the topmost layer d is expanded by 10% with respect to a_3 (*solid red line*). **(b)** Corresponding schematic models; (*left*) bulk-terminated; (*middle*) atomically rough surface; (*right*) expanded first layer

The intensity variations between the maximum of the Bragg peaks and the minimum of the CTR span about five orders of magnitude. Therefore, an intense x-ray source is needed, such as a third-generation synchrotron source, to be able to measure the entire profile of the rod. The data analysis determining the surface structure is based on a trial-and-error approach similar to LEED I–V structure determination. Intensity (structure factor) distributions along the CTRs are calculated for different trial geometries and compared with the experimental data. The atom positions within the trial geometries are optimized until the best possible agreement is achieved.

Reflectivity scans measure the intensity of the specularly reflected x-ray beam as a function of incidence angle. This is a special case of CTR with $h = k = 0$. As no lateral momentum transfer is involved, the signal contains no information about the lateral distortions near the surface. The reflectivity signal can thus be used for an independent determination of only the vertical interlayer distances. Lateral parameters can be determined from CTRs with $h, k \neq 0$.

When an ordered superstructure is present at the surface, additional weak rods are observed at fractional h, k values, as discussed in Sect. 7.1.1. As superstructures are located at the surface, the intensities of these spots show very little variation as a function of $\boldsymbol{q}_3$ and predominantly contain information about the lateral positions and electron densities of atoms within the surface unit cell. These can be extracted by means of the two-dimensional Patterson function [7.39, 42]

$$P(x,y) = \frac{1}{A}\sum_{hk} |F(h\boldsymbol{b}_1, k\boldsymbol{b}_2)|^2_{\text{exp}} \cos\left[(h\boldsymbol{b}_1 + k\boldsymbol{b}_2)\begin{pmatrix}x\\y\end{pmatrix}\right], \quad (7.26)$$

where A is the area of the surface unit cell, $\binom{x}{y}$ is a vector parallel to the surface within the superstructure unit cell, and $|F(h\boldsymbol{b}_1, k\boldsymbol{b}_2)|^2_{\text{exp}}$ are proportional to the experimentally determined intensities at the h, k superstructure spot positions. The latter are extracted from the spot intensities measured at constant $\boldsymbol{q}_3$ and using (7.20).

The Patterson function can be interpreted as a real-space map of interatomic distances, i.e., the vectors from the origin of the Patterson map to each maximum correspond to vectors between atoms. Figure 7.12 shows an early example of a Patterson function constructed from the fractional-order Bragg peaks by *Robinson* [7.43], together with a schematic structure model for the missing-row reconstruction. The map clearly shows a main maximum for the vector connecting the lateral coordinates of the first- and second-layer atom. It also clearly shows the absence of maxima corresponding to the atoms of the missing row.

Because of the low scattering cross section of x-rays compared with electrons, and because the cross section scales roughly with the square of the atomic num-

ber Z, the positions of light atoms such as hydrogen, carbon, nitrogen, or oxygen are difficult to determine with surface x-ray diffraction. To date, the method has largely been applied to determine the structures of complex metal, oxide, and semiconductor surface reconstructions. Recently, the fact that hard x-rays can penetrate matter, and therefore x-ray diffraction experiments do not necessarily require vacuum conditions, has been used extensively to study model catalyst surfaces in reactive gas-phase environments [7.40, 44] and even electrochemical interfaces under reaction conditions [7.45].

7.1.5 X-ray Standing Waves (XSW)

The x-ray standing wave (XSW) technique is another crystallographic method that makes use of the photoelectric effect. In contrast to photoelectron diffraction, however, the crystallographic information is derived from the interference of the incoming and outgoing x-ray waves [7.46–49]. As a consequence, hard x-rays (typically $h\nu > 3\,\mathrm{keV}$) are used in order to match the wavelengths with interatomic distances. The principle is illustrated in Fig. 7.13. Photoelectron spectra from a single-crystal sample are measured over a range of photon energies near the Bragg condition for x-ray diffraction from a set of crystallographic planes. When the Laue condition is fulfilled, the superposition of the incoming x-ray beam and the outgoing beam of the Bragg refection results in a standing wave field parallel to the Bragg planes with well-defined periodic maxima and minima. Depending on where an atom sits with respect to the standing wave, the cross section for photoemission will be different. If the atom is near a maximum of the wave field, the photoemission probability will be high; near a minimum it will be low. The relative intensity I of the standing wave field is given by

$$I = \left|1 + \left(\frac{E_\mathrm{h}}{E_0}\right) \exp\left(\frac{-2\pi \mathrm{i} z}{d_\mathrm{h}}\right)\right|^2 , \qquad (7.27)$$

where z is the vertical distance above the Bragg plane corresponding to the reflection used, and d_h the distance between these planes. E_h/E_0 is the ratio of amplitudes of the reflected and incident x-ray beams, given by

$$\frac{E_\mathrm{h}}{E_0} = -\sqrt{\frac{F_\mathrm{h}}{F_{\bar{\mathrm{h}}}}} \left(\eta \pm \sqrt{\eta^2 - 1}\right) , \qquad (7.28)$$

where F_h and $F_{\bar{\mathrm{h}}}$ are the structure factors corresponding to the incident and reflected beams, and η is a quantity that depends on the deviation from the actual Laue condition in terms of angle or photon energy (for an exact definition and a complete description see [7.47]). With the latter expression (7.28), (7.27) can be rewritten as

$$I = 1 + R + 2\sqrt{R}\, \cos\left(\Phi - \frac{2\pi z}{d_\mathrm{h}}\right) , \qquad (7.29)$$

whereby R and the phase angle Φ depend only on the crystal structure and the x-ray properties, and can be easily calculated. By either rocking the sample or varying the photon energy around the Laue condition (within the natural width of the Bragg peak), Φ and hence the positions of the maxima can be moved with respect to the crystal lattice in the direction perpendicular to the Bragg planes. Thus, positions of the emitter atoms can be determined from fits to the intensity variations of the photoemission signal versus rocking angle or photon energy, respectively. In cases where the emitter atoms are in identical well-defined z positions above the Bragg planes, the experimental data will yield their vertical position. If this is not the case, the parameters determined by the fits are the so-called coherent fraction f_co and position d_co. They are defined through

$$f_\mathrm{co} \exp\left(\frac{2\pi \mathrm{i} d_\mathrm{co}}{d_\mathrm{h}}\right) = \int_0^{d_\mathrm{h}} f(z) \exp\left(\frac{2\pi \mathrm{i} z}{d_\mathrm{h}}\right) \mathrm{d}z , \qquad (7.30)$$

and can be seen as weighted average values of positions z and occupancies $f(z)$ of all emitter atoms, which also

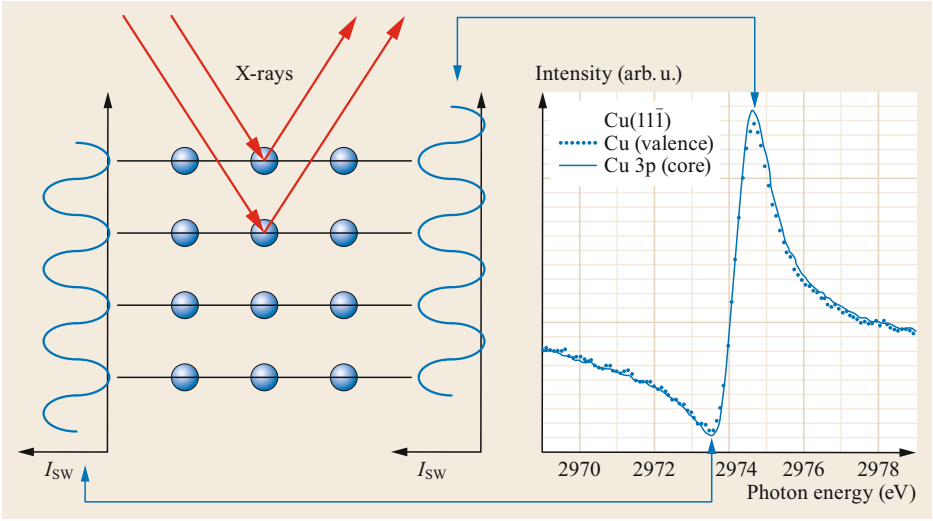

Fig. 7.13 The principle of the x-ray standing wave (XSW) technique. At the low-energy side of the Bragg maximum, the maxima of the standing wave field are between the atomic planes of the bulk crystal (*left*), and at the high-energy side, the maxima are on the atomic planes (*middle*). This leads to a minimum followed by a maximum of the integrated XPS signal from the atoms within the atomic planes. The spectrum on the *right* shows the integrated Cu 3p and valence band signal from a Cu single crystal (Right part of the figure reprinted from [7.48] with permission from Elsevier)

Table 7.1 Key properties of techniques with examples (UHV = ultra-high vacuum)

Technique	LEED	XPD/PhD	SXRD	XSW
Incoming beam	Electrons	X-rays	X-rays	X-rays
Typical energy (eV)	50–500	< 1500	≈ 10 000	3000–10 000
Detected signal	Electrons	Electrons	X-rays	Electrons (fluorescence)
Order necessary	Long-range	Identical sites	Long-range	Identical sites
Element-specific	No	Yes	No	Yes
Information obtained	Complete surface structure	Relative position of emitter atom w/r to neighbors	Complete surface structure	Position of emitter atom w/r to bulk lattice

take into account static and dynamic (thermal) disorder within the sample.

Photoelectrons provide the signal that is normally detected, but other secondary signals, such as Auger electrons or fluorescence, can also be used to determine changes in the photoemission cross section, as long as the measured signal is element-specific.

The standing wave technique has been used very successfully for studying the adsorption geometries of large organic molecules and self-assembled monolayers [7.50, 51]. A very recent new application of XSW is the study of electrochemical interfaces in combination with ambient-pressure XPS analyzers [7.52].

7.1.6 Comparison of Surface Crystallographic Techniques

Table 7.1 summarizes the key properties of the surface crystallographic techniques discussed in the previous sections, together with examples of applications.

7.1.7 Non-Crystallographic Techniques

Scanning probe microscopy and a number of surface spectroscopies are non-crystallographic techniques which provide valuable information about the coordination and orientation of atoms and molecules on surfaces. This information is often used as a starting point to inform the choice of model geometries for crystallographic trial-and-error optimization. Some of the most relevant non-crystallographic techniques are briefly discussed below; details can be found in other chapters of this handbook.

Scanning Probe Microscopy

Scanning probe microscopy techniques such as scanning tunneling microscopy (STM) and atomic force microscopy (AFM) have become standard tools of surface science [7.1]. STM typically reaches lateral resolutions of the order of 1 Å, while the vertical resolution is typically better than 0.1 Å. As STM interacts predominantly with valence electrons, the positions of the atom nuclei are not directly accessible. It is therefore a very useful tool for qualitative surface structure determination and for assessing the degree of long-range order; however, it is difficult to extract accurate crystallographic data, especially for the layers below the uppermost surface layers. Despite this, modeling STM images for structures predicted by density functional theory (DFT) can, to some extent, help in discriminating between different low-energy structures.

Spectroscopic Techniques

The chemical environment of atoms will always affect their electronic and vibrational properties. Therefore, spectroscopies which probe these properties will, in many cases, yield indirect information about the coordination and orientation of atoms and molecules. Chemical shifts in x-ray photoelectron spectroscopy (XPS) and vibrational spectroscopy, as well as selection rules and angular dependencies in infrared (IR), ultraviolet/visible (UV/Vis), and x-ray absorption spectroscopies, are common examples of how spectroscopy can be used to extract crystallographic information. Spectroscopies have the particular advantage that they do not depend on long-range order, in contrast to most diffraction techniques.

7.2 Examples of Surface Geometries

In the following we will discuss some common trends in surface structures of metals with and without adsorbates, and present examples to illustrate these. A full discussion of all surface structures that have been characterized using surface crystallographic methods would far exceed the scope of this chapter. The most complete compilation of crystallographically characterized surface structures is the National Institute of Standards and Technology (NIST) Surface Structure Database (SSD) [7.53]; other compilations are included in [7.17, 54, 55].

7.2.1 Clean Metal Surfaces

The majority of solid elemental metals have either hexagonal close-packed (hcp), cubic close-packed/face-centered cubic (fcc), or body-centered cubic (bcc) crystal structures. For these, the equilibrium crystal shapes are terminated by close-packed facets with low Miller indices: {0001} and $\{10\bar{1}0\}$ for hcp; {111}, {100}, and {110} for fcc; {110} and {100} facets for bcc. Therefore, single-crystal surfaces with these terminations have received most of the attention over the past few decades. Practically all close-packed surfaces of metals which can be prepared and cleaned under ultrahigh vacuum conditions have been characterized in some way with surface crystallographic techniques, mostly LEED *I–V* [7.9, 54, 55]. Some examples are listed in Table 7.2. Most of the clean close-packed metal surfaces show the same two-dimensional periodicity parallel to the surface as the bulk-terminated surface geometry. However, in many cases, the vertical distance between the first few atomic layers (d_{12}, d_{23}, etc.) shows significant deviations from the bulk interlayer distance. Generally, the topmost layer moves closer to the second layer as a means of partially compensating for the missing neighbors at the surface. For the closest-packed surfaces, such as fcc {111} and {100}, hcp {0001}, and bcc {110}, these vertical relaxations are very small, typically less than 2% of the bulk interlayer distance; some metals, such as Al and Pt, even show a slight expansion. The more open fcc {110}, hcp $\{10\bar{1}0\}$, and bcc {100} display significantly larger deviations in the interlayer distances near the surface. Typically they show an oscillatory behavior, with d_{12} contracted by around -10%, d_{23} expanded, and d_{34} contracted again, by a few percent each.

Large-scale lateral reconstructions are found for the late 5d transition metals Ir, Pt, and Au. These include the p(23×1) *herringbone reconstruction* of Au{111} [7.68, 76], the p$(5\times N)$ quasi-hexagonal reconstructions of Au{100} ($N\geq1$) [7.69], Pt{100} ($N=1$) [7.67], and Ir{100} ($N=1$) [7.63, 64], and

p(2 × 1) *missing-row* reconstructions of Ir{110} [7.65], Pt{110} [7.67], and Au{110} [7.43, 77]. Both the herringbone reconstruction and the quasi-hexagonal reconstruction lead to a denser packing of atoms within the topmost layer, at the expense of some of the coordination with atoms in the layer below. In the p(5 × 1) superstructure, six first-layer atoms are arranged in the space that would be occupied by five atoms in a bulk-terminated arrangement, as shown in the left panel of Fig. 7.14. In the herringbone reconstruction of gold, the compression is 22 : 23. The missing-row reconstruction (Fig. 7.14b) is also driven by the surface atoms, maximizing their overall lateral coordination, if one considers the slopes as the actual surface rather than the nominal surface plane. All three types of reconstruction show interesting structural changes and roughening

transitions at higher temperatures, which have been studied by SXRD [7.68, 69, 78].

More open single-crystal surfaces of metals with large numbers of low-coordinated atoms are characterized by high surface energies and are therefore normally not exposed in equilibrium-shaped crystals. Nevertheless, they are frequently studied as model systems for low-coordinated sites of nanoparticles [7.79, 80] and/or for chirally modified catalyst surfaces [7.81–84]. Combined quantitative LEED *I–V* and DFT studies of the {531} surfaces of Pt and Cu [7.85–87] showed that these surfaces do not reconstruct, and have lateral arrangements of atoms very similar to bulk termination, except for very strong inward relaxations of the low-coordinated atoms in the topmost layer. On the other hand, theoretical and experimental studies have also shown that Pt{531} is thermally relatively unstable [7.85, 88] and tends to roughen. The structures of several other open Cu, Pd, and Pt surfaces have been studied by LEED *I–V* and DFT, including Cu{211} [7.89], Cu{210} [7.90, 91], Pt{210} [7.92], Cu{311} [7.93], Cu{320} [7.94], Pd{320} [7.95], and Cu{532} [7.96]. Again, these studies report no indications of large-scale lateral reconstructions, which indicates that there is enough space for rearrangement of atoms within the larger unit cells of these open surfaces and no need for expanding the periodicity of the surface. In all these surfaces, however, one finds large relaxations of the under-coordinated atoms, as predicted theoretically [7.97]. STM studies of the clean Cu{643}, Cu{610}, and Cu{5 8 90} surfaces [7.98–100] show high mobility of the Cu surface atoms but, on average, a regular arrangement of kinks and steps.

7.2.2 Small Single-Site Bonded Adsorbates on Metal Surfaces

Atomic adsorbates and small diatomic molecules such as CO, NO, and N_2 only bind to one adsorption site of a metal surface, which can involve one (atop sites) or multiple metal atoms (hollow or bridge sites). The (vertical) bond with the surface is usually covalent for these adsorbates and causes some degree of charge transfer; therefore, (through space) electrostatic interactions and (surface-mediated) charge depletion dominate the lateral forces between the adsorbates, and no direct chemical bonds are formed between them, except when a surface reaction occurs, upon which the reaction product is usually desorbed from the surface.

On close-packed metal surfaces, pure layers of these atoms and molecules typically form well-ordered superstructures with small unit cells, which are often driven by the competition for the most favorable adsorption sites and by maximizing the adsorbate–adsorbate distance. In co-adsorbed systems, lateral interactions are more complicated, but mutual site-blocking is still a factor in the formation of ordered structures. In cases where clean metal surfaces reconstruct, strongly chemisorbed adsorbates tend to lift these reconstructions. Examples are the missing-row reconstruction of Pt{110}, which is lifted by the adsorption of CO [7.101–103], and the herringbone reconstruction of Au{111}, which is lifted by the adsorption of halogens in favor of a much simpler p($\sqrt{3}\times\sqrt{3}$) superstructure [7.104]. Unreconstructed open and stepped metal surfaces, on the other hand, can show large-scale reconstructions and etching, in particular upon adsorption of oxygen. Examples of such oxygen-induced effects are large-scale nanofaceting of open Cu [7.99, 105, 106] and Ir surfaces [7.107], step-bunching of Ni [7.108], Rh [7.109], and Ru surfaces [7.110], and adatom extraction on Ag{110} [7.111, 112].

As the surfaces are well ordered, the unit cells are small, and the adsorbates normally occupy identical adsorption sites, such structures can be easily determined by LEED or PhD. Reference [7.17] provides an excellent critical overview of surface structures of pure and co-adsorbed layers of atoms (e.g., oxygen, nitrogen, sulfur) and small molecules (e.g., CO, NO, NH_3) relevant to heterogeneous catalysis which had been determined before 1998.

More recent examples are the co-adsorption structures of CO and oxygen or hydrogen on Ni{111} [7.14, 113]. The former is shown in Fig. 7.6 of the previous section. It shows that both adsorbates lead to an expansion of the first substrate layer distance, d_{12}, which depends on the strength of the chemisorption bond (greater for O than for CO). In the clean surface, the first layer of the metal substrate is bulk-terminated with an interlayer distance of $d_{12} = 2.04$ Å (Table 7.2).

7.2.3 Chemisorbed Molecular Adsorbates with Strong Intermolecular Interaction

Larger molecules, in particular those with relevance to biology, often show attractive lateral interactions on surfaces, which are due to hydrogen or ionic bonds. This leads to an interesting competition between the vertical molecule–substrate and the lateral molecule–molecule bonds, which affects the complexity of the adsorption geometry (size of unit cell, adsorption sites) as well as the strength and chemical composition of the adsorbate layer. In the following sections we will concentrate on two groups of molecular adsorption systems which have been covered relatively well by surface crystallographic methods, water and amino acids.

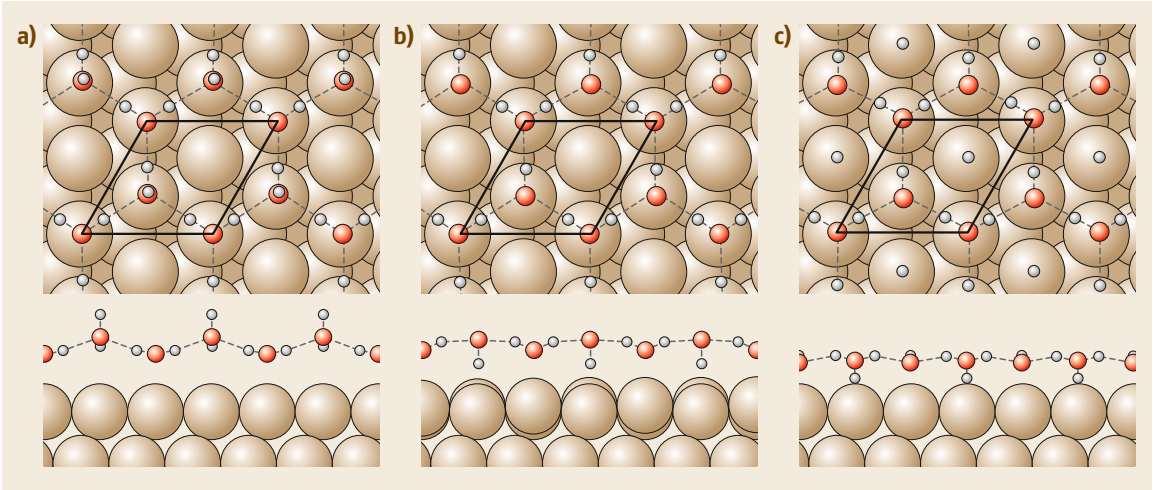

Fig. 7.15a–c Structures of two variants of water bilayers, H-up **(a)** and H-down **(b)**, and an H_2O-OH-H overlayer **(c)** on a hexagonal metal surface. Water

The adsorption of water on metal surfaces has been studied extensively since the early days of surface science, owing to its relevance to many fields ranging from catalysis and corrosion to bio-inorganic interfaces [7.115–117]. As water molecules form strong hydrogen bonds in liquid water and ice, it was at first assumed that the observed superstructures on hexagonal close-packed metal surfaces were essentially two-dimensional ice layers, consisting of a bilayer of H_2O molecules arranged in puckered hexagons, as shown in Fig. 7.15a,b. A combination of surface crystallography (LEED), spectroscopy (XPS, RAIRS), and DFT modeling revealed, however, that in many cases, water partially dissociates. In the dissociated layer, the oxygen atoms have a similar arrangement as in the water bilayer, but the chemical composition of the adsorbed layer is a mixture of H_2O, OH, and H [7.114, 118–121].

The simplest of these structures has a p($\sqrt{3}\times\sqrt{3}$)R30° superstructure, as observed on Ru{0001} [7.118, 120] (Fig. 7.15c), but larger unit cells with more complicated structures, such as p(3 × 3) on Pt{111} [7.121] or p($\sqrt{7}\times\sqrt{7}$)R19° on Ni{111} [7.122], have also been observed. The lateral hydrogen bonds and the water–substrate bond are of similar magnitude. As a consequence, the chemical composition and arrangement of atoms at the surface are determined by the details of the molecule–substrate interaction and can be very different even for metal surfaces, which otherwise behave very similarly, such as the Pt group metals [7.123].

Amino Acids and Other Biomolecules

The adsorption of amino acids has been studied in great detail over the past two decades, for two reasons. First, they can be used as chiral modifiers for metal catalysts, and second, they are model systems for bio-inorganic interfaces. All proteins consist of macromolecular chains of amino acids. Therefore, the protein–metal interaction ultimately comes down to the interaction of individual amino acids with a metal surface. Adsorption structures of amino acids have been discussed in several recent reviews [7.5, 84, 124–126]. All amino acids, except glycine, are chiral. The lack of mirror symmetry in the adsorption complex and lateral interactions is usually reflected in the unit cell and the lattice symmetry of ordered superstructures formed by these amino acids. As a consequence, the superstructures of adsorbed layers depend on the chirality (*handedness*) of the molecules [7.5, 126]. Adsorption of amino acids or other organic molecules on copper surfaces can even cause large-scale reconstructions with facets that expose surface termination with chiral symmetry when the adsorbed molecules are chiral [7.127–131].

Despite the relevance of chiral amino acids for the modification of catalyst surfaces, the best-studied amino acid in terms of surface crystallography is the non-chiral glycine. It has been extensively studied by PhD [7.133–136], STM [7.137], and LEED [7.132]. The structure of the ordered p(3 × 2)pg superstructure of glycine on Cu{110}, as determined by LEED *I–V*, is shown in Fig. 7.16. Although the gas-phase molecule is non-chiral, it still forms a chiral adsorption com-

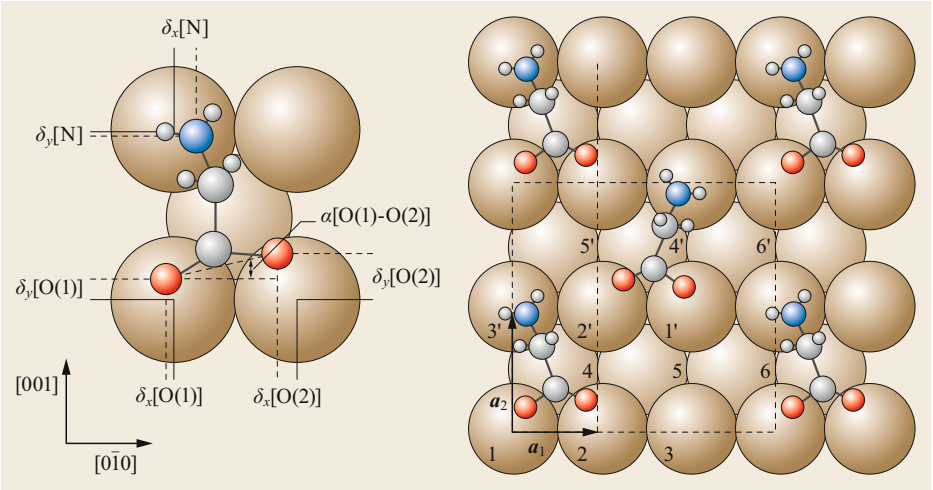

Fig. 7.16 Structure of the p(3 × 2) overlayer of glycine on Cu{110} (Reprinted with permission from [7.132] Copyright 2011 American Chemical Society)

plex, breaking the mirror symmetries of the Cu{110} surface, parallel to the [100] and [1$\bar{1}$0] directions. The unit cell contains two molecules with opposite handedness, resulting in an overall glide-line symmetry of the adsorbate layer. The latter leads to missing spots in the LEED pattern, which enables a very accurate determination of the structure [7.132, 135]. The adsorption geometry is prototypical for amino acid adsorption. The molecules are deprotonated and form a total of three bonds each with Cu atoms through the two oxygens of the carboxylate group and the nitrogen of the amino group. Their arrangement on the surface is such that each molecule is involved in four hydrogen bonds between the amino and carboxylate groups of neighboring molecules, which account for about one third of the adsorption energy [7.138]. Similar adsorption geometries with respect to the substrate are expected for other amino acids on Cu and Ag surfaces, based on crystallographic and spectroscopic data and theoretical predictions. The superstructures do, however, vary due to different sizes of the molecules and different hydrogen bonding configurations [7.5, 126].

Besides amino acids, the adsorption complexes of a small number of other bio-related molecules adsorbed on Cu surfaces have also been studied by PhD and XPD. These include the nucleobases cytosine [7.139], thymine [7.140], and uracil [7.136], which only adsorb with no or poor long-range order, thus making LEED analysis difficult, and tartaric acid [7.28], which does show good long-range order but has not been studied with any other crystallographic method. The latter work, alongside other XPD studies of chiral molecules [7.29], demonstrated that XPD is a very straightforward method for determining the absolute chirality of adsorbed molecules.

On most metal surfaces other than those of group 11, even small organic molecules like glycine do not form long-range ordered structures, nor do they assume identical adsorption sites, which has prevented detailed crystallographic studies on these systems up to now. The adsorption of numerous amino acids and other small biomolecules, in particular on Ni, Pd, and Pt surfaces, has been characterized by means of STM and various spectroscopic techniques [7.141].

7.2.4 Carbon Materials

The adsorption geometries of large aromatic carbon systems are dominated by the interaction of π-electrons with strong contributions of van der Waals interaction. We will discuss three examples here: aromatic molecules, graphene, and C_{60}.

Aromatic Molecules: Benzene and PTCDA

The adsorption of benzene on close-packed metal surfaces is dominated by the interaction between the aromatic π-system and the d-electrons of the metal, which causes the molecules to adsorb parallel to the surface. The late transition metals provide a strong vertical interaction and allow enough mobility for chemisorbed benzene layers to arrange in ordered structures with unit cells that are essentially determined by the repulsive interaction between the molecules. Many ordered overlayer structures of benzene adsorbed on transition metals have been studied by LEED I–V [7.143]. The example of the p($\sqrt{7} \times \sqrt{7}$)R19° structure of benzene on Ru{0001} [7.142] shown in Fig. 7.17 includes the determination of the hydrogen positions, which are usually difficult to determine because of their low scattering cross section. The upward bending of the C–H

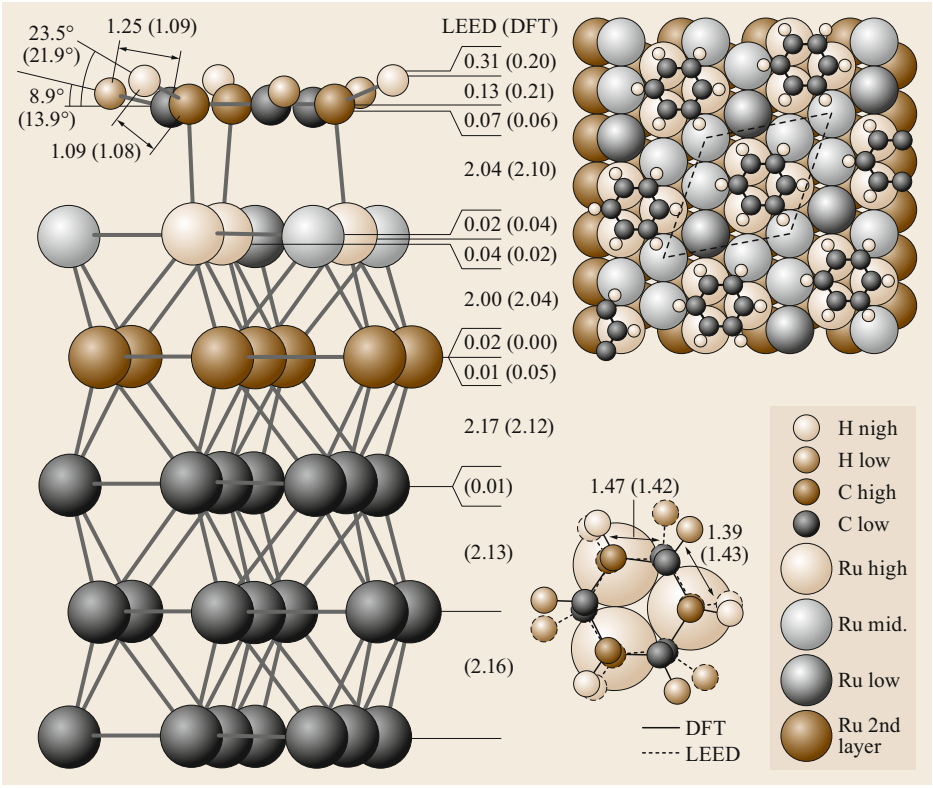

Fig. 7.17 Structure of the $p(\sqrt{7} \times \sqrt{7})R19°$ structure of benzene on Ru{0001} (Figure reprinted with permission from [7.142] Copyright (2001) by the American Physical Society)

bonds agrees well with predictions from DFT modeling, which are also indicated in the figure.

The adsorption of a number of larger aromatic molecules has been studied with surface crystallographic methods as well. The most complete body of work concerns 3,4,9,10-perylene tetracarboxylic dianhydride (PTCDA), which tends to adsorb with its perylene core parallel to the surfaces of weakly bonding metal surfaces [7.144]. On coinage metal surfaces, these molecules form very well long-range ordered structures with unit cells that are generally too large to be analyzed by LEED *I–V*. The adsorption heights of PTCDA above several Au, Ag, and Cu surfaces have been determined by XSW [7.51, 145–151] in combination with DFT modeling and other experimental techniques. It was shown that differences in adsorption heights and bending of the peripheral oxygen atoms correlate with the work function of the bare metal surfaces and, hence, with the charge transfer between substrate and PTCDA [7.51, 151, 152].

Graphene

Graphene could be considered as an infinitely large aromatic molecule. It is certainly one of the most interesting materials that has been discovered in recent years. As a consequence, a large number of surface science studies exist. Graphene can be synthesized relatively easily on close-packed surfaces of the transition metals [7.153, 154]. Depending on the lattice (mis)match between graphene and the substrate surface and on the nature of the graphene–substrate bond, three types of structures are observed on hexagonal surfaces:

- If the lattices of substrate and graphene match (i.e., two-dimensional lattice constants ≈ 2.46 Å), a strong covalent interaction can be expected and a commensurate $p(1 \times 1)$ overlayer is formed. This is the case for Ni{111} [7.155] and Co{0001} [7.156]. The structure of the $p(1 \times 1)$ overlayer of graphene on Ni{111}, as determined by LEED *I–V*, is shown in Fig. 7.18a. The vertical C–Ni distances are 2.11 and 2.16 Å, which indicates strong covalent bonds.
- For metals with larger lattice constants, more complex moire-like superstructures are formed, which manifest themselves through satellite spots around the integer-order spots in LEED. A weak interaction leads to flat graphene layers (Fig. 7.18b) at a vertical distance of ≈ 3.35 Å from the substrate, which is close to the interlayer distance in graphite and indicates that the substrate bond is van der Waals-like. Examples are Pt{111} [7.157] and Ir{111} [7.160], which have been studied by LEED *I–V* and SXRD, respectively.

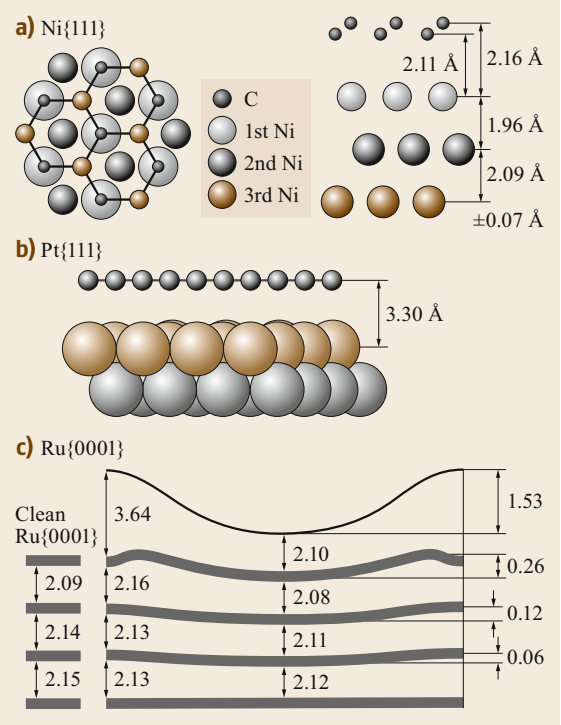

Fig. 7.18 **(a)** Adsorption geometry of the p(1 × 1) structure of graphene on Ni{111} (Reprinted with permission from [7.155] Copyright (1997) of Elsevier). **(b)** Schematic adsorption geometry of graphene on Pt{111} (Reprinted with permission from [7.157] Copyright (2009) of the American Physical Society). **(c)** Adsorption geometry of the p(22 × 22) structure of graphene on Ru{0001}; the numbers indicate the vertical distances at the maxima and minima, as determined by LEED (Reprinted with permission from [7.158] Copyright (2010) by the American Physical Society)

- For metals with larger lattice constants and strong graphene–substrate interaction, the overlayer is strongly corrugated. Examples are the p(9 × 9) overlayer on Re{0001} [7.161] and the p(22 × 22) overlayer on Ru{0001} [7.158]. Within the latter unit cell, the positions of the carbon atoms with respect to the first Ru layer change from hollow to atop sites. The structure, as determined by LEED *I–V* [7.158], is shown in Fig. 7.18c. The graphene layer is strongly corrugated, which is also reflected in the heights of the Ru atoms in the first and second substrate layers, albeit to a lesser degree. The vertical C–Ru distances oscillate between 2.10 (atop sites) and 3.64 Å (hollow sites). This indicates that the bonding varies between covalent and van der Waals, depending on the relative position of the carbon atoms with respect to the Ru layer.

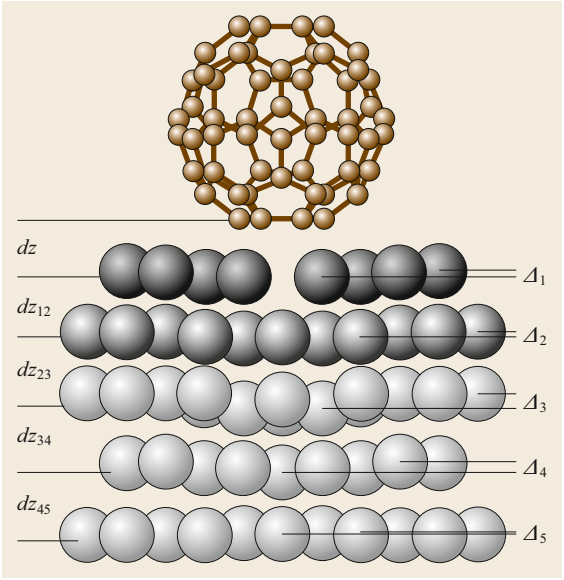

Fig. 7.19 Adsorption geometry of the p($2\sqrt{3} \times 2\sqrt{3}$)R30° superstructure of C_{60} on Ag{111} (Reprinted with permission from [7.159] Copyright (2009) by the American Physical Society)

Thus the growth of graphene on transition-metal surfaces provides an excellent example of how the interplay between lateral interaction (within the adsorbate layer) and adsorbate–substrate bond shapes the structure of the overlayer. In the case of graphene, the lateral C–C bonds are strongly covalent, whereas the substrate bond varies from strongly covalent to relatively weak van der Waals bonding.

Fullerene (C_{60})

The perfect symmetry, the cage structure, and the high stability of fullerenes have attracted significant attention over the past three decades since their discovery. The interaction of C_{60} and other carbon-cage molecules with metal surfaces has been studied extensively as well. On many surfaces, well-ordered superstructures are formed. In terms of surface crystallography, the large size of the molecules certainly poses a challenge; however, the high symmetry helps to reduce the number of independent structural parameters that have to be determined. Adsorption structures of C_{60} on several metal surfaces have been determined at different levels of completeness by XPD [7.25], SXRD [7.162], and LEED *I–V* [7.159, 163]. Figure 7.19 shows the result of a LEED *I–V* structure determination of the p($2\sqrt{3} \times 2\sqrt{3}$)R30° superstructure of C_{60} on Ag{111} [7.159]. The most remarkable finding is that there is an atom missing in the topmost Ag layer, just below the molecule. A similar

substrate vacancy underneath the molecule was found in an SXRD study of the p($\sqrt{13} \times \sqrt{13}$)R13.9° superstructure of C_{60} on Pt{111} [7.162]. For C_{60} on Cu{111}, a structure with as many as seven substrate vacancy sites was recently found by LEED *I–V* study [7.163].
C_{60} is probably the largest adsorbate molecule for which complete structure determinations have been performed to date. The structures clearly demonstrate that even molecules which are generally regarded as weakly interacting with metal surfaces can induce very significant surface reconstructions.

7.3 Conclusion

The accurate determination of atom positions near the surface usually relies on diffraction of either electrons or x-rays with wavelengths of typically ≈ 1 Å. While direct diffraction techniques such as low-energy electron diffraction and surface x-ray diffraction are capable of determining the complete surface structure, these techniques usually require long-range order, and the data analysis can be complicated and ambiguous if the data set is not large enough. Photoelectron diffraction and the x-ray standing wave technique are based on electron and x-ray diffraction, respectively, combined with photoemission (x-ray-induced emission of electrons). As a consequence, these techniques are element-specific and enable the determination of the structural parameters of specific atoms only, which makes them less dependent on long-range order. All the above techniques allow for the determination of atom positions with accuracies at the 0.01–0.1 Å level. The greatest problem in surface crystallography is often the relatively small size of the available data set, which can lead to ambiguities in the resulting structures.

Georg Held is Principal Beamline Scientist at Diamond Light Source and Visiting Professor at the University of Reading. His research interests concentrate on fundamental aspects of heterogeneous catalysis, in particular structure-functionality relationships at surfaces. Key activities are experimental studies of surface geometries and adsorbate-substrate. His current research focuses on the surface chemistry of small bio-relevant molecules and water on metal surfaces, and fundamental aspects of chiral modification of metal catalysts.

8. Local Information with Scanning Tunneling Microscopy

Francesca Moresco

This chapter reviews the main concepts of imaging, spectroscopy, and manipulation by scanning tunneling microscopy, an experimental technique that, since its invention in 1981, has strongly changed surface science and has proven to be much more than an imaging technique. After a historical introduction, we will describe the working principle of scanning tunneling microscopy and the role of tunneling electrons for performing local electron spectroscopy. In the second part of the chapter, we present the different possible manipulation methods that allow us to build structures atom by atom or molecule by molecule. Manipulation with the tip of a scanning tunneling microscope allows us to obtain precise local information about mechanical properties and interactions, and opens the way to applications in atomic-scale technologies.

8.1 Short History

The invention of scanning tunneling microscopy (STM) in 1981 dramatically changed the field of surface science, making it possible for the first time to image conducting surfaces and adsorbates with very high resolution in real space [8.1]. This revolutionary technique for imaging provided in a short time after its invention the first image of atoms of a surface [8.2], the first image of adatoms [8.3], and the first image of a molecule adsorbed at a surface [8.4, 5]. Since that time, STM has become a standard imaging technique, able to solve many problems in surface science and crystallography. The use of tunneling electrons to obtain high-resolution images is accompanied by the possibility of using tunneling electrons in spectroscopy. Scanning tunneling spectroscopy (STS) has proven to be a very useful technique for studying electronic properties of materials and adsorbates locally and with high spatial resolution. STM is presently used in modern surface science in many laboratories worldwide to solve problems related to the structure of conducting and semiconducting surfaces, adsorption processes, excitations at the atomic and molecular scale, on-surface chemistry, and several others [8.6].

The history of STM started in the late 1970s at IBM's research Laboratory in Zürich. Heinrich Rohrer was studying nanometer-size defects on ultrathin insulating films deposited on metal or semiconducting surfaces, important for electronic applications and the development of semiconductor technologies. Looking for an experimental technique able to resolve such defects, he came together with Gerard Binnig to the idea of using the tunnel effect to do microscopy [8.7]. They understood that the exponentially vanishing tunnel current between a very fine metal tip and a conducting surface can give rise to a very powerful tool for imaging nanometer structures with high spatial resolution. With the help of Christoph Gerber, they constructed a simple instrument constructed of a very thin metallic tip that can scan the surface at a few atomic distances. In 1981, the first prototype was working [8.8]. By apply-

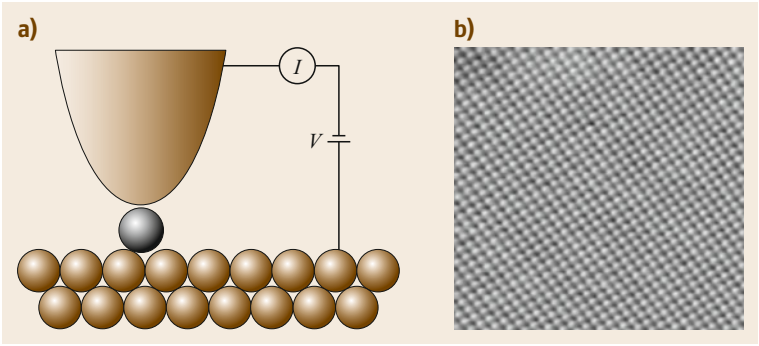

Fig. 8.1 (**a**) Principle of scanning tunneling microscopy. A bias voltage V is applied between metallic tip and conducting sample kept at a few atomic distances, measuring a tunneling current I. (**b**) STM image of the Ag(100) surface with atomic resolution

ing a bias voltage of the order of magnitude of 1 V between tip and surface, a tunneling current of a few nA could be measured, which is strongly dependent on the tip–surface distance, showing an increase of the current of a factor 10 when the tip moves 0.1 nm towards the surface. A schematic view of the working principle of a scanning tunneling microscope is shown in Fig. 8.1a. Soon after, in 1982, the first atomic-resolution images were recorded [8.2]. Karl-Heinz Rieder provided the first samples and experienced with all the inventors the first exciting atomic-resolution images of a surface [8.9]. The scanning tunneling microscope had been invented, opening up a completely new way of doing surface science. Figure 8.1b shows an example of an STM image of the Ag(100) surface with atomic resolution. Heinrich Rohrer and Gerard Binnig won for this invention the Nobel Prize in Physics in 1986.

Besides atomic-resolution imaging, STM also offers the opportunity to use tunneling electrons for spectroscopic investigations. The bias voltage defines not only the direction of electron tunneling, but also the energy of the tunneling electrons. Hence, the different electronic states of the sample can be probed by ramping the bias voltage over the desired energy range. STS was already used in 1986 to probe the electronic density of states around the Fermi level and is now a standard technique in many laboratories [8.10].

Crucial for STM to work is the precise control of the tip position in the three spatial directions. In the first prototypes, the movement of the tip was driven by three piezoelectric elements, as schematically shown in Fig. 8.2. In the following decades, several other geometries were proposed to optimize the tip approach and the scanning over the surface. However, the principle of the instrument did not change and modern STMs are still based on piezoelectric elements driving a thin metal tip.

With the invention of STM, a new adventure could begin, impossible with other microscopy techniques: for the first time it was possible to position exactly a thin metallic tip on a surface with atomic-scale precision, and to be therefore able to touch an atom or a molecule with its tip apex. In this way, the tip apex can be imagined to be the extension of the researcher's finger, touching and modifying atoms and molecules on a surface [8.7]. The invention of STM therefore revolutionized our relationship to matter, not only because it allows us to see matter down to the atomic scale, but also because it opens up a completely new way to build structures atom by atom in a bottom-up approach. With this microscope as a tool, a novel scientific and technological approach began, where molecular structures could be assembled artificially atom by atom. Equipped with STM, scientists have the opportunity to design new molecules and to produce tiny nanomachines.

Extraordinary results have been obtained in the last two decades in imaging individual molecules adsorbed at surfaces and the ultimate spatial resolution of STM [8.11] and atomic force microscopy (AFM) [8.12] has allowed us to gain an exceptional insight into the structure and the intra- and intermolecular bonding of a large number of molecules [8.13, 14]. Besides imaging, STM permits us to probe the electronic, vibrational,

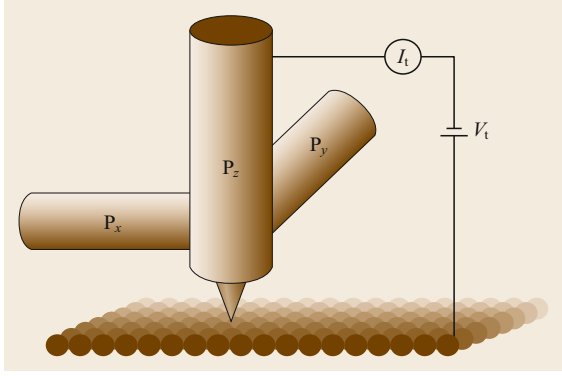

Fig. 8.2 Schematic principle of a STM scanner: A metallic tip is fixed to three piezocrystals (P_x, P_y, P_z). The piezoelectric elements allow a precise positioning of the tip

and optical properties of single atoms and molecules by means of STS and inelastic electron tunneling spectroscopy (IETS) [8.15]. These exceptional advances generate a remarkable improvement in our fundamental understanding of processes occurring at the nanoscale and can now be applied to the controlled fabrication of atomic and molecular devices and to investigate signal transport at the atomic and molecular scale.

Many books [8.16, 17] and reviews [8.1, 6, 18] have been written on STM development, theory, and applications. In this chapter we do not aim at covering the vast range of technical developments and applications that have occurred in STM to make it one of the most important experimental methods in surface science. Instead we want to focus on the basics of imaging, spectroscopy, and manipulation done by STM at low temperature and consider a few examples that can open up new ways for the development of nanoscale electronics and to study mechanics at the molecular level.

8.2 Principles of Scanning Tunneling Microscopy

The working principle of STM is based on the quantum-mechanical tunnel effect, where electrons are able to overcome a potential barrier that would be classically forbidden. The exponential dependence of the transmission coefficient with the barrier width leads to the same dependence of the tunneling current with the tip–surface distance, and is the main reason for the high spatial resolution of this instrument.

A schematic representation of the tunneling process in one dimension (1-D) is shown in Fig. 8.3. If the two electrodes are at the same potential, the tunneling probability would be the same in both directions and the resulting current would vanish. Therefore, a bias voltage must be applied to the tunnel junction to favor one tunneling direction with respect to the other and thereby to induce a measurable tunneling current [8.17]. In Sect. 8.3, the basic principle of the tunneling effect will be explained in more detail, discussing STM imaging, and further details will be given in Sect. 8.4, discussing STS.

To create a two-dimensional image of a surface, a sharp metallic tip is kept at a controlled distance and scanned with a distance of a few tenths of a nanometer over a conductive surface and a bias voltage in the order of 1 V is applied. A tunneling current in the order of nA will be detected in each point, amplified and visualized on a computer display. A feedback loop allows us to control the position of the tip on the surface with respect to the tunneling current. The STM is normally used in one of two different imaging modes: constant

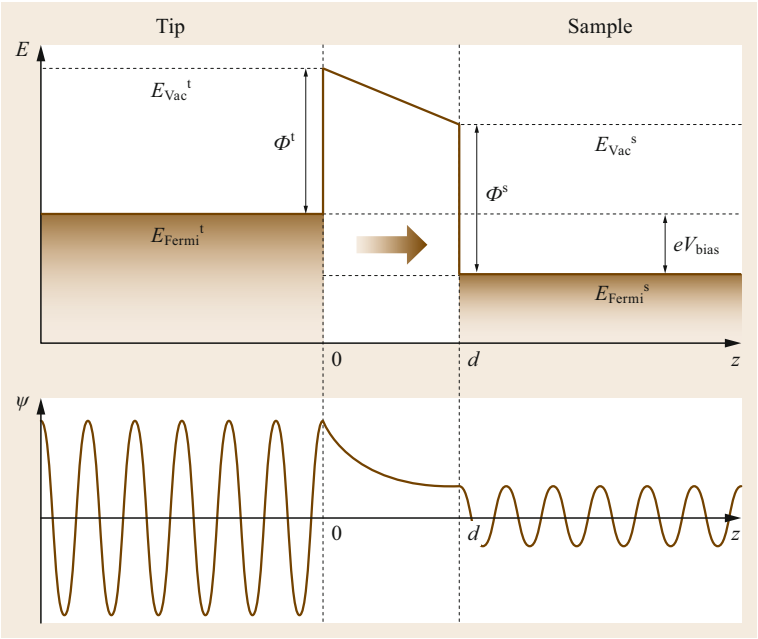

Fig. 8.3 Schematic energy diagram and wave function ψ in one dimension: only the real part of the wave function is imaged. Electrons tunneling from the tip to the sample ($E_{Fermi}^{t/s}$ Fermi energies, $E_{Vac}^{t/s}$ vacuum levels, $\phi^{t/s}$ work functions for tip/sample respectively, V_{bias} bias voltage)

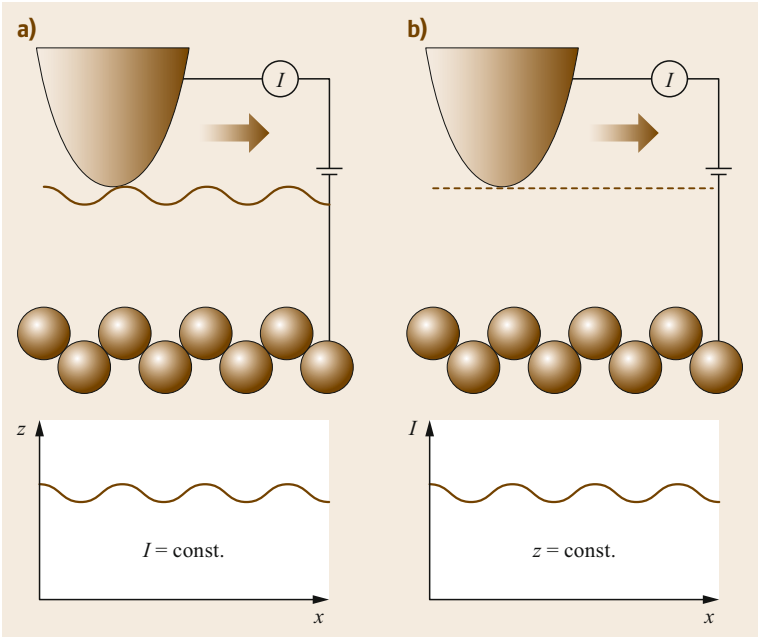

Fig. 8.4a,b Schematic of STM imaging modes: the measurement principles of constant current mode are shown in **(a)**, while constant height mode is depicted in **(b)**. The corresponding measurement signals are shown underneath

current mode and constant height mode, as schematically shown in Fig. 8.4.

In the constant current mode, the tunneling current between the sample and the tip is held constant by the feedback loop. Therefore, the distance between tip and sample remains the same for every point of the image. According to the variations of the sample's topography, the tip height is varied by the feedback loop to keep the current constant and the z-displacement of tip is imaged. In the constant height mode, in contrast, the absolute height of the tip is held constant. In this case the distance between sample and tip changes according to the sample's topography. The resulting changes in tunneling current are imaged. In general, the constant height mode is rarely used and normally only when it is necessary to image the surface very fast, like for example when dynamic processes are studied. The image acquisition time in constant height mode can be in fact considerably lower than in constant current mode, since no feedback related tip height adjustments need to be made. On the other hand, the absence of a feedback loop might easily cause tip crushes into step edges or other defects present on the surface while scanning with constant height. Accordingly, constant height mode is normally applied to small or very flat surface areas [8.17].

Since STM is a surface-sensitive measurement technique, as is common in surface science it is crucial to have an extremely clean surface. Even a very low amount of adsorbed gas molecules strongly influences the STM measurements. At a pressure of 10^{-6} mbar one gas molecule hits each surface unit cell once per second. Even if not every contact leads to surface contamination, these numbers give a rough estimate of the base pressure needed to investigate single molecules on clean metal surfaces. The STM measurements presented in this chapter have been therefore performed in ultrahigh vacuum (UHV) conditions, at a basis pressure $P \approx 10^{-10}$ mbar.

A further problem, especially for experiments with single atoms and molecules, is the diffusion of the investigated adsorbates on the substrate, also considering that STM is a quite slow experimental technique (one needs several minutes for a high-resolution image of a few square nm). Since the diffusion is temperature dependent, STM experiments on single atoms and molecules are mostly conducted at low temperatures (e.g., liquid helium (5 K)). The low temperature has some other beneficial influences on the experiments: the drift of the piezodriven tip is lowered, the base pressure is reduced because of the increased adsorption on the cryostat walls, and the thermal noise is also reduced. Low-temperature STM (LT-STM) at cryogenic temperatures and in UHV conditions allows us to investigate and manipulate single molecules and atomic adsorbates on surfaces with atomic precision, showing moreover a stability of the tip position at the picometer scale.

8.3 Local Imaging

To understand the high spatial resolution of STM, we have to start from the basics of the tunnel effect. Quantum mechanically, electrons are able to tunnel across the barrier given by the surface–tip separation.

In general, the wave function of an electron in a one-dimensional junction with a rectangular barrier (Fig. 8.5) is

$$\psi(z) = \Psi(0)\mathrm{e}^{-kz}\,, \tag{8.1}$$

where

$$k = \frac{\sqrt{2m(V-E)}}{\hbar} \tag{8.2}$$

ψ is the electronic wavefunction, z the tip–sample separation, m the electron mass, V the potential of the barrier, E the energy of the tunneling electron, and $\hbar$ the Planck constant.

The tunneling current I is proportional to the probability distribution of the electron and therefore to the square of the wavefunction

$$I(z) \propto |\Psi(x)|^2 \propto \mathrm{e}^{-kz}\,. \tag{8.3}$$

For small biases, the quantity $(V-E)$ can be approximated as the work function of the metal (≈ 5 eV) [8.19] and therefore the tunneling current changes by about an order of magnitude for every 1 Å change in z. The atomic-scale precision of STM is enabled by this exponential current decay. In other words, this means that the tunneling current is extremely localized under the tip apex, making STM sensitive to both lateral and vertical changes in topography and allowing for atomic resolution. It is also important to note that the macroscopic form of the tip has in STM a secondary importance, being the tunneling current localized under the last atom (or the few last atoms) of the tip.

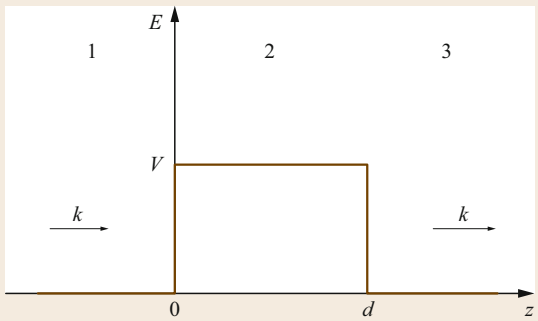

Fig. 8.5 One-dimensional rectangular potential barrier of height V and thickness d

In Fig. 8.6 some examples of STM images on metals and semiconductors are shown. Further examples include molecules adsorbed on metals [8.20], thin insulating films [8.11], or nanostructures adsorbed on oxide thin films [8.21].

To theoretically describe the STM tunneling current in the three-dimensional case and to be able to extract the topographic information from a STM image, further theoretical considerations are needed.

The extension from the one-dimensional to the three-dimensional case can be done following the approach of *Bardeen* [8.22] already published in 1961 and initially applied to the case of two metal plates. He calculated the tunneling matrix element for the electrons tunneling between two weakly coupled electrodes using

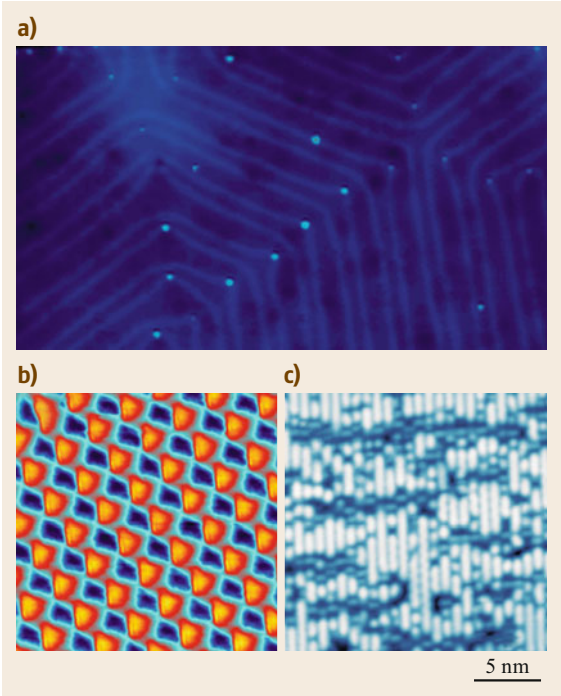

Fig. 8.6a–c Examples of STM images of clean metallic and semiconducting surfaces. **(a)** Au(111) with herringbone reconstruction (image size: 80 nm × 45 nm); **(b)** Ag(100) surface (image size: 2.5 nm × 2.5 nm); **(c)** Si(001)2×1 surface, where dangling bond rows and several defects are visible (image size: 20 nm × 20 nm, I = 30 pA; $V = -2.0$ V)

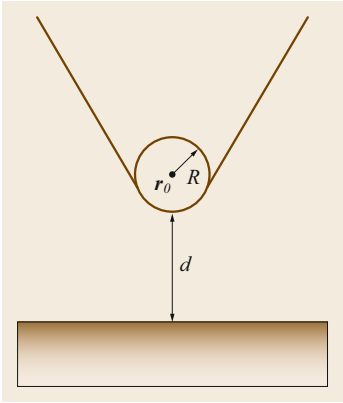

Fig. 8.7 Schematic representation of the geometry of the tunneling junction for a tip with apex radius R in position $\boldsymbol{r}_0$

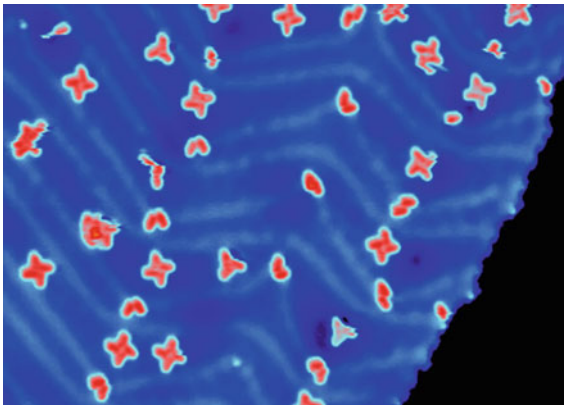

Fig. 8.8 Example of STM image of molecular adsorbates. Acetylbiphenyl molecules adsorbed on Au(111) and forming H-bonded nanostructures (image size 80 nm × 50 nm)

the time-dependent perturbation theory. The resulting tunneling matrix depends on the wave functions of both electrodes (in our case tip and sample).

To calculate the matrix element and consequently the tunneling current we would therefore need to know the wave functions of tip and sample at every point in space. In the case of STM this turns out to be nontrivial, since the atomic structure of the tip is generally unknown. In 1983, *Tersoff* and *Hamann* developed an approximated calculation of the tunneling current in a STM junction [8.23, 24]. They represented the tip by a s-wave function, practically considering only the radial symmetric atomic s-states and a plane sample. The modeled tip has an apex of radius R and the position of the apex is $\boldsymbol{r}_0$ (Fig. 8.7).

Moreover, they assumed a small bias voltage and low temperature. In such an approach, one can rewrite the Bardeen tunneling matrix element and obtain the following expression for the tunneling current I in a three-dimensional STM junction

$$I(z) \propto D_\mathrm{t}(E_\mathrm{Fermi})\rho_\mathrm{s}(\boldsymbol{r}_0, E_\mathrm{Fermi}) \,, \tag{8.4}$$

where $D_\mathrm{t}(E_\mathrm{Fermi})$ is the density of states of the tip per unit volume and $\rho_\mathrm{s}(\boldsymbol{r}_0, E_\mathrm{Fermi})$ is expressed by

$$\rho_\mathrm{s}(\boldsymbol{r}_0, E_\mathrm{Fermi}) = \sum_\mathrm{s} |\psi_\mathrm{s}(\boldsymbol{r}_0)|^2 \delta(E_\mathrm{s} - E_\mathrm{Fermi}) \,, \tag{8.5}$$

which represents the local density of states (LDOS) of the surface at the Fermi energy, at the position of the tip apex, where the sum runs over all involved states.

In other words, the Tersoff–Hamann approximation formally demonstrates that the tunneling current depends on the local electronic density of states of the surface, and not only on the tip–surface distance. This result opens up the way for using STM to study the electronic properties of surfaces and adsorbed molecules (as discussed in detail in Sect. 8.4). In semiconductors and molecules, the tunneling current results from electrons tunneling from the occupied states of the tip through the vacuum barrier into unoccupied states of the surface or vice versa (Fig. 8.3).

The local density of states is normally calculated by density functional theory (DFT) [8.25, 26] and then the tunneling current is determined from it using the Tersoff–Hamann approach. This is a quite simple method that is therefore largely applied. The role of the tip is however completely neglected, limiting the agreement between theory and experiments. For example, the Tersoff–Hamann approach is not able to describe atomic resolution on metal surfaces, the STM images of many atomic and molecular adsorbates, as well as high-resolution STM images with functionalized tips. For a precise theoretical determination of STM images, image charge effects, van der Waals forces, and chemical forces between tip and sample have to be included and demands that we treat the surface–adsorbate–tip system as an entity [8.6].

More sophisticated methods to calculate STM images have been developed that are, however, much more time consuming. In such cases, the tip–adsorbate–surface system is not anymore separated into tip and sample. A total wave function is calculated, where the tunnel junction is considered as a defect in which the electrons are scattered. In this way a scattering matrix can be calculated, which allows us to determine the transmission coefficient, the conductance, and finally the STM images point by point. Some examples of such approaches have been proposed [8.27–29] that are able to precisely determine the tunneling current.

An example of an STM image of molecular adsorbates is shown in Fig. 8.8. As one can see, no intramolecular details are normally visible. The resolution of adsorbed molecules in STM images is normally limited by the strong contribution of the electronic resonances to the tunneling current. This is one of the reasons why the best spatial resolution of molecular adsorbates is obtained by noncontact AFM with a functionalized tip [8.13, 14]. However, as shown in Fig. 8.9, STM images at very low bias voltage and with a tip functionalized with CO can also show submolecular resolution with the possibility to precisely image the molecular structure [8.30, 31]. Similar to the case of AFM, high-resolution molecular images are possible with flat molecules but more difficult with three-dimensional geometrical arrangements.

To conclude this section, the recorded topography STM image is dependent on both the geometric structure and the local density of states of tip and sample. Especially for the case of molecular adsorbates and semiconducting surfaces, the influence of the local density of states on the STM images plays a relevant role. As described in Sect. 8.4, this fundamental property of the STM current signal allows us to use this instrument not only to determine a topographic structure, but also to record the electronic density of states at the position of the tip, thus performing local spectroscopy.

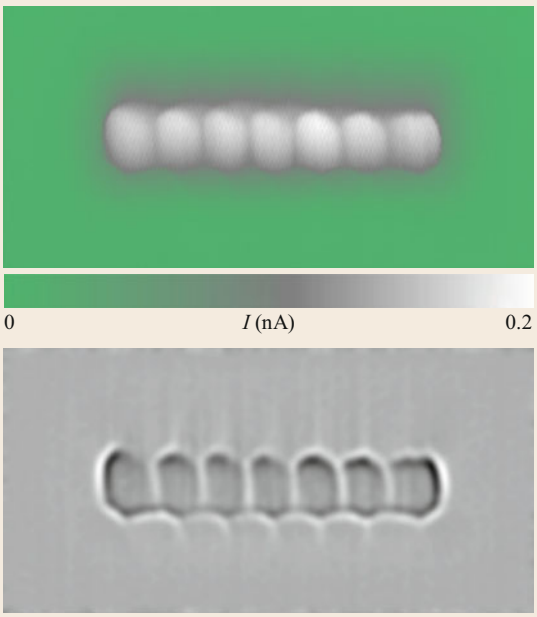

Fig. 8.9 Example of a high-resolution image of a molecular adsorbate, recorded in constant height mode with a CO-functionalized tip. Hexacene on Au(111). The *bottom panel* shows the same image after a Laplace filtering (image size: 1.5 nm × 3.0 nm)

8.4 Local Spectroscopy

A very important aspect of STM is the dependence of the tunneling current on the local density of states. This fundamental property can be applied to locally study the electronic properties of surfaces and adsorbates. Already observed in 1986 [8.10], scanning tunneling spectroscopy (STS) has developed in the last decade as an experimental technique that is commonly applied in many laboratories.

Starting from (8.4) and further following the Tersoff–Hamann approximation, one can conclude that the tunneling current at a small voltage V is obtained by integrating over the electron energy, giving the final result

$$I(\boldsymbol{r}_0, V) = \frac{2\pi}{\hbar} \int_{E_{\mathrm{Fermi}}}^{E_{\mathrm{Fermi}}+eV} \rho_{\mathrm{t}}(\boldsymbol{r}_0, E-eV) \times T(\boldsymbol{r}_0, E-eV)\rho_{\mathrm{s}}(\boldsymbol{r}_0, E)\mathrm{d}E\,, \tag{8.6}$$

where ρ_{t} is the density of states of the tip, ρ_{s} the density of states of the sample, and T the transmission coefficient that depends on the energy of the electrons and on the applied voltage.

From this relation it is straightforward to conclude that the first derivative of the tunneling current is directly proportional to the electronic local density of states of sample and tip at the position of the tip, assuming that the transmission coefficient T varies very slowly with energy. By extracting the first derivative of the tunneling current it is therefore possible to perform local electronic spectroscopy [8.17].

To experimentally obtain the first derivative of the tunneling current, a lock-in amplifier is commonly used, allowing us to measure not only the electronic local density of states at the Fermi energy but also at any other (low) energy. To do this, the bias voltage, defining the energy level, is modulated with a small sinusoidal voltage of a given frequency. This modulation is consequently also superposed onto the tunneling current. The lock-in amplifier can now act as a band pass filter for this frequency and gives the amplitude of the signal related to the modulation. If the modulation is small compared to the bias voltage, the measured amplitude is equal to the derivative of the tunneling current at the bias voltage.

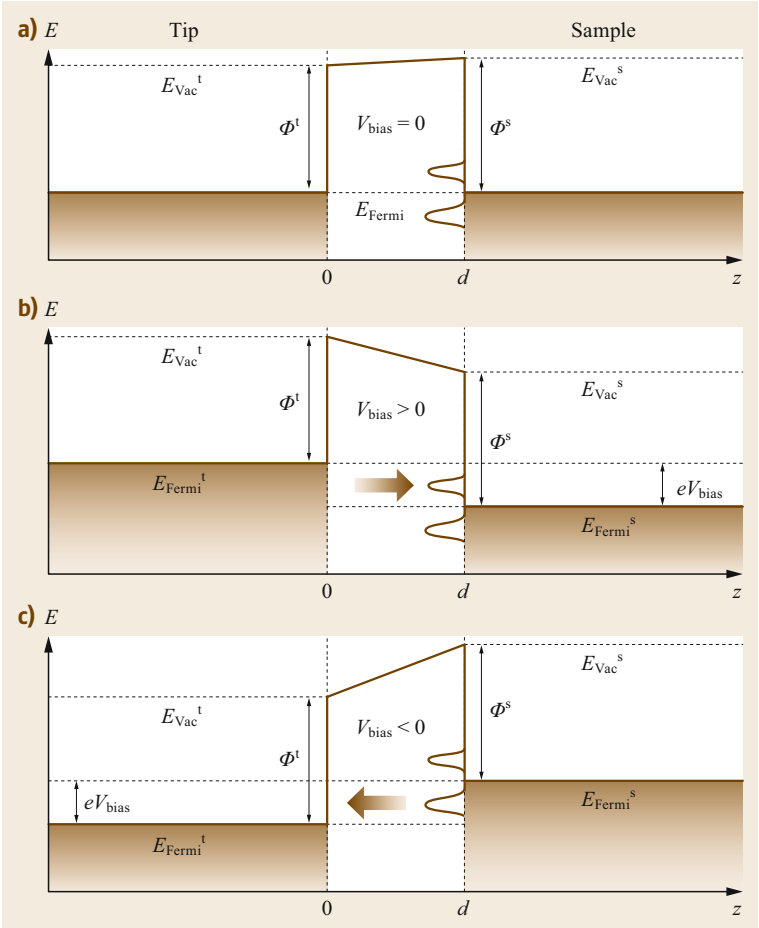

Fig. 8.10a–c Schematic representation of scanning tunneling spectroscopy (STS) **(a)** without bias voltage, **(b)** with positive bias voltage (unoccupied states), **(c)** with negative bias voltage (occupied states)

In more detail, if we consider a modulated bias voltage V_{bias} applied between tip and sample

$$V_{bias} = V_0 + V_{mod}\cos(\omega t)\,, \tag{8.7}$$

where the sinusoidal modulation voltage V_{mod} is typically a few mV, this modulation leads to a corresponding modulation of the tunneling current I with the same frequency. The tunneling current I can be therefore expressed in terms of its Fourier components, with respect to the applied modulation frequency ω,

$$\begin{aligned} &I\left[V_0 + V_{mod}\cos(\omega t)\right] \\ &= I_0 + V_{mod}\frac{\mathrm{d}I(V_0)}{\mathrm{d}V}\cos(\omega t) \\ &\quad + \frac{1}{2}V_{mod}^2\frac{\mathrm{d}^2I(V_0)}{\mathrm{d}V^2}\cos^2(\omega t) + \ldots\,. \end{aligned} \tag{8.8}$$

The first summand I_0 corresponds to the tunneling current in the unmodulated case. The second summand, proportional to $\mathrm{d}I/\mathrm{d}V$, is related to the LDOS of the sample. Its amplitude can be recorded with the aid of a lock-in amplifier tuned to V_0. For small modulation voltages this amplitude is in first approximation proportional to the slope in I/V and consequently to the first derivative of the current, $\mathrm{d}I/\mathrm{d}V$.

In a similar way, it is possible to record the second-derivative signal, obtaining information about the vibrational excitations of a molecule adsorbed on the surface. This kind of spectroscopy is called inelastic electron tunneling spectroscopy (IETS) and was first applied by the group of *Wilson Ho* in 1998 [8.32]. In IETS, the small increase in conductance given by the opening of an inelastic channel due to a molecular vibrational mode can be recorded. Details and applications of IFTS are presented in Chap. 25.

Figure 8.10 shows a schematic of STS for the case of a molecule adsorbed on a metallic surface. At zero bias (Fig. 8.10a), the Fermi levels of substrate and tip are in equilibrium and no tunneling current is measured. The two peaks at the substrate side of the gap symbolize hybridized states related to the highest

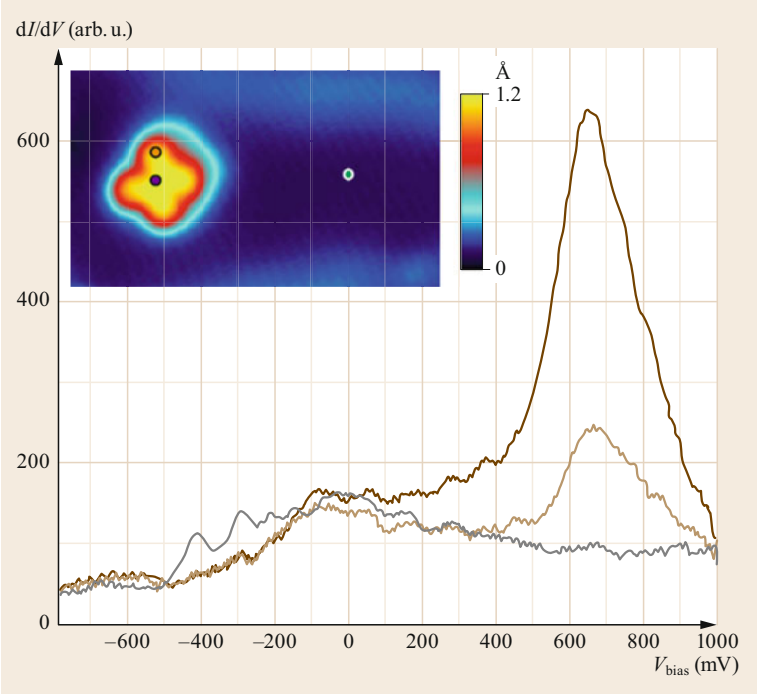

Fig. 8.11 STS spectrum of an aza-BODIPY molecule on Au(111): spectral positions are marked in the STM topography image according to the color code used in the STS graphs (image size: $8 \times 5\,\mathrm{nm}^2$)

occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) of an adsorbed molecule. For positive bias (Fig. 8.10b), the Fermi level of the tip is shifted upward by $|eV_{\mathrm{bias}}|$ and electrons can tunnel from the tip into the unoccupied states of the substrate (including the LUMO of the adsorbate). The tunneling current is determined by the density of unoccupied states of the substrate–adsorbate system within the energy range $|eV_{\mathrm{bias}}|$. For negative bias (Fig. 8.10c), the Fermi level of the substrate is increased by $|eV_{\mathrm{bias}}|$ and hence electrons can tunnel from the occupied states of the sample (including the HOMO of the adsorbate) to the tip. In this case, the tunneling current is determined by the density of occupied states of the substrate–adsorbate system within the energy range $|eV_{\mathrm{bias}}|$.

It is important to note that the electronic resonances of a molecule on a metallic surface are not exactly the HOMO and LUMO orbitals on the molecule in the gas phase, but are slightly shifted in energy and broadened by the interaction with the metallic surface electron continuum and with the tip. Moreover, a mutual electronic coupling of different molecular states through the surface can influence the energy resonances. It is also important to note that it is difficult to compare the HOMO–LUMO gap measured by STS with an optical measured gap, because in the case of STM there is no direct transition of electrons from one orbital to the next [8.11, 33].

Figure 8.11 shows an example of STS spectra recorded on a single aza-BODIPY molecule and on the bare Au(111) surface [8.34]. The spectra recorded on the molecule show a single broad and intense peak centered approximately at $V = 0.7\,\mathrm{V}$ corresponding to unoccupied electronic states. The amplitude of this peak is maximal at the center of the molecule and decreases to the edge. This can be seen by comparing the orange to the violet graph in Fig. 8.11 (see inset for spectra positions). The two spectra are almost identical on the occupied states ($V_{\mathrm{bias}} < 0$), indicating that these states are delocalized over the whole molecule. Furthermore, the absence of peaks and the small difference to the spectrum acquired over bare Au(111) point to a strong hybridization between metal substrate and adsorbate for these states.

In STM experiments, it is also possible to combine the measuring principles of topography and spectroscopy. In this way, one can image the spatial distribution of distinct electronic resonances of surfaces and molecular adsorbates with high spatial resolution. To create such a map of distinct states, the bias voltage is set at the energy of a distinct state (previously determined by $\mathrm{d}I/\mathrm{d}V$ spectroscopy) and the modulation of the bias is switched on. Then the $\mathrm{d}I/\mathrm{d}V$ signal is recorded point by point in parallel to the STM topography signal while scanning the area of interest. Note that due to the modulation period and the limited speed of the feedback loop, the time to measure a $\mathrm{d}I/\mathrm{d}V$ map

is far longer than the time needed for a STM topography image. While a constant current image can be acquired in about 5 min, a dI/dV map takes about 3–6 h. The measurement time strongly depends on the feedback loop and lock-in amplifier parameters. It is common to directly measure the tunneling current during dI/dV maps to be able to detect small changes in the current signal, which indicate a too-high scanning speed.

An example of a dI/dV map of the molecular resonances of a single hexacene molecule adsorbed on Au(111) is shown in Fig. 8.12. The molecule was obtained by surface-assisted reduction of specially designed precursors [8.35, 36]. As one can see, and as similarly observed for several acenes to the length of hexacene [8.37], the interaction of the molecules with the gold surface is weak enough to observe the electronic structure of the molecules with high precision.

Furthermore, it is possible to take a grid of spectra of the desired area. In these measurements a dI/dV spectrum is recorded for each image point. This leads to a data cube where two axes are the coordinates on the sample surface and the third one is given by the applied bias and represents the energy. A dI/dV signal is available at each point of this cube. Being very time consuming however, this technique is only applied if the spectral information is essential for the experiment. Note that this method also provides a dI/dV map at every energy in the range of the spectrum (dependent on spectral resolution) [8.38].

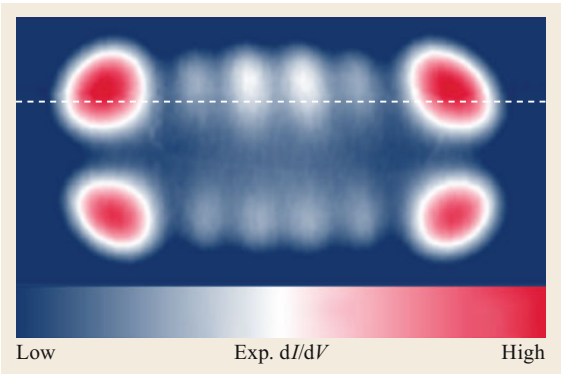

Fig. 8.12 dI/dV map of a single hexacene molecule on Au(111) recorded at a voltage of −0.65 V. The map shows the molecular orbital resonances of hexacene of the molecule on Au(111) (corresponding to the HOMO). Image size: 1.3 nm × 2.6 nm

8.5 Manipulation

STM was invented to image surfaces and adsorbates in real space with an unprecedented resolution and it is successfully used to resolve several problems of surface structure and electronic contrast. However, for many scientists daily working with LT-STM, the most fascinating property of this instrument is the concrete possibility to touch atoms and molecules by means of the STM tip and to modify matter at the nanoscale, constructing new functional structures and new molecules. Already in 1990 the first manipulation experiments were performed [8.39], opening up a completely new way to relate with matter at the atomic and molecular scale. In the following decades, STM was proven to be a versatile tool for atomic-scale manipulation and the construction of nanostructures [8.6, 39–43]. Single atoms and molecules have been precisely positioned by lateral [8.43] or vertical manipulation [8.44]. Different mechanisms of manipulation were developed on metals [8.43], ultrathin insulators [8.45], and semiconductors [8.46]. Voltage pulses are used to desorb [8.47] or dissociate [8.48] molecules, and to induce conformational changes [8.49, 50] or chemical reactions [8.36, 48, 51].

If we consider the kind of tip–sample interaction inducing the manipulation, three different manipulation mechanisms can be distinguished that are schematically shown in Fig. 8.13. In all these cases, it is first of all necessary to exactly position the tip on the adsorbate. Then, different parameters can be varied by selecting the physical principle driving the manipulation. In the first case (Fig. 8.13a) the height of the tip on the surface is reduced and the tip moved over the adsorbate, activating chemical and van der Waals forces [8.43]. In the second case (Fig. 8.13b) an electric field is ap-

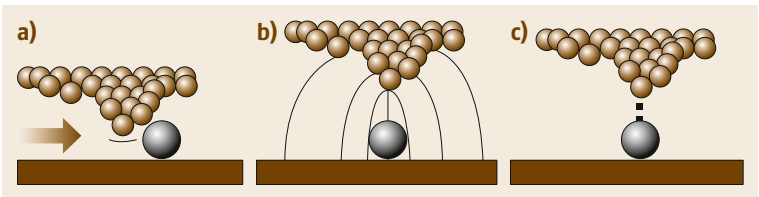

Fig. 8.13a–c Schematic representation of the different mechanisms of manipulation: **(a)** lateral manipulation induced by van der Waals interaction; **(b)** electric-field-induced manipulation; **(c)** manipulation driven by inelastic tunneling electrons

plied by tuning the tunneling current and the applied bias voltage [8.52, 53]. Due to the close distance between tip and surface, electric fields in the range of 10^7 V/cm can be normally applied under the STM tip. Finally, as shown in Fig. 8.13c, the energy of the electrons can be varied, allowing the electrons to perform an inelastic electron-induced manipulation, where the tunneling electrons can lose energy, exciting vibrational, rotational, or electronic resonances that can result in motion. The tunneling current determines the number of electrons tunneling through the tunnel barrier formed by adsorbate and surrounding substrate [8.53]. Using these different mechanisms of interaction, it is possible to perform lateral or vertical manipulation, and to induce chemical reactions, dissociation, or desorption. Vertical manipulation, in particular, is the case of an adsorbate picked up from the surface. The tip is then moved to the desired place and the adsorbate is released. A first case of vertical manipulation in 1991 showed the possibility of reversibly transferring a Xe atom between the tip and the surface [8.44]. However, as vertical manipulation strongly modifies the tip apex and is not always controllable and reversible, it is mostly used to functionalize the STM tip with selected atoms or small molecules, in order to change or increase the tip resolution.

8.5.1 Lateral Manipulation with the STM Tip

Lateral manipulation is commonly considered the lateral displacement of a molecule or an atom adsorbed on a surface, taking advantage of the van der Waals interaction between the adsorbate and the STM tip [8.43]. By lateral manipulation it is possible to controllably move small molecules and single atoms, as well to induce translation and conformational changes in larger molecules.

The standard method for lateral manipulation of single atoms [8.43], single molecules [8.40], or small groups of molecules [8.54] is to use short-range forces between tip and sample, bringing the tip of the STM close to the adsorbate and thereby increasing the tip adsorbate interaction, and then moving the tip to the desired final location on the surface [8.42, 43], as schematically shown in Fig. 8.14. In the first example of a single-atom STM lateral manipulation, Xe atoms were moved one at a time on a metal surface [8.39].

In general, the forces between adsorbate and tip can be attractive or repulsive and this results in different manipulation modes. In all cases, for the manipulation the distance between the tip and the adsorbate is varied in order to tune the force. Typical distances are between 3 and 5 Å. With lateral manipulation exper-

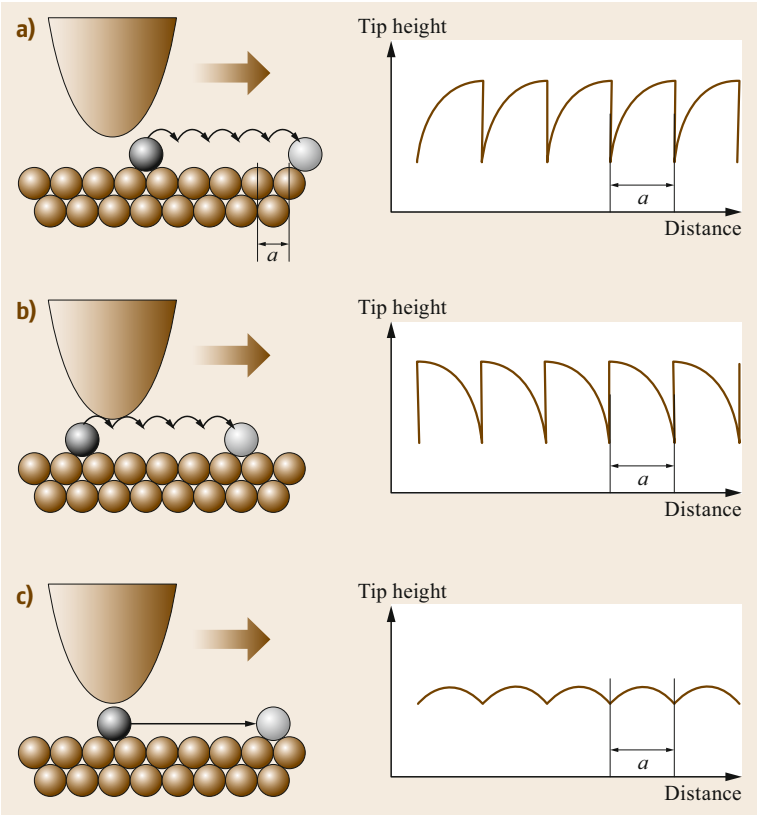

Fig. 8.14a–c The different modes of lateral manipulation: **(a)** pushing, **(b)** pulling, **(c)** sliding

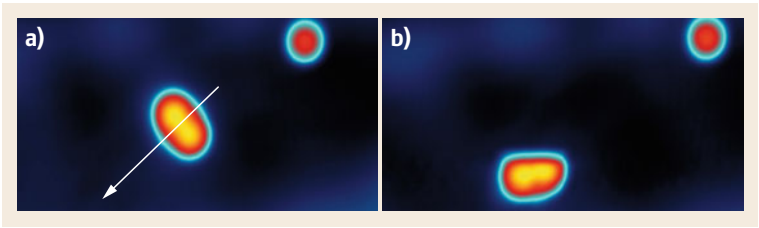

Fig. 8.15a,b Examples of lateral manipulation of a double-wheel molecule. **(a)** STM images before the manipulation; **(b)** STM images after the manipulation. $V = 0.08$ V; $I = 35$ pA; tunneling resistance by lateral manipulation $R = 6$ MW. Image size: $6 \times 3.6\,\mathrm{nm}^2$

iments on single atoms or small molecules, different modes of manipulation such as pushing, pulling, and sliding can be distinguished by measuring the feedback signal during manipulation [8.43]. In particular, by manipulation in constant current mode, detailed information on the process is obtained from the tip height signal, which reflects the interaction between the tip apex and the adsorbate [8.55]. The common procedure includes moving the tip to the desired particle in imaging distance (about 10 Å), then decreasing the distance and moving the tip with the adsorbate to the desired place and subsequently increasing the distance to lose contact. During the process the tip height is recorded. From these curves, different modes of manipulation can be distinguished. Such modes and the corresponding curves are illustrated in Fig. 8.14 [8.43]. In the pushing mode, repulsive forces are used to push the adsorbate in front of the tip across the surface. The tip is moved over the adsorbed particle until a threshold is reached, which induces hopping of the adsorbate away from the tip. In this moment the tip height decreases, before it increases again and the process is repeated. Most of the time, a jumping distance that corresponds to the lattice parameter of the substrate surface can be observed. The pulling and sliding modes make use of attractive forces between tip and adsorbate to perform the manipulation. In the pulling mode the adsorbed particle jumps to the tip, which is why the tip height increases. When the tip is moved further the height decreases until a threshold is reached and the adsorbate jumps below the tip, increasing the height again. In the sliding mode adsorbates are moved continuously across the surface. To achieve this mode, the force between tip and adsorbed particle has to be significantly higher than in the pulling mode. The adsorbate can stay under the tip and does not jump to the energetically favored positions on the surface. The corrugation in the corresponding tip-height trace is due to the atoms on the surface.

A similar procedure can be used to manipulate complex molecules, most of the time also inducing conformational changes [8.40]. In these cases, the manipulation signal that is recorded is normally more complex than for single atoms or small molecules like CO, especially when the molecule presents internal mechanical degrees of freedom. For example, intramolecular conformation changes can be induced during the manipulation of porphyrine-based molecules [8.56]. This type of movement is added to a rigid-like lateral-type motion on the surface, as one can observe from the manipulation signal. Manipulation signals for complex molecules therefore normally do not show the regular periodic modes over long periods observed for single atoms and small molecules. Changes from one mode to another during manipulation are often observed [8.57]. In some cases, manipulation signals do not present any periodicity and the peaks are irregular in intensity, length and shape [8.58]. Molecular flexure and reorientation of the internal conformations play a major role, as well as the reorientation of the molecule relative to the surface. In Fig. 8.15 an example of lateral manipulation of a subphthalocyanine double-wheel molecule is shown. Even if in particular cases the molecular wheels rotate on the Au(111) surface, they are normally pushed by the tip in the same way as smaller adsorbates [8.57].

8.5.2 Manipulation by Electric Field

If the adsorbate is charged or has a dipole moment, electric-field-assisted diffusion is possible. In general, every time a bias voltage is applied between the STM tip and the surface, a static electric field is created. This field can be used to manipulate atoms or molecules. The strength of such an electric field is relatively large, due to the close proximity of the tip to the surface. In a common STM experiment where a bias voltage of about 1 V is applied with a tunneling current of about 1 nA, the electric field between tip and surface has a typical value of 10^8 V/cm and is comparable with the fields experienced by electrons in atoms or molecules. Depending on the tip shape, such an electric field is concentrated in an inhomogeneous way near the tip apex, but its extension can reach hundreds of nanometers. The interaction of an adsorbate with such a strong electric field in the STM junction was first used to position Cs atoms on a semiconductor surface [8.59]. In this case, the inter-

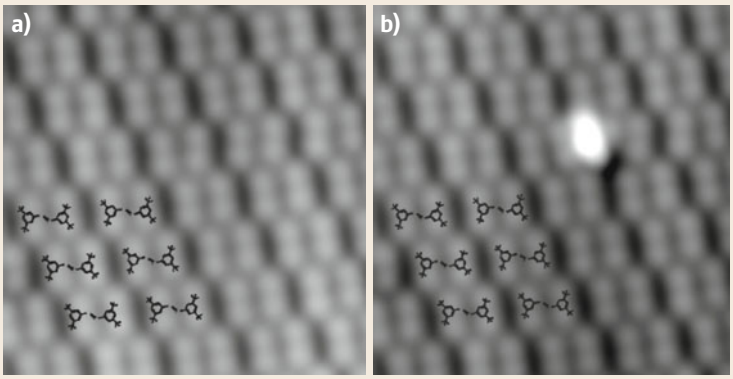

Fig. 8.16a,b **(a)** STM image of a molecular island of *trans*-tetra-*tert*-butylazobenzene molecules on Au(111). **(b)** By applying an electric field, a molecule has been switched to the *cis*-configuration (*bright lobe*)

action between the dipole moment of a Cs atom and the electric field induces a potential energy gradient along the surface, which allows the lateral positioning of single atoms.

Atoms and molecules can be manipulated by electric field even in the limit of zero tunneling current. In such a case, no tunneling current can be measured between tip and sample, but an electric field is present, which is able to manipulate molecules showing a dipole moment. Another kind of electric-field-induced manipulation is possible when the applied voltage overcomes the value of the work function of the tip or the surface and electrons are therefore field emitted [8.60].

The reversible isomerization of azobenzene derivatives by means of the electric field has been demonstrated [8.61]. A detail of that experiment is shown in Fig. 8.16. The *trans–cis* isomerization of 3,3′,5,5-tetra-*tert*-butylazobenzene, an azobenzene molecule carrying four lateral *tert*-butyl groups, can be reversibly induced on Au(111). The relationship between the applied bias voltage necessary for switching and the tip height shows that the process is caused by the electric field between the STM tip and the sample surface.

8.5.3 Manipulation by Inelastic Tunneling Electrons

Inelastic electron-tunneling-induced manipulation is a process where tunneling electrons are injected from the tip positioned above the adsorbed molecule, thus moving it. The electron energy is normally transferred through an excited state, leading to excitation (rotational, vibrational, or electronic), the rate of which is controlled by the applied bias and the tunneling current [8.18].

Experimentally, electron-tunneling-induced manipulation is realized by positioning the STM tip above the molecule at a fixed height. The feedback loop is switched off and tunneling current and/or voltage are increased from imaging to manipulation parameters. The electrons can be injected either from the tip or from the substrate depending on the bias polarity. The moment where a change happens is determined by monitoring the tunneling current versus time. A sudden change in current is indicative of the success of the manipulation. These sudden changes are caused by changes in the apparent height of the molecule either

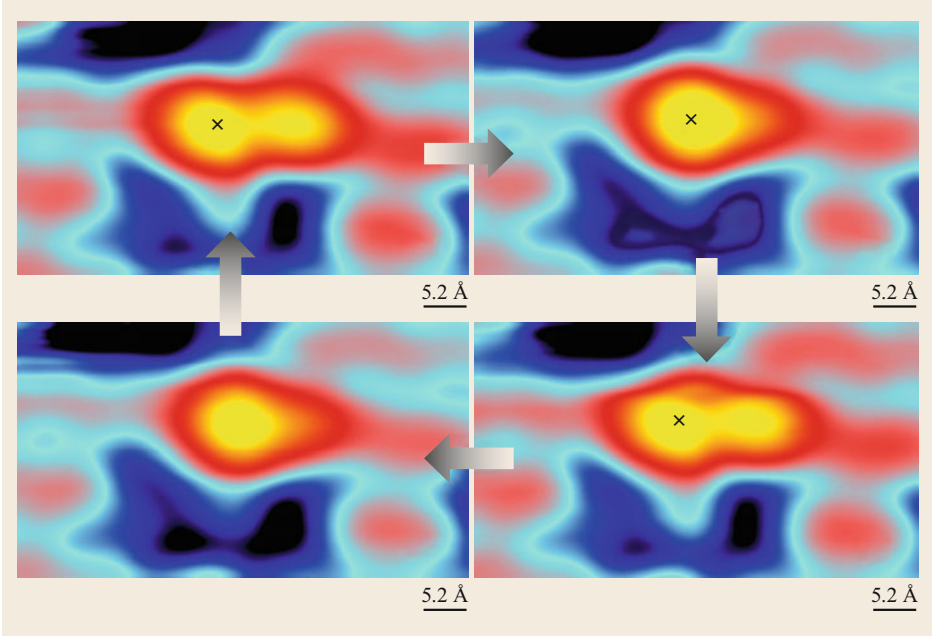

Fig. 8.18 Reversible switching of an acetylbiphenyl molecule anchored on a Si(100) dangling bond. The *crosses* indicate the position of the tip during voltage pulses of −2.6 V

through the motion of the molecule or through a modification of this electronic structure [8.62].

Electron tunneling can be used for example to induce the controlled rotational switching of a molecular motor [8.63]. A molecular motor adsorbed on a gold surface can be rotated in a clockwise or anticlockwise direction by selective inelastic electron tunneling through different subunits of the motor.

Recently, it was demonstrated that by electron-tunneling-induced manipulation it is possible to move in a controlled way supramolecular structures [8.64]. By applying voltage pulses just on one selected molecule of the structure, the complete supramolecular assembly moves to a chosen position on the surface without being destroyed (Fig. 8.17). Moreover, by moving the same nanostructure it is possible to collect a gold adatom and to rotate or translate it by manipulating the molecular structure [8.65]. With the help of theoretical calculations one can determine the work done by the nanostructure to move the atom.

The reversible switching of an acetylbiphenyl molecule on the Si(100) surface can be induced by inelastic tunneling electrons, proving the principle of an electrically driven molecular latch, able to passivate and depassivate Si dangling bonds. As one can see in Fig. 8.18, the molecule can be switched from its native surface conformation with two lobes to a one-lobe conformation and back by applying voltage pulses.

8.6 Outlook

As described in this chapter, extraordinary results have been obtained in the last decades in imaging individual molecules adsorbed on surfaces, and the high spatial control and resolution of STM has allowed us to gain an exceptional insight into the structure and the intra- and intermolecular bonding of a large number of molecules. Since the pioneering works of D. Eigler, many different methods to control the manipulation of atoms and molecules with a STM tip have been developed. Mechanical interaction, tunneling current, bias voltage, and enhanced electric field are the main means to modify the position or the conformation state of a molecule. Tip height and current signal recorded during the manipulation process provide detailed information on the molecular movement, and conformational molecular switches can be operated by manipulation [8.40].

The mechanics of single molecules have been investigated extensively in the last years. In particular, atomic and molecular manipulation allows us today to create new molecules and nanostructures on a surface, and to investigate mechanics at the molecular scale. The next step is now to construct complex mechanical machines molecule by molecule [8.66]. Single-molecule motors working collectively in a synchronous manner

will represent a milestone for nanotechnology. To this aim, a deep understanding of processes and laws governing transmission of motion from molecular motors to molecules and from molecule to molecule is demanded and will be the focus of research in the next years.

Additionally, besides imaging, STM permits us to probe the electronic, vibrational, and optical properties of single atoms and molecules by studying the details of the tunneling current of its derivatives. These exceptional advances generate a remarkable improvement in our fundamental understanding of processes occurring at the nanoscale and can now be applied to the controlled fabrication of atomic and molecular devices and to investigate signal transport at the atomic and molecular scale. The possibility to replace solid-state transistors with molecular electronic devices in ultraminiaturized circuits is a fascinating perspective. Serious limitations of this approach are the low conductance and low power gain of a molecular device, together with the problem of tunneling leakage currents that can exist between the devices and between the interconnections. An alternative approach is to develop an atomic-scale technology, where surface electronic circuits are constructed by manipulating atoms of a passivated semiconductor surface, opening up the way to new approaches to quantum computation [8.67]. In this framework, STM will be a fundamental tool for the development of new electronic technologies at the atomic scale, building structures one by one and addressing them with tunneling electrons.

Francesca Moresco studied physics at the University of Genova and received her PhD at the University of Hannover (1998). Her habilitation work at FU Berlin was awarded with the Karl-Scheel Prize of the German Physical Society in Berlin (2003). She joined the Institute of Materials Science at TU Dresden at the end of 2009. Since October 2017 Francesca Moresco leads the Single Molecule Machines research group at the Center for Advancing Electronics Dresden (cfaed).

9. Two-Dimensional Crystals: Graphene, Silicene, Germanene, and Stanene

Yu-Yang Zhang, Jinbo Pan, Shixuan Du, Hong-Jun Gao

Since the successful exfoliation of graphene from graphite in 2004, research on two-dimensional crystals has attracted significant attention. An increasing number of new two-dimensional materials have been synthesized, ranging from graphene-like crystals such as hexagonal boron nitride (h-BN) and germanene, to three-atom-thick transition-metal dichalcogenides, and to layered oxides and hydroxides. A wide spectrum of electronic and magnetic properties of great interest have been discovered in these new two-dimensional materials. In this chapter, we review the history and current status of research on group IVA two-dimensional crystals, i.e., graphene, silicene, germanene, and stanene. We give an overall summary of the syntheses of these two-dimensional crystals, especially epitaxial growth in an ultrahigh-vacuum environment. We hope that the knowledge gained from the reviewed systems will guide the design and synthesis of other two-dimensional crystals.

In this chapter, we give a brief review on the epitaxial growth of group IVA two-dimensional (2-D) monolayers on transition-metal substrates in ultrahigh-vacuum (UHV) environments. In Sect. 9.1, we discuss the epitaxial growth of graphene on a Ru(0001) and other transition-metal substrates. In Sects. 9.2 and 9.3, we review the synthesis of silicene and germanene. Stanene and several other monolayers made with metallic elements are discussed in Sect. 9.4.

Part B | 9

The family of 2-D materials containing one to several layers of atoms has been widely investigated in recent decades. They are not only important for fundamental physics but also show great potential for future applications; for example, taking advantage of its high carrier mobility, graphene (Gr) has been used in transistors that can work at extremely high frequencies [9.1, 2]. MoS_2 has been used in the smallest transistors, only 1 nm in size [9.3]. Due to their extremely high surface-to-volume ratio, some 2-D materials are also good catalysts [9.4–8]. Scientists have also shown interest in putting several 2-D materials together to build both lateral and vertical heterostructures [9.9–13].

Recent research regarding 2-D materials started from the exfoliation of graphene from graphite in 2004 [9.14]. Then, it quickly expanded to h-BN and boron carbon nitride (BCN), which have honeycomb structures and satisfy the same electron counting rule [9.15–17]. Monolayers of silicon and germanium, other group IVA elements that also have four valence electrons, are also theoretically predicted to be stable [9.18–20]. Experimental evidence of these two

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-46906-1_9

monolayers has been found, although some debate remains regarding the names of these two materials [9.21, 22]. Recently, stanene, a monolayer of Sn, was synthesized, enriching the family of group IVA 2-D materials [9.23].

Another major class of 2-D materials is transition-metal chalcogenides (TMCs) [9.24, 25]. Some of these are also star materials; for example, MoS_2, a traditional solid lubricant, was used to fabricate the smallest transistors [9.3]. Monolayer FeSe has attracted substantial attention as a superconductor [9.26]. $NbSe_2$ shows an abnormal incommensurate charge density wave (CDW) [9.27, 28]. As most chalcogenides/dichalcogenides have a layered structure, exfoliation from bulk materials has been used to produce monolayer dichalcogenides [9.29]. Large-scale and high-quality molecular beam epitaxy (MBE) and chemical vapor deposition (CVD) methods have also been applied to produce monolayer dichalcogenides [9.30, 31].

Monolayer oxide materials constitute another booming research direction in 2-D materials. Though most bulk oxide materials are not layered structures, several-atomic-layer thick oxides in 2-D form have been synthesized in various ways [9.32]; for example, a perovskite-type $LaNb_2O_7$ monolayer was formed via a nanosheet deposition process [9.33], TiO_2 monolayers were grown on Ag(100) substrates [9.34], and recently, single-atom-thick CuO and ZnO membranes were synthesized in graphene pores and on a graphene substrate, opening a new window for research into monolayer oxide materials [9.35, 36].

Exfoliation from layered bulk parents has been demonstrated to be an effective way to fabricate 2-D materials [9.16, 37, 38]. In addition to graphene, which was historically exfoliated from graphite using Scotch tape, there are plenty of other examples of 2-D materials that can be mechanically exfoliated from their three-dimensional parent, such as MoS_2, $MoSe_2$, and $NbSeO_2$. Chemical exfoliation methods are then typically used to break the van der Waals (vdW) interactions inside the layered structures to obtain 2-D materials.

Epitaxial growth of 2-D materials is another synthesis strategy. CVD and physical vapor deposition (PVD) have been successfully demonstrated for the fabrication of many 2-D materials on a large scale [9.39–41]. The as-fabricated 2-D materials are then generally transferred to another substrate, such as a silicon wafer. Direct selenization of a Pt substrate to fabricate a $PtSe_2$ monolayer and the synthesis of graphene on a transition-metal (TM) substrate by chemical reactions are other examples of epitaxial growth of 2-D materials [9.42, 43]. The advantage of the epitaxial growth method is that the fabricated 2-D materials have high quality for further applications. Another advantage of the epitaxial growth method is that it can be used to synthesize 2-D materials without relying on layered 3-D (three-dimensional) parents, e.g., silicene and germanene.

9.1 Graphene on Transition-Metal Substrates

In the 1960s, graphene was found to form on transition-metal surfaces [9.44, 45]. Indeed, it required considerable effort from scientists to get rid of these carbon films to obtain a clean transition-metal surface. However, since its successful exfoliation [9.14, 46], graphene on transition-metal surfaces has again attracted attention from scientists. Due to the convenient synthesis process and the high quality of the fabricated graphene, systems formed of graphene on a transition-metal substrate have been comprehensively investigated [9.47]. For certain transition-metal substrates, the strong interaction between the graphene adlayer and the transition-metal substrate reduces the carrier mobility of the graphene and makes it difficult to open an energy gap [9.48, 49]. These obstacles can now be overcome in several ways, such as intercalation techniques [9.50, 51]. It has also been reported that the interaction of Au or Si can restore graphene nanoislands (GNIs) and graphene nanoribbons (GNRs) to a pristine state [9.52, 53]. The as-prepared epitaxial graphene can also be decoupled from the substrate by etching [9.54]. Thus, the epitaxial growth of graphene on a transition-metal substrate is still a promising method for industrial production of graphene in the future.

9.1.1 Epitaxial Growth of Graphene on Ru(0001)

Large-scale and highly ordered graphene can be synthesized by annealing a ruthenium single-crystal substrate containing a small amount of carbon [9.48, 49, 55] or using precursors containing carbon atoms [9.56]. During the annealing process, the carbon atoms segregate from the bulk ruthenium, and graphene grows on the Ru(0001) surface. The annealing process is described in the literature [9.48, 55]. A brief description of the sequence is as follows: the temperature of the ruthenium substrate is slowly increased to 1000 K and held for 20 min, then the substrate is cooled to room temperature. Comparison of the Auger electron spectroscopy

(AES) and x-ray photoemission spectroscopy (XPS) results before and after the annealing process confirmed the segregation of carbon. XPS and AES also helped to confirm that no other new elements were present.

Taking the above work as an example, the quality of the as-fabricated graphene on an 8-mm-diameter Ru(0001) substrate was examined from edge to edge by low-energy electron diffraction (LEED). As shown in Fig. 9.1a, LEED patterns were collected at each pink spot. Compared with bare Ru(0001), which generates a simple hexagonal pattern, extra spots due to epitaxial graphene can be clearly identified in Fig. 9.1d–f. The spots in the graphene pattern show the same orientation, indicating that the whole sample was covered by a homogeneous, high-quality epitaxial graphene layer. It is only at the edge of the sample (Fig. 9.1b,c) that the spots related to graphene become weak.

Based on many high-quality atomic-resolution STM images and density functional theory (DFT) calculations [9.57–60], the atomic structure of graphene on Ru(0001) has been fully revealed. It is now believed that the moiré pattern is due to the lattice mismatch between graphene and the Ru substrate. As shown in Fig. 9.2a, in a relaxed configuration of a (12×12) graphene lattice sitting on a (11×11) Ru(0001) lattice, there are three typical regions. For the higher region, C atoms of both sublattices in graphene are located in (or close to) the face-centered cubic (fcc) and hexagonal close-packed (hcp) hollow site of the Ru substrate. The centers of the honeycomb lie above (or close to) the top of a top-layer Ru atom. This upper region is thus commonly called the top or atop region. For the lower region, the center of the honeycomb is above (or close to) second- or third-layer Ru atoms. These regions are commonly named the hcp (above a second-layer Ru atom) or fcc (above a third-layer Ru atom) regions. For the region with intermediate height, close inspection of the atomic structure reveals that the centers of the honeycomb are located above the centers of two top-layer Ru atoms. This region is called the bridge region. Sometimes, this region is further divided into several different regions depending on the neighbors; for example, the bridge region between the atop and fcc regions can be referred to as the atop–fcc region.

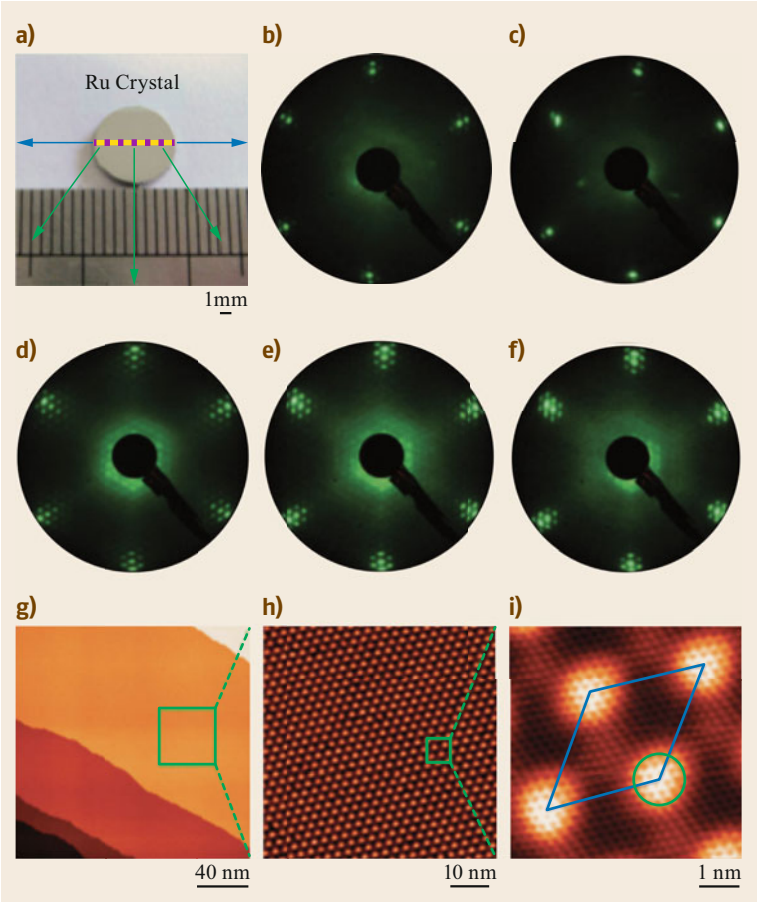

Fig. 9.1a–i LEED patterns and STM images confirming the high quality of graphene on Ru(0001). **(a)** A sample 8 mm in diameter. The electron beam was moved along the *yellow line* to obtain the different LEED patterns. The *pink spots* are the locations where the photographs shown in **(b–f)** were taken. **(b,c)** At the edge of the sample, the additional spots are weak. **(d–f)** In other parts of the sample, the additional spots are sharp and have the same arrangement. Scanning tunneling microscopy (STM) images at large scale **(g)**, zoomed in **(h)**, and at atomic resolution **(i)** show that a flat graphene flake extended over entire Ru terraces (reprinted by permission from [9.48], © Wiley 2009)

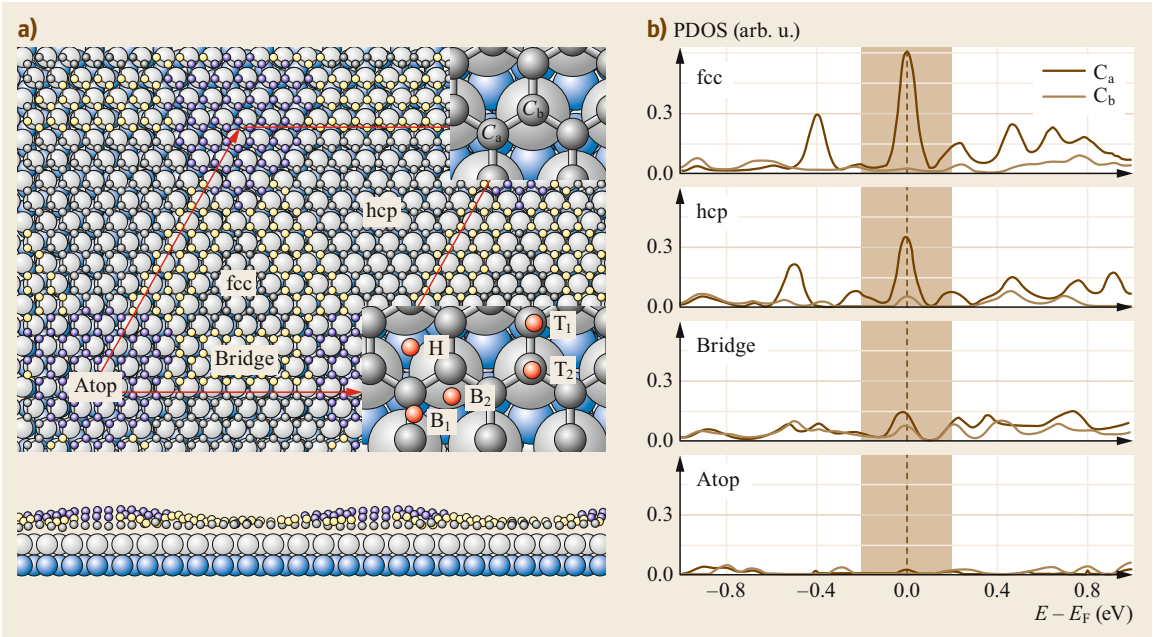

Fig. 9.2a,b Atomic structure and electronic properties of a (12×12) graphene lattice on a (11×11) Ru(0001) substrate. **(a)** Top view (*top panel*) and side view (*lower panel*) of the atomic structure. **(b)** Density of states projected (PDOS) to p_z orbits for different C atoms at different locations (reprinted by permission from [9.60], © Wiley 2014)

Although debate continues on whether this represents a (12×12) graphene lattice sitting on a (11×11) Ru(0001) substrate or a (25×25) graphene lattice sitting on a (23×23) Ru(0001) surface [9.56], most quantum-mechanical calculations based on DFT have adopted the former atomic model, which is much smaller in size than the second. The atomic structure and electronic properties of the graphene-on-Ru(0001) system have been investigated [9.57–59]. The choice of the exchange-correlation function, how to treat the van der Waals interactions, the number of Ru layers in a slab model, the energy cutoff on the wavefunction expansion, and other numerical parameters generally affect the details of the resulting atomic structure and electronic properties. It is widely accepted that the large ripple revealed in STM images is not only caused by the electronic structure but also a real atomic corrugation.

Carbon atoms within one period of the moiré pattern at different locations have different electronic structures. The projected density of states (PDOS) on p_z orbitals of different carbon atoms is shown in Fig. 9.2b, where C_a and C_b denote atoms located on hollow and top sites of Ru(0001) in the fcc and hcp regions, respectively [9.60]. The intensity of the PDOS of C atoms at the Fermi level in fcc regions is much higher than that in the other regions, implying stronger sp^3 hybridization and higher activity of C_a atoms in the fcc region. This difference further affects the physical and chemical properties of graphene; for example, at low coverage, many transition-metal atoms selectively adsorb on the fcc region of graphene/Ru(0001) and form ordered dispersed metal nanoclusters [9.61–63].

As one of the earliest systems comprising high-quality epitaxial graphene on a transition-metal substrate, Gr/Ru(0001) has attracted significant attention. Many fundamental studies and potential applications have been explored in this system; for example, quantum-dot and quantum-well effects have been investigated [9.64–66]. This system is also used as a template for selective adsorption and self-assembly patterns [9.67, 68]. Many intercalations between graphene and the Ru substrate have also been achieved for future applications [9.50, 69–71].

9.1.2 Epitaxial Growth of Graphene on Other Transition-Metal Substrates

Graphene has also been epitaxially grown on other transition-metal substrates, including Pt [9.72, 73], Ir [9.74, 75], Rh [9.76, 77], Ni [9.7, 76], and Cu [9.78]. Various sizes of moiré patterns have been observed. Figure 9.3 shows moiré patterns of graphene on several widely investigated transition-metal substrates with a typical periodicity of 1–2 nm.

For all such samples, the epitaxial growth method and kinetic factors during the growth process strongly

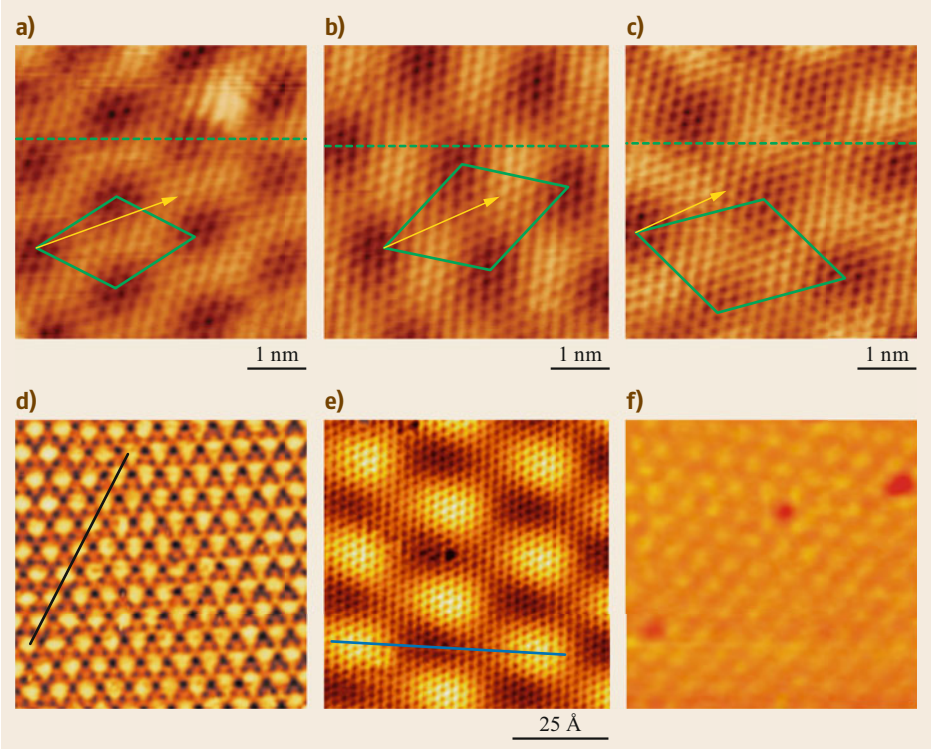

Fig. 9.3a–f STM images of graphene epitaxially grown on transition-metal substrates. **(a–c)** Graphene grown on a Pt(111) surface, showing domains with different orientations [9.72]. **(a)** is for $(\sqrt{37}\times\sqrt{37})$R21°. **(b)** is for $(\sqrt{61}\times\sqrt{61})$R26°. **(c)** is for $(\sqrt{67}\times\sqrt{67})$R12°. **(d)** Graphene on a Rh(111) $10\times10\,\mathrm{nm}^2$ surface [9.76]. **(e)** Graphene on an Ir(111) $6\times6\,\mathrm{nm}^2$ surface [9.75]. **(f)** Graphene on a Cu(111) $20\times20\,\mathrm{nm}^2$ surface [9.78] (reprinted by permission from [9.72, 75, 76, 78], © American Institute of Physics, Institute of Physics, American Chemical Society)

affect the quality of the resulting graphene [9.79, 80], as do a high-quality transition-metal substrate, suitable precursor partial pressure, and controlled annealing temperature.

The lattice mismatch between the graphene and transition-metal substrate affects not only the size of the moiré pattern [9.81] but also the quality of the graphene. *Preobrajenski* and collaborators showed that, with a larger lattice mismatch, the graphene film corrugated more because of the inhomogeneous interaction between the graphene and substrate [9.82]. XPS measurements confirmed this effect.

The quality of the graphene on a transition-metal substrate prepared by the epitaxial growth method is also affected by the interaction between them. For strongly interacting systems, at the initial stage of growth, the graphene islands have the same orientation and thus connect to each other seamlessly during growth. The as-fabricated graphene thus contains fewer defects. However, if the graphene–substrate interaction is weak, the initial islands have different orientations and the as-fabricated graphene may thus show many domains. Grain boundaries may also affect the electronic properties of the graphene [9.83–86].

An example of a strongly interacting graphene–substrate system is Gr/Ru(0001), described above. The moiré pattern is well defined. In contrast, graphene on Pt(111) is an example of a weakly interacting graphene–substrate system. In contrast to the case of a unique (12×12) graphene lattice sitting on a (11×11) Ru(0001) substrate, graphene on Pt(111) forms different moiré patterns that may rotate to different orientations. Figure 9.3a–c shows typical STM images of Gr/Pt(111), indicating $(\sqrt{37}\times\sqrt{37})$R21°, $(\sqrt{61}\times\sqrt{61})$R26°, and $(\sqrt{67}\times\sqrt{67})$R12° orientations. Compared with Gr/Ru(0001), Gr/Pt(111) shows lesser corrugation.

In scanning tunneling spectroscopy (STS), the $\mathrm{d}I/\mathrm{d}V$ curve of the sample is measured, thus when the tip is carefully treated, it reflects the local density of states (LDOS) of the sample. This method is widely used to investigate the electronic structure of epitaxial graphene on transition-metal substrates with high spatial resolution. Taking the Gr/Ru(0001) system as an

example, STS results show that the graphene retains some of its physical properties after being placed on the metal surface but with a shift of the Dirac point by −0.3 eV [9.48, 49].

Epitaxial graphene on an Ir(111) substrate is another system that has been well investigated by STM/STS, especially regarding the effect of silicon intercalation [9.87]. Figure 9.4a shows STS measurements of Gr/Ir(111) on both an intercalated area (black curve) and an un-intercalated area (red curve). It is clear that, after silicon intercalation: (i) the surface state of the Ir substrate disappears and (ii) the occupied states and unoccupied states become symmetric. After silicon intercalation, the two prominent features of graphene, viz. the G and 2-D peaks, become visible (Fig. 9.4c). These results indicate that the coupling between graphene and Ir(111) is weakened by silicon intercalation [9.87].

Taking advantage of its high spatial resolution, STS has also been used to reveal the edge states of graphene

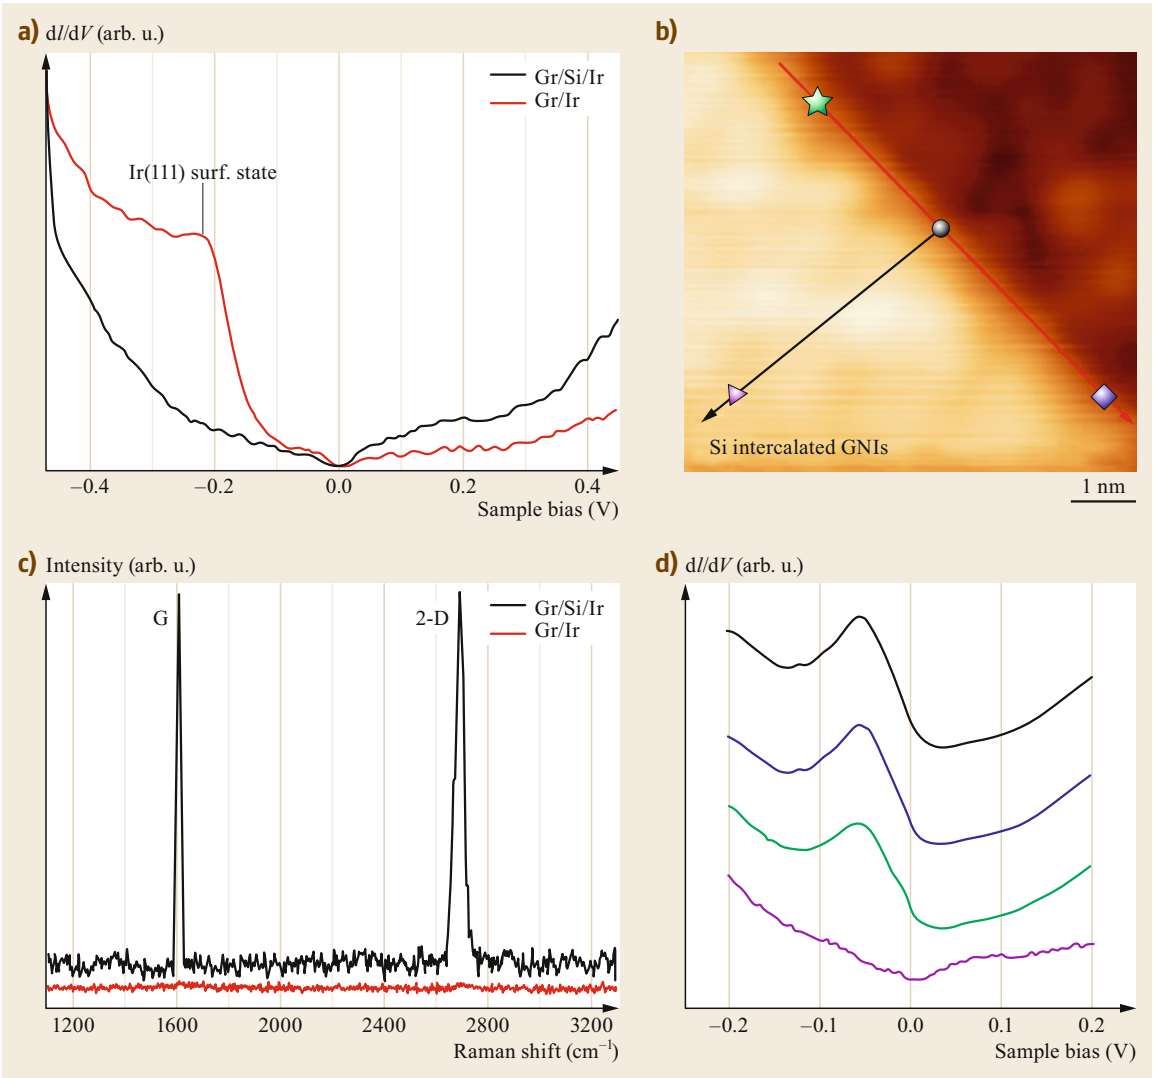

Fig. 9.4a–d STS measurements on Gr/Ir(111). **(a)** dI/dV spectra measured on both an intercalated (*black line*) and an un-intercalated area (*red line*) [9.87]. **(c)** Comparison of Raman spectra at 532 nm for graphene grown on Ir(111) before and after silicon intercalation, denoted by *red* and *black lines*, respectively [9.87]. **(b)** STM image showing a straight edge of a Si-intercalated graphene nanoisland [9.88]. **(d)** dI/dV spectra collected at different points along the line perpendicular to the edge marked by *black dots* in **(b)** [9.88] (reprinted by permission from [9.87, 88], © AIP 2012, Springer Nature 2017)

nanoribbons (GNRs) and nanoislands (GNIs) [9.88, 89]. Figure 9.4b is an STM image showing a straight edge of a GNI on Ir(111). The dI/dV spectra collected at different points around the edge (Fig. 9.4d), marked by different dots in Fig. 9.4b, indicate that a pronounced peak appears at -50 mV in the dI/dV spectra acquired at this straight edge. This pronounced peak is not the surface state of the Ir(111) substrate, which is located at ≈ -0.2 eV, and is attributed to the edge state of the graphene nanoisland [9.88].

The electronic properties of graphene on transition-metal substrates have also been investigated using theoretical calculations. Some use a more realistic model, which contains the full moiré pattern. However, because of the size of the supercell, these calculations usually adopt the local density approximation (LDA) and generalized gradient approximation (GGA) with or without van der Waals interactions [9.90–94]. Higher-level calculations based on a more accurate approach, such as the random phase approximation (RPA) or *GW* approach, can only handle tens of atoms. In these high-level calculations, a (1×1) or $(\sqrt{3}\times\sqrt{3})$ graphene lattice is often used, which neglects the lattice mismatch between graphene and the transition-metal substrate [9.95, 96]. There are also theoretical calculations to address the growth process and mechanism [9.97].

9.2 Epitaxial Silicene on Transition-Metal Substrates

Silicene, made up of silicon atoms rather than carbon atoms, is a 2-D atomic crystal with a honeycomb structure similar to graphene. It has attracted considerable attention due to its peculiar properties [9.19, 20, 98–101], e.g., compatibility with current silicon-based technology and the quantum spin Hall effect. Due to the long Si−Si bond length and the partial sp^3 hybridization, freestanding silicene is a low-buckled structure. Recently, silicene has been successfully synthesized on several transition-metal substrates, e.g., Ag(110) [9.102], Ag(111) [9.98, 103–107], Ir(111) [9.21], and ZrB_2 thin films [9.108]. In this section, we discuss in detail the epitaxial growth and characterization of silicene on Ir(111) and Ag(111) surfaces.

9.2.1 Silicene on Ir(111)

Epitaxial silicene on an Ir(111) surface, as shown in Fig. 9.5, was synthesized by depositing silicon atoms on the Ir(111) surface at room temperature followed by annealing at 670 K for 30 min [9.21]. The LEED pattern of the sample is shown in Fig. 9.5a. The spots highlighted by the yellow dashed circles are assigned to the (1×1) Ir(111) substrate. The other diffraction spots originate from the silicon superstructure on the Ir(111) substrate. The diffraction spots can be separated into two identical patterns with different orientations, as shown in the sketch map in Fig. 9.5b, in which two different spots highlighted by different colors correspond to two domains. Each domain can be identified as a $(\sqrt{7}\times\sqrt{7})$ superstructure with respect to the Ir(111) substrate. The corresponding angles between Ir[110] and the high-symmetry direction of $(\sqrt{7}\times\sqrt{7})$ of the two silicene domains are 40.9° and 19.1°, respectively.

Figure 9.5c,d shows large-area and zoomed-in STM images of one silicene domain. The angle between the orientation of the silicene superstructure and the Ir[110] direction is 40.9°, consistent with the result detected in the $(\sqrt{7}\times\sqrt{7})$ LEED patterns in Fig. 9.5a. The overview STM image shows a long-range ordered hexagonal lattice of protrusions. Figure 9.5e shows the line profile along the black line in Fig. 9.5d. The periodicity of the bright protrusions in the STM image is approximately 0.72 nm, which is $\sqrt{7}$ times the Ir(111) lattice constant (0.271 nm). The height of the protrusions in the silicene overlayer is approximately 0.6 Å, indicating that silicene on Ir(111) is buckled.

In the high-resolution STM image shown in the upper part of Fig. 9.5f, the different regions of a unit cell are marked by upward and downward triangles. The middle and bottom parts are the STM simulation and the optimized geometric structure of silicene on Ir(111) based on DFT calculations, respectively [9.19, 20]. The protruding silicon atoms are yellow, while the other silicon atoms are orange. The unit cell of the $(\sqrt{7}\times\sqrt{7})$ superstructure is indicated by a black rhombus. There are six silicon atoms in the unit cell: one (yellow) sits on the top site, two are located at the hcp hollow and fcc hollow sites, and the other three are located at the bridge sites. The silicon atoms at different sites exhibit different silicon–substrate interactions and thus have different heights and electron density distributions. The simulated STM image shown in the middle part of Fig. 9.5f is highly consistent with the experimental STM image.

A further electron localization function calculation implies that the interaction between silicon atoms is via covalent bonding, while the interaction between silicon and iridium is mainly electrostatic. This electrostatic in-

teraction is not strong enough to affect the formation of Si–Si bonds or the extension of the silicon sheet; two-dimensional continuous silicene has indeed been successfully fabricated on Ir(111).

9.2.2 Silicene on Ag(111) and Other Transition-Metal Substrates

Epitaxial silicene on Ag(111) is synthesized by directly depositing silicon atoms onto the Ag(111) surface and then annealing in UHV [9.103–105, 107]. A variety of silicene superstructures can be formed depending on the substrate temperature, deposition rate, and silicon coverage. At lower substrate temperature, below 400 K, silicon atoms deposited on Ag(111) tend to form silicon clusters or disordered structures. When the substrate temperature is above 400 K during deposition, the resulting silicene sheet typically exhibits five ordered phases: from the T phase to (4×4), $(\sqrt{13}\times\sqrt{13})$ R $\pm$ 13.9°, $(2\sqrt{3}\times 2\sqrt{3})$, and finally to a $(\sqrt{3}\times\sqrt{3})$ phase with increasing substrate temperature, while other ordered structures can also be observed. The deposition rate also plays an important role because it can affect the nucleation rate and growth rate of silicene. A recent DFT calculation by *Shu* et al. revealed that the silicene nucleation rate on Ag(111) is very high compared with the rate of graphene nucleation on TM surfaces due to the low diffusion barrier of Si atoms and the low nucleation barrier [9.109]. Such higher deposition rates would lead to silicene samples that have smaller domains and more defects. In addition, the coverage of silicon is also important, since an inappropriate value will lead to other silicon phases.

The structure and properties of silicene on Ag(111) remain under debate, although the silicene/Ag(111) system has been intensively studied in the past few years. Synthesis of monolayer silicene was first reported by *Lalmi* et al. on an Ag(111) surface [9.107]. However, based on their experimental measurements, the reported lattice parameter of silicene was approximately 17% smaller than that of bulk silicon. *Lay* et al. later argued that such a small lattice actually corresponds to a clean Ag(111) (1×1) surface rather than silicene [9.111]. *Vogt* et al. claimed to have synthesized monolayer silicene on Ag(111) for the first time, revealing a superstructure of (3×3) silicene on a (4×4) Ag(111) surface in STM images, as shown in Fig. 9.6a [9.98]. This phase was also observed by Feng et al. However, *Feng* et al. proposed it to be incomplete silicene stabilized by hydrogen with ordered holes (Fig. 9.6b) [9.103]. In-

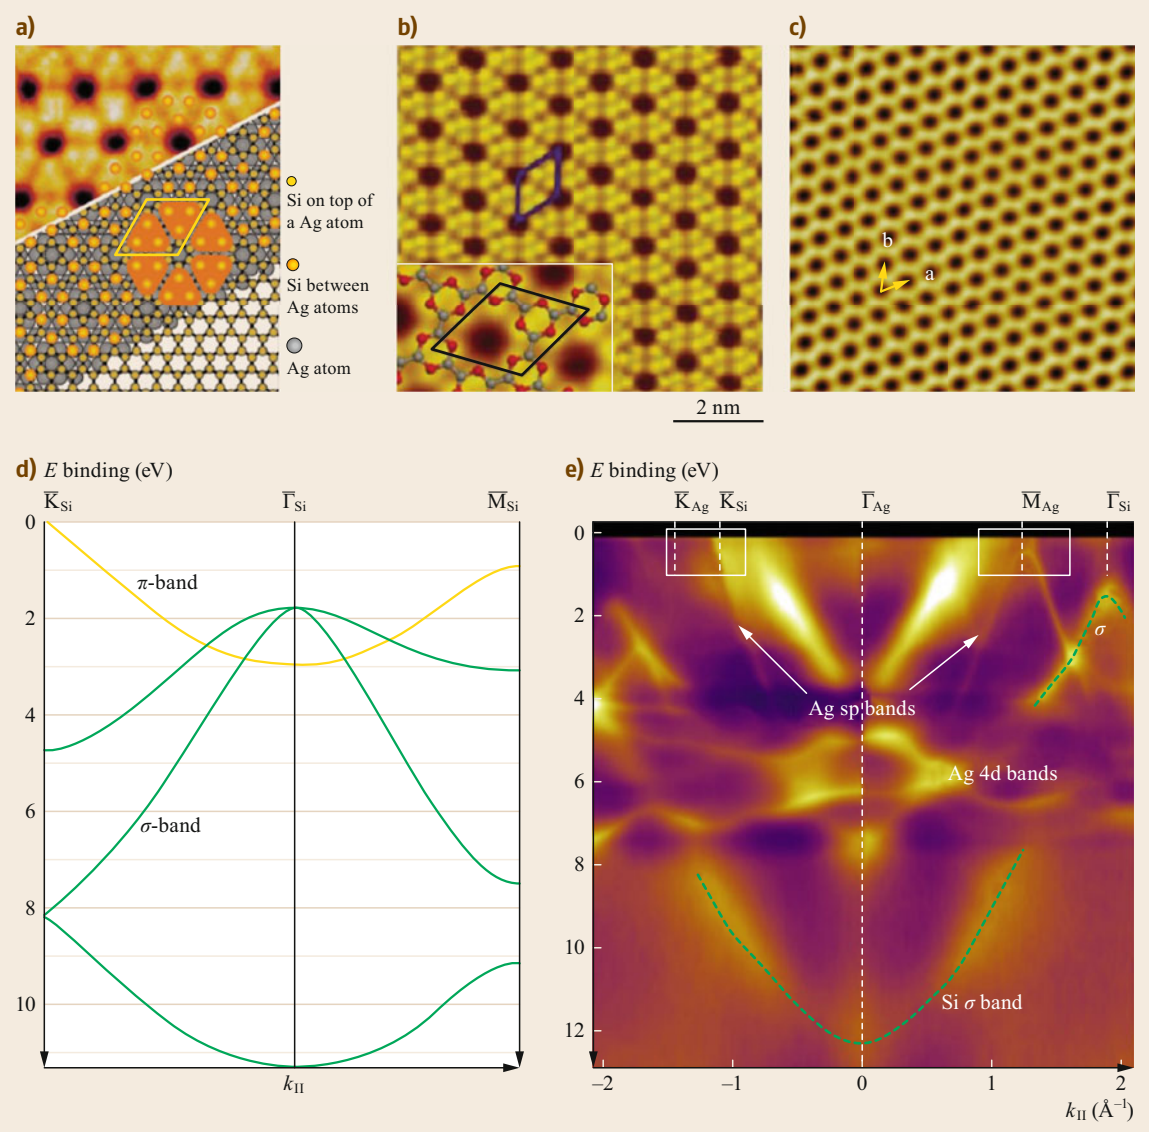

Fig. 9.6a–e Silicene on Ag(111). **(a)** STM image, atomic structure, and simulated STM image of silicene on Ag(111) [9.98]. **(b)** STM image of (3×3) superstructure of silicene on Ag(111) with one-potential atomic models [9.103]. **(c)** STM image of silicene monolayer showing the $(\sqrt{3}\times\sqrt{3})$ R30° honeycomb superstructure ($U = 1.2$ V, measurement temperature 77 K [9.103]). **(d)** Calculated band dispersion of σ (*green*) and π (*yellow*) states of a free-standing (1×1) silicene layer [9.110]. **(e)** Angle-resolved photoemission spectra of (4×4) silicene grown on Ag(111) using photon energy of 135 eV. *Dashed green lines* follow the dispersion of the Si-σ state [9.110] (reprinted by permission from [9.98, 103, 110], © APS 2012, ACS 2012, and Elsevier 2017)

stead, true monolayer silicene is in another phase with a honeycomb-like $(\sqrt{3}\times\sqrt{3})$ R30° superstructure, as shown in Fig. 9.6c. Later, *Resta* et al. and other groups reported their observation of the same phase as shown in Fig. 9.6b; they found that the $(\sqrt{3}\times\sqrt{3})$ R30° phase is always found on the thicker patch of the sample, indicating that it may possibly be multilayer silicene [9.112]. Later, *Chen* et al. found a phase transition of silicene on Ag(111) [9.113]. At temperatures above 40 K, silicene on Ag(111) has a $(\sqrt{3}\times\sqrt{3})$ R30° honeycomb structure; however, below 40 K, it transforms into two mirror-symmetric rhombic structures that are boundary

separated but energy degenerate. DFT calculations on monolayer silicene structures have indicated that the energy barrier between these two configurations is very small (no more than 38 meV). This enables a dynamic flip–flop motion that cannot be followed by STM at sample temperatures higher than 40 K, resulting in the $(\sqrt{3}\times\sqrt{3})$ R30° honeycomb structure observed in STM images.

The electronic properties of silicene on Ag(111) have also been investigated. It has been reported that silicene on Ag(111) exhibits linear electronic dispersion resembling that of relativistic Dirac fermions at the K points of the Brillouin zone based on angle-resolved photoemission spectroscopy measurements [9.98], and STS measurements [9.105]. *Feng* et al. also provided direct evidence for the existence of Dirac cones in the monolayer silicene (3×3)/Ag(111) system by observing that the Dirac cones evolve with increasing binding energy around both the M and K points [9.114]. However, their arguments were questioned later because the influence of the Ag substrate was shown to be nonnegligible. *Lin* et al. argued that silicene would lose its Dirac fermion characteristic due to substrate-induced symmetry breaking and that the linear dispersion characteristic originates from the Ag bulk sp-band along the Γ-K direction [9.115]. Moreover, *Carbone* et al. investigated (4×4) silicene on Ag(111) and mixed (4×4) and $(\sqrt{13}\times\sqrt{13})$ R13.9° silicene on Ag(111) [9.110, 116, 117]. They found that the Ag(111) substrate modified the π band of freestanding silicene (Fig. 9.6d) and that the reported Dirac fermion feature derives from the Ag interface state (Fig. 9.6e) rather than silicene. Further experimental and theoretical studies are thus needed to clarify this phenomenon.

9.3 Germanene Growth on Transition-Metal Surfaces

Freestanding germanene is also a low-buckled structure similar to silicene. The spin-orbital effect can open a bandgap of 23.9 meV, much wider than those of graphene and silicene (1.55 and 2.9 meV, respectively) [9.20]. The quantum spin Hall effect can thus be observed in germanene. Germanene has been fabricated on several substrates by an epitaxial growth method, e.g., on Pt(111) [9.22], Au(111) [9.118], Al(111) [9.119], and MoS_2 [9.120] surfaces. In this section, we discuss in detail the epitaxial growth and characterization of germanene on Pt(111), Au(111), and MoS_2 surfaces.

9.3.1 Germanene Growth on a Pt(111) Surface

Epitaxial germanene on Pt(111) has been synthesized by depositing germanium atoms on a clean Pt(111) surface at room temperature under UHV conditions and then annealing in the temperature range of 600–750 K for 30 min [9.22]. The annealing temperature was kept below 800 K to avoid the formation of Ge-Pt surface alloy. Germanene was then fabricated, as shown in Fig. 9.7. LEED was used to characterize the superstructure, as shown in Fig. 9.7a. The six outer bright spots correspond to the (1×1) diffraction spots of the Pt(111) surface. The additional distinct diffraction spots originate from the germanium superstructure. These diffraction spots can be divided into two groups, identified by red and blue spots in Fig. 9.7b, originating from two different germanium superstructures with rotation of 23.4° and 36.6° relative to the Pt[$1\bar{1}0$] direction, respectively. From the LEED pattern, a $(\sqrt{19}\times\sqrt{19})$ superstructure with respect to the Pt(111) surface can be identified.

The long-range order of the germanium superstructure formed on a Pt(111) surface can be seen in Fig. 9.7c. The small rhombus indicates the supercell of the superstructure. The orientation of the supercell is rotated by approximately 23° relative to the Pt[$1\bar{1}0$] direction, which is consistent with the LEED results. Figure 9.7d shows a zoomed-in STM image of Fig. 9.7c. There are three bright spots in the supercell; one spot is at the corner of the rhombus, while two lie inside the rhombus. Figure 9.7e shows the line profile along the dashed line in Fig. 9.7d, revealing that the periodicity of the superlattice in the STM image is approximately 1.2 nm. The corrugation of the germanium layer is approximately 0.6 Å. Previous theoretical studies predicted the lattice constant of free-standing germanene to be approximately 3.97–4.02 Å. In that case, a (3×3) superlattice of germanene has a lattice spacing of approximately 11.91–21.06 Å, matching well with the periodicity of the superlattice obtained from the STM measurements.

DFT calculations were performed to obtain the detailed structure and properties of the germanium adlayer on Pt(111). Several models with (3×3) germanene on Pt(111) surface were considered, in which the germanium atoms have different locations with respect to the substrate. Figure 9.7f shows the most stable configuration; the binding energy per germanium atom

The close-packed direction of Pt[110] is indicated by the *black arrow*. The angle between the *blue* and *black arrows* is approximately 23°. **(d)** Zoomed-in STM image ($U = 1$ V, $I = 0.05$ nA) of germanene on the Pt(111) surface. **(e)** Line profile along the *dashed line* in panel **(d)**, revealing the periodicity of the germanium superstructure (1.2 nm). **(f)** Optimized geometric structure of germanene on the Pt(111) surface; the *yellow rhombus* indicates the unit cell. *Blue*, *yellow*, and *orange spheres* represent Pt, protruding Ge, and other Ge atoms, respectively. **(g)** Simulated STM image of germanene on Pt(111) surface, showing similar features to the STM image (reprinted by permission from [9.22], © Wiley 2014)

is approximately 1.39 eV. After relaxation, the honeycomb structure of the germanium adlayer becomes distorted; however, the six-membered rings structure is maintained. There are four protrusions labeled in yellow at the vertices of the rhombus and two at the centers of the two triangular regions in a supercell. These features match well with the STM observations in Fig. 9.7d. STM simulations were performed using the Tersoff–Hamann approach for comparison with the STM observations. The simulated STM image is shown in Fig. 9.7g; it has the same features as the STM image, namely four bright spots at the vertices of the rhombus and two at the center. This STM simulation further confirms that the superstructure observed by STM is a distorted germanium adlayer (germanene) on the Pt(111) surface.

Although the germanene layer has a distorted and buckled structure, it is a continuous layer rather than a germanium adatom array, according to electron localization function (ELF) calculations [9.22]. The charge localization between any two neighboring germanium atoms is very strong, indicating strong covalent bonding between neighboring germanium atoms. The charge localizations between germanium atoms and the underlying Pt atoms are all very weak; the interactions between germanium and the underlying Pt atoms are mainly electrostatic. The interactions are not strong enough to affect the formation of Ge−Ge bonds and the extension of the germanium sheet. STM measurements and DFT calculations demonstrate that a continuous 2-D germanene layer was successfully fabricated on Pt(111).

It is worth noting that Ge-Pt surface alloys have also been reported previously. *Ho* et al. prepared their samples by annealing at 900–1200 K to form a Ge-Pt surface alloy [9.121]; this annealing temperature is much higher than that used when preparing germanene samples [9.22]. In STM images of the Ge-Pt alloys, only four bright protrusions were located at the corners of each $(\sqrt{19} \times \sqrt{19})$ supercell with respect to the (1×1) Pt(111) surface. It has fewer features per unit cell than the present high-resolution STM image shown in Fig. 9.7d. *Švec* et al. also proposed a $(\sqrt{19} \times \sqrt{19})$ Ge-Pt surface alloy tetramer model [9.122]. In their simulated STM image, there are also only four bright spots at the corner of each $(\sqrt{19} \times \sqrt{19})$ supercell. At the center of the supercell, the brightness is much lower. One bright and one dark triangular-shaped feature can

be found at the centers of the supercell. Thus, these two Ge-Pt surface alloy models are not applicable to the germanene case.

9.3.2 Germanene Growth on a Au(111) Surface

An atomically thin, two-dimensional multiphase germanene film was fabricated using germanium molecular beam epitaxy on a Au(111) surface as the substrate [9.118]. Several different substrate temperatures were used to anneal the film. A combination of LEED and STM observations was performed at room temperature at different growth stages. The reason for choosing Au(111) as the substrate is that the inverse system, viz. gold grown on a Ge(111) surface, was confirmed in a recent study to form atomically sharp interfaces, without intermixing [9.123].

Figure 9.8 shows an STM image of a monolayer germanium adlayer on a Au(111) surface obtained at a growth temperature of $\approx 200\,^{\circ}\mathrm{C}$. The size of the germanium adlayer on the Au(111) surface is greater than $50 \times 50\,\mathrm{nm}^2$ with a honeycomb appearance and a very small corrugation of only 0.01 nm. Here, the cell size of the honeycomb arrangement is much larger than that of a freestanding monolayer germanene. The cell size of the honeycomb structure in the bottom left corner fits to a $(\sqrt{7} \times \sqrt{7})$ R19.1° superstructure in terms of Au(111). Figure 9.8b shows the LEED pattern of the germanium adlayer superstructures on the Au(111) surface. Figure 9.8c shows a schematic diagram of the diffraction spots in Fig. 9.8b. Diffraction spots from different phases can be observed, namely those from the $(\sqrt{19} \times \sqrt{19})$ R23.4°, (5×5), and $(\sqrt{7} \times \sqrt{7})$ R19.1° phases.

Although the unit cell of the superstructures with respect to the Au(111) surface is confirmed by the STM image and LEED pattern, detailed information regarding the surface adlayer is still difficult to obtain due to the lack of atomic-resolution STM images. According to the previous study, the distance between neighboring germanium atoms is $d_{\mathrm{Ge-Ge}} = 0.238\,\mathrm{nm}$. For the $(\sqrt{7} \times \sqrt{7})$ superstructure, both (2×2) and $(\sqrt{3} \times \sqrt{3})$ R30° germanene adlayers could be possible structures of the unit cell due to the small lattice mismatch. The Ge−Ge distances are 0.221 and 0.255 nm (projected in-plane Ge−Ge distance) for (2×2) and $(\sqrt{3} \times \sqrt{3})$ R30° germanene, respectively.

DFT calculations were performed to optimize the possible geometric structures and simulate the STM images. Figure 9.9 shows several optimized structures and their STM simulations. Due to the lattice mismatch of (2×2) freestanding germanene on the $(\sqrt{7} \times \sqrt{7})$ Au(111) surface, the 4.2% compression strain distorts the germanene lattices and induces considerable buckling in the structure. The atomic structures and simulated STM images of the two lowest-energy structures for (2×2) germanene on top of the $(\sqrt{7} \times \sqrt{7})$ Au(111) supercell are shown in Fig. 9.9a,b. The average height variations in structures 1 and 2 are 0.150 and

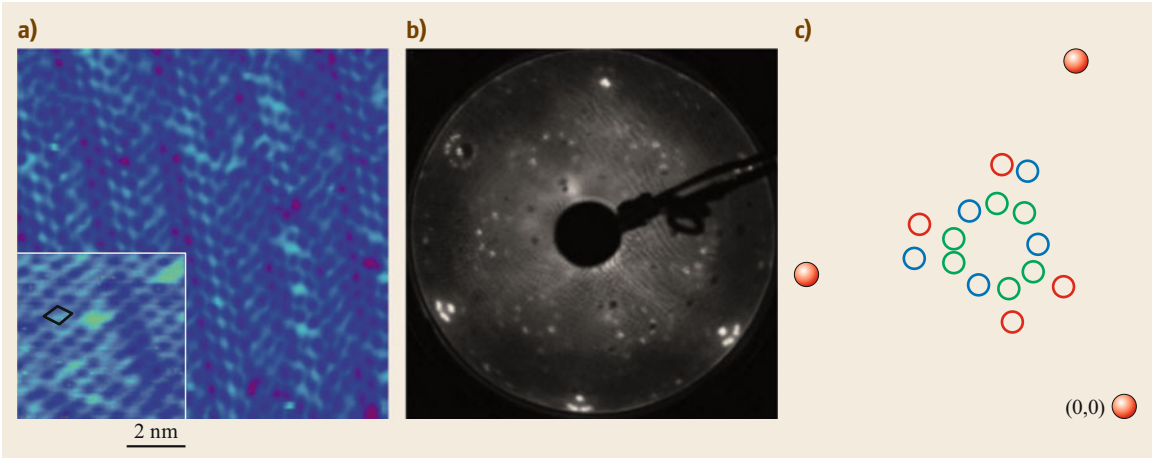

Fig. 9.8a–c STM image and LEED pattern of germanene/Au(111) superstructure. **(a)** STM image of germanium honeycomb structure on a Au(111) surface, where the modulated honeycomb $(\sqrt{7} \times \sqrt{7})$ superstructure is in the *bottom left corner* ($U = -1.12\,\mathrm{V}$, $I = 1.58\,\mathrm{nA}$; the $(\sqrt{7} \times \sqrt{7})$ unit cell is drawn in *black*). **(b)** LEED pattern taken at 59 V; **(c)** schematic illustration of one-sixth of the pattern, with *filled dots*: hidden (0,0) spot and integer order spots, *open circles*: *red*, *blue*, and *green spots* corresponding to the $(\sqrt{7} \times \sqrt{7})$, $(\sqrt{19} \times \sqrt{19})$ and (5×5) superstructure, respectively (reprinted by permission from [9.118], © Institute of Physics 2014)

Structures 1 **(a)** and 2 **(b)** have (2×2) periodicity, while structure 3 **(c)** has $(\sqrt{3}\times\sqrt{3})$ periodicity with respect to germanene. Protruding Ge atoms are highlighted in *dark red*. The *yellow rhombus* in the STM image indicates the supercells. **(d)** Comparison between STM image (*upper panel*) and simulated STM image for structure 3 after smearing (*lower panel*) (reprinted by permission from [9.118], © Institute of Physics 2014)

0.142 nm, respectively, much larger than what is measured in experiments. In contrast, for the $(\sqrt{3}\times\sqrt{3})$ germanene structure on the $(\sqrt{7}\times\sqrt{7})$ Au(111) surface, the surface adlayer is much flatter (with buckling of less than 0.05 nm). Figure 9.9d shows a comparison between the STM image and the smeared STM simulation image in Fig. 9.9c; their bright spot features match well. DFT calculations also found that structure 3 is more stable than structures 1 and 2. The absorption energy per germanium atom of structure 3 is approximately 10 meV lower than that of structures 1 and 2. In addition, the Au-Ge alloy was also considered. However, the 3d core-level spectra of Ge does not match the experimental observations. The possibility of a Au-Ge alloy can thus be excluded. Finally, a $(\sqrt{3}\times\sqrt{3})$ reconstructed germanene layer on top of a $(\sqrt{7}\times\sqrt{7})$ Au(111) surface can be identified.

9.3.3 Germanene Growth on a MoS_2 Surface

When a germanene epitaxial layer forms on a transition-metal substrate, the pristine Dirac nature of germanene will be destroyed due to the hybridization effect between the epitaxial germanene and the transition-metal substrate [9.22, 118, 119]. Therefore, it is of vital importance to fabricate germanene on a semiconductor (or insulator) with a weak germanene–substrate interaction. Recently, *Zhang* et al. reported the growth and electronic properties of germanene on MoS_2 [9.120].

The MoS_2 samples were cleaved from synthesized 2H-MoS_2 and mounted on a Mo sample holder then introduced into an ultrahigh-vacuum system. Ge was deposited onto the MoS_2 substrate at room temperature and annealed at 1100 K. After the deposition of germanium, the MoS_2 sample was immediately inserted into the STM chamber. The deposition rate was estimated by analyzing several STM images.

Figure 9.10a shows a small-scale STM image of the MoS_2-germanium system. The much brighter STM image of germanium islands on the substrate can be observed clearly. Figure 9.10b,c shows zoomed-in images of the bare MoS_2 substrate and germanium island part, respectively. Differential conductivity (dI/dV) spectra for a germanium island and the bare MoS_2 substrate are depicted in Fig. 9.10d. On the bare MoS_2 region, the dI/dV curve shows a gap near zero bias, which can be explained by the semiconductor properties of MoS_2. In contrast, the dI/dV curve shows a well-defined V shape around zero bias on the germanium island. Un-

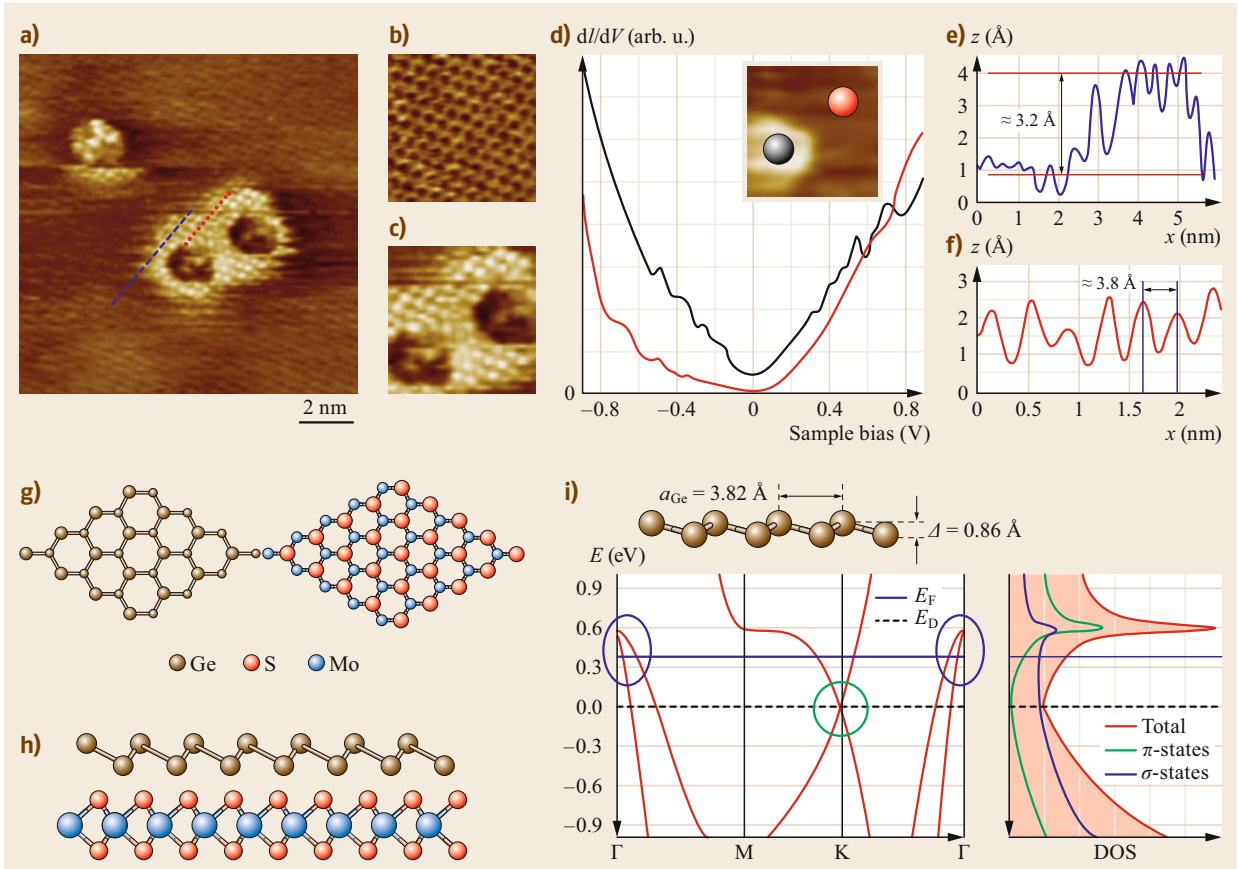

Fig. 9.10a–i Germanium structure on MoS_2. **(a)** STM image of germanium island on MoS_2 substrate ($U = 0.5$ V and $I = 0.3$ nA). **(b)** Zoomed-in STM image on a bare MoS_2 area. **(c)** Zoomed-in STM image on the germanene island of panel **(a)**. **(d)** dI/dV curves on a germanene island (*black curve*) and bare MoS_2 surface (*red curve*). **(e)** Line profile taken across the germanene island indicated by the *blue dashed line* in **(a)**. The apparent height of the germanene islands is ≈ 3.2 Å. **(f)** Line scan taken on top of the germanene island indicated by the *red dashed line* in **(a)**. The measured lattice constant of the germanene island corresponds to 3.8 ± 0.2 Å. **(g)** *Top* and **(h)** *side view*, respectively, of the schematic model of germanene on MoS_2. **(i)** Band structure and projected density of states of the contracted germanene with lattice constant of 3.8 ± 0.2 Å (reprinted by permission from [9.120], © American Physical Society 2016)

der a small bias voltage, the differential conductivity is proportional to the density of states; the density of states of the germanium islands should thus also exhibit a V shape, which is one of the hallmarks of a 2-D Dirac system. Based on the dI/dV measurements, it was concluded that the germanium islands are actually germanene islands. Figure 9.10e,f shows the line profiles across the germanene island as labeled by blue and red dashed lines in Fig. 9.10a. The height of the germanene island is ≈ 3.2 Å, and the periodicity is ≈ 3.8 Å. After increasing the deposition of germanium, the germanium islands become much larger, and a near-monolayer island can be obtained. Figure 9.10g,h shows the top view and side view, respectively, of the schematic model of germanene on MoS_2. The germanium island and the underlying MoS_2 substrate have the same threefold symmetry.

DFT calculations were performed to elucidate the STM observations. Figure 9.10i shows the band structure and projected density of states of contracted germanene with a lattice constant of 3.8 ± 0.2 Å. The germanene is metallic since there are two σ bands close to the Γ point crossing the Fermi energy, while the π bands lead to the formation of a Dirac cone in the vicinity of the K point. The contribution of the σ states to the density of states (DOS) is weakly dependent on energy, as the corresponding dispersion is nearly quadratic [$E_\sigma(k) \propto k^2$]. Therefore, the observed V shape of the total DOS originates predominantly from the π states of germanene.

9.4 Synthesis of Stanene and Other Related Monolayers

In comparison with the first three elements in group IVA (carbon, silicon, and germanium), tin behaves differently. The element tin is usually classified as a post-transition metal. Thus, it is not natural for tin to form a honeycomb monolayer.

9.4.1 Epitaxial Stanene on a Bi_2Te_3 Surface

Stanene is also an important member of the two-dimensional group IVA materials. Theoretical studies have predicted that two-dimensional stanene has a larger bandgap [9.124, 125] and could support a near-room-temperature quantum anomalous Hall (QAH) effect [9.126]. Thermoelectricity enhancement and topological superconductivity of stanene have also been reported [9.127, 128]. Two-dimensional stanene was first synthesized on a $Bi_2Te_3(111)$ surface by using the MBE method [9.23]. High-purity (99.999%) Sn was evaporated from effusion cells onto a flat and well-ordered Bi_2Te_3 surface. The deposition rate was approximately 0.4 ML/min, while the substrate was kept at room temperature. The thickness and growth mode of the Sn film were monitored by reflection high-energy electron diffraction (RHEED) and STM. The STM images were acquired at 77 and 4 K.

Figure 9.11 shows the atomic structure of freestanding stanene and stanene on a Bi_2Te_3 surface. Freestanding stanene has a two-dimensional structure similar to that of silicene and germanene, with a buckled honeycomb lattice as shown in Fig. 9.11a. The height difference between the upper and lower Sn atoms is approximately 0.1 nm. Figure 9.11b shows the RHEED pattern after deposition of an ultrathin Sn film. According to the distance between adjacent diffraction lines in the RHEED patterns obtained before and after deposition of stanene, the in-plane lattice constant of the Sn film matches the substrate within the experimental uncertainty. Figure 9.11c shows the RHEED intensity as a function of deposition time, revealing an obvious variation of the RHEED intensity. The stanene film was formed when deposition was stopped near the peak position of the RHEED intensity, as marked by the blue arrow. STM was also used to investigate the structure of stanene on the $Bi_2Te_3(111)$ surface. Figure 9.11d,e shows large terraces and steps of single quintuple-layer height of the $Bi_2Te_3(111)$ surface and STM topography of Sn films of more than single biatomic layer coverage. Under this coverage, several layers of Sn are observed. According to the measured height line profile in Fig. 9.11f (corresponding to the black line in Fig. 9.11e), the height between the first, second, and third layers of Sn is the same, viz. approximately 0.35 ± 0.02 nm, consistent with the spatial distance between the biatomic layers along the $\langle 111 \rangle$ direction in α-Sn. This indicates that the observed Sn film is a biatomic-layer structure. The large-scale STM topography of the stanene film in Fig. 9.11g indicates that the stanene film is unperturbed after stanene growth. Sharp Bi_2Te_3 steps with a height of 1 nm were still observed, as shown in Fig. 9.11j. Figure 9.11h shows a zoom-in STM image of the stanene film, revealing that it covers about 90% of the substrate and that about 10–15% of the Sn atoms stay on top of it as small islands. From the atomic-resolution STM image in Fig. 9.11i, a (2×2) reconstruction of the surface Sn atoms was observed. The stanene film is not perfectly flat, showing a random height modulation of approximately 0.06 nm, which can be observed from the height line profile in Fig. 9.11k. The biatomic-layer structure of the stanene film is further confirmed by Fig. 9.11l, m. The height difference between the upper and lower atoms is approximately 0.12 ± 0.02 nm, which matches well with the distance between Sn atomic layers in the biatomic-layer structure of stanene.

9.4.2 Epitaxial Hafnene Growth on an Ir(111) Surface

Studies on graphene, silicene, germanene, and other 2-D atomic crystals have been highly successful. However, all these materials are made of group IVA elements, in which the atoms are bonded through sp^2-hybridized orbitals. Meanwhile, two-dimensional atomic crystals made of elements with d electrons are still rare. The questions of whether transition-metal atoms can form monolayer atomic crystals and whether such structures will exhibit novel properties have attracted tremendous interest. Recently, the first pure transition-metal epitaxial honeycomb lattice of hafnium, so-called hafnene, was reported by *Li* et al. [9.129].

Experiments were performed in an UHV system with base pressure in the range of 10^{-10} mbar. Epitaxial hafnene was synthesized by depositing Hf on a clean Ir(111) surface at room temperature and then annealing at 673 K. The sample was subsequently annealed until a well-ordered structure was observed. STM and LEED were performed to characterize the structure and electronic properties of the sample.

Figure 9.12a shows an STM image of a continuous two-dimensional lattice with a honeycomb structure. The orientation of the honeycomb structure is parallel

to the close-packed $[1\bar{1}0]$ direction of the Ir(111) lattice. The inset LEED pattern reveals that the hafnium honeycomb structure on Ir(111) is a (2×2) superstructure with respect to the Ir(111) lattice. Figure 9.12b shows a zoom of the image in Fig. 9.12a; a perfect honeycomb lattice can be observed. The height profile curve in Fig. 9.12c indicates that the periodicity of the honeycomb lattice is 5.4 Å, consistent with the (2×2) superstructure implied by the LEED pattern. The distance between neighboring hafnium atoms can thus be estimated to be approximately 3.12 Å, very close to the hafnium–hafnium bond length in the bulk material. This suggests that the honeycomb structure is a compact graphene-like structure rather than a hafnium adatom array on the Ir(111) surface.

DFT calculations were also conducted to confirm the experimental observations. To determine the most likely structure on the Ir(111) surface, several different geometric structures thereon were considered. The pure Hf honeycomb lattice on the Ir(111) surface was found to be the most stable structure. Figure 9.12d shows the STM images (top panel), STM simulations (middle panel), and optimized geometry of a hafnium layer on the Ir(111) surface deduced from STM images (lower panel). The simulated STM image shows perfect honeycomb electronic states, consistent with the STM image, further confirming that the hafnium honeycomb structure was successfully fabricated on the Ir(111) surface. Since the hafnium monolayer structure is made of only hafnium atoms and has a similar honeycomb structure to graphene, it can thus be called *hafnene*. Apart from the Ir(111) surface, hafnene can also form on a Rh(111) surface, indicating that hafnene has a very stable honeycomb structure and can be easily synthesized [9.129].

Because hafnium is a transition metal, unlike carbon, silicon, germanium, and other group IVA atoms, monolayer hafnene exhibits its own peculiar properties. Figure 9.12e shows the spin-polarized band structure and density of states of freestanding monolayer hafnene. The density of states of hafnene reveals that d-orbitals are the major contributors to the electronic states around the Fermi energy. This honeycomb structure is metallic, and an obvious spin-polarized density of states can be observed. Further calculations showed that hafnene is ferromagnetic with a magnetic moment of $1.46\,\mu_B$ per Hf atom. Band structure calculations also suggest that Dirac cones exist at the Fermi energy near the K and K′ points of the Brillouin zone for spin-up states. The Fermi velocity at the Dirac cone is approximately 25% of that in graphene. The spin–orbit coupling effect can open a gap of 0.05 eV at the Dirac point. Due to the exchange coupling effect between electrons, the Dirac cone for the spin-down states is about 1.0 eV higher than that for the spin-up states. Such a spin-polarized density of states with d-dominated orbitals around the Fermi energy opens up potential applications for hafnene in spintronics and catalysis.

Although hafnene can be formed on different metal surfaces, the nature of the bonding still needs to be uncovered. This would be helpful for the future construction of transition-metal and other atomic honeycomb structures. These honeycomb structures could provide new platforms to investigate hitherto-unknown quantum phenomena and electronic behaviors in 2-D systems, which may have broad potential applications in future nanotechnology and related areas.

In addition to stanene and hafnene, there has also been progress in synthesizing other metallic element monolayer structures. One such advance is the formation of unsupported iron membranes in graphene nanopores [9.130]. Zhao et al. noticed that, when transferring graphene to TEM grids using $FeCl_3$ etching solution, remnant Fe species from decomposed $FeCl_3$ formed in graphene nanopores. Comprehensive experimental observations and theoretical calculations showed that 2-D crystalline Fe membranes formed in graphene nanopores. Theoretical calculations also predict that a Au membrane can exist in graphene nanopores [9.131]. Meanwhile, recent experiments have shown that a monolayer oxide membrane can form as well [9.35, 36].

9.5 Outlook

As an effective method for synthesizing various types of 2-D material, epitaxial growth on transition-metal substrates has made significant advantages. The growth process is well controlled. The fabricated materials are of extremely high quality. However, challenges remain. To take advantage of the as-fabricated high-quality 2-D materials for devices, scientists either need to develop easy and reliable transfer techniques that do not cause too much damage, or fabricate devices in situ. There has been significant progress in both directions in recent years. We can expect an increasing number of high-quality group IVA monolayer materials to be synthesized on more transition-metal surfaces, ultimately leading to the construction of devices.

Yu-Yang Zhang

Institute of Physics and University of Chinese Academy of Sciences
Chinese Academy of Sciences
Beijing, China
zhangyuyang@ucas.ac.cn

Yu-Yang Zhang is associate professor at the School of Physical Sciences, University of Chinese Academy of Sciences. He obtained his PhD degree from the Institute of Physics, Chinese Academy of Sciences and completed two terms as a postdoc at Rensselaer Polytechnic Institute and Vanderbilt University. His research includes quantum-mechanical DFT calculations to understand the fundamental physics of materials and devices for future nanoelectronics and energy-related applications.

Jinbo Pan

Institute of Physics and University of Chinese Academy of Sciences
Chinese Academy of Sciences
Beijing, China
jbpan@iphy.ac.cn

Jinbo Pan received his PhD in physics from the Institute of Physics, Chinese Academy of Sciences in 2016. He subsequently held a postdoctoral position at Temple University. He became an associate professor at the Institute of Physics, Chinese Academy of Sciences in 2019. His research interests focus on the construction of a two-dimensional materials database, and their applications in electronics and catalysis.

Shixuan Du

Institute of Physics and University of Chinese Academy of Sciences
Chinese Academy of Sciences
Beijing, China
sxdu@iphy.ac.cn

Shixuan Du studied at Peking University (B.S.), and received her PhD in physical chemistry from Beijing Normal University in 2002. She was appointed as associate professor in 2002 and became a professor at the Institute of Physics, Chinese Academy of Sciences in 2009. Her research interests focus on DFT calculations of the structural, physical, and dynamic properties of low-dimensional materials.

Hong-Jun Gao

Institute of Physics and University of Chinese Academy of Sciences
Chinese Academy of Sciences
Beijing, China
hjgao@iphy.ac.cn

Hong-Jun Gao received his PhD in physics from Peking University in 1994. He became a professor at the Institute of Physics, Chinese Academy of Sciences in 1995. He is an academician of the Chinese Academy of Sciences and of the Developing-Country Academy of Sciences (TWAS). His research interests include the construction and physical properties of quantum nanostructures, including two-dimensional atomic/molecular crystals, and scanning tunneling microscopy/spectroscopy.

10. Thin Oxide Films as Model Systems for Heterogeneous Catalysts

Hans-Joachim Freund, Markus Heyde, Helmut Kuhlenbeck, Niklas Nilius, Thomas Risse, Swetlana Schauermann, Thomas Schmidt, Shamil Shaikhutdinov, Martin Sterrer

This chapter summarizes efforts to use thin oxide films as model supports for heterogeneous catalysts. We demonstrate that the oxide film route provides a useful platform to study oxide surfaces, per se its interaction with species from the gas phase, supported metal and oxide nanoparticles using the entire tool box of surfaces science under ultrahigh vacuum conditions. The extension to use thin oxide films as template also under ambient conditions or under water, is discussed and the potential to use oxide films as genuine two-dimensional materials is exemplified with vitreous and crystalline silica films.

10.1 Preamble

> "A detailed understanding of processes at surfaces requires knowledge of the surface structure at the atomic scale. Unraveling this knowledge for metal surfaces caused the success of surface science and its application to chemical reactions at surfaces and heterogeneous catalysis culminating in the 2007 Nobel Prize for *Gerhard Ertl* [10.2]. The surface science approach was limited for quite a while to metal single crystal surfaces. Only in the mid-nineties, the books by *Cox* [10.3], by *Henrich* and *Cox* [10.4] as well as by *Noguera* [10.5] on oxide surfaces alerted the broader community that this important class of materials should also be included into consideration of surface scientists. The field of oxide surface science has been developed since. The oxide single crystal surface for which most of the data have been published is $TiO_2(110)$ [10.6, 7]. *Henrich* and *Cox* [10.3, 4] also pointed out that reproducible preparation is at the heart of studies on oxide surfaces, specifically bulk single crystal surfaces. Based on this comment researchers started to think about alternative routes to reproducibly prepare oxide surfaces, which led to the birth of thin oxide film surface science [10.8–17]. The idea was to grow oxide films on metal single crystals using the rules of epitaxial growth. If made sufficiently thin, surface charg-

ing, which hampers the investigation of insulating bulk oxides when using charged information carriers, such as electrons or ions, does not occur. The field has further developed tremendously in recent years. Two books [10.18, 19] and a number of review articles have been published on the subject [10.8–17] providing the reader with an impression of what has been achieved. A wide variety of techniques has been applied to study oxide thin films, as collected therein. The present chapter will discuss a number of examples, mainly from the laboratories of the authors, to demonstrate how the field has developed and to highlight interesting avenues for future research in this area.

Before we discuss specific examples, we would like to address a few general scenarios, as schematically indicated in Fig. 10.1. Figure 10.1a shows an oxide film of a thickness chosen in such a way that the buried interface between oxide film and metal support does not influence the surface properties of the oxide film. Molecules, metal or compound (for example another oxide) nanoparticles, deposited and adsorbed on the surface, would experience the same geometric and electronic environment as on a bulk single crystal surface. A different situation is depicted in Fig. 10.1b. Here, the film is so thin that the buried interface influences the properties of the oxide surface, at least electronically, even if the geometric structure were the same as on a bulk single crystal surface, or, instead, it radically changes structure and properties. These ultrathin films are used to create novel materials or grow films that are hard to prepare as thicker samples [10.19]. Examples are silica films [10.20–22], aluminosilicate films [10.23], modeling zeolites or films of quasi crystals [10.24]. However, it may also be used to develop and test general concepts by controlling certain parameters via the presence of the oxide–metal support interface. Consider, for example, charge transfer processes. If the energy to remove an electron from the buried oxide–metal interface is smaller than the energy released by attaching this electron to an adsorbate, then this process is favorable and will occur if an appropriate electron transport mechanism is available in the system under consideration [10.25–27]. Such systems may be of interest for studying electron transfer to adsorbed metal nanoparticles, in order to investigate the general influence of electron transfer on the chemistry on supported particles and on the interface between the metal nanoparticle and the oxide film. Another option is to create a film, which does not fully cover the metal support, so that there is an open oxide metal interface between the oxide film and the metal single crystal (Fig. 10.1c) [10.28]. This is often called an inverse catalyst (inverse with respect to metal particles on oxides) which allows the interrogation of the oxide–metal interface [10.29–31]. The nomenclature is, however, somewhat misleading, as it implies that for the interface it does not matter whether one investigates metals on oxides or oxides on metals. Obviously, this is incorrect, because the surface will be different.

Still, those investigations may be useful in their own right. A situation, schematically represented in Fig. 10.1c may be encountered when dealing with the so-called *strong metal support interaction* (SMSI) [10.32–41]. The scenarios sketched in Fig. 10.1b and Fig. 10.1c are, of course, relevant to model catalysts and conceptually such studies also offer the possibility to combine them with approaches modeling the bulk situation based on the scheme depicted in Fig. 10.1a. Figure 10.1d, again, shows an oxide film of sufficient thickness to model the bulk without interference of the buried metal–oxide interface. However, in this case, dopants have been implanted into the oxide film [10.42–48]. If the appropriate combination between host material and dopant is chosen then one might envision that those dopants serve as sources for electron transfer to induce a situation, which is similar to the one encountered for ultra-thin films, described above. Within limits, such an approach may be compared with the standard approach in semiconductor physics, where n- and p-doped semiconductors are used to engineer the band structure and, thus, the electronic properties of those materials [10.49, 50]. Realizing that dopants control the electronic properties of oxides offers yet another possibility for studying ultra-thin films. Imagine the situation depicted in Fig. 10.1e: Here, an ultrathin oxide film is grown homoepitaxially on a specially prepared substrate of the same oxide [10.51–53]. In this substrate oxygen vacancies have been created in the oxide by reduction, which renders the substrate conductive. Given the envisioned homo-epitaxial growth on top, those oxygen vacancies would diffuse into the film grown on top upon thermal treatment. However, if a so-called *blocking layer* is introduced, the ultrathin film, grown on top will not be influenced by the exchange of vacancies with the underlying substrate and will behave, as if it was grown on a conductive substrate. Yet the entire system would represent a bulk material. This might be a procedure to approach the situation encountered for bulk single crystals, using, however, the advantages of thin film preparations. There is one aspect, which needs to be included conceptually in this introduction. This aspect is concerned with the possibility to remove ultrathin films from their substrate to create truly two-dimensional materials (Fig. 10.1f), similar to graphene [10.54–56], but based on oxides [10.57, 58]. Those films may, of course, be used to create stacks of two-dimensional materials of varying stoichiometry and varying electronic properties [10.59]."

The paper is organized in four sections: We first report on structural properties of epitaxial oxide films, then we turn to tuning the structural and electronic properties of oxide films, before we discuss their chemical reactivity. While in those sections we report on properties characterized mainly under UHV (ultra-high vacuum) conditions, in the final section we attempt to look at oxide films beyond UHV in an ambient.

10.2 Structural Properties of Epitaxial Oxide Films

"The number of thin-film model systems that have been prepared and characterized in the past is enormous and covers almost all binary oxides existing in the bulk [10.8, 11, 19, 61]. In fact, the variability of thin-film oxides is even larger than that of their bulk counterparts. The reason can be found in the much higher structural and compositional flexibility of oxide films of few-monolayer thickness, giving rise to a plethora of nonstoichiometric, strained and polar structures that would be unstable in the bulk limit [10.8, 62]. Moreover, the geometric template effect of the substrate combined with different electronic coupling schemes is able to stabilize various unusual thin-film configurations [10.19, 63]. In the following, we will introduce the oxide films explored in our group starting with binary ionic alkaline earth oxide surfaces with simple rock salt structure towards transition metal oxides, which can pose considerable challenges with respect to possible surface terminations. The structural properties provide the necessary basis for the subsequent discussion of the electronic as well as chemical properties discussed in Sect. 10.3 to 10.5.

10.2.1 MgO and CaO(100) Films

The two rocksalt oxides MgO and CaO are probably the most prominent model systems for chemically and catalytically-driven surface science stud-

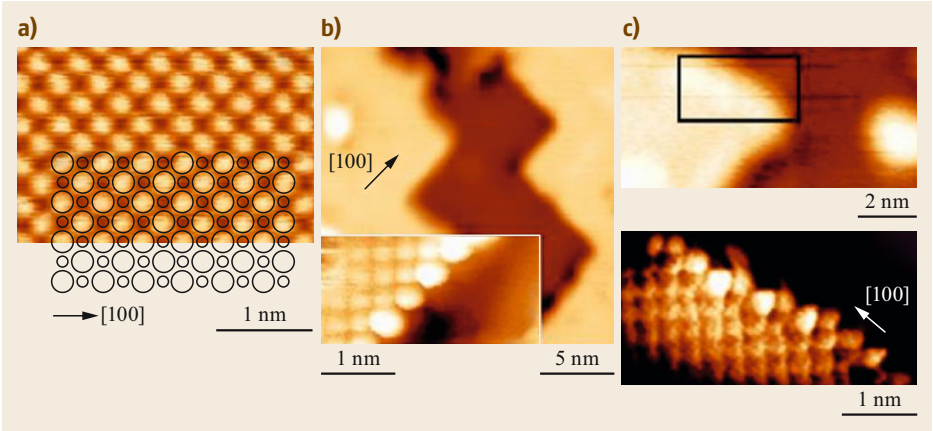

Fig. 10.2a–c Low-temperature STM (scanning tunneling microscopy) images of a 4 ML (monolayer) MgO(100) film on Ag(001), showing an atomically resolved terrace region **(a)**, overview and atomically resolved images of a regular step edge **(b)** and an irregular step edge **(c)**. Only one ionic sublattice of the MgO is resolved in the measurement. Reproduced with permission from [10.60], © Materials Research Society 2019

ies [10.10]. Their importance relies on several aspects. The rocksalt oxides are characterized by particularly simple structural and electronic properties, i.e., a cubic unit cell with two atoms in the base and a wide, electronic band gap, respectively. As a consequence, they are highly accessible to theoretical calculations, but can also be prepared on a variety of squared atomic lattices with matching dimensions. Suitable supports for MgO (lattice parameter 4.2 Å) are Ag(001) [10.64], Fe(001) [10.65] and Mo(001) [10.66, 67], while CaO (lattice parameter 4.8 Å) is typically grown on Mo(001) [10.68]. Given the symmetry of the support, the rocksalt layers develop their thermodynamically preferred (100) termination that is both structurally compact and charge compensated (Fig. 10.2). Attempts to stabilize alternative rocksalt surfaces, e.g., the (111) termination, turned out to be challenging at least in an UHV environment [10.69]. This can be explained with the polar nature of the hexagonal rocksalt plane, which needs to be compensated for either by surface reconstruction or adsorption of charged adspecies [10.70, 71].

The structural quality of MgO and CaO(100) films is largely governed by a nonperfect lattice match with the support, which induces interfacial lattice strain and needs to be released by structural distortions in the film. Not surprisingly, relatively smooth and homogenous MgO films has been grown on Ag(001) that features only 3° lattice mismatch with bulk MgO (Fig. 10.2) [10.64]. The film quality can be further improved by post-annealing these layers at 773 K, followed by a slow cooling-down procedure [10.72, 73]. The lattice mismatch due to Mo(001) is considerably larger (5.3°) and results in the development of a dense dislocation network to compensate the strain [10.67]. These line defects share a number of properties with the grain boundaries in realistic, polycrystalline MgO, and shall thus been discussed in more detail [10.74].

The dislocation network has a periodicity of 55–60 Å with straight defect lines running parallel to the MgO[110] direction, as revealed with STM and grazing incidence x-ray diffraction (GIXD) in real and reciprocal space, respectively [10.75]. Along these directions, an extra Mg–O row that has no counterpart in the Mo support is introduced for 18 regular oxide rows. The result is a (19×19) MgO on (18×18) Mo coincidence lattice with square symmetry (Fig. 10.3). On the atomic scale, the dislocation network is associated with periodic switches of the interface registry, changing from O to Mg ions sitting atop the Mo atoms of the support. Energetically, the O–Mo registry is preferred, as reflected in a shorter interface binding length (2.3 Å) as compared to the Mg–Mo domains (3.5 Å) [10.76]. As the O–Mo and Mg–Mo regions lie on different height levels, the MgO films develops a considerable mosaicity, being reflected in a prominent splitting of the fundamental MgO spots in low-energy electron diffraction data [10.75]. The modulated interface distance also produces a work function pattern on the MgO film, in which high work function values are found for the Mg–Mo registry, while values for the O–Mo domains are 1.5 eV lower. The differ-

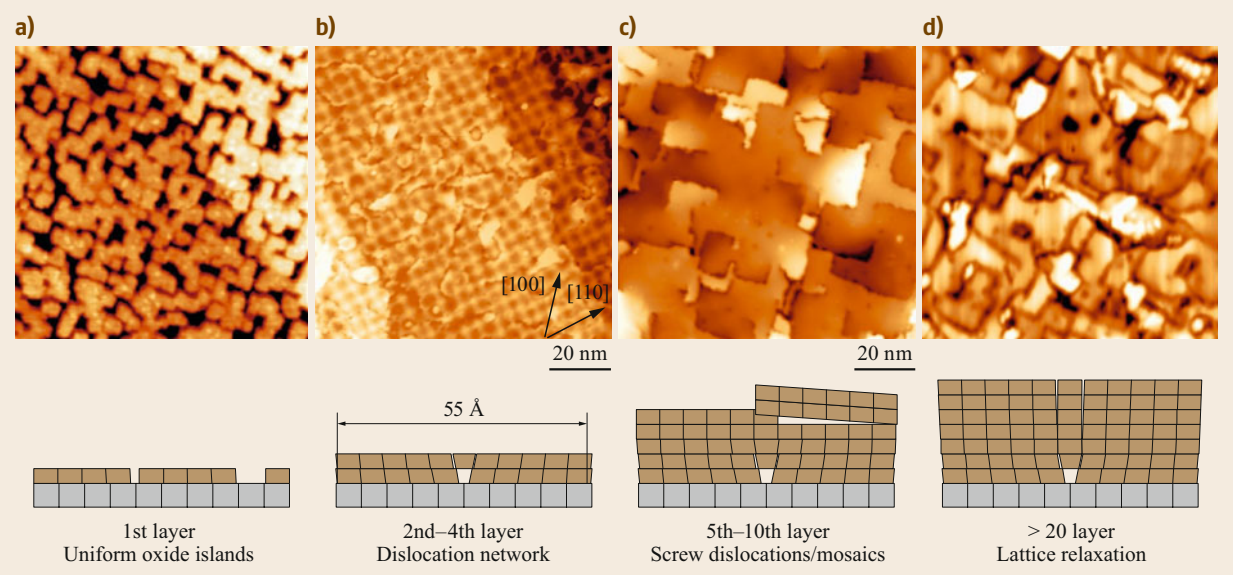

Fig. 10.3a–d STM images showing several states of strain relaxation in MgO thin films on a Mo(001) support ($100 \times 100\,nm^2$, $V_S = 4.0\,V$). **(a)** Submonolayer coverage with square shaped MgO islands. Their size is controlled by the interfacial lattice strain. **(b)** 3 ML thick film displaying a squared coincidence lattice. **(c)** 7 ML thick film characterized by wide, atomically flat terraces, separated by edge and screw dislocations. **(d)** 18 ML film with bulk-like lattice parameter. ence can be explained with the suppressed electron spill-out from the Mo support at the compact O–Mo interface [10.77]. The reduced thermodynamic stability of the Mg–Mo registry finally leads to a higher concentration of point defects in these domains [10.78]. The strain-induced dislocation network on MgO/Mo thin films gives rise to a spatially modulated adsorption behavior that can be exploited as template for the preparation of well-ordered ensembles of metal particles [10.76].

With increasing oxide thickness, additional defect types develop next to the dislocation network (Fig. 10.3). Prominent defects at 10 ML film thickness are screw and edge dislocations the latter being aligned with the nonpolar MgO[100] direction [10.75]. Also point defects, in particular oxygen vacancies, become more abundant. They mostly locate along step edges, where the atomic coordination is reduced with respect to atoms embedded in a compact terrace. The lattice position of oxygen vacancies has been thoroughly characterized by angle-dependent EPR (electron paramagnetic resonance) measurements in combination with scanning probe techniques [10.79, 80]."

Oxygen vacancies can be stabilized in three charge states on the oxide surface that is as neutral (F^0), singly (F^+) and doubly charged color centers (F^{2+}). The latter turned out to be energetically unfavorable in thin films given the quasi infinite electron reservoir of the metal support just below the film. Recent STM and AFM (atomic force microscopy) experiments have proven that the precise charge state of the color centers can be determined on the single-defect level (Fig. 10.4). Whereas STM conductance spectroscopy evaluates the energy position of defect-induced gap states in MgO [10.81], AFM probes the electrostatic interactions between the charged defect and the probe tip [10.82].

Charge trapping is not only observed for point defects, but plays an even larger role for extended line defects in MgO thin films. Several experimental and theoretical evidences have been accumulated that show the enormous ability of line defects to trap excess electrons [10.74]. Quantitative data comes from EPR spectroscopy, where a pronounced bulk-like resonance at $g = 2.003$ shows up after filling the electron traps by exposure to atomic hydrogen [10.83]. From the disappearance of the signal after annealing to 500 K, the depth of the trap states was estimated to ≈ 1.0 eV below the conduction band onset, in good agreement with DFT (density functional theory) models of the MgO grain boundaries [10.84]. Local information on the po-

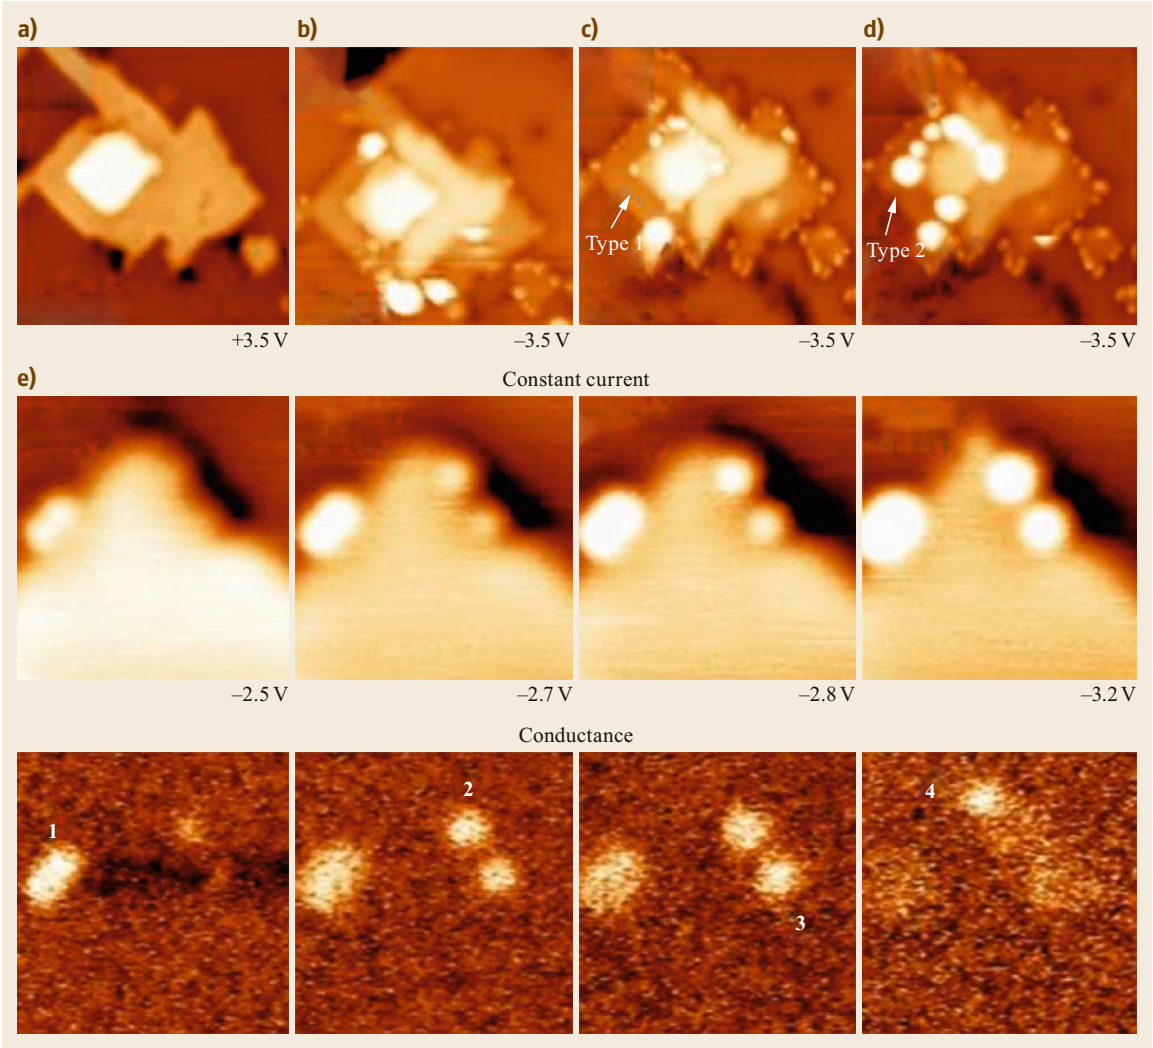

Fig. 10.4 **(a,b)** STM images ($25 \times 25\,nm^2$) of a MgO island on 4 ML MgO/Ag(001) imaged at $V_S = +3.5$ and -3.5 V. **(c,d)** Continuous scanning of the same surface region at high positive bias produces distinct defects that can be assigned to F^+ (type 1) and F^0 (type 2) color centers. **(e)** Constant current and conductance images of type 1 defects located at an MgO step edge taken at different bias voltages ($5 \times 5\,nm^2$) [10.81]

sition of the electron traps inside the MgO film comes from STM topographic and luminescence data [10.85]. In high-bias STM images, the MgO line defects appear with negative contrast as compared to the regular film (Fig. 10.5a). As the true geometric corrugation is small, the dark appearance of the dislocations network is interpreted as an electronic effect. In fact, the high number of electrons trapped in the defects leads to a local increase of the electron potential, which in turn reduces the transmissibility for tunneling electrons and forces the STM tip to approach the surface. The shift of the local electron potential due to excess electrons can be quantified by probing the vacuum states above the MgO surface via tunneling spectroscopy [10.86]. The spectra reveal an upshift of the lowest resonance from 3.7 eV on defect-free oxide patches to 4.4 eV above the dislocation lines, in agreement with the anticipated presence of excess charges in the defects [10.83].

Similar information is obtained from STM luminescence maps taken on MgO/Mo films. The oxide's optical response is governed by radiative electron transitions from higher vacuum states to the ground state, and defect-related potential shifts thus produce a contrast in the luminescence pattern (Fig. 10.5b) [10.85]. On regular MgO, the emission channel opens up already at 5.1 V excitation bias and oxide terraces con-

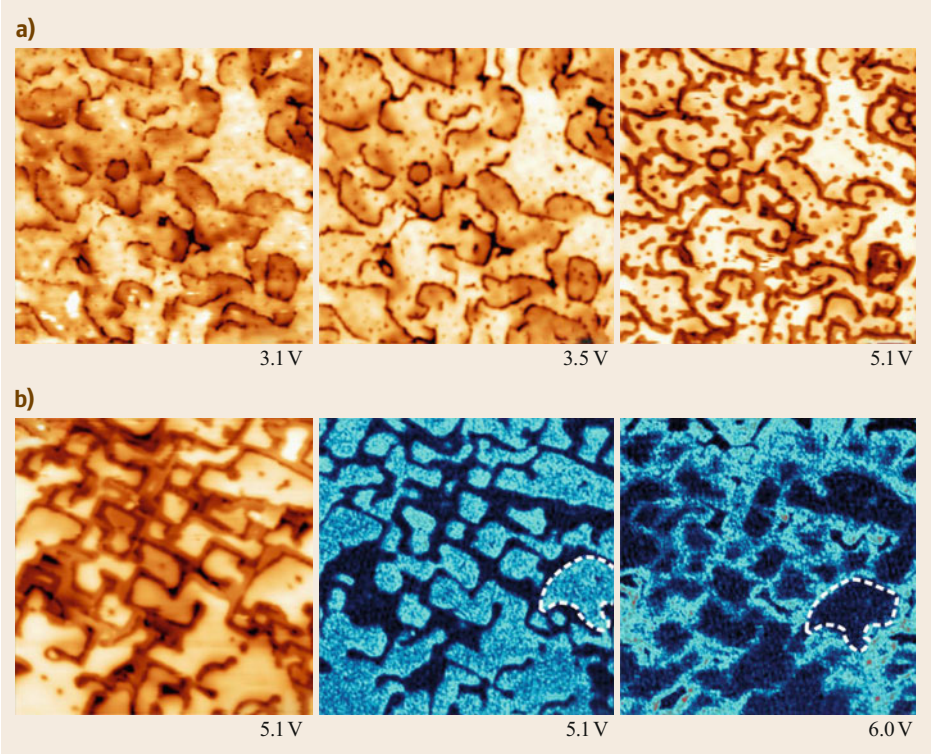

Fig. 10.5 **(a)** STM image of 12 ML MgO/Mo(001) ($100 \times 100\,nm^2$) taken as a function of bias voltage. The line defects appear as deep grooves in the oxide surface as the bias increases. **(b)** Topographic image and photon maps ($75 \times 75\,nm^2$) taken at the bias position of the second vacuum state on MgO terraces (*middle*) and line defects (*right*). sequently appear bright in those images. Conversely, the optical channel becomes available only at 6.0 V in defect regions, due to the upward shift of the vacuum states, which results in a contrast reversal with respect to the low-bias luminescence maps [10.83].

Charge trapping is a unique behavior of both, point and line defects in MgO thin films. The often weakly bound electrons are susceptible to be transferred into adsorbates, making defects indispensable for the redox chemistry of oxide materials [10.87, 88]. This interrelation has been verified in a number of adsorption and reaction experiments on MgO films, demonstrating for instance low-temperature CO-oxidation over defective MgO/Mo(001) [10.89].

10.2.2 The Silica Film

Reprinted with permission from [10.60]. © 2019 Materials Research Society.

> "The alkaline earth oxides discussed above represent a class of oxides, which tends to crystallize in a well-defined simple lattice driven by the Madelung potential of the highly ionic system. As discussed above even such prototypical ionic systems exhibit considerable structural complexity in particular with respect to the defect structure. Another level of complexity arises if the system under consideration tends to form amorphous structures.
>
> The prototype for amorphous network structures is silicon dioxide. This material is the simplest and most common type of glass. Many elements and compounds can form glasses and some of the oldest man-made objects found are made from glass materials [10.90–92]. Glass materials and especially silicates are relevant in nature and various branches of modern technologies, e.g., in semiconductor devices, optical fibers and as a support in industrial catalysis [10.93]. In order to push this material class forward and to understand chemical reaction at surfaces in the context of heterogeneous catalysts, we should characterize their structures and properties at the atomic scale.

W.H. Zachariasen postulates laid the foundation to the so-called *Random Network Theory* 80 years ago to explain the structure of amorphous materials [10.94]. Due to the comparable mechanical properties of amorphous and crystalline materials he assumed that the bonding forces between the atoms in the two phases should be essentially identical. The lack of periodicity and symmetry are the main features that distinguish a glass from a crystal. Early on, it had been suggested that tetrahedral atomic configurations were required to form glasses. Zachariasen used these predictions to sketch an atomic picture of a glass. In his paper he reduced the three-dimensional (3-D) picture into a two dimensions (2-D) analogy (Fig. 10.6b). For silicon dioxide, the simplest structural unit in the 3-D case is a SiO_4 tetrahedron. If the complexity of the system is reduced from 3-D to 2-D, the simplest structural unit for silicon dioxide changes from the SiO_4 tetrahedron to a SiO_3 triangle. The brown circle in Fig. 10.6 marks the SiO_3 building unit. The SiO_3 triangles are linked to each other as individual building blocks at fixed 180° angles, corresponding to a crystalline material. This creates long-range order and periodicity. If the angle between these structural units varies, the building blocks can develop an extended network with rings of different sizes. As can be seen in Fig. 10.6b (bottom) the uniform structural units are linked to each other at apparently random angles. Zachariasen drew a 2-D diagram in which trigonal units are linked together to create the amorphous network. Due to the large variety of Si–O–Si angles which bridge two neighboring building units, the glass structure lacks periodicity and long range order.

In our department we have developed a recipe to grow thin silica bilayer films on Ru(0001). This film system nicely verifies the complex atomic arrangement of the Random Network Theory with a striking similarity. The observed protrusions at atomic separations in the STM images shown in Fig. 10.6a,c. are arranged in propeller shaped structures. By comparing to Zachariasen's model and based on this propeller symmetry the protrusions can be assigned to Si atoms (green balls in Fig. 10.6a,c). Such propeller shaped units have been separately marked in Fig. 10.6. Here, a Si sensitive contrast is observed and the position of the O atoms has been calculated based on the Si coordinates. In this way the 2-D model of the topmost O and Si atoms has been completed. Please note that a modified tip termination can make the O instead of the Si positions visible [10.21]. This silica film system corroborates crystalline structures [10.20], but also verifies Zachariasen's predictions of a vitreous random network for a glass [10.22].

Besides the separate characterization of each phase, also interface structures between crystalline and amorphous phases have been addressed [10.95]. In the glass community, there has always been a controversy about how crystalline and vitreous phases are connected to one another. From the experimental point of view, a real-time observation at the atomic scale of an active front during a glass transition process is not currently feasible. But a static image of such an interface region can be gained. For further details see [10.95].

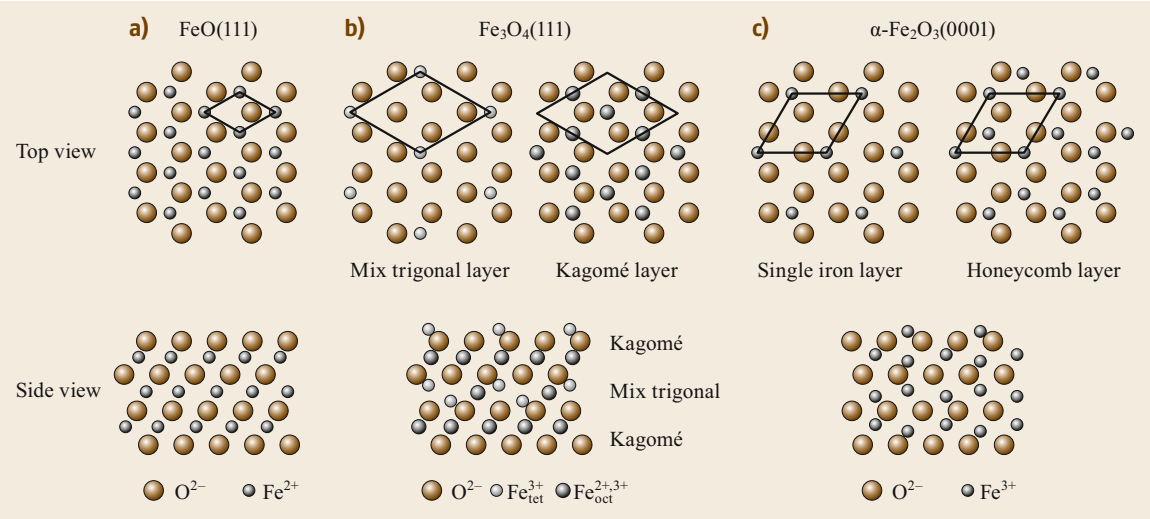

Fig. 10.7a–c Models of iron oxides structure for (a) wustite (FeO), (b) magnetite (Fe_3O_4), and (c) hematite (α-Fe_2O_3)

Furthermore, it should be mentioned that silica bilayer films can be grown on a number of substrates [10.22, 96–98], which leaves room for tuning the properties of these films, but also shows that these films resemble a completely new materials class of its own.

With these experiments, a clear image of an amorphous material has been obtained which allowed for the first time the derivation of atomic sites and a detailed analysis from real space coordinates. The text book example of the amorphous silica structure proposed by Zachariasen in 1932 has thereby finally been verified. Also Mo(112) and Pt(111) substrates have been used to prepare thin silica films.

10.2.3 Iron Oxide Films

The oxide films discussed so far were simple in the sense that the oxidation state of the constituents is well-defined. This restriction is lifted if transition metal oxides are considered. In addition, the ability to form oxides with different formal oxidation states of the metal ion is associated with changes in the bulk crystal structures. With respect to the atomic structure of the surfaces observed for different oxides the surface termination becomes a central aspect. To illustrate these aspects we will present results on iron oxide films.

Iron oxides films have a wide field of technological applications, ranging from magnetic devices to heterogeneous catalysis [10.99, 100]. This class of material exhibits rather different magnetic or conducting properties [10.101] depending on their crystal structures, which is strongly determined by the way of preparation. The morphology and termination of the oxide film have a strong influence on the chemical properties and are, therefore, subject of intense studies [10.102–105]."

Figure 10.7 briefly sketches the crystal structures of iron oxide phases discussed in the following, the main ones being FeO (wustite), Fe_3O_4 (magnetite) and α-Fe_2O_3 (hematite). For a more detailed overview of these different crystalline structures see *Weiss* and *Ranke* [10.102] α-Fe_2O_3 crystallizes in the corundum structure with a hexagonal unit cell. Along the [0001] direction the O anions form a close-packed hcp sublattice with ABAB stacking. The Fe^{3+} species between these layers are arranged in honeycomb $(\sqrt{3}\times\sqrt{3})R30°$ like layers. Fe_3O_4 crystallizes in the inverse spinel structure. The O anions form a close-packed fcc sublattice (ABC stacking along the [111] axis of the lattice) with Fe^{2+} and Fe^{3+} cations located in the interstitial sites. The O planes are similar to those in α-Fe_2O_3. Between the close-packed planes of oxygen ions either one Kagomé or three hexagonal (mixtrigonal) Fe layers alternate. Both ion sublattices are arranged in a (2×2) like fashion on the close-packed oxygen layer. FeO crystallizes in the rock salt structure, hence the O and Fe (111) planes form ideal two-dimensional hexagonal lattices with a cubic ABC stacking sequence along the [111] direction. FeO films in (111) termination are intrinsically unstable as they develop a polar dipole that increases with film thickness. The impact of the polarity on the

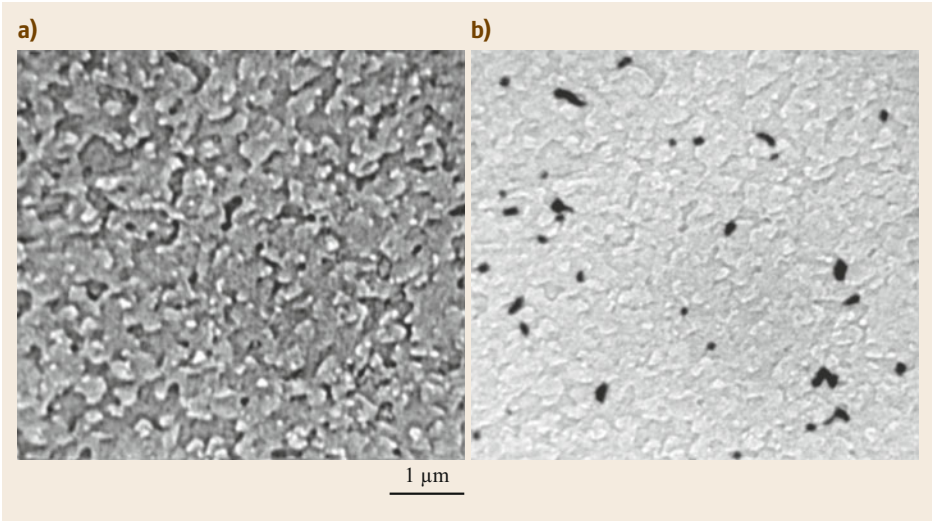

Fig. 10.8a,b Morphology of a well-prepared Fe_3O_4 film, completely covering the Pt(111) support. Both LEEM images show the identical surface area in **(a)** bright- and **(b)** dark-field imaging mode, utilizing the (0;0) and the (1/2;0) diffraction spots, respectively. The contrast is caused by the morphology. Additionally, domains rotated by 180° become visible as dark areas in the dark-field image. Reprinted with permission from [10.106]. Copyright (2012) by the American Physical Society

local surface potential largely governs the adsorption behavior of the film, and can be probed with STM, for example [10.107].

Morphology of Thin Fe_3O_4(111) Films

Fe_3O_4(111) films of about 10 nm thickness were grown on a Pt(111) single crystal support by repeated cycles of Fe deposition at room temperature (RT) and oxidation at elevated temperatures, after one complete FeO layer was formed initially [10.102]. In each cycle, between 5 and 10 ML of Fe was deposited, and oxidized at 1×10^{-6} mbar of O_2, starting at RT, followed by annealing to 900 K, which was kept for 5 min. Upon cooling, the oxygen pressure was reduced only after cooling to 500 K. By following this procedure, the Pt(111) crystal is completely covered by an Fe_3O_4 film (Fig. 10.8a). The LEED (low energy electron diffraction) pattern of the film matches perfectly the one described in literature [10.108]. The film consists of terraces up to a width of 100 nm, most of them with polygonal shape. As seen in LEEM (low energy electron microscopy), the step density increased after every cycle, especially > 20 nm of film thickness. However, the film could be smoothed if the final oxidation treatment was done at an elevated temperature of ≈ 1000 K. Here, it was necessary that the film was completely closed and thicker than 7 nm, otherwise the annealing up to 1000 K led to a de-wetting (see the following section). A subsequent thermal flash in UHV did not produce further morphological changes, but improved the homogeneity of the surface structure (see Sect. 10.2.3).

Magnetite crystallizes in an inverse spinel structure with space group *Fd*3*m*, while the Pt substrate exhibits a fcc structure with space group *Fm*3*m*. Therefore, the Fe_3O_4

> "islands created by initial nucleation on a clean Pt(111) surface may coalesce with improper stacking [10.109, 110] and form a complete film with two twin domains rotated by 180°. Dark field LEEM studies using the (1/2;0) and (0;1/2) spots showed a predominance of one rotational domain; coverage ratio for these rotational domains ranged between 75°/25° and 98°/2°, depending on the preparation condition. Figure 10.8b shows a dark-field LEEM image visualizing the two rotational domains as dominating bright and small black areas. This preponderance is maintained even after subsequent cycles of Fe deposition and oxidation. On average, the rotational domain size is larger than the terrace width; some of the domains were even several µm wide. A comparison between dark field and bright field LEEM images shows that the rotational domains are preferentially placed in correspondence of the step bunches of the substrate, providing a partial correlation be-

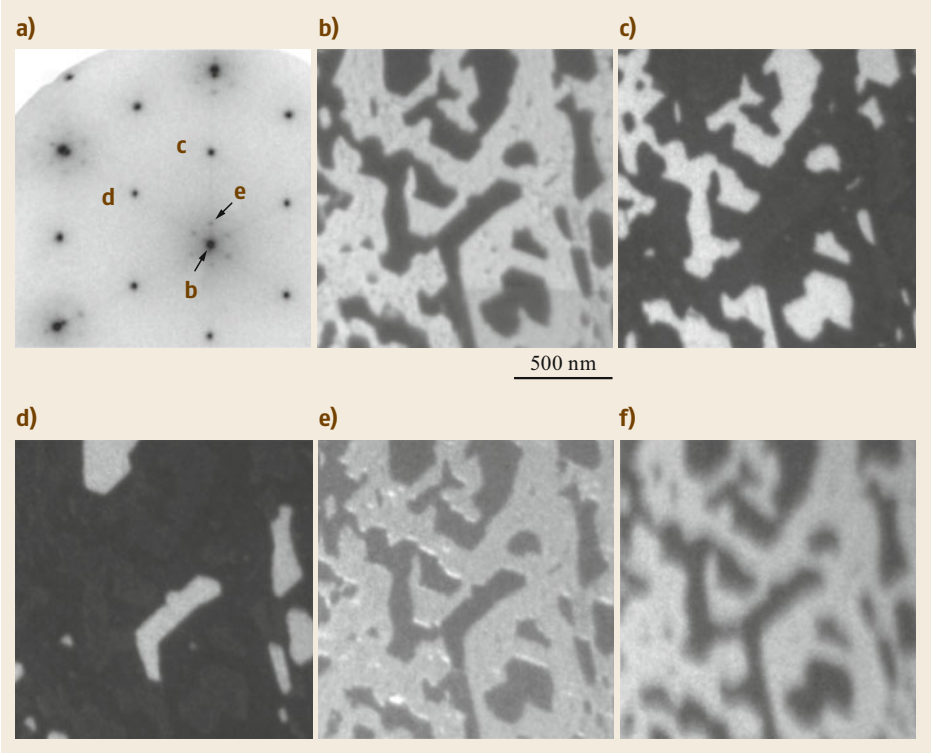

Fig. 10.9a–f Dewetted Fe_3O_4 film, studied by **(a)** LEED, **(b–e)** LEEM and **(f)** XPEEM. The LEED pattern shows a superposition of the Fe_3O_4 and FeO structures. The LEEM images use selected LEED spots as labelled in **(a)**. In the bright-field LEEM image **(b)** the Fe_3O_4 and FeO surface areas appear dark and bright, respectively. Morphological Inhomogeneities

The oxidation temperature plays a crucial role for the uniformity of the thin film.

Reprinted excerpt with permission from [10.106] © 2012 by the American Physical Society.

> "On the one hand it should be high enough to enable the oxidation process, but on the other hand not too high, especially during the first deposition cycles, to avoid a de-wetting of the Fe_3O_4 film. The latter was observed for a film thickness of 7 nm at oxidation temperatures above 900 K, as FeO areas became clearly visible in the *holes* of the $Fe_3O_4(111)$ film. The width of these FeO domains increased dramatically at further increase of the temperature, from approximately 100 nm to several μm for an oxidation temperature of 1000 K. The FeO areas could be identified by various experiments: bright and dark field LEEM (Fig. 10.9b–e), LEED (Fig. 10.9a) and XPEEM (x-ray photoelectron emission microscopy) (Fig. 10.9f). In the de-wetted case bright field LEEM images (Fig. 10.9b), Fe_3O_4 (dark) and FeO (white) areas are visible with different contrast, while the corresponding LEED pattern shows the superposition of the $Fe_3O_4(111)$ pattern and the Moiré pattern (six satellite spots surrounding the central (0;0) spot) typical for the FeO(111)/Pt(111) interface. By dark field imaging using the Fe_3O_4 (1/2;0) and (0;1/2) spots (Fig. 10.9c,d) the FeO areas appear dark, while the Fe_3O_4 areas show a contrast between rotational domains due to the three-fold symmetry of the $Fe_3O_4(111)$ crystal structure. On the contrary, the FeO domains can be unambiguously identified as brighter areas if one of the satellite spots around (0;0) is selected (Fig. 10.9e). XPEEM images obtained with Pt $4f_{7/2}$ core level

emission line (Fig. 10.9f) additionally reveal that the FeO domains formed by de-wetting are indeed deep holes in the Fe_3O_4 film."

Reprinted excerpt with permission from [10.106] © 2012 by the American Physical Society.

The FeO areas are so thin that the electrons photoemitted in the Pt substrate can still pass through, while the Fe_3O_4 film is thick enough to completely damp the Pt signal. Considering the electron mean free path length of ≈ 0.5 nm at the used kinetic electron energy (104.2 eV), one can estimate the thickness of the FeO areas as a few Angstroms. Once the Fe_3O_4 film had de-wetted and FeO holes were formed, it was not possible to recover a closed Fe_3O_4 film by several additional cycles of Fe deposition and oxidation. Obviously, the Fe atoms adsorbed on the FeO areas at room temperature migrated onto the Fe_3O_4 areas during the oxidation process at 900 K. Consequently, only the Fe_3O_4 grew in thickness, while the FeO zones remained unchanged. Furthermore, wide-range LEEM images of an almost closed Fe_3O_4 film show that FeO domains are formed preferentially at the step bunches of the Pt(111) substrate, where the Fe_3O_4 is unstable, most likely due to the strain induced by the steps and step bunches [10.106].

Surface Termination

Besides the two inhomogenities in the rotational domains and in the morphology, a third type related to the surface termination was found and was investigated using four techniques:

(i) SPALEED (spot profile analysis low energy electron diffraction (profile analysis of LEED spots)) studying the profile of the LEED spots in-real-time during oxidation and flash in UHV yielding the domain sizes for different preparations
(ii) XPS (x-ray photoelectron spectroscopy) of the surface before and after the final annealing, determining the chemical composition of the surface, excluding contaminations of carbon, nitrogen or molybdenum containing species
(iii) STM of the *as prepared* surface, visualizing about 2 nm wide objects and therefore smaller than the LEEM resolution
(iv) Dynamical LEED analysis of the spot intensities for differently prepared surfaces, studying the surface unit cell structure and therefore the termination [10.106].

In the special LEEM set-up, we collected *I*/*V*-LEED (intensity/voltage low energy electron diffraction (intensity analysis of LEED spots)) spectra of the Fe_3O_4 thin film at room temperature before and after the flash at 900 K. The intensity of six different diffraction spots, (0;0), (1/2;0), (0;1/2), (1;0), (0;1) and (1/2;1/2), were analyzed within an energy range between 40 and 300 eV, equivalent to an overall dataset of 1560 eV. In contrast to a standard back-view LEED, the operation condition of the electron gun and the image columns of our system are not altered during the energy scan, but solely the sample potential is changed. Consequently, the beam current on the sample is constant during the scan, for all experiments. Additionally, due to the special LEEM optics the investigated diffraction spots do not move in position on the detector during the energy scan and the (0;0) spot is visible even at full perpendicular illumination. It is also possible to directly inspect the probed surface region from where the diffracted electrons are collected. Combining this with a dark field image, which gives the portions of the two possible rotational domains, one can easily disentangle the contributions of the two rotational domains and extract the real spectra of (1/2;0), (0;1/2), (1;0) and (0;1) spots of a single rotational domain. This is not possible with a standard back-view LEED set-up because of the superposition of two threefold pattern with unknown relative abundance. Therefore, one is usually forced to average the spectra of spots of the same diffraction order, with consequent loss of information.

The resulting disentangled I/V-LEED spectra for the *as prepared* and *after flash* surfaces differ strongly in some energy ranges (see arrows in Fig. 10.10). This can be interpreted as a change in the surface termination. Additionally, we found that the spectra of the *as prepared* surface do not change significantly for different cooling rates. For a full I/V-LEED analysis different models for the surface atomic structure were assumed, from simple truncation of the bulk crystal unit cell along the (111) plane, yielding six different terminations, up to more complex structure models, i.e., with incomplete site occupation and/or changed coordination sites. Every configuration was optimized until the change in each atomic coordinate in a single iteration loop was < 0.1 Å. The most reliable model with a resulting Pendry reliability (R) factor of $R = 0.14$ is 1/4 ML Fe atom belonging to the MixTrigonal layer on a closed-packed oxygen layer resting upon a Kagomé iron layer. The surface after the flash presents the expected atomic termination and confirms the results obtained first by *Barbieri* et al. [10.104] and then by *Ritter* and *Weiss* [10.111].

The fit of the I/V curves measured for *as prepared* films gave no clear resulting structure because all R-factors were much larger with respect to the values obtained for the flashed surface. The most reliable model

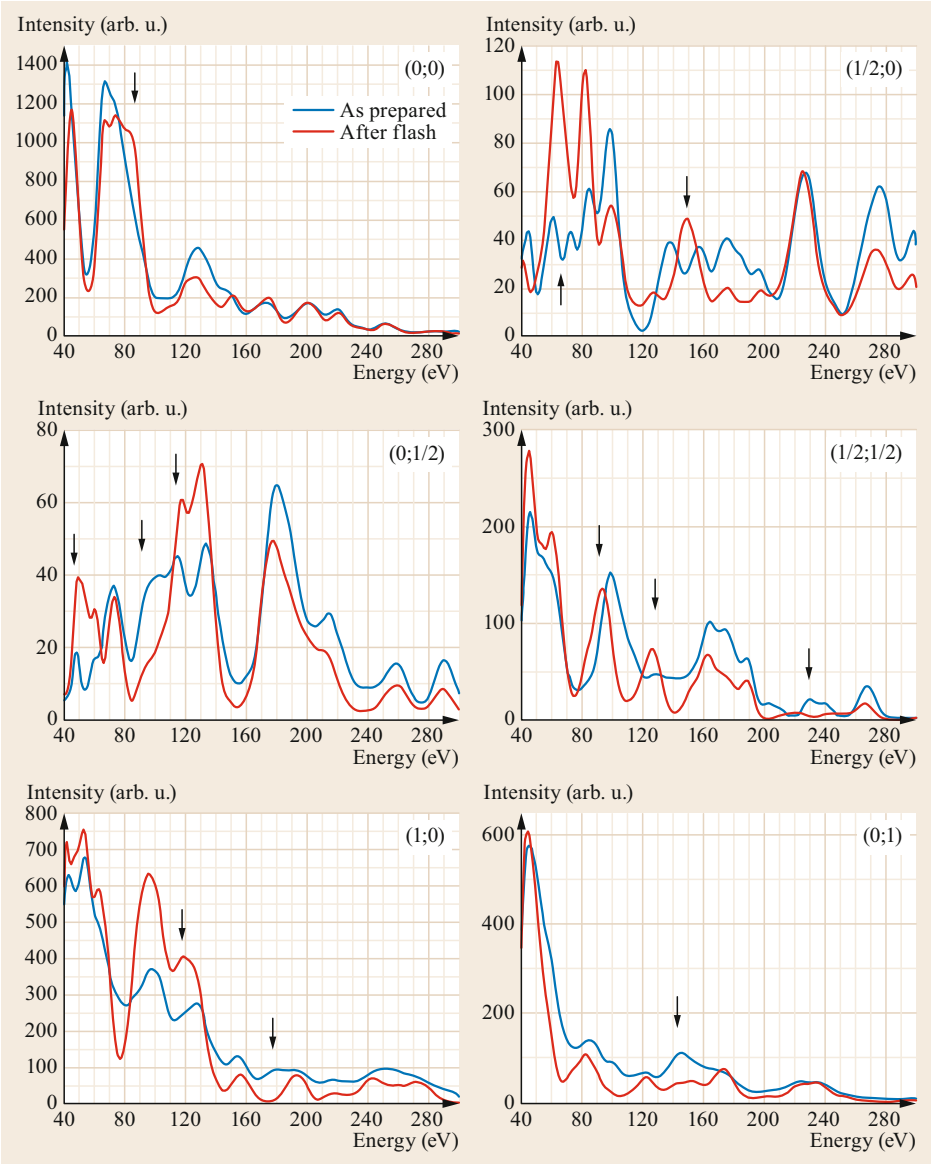

Fig. 10.10 Surface termination of the Fe_3O_4 films at different preparation steps. IV-LEED curves of the first six diffraction spots for the as-prepared film (in *blue*) and after annealing at 900 K in UHV (in *red*). The major changes due to this flash are indicated by *arrows*. Reprinted with permission from [10.106]. Copyright (2012) by the American Physical Society

was still the one described above for the flashed surface, but with a *R*-factor of 0.33 much worse than before. One can assume that, as shown by STM, part of the *as prepared* surface exposes the termination dominant after the annealing. Therefore, the spectra were also fitted with a linear combination of the *after flash* surface and the unknown structure. Even with this extra parameter, the analysis did not result in structures with acceptable *R*-factor. Simple explanations, that the IV-LEED method fails in this case, are (i) the low atomic order of the objects, as seen in STM, and (ii) the small object size of 2 nm (i.e., $\approx$ 7 atomic distances), not suitable for the method, which assumes infinite periodic conditions.

The nature and the origin of these *extra objects* could be studied indirectly. In the (0;0) LEED spot profiles they exhibit a significant shoulder like broadening, corresponding to an average domain size of 2 nm, as also observed in STM. Real time SPALEED measurements clearly show, that the extra objects were not present during the oxidation process at temperatures > 900 K, but were formed during the cooling down at temperatures < 750 K. Furthermore, if the oxygen exposure was cut off during the cooling process > 750 K, no extra object was detected. Therefore, the formation of extra objects on the surface must be directly related to the O_2 exposure at lower temperature.

Once formed, the extra objects can be completely removed by annealing up to 900 K in UHV. As shown in LEEM and SPALEED, this flash in UHV transforms the *as prepared* surface with a rough morphology and small objects of less-ordered and highly oxygen containing domains into a smooth surface with a homogeneous 1/4 Fe termination. Therefore, this final flash determines the morphology and termination of the prepared Fe_3O_4 film. Recent studies indicate that the extra objects may be due to water adsorption from the background.

Interconversion of Fe_3O_4(111) and α-Fe_2O_3(111) Thin Films

An additional inhomogeneity observed in oxide films are domains of different bulk structures. Under our preparation conditions iron oxide films grown on the Pt(111) or Ag(111) surfaces were composed of the Fe_3O_4 phase and of a few microns large domains of α-Fe_2O_3, covering a few percent of the entire surface. The two phases coexist for intermediate preparation parameters [10.112], often also showing small FeO domains due to partial dewetting (Fig. 10.11a). The annealing of the film in 3×10^{-5} mbar O_2 pressure (i.e., a higher pressure than used for the initial preparation) starting at RT up to 700 K, leads to an oxidation of the Fe_3O_4 area into α-Fe_2O_3 as monitored in LEEM (Fig. 10.11b–i). The conversion starts at 670 K (Fig. 10.11c) as a growth front of dendritical shape. The process becomes faster when the temperature is increased, indicating that the transformation process is thermally activated [10.113].

The conversion can be inverted by extra Fe deposition, which leads to a shrinkage of the α-Fe_2O_3 upon annealing in UHV. Here, the Fe is incorporated into the hematite area, causing a change in stoichiometry and crystal structure [10.112]. Without Fe deposition, annealing in UHV can also lead to a reduction of the α-Fe_2O_3 by desorption of oxygen. This was observed when Ag(111) was used as support [10.112, 114]. However, on a Pt(111) support, the UHV annealing yields the opposite result: the Fe_3O_4 is converted into α-Fe_2O_3. The reason for this unexpected behavior is the special ability of the Pt(111) support to dissolve Fe. Therefore, Fe from the Fe_3O_4 phase can diffuse into the bulk, producing an intermediate nonstoichiometric Fe_3O_4 phase or even α-Fe_2O_3, which subsequently is structurally transformed into hematite.

The preparation of $\approx$ 10 nm thin iron oxide films on metal supports is determined by various parameters like growth temperature, oxidation temperature and pressure but also kind and morphology of the supporting substrate. These parameters may have a crucial influence on e.g., the film morphology, the film roughness, surface termination and crystal structures. Therefore, the control of the preparation is essential for the proper characterization of the chemical properties of oxide films.

10.2.4 Other Transition Metal Oxide Surfaces

Surface Structure of V_2O_5(001) and V_2O_3(0001)

Vanadium oxides are catalytically active for a number of reactions, most of them involve the transfer of oxygen atoms [10.115] which triggered a number of studies in the areas of basic and applied research. Some aspects are summed up in recent review papers [10.14, 62, 116–120]. Vanadium catalysts are often based on V^{5+} but lower oxidation states are likely to play a role during catalytic processes. The relevance of vanadium oxides in catalysis has motivated scientists to perform model catalytic studies for which well-characterized high-quality crystalline oxide surfaces are required.

Ordered V_2O_5(001) layers have been prepared on Au(111) only [10.121, 122], while V_2O_3(0001) layers have been grown on a number of substrates: Au(111) [10.123, 124], W(110) [10.125], Rh(111) [10.126], Pd(111) [10.127], and Cu_3Au(100) [10.128]. There have also been reports of VO_2(110) growth on TiO_2(110) [10.129] and SnO_2(110) [10.130, 131] but extended adsorption/reaction studies have not been reported.

The main difference between the preparation recipes for V_2O_5(001) and V_2O_3(0001) is that the preparation of V_2O_5(001) layers requires higher oxygen pressures than the preparation of V_2O_3(0001) layers: the former is prepared in an oxygen pressure in the 50 mbar range [10.121, 122] while for the latter UHV compatible pressures in the 10^{-6} mbar range suffice [10.123–125]. The preparation recipe for V_2O_5(001) on Au(111) is described in detail in [10.122]: well defined layers with a very low density of point defects may be produced as shown in Fig. 10.12. The bonding of the V_2O_5(001) layers to the Au(111) substrate is so weak that the islands in in the left panel of Fig. 10.12 exhibit different azimuthal lattice directions which leads to ring-type intensity patterns in the LEED images [10.122]. When enough material is deposited to close the layers then the islands grow together which leads to the lines in the center panel where azimuthally differently oriented areas meet. V_2O_5(001) is terminated with vanadyl double rows which are clearly recognizable in the right panel of Fig. 10.12.

V_2O_3(0001) layers may also be grown on Au(111) [10.123–125]. These layers are also well ordered but with a somewhat higher density of point defects, see Fig. 10.13. The surface structure of a model

catalyst is a relevant parameter for its catalytic activity and therefore this aspect was investigated in detail in the first stages of the V_2O_3(0001) related studies.

V_2O_3 has a corundum lattice and the (0001) surface is a basal plane of this hexagonal lattice. Seen from the side, this lattice consists of alternating quasi-hexagonal oxygen layers and vanadium double layers. Three different surface terminations may be obtained by cutting the structure parallel to (0001): DM, SM, and bulk O_3, see Fig. 10.14. The stability of such surfaces from an electrostatic point of view has been initially analyzed by *Tasker* [10.133] who could show that polar structures, i.e., structures with electrically nonneutral layers parallel to the surface may energetically be stable only under certain conditions. The consequences have been discussed for a large variety of systems and the interested reader may be referred to the current literature [10.8, 70] Among the V_2O_3 terminations shown in Fig. 10.14 only SM is electrostatically stable according to the *Tasker* criteria [10.133]. However, the vanadium atoms at the SM terminated surface are chemically rather active and therefore it was assumed that the surface might actually be terminated by vanadyl groups, V=O in Fig. 10.14. This assumption was later supported by infrared spectroscopy and HREELS (high resolution electron energy loss spec-

troscopy) data which feature intense structures related to the vanadyl V=O vibration and by STM data like the one shown in Fig. 10.13 [10.125, 126]. This model was later challenged by studies featuring ion scattering experiments and DFT calculations which came to the conclusion that the surface termination should be the one named rec. O_3 in Fig. 10.14 [10.127, 134, 135]. This structure is similar to the bulk O_3 termination with the difference that a vanadium atom from the second double layer below the surface moves into the first vanadium double layer below the surface. This view was recently refuted by a detailed combined I/V-LEED + STM + ion scattering study which could conclusively show that the surface is terminated by vanadyl groups under standard UHV conditions [10.123, 124].

Preparation of Rutile $TiO_2(110)$ Layers on Rutile $TiO_2(110)$ Single Crystals with a Diffusion Blocking Layer

Mixed or doped oxides may offer additional catalytic reaction paths due to the presence of the additional component which may play a role for a specific reaction. This issue was studied with the example of vanadium mixed into rutile $TiO_2(110)$. The first step of that project was the preparation of a suitable sample. Several tries were made to prepare ordered $TiO_2(110)$ layers on different gold and platinum surfaces but suitable layers could not be obtained (see *Sedona* et al. [10.136] for TiO_x on Pt(111)). Interface stress due to overlayer-substrate lattice mismatch was assumed to be the reason for this failure and therefore it was tried to prepare $TiO_2(110)$ layers on rutile $TiO_2(110)$ single crystals [10.51] since in this case the lattice parameters of the overlayer and the substrate would be identical. High-quality layers could be prepared in this way, but when vanadium was mixed into the layers it turned out that the vanadium diffused into the substrate at temperatures required for the preparation of the films, so that vanadium doped oxide layers could not be prepared. In the next step a layer between the overlayer and the substrate was introduced with the aim of blocking vanadium diffusion. The blocking layer was a $TiO_2(110)$ layer with ions of another metal mixed into it. The admixed metal was chosen such that the ionic diameter of its 4+ ions was somewhat larger than that of the Ti^{4+}

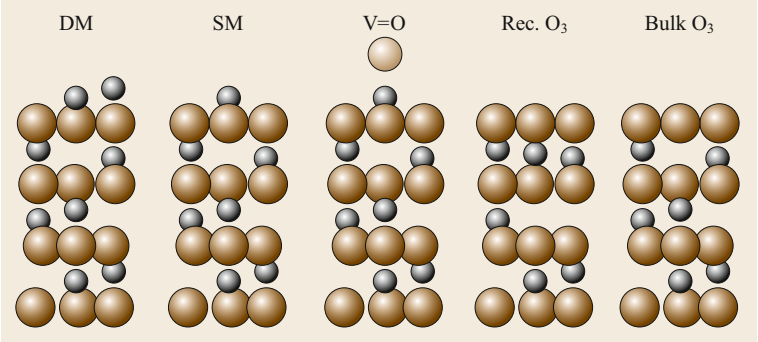

Fig. 10.14 Different possible $V_2O_3(0001)$ surface terminations (DM: double metal termination; SM: single metal termination). ions in $TiO_2(110)$. This stresses the rutile lattice of the TiO_2 host oxide, thereby increasing the diffusion barrier. A relevant property of the blocking layer is that it is a good support for the growth of rutile $TiO_2(110)$ overlayers, with and without vanadium doping. Therefore the structure and the lattice parameters of the blocking layer had to be very similar to the corresponding rutile TiO_2 properties. For this reason the metal ions mixed into the blocking layer were chosen among metals having oxides with rutile structure. Another relevant property is the thermal stability with respect to diffusion of the admixed metal ions, which should be high to prevent diffusion of the admixed ions into the overlayer and finally to the surface. Lead, tungsten and tantalum were tested as admixed components in the blocking layer. Lead appeared to segregate and was therefore discarded. Tungsten ions turned out to be thermally less stable than tantalum ions and therefore tantalum was selected to be the metal admixed to the TiO_2 in the blocking layer [10.51]. The prepared blocking layers were usually ≈ 3 nm thick and had an approximate composition of $Ti_{0.8}Ta_{0.2}O_2$. The thermal stability of the layers was such that with XPS weak tantalum signals could only be detected in surface-near regions of the top layer after 10 h of annealing at 800 K or 2 h at 900 K.

It was demonstrated that the blocking layer does not only impede vanadium diffusion but also the diffusion of Ti^{3+} ions resulting from the reduction of $TiO_2(110)$ [10.51]. This is illustrated in Fig. 10.15 which shows UPS (ultra-violet photoelectron spectroscopy) spectra of the $TiO_2(110)$ band gap state which is known to be related to Ti^{3+} ions [10.137–139]. The spectra have been measured at a grazing electron detection angle which means that most of the intensity in the spectra stems from just the topmost layer of the respective sample. Spectrum (b) was recorded from a sputtered single crystal after annealing at 800 K in vacuum for 10 min while spectrum (d) is the spectrum of a $TiO_2(110)$ layer subjected to the same procedure. Both, sputtering and annealing produce Ti^{3+} ions. However, the Ti^{3+} related feature at ≈ 0.75 eV is much

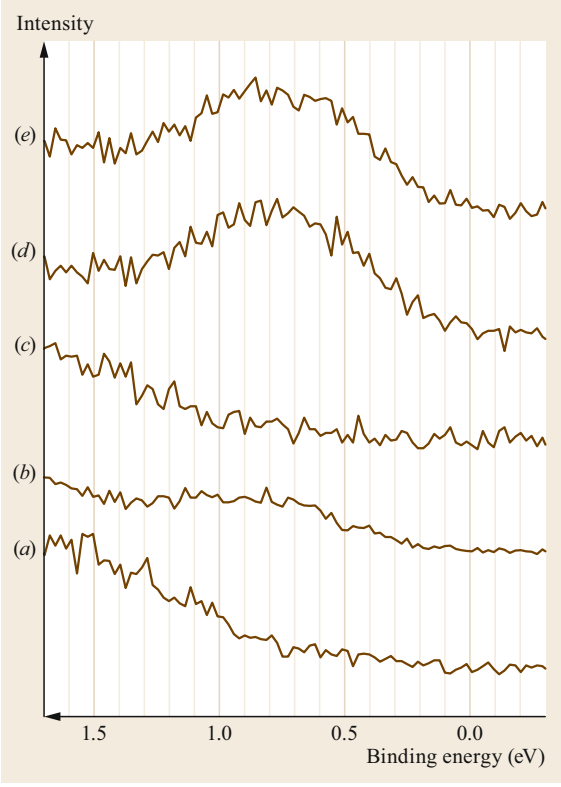

Fig. 10.15 HeI UPS spectra of differently prepared $TiO_2(110)$ surfaces recorded at an electron detection angle of 70° with respect to the crystal surface normal. more intense in the spectrum of the thin film. This would not be the case if the Ti^{3+} ions could pass the blocking layer since in this case the Ti^{3+} ions would have diffused into the substrate, which happened in the case of the single crystal substrate (spectrum (b)) and led to the smaller intensity in the spectrum. Further annealing of the thin film did not change the intensity of the band gap state since the Ti^{3+} ions could not diffuse into the substrate (spectrum (e)).

TiO_2(110) single crystals studied with electrons (using electron spectroscopy, electron scattering, STM, ...) have to be electrically conductive which is usually achieved by a mild reduction which produces Ti^{3+} ions. In addition to vacancies in the bulk this leads to oxygen vacancies at the surface (*bridging oxygen vacancies*) which may and often do play a role in catalytic surface reactions. The introduction of blocking layers offers a way to prepare surfaces without bridging oxygen vacancies which do not charge and can therefore be studied with charged particles, provided that the layers are not too thick. Also strongly reduced layers may be prepared without reducing the substrate notably.

Figure 10.16a displays a STM image of a TiO_2(110) film ($\approx$ 10 nm thick, on a blocking layer) after annealing in vacuum. A high density of bridging oxygen vacancies (the links between the continuous rows) is observed as expected from the discussion above. After annealing in oxygen (Fig. 10.16b) the bridging oxygen vacancies are not visible anymore and some bright features on the rows show up, which are attributed to oxygen adatoms, resulting from oxygen dissociation [10.138, 140]. The result is different if the single crystal is exposed to oxygen (Fig. 10.16c). In this case extended structures form which result from the diffusion of Ti^{3+} ions to the surface where they are oxidized [10.141]. Since there is no blocking layer in the case of the single crystal, Ti^{3+} ions from far below the surface can diffuse to the surface which the reason for the formation of the extended protrusion in Fig. 10.16c.

It could be shown that vanadium admixed to TiO_2(110) prefers subsurface locations under reducing conditions [10.53]. The vanadium has the effect that the host oxide becomes more reducible, which was traced back to the lower binding energy of vanadium to oxygen [10.53]. This has the effect that layers containing vanadium are usually more reduced than layers without vanadium, which affects the surface reactivity: bridging oxygen vacancies and extended reduction induced defects like the strands known for heavily reduced (1×2) reconstructed TiO_2(110) appear in elevated concentrations at the surface, where they may interact with adsorbates, modifying reactions rates, selectivities and reaction paths.

10.3 Tuning the Properties of Oxide Films

Apart from the structural properties of oxide films, which have been addressed in the previous section, it is important to elucidate the physical and chemical properties of these systems in more detail. Within this section we would like to elucidate the possibilities to tune the properties of the oxide films. A variety of strategies have been reported in literature on how the properties of these systems can be modified. We will

restrict the discussion to two aspects. First we would like to discuss the effect of film thickness. We will refrain from discussing the complex structural variability of several ultrathin oxide film systems, which have been reviewed recently, but we will focus on charge transfer processes and their impact on the properties of molecular adsorbates as well as metal atoms and particles. While a discussion of ultrathin oxide films may sound like an academic curiosity it is important to note that the concepts observed for the ultrathin films can largely be transferred to bulk oxides if suitable electron donors or acceptors are provided. We will use CaO as an exploratory example to show how suitable doping of a bulk, wide-band gap oxide can modify the properties of the system, which is very comparable to the observations made for the ultrathin MgO film.

10.3.1 Charge Transfer Effects on Thin Oxide Films

MgO as the prototype of an ionic oxide is a good starting point for the discussion of charge transfer effects on thin oxide films. The interaction of molecules as well as metal atoms with the stoichiometric (001)-plane of the rock salt lattice is rather weak resulting in a low stability of individual metal atoms and growth of 3-dimensional metal particles at ambient temperature. Gold atoms adsorbed on bulk like 30 ML MgO(001) films were shown to be neutral entities [10.142]. However, the binding of the atoms on-top of the oxygen ions of the MgO lattice leads to a polarization of the valence electrons of the Au atom, which enables charge transfer to molecular adsorbates such as CO [10.143]. Theory had proposed that Au atoms deposited onto ultrathin MgO films get negatively charged due to a charge transfer from the metal substrate to the Au atom [10.25, 144, 145]. This is due to the fact that the unoccupied part of the Au 6 s level found in the band gap on thick films is located below the Fermi-energy of the support for the thin film system. There are different contributions to this effect. First, the deposition of MgO onto the metal substrate reduces the work function of the system, which has been confirmed both theoretically as well as experimentally [10.64, 77, 146]. Second, charged Au atoms adsorbed on the surface of the ultrathin MgO film are stabilized by polaronic distortions of the oxide lattice [10.144, 147].

Experimental evidence for the charging of Au atoms on ultrathin MgO(001) films comes from low-temperature STM experiments. As seen from the STM image (Fig. 10.17a) Au atoms deposited on a 3 ML MgO film ($T = 5-10$ K) form an ordered structure indicating significant repulsion between them [10.27]. In contrast to that adsorption of Pd atoms (3 ML thick MgO film, $T = 5-10$ K) is in perfect agreement with expectations based on a statistical distribution of the atoms [10.27]. Further evidence for a charged state of the Au atoms can be found from the STM signatures of single Au in comparison with simulated ones applying the Tersoff–Hamann approximation (Fig. 10.17b,c) [10.149]. The experimental appearance of the Au atoms showing a *sombrerolike* protrusion surrounded by a depression is nicely reproduced theoretically, however, it is absent in the simulated STM images of neutral atoms [10.150]. Similar observations were found for other systems such as Au on ultrathin NaCl films [10.151]. To elucidate this question in more detail it is interesting to note that on bulk MgO or thick films Au atoms were found to nucleate on top of oxygen ions [10.142], while theory predicts charged Au atoms on thin films to adsorb preferably on Mg sites or hollow sites [10.25, 144, 152]. STM can provide evidence for the change in the distribution of the adsorption sites by superimposing the

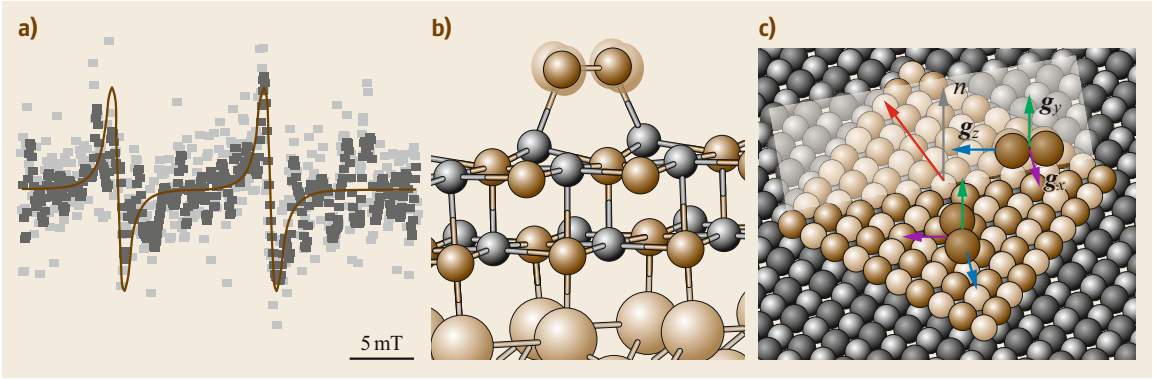

Fig. 10.18 **(a)** EPR spectrum of 20 L O_2 adsorbed at 40 K on a 4 ML thick MgO(001) film on Mo(001) with the magnetic field in the surface plane along a [110] equivalent direction. **(b)** Result of a DFT calculation of O_2 on a 2 ML thin MgO(001) film on Mo(001) showing the polaronic distortion of the MgO lattice. **(c)** Sketch of oxygen molecules adsorbed on 2 ML MgO films as predicted by theory. The *transparent area* indicates the plane in which the magnetic field was lying in **(a)**. The orientation of the three principal components of the $\boldsymbol{g}$-matrix of the two symmetry equivalent molecules are shown as *color coded arrows*. As an EPR experiment probes the $\boldsymbol{g}$-value oriented along the static magnetic field it is readily clear that both molecules are not identical for the magnetic field lying in the surface plane. Adapted from [10.148]

MgO lattice on the STM images of Au atoms. For an 8 ML film > 80% of the atoms occupy one adsorption site, while at least two different adsorption sites are populated with almost equal probability on 3 ML films (Fig. 10.17d), which clearly shows the change in adsorption site [10.27].

Charge transfer is not restricted to metal atoms with sufficiently high electron affinity, but was theoretically predicted for molecules with high electron affinities such as NO_2 or O_2 adsorbed on ultrathin MgO(001) films grown on Ag(001) or Mo(001) [10.147, 153, 154]. From an experimental point of view the characterization of the superoxide anion (O_2^-) can be approached using EPR spectroscopy [10.155] as the superoxide anion is a radical with a doublet ground state. Figure 10.18a shows an EPR spectrum of molecular oxygen adsorbed at 40 K on a 4 ML thick MgO(001) film grown on Mo(001) [10.148]. The spectrum consists of a doublet of lines at $\boldsymbol{g}$-values of 2.072 and 2.002, which are well in line with expectations based on O_2^- radicals observed on MgO powder [10.156–158]. In line with theoretical predictions the radicals show significant stability ($T_{\mathrm{des}} \approx 350$ K) and disappear for thicker MgO films (> 15 ML). A detailed analysis of angle dependent spectra reveals that the O_2^- radicals are adsorbed on the terraces of the MgO(001) surface aligned with [110] equivalent directions as predicted theoretically (Fig. 10.18b). A comparison of the $\boldsymbol{g}_{zz}$ component (for an alignment of the $\boldsymbol{g}$-matrix with the molecular framework see Fig. 10.18c) of the $\boldsymbol{g}$-matrix ($\boldsymbol{g}_{zz} = 2.072$) with values observed for O_2^- radicals on terraces of MgO powders ($\boldsymbol{g}_{zz} = 2.091$) [10.157] provides additional physical insight into the interaction between the molecule and the surface as the observed value depends critically on the local electric field experienced by the radical. The reduction of the $\boldsymbol{g}_{zz}$ component on the film as compared to bulk MgO is associated with an increase of the local electric field, which is due to the polaronic distortion of the MgO lattice in case of the ultrathin film (Fig. 10.18b) as revealed by quantum chemical calculations [10.148].

We have already shown that single Au atoms become charged upon adsorption on very thin MgO(001) films. Hence, it is interesting to explore the consequences of charge transfer on the growth mode of Au particles. Theory predicted that charge transfer onto the gold particles leads to the formation of 2-dimensional structures on ultrathin MgO films in contrast to expectations on bulk MgO, where 3-dimensional particles are expected [10.9, 10, 26]. The reduced stability of the 2-dimensional structure with film thickness is due to a decreasing stabilization due to the image charge as well as the increasing cost for the polaronic distortion with increasing film thickness. The latter is caused by a stiffening of the MgO lattice due to the long-range nature of the Coulomb interaction. A low temperature STM study provided experimental evidence for the predicted crossover in growth mode. For an 8 ML MgO/Ag(001)-film 3-dimensional particles are observed after annealing to room temperature, whereas the Au-structures on 3 ML MgO/Ag(001) stay 2-dimensional after the corresponding annealing step (Fig. 10.19) [10.27].

An increase of the contact area between metal and oxide film allows to optimize the charge transfer. For a close-packed Au layer on an ultrathin MgO(001)/Ag(001) an average charge transfer of about

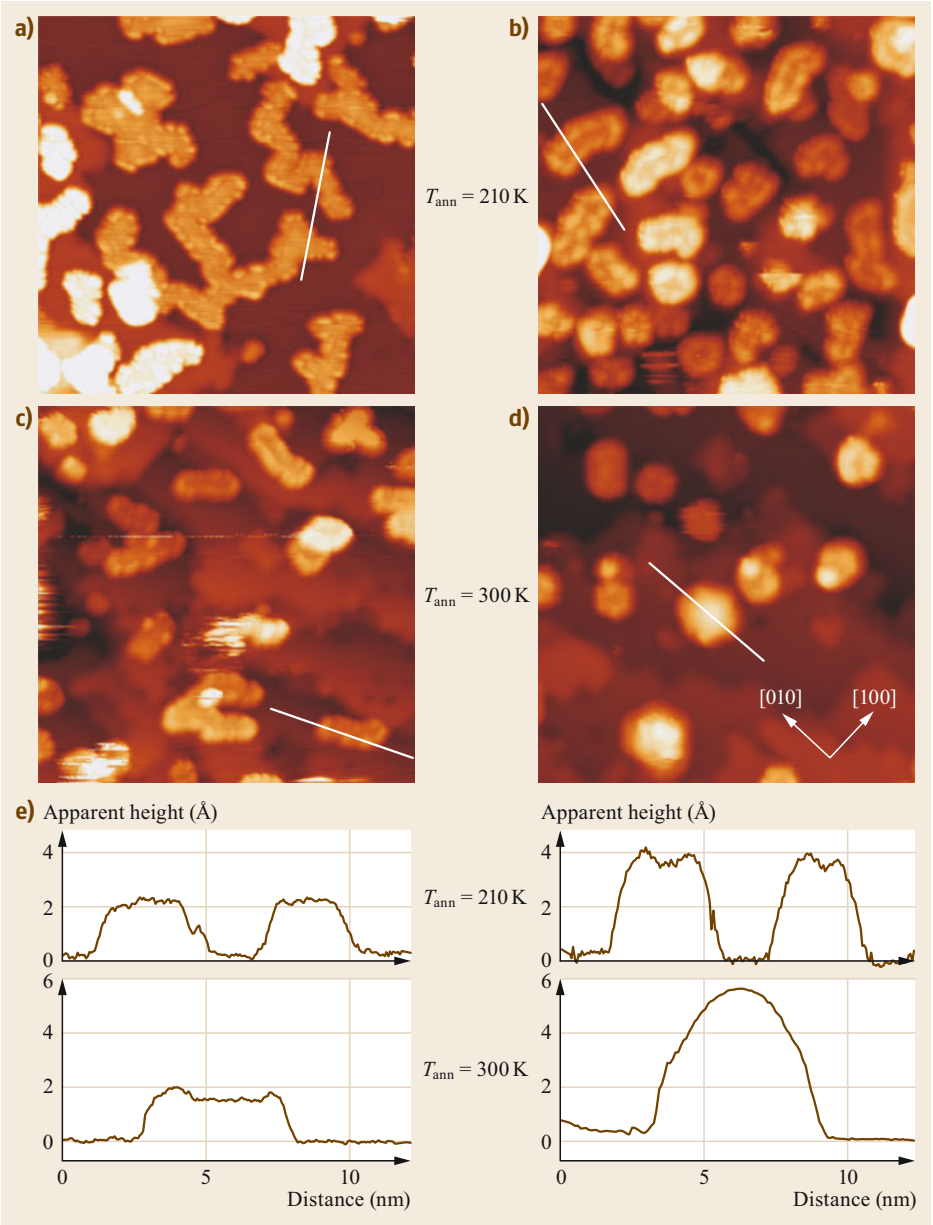

Fig. 10.19a–e STM images of Au deposits on 3 ML **(a,c)** and 8 ML **(b,d)** MgO(001)/Ag(001) ($30 \times 30\,nm^2$) after annealing of Au deposits to 210 K and 300 K, respectively. **(e)** Line profiles of characteristic clusters found in **(a–d)** [10.27]

$-0.2|e|$ per adatom has been calculated [10.159]. As shown for Au chains on alumina/NiAl(110) it is not expected that the charge distribution within Au islands is homogeneous [10.160]. Experimentally, this distribution can be interrogated by so-called conduction maps, which show an enhanced dI/dV contrast around the Fermi level at the island edges indicating a higher density of states at these sites [10.161]. This observation is nicely reproduced by semi-empirical tight-binding DFT calculations, which reveal an increase of charges at the perimeter of the particles [10.161].

A more detailed picture of the electronic structure of the adsorbed Au particles can be obtained by exploring so called quantum well states (QWS), which are derived from the 6 s levels of the Au atoms and hence allow for an analysis in a 2-dimensional electron gas model [10.162]. Figure 10.20a,b shows three STM images providing information on topography as well as electronic structure of occupied as well as unoccupied states of a small Au cluster with about 10 Å diameter grown on a 2 ML MgO/Ag(001) film [10.159]. The image taken around the Fermi energy reveals mainly the

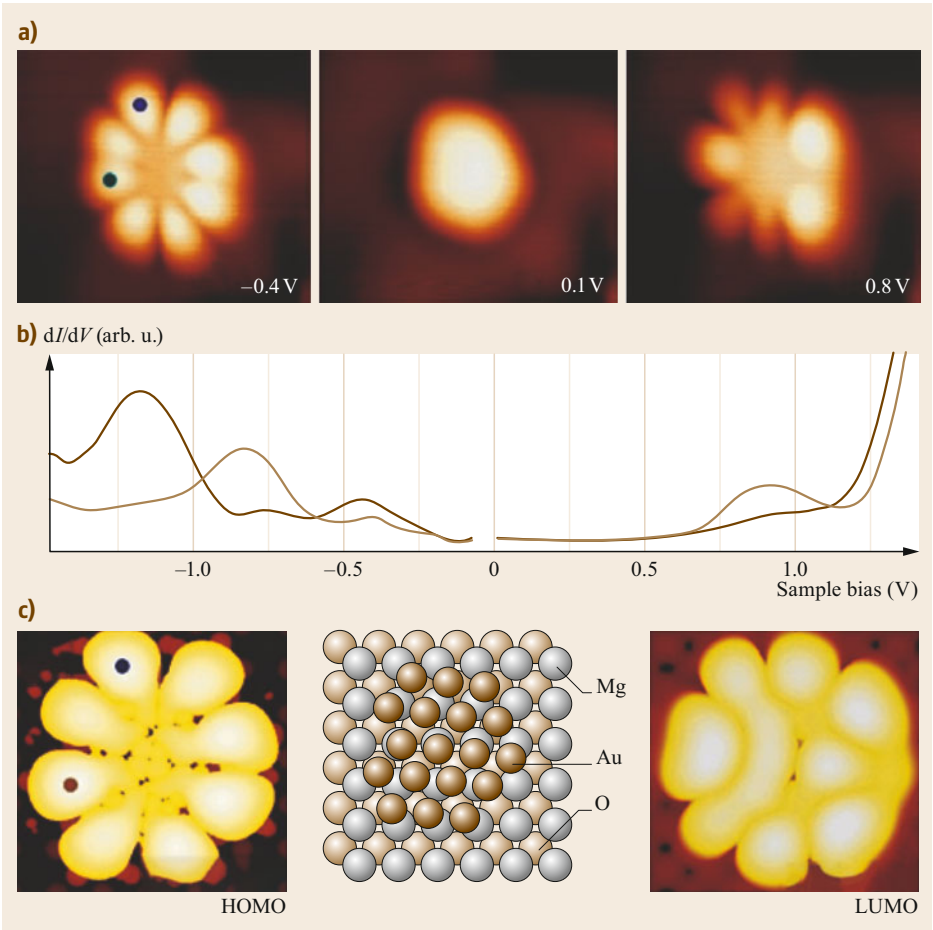

Fig. 10.20 **(a)** STM images of a symmetric Au cluster on 2 ML MgO/Ag(001) taken at the given sample bias. **(b)** dI/dV spectra of top (*dark brown*) and left part (*light brown*) of the Au cluster in panel **(a)**. **(c)** Calculated images of the HOMO (highest occupied molecular orbital) and LUMO (lowest unoccupied molecular orbital) as well as structure model of an Au_{18} cluster on MgO/Ag(001). cluster morphology as no states are available in the energy range probed by the STM experiment. At higher bias the appearance of the cluster changes to flowerlike protrusions. The bias-dependent contrast is clear evidence for tunneling governed by electronic and not topographic properties of the island. Both observed QWS probed by STM resemble the eigenstates of a free-electron gas in a 2-dimensional parabolic potential, which can be characterized by an angular momentum quantum number j [10.163]. Both states, observed at −0.4 and +0.8 V, respectively, exhibit four nodal planes ($j = 4$), which corresponds to G-symmetry. The next two lower lying occupied states, found at −0.8 and −1.2 V, exhibit P-symmetry (not shown). A detailed analysis of the electronic structure of this Au cluster including its charge state was achieved by comparing the experimental results to DFT calculations [10.159]. However, an extensive search of the parameter space is required to determine the number of atoms, the geometric structure as well as the charge state of the cluster. The degree to which theory is able to reproduce the experimental results is nicely shown in Fig. 10.20c assuming a planar Au_{18} cluster lacking one corner atom of a Au_{19} cluster, the latter being a so-called magic-size. In agreement with the experiment, the highest occupied as well as the lowest unoccupied state are of G-symmetry being located in the 5th level of the harmonic potential, whereas the highest states of the 4th shell of this potential are of P-symmetry in line with the experimental results. Once this has been established, the charge state is readily determined by counting the filled states in the potential. There are 11 doubly occupied orbitals,

hence, 22 electrons. The 18 Au atoms contribute 18 electrons, which leads to a 4-fold negatively charged cluster being provided by charge transfer from the support. A Bader analysis of the DFT calculation yields a value of $-3.54|e|$ for the Au_{18} cluster. Please note that this amounts to an average transfer of almost $0.2|e|$ per atom as calculated for closed-packed Au layers on the MgO thin film [10.161].

In this chapter we have discussed charge transfer effects on ultrathin oxide films using MgO as an exploratory example. We have shown how microscopy as well as spectroscopy can be used to provide experimental evidence for charge transfer between the substrate and adsorbed species such as metal atoms or molecular adsorbates with appropriate properties. The tools and concepts used here are, however, not limited to the ultrathin films, but it is possible to transfer some of them to bulk like oxide films if suitable electron donors or acceptors are provided. Such species can be introduced into oxide films by doping, which will be discussed in more detail in following section.

10.3.2 Modifying the Properties of Oxide Materials via Doping

The former paragraphs have illustrated that spontaneous electron transfer through oxide thin films has an enormous impact on the equilibrium shape of metal particles and even enables molecular activation [10.27, 148]. So the question arises, whether the concept of charge-mediated control of the oxide properties is restricted to ultrathin films, or can be extended to thicker layers or even bulk materials, as used in heterogeneous catalysis [10.29, 164]. A possible route might be the insertion of suitable charge sources directly into the oxide material, preferentially into a near-surface region to allow for charge exchange with adsorbates [10.165]. By this means, all advantages of charge control could be maintained for oxide slabs of arbitrary thickness. Although the fundamental concepts of doping were introduced and brought to perfection in the semiconductor technology already decades ago, a direct transfer to oxide materials is challenging due to several structural and electronic peculiarities [10.166]. Oxides are subject to self-doping by native defects and unwanted impurities, the concentration of which is difficult to control experimentally [10.138]. Both lattice defects and impurity ions may adopt different charge states in the oxide matrix [10.167], a variability that leads to pronounced compensation effects and is less common in semiconductors. And finally, the dopants may be electrically inactive in wide-gap oxides, as thermal excitation is insufficient to promote electrons from the defect states to the bulk bands. The excess charges thus remain trapped at the host ions and are unavailable for charge transfer. However, the following examples demonstrate that doping is a versatile approach to tailor the properties of bulk-like oxides as well.

In general, doping is carried out with impurity ions that adopt either a higher or a lower valence state than the native oxide ions [10.165]. Whereas high-valence dopants may serve as charge donors and provide extra electrons, low-valent dopants have acceptor character and may accommodate electrons from suitable adsorbates. In rare cases, charge-preserving doping is realized where geometric and strain effects take the role of the charge transfer [10.168]. Based on the above considerations, we expect that charge donors inserted in an oxide lattice may resume the role of the metal support in the case of ultrathin oxide films. This assumption has first been verified in studies of the growth morphology of gold on crystalline CaO(100) doped with trace amounts of Mo (Fig. 10.21) [10.47]. On the doped oxide, gold was found to spread out into extended monolayer islands, while the conventional 3-D growth prevailed on the nondoped material. Evidently, the donor character of the Mo ions is responsible for the 2-D growth morphology, while the metal–oxide adhesion on pristine CaO(100) is negligible.

According to DFT calculations, Mo dopants in CaO mainly occupy Ca substitutional sites and adopt the typical 2+ charge state of the rock salt lattice. In the 2+ configuration, four Mo 4d electrons are localized in the dopant, three of them occupying (t_{2g}-α) crystal field states and one sitting in a (t_{2g}-β) level close to the conduction band onset (Fig. 10.21c) [10.169]. Especially, the latter is in an energetically unfavorable position and thus susceptible to be transferred into an acceptor state with lower energy. Such states are provided by the Au ad-atoms that exhibit a half-filled Au 6s affinity level, being ready to take the topmost Mo 4d electron. The result is an Au^- anion that, as discussed before, experiences reinforced bonding to the CaO surface [10.25]. DFT calculations find an increase of the binding energy from ≈ 1.5 to ≈ 3.5 eV upon doping, whereby the electrically-active Mo ion may be located up to ten layers below the CaO surface [10.47]. Moreover, not only Mo^{2+} ions are susceptible to electron transfer into gold, but also Mo^{3+} and Mo^{4+} are active donors as their topmost occupied d states are still higher in energy than the Au 6s affinity level [10.169]. Mo impurities in the CaO lattice are therefore robust electron donors, and as such directly responsible for the 2-D growth of gold found experimentally [10.47].

The presence of suitable dopants is, however, not the only requirement for a stable donor characteristic and also the interplay between dopants and the host oxide governs the redox activity, as shown for Cr-

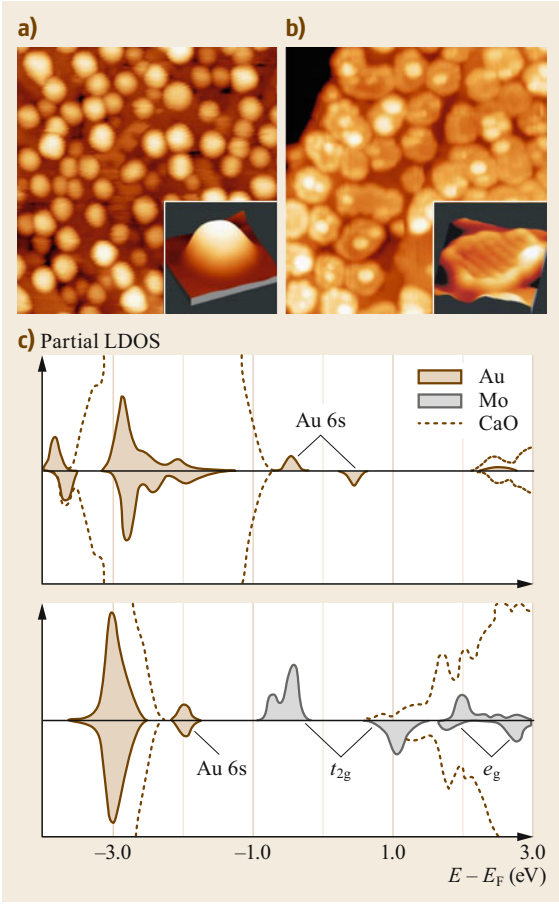

Fig. 10.21a–c STM images of 0.7 ML Au deposited onto **(a)** pristine and **(b)** doped CaO films (4.5 V, $50 \times 50\,nm^2$). The *insets* display close-up images of two characteristic particles (−5.0 V, $10 \times 10\,nm^2$). **(c)** PBE (Perdew–Burke-Ernzerhof (DFT functional)) projected state-density calculated for nondoped (*top*) and doped (*bottom*) CaO films in presence of an Au adatom. doped MgO films next [10.170]. Although chromium has a similar electronic structure as Mo, i.e., the same number of d electrons, it is unable to influence the Au growth on MgO supports (Fig. 10.22). Even at high Cr concentration, gold adopts 3-D shapes and hardly any 2-D islands are found on the surface [10.44]. The reason is the low energy position of the Cr t_{2g} levels in the MgO band-gap, reflecting the large stabilization effect of the MgO crystal field on the Cr electrons. Note that the crystal field in MgO is much stronger than in CaO given the larger lattice parameter of the latter [10.171]. In addition, the Cr ionization energies are higher than those for Mo, and formation of Cr^{4+} and Cr^{5+} ions is energetically costive. As a result, Cr is able to donate only a single electron to gold, which compares to three in the case of Mo ions in CaO [10.169, 170]. More critically, not even this electron may reach the ad-metal, but is likely captured by parasitic electron traps in the oxides, such as cationic defects or grain boundaries. Cation vacancies or *V*-centers are the preferred compensating defects for high-valance dopants, as they are able to neutralize the extra charges released by the impurity ions (Fig. 10.22e) [10.166]. According to DFT calculations, the formation energy of a *V*-center decreases from 8 eV in bare CaO or MgO to 1.0−1.5 eV in the presence of high-valence dopants [10.44]. Accordingly, an effective compensation mechanism becomes available that fully annihilates the donor character of the Cr ions. Because Mo impurities in CaO are able to release more electrons, full charge compensation is impossible and the impact of the donors prevails in that case.

Low-valence dopants generate hole-states in the electronic structure of rocksalt oxides and are able to trap excess electrons as well [10.172, 173]. Their response is therefore similar to the one of compensating lattice defects, as shown in a codoping experiment on CaO using both, Mo donors and Li acceptors [10.46]. At low Li concentration with respect to Mo, most of the Au particles still adopt 2-D shapes, indicating that the charge transfer into the gold is maintained. With increasing Li doping level, more and more charges get trapped in the Li-induced defects until the charge flow into the ad-gold breaks down completely and the Au particles turn 3-D. In fact, monovalent Li^+ substituting a Ca^{2+} ion produces a deep hole in the O 2p states of adjacent oxygen that effectively traps all available free carriers and neutralizes the Mo donors. Let's note that Li doping alone did not result in any observable change in the Au growth characteristic on the CaO surface. This finding suggests an effective intrinsic compensation mechanism to be active also in the case of low-valence dopants [10.174]. Hereby, oxygen vacancies play the role of the compensating defect, as they are able to release electrons according to

$$F^0 \rightarrow F^+ + e^- \rightarrow F^{2+} + 2\,e^-$$

which then fill up the hole states produced by the Li ions. Hole-doping of oxides, as a means to tailor the properties of metal ad-particles, is therefore more difficult to realize than electron-doping with donor-type impurities [10.175].

So far, electron-transfer processes induced by dopants in the oxide lattice have been shown to modify the growth behavior of ad-metals on oxide surfaces. However, charge exchange is also a promising route for molecular activation, as demonstrated before for oxy-

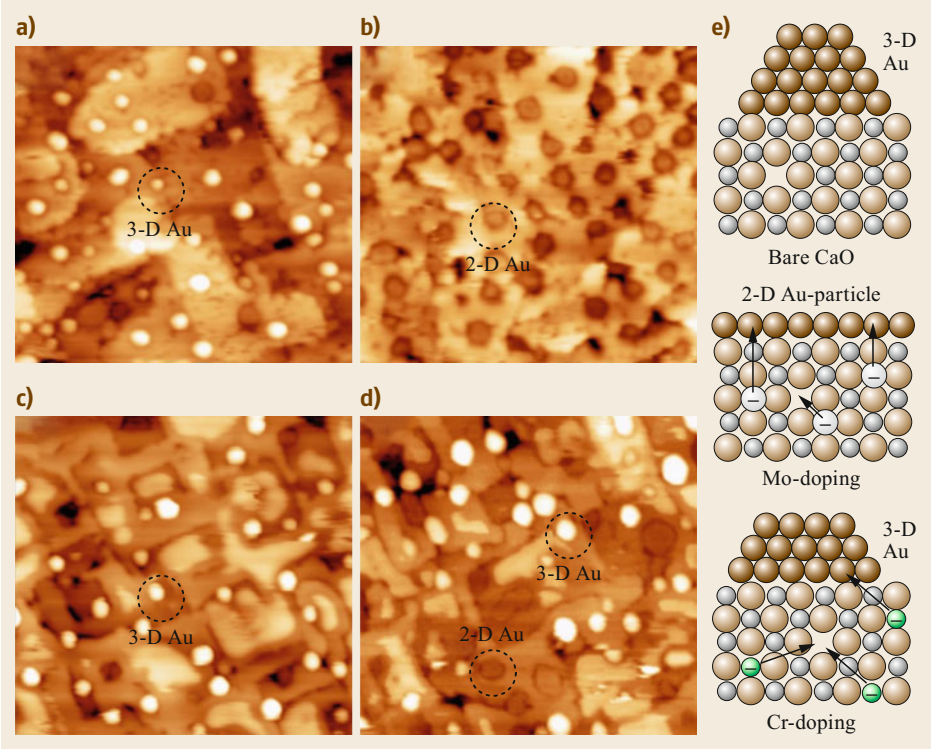

Fig. 10.22a–e STM images of **(a)** bare and **(b)** Mo-doped CaO(100) films of 60 ML thickness after dosing 0.5 ML of Au ($60 \times 50\,nm^2$, $V_S = 6.0\,V$). The 2-D Au islands appear as depressions on the insulting oxide, because electron transport through the gold is inhibited at high positive bias. Similar measurements on **(c)** bare and **(d)** Cr-doped MgO(100) films of 20 ML thickness. The particle shape is not affected by the dopants in this case. **(e)** Ball models visualizing charge-transfer processes between the doped oxide and the ad-metal and their effect on the particle shape

gen exposed to thin MgO/Mo films [10.148]. In the following section, we will show that a similar scheme holds for bulk-like oxides, in which high-valence dopants have been inserted as intrinsic charge source.

Not unexpectedly, stoichiometric CaO(100) as a chemically inert, wide gap insulator shows little activity toward adsorption and dissociation of oxygen (Fig. 10.23a) [10.176]. Neither at room nor low temperature (20 K) is the oxide able to bind oxygen, apart from some trace amounts attached to low-coordinated edge and corner sites. This situation changes considerably for a material doped with Mo ions [10.43]. The STM images now reveal a high concentration of depressions on the CaO surface after oxygen exposure, both at 20 and 300 K (Fig. 10.23b). In fact, two oxygen species are distinguished on the surface. The first one shows up as 0.6 Å deep and 10 Å wide depression and is assigned to an oxygen molecule (Fig. 10.23c). Exposing it to electrons from the tip, it can be converted into a pair of shallow dents surrounded by a bright halo. Apparently, the molecule gets dissociated into its atomic constituents via electron injection [10.177]. Whereas a mean O–O separation of 10−15 Å is observed directly after dissociation, the distance increases over time, indicating the repulsive character of the O–O interaction on the surface (Fig. 10.23c).

The ability of the CaO(100) surface to adsorb oxygen is apparently triggered by the presence of high valence Mo ions in the lattice. The underlying interaction mechanism relies again on an electron transfer between the high-lying Mo 4d states and the LUMO of the oxygen molecule, as revealed by DFT calculations performed at the B3LYP (Becke, three-parameter, Lee–Yang–Parr (DFT functional)) +D level [10.43]. On nondoped CaO(100), the oxygen physisorbs with ≈ 0.13 eV to a Ca–Ca bridge position. On doped CaO, an O_2^- species develops due to charge transfer from the Mo dopants, which strongly interacts with a surface Ca^{2+} ion. The calculated binding energy amounts to 0.87 eV if the associated donor is a Mo^{3+} ion located in the third subsurface plane. Even larger adsorption energies are found for Mo^{2+} species serving as donor, as well as

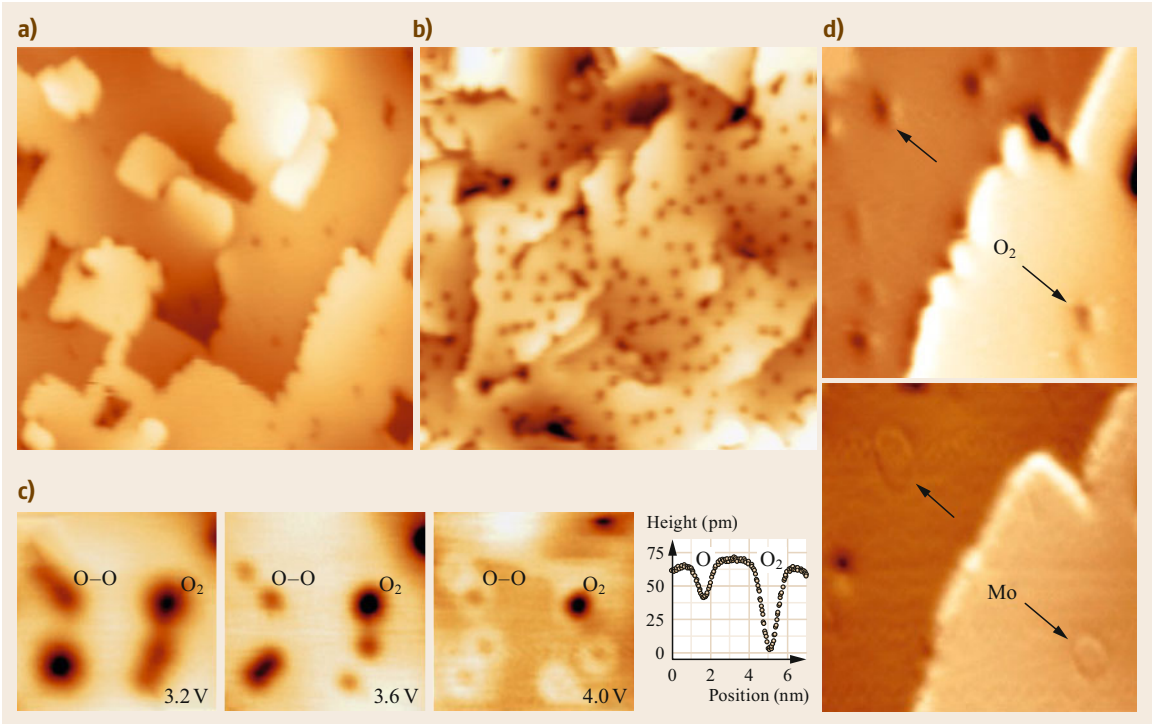

Fig. 10.23 **(a,b)** STM images of bare and Mo-doped CaO after dosing 5 Langmuir O_2 at 20 K ($40 \times 40\,nm^2$). **(c)** Bias-dependent contrast and height profile of oxygen molecules (deep minima) and atoms (faint double dents). for dopant positions closer to the surface [10.43]. Further evidence for the formation of O_2^- species comes from the bond elongation (121−133 pm) and the reduced stretching frequency (1537−1200 cm^{-1}) of the oxygen molecule after charge transfer. In addition, a decreasing total spin of the system has been calculated, evolving from 5/2 (3/2 for Mo^{3+} plus 2/2 for neutral O_2) to 3/2 (2/2 for Mo^{4+} plus 1/2 for the O_2) due to the electron exchange. The superoxo species formed on the doped CaO surface exhibits, finally, a two times lower barrier for dissociation, if compared with a neutral O_2 on pristine CaO. This theoretical finding is in good agreement with the observation that oxygen adspecies can be effectively dissociated via electron injection from the tip. The DFT calculations therefore clearly corroborate the idea that electron transfer from Mo dopants is responsible for the adsorption, activation and finally dissociation of O_2 molecules on the CaO surface [10.43].

Further experimental evidence supports the above mechanism. If single oxygen molecules are removed from the surface by means of a controlled bias pulse given to the STM tip, a Mo donor shows up via a characteristic ring structure on the CaO surface, arising from a temporal change of the Mo charge state as the tip scans this oxide region (Fig. 10.24d). The spatial correlation between the impurity position in the oxide and the preferred O_2 adsorption site underlines that the dopant indeed mediates the binding of oxygen. Interestingly, the active dopant never occupies a position directly in the CaO top layer, but sits in subsurface planes as deduced from the diameter of characteristic charging rings emerging in the STM images [10.178]. The charge transfer to adsorbates hereby occurs via electron tunneling over distances as large as 1 nm. A last experimental hint for O_2^- formation on doped CaO films comes from the evaluation of the vacuum states above the oxide surface (Fig. 10.24). As mentioned already in Sect. 10.2.1, the vacuum states are a sensitive probe of the local surface potential [10.86] and up-shift in energy if negatively charged species accumulate at the surface but downshift on surfaces holding a positive net-charge. This provides a direct probe of the direction of charge transfer in the CaO/Mo(001) system. An oxide region densely covered with O_2^- species exhibits a series of vacuum states, the lowest of which being located

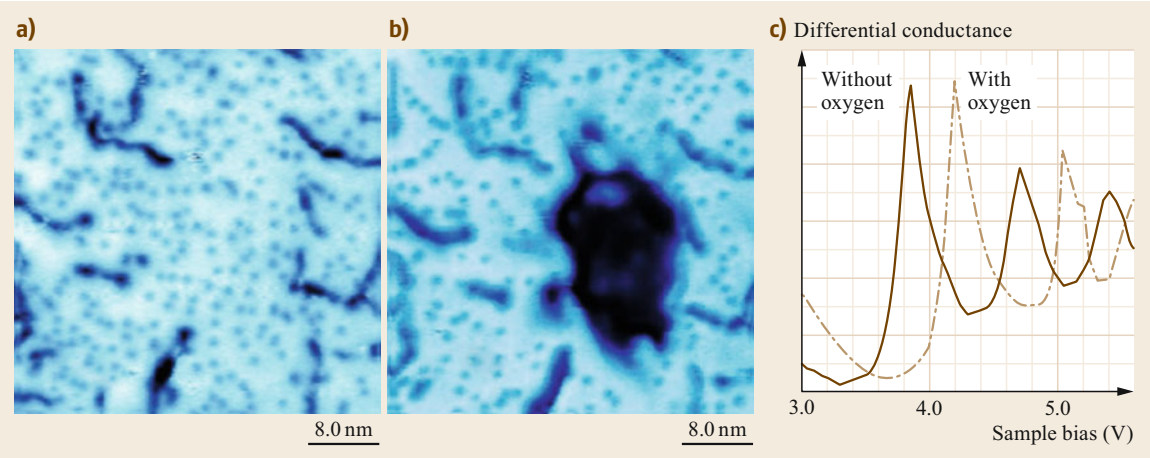

Fig. 10.24 (a,b) Conductance images of CaO/Mo(001) before and after desorbing O_2 molecules from the central region with a tip voltage pulse ($40 \times 40\,nm^2$). The bias voltage for imaging has been tuned to the first vacuum state of the oxygen-covered surface (4.0 eV), which consequently appears with bright contrast. After oxygen removal, the local surface potential, and hence the vacuum states, downshift and the affected surface region shows lower conductance and appears dark. (c) STM conductance spectra showing the energy shift of CaO vacuum states after O_2 desorption from the surface. Reprinted with permission from [10.43]

at 4.2 V above the Fermi level (Fig. 10.24c) [10.43]. After desorbing the molecules with a tip pulse, the vacuum states experience a clear downshift, reflecting the decreasing electron density after removing the negatively charged superoxo species. The excess electrons released during desorption return to their Mo host-ions located in subsurface CaO planes, where they do not perturb the surface potential anymore. The effect of a decreasing surface potential after oxygen desorption can best be visualized in work function maps, plotting the contribution of selected vacuum states to the electron transport between tip and sample (Fig. 10.24a,b). Whereas the overall electron transmissibility is high on the oxygen covered surface, with the exception of certain CaO line defects, a localized patch of low contrast emerges after removal of the O_2^- species from this region. The measurement reflects the local drop of the surface potential after oxygen desorption, which suddenly makes the lowest vacuum state unavailable for electron transport and explains the low contrast in this region. Also this data cannot be explained without taking the effect of charge transfer between the doped oxide and the O_2 molecules into account.

In summary, doped bulk oxides display in many respects similar adsorption properties as ultrathin oxide films [10.179]. In both systems, excess electrons are transferred into the ad-species and open up specific charge-mediated interaction schemes. Whereas for ultrathin films, the extra electrons are provided by the metal substrate below the film, doped oxides contain intrinsic charge sources in the form of aliovalent impurity ions. As shown here, high-valence dopants in the CaO lattice are able to alter the equilibrium shape of metal particles from 3-D to 2-D, which is expected to change the reactivity pattern of the metal–oxide system as well. Moreover, the charge transfer opens a suitable pathway to activate small molecules, such as oxygen or carbon dioxide, even on smooth, defect-free surfaces of a nonreducible, but doped oxide. Whereas thin oxide films on metal single crystals are of large academic interest, as they provide easy access to the properties of oxide materials via conventional surface science methods, doped oxides are of direct, practical relevance for heterogeneous catalysis.

10.3.3 Metal Deposits on Silica Films

In order to make use of the silica film system in the context of heterogeneous catalysts and to further characterize its chemical and physical properties, the adsorption behavior of

> "Au and Pd over bilayer SiO_2/Ru has been investigated by using scanning-probe microscopy, XPS, and density functional theory (DFT) [10.180]. Low temperature (≈ 5 K) AFM and STM measurements reveal the presence of small adsorption features after exposing the samples to small doses of either metal (Fig. 10.25a,b). In the case of

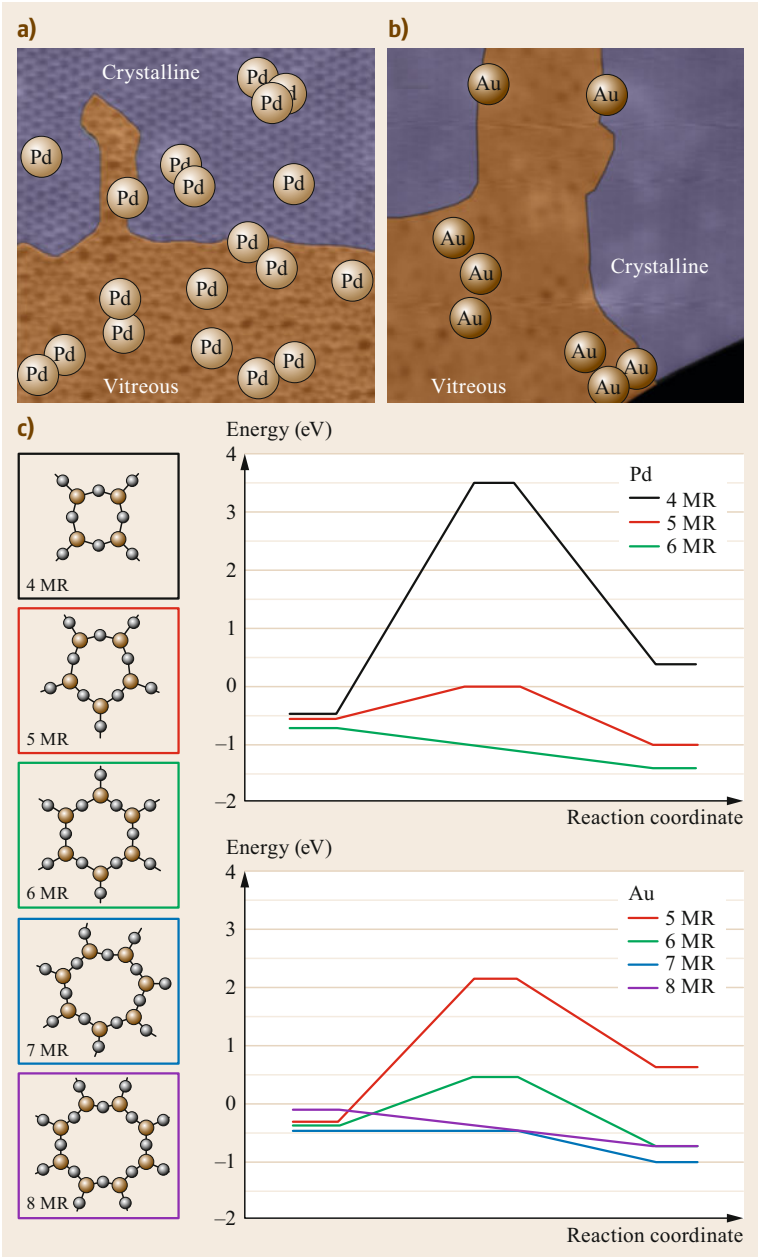

Fig. 10.25a–c STM images showing Pd and Au adsorption over silica. **(a)** Pd on SiO_2; **(b)** Au on SiO_2. Crystalline regions are colored *purple* and amorphous regions are colored *brown*. Note: The nonregular dimmer features throughout the crystalline portions of both samples likely result from native SiO_2/Ru species, as they are present both before and after metal adsorption. All images: 15 nm × 15 nm, $V_S = 2$ V, $I_T = 100$ pA. **(c)** Penetration profiles for Pd and Au through rings of different size. Energies are computed with respect to the metal atom in the gas phase. Pd, we note a homogeneous distribution of adsorbates across the entire surface, marked by circles and elemental symbols (Fig. 10.25a), which consists of both amorphous and crystalline phases. Au, however, adsorbs only over amorphous areas and domain boundaries, which possess larger pores than can be found in the ordered portions of the film (Fig. 10.25b). DFT calculations reveal that this difference is rooted in the pore-size-dependent barriers for diffusion of the two metals into the film, where they can then bind stably at the Ru interface (Fig. 10.25c). Auger parameter analysis of the Pd 3d and Au 4f core-levels from atoms binding in this manner show upward orbital-energy shifts, which, according to the results of theoretical calculations, originate from effects similar to those causing surface core-level-shifts for such metals [10.181]. Further analysis of the computational results shows that such atoms donate electron density to the Ru support, which is consistent with

> XPS results that show band-bending effects related to decreases in the work function of the sample after adsorbing either metal. Additional features in the XPS studies suggest that a secondary binding mechanism, mediated by cluster formation over the SiO_2 film, becomes increasingly favorable as temperature and loading increase."

For the crystalline SiO_2 film on Mo(112), a similar size-dependent adsorption behavior has been observed. Whereas Pd and Ag atoms were found to penetrate the six-membered –Si–O– rings with little barrier, Au atoms can pass the silica over-layer along domain boundaries only, which contain larger, i.e., eight-membered rings [10.182]. However, it is not the size of the atoms that governs the penetration behavior, but their electronic structure. Both, Pd and Ag atoms deplete their spatially expanded 5s orbital before passing the film, while the highly electronegative Au cannot strip off its 6s-electron and is thus unable to penetrate the regular SiO_2. Inserting metal atoms at the interface between ordered silica films and the Mo support opens a number of other fascinating functionalities. Addition of interfacial Li, for example, gives rise to a dramatic decrease of the work function of the thin film system, controlled by the highly electropositive character of the Li-ions [10.183]. Iron deposition, on the other hand, leads to the formation of single-ion magnetic units at the metal–oxide interface [10.184].

10.4 Chemical Reactivity of Oxide Surfaces

Chemical reactions at oxide surfaces play a pivotal role in a variety of technological processes in particular in heterogeneous catalysis. Therefore, it is of great interest to understand these processes at the atomic level. Tremendous efforts have been made for powdered materials to get to this point, but the complexity of these systems usually hampers an atomistic characterization. In this section we will exemplify the level of understanding that can be achieved by discussing first the interaction of water with oxide surfaces as well as the impact of hydroxylation on the growth of metal nanoparticles using the systems introduced above. Subsequently, we will focus on chemical transformations of gas phase molecules on oxide surfaces using vanadium oxide as an exploratory example and will finally show results on CO oxidation on an thin FeO(111) film grown on Pt(111) at elevated pressures and molecular beam studies on alkene hydrogenation as well as the H_2/D_2 exchange reaction using a model catalyst consisting of oxide supported metal nanoparticles.

10.4.1 Interaction of Gas-Phase Water with Well-Defined Oxide Surfaces

The interaction of water with oxide surfaces is of major interest in surface science because of the strong impact of hydroxyl groups on the surface properties, in particular, the reactivity of solid surfaces, which is important in diverse fields such as biology, materials science, environmental science, geochemistry, and heterogeneous catalysis. Depending on the chemical potential of water (and oxygen) and the chemical properties of the oxide surface, the adsorption state of water is either molecular or dissociated, or a combination of the two.

> "In this section, we review some of the results obtained with the thin oxide films introduced in Sect. 10.2 with regard to water interaction, showing how a combination of different methods allows to gain atomistic insight into the energetics of adsorption processes as well as the nature of the surface species.

Water on Alkaline Earth Oxide and Silica Surfaces: Monolayer Structures and Hydroxylation

A comparison of water adsorption on the (100) surfaces of the alkaline earth oxides is interesting because they all have the same structure (fcc, rocksalt), but different lattice constants and basicity, which is expected to strongly influence the water adsorption (molecular or dissociative) and the ability to form long-range ordered 2-dimensional structures. While monolayer water adsorption on MgO has extensively been studied in the past both experimentally and theoretically and is now well-understood, details about the higher alkaline earth oxides such as CaO and SrO have only recently become available. It is well established that a single water molecule adsorbs molecularly on the MgO(100) surface, but may dissociate, even under UHV conditions, on defects such as low-coordinated cation-anion pairs on step edges. By contrast, single molecule adsorption is dissociative on CaO and SrO and involves considerably higher adsorption energies, as shown in

Fig. 10.26a, which displays the computed E_{ads} for water on the various oxides [10.185]. The dissociated monomer consists of a dynamic ion pair with the hydroxyl group (*free* OD, OD_f) adsorbed in bridge position between two cations and the proton transferred to a nearby oxygen ion (*surface* OD, O_sD, Fig. 10.26c) [10.186]. An interesting trend is seen for increasing water coverage, i.e., for increasing the number of water molecules per (3×4) unit cell used in the calculations: While the adsorption energy increases with increasing coverage for MgO and 2-dimensional monolayer structures are found to be the most stable water adsorption states, the calculated adsorption energy for water on CaO(001), although very similar in the entire coverage range, is highest for 1-dimensional structures. For SrO, isolated and dissociated monomer and dimer species are expected to be more stable than the oligomer species. Experimentally, evidence for the 2-dimensional ordered arrangement of the water monolayer on MgO has been provided by diffraction and scattering methods more than 20 years ago [10.187, 188]. More recently, the stability of 1-dimensional water structures was proven by STM upon water adsorption on thick CaO(001) films at room temperature (Fig. 10.26b) [10.185, 189], and the confirmation of the dynamic ion pair nature of a single, dissociated water molecule, as well as the stability of dimer species, on SrO has been obtained by STM on SrO-terminated $Sr_3Ru_2O_7$ [10.190].

Generally, diffraction methods and STM do not allow the positions of the individual water species and their chemical nature (molecular or dissociated) within the 1- and 2-dimensional water structures found on MgO(001) and CaO(001) to be determined, and one has to resort to high-level computations and spectroscopic methods to learn more about the molecular-scale details of these structures. Whereas electron spectroscopies can provide information about the presence of dissociated and molecular water, which, for example, has provided first experimental proof for the existence of mixed molecular/dissociated water molecules in the water monolayer on MgO(001) [10.192], comparison of experimentally measured and computationally obtained frequencies of water and hydroxyl vibrations is considered to provide additional information about the structural details.

The latter approach has been used to identify and confirm the structural models of the 2-dimensional water monolayer on MgO(001) [10.191], and of the 1-dimensional chain structures found by STM on CaO(001) [10.185, 189]. Figure 10.26d shows the experimental IRAS (infrared reflection absorption spectroscopy) spectra (top panel) for the water monolayer prepared on MgO (left panel) at low temperature (160 K), and for the water chain structures prepared on CaO(001) at room temperature (right panel), and the corresponding calculated anharmonic vibrational spectra (lower panel). (Note that the experiments and calculations were performed with D_2O instead of H_2O). The experimental spectra are qualitatively similar and exhibit reasonably narrow bands in the range $2600-2750\,cm^{-1}$ and broad absorption between 2000 and $2500\,cm^{-1}$. The individual spectral contributions can be assigned based on the good agreement between the experimental spectra and the calculated spectra of the most stable structures shown in Fig. 10.26. For both, the MgO(001) and CaO(001) surface, the ordered water structures are comprised of dissociatively and molecularly adsorbed water. In the case of MgO, two ordered structures with different water coverage, the high coverage $c(4 \times 2)$ and the low-coverage $pg(3 \times 2)$ structure, coexist at 160 K and can be distinguished based on the different frequencies of the O_sD groups [10.191]. Note that, due to the metal surface selection rule, the molecular water species, which are oriented almost parallel to the surface in both structures, give rise to only weak absorption signals. In fact, they do not contribute to the IR spectrum of the $pg(3 \times 2)$ structure. In the case of the $c(4 \times 2)$ structure, the molecular water species stabilize the protruding OH_f group, and combinations of their symmetric and anti-symmetric stretch vibrations lead to signal contributions in the $2100-2400\,cm^{-1}$ spectral range, which are detected in the experiment as a broad featureless absorption. Molecular water species in the 1-dimensional chain structure on CaO(001) are also oriented parallel to the surface and contribute only little to the IR signal on the thin film sample. The more defined signals for water on CaO(001) originate from OH_f (at highest wavenumber) and O_sD groups from dissociated water. Note that the O_sD groups in the 1-dimensional chain structure on CaO(001) are spectrally much more separated than in the 2-dimensional structures on MgO because the strength of hydrogen bonding between O_sD groups and OD_f groups is markedly different in the tetramer unit and in the linker unit [10.185].

The combined experimental and computational analysis of water adsorption on the alkaline earth oxides has not only contributed to a better understanding of the molecular details of wa-

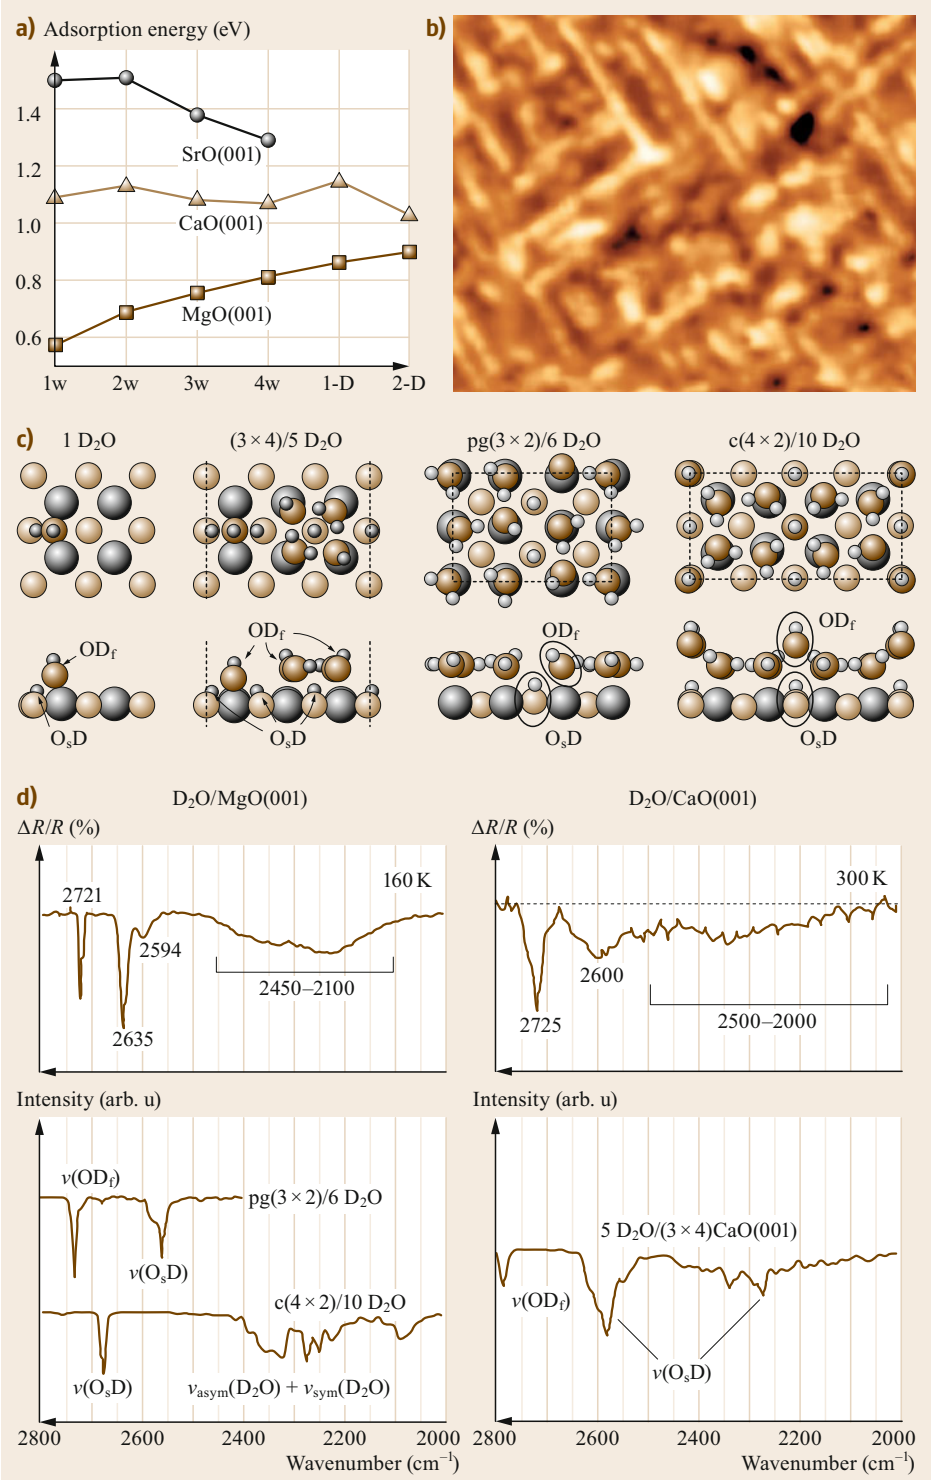

Fig. 10.26
(a) Calculated adsorption energy per water molecule on CaO(001), MgO(001), and SrO(001) for increasing water coverage (1w, etc.: 1 water molecule per (3×4) unit cell; 1-D, etc.: 1-dimensional water/hydroxyl structures). **(b)** RT-STM image ($30 \times 25\,nm^2$) of 1-dimensional water chains formed on CaO(001). **(c)** Most stable structures of the dissociated water monomer on CaO(001), the 1-D chain structure on CaO(001), and the two most stable ordered 2-D water phases (pg(3×2) and c(4×2)) on MgO(001). **(d)** Experimental (*top*) and computed (*bottom*) IR (infrared) spectra of the 2-D (D_2O) structures on MgO(001) (*left*) and the 1-D (D_2O) chain structure on CaO(001) (*right*). After [10.185, 189, 191]

ter structures, but additionally allows conclusions about the evolution of different structures on the surfaces to be drawn. Dissociation of a single water molecule is favored and involves larger adsorption energies when going from MgO to SrO. This can be explained by the increasing lattice constant and substrate flexibility when descending the AEO series [10.193]. Additionally, the subtle balance between intermolecular and molecule-surface interactions determines also the stability of higher coverage structures: Two-dimensional ordered structures are stabilized on MgO(001) because of the weak interaction between water and the MgO surface and the favorable dimension of the MgO lattice parameter, which allows a strong hydrogen bonding network between adsorbed water and hydroxyl species to be established. The CaO lattice is slightly too large to enable the formation of a hydrogen-bonded network, and the water structures therefore collapse into a 1-D configuration at low coverage. Similar 1-D assemblies become stable also on MgO(001) when its lattice parameter is artificially increased to reduce the effect of intermolecular coupling. In contrast on SrO(001), the water residuals are always too far away to form uniaxial or 2-dimensional hydrogen-bonded arrangements [10.185].

The results presented for the alkaline earth oxides demonstrate that not only the acid-base properties of the oxide surface, but also the lattice parameter and hence, the ability to form hydrogen-bonds between neighboring hydroxyl groups, has a major impact on the adsorbed water structures.

The examples discussed so far refer to water adsorption on bulk-like thin films (i.e., films of reasonable thickness and structurally similar as the corresponding bulk oxides) at UHV conditions, where no structural modifications of the oxide lattice take place during adsorption. For complete hydroxylation of the oxide surfaces, which is expected to occur when environmentally more realistic water partial pressure conditions (mbar range) or higher water coverages are approached, reactions between water and the oxide surfaces have to be considered as well. For the more ionic oxides in particular, this may involve hydrolysis of cation-anion bonds and strong structural modifications. The hydroxylation of MgO and CaO single crystal surfaces and the partial transformation into the corresponding hydroxide as a function of relative humidity have been studied by ambient pressure XPS. Those studies revealed that the CaO(001) surface gets fully hydroxylated even under UHV conditions and transforms into the hydroxide, involving hydroxylation of the subsurface regions, at elevated water partial pressure [10.194]. On the other hand, a certain threshold water pressure in the sub-mbar range has to be applied to achieve sufficient surface hydroxylation of MgO(001) [10.195]. Studies on the corresponding thin film surfaces confirmed these results. Figure 10.27a compares STM images of the surface of a clean CaO(001) film (top) and after a saturation dose of water under UHV conditions at room temperature (bottom) [10.185, 189]. Clearly, water adsorption leads to strong structural modification of the surface, which is due to complete surface hydroxylation and partial solvation of Ca^{2+} ions. The latter can in part be explained by the sufficiently large structural flexibility of the CaO lattice, which allows easy rupture of cation–anion bonds.

By contrast, hydroxylation of thick, bulk-like MgO(001) films at room temperature and in UHV conditions is limited to defect sites, and in order to obtain complete hydroxylation a threshold water partial pressure of about 0.01 mbar has to be applied (Fig. 10.27b) [10.196]. Titration of Mg^{2+} sites with CO has shown that the number of low-coordinated Mg^{2+} sites gets strongly enhanced upon hydroxylation, suggesting the occurrence of similar structural modifications as in the case of CaO(001). Interestingly, the threshold pressure for hydroxylation decreases by 3 orders of magnitude as the film thickness is reduced from 12 to 2 ML (Fig. 10.27b) [10.196]. This effect is not related to an increased abundance of defects on the ultrathin film, but can be explained by a decreased energetic barrier for the rupture of $Mg^{2+}-O^{2-}$ bonds, which is related to the greater structural flexibility of the MgO lattice in the ultrathin regime [10.197].

Polar oxide surfaces are intrinsically reactive towards water because surface hydroxyls provide compensating charges necessary to remove polarity. Similarly, in polar oxide films grown on metal substrates, while the compensating charge density at the metal–oxide interface is readily provided by the metal, the free film surface needs to be compensated by conventional mechanisms, e.g., surface hydroxylation. Conversely, the thinnest oxide films (monolayers) are intrinsically non-polar, thus reducing their activity towards water. In fact, the FeO(111) monolayer film is stable in pure water vapor environment, as shown by the O 1s XP spectrum obtained after exposure to 1 mbar water vapor, which exhibits only one component attributable to the lattice oxygen

species, and no further contribution from hydroxyls (Fig. 10.28a) [10.198]. In addition, the structural integrity of the FeO(111) monolayer appears to be maintained upon exposure to air ambient and even liquid water, as shown by the STM images presented in Fig. 10.28c, where the long-range ordered Moiré superlattice characteristic of FeO(111)/Pt(111) is proven to persist in the corresponding environment.

As will be discussed in more detail below (Sect. 10.4.3), exposure of FeO(111) to a high-pressure oxygen atmosphere leads to a transformation of the FeO bilayer to a O–Fe–O trilayer [10.35, 37, 39]. Both, the additional oxygen incorporated in the film, which shows up in XPS as a shoulder on the high binding energy side of the main O 1s component (Fig. 10.28a), and the similarity of the STM appearance suggest that this transformation occurs also upon exposure of the FeO film to air. In addition, the IRA spectrum of an air-exposed film reveals the presence of hydroxyl species with characteristic vibrations at $3650\,cm^{-1}$. It can, therefore, be concluded that the trilayer structure is not only highly active in the catalytic oxidation of CO, but also in water dissociation. As a result, an O–Fe–OH trilayer is formed (Fig. 10.28d) and the additional O 1s signal in XPS can be attributed to hydroxyl species [10.198]. XPS quantification reveals a maximum hydroxyl coverage of 0.45 ML. Together with the ordered appearance in STM this suggests that the hydroxylation activity is restricted to the most reactive region within the Moiré unit cell, which, according to DFT calculations, is the Fe-hcp region [10.37]. Note that also the hydroxylated FeO layer is highly active in CO oxidation [10.198].

All UHV-based, well-defined silica models have a common structural motif, which consists of corner-sharing [SiO_4] tetrahedra arranged in a honeycomb structure (Sect. 10.2.2) [10.202]. The fact that the surfaces are terminated by siloxane bonds renders the regular parts of the films hydrophobic and, thus, unreactive towards water. Indeed, the silica bilayer on Ru(0001) can be exposed to air and pH neutral aqueous solutions without any noticeable accompanying chemical and structural modifications to the film (see also Sect. 10.5.1). Hydroxylation of these model systems occurs only at defect sites, which, on well-prepared films, are scarce [10.203]. Since hydroxyl groups on silica (silanol groups) are of enormous importance for several technological applications, their creation and further utilization on well-defined model systems may help obtain more fundamental insight into specific interfacial reactions where silanols are involved. Hydroxylation of the films could be achieved with the help of electron bombardment of the water (ice) layer [10.199]. This is exemplified by the TPD spectra shown in Fig. 10.28e, which have been obtained after dosing water (D_2O) at a substrate temperature of 100 K and followed by heating to RT (normal route, black curve), or with an additional electron bombardment prior to heating (electron-assisted route, red curve). The strong

enhancement of water desorption from the electron-bombarded sample in this region is related to a significantly increased abundance of D_2O and OD's on the silica surface. More specifically, the thermal route leads to the formation of isolated hydroxyl groups at defect sites within the film, which recombine at elevated temperature and desorb as molecular water at 900 K, and some additional hydrogen-bonded physisorbed water, which desorbs at lower temperatures (< 500 K). The small amount of water desorbing from this sample supports the idea of the inert nature of the silica bilayer film surface. By contrast, enhanced hydroxylation of the electron-bombarded sample gives rise to much larger and more clearly defined water desorption peaks with maxima at 450 and 600 K, as well as an additional high temperature desorption feature at ≈ 1070 K [10.199, 204]. It is interesting to see that in terms of peak temperatures associated with individual desorption states, there is general agreement with analogous TPD spectra collected from hydroxylated bulk silica samples,

which suggests the presence of similar water and hydroxyl species on the hydroxylated silica film. According to the *Zhuravlev* model [10.205], the desorptions are attributed to the following adsorption states and processes: Chemisorbed molecular water gives rise to desorption at 400 K, whereas the high temperature peaks are assigned to recombinative water desorption originating from vicinal (at 600 K) and isolated hydroxyls (above 800 K). The creation of silanols requires the rupture of siloxane bridges and several possibilities how this could be achieved have been modeled by DFT [10.199]. As shown by the structural models presented in Fig. 10.28f, rupture of an in-plane siloxane bridge results in two silanol groups, which are both engaged as donor groups in hydrogen bonds (structure Ia). On the other hand, breaking the Si–O–Si linkage between the two silicate layers results in one hydrogen-bonded silanol and one terminal silanol species (structure Ib). In addition to these processes, which are basically the same as assumed for bulk silica surfaces, the presence of the metallic substrate underneath the silica film opens the possibility for another mechanism, which involves hydrogen release and Ru oxidation (structure II). According to the computed hydroxylation energies and further experimental observations (D_2 desorption observed in TPD and infrared signals of terminal OD groups) [10.199], all three proposed structures are likely to be formed initially during electron bombardment or are created via transformation of one structure into the other during heating to elevated temperature. Further experimental studies into the mechanism of electron-assisted hydroxylation of the silica films support the idea that the primary effect of electron irradiation is not the creation of defects (i.e., rupture of siloxane bridges) in the films, but the formation of reactive water radiolysis products (e.g., hydroxyl radicals) in the ice layer, which diffuse to the silica-ice interface and attack the siloxane bridges [10.204]."

Metal Nucleation on Hydroxylated MgO Surfaces

Controlled creation of hydroxylated oxide thin film surfaces allows the influence of the hydroxyl groups on surface processes to be studied. As an example, the effect of hydroxyls on metal nucleation on hydroxylated MgO is presented. A most conspicuous evidence for the influence of hydroxyls on nucleation and sintering of Au on MgO(100) is provided by STM. The images displayed in Fig. 10.29a present the surface morphology for gold deposited at 300 K and after subsequent heating to 600 K on clean MgO(100) and hydroxylated MgO, respectively [10.200]. Two main conclusions can be drawn from these results: (i) the density of nucleation sites is much higher on MgO_{hydr}, and (ii) the stability of Au particles towards sintering is greatly enhanced on MgO_{hydr}. This latter point is essential for catalysis because it basically means that the high Au dispersion is maintained at elevated temperature, a result that is corroborated by related CO-TPD studies showing a higher CO adsorption capacity for Au/MgO_{hydr} as compared to Au/MgO(100) [10.206]. With the help of additional XPS and IRAS measurements the enhanced Au sinter stability could partly be explained by the stronger adhesion of Au to the hydroxylated surface, which is a result of the chemical modification (oxidation) of interfacial Au because of the interaction with hydroxyls [10.200]. In addition, one has to take into account that the microscopic roughness of MgO increases upon hydroxylation [10.196], which might also contribute to limited diffusion of Au clusters on the surface.

Similar experiments have also been performed with Pd instead of Au, and in this case more details about the chemical interaction between the metal atoms and the surface hydroxyl groups could be obtained [10.201]. The interaction of metal atoms with hydroxyls is expected to follow a redox reaction

$$\mathrm{Me} + -\mathrm{OH}^- \rightarrow -\mathrm{O}_2^- - \mathrm{Me}^+ + \frac{1}{2}\mathrm{H}_2 \,,$$

resulting in the simultaneous oxidation of the metal and evolution of H_2. This could indeed be observed with Pd atoms deposited on MgO_{hydr} (hydroxylation was performed with D_2O) as shown in Fig. 10.29b. The top panel displays D_2-TPD spectra taken from MgO_{hydr} and Pd deposited on MgO_{hydr}, which shows that the presence of Pd leads to a strong enhancement of D_2 evolution from MgO_{hydr} at elevated temperature (> 350 K). To correlate D_2 evolution with electronic structure changes of Pd, Pd 3d spectra and in particular, a deconvolution of the Pd 3d binding energy shift in initial-state and final-state contributions using Auger parameter analysis was performed. The bottom panel of Fig. 10.29b compares the initial-state binding energy shift relative to the Pd 3d binding energy of bulk Pd (352.1 eV) for Pd on clean MgO(001) (black data points) and Pd on MgO_{hydr} (blue data points). The shift from negative to positive ΔBE values for $Pd-MgO_{hydr}$ at 373 K, which correlates with the onset of D_2 evolution from the $Pd-MgO_{hydr}$ sample, indicates that Pd gets oxidized at this temperature. Thus, the interrelation of these processes provides direct evidence of the redox reaction between Pd and hydroxyls, which results in Pd oxidation and hydrogen (deuterium) evolution [10.201].

10.4.2 Methanol Partial Oxidation on $V_2O_3(0001)$ and $V_2O_5(001)$

An often studied reaction in model catalysis is the partial oxidation of methanol. This can be readily investigated under low pressure conditions since the educt (methanol) as well as the common precursor (methoxy) are reasonably strongly bound to the surface and do not desorb at low pressure and not too high temperature. $V_2O_5(001)$ and $V_2O_3(0001)$ were studied with respect to their catalytic performance using the partial oxidation of methanol as a test reaction [10.132, 207, 208]. It turned out that the vanadyl terminated surfaces are not reactive with respect to this reaction since methanol just binds molecularly to the surface without forming the methoxy intermediate [10.132, 208]. Therefore, the surfaces were reduced prior to methanol exposure by electron irradiation. For small electron doses the electron beam leads to the removal of vanadyl oxygen atoms resulting in isolated or aggregated point defects, see Fig. 10.30a,b. The surface structure after irradiation with a high electron dose was studied with I/V-LEED in the case of $V_2O_3(0001)$ [10.209]. An STM image is displayed in the right panel of Fig. 10.30. It could be shown that this surface exposes the SM termination as schematically depicted in Fig. 10.14. The dark areas exhibit the same surface structure as the more elevated areas.

The following will discuss methanol adsorption for the case of a low degree of reduction where isolated vacancies or small groups of them prevail. Figure 10.31 shows STM images of a $V_2O_3(0001)$ surface before electron irradiation, after electron irradiation and after dosage of methanol onto the reduced surface. The point defects found at the surface of a freshly prepared oxide layer (Fig. 10.31a) are not active for methoxy formation, but the vacancies produced by electron irradiation are [10.132]. Therefore, only part of the surface defects is covered by methoxy groups (seen as bright protrusions) in Fig. 10.31c.

STM data of the type shown in Fig. 10.31 were recorded for two different energies of the reducing electrons (50 and 500 eV) and different electron doses

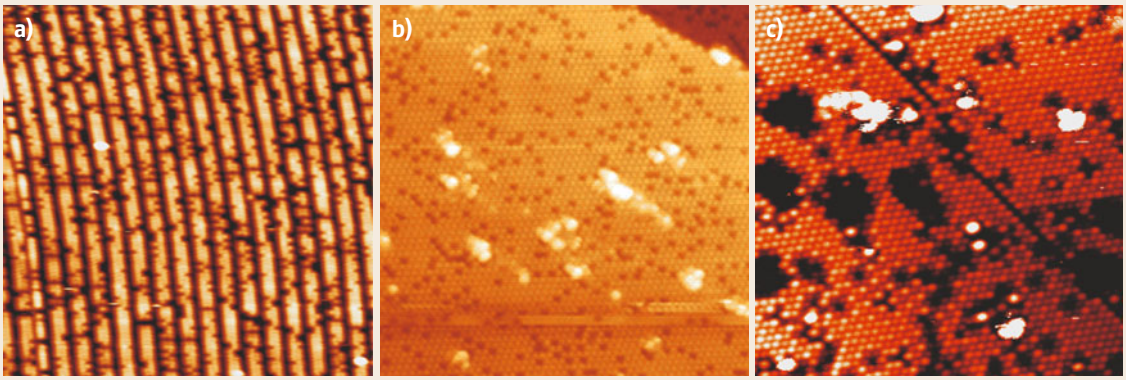

Fig. 10.30a–c STM images on vanadium oxide layers on Au(111) reduced by electron irradiation. **(a)** Weakly reduced $V_2O_5(001)$, $20 \times 20\,nm^2$, $U = 2\,V$, $I = 0.2\,nA$. **(b)** Weakly reduced $V_2O_3(0001)$, $25 \times 25\,nm^2$, $U = -1.5\,V$, $I = 0.2\,nm$. **(c)** Fully reduced $V_2O_3(0001)$, $20 \times 20\,nm^2$, $U = -1\,eV$, $I = 0.2\,nA$. The electron doses (energies) used for reduction are **(a)** 3 mC (50 eV), **(b)** 1.5 mC (50 eV), **(c)** 80 mC (500 eV)

< 0.8 mC (500 eV) and 1.6 mC (50 eV), respectively. In each series the number of defects before and after electron irradiation and the number of methoxy groups after exposure of the surface to methanol were counted. The methanol layer was prepared by dosing multilayer amounts of methanol at 90 K and the STM images of the methoxy-covered surfaces were recorded after a flash to 400 K in order to desorb the molecularly adsorbed methanol.

Figure 10.32 displays the results of the evaluation. The main outcome is that the number of methoxy groups is approximately twice as large as the number of surface defects which is the consequence of a self-limiting chain reaction at the surface [10.132]. In the initial step, which occurs already when methanol is adsorbed at 90 K all electron induced defects carry one methoxy group

$$n\,CH_3OH + n\,V + n\,VO \rightarrow n\,CH_3OV + n\,VOH \quad (10.1)$$

V denotes a vanadium site produced by electron irradiation, VO is a surface vanadyl group, and n is the number of surface vanadyl oxygen vacancies.

If the sample is warmed up water forms at 270 K due to the recombination of hydroxyl groups as shown by TPD [10.132]. This reaction consumes substrate oxygen which is the signature of *Mars–van Krevelen* type reactions [10.210]

$$n\,VOH \rightarrow \tfrac{1}{2}n\,H_2O + \tfrac{1}{2}n\,VO + \tfrac{1}{2}n\,V \quad (10.2)$$

This step occurs at a temperature where molecular methanol is still at the surface. Therefore, the surface

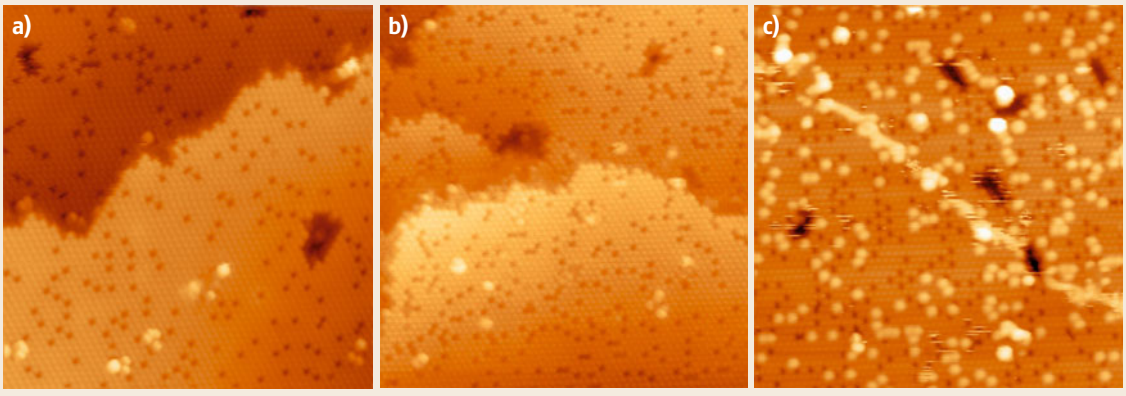

Fig. 10.31a–c STM data of freshly prepared **(a)**, reduced **(b)**, and methoxy covered reduced **(c)** $V_2O_3(0001)$. Vanadyl oxygen vacancies were prepared by irradiation with 1.5 mC of 50 eV electrons. $25 \times 25\,nm^2$, $U = -1.5\,V$, $I = 0.2\,nA$. After [10.132]

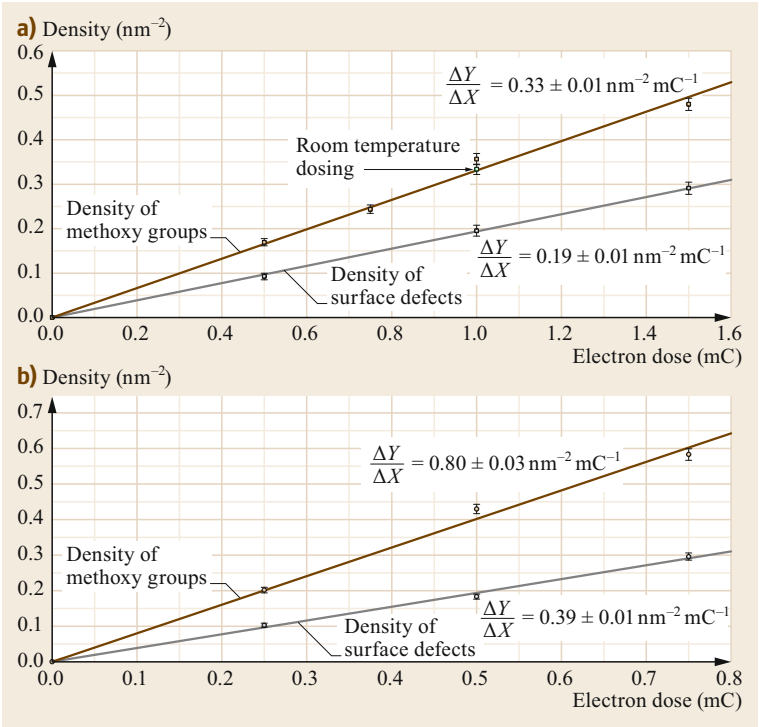

Fig. 10.32a,b Density of defects induced by electron irradiation and the number of methoxy groups as a function of the electron dose for two electron energies **(a)** $E = 50\,\text{eV}$ and **(b)** $E = 500\,\text{eV}$. The data were obtained from STM images like the ones shown in Fig. 10.27 (CH_3OH/weakly reduced $V_2O_3(0001)$). The number of surface defects in this figure is the number of surface defects in images recorded after electron irradiation minus the number of defects already present at the surface before exposure to the reducing electron beam. After [10.132]

with its $n/2$ V sites can split $n/2$ methanol molecules into $n/2$ methoxy groups and $n/2$ hydroxyl groups

$$\tfrac{1}{2}n\,CH_3OH + \tfrac{1}{2}n\,V + \tfrac{1}{2}n\,VO \rightarrow \tfrac{1}{2}n\,CH_3OV + \tfrac{1}{2}n\,VOH \quad (10.3)$$

The $n/2$ hydroxyl groups produced in this step can again form water

$$\tfrac{1}{2}n\,VOH \rightarrow \tfrac{1}{4}n\,H_2O + \tfrac{1}{4}n\,VO + \tfrac{1}{4}n\,V \quad (10.4)$$

With this reaction the cycle goes on. The overall number of methoxy groups produced in this reaction is

$$N_{\text{methoxy}} = n + \tfrac{1}{2}n + \tfrac{1}{4}n + \ldots = 2n \quad (10.5)$$

This is in full agreement with the data in Fig. 10.32.

Figure 10.33 shows the effect of this self-limiting chain reaction on IRAS spectra. The intensity increase of the methoxy C–O vibration at $\approx 1040\,\text{cm}^{-1}$ can be attributed to the chain reaction occurring at $\approx 270\,\text{K}$ where the hydroxyl groups at the surface react to form water: the methoxy coverage doubles and so does (approximately) the intensity of the C–O vibrational band. The band labelled V=^{18}O and V=^{16}O are due to vibrations of vanadyl groups with ^{18}O and ^{16}O. The presence of both isotopes is a result of the preparation history of the $V_2O_3(0001)$ sample.

The case of methanol on $V_2O_5(001)$ is different from the case of methanol on the case for methanol on $V_2O_3(0001)$ due to somewhat different activation energies [10.132, 207]. The reaction kinetics of methanol on $V_2O_5(001)$ has been studied in some detail with TPD [10.208]. Figure 10.34 displays the amount of formaldehyde formed by methanol partial oxidation at the surface of slightly reduced $V_2O_5(001)$ as a function of the methanol dose. This quantity was estimated from the area of the formaldehyde mass 29 desorption peak in TPD spectra. At elevated temperature the methoxy groups react on the surface, forming formaldehyde and therefore the mass 29 peak area is a good measure for the methoxy coverage. The red line in Fig. 10.34 shows the best fit to the data assuming a sticking coefficient proportional to the number of unoccupied adsorption sites. It is clear that this simple model is not correct which means that the reality must be more complex.

Therefore a model considering water formation from hydroxyl groups and methanol formation from methoxy and hydroxyl groups was formulated, i.e., the following two reaction step were incorporated

$$VOH + VOH \rightarrow VO + V + H_2O \quad \text{(water formation)} \quad (10.6)$$

$$VOH + CH_3OV \rightarrow VO + V + CH_3OH \quad \text{(methanol formation)} \quad (10.7)$$

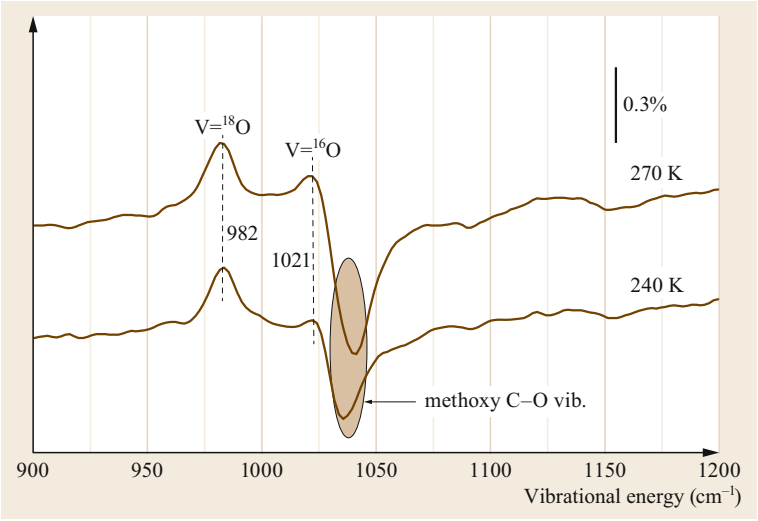

Fig. 10.33 IRAS spectra of methanol-dosed moderately reduced $V_2O_3(0001)$ after annealing at 240 and 270 K, respectively. Methanol was dosed at 90 K and the surface was reduced with an electron dose of 8 mC. After [10.132]

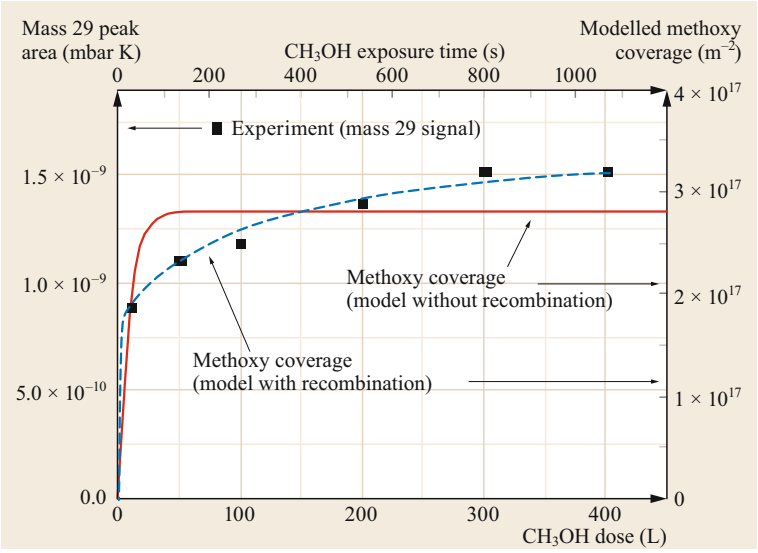

Fig. 10.34 TPD formaldehyde peak area (*solid black squares*) as a function of methanol dose for methanol on weakly reduced $V_2O_5(001)$ in comparison with surface methoxy coverages calculated according to two different models (*solid red* and *dashed blue line*, see text). The sample was reduced by irradiation with electrons with a kinetic energy of 50 eV, dose: 1 mC. Dosing was performed at room temperature to prevent the formation of a molecularly adsorbed methanol layer. Reproduced from [10.208] with permission of The Royal Society of Chemistry

Herewith the following differential equation system was set up for the time-derivative of the methoxy coverage θ_M and the hydroxyl coverage θ_{OH} [10.208]

$$N_{tot}\frac{d\theta_M}{dt} = S(\theta)\Phi_M - N_{tot}\theta_M\theta_{OH}\nu\exp\left(-\frac{E_1}{kT}\right) \quad (10.8)$$

$$N_{tot}\frac{d\theta_{OH}}{dt} = S(\theta)\Phi_M - 2N_{tot}\theta_{OH}^2\nu\exp\left(-\frac{E_2}{kT}\right) - N_{tot}\theta_M\theta_{OH}\nu\exp\left(-\frac{E_1}{kT}\right) \quad (10.9)$$

$S(\theta)$ is a coverage-dependent sticking coefficient, t is the time, N_{tot} is the number of vanadyl lattice sites (4.8×10^{18} m^{-2}), ν is the attempt frequency (set to 10^{13} s^{-1}), E_1 and E_2 are the energy barriers for methoxy–OH recombination and OH–OH combination, respectively, θ_M is the flux of methanol molecules per unit area and time, k is Boltzmann's constant and T is the adsorption temperature ($T = 298$ K). It is assumed that there are no further reaction paths and that diffusion can be neglected which is reasonable if it is much quicker than the water and methanol formation reactions. The sticking coefficient $S(\theta)$ is assumed to be coverage-dependent

$$S(\theta) = \frac{N_0 - N_M}{N_{tot}} \quad (10.10)$$

with N_0 and N_M being the number of possible adsorption sites per unit area and the number of methoxy groups per unit area, respectively ($N_M = \theta_M N_{tot}$). Methanol molecules that hit the surface at an unoccupied defect site do stick, while molecules that hit a nonreduced or occupied surface site do not. We note that the calculated water and methanol formation rates are three orders of magnitude smaller than the rate at which methanol molecules impinge onto the surface. Therefore the reactive defect sites are nearly fully covered and details of the sticking coefficient equation do not play a relevant role.

The set of differential equations was solved numerically with E_1 and E_2 as parameters to fit the experimental data in Fig. 10.34. N_0 was set to 7.5% which is approximately the density of surface oxygen vacancies after exposing the surface to 1 mC of electrons with a kinetic energy of 50 eV. The best fit was obtained for $E_1 = E_2 = 0.85$ eV (blue curve in Fig. 10.34). The blue curve reproduces the experimental data quite well and the activation energies for water and methanol formation are indeed identical within the error range of the fit. Somewhat similar activation energies ($E_1 = E_2 = 0.75$ eV) could be obtained from a fit of TPD data [10.208].

These studies highlight the role of hydroxyl groups in the methanol partial oxidation reaction. Hydroxyl groups are not just spectators in this reaction (with the side effect that they reduce the substrate when they react to form water), they can affect the kinetics and therefore the reaction rate. They may also affect the selectivity as observed for $V_2O_3(0001)$ [10.132] (not discussed here).

10.4.3 Strong Metal Support Interaction Effects on Reactivity: FeO/Pt in CO Oxidation

> "The reactivity of ultrathin transition metal oxide (TMO) films is closely related to so called *strong metal-support interaction* (SMSI) [10.212], which is mostly discussed in terms of a full or partial encapsulation of metal particles by a thin oxide layer stemming from a support.
>
> A number of studies have addressed this problem. In particular, our own studies [10.33, 38, 40] of Pt nanoparticles deposited onto well-defined iron oxide surfaces showed encapsulation of the Pt surface by an iron oxide layer identified as FeO(111) monolayer film that is virtually identical to the one grown on a Pt(111) single crystal [10.213]. However, the FeO(111) film, initially stacked as an O–Fe bilayer, transforms at elevated oxygen pressures to an O-rich, FeO_{2-x} film with a trilayer (O–Fe–O) structure [10.37, 39]. Although the film stoichiometry implies Fe cations in the formal oxidation state 4+, i.e., unusual for iron compounds, DFT results showed that Fe ions in the trilayer structure are in the oxidation state 3+ due to a substantial electron transfer from the Pt(111) substrate. However, for brevity, we will use FeO and FeO_2 for the bi-layer and tri-layer structures, respectively. The CO oxidation reaction has been used as a probe reaction.
>
> The reaction mechanism of CO oxidation, addressed by DFT using the model of a continuous FeO_2 film, suggested CO reacting with the weakly bound, topmost oxygen atom in the O–Fe–O trilayer, thus forming CO_2 that desorbs leaving an oxygen vacancy behind [10.39]. The vacancy must be replenished by the reaction with molecular oxygen to complete the catalytic cycle. Our systematic study of reactivity of ultrathin oxide films formed from a number of different transition metals, such as Ru, Zn, Fe, and Mn, suggested the oxygen binding energy as a good descriptor for reactivity of the ultrathin oxide films [10.214] which may also be present at the rim of oxide islands.
>
> *Bao* and coworkers have addressed the reactivity of FeO(111) and other TMO(111) monolayer structures on Pt(111) exposing the oxide/metal boundary [10.215–218]. On the basis of DFT calculations [10.216, 218], a Pt–cation ensemble was proposed, where coordinatively unsaturated TMO cations at the edges of TMO islands are highly active for O_2 adsorption and dissociation. Dissociated oxygen binds to Pt at the TMO/Pt interface and is responsible for the facile CO oxidation. Note, however, that the calculations employed a simplified model, using a TMO ribbon, which does not account for the experimentally observed epitaxial relationships of oxide and Pt and related lattice mismatches, in turn resulting in various edge structures as observed [10.219]. More importantly, the oxide phase was modelled by the bilayer, i.e., O–TM–Pt(111), structure, which is not the structure relevant for technological CO oxidation reaction conditions, neither for FeO(111) nor for ZnO(0001) films on Pt(111) [10.28, 39]. Nonetheless, following these studies, the highest reactivity is expected to be on the rim of the FeO(111) islands, which are oxygen deficient and expose the unsaturated Fe^{2+} cations [10.215, 217, 218].
>
> Recently, *Huang* and coworkers [10.220] have addressed the reactivity of FeO(111)/Pt(111) sur-

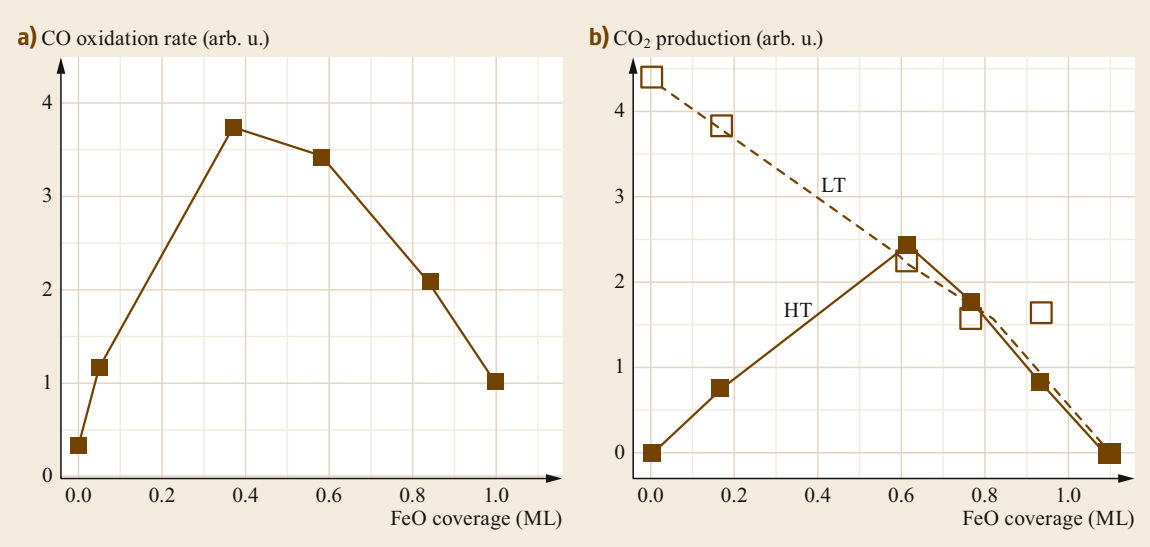

Fig. 10.35 **(a)** CO oxidation rate as a function of the FeO(111) coverage on Pt(111). Reaction conditions: 10 mbar CO and 50 mbar O_2, balanced by He to 1 bar; 450 K. **(b)** Total CO_2 production measured by TPD in low and high temperature (LT, HT) regions as a function of FeO coverage in original films

faces in the water gas shift reaction and preferential oxidation of CO in excess of H_2 using temperature programmed desorption (TPD) technique. It appears that the oxide structure is strongly affected via the reaction with water and hydrogen. A DFT study [10.221] performed on a more realistic model of FeO_x/Pt(111), showed that, beyond terraces of the oxygen-rich FeO_{2-x} phase, considered for a close film [10.39], also FeO_2/FeO and FeO_2/Pt boundaries may be involved in reactions. Finally, the metal–oxide synergy effect may also result from oxygen spillover from the oxide to the metal support.

We also studied the reactivity of FeO(111)/Pt(111) films at submonolayer coverage both under near atmospheric and UHV-compatible pressures in order to bridge the *pressure gap* that may cause some controversy in results obtained by different groups [10.211]. We have shown that a much higher reactivity is, indeed, achieved by exposing an interface between the Pt support and the oxygen-rich FeO_{2-x} phase. Two synergetic effects concur: a low oxygen extraction energy at the FeO_2/Pt interface and a strong adsorption of CO on Pt(111) in its direct vicinity. Weak adsorption of CO on oxide surfaces levels out the (negligible) role of CO adsorption characteristics in the reaction over the closed oxide films, thus rendering the oxygen binding energy as the decisive parameter for reactivity of ultrathin oxide films [10.214].

Figure 10.35a shows the CO oxidation rate (measured by gas chromatography) over FeO(111)/Pt(111) films at 450 K in the reaction mixture of 10 mbar CO and 50 mbar O_2 (balanced by He to 1 bar) for different oxide coverages. (Note, that the initial rate was solely measured in order to neglect any deactivation effects). In the course of the reaction the initially grown FeO(111) islands transformed into the FeO_{2-x} islands in agreement with STM results of *Fu* et al. [10.217] The rate vs coverage plot revealed a maximum at ≈ 0.4 ML coverage. The rate is substantially (by a factor of 3.5) higher than obtained for a closed, monolayer film, which is, in turn, more active than the pristine Pt(111) surface, in full agreement with our previous studies [10.39]. Obviously, the oxide/metal interface provides reaction sites more active than those on the (interior) surface of FeO_2 islands.

More detailed experiments on FeO(111)/Pt(111) films at sub-ML coverages using CO TPD as a function of oxide coverage, exposure, and preparation conditions revealed that CO_2 production from CO oxidation came in two temperature regimes. The one at low temperature (LT, below 350 K) is very similar to that obtained on pristine Pt(111), whereas the reaction at high temperature (HT, 350−550 K) originates only on oxide covered surface.

Figure 10.35b depicts the total amounts of CO_2 measured in six consecutive CO TPD spectra in

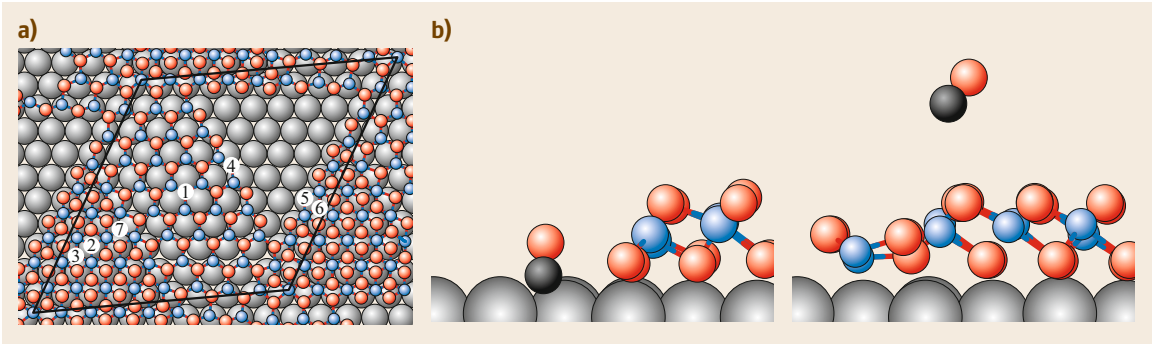

Fig. 10.36 **(a)** Computational model of a sub-monolayer FeO_x film on the Pt(111) surface. The nonequivalent oxygen sites are labeled 1–7: T–FeO (1), T_I-FeO_2 (2), T_S-FeO_2 (3), E-FeO/Pt (4), E_I-FeO_2/Pt (5), E_S-FeO_2/Pt (6), E-FeO_2/FeO (7). Pt, O and Fe atoms are represented by *gray*, *red* and *blue spheres*, respectively. **(b)** Most stable CO adsorption configurations at the FeO_2/Pt (*left*) and FeO_2/FeO (*right*) boundaries depicted in panel **(a)**. Pt, O, C and Fe atoms are represented by *gray*, *red*, *black*, and *blue spheres*, respectively. Reprinted with permission from [10.211]

the LT and HT regions, respectively, as a function of oxide coverage. The LT signal reversely scales with the oxide coverage, in full agreement with reaction taking place on uncovered areas of Pt(111). The observed linear relationship also suggests no (or negligible) oxygen spillover from FeO_2 islands onto the Pt(111) surface. In contrast, CO_2 production in the HT state goes through the maximum in the same manner as observed for the CO oxidation rate at near atmospheric pressures (Fig. 10.35a), thus providing compelling evidence that the enhanced activity must be attributed to the reaction at the interface between Pt(111) and FeO_2 trilayer.

Also, DFT calculations have been performed to estimate the thermodynamic stability of oxygen at a variety of alternative terrace and boundary sites, characteristic of Pt-supported FeO_x film at sub-ML coverage. The computational model depicted in Fig. 10.36a represents an oxide coverage of 0.6 ML, with an equal proportion of FeO and FeO_2, accounting for the case of large FeO_x islands on the Pt(111) surface. It consists of embedded FeO_2 islands, with trilayer O–Fe–O structure, located primarily in the region of the so-called *hcp* lattice registry (O ions on-top of surface Pt atoms, Fe ions in the hollow sites), where the oxygen-rich film forms the most easily [10.37]. Conversely, bare FeO(111) is most stable in regions of *fcc* registry (both O and Fe ions in three-fold hollow sites of a Pt(111) substrate). The large unit cell contains also the region of a bare Pt(111) surface created by removing the oxide from regions of *top* registry (O ions in the hollow sites, Fe ions on-top of a surface Pt), where the stability of a FeO_x film is the lowest [10.37, 222].

While the oxygen extraction thermodynamics identified edge (E-FeO_2/Pt and E-FeO_2/FeO) sites as the most plausible candidates to react with CO (with a small preference for the latter), the very different characteristics of CO adsorption (2.05 vs 0.05 eV, respectively) clearly indicates that these two sites have a different efficiency for CO oxidation. Since CO binds only weakly to the FeO_2/FeO boundary, the Eley–Rideal reaction mechanism is anticipated on these sites. Conversely, strong CO binding in the direct vicinity of the FeO_2/Pt boundaries makes the Langmuir–Hinshelwood mechanism operative. Although in the latter case CO and O binding characteristics are close to those obtained on the bare Pt(111) surface, the FeO_2 oxide phase provides O atoms which do not suffer from the CO blocking effect which, otherwise, poisons the CO oxidation reaction on the bare Pt surface.

Certainly, for the rate enhancement to occur CO must adsorb sufficiently strongly, otherwise it desorbs intact before reaction with oxygen. Therefore, weakly adsorbing metal surfaces, such as Ag(111), do not show such effect as previously reported for ZnO(0001) films [10.223]. Accordingly, using oxygen binding energy as a principal descriptor for CO oxidation over ultrathin oxide films seems to be valid only for the systems exhibiting relatively weak CO adsorption which does not compete for oxygen adsorption sites. In the case of systems exposing a metal/oxide interface, the reactivity may be considerably enhanced by metals strongly adsorbing CO like Pt. In such cases, the model of overlapping states [10.224] seems to be fairly predictive, suggesting high activity when the

desorption profiles for each individual molecule reacting at the surface overlap.

10.4.4 Olefin Hydrogenation over $Pd/Fe_3O_4(111)$

Real catalytic processes often require small amounts of some additives (promoters), such as e.g., alkali metals or halogens [10.100], that ensure high catalytic activity and selectivity. The role that these compounds play at a microscopic level remains unclear for most of the known catalytic systems in operation. One of the most important coadsorbates, particularly in hydrocarbon chemistry, is carbon resulting from decomposition of the reactants. Accumulation of carbon was recognized to considerably affect the activity and the selectivity in hydrocarbon conversions promoted by transition metals [10.226]. In our studies, by comparing the hydrogenation activity of clean and C-containing Pd nanoparticles we addressed the underlying microscopic mechanisms of C-induced changes in the catalytic performance for hydrogenation of olefins [10.227–229].

Hydrogenation rates of *cis*-2-butene over clean and C-containing Pd nanoparticles supported on $Fe_3O_4(111)/Pt(111)$ film are shown in Fig. 10.37a. Pd nanoparticles were saturated first with deuterium to form both surface and subsurface D species [10.230] and then short pulses of *cis*-2-butene were applied. Clean Pd nanoparticles exhibit high hydrogenation activity for an initial short period of time (a few butene pulses), after which it drops to zero. In contrast, if carbon was deposited on Pd nanoparticles before the reaction, a sustained hydrogenation rate was observed. Using CO as a probe molecule for different adsorption sites, it can be shown that deposited carbon modifies the low-coordinated site such as edges and corners [10.230]. However, it is not clear whether carbon resides on the surface or might penetrate into the subsurface region as predicted theoretically [10.231]. This effect demonstrates the exceptional importance of carbon for olefin hydrogenation, which can be carried out in a truly catalytic fashion for many turnovers, only on C-containing Pd nanoparticles.

The role of carbon in promotion of sustained hydrogenation was rationalized by employing transient molecular beam experiments and resonant nuclear reaction analysis (rNRA) for hydrogen depth profiling. First, we obtained the first direct experimental evidence that the presence of H(D) absorbed in the Pd particle volume is required for olefin hydrogenation, particularly for the second half-hydrogenation step [10.227], in agreement with previous experimental evidences [10.232]. This result explains the high initial hydrogenation rates, observed on the clean particles fully saturated with D, and vanishing hydrogenation activity in steady state because of the depletion of the subsurface D reservoir (Fig. 10.37a). Apparently, the inability to populate subsurface D sites arises from hindered D subsurface diffusion through the surface covered with hydrocarbons. Further, it was shown that even a submonolayer coverage of carbon significantly affects the H(D) depth distribution in Pd particles [10.227]. Based on these observations, and on the analysis of the hydrogenation kinetics [10.229], we attribute the sustained hydrogenation activity to facilitation of H(D) diffusion into the particle volume by deposited carbon.

The proposed mechanism was confirmed both theoretically and experimentally [10.233, 234]. Computational studies on Pd nanoclusters demonstrated that deposited carbon dramatically enhances the hydrogen diffusion rate into subsurface, mainly due to a local elongation of Pd–Pd bonds and a concomitant lowering of the activation barrier [10.233]. This dramatic reduction of the activation barrier can account for the experimentally observed unusual promotion of sustained hydrogenation activity by carbon. In contrast, the lateral rigidity of the extended Pd(111) surface was predicted to hinder this effect, in agreement with experimental observations [10.228]. The results demonstrate the conceptual importance of atomic flexibility of sites near particle edges, which, in contrast to intrinsically rigid regular single crystal surfaces, play a crucial role in H subsurface diffusion on Pd.

Finally, we provided direct experimental evidence for a faster subsurface H diffusion through C-modified low-coordinated surface sites on Pd nanoparticles by probing the diffusion rate via $H_2 + D_2 \rightarrow HD$ exchange in different temperature regimes [10.234]. It was previously shown [10.230] that the formation of HD can occur either via recombination of two surface H and D species or an involvement of subsurface H or D species. The latter pathway dominates at low

temperatures between 200 and 300 K. Our experimental results are consistent with the scenario implying that one subsurface atom (H or D) recombines with a surface-adsorbed atom to form HD. In the case of slow subsurface H(D) diffusion, the formation rate of subsurface species will be the limiting step in HD production, and can, therefore, be addressed by probing the rate of isotopic scrambling.

Figure 10.37c shows the steady state HD formation rates at 260 and 320 K on clean and C-modified Pd nanoparticles. C–modification of the particles edges was found to affect the HD formation rate in a dramatically different way for two reaction temperatures: whereas at 320 K preadsorbed C *reduces* the overall reaction rate by about 30°, the reaction rate *increases* by about 100° at 260 K on the C-modified particles. The decreased HD formation rate at 320 K, where HD formation is dominated by the recombination of the surface H and D species [10.230], can be rationalized as a consequence of the blocking of surface adsorption sites by carbon. Interestingly, even though a part of the surface is blocked by carbon, the HD formation rate is significantly increased at 260 K, where desorption involves at least one subsurface H(D) species. This effect can be explained only by the higher formation rate of the subsurface H(D) species on the C-modified particles, resulting in a higher steady state concentration.

Such insight allowed us to identify an exceptionally important role of carbon in hydrogenation chemistry on nanostructured catalysts that was previously not clearly appreciated. According to our model, small amounts of carbon modify the low-coordinated surface site of Pd nanoclusters (edges, corners), thus allowing for effective replenishment of subsurface H in steady state and enabling sustained hydrogenation. These results also highlight the crucial role of subsurface H diffusion, which is a strongly structure-sensitive process on Pd surfaces, in hydrogenation of the olefinic bond. Computational studies suggest that the atomic flexibility of the low-coordinated surface sites is an important structural feature that is responsible for easy subsurface diffusion of H under operation condition."

10.5 Oxide Films Beyond UHV

Reprinted with permission from [10.60]. © 2019 Materials Research Society.

"The investigations discussed so far were limited to systems studied under UHV conditions which immediately poses the question how these results relate to oxide systems at ambient conditions such as an aqueous environment. In the following we illustrate how such well-defined systems prepared under UHV conditions can be used to study the properties of the oxide surfaces under ambient conditions.

10.5.1 Alkaline Earth Oxides, Iron Oxides and Silica Out of UHV into Solution

Stability and Dissolution of Thin Oxide Films in Aqueous Environment

A variety of technologically important processes, such as catalyst preparation by wet impregnation, involve processes at the liquid/oxide interface. Aiming at the investigation of such processes using well-defined thin oxide films the system has to be stable under the specific environmental conditions of interest. For surface science investigations in particular, it is desirable that the structural order is maintained. Since the chemical properties of (most) oxide thin films are similar as those of the corresponding bulk analogues, their stability and dissolution behavior is expected to follow the same trends. Dissolution rates for oxide thin film samples can be derived from the measured decrease of film thickness upon exposure to aqueous solution, which can straightforwardly be determined from the intensities of the oxide and substrate XPS or AES (Auger electron spectroscopy) emissions.

XP spectra (O 1s and Si 2p regions) taken after exposing bilayer SiO_2/Ru to deionized water at 90 °C, and NaOH(aq) at 25 °C for various times are displayed in Fig. 10.38a [10.204]. Clearly, deionized water (pH 7) does not affect the film structure to any significant extent, even at elevated temperature. While a small shift of all silica-related XP peaks to higher BE, which reflects a slight change in the electronic structure of the system (band bending), is noted, neither the Si 2p nor the O 1s peaks suffer any loss of intensity. In

contrast, the intensity of both peaks decreases significantly, even at 25 °C, when the silica bilayer is exposed to alkaline media (NaOH, pH 13). The equal relative signal intensity loss of Si and O peaks observed with time of exposure allows to conclude that, in accordance with general experience, the dissolution process in alkaline media can be described as the OH^- catalyzed hydrolysis of SiO_2 ($SiO_2 + 2\,H_2O \rightarrow H_4SiO_4$). One can further state that the bilayer SiO_2/Ru films resemble the dissolution behavior of other, more abundant forms of silica (quartz, amorphous silica), which are found to be practically insoluble in the neutral pH range, and more strongly soluble in alkaline conditions. From more systematic studies of dissolution as a function of temperature and pH (Fig. 10.38a, lower part) it is clear that removal of SiO_2 from the sample shows a preference for larger values of both parameters, which is also qualitatively consistent with the behavior noted from bulk-phase silica analogues [10.236]. The dissolution rates for the thin film sample can be modeled by the general silica dissolution rate model derived by *Bickmore* et al. [10.236], which accounts for variations in pH, temperature, and the coverage of neutral (θ_{Si-OH}) and deprotonated (θ_{Si-O-}) silanols. Because the silica film is hydrophobic and lacks significant initial silanol coverage, the latter two contributions can be neglected and the rate equation simplifies to

$$\frac{\mathrm{dSi}}{\mathrm{d}t}\frac{\mathrm{mol}}{\mathrm{s}} = \mathrm{e}^{6.7\pm1.8}\,T\mathrm{e}^{\frac{-77.5\pm6.0}{RT}}[\mathrm{OH}^-].$$

A comparison of the dissolution rates predicted from that relation to those estimated on the basis of the initial rates of Si XPS peak attenuations from the thin films shows good agreement between the model and the experiment [10.204]. From this, it

is concluded that dissolution of the film in alkaline media is initiated by OH^- attack at Si centers. Note that this leads to rupture of siloxane bonds. Thus, the initial step in the dissolution process can qualitatively be described by models that are similar to those used to explain electron-assisted hydroxylation of the silica film (Fig. 10.28f). In general, the silica bilayer films were found to be stable (i.e., negligible dissolution rates observed) at room temperature in acidic and neutral aqueous solutions, and in alkaline media up to pH 10 [10.204].

MgO is a basic oxide (point of zero charge (PZC) in the pH 10 range) and therefore expected to be more stable in alkaline media than in neutral and acidic environment [10.237]. Results of dissolution experiments performed with MgO(001)/Ag(001) thin films are presented in Fig. 10.38b, where the variation of MgO film thickness as a function of time is displayed for exposure to acidic (pH 2, 0.01 M HCl), alkaline (pH 12, 0.01 M NaOH) and close to neutral (pH 6, Millipore water) environments, respectively [10.235]. The data shown in Fig. 10.38b is consistent with the expected faster dissolution of MgO in acidic media. In fact, in 0.01 M HCl solution the dissolution is so fast that a 11 ML thick film was completely dissolved within the first 5 s of exposure. The dissolution rate is smaller at pH 6; however, even under these conditions a 13 ML thin MgO film was completely dissolved within 5 s of exposure. During the same period, only 3 ML MgO were dissolved from the MgO sample upon exposure to alkaline (pH 12) solutions. For the latter, the dissolution behavior was studied for prolonged exposures (up to 90 min), the results of which show that the dissolution is initially fast and considerably slows down with time, until a stable surface state is obtained after 20–30 min of exposure. This suggests the formation of a brucite ($Mg(OH)_2$)-like passivating surface layer during exposure to alkaline solution, for which dissolution rates are considerably smaller than for MgO [10.238]. Because of the partial dissolution, and transformation of the surface layers into a hydroxide, MgO films exposed to alkaline media are subject to strong restructuring. Even if the crystallinity of the films can partially be recovered by annealing at elevated temperature, the initial structure of the MgO(001) films cannot be restored [10.235].

Iron oxides are, according to the corresponding Fe-water Pourbaix diagram, stable in aqueous solutions in a wide range of pH. Thus, it is not surprising that also thin iron oxide films are very stable in aqueous solutions. As an example, STM images taken in air from $Fe_3O_4(111)/Pt(111)$ films, which have been prepared in UHV and subsequently transferred to air ambient and exposed to aqueous solutions (pH 1, 0.1 M HCl and pH 10, $NaOH_{aq}$) for 1 h, are shown in Fig. 10.40c [10.239, 240]. These images reveal that the island-terrace-step structure of the thin film remains intact. Furthermore, the step edges run straight along the crystallographically preferred directions and the terraces are atomically flat. XPS taken from the exposed films indicates a slight oxidation of the surface, but this does obviously not lead to structural modifications. Both, $Fe_3O_4(111)/Pt(111)$ and bilayer silica films (and to a limited extent also MgO(001)/Ag(001)) are therefore well suited for further investigations of processes involving oxide-liquid interfaces."

Surface Science Approach to Catalyst Preparation: Pd–Fe_3O_4 as an Example

In Sect. 10.4.4 we have already shown that Pd nanoparticles deposited on a $Fe_3O_4(111)$ surface are good catalysts for hydrogenation reactions. The system discussed above was prepared by physical vapor deposition of Pd atoms onto the oxide surface under UHV conditions. However, almost all supported catalysts employed industrially are prepared by wet-chemical methods such as impregnation, deposition–precipitation, spreading, and ion exchange [10.74]. The first step in a commonly applied wet-chemical catalyst preparation procedure consists of the interaction of the support with precursor solutions that contain the metal component in the form of salts or complexes. This is followed by drying, calcination and reduction steps, which are necessary to transform the adsorbed metal precursor into the catalytically active phase. Among other approaches, thin oxide films have recently been used to model typical catalyst preparation procedures with flat, single-crystalline substrates [10.235, 239–242].

With $Fe_3O_4(111)/Pt(111)$ as support, the preparation of supported Pd nanoparticles using $PdCl_2$ as a precursor has been studied [10.239, 240]. The speciation of $PdCl_2$ in aqueous solutions has been the subject of intense research in the past. In strongly acidic conditions, the tetrachloro complex $PdCl_4^{2-}$ is the most abundant species (Fig. 10.39a). Upon hydrolysis, the chlorine ligands are gradually replaced by aqua or hydroxo ligands, leading finally to $Pd(OH)_4^{2-}$ species in strongly basic medium [10.243, 244]. Neutral Pd complexes of the kind $[PdCl_2(H_2O)_2]$ are formed at an intermediate stage of hydrolysis. These complexes

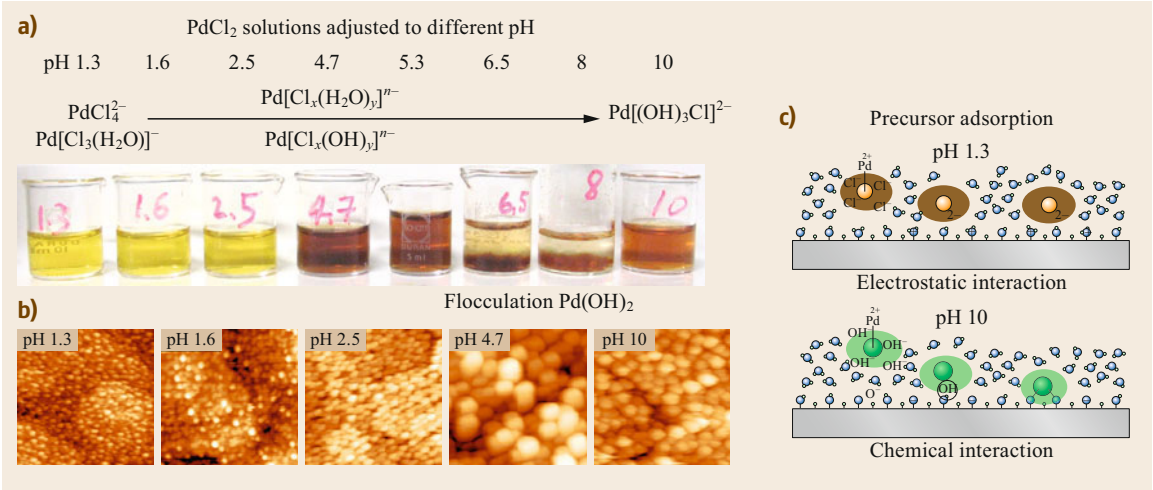

Fig. 10.39 **(a)** pH-dependent speciation of $PdCl_2$ in aqueous solution. **(b)** STM images ($75 \times 75\,nm^2$) of Pd nanoparticles on $Fe_3O_4(111)$ obtained by exposure of freshly prepared $Fe_3O_4(111)/Pt(111)$ to $PdCl_2$ solutions of different pH followed by drying and annealing at 600 K in UHV. **(c)** Schematic representation of the adsorption of Pd-complexes on oxide surfaces in acidic (pH below the PZC of the oxide) and alkaline media (pH above the PZC of the oxide)

are most probably responsible, because of their tendency for polymerization (→ polynuclear Pd-hydroxo complexes, PHC), for the formation of colloidal particles [10.245], seen with the appearance of the dark brown color of the Pd solution (Fig. 10.39a). The pH at which formation of PHC's sets in can be slightly varied by changing the Pd^{2+} and Cl^- concentration. The strong influence of the solution pH on the Pd loading and the particle morphology is demonstrated by means of the STM images displayed in Fig. 10.39b. These images were obtained following exposure of the $Fe_3O_4(111)$ films to precursor solutions (5 mM $PdCl_2$) exhibiting different pH (as indicated in Fig. 10.39b), and subsequent thermal treatment at 600 K in UHV, which transforms the adsorbed Pd precursor into Pd particles. First, the samples prepared with the low pH solutions (pH 1.3–2.5), where the influence of PHC's can be excluded, are considered. The trend toward higher Pd loading and slightly increasing Pd particle size with increasing pH is obvious and in agreement with results obtained for similar preparations carried out with powder samples [10.246]. Within the *strong electrostatic adsorption* model (Fig. 10.39c, top), which seems to be applicable for the given conditions (negatively charged precursor and positively charge support surface, PZC of Fe_3O_4 is ≈ pH 6.5) the suppression of Pd precursor adsorption at low pH, which results in low Pd loading, is typically explained by the lowering of the equilibrium adsorption constant as an effect of the higher ionic strength of the strongly acidified precursor solution [10.247].

While small and homogeneously distributed Pd particles are formed following exposure to the low pH solutions, a high Pd loading and large Pd particles are obtained if the pH 4.7 precursor solution is applied (Fig. 10.39b). At first glance, this result might be related to the adsorption of colloidal particles present in the precursor solution. However, deposited particles could not be identified by STM directly after deposition. Therefore, a different adsorption mechanism for the Pd precursor needs to be considered at this pH conditions. Since at pH 4.7 the Fe_3O_4 surface is essentially uncharged and a considerable fraction of the solution species is charge-neutral, a strong chemical interaction via hydrolytic adsorption of the precursor complexes could be the reason for the high Pd loading. With the basic pH 10 precursor solution the Pd loading decreased again and a particle size distribution that is more homogeneous as compared to the one obtained with the pH 4.7 precursor solution was obtained. Since both the oxide surface and the solution complexes are negatively charged in this case, electrostatic adsorption is believed to play a negligible role and the adsorption of Pd occurs mainly via hydrolytic adsorption of the Pd-hydroxo complexes on the surface hydroxyl groups (Fig. 10.39c, bottom). Copyright Springer [10.242].

More detailed studies regarding the stepwise decomposition of the adsorbed precursors into metallic nanoparticles were conducted with samples prepared by exposure to pH 1.3 and pH 10 precursor solutions, respectively [10.239, 240]. As an example, the results obtained with the alkaline precursor solution

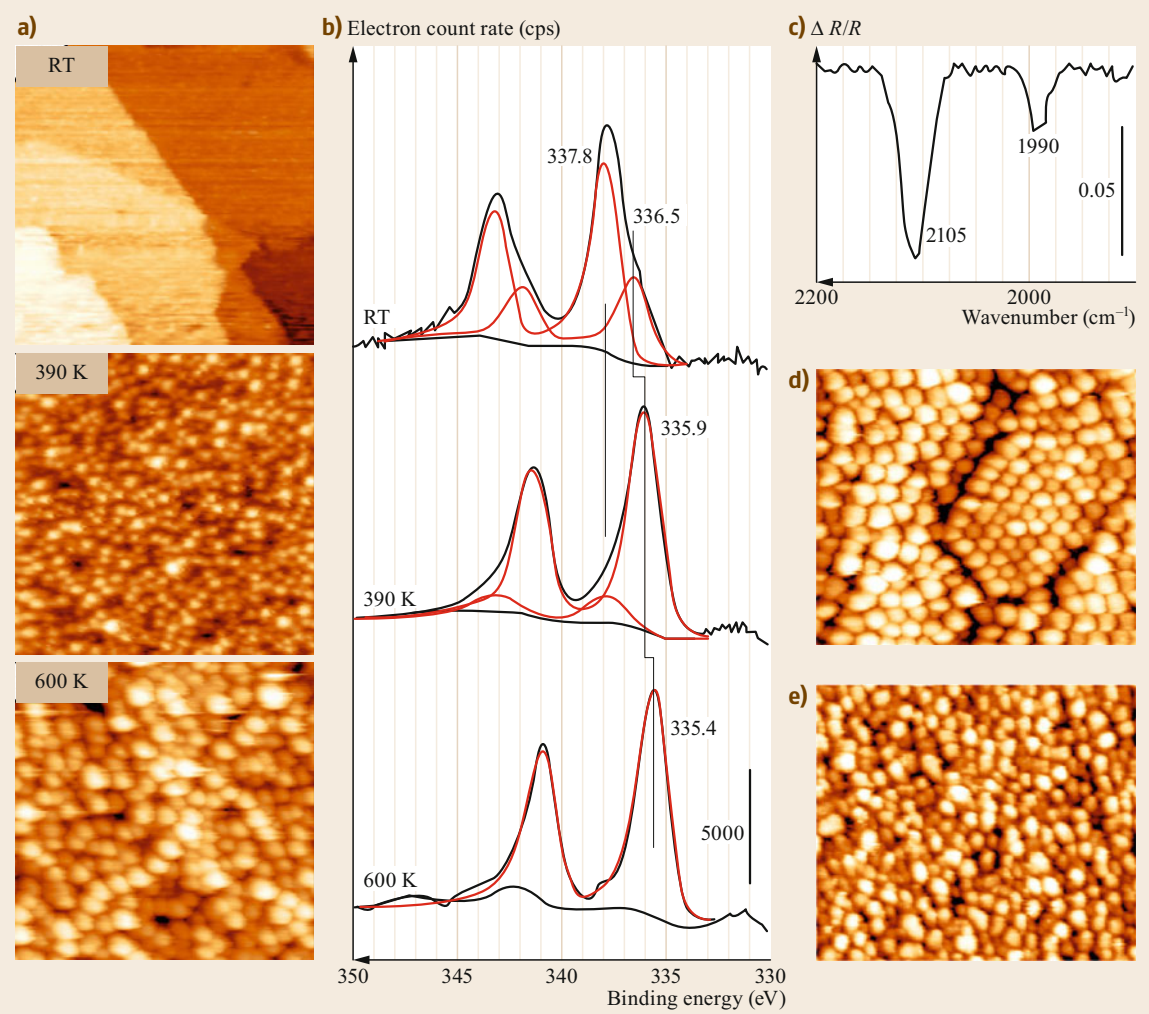

Fig. 10.40 **(a)** STM images ($100 \times 100\,nm^2$) and **(b)** corresponding Pd 3d XP spectra of a $Fe_3O_4(111)$/Pt(111) thin film surface acquired after exposure to Pd precursor solution (5 mM $PdCl_2$, pH 10) and subsequent drying (RT, *top*), after drying at 390 K (*middle*), and subsequent heating to 600 K (*bottom*). **(c)** IRA spectrum taken after adsorption of CO at 80 K on a Pd/$Fe_3O_4(111)$ model catalyst prepared by exposure to pH 10 $PdCl_2$ precursor solution. **(d)** STM image ($100 \times 100\,nm^2$) of Pd/$Fe_3O_4(111)$ prepared by physical vapor deposition of Pd onto a $Fe_3O_4(111)$ surface modified by treatment with NaOH solution. After [10.242]

are reproduced in Fig. 10.40a (STM) and Fig. 10.40b (XPS) [10.240]. An STM image of the $Fe_3O_4(111)$ surface following exposure to the precursor solution (2 mM $PdCl_2$, pH 10) and subsequent water rinsing and drying shows an apparently *clean* oxide surface with the typical morphological features of $Fe_3O_4(111)$ (Fig. 10.40a, top). However, the corresponding XPS spectrum confirms the presence of Pd on this surface (Fig. 10.40b, top). Obviously, the adsorbed precursor complexes are homogeneously distributed across the surface and cannot be individually resolved in STM. The two Pd $3d_{5/2}$ photoemission signals identified at 337.8 and 336.5 eV BE can be assigned to Pd-hydroxo and PdO species, respectively. It has to be mentioned that the high BE component was found to be sensitive to x-ray irradiation, and the PdO component identified at this stage of the preparation results most probably from x-ray induced decomposition of the Pd-hydroxide into PdO. Only mild drying at 390 K completely changes the surface morphology, which displays small particles with an average diameter of 2.5–3 nm (Fig. 10.40a, middle). This morphological change is accompanied by an almost complete transformation of the adsorbed Pd-hydroxide precursor into PdO, as deduced from the loss

of the high BE component in XPS and the concurrent increase of the 335.9 eV feature (Fig. 10.40b, middle). Finally, fully reduced Pd particles (particle diameter: 3–7 nm) are found after further thermal treatment at 600 K (Fig. 10.40a,b, bottom). These particles contain some carbon contamination remaining from the preparation process, which can be eliminated by oxidation at 500 K in 1×10^{-6} mbar O_2. Subsequent reduction in CO atmosphere restores the metallic state, which then presents CO-IRAS signatures typical for supported Pd nanoparticles (Fig. 10.40c) with two bands arising, respectively, from on-top bound (2105 cm^{-1}) and bridge-bonded CO (1990 cm^{-1}) [10.248]. Alternatively, the final reduction step was performed in H_2 instead of CO atmosphere, which led to the formation of bimetallic Pd–Fe particles due to strong metal support interaction (SMSI). This modification can be easily understood on the basis of the catalytic action of Pd in providing H atoms for reduction of the Fe_3O_4 support via H_2 dissociation and H spill-over. Iron atoms from the reduced support then migrate into the Pd particles.

An important question to ask at this point is whether or not the morphology of a model catalyst prepared by wet-chemical procedures as described above differs from that of a corresponding model catalyst prepared exclusively in UHV. In other words, does the nature of the precursor (single atoms in UHV vs. metal complexes in solution) or the support properties (clean surface in UHV vs. a surface modified by exposure to precursor solution) affect the properties of the activated model catalyst? In order to answer this question two additional $Pd/Fe_3O_4(111)$ model catalysts were prepared: One, where Pd was deposited onto a clean $Fe_3O_4(111)$ support in UHV by vapor deposition (Pd/Fe_3O_4(UHV), Fig. 10.40d), and another one, where Pd was deposited by vapor deposition onto a $Fe_3O_4(111)$ surface following a treatment with NaOH (pH 12) solution (Pd/Fe_3O_4(hydr), Fig. 10.42b,e). The NaOH treatment was applied in order to achieve a surface functionality comparable to the solution deposition experiment. Inspection of the corresponding STM images (Fig. 10.40d,e) reveals differences between the two samples with respect to the arrangement of the Pd particles and the particle size distribution. While the Pd particles are uniform in size and arranged in an almost perfect hexagonal array on the clean $Fe_3O_4(111)$ surface, the surface order is lost on the pretreated Fe_3O_4 surface and a deviation from the normal particle size distribution is apparent. Most notably, the morphology of the Pd/Fe_3O_4(hydr) sample (Fig. 10.40e) closely resembles that of the model catalyst prepared by deposition of Pd from the pH 10 precursor solution (Fig. 10.40a, bottom). This finding suggests that in the present case the morphology of the activated model catalyst is mainly governed by the interfacial properties, and not by the nature of the precursor. The more heterogeneous sintering of Pd particles on the modified surfaces is attributed to the presence of hydroxyl groups and the existence of a variety of adsorption sites with differing Pd adhesion properties [10.240], Copyright Springer [10.249].

10.5.2 Water/Silica Interface

To date, most of the research on silica bilayers has been performed in idealized ultra-high vacuum environments. These conditions provide a high degree of experimental control which enables unambiguous structural assessment. Yet real world applications of silica and its derivatives demand higher pressures and temperatures and occur under ambient condition. Recent research on silica bilayers beyond ultra-high vacuum addresses these practical considerations by bridging the gap between UHV and ambient.

In order to bridge such gap, the structure of silica has been investigated with high-resolution liquid atomic force microscopy (AFM). Silica films are grown in UHV and subsequently transferred through ambient to the liquid environment (400 mM NaCl solution). Figure 10.41 shows images of the bilayer silica structure attained with ultra-high vacuum STM and high resolution liquid-AFM [10.250]. The low-temperature UHV STM images exhibit atomic resolution of the silica structure while the resolution of the room temperature liquid-AFM images allows to identify the ring structures. The structures appear remarkably similar as confirmed quantitatively from pair distribution functions of the ring center positions. These results show that the silica film is structurally robust against ambient and aqueous conditions; this result is consistent with the conclusions of the previous study which found the silica bilayer film to be exceptionally stable against hydroxylation [10.199]. In contrast, many UHV surface structures are not stable under ambient conditions due to unsaturated bonds [10.198, 235]. The stability of the silica bilayer makes it an optimal playground to test the resolution of liquid AFM as the amorphous structure circumvents the common challenge of distinguishing between true atomic resolution and lattice resolution [10.251]. Furthermore, establishing the stability of the silica bilayer under ambient conditions opens the door to future device applications.

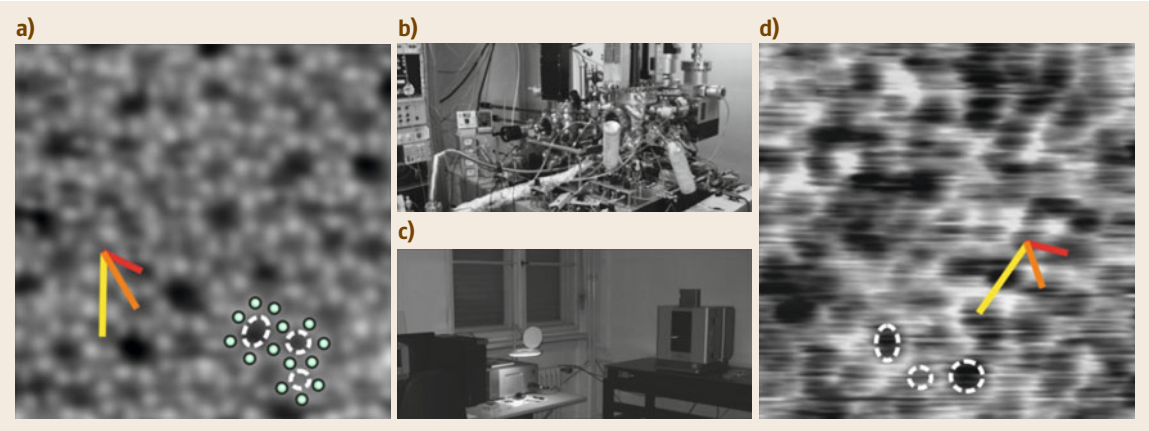

Fig. 10.41a–d An amorphous silica bilayer film with atomic resolution of silicon atoms by STM in UHV **(a)** and ring resolution by liquid-AFM in **(d)**. Both images have a scan frame of 5 nm × 5 nm. *Red*, *orange*, and *yellow measurement bars* show examples of ring center–center distances for the first three families of ring neighbors identified in the amorphous silica bilayer. Several individual rings are marked in each image. **(d)** Reprinted from [10.250], with the permission of AIP Publishing. The measurement in **(a)** has been obtained with a custom-made low temperature ultra-high vacuum STM shown in **(b)** while **(d)** has been taken with a commercial liquid-AFM photographed in **(c)**

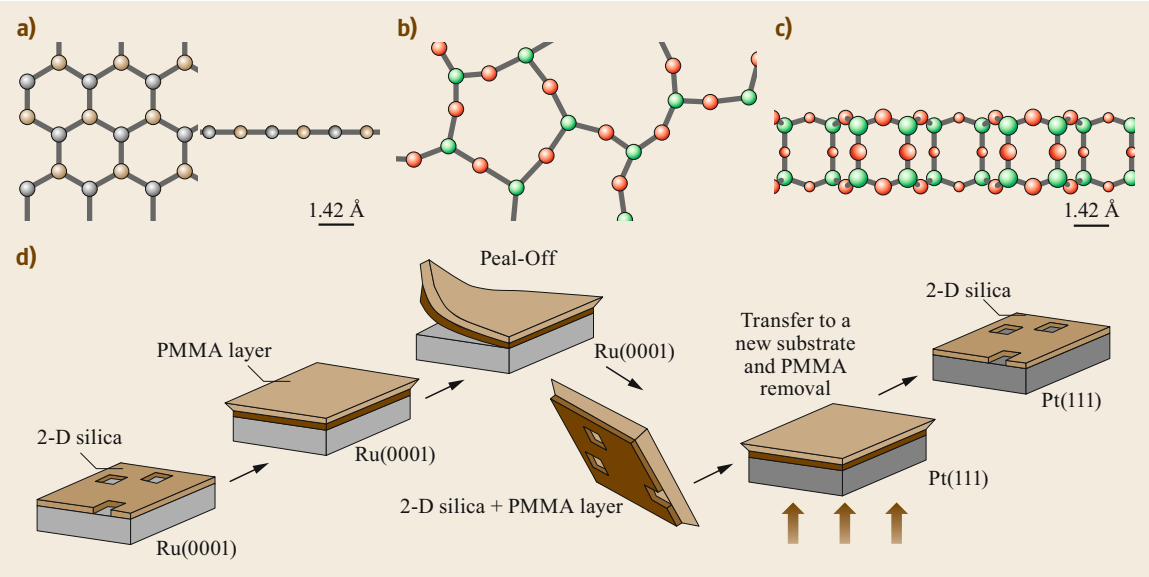

Fig. 10.42 **(a)** Top and side view of a boron nitride layer in comparison to the silica bilayer **(b)** and **(c)**. In contrast to graphene both shown 2-D materials are wide band-gap insulators. **(d)** Schematic of the transfer procedure: silica bilayer on ruthenium substrate, spin coating of system with polymethyl methacrylate (PMMA) layer, mechanical exfoliation of PMMA, silica adheres to PMMA layer, silica supported on PMMA layer, placing the PMMA-supported silica layer on clean Pt(111) substrate, subsequent heat treatment, after PMMA removal, silica is supported on Pt(111) substrate. 10.5.3 Peal-Off Experiments with Silica Films

Silica bilayers are an ideal candidate material for inclusion in two-dimensional nanoelectronic heterostructures due to its insulating character and high degree of structural integrity under ambient conditions [10.252]. Novel nanoelectronic heterostructure devices are designed with tailored properties by bottom-up production which combines two-dimensional insulating, semi-

conducting, and conducting materials. Numerous options exist for two-dimensional semiconductors, yet to date hexagonal boron nitride is the most widely used two-dimensional insulator. Silica bilayers are wide band-gap insulators with band gaps on the order of 6.5–7.3 eV [10.253, 254] and provide a two-dimensional analog of the SiO_x insulating layer used in the semi-conductor industry. In order to use bilayer silica for nanoelectronic devices, transfer of the bilayer from the growth substrate is necessary. This procedure has been sketched in Fig. 10.42. Silica bilayers are grown on Ru(0001) in vacuum and subsequently moved to ambient [10.57]. The silica bilayer has been successfully transferred to a new Pt(111) substrate via polymer assisted mechanical exfoliation. The transferred sample is heated to remove polymer residue and the structural integrity of the silica film is maintained throughout the process. With this achievement, silica has been added to the toolbox of two-dimensional materials for nanoelectronics, bridging the gap between fundamental structural studies and technological applications.

10.6 Conclusions

In this chapter we have compiled a range of experimental results to address some of the important questions that need to be understood if aiming at an atomistic understanding of chemical processes at oxide surfaces. The experiments described here use well-defined, single crystalline oxide films as model systems, which were proven to be suitable to address the properties of oxide surfaces and allow for their characterization with the rigor of modern surface science methodology. The basis for the atomistic understanding is a detailed knowledge of the structural properties of the system at hand. Using some selected systems, we have shown how the machinery of modern surface science can be used to determine the structural properties of oxide surfaces. It is important to emphasize the increased complexity of oxide surface structures in comparison to metals and we have addressed some of these such as surface termination and defect structures, among others. Oxides cover a wide range of chemical and physical materials properties from wide band-gap insulators to metallic systems. We provide some examples how the properties of the oxides can be tuned focusing on the ability to control charge transfer processes at the surface of oxides using the film thickness or appropriate doping of the system as exemplified for alkaline earth oxide surfaces. Oxide surfaces play a pivotal role in heterogeneous catalysis not only as support for transition metal nanoparticles but also as catalytically active phases. In addition, alterations of the surface structure may occur by reaction of the surface with gas phase species not necessarily being educts of the chemical reaction. To this end as well as because of its great importance for a variety of technological and natural processes, the interaction of water with oxide surfaces is of great interest. We have compiled a variety of experimental results to indicate the level of information that may be obtained. Furthermore, as an example for transition metal oxide surfaces we allude to vanadia in order to show how a detailed characterization of surface species on model systems can help to gain insight that may also be transferred onto more complex powder systems. Apart from these studies we demonstrate the ability to study the kinetics of chemical reactions on such model systems in great detail using molecular beam techniques. The model systems also lend themselves to studies at elevated pressures to learn about modifications of the surface under those conditions, which may have direct consequences for the chemical reactivity of the system. Finally, we discuss the possibility to transfer these systems prepared under UHV conditions into the ambient, exemplifying this by discussing the growth of metal nanoparticles from solution as well as the ability to peal silica films off the supporting metal surface.

Hans-Joachim Freund

Chemical Physics Dept.
Fritz Haber Institute of the Max Planck Society
Berlin, Germany
freund@fhi-berlin.mpg.de

Hans-Joachim Freund received his PhD (1978) and his habilitation (1983) from the University of Cologne. 1983, he became Associate Professor at Erlangen University and in 1987 Professor at Bochum University. In 1995, he accepted a position as scientific member and director of the Department of Chemical Physics at the Fritz-Haber-Institut der Max-Planck-Gesellschaft in Berlin. He serves as Honorary Professor of five universities. He received several national and international awards.

Markus Heyde

Chemical Physics Dept.
Fritz Haber Institute of the Max Planck Society
Berlin, Germany
heyde@fhi-berlin.mpg.de

Markus Heyde heads the Scanning Probe Microscopy group in the Department of Chemical Physics at the Fritz-Haber-Institute. His research is focused on high-resolution local structure measurements on model systems for heterogeneous catalysis. Well-defined crystalline and amorphous oxide thin film systems are characterized by atomic resolution microscopy to gain insight into the chemical reactions taking place at these surfaces.

Helmut Kuhlenbeck

Chemical Physics Dept.
Fritz Haber Institute of the Max Planck Society
Berlin, Germany
kuhlenbeck@fhi-berlin.mpg.de

Helmut Kuhlenbeck studied physics at the University of Osnabrück. In 1995, he finished the habilitation procedure at the University of Bochum. He has been a work group leader at the Chemical Physics department of the Fritz Haber Institute in Berlin since 1996. His activities are focused on areas related to structural studies and spectroscopy of chemical processes on well-ordered oxide surfaces.

Niklas Nilius

Institut für Physik
Carl von Ossietzky Universität Oldenburg
Oldenburg, Germany
niklas.nilius@uni-oldenburg.de

Niklas Nilius studied physics and received his PhD in the group of H.-J. Freund for investigating the optical properties of individual nanoparticles. In 2002/2003, he worked as a postdoc with W. Ho on monatomic chains artificially assembled from single metal atoms. He has held a professorship at Oldenburg University since 2013, where he develops oxide model systems for photovoltaic and photochemical applications.

Thomas Risse

Institute of Chemistry and Biochemistry – Physical and Theoretical Chemistry
Freie Universität Berlin
Berlin, Germany
risse@chemie.fu-berlin.de

Thomas Risse received his Doctorate in Physical Chemistry from Ruhr-Universität Bochum. From 1997 until 2010 he was staff scientist at the Fritz Haber Institute, with an interlude of 1 year as a postdoc at UCLA. In 2010 he became Professor of Physical Chemistry at Freie Universität Berlin. He is interested in ESR spectroscopy and its application to surfaces and spin labeled proteins.

Swetlana Schauermann

Institut für Physikalische Chemie
Christian-Albrechts-Universität zu Kiel
Kiel, Germany

Swetlana Schauermann studied chemistry and received her PhD (2005) in the group of H.-J. Freund investigating heterogeneously catalyzed reactions at the atomistic level. Between 2006 and 2007, she was a postdoctoral fellow with R.M. Lambert (Cambridge University) and C.T. Campbell (University of Washington).She has been a professor at Kiel University since 2015. Her current research is focused on the kinetics of complex surface reactions and thermodynamics of gas–surface interactions.

Thomas Schmidt

Chemical Physics Dept.
Fritz Haber Institute of the Max Planck Society
Berlin, Germany
(BESSY II)

Helmholtz-Zentrum Berlin für Materialien und Energie
Berlin, Germany
thomas.schmidt@fhi-berlin.mpg.de

Thomas Schmidt studied physics at the University of Hanover, where he received his PhD in 1994. After postdoc positions in Clausthal, ELETTRA (Trieste), and Würzburg, he became a group leader at the FHI in 2008. Using XPEEM, XPS, XEXAFS, LEEM, and LEED he investigates the growth and properties of ultrathin oxide films supported by metal single crystals.

Shamil Shaikhutdinov

Chemical Physics Dept.
Fritz Haber Institute of the Max Planck Society
Berlin, Germany
shaikhutdinov@fhi-berlin.mpg.de

Shamil Shaikhutdinov has received his PhD (1986) from the Moscow Institute of Physics and Technology. He has worked at the Boreskov Institute of Catalysis (Novosibirsk) and as a postdoctoral fellow in Germany and France. Since 2004, he has been leading the group Structure and Reactivity in the Fritz-Haber Institute (Berlin). His research interest is focused on understanding of the atomic structure and surface chemistry of functional materials.

Martin Sterrer

Institute of Physics
University of Graz
Graz, Austria
martin.sterrer@uni-graz.at

Martin Sterrer received his PhD in Physical Chemistry from TU Vienna. In 2003 he joined Professor Freund's department as a postdoc and later headed the Catalysis and Laser Spectroscopy group in the department. In 2014, he moved to University of Graz, where he is now Professor of Experimental Physics and Head of the Surface Science group, working on model catalysis, solid–liquid interfaces and adsorption structures of large organic molecules.

Part C Electronic Structure Of Surfaces

Part C encompasses six chapters devoted to surface electronic structure, presenting both experimental and theoretical points of view. A number of experimental techniques and related state-of-the-art theoretical methods are described. This field is characterized by a strong interaction between experiment and theory, since the latter is required to interpret the complexities often encountered in experimental findings. A lack of correspondence between theoretical and experimental results also points to the need to refine the theory of surface electronic structure to make it accurate enough to use for reliable predictions in the future.

Chapter 11 initially describes the experimental methods of photoemission and inverse photoemission spectroscopy, which are widely used to investigate filled and empty electronic states, respectively. Group theory, dipolar theory, and the relevant selection rules are then applied to explain the observed spectra of CO in the gas phase and when adsorbed on metal surfaces. In the second part of the chapter, x-ray photoelectron spectroscopy and core-level shifts are introduced, and examples are given of the possible effects that may be observed and identified from the changes in the chemical environments of adsorbates on both metallic and organic substrates.

Chapter 12 describes electronic states at vicinal surfaces of metals. The presence of ordered sequences of terraces and steps generates a high density of step-based atoms with identical coordination numbers that are lower than and relaxations that differ from those of the atoms on the terrace, causing well-defined core-level shifts. Moreover, the presence of atomic steps leads to a periodic modulation of the surface potential, which in turn results in scattering and ultimately the confinement of the surface electronic states. Interestingly, one-dimensional quantization across the steps is also observed. Therefore, all of the electronic levels of the atoms in the steps are affected, from deep core levels to surface states. This influences physical and chemical phenomena at the surface/vacuum interface, such as chemical reactions and epitaxial growth. Detailed studies are performed either with samples cut at a specific miscut angle, which produces a vicinal surface with specified high Miller indices, or using curved surfaces through which a number of vicinal surfaces with varying high Miller indices can be accessed. At least in principle, stepped surfaces allow the surface electronic structure to be tailored almost at will.

Chapter 13 reviews the use of low-energy and photoemission electron microscopes and their application to the investigation of model systems of interest for nanotechnology, nanomagnetism, materials science, catalysis, energy storage, thin films, and 2-D materials. After an historical overview of these techniques, the chapter describes their basic operating principles, procedures for extracting spectroscopic information, and the origin of contrast in the images. A number of examples are presented to illustrate state-of-the-art capabilities, such as the identification of graphene domains with different thicknesses and the magnetic imaging of Fe nanowires.

Chapter 14 is devoted to scanning photoelectron microscopy. In order to achieve the desired lateral resolution without losing spectral resolution, it is necessary to use third-generation synchrotron light sources. High spatial resolution can be achieved by either magnifying the image of the irradiated surface area using a suitable electron optical system, as described in Chap. 13 (LEEM and PEEM), or—as explained here—by demagnifying the incident photon beam to a very small spot using x-ray photon optics and scanning the beam over the crystal surface. Under realistic conditions, subnanometer spatial resolution can be attained. The advantage over optical microscopy is the contrast achieved with x-ray photoelectron spectroscopy or x-ray absorption spectroscopy. Many examples are given, including those illustrating the surface reactivities of metals used as catalysts and the degradation mechanism of light-emitting diodes, as well as images of different nano- and microstructures.

The section ends with two theoretical chapters.

Chapter 15 focuses on topological insulators—materials which are insulating in the bulk but host topologically protected metallic states at the surface. Interest in these materials arises from their possible use in spintronics and quantum computing. This chapter is devoted to natural topological heterostructures composed of different sublattices, at least one of which is a topological insulator, and demonstrates that they all support Dirac surface states.

Chapter 16 covers methods of calculating the energetic ground state and electronic band structure of a surface. First, DFT methods utilizing the local density and general gradient approximations are introduced. Hybrid functionals are also discussed. Then the issue of van der Waals interactions is tackled. Several examples are presented, ranging from clean single-crystal surfaces to the adsorption of simple molecules at different surfaces and recent results on organic adsorbates. The theoretical results are compared with state-of-the-art experimental findings showing that the interplay of theory and experiments has led to the successfully determination of adsorption sites, geometries, possible surface reconstructions, molecular orientations, potential energy barriers, wavefunctions, and vibrational frequencies.

11. Integrated Experimental Methods for the Investigation of the Electronic Structure of Molecules on Surfaces

Andrew J. Yost, Prescott E. Evans, Iori Tanabe, Guanhua Hao, Simeon Gilbert, Takashi Komesu

In this chapter, we introduce the efficacy of photoemission and inverse photoemission in determining the interactions of adsorbates with a substrate, with an emphasis on simple adsorbates on various metallic and oxide surfaces. We cover symmetry and selection rules, and how hybridization, bonding, and molecular orientation affect x-ray photoemission (XPS), angle resolved photoemission (ARPES), and angle resolved inverse photoemission (ARIPES). The application of ARPES and ARIPES in the determination of the orientation of molecular adsorbates and the wave vector dependence of the adsorbate molecular orbitals is addressed. We also address some of the difficulties associated with photoemission data interpretation as they relate to initial states and screened and unscreened final states, surface-to-bulk core level shifts, and core level satellites. This chapter is intended to help those new to photoemission spectroscopy with a basic understanding of the photoemission phenomenon and the associated intricacies that will be encountered in an experimental setting.

11.1 Photoemission Spectroscopy

11.1.1 Introduction to Photoemission

Photoemission spectroscopy is an extremely powerful technique in the identification and investigation of materials with reference to their electronic environment and band structure. This process is also appropriate for molecular adlayers on materials which can additionally show bonding structure and orientation. Essential to in-depth studies of materials are ARPES techniques, which exploit the use of highly plane-polarized incident light. The combination of highly plane-polarized incident light and angular resolution means that photoemission selection rules can be applied. This means more than simply atomic angular momentum conservation, which restricts resonant photoemission to a change in ℓ, (orbital angular momentum quantum number), such that $\Delta\ell = \pm 1$, but also symmetry selection rules. For a highly symmetric molecule (as opposed to a molecule which lacks invariance under applied symmetry operations), the molecular orbitals will have a photoemission cross-section that varies with the photoemission geometry and the symmetry of the molecular orbital. This has a profound consequence for a molecule aligned along the surface normal, or parallel to the surface and aligned along a high-symmetry crystallographic axis of the substrate, as the molecular orientation can be determined. Similarly, overlapping molecular orbitals within a material or molecular adlayer can sometimes be isolated through changing photoemission geometry. Here, one molecular orbital will have greater intensity in the photoemission spectra than other closely lying photoemission features based on selection rules. Varying photon energy can also be of great benefit, allowing access to a wider portion of a material's electronic states. However, changing photon energy and exploiting highly-polarized light generally implies the need for a synchrotron light source, although bright laboratory light sources with polarization capabilities are becoming available. The details of the photoemission process and the symmetry selection rules follow.

11.1.2 Symmetry and Selection Rules in Electron Spectroscopy

Photoemission Spectroscopy and Inverse Photoemission Spectroscopy

In the past several decades, photoemission spectroscopy has proven to be a powerful tool to study the band structure and electronic structure of various types of materials, including molecular adlayers. There are several types of photoemission spectroscopies, dependent upon the light source, such as a ultraviolet (UV) lamps, x-rays, or synchrotron radiation. UV photoemission spectroscopy, which uses ultraviolet photons with energy below 200 eV, has been a fundamental experimental method to probe the occupied band (valence band) structure of materials [11.1–11]. When a photon impinges on a sample, the electrons excited by the photoelectric effect are ejected into the vacuum with a kinetic energy, E_{kin}. From the principle of conservation of energy, one can write the following equation describing the photoemission process as

$$E_{\mathrm{kin}} = h\nu - E_{\mathrm{b}} - \Phi \,, \tag{11.1}$$

where $h\nu$ is the incident photon energy, $E_{\mathrm{b}}$is the binding energy of the electrons in the sample, and Φ is the work function (Fig. 11.1b). An electron energy analyzer detects the photoelectron kinetic energy, E_{kin}, and its angle with respect to the incident light $(\theta_{\mathrm{i}} + \theta_{\mathrm{f}})$ and the surface $(\theta_{\mathrm{f}}, \phi)$ as schematically shown in Fig. 11.1a, where θ_{f} and ϕ are the polar and azimuthal angles of the photoelectrons, respectively. The momentum of the photoelectrons is given as

$$E_{\mathrm{kin}} = \frac{p^2}{2m} \;\Rightarrow\; p = \sqrt{2mE_{\mathrm{kin}}} \tag{11.2}$$

and the direction of $\boldsymbol{p}/\hbar$ is determined from θ_{f} and ϕ [11.12].

Inverse photoemission spectroscopy (IPES) [11.14–23] has been utilized to study the unoccupied electronic structure of solids (conduction band). In the case of IPES, an electron with energy E_{i} impinges the sample surface, and the electron loses its energy and decays to an unoccupied bound state with energy E_{f}, while emitting a photon with the energy $h\nu = E_{\mathrm{i}} - E_{\mathrm{f}}$, as shown in Fig. 11.2. A Geiger–Müller detector can be used to measure the photon counts while the e-gun sweeps a range of energy to elicit the photon energy emitted. If the kinetic energy of the incoming electron, E_{i}, and momentum are well defined from the experimental conditions, then the energy of the unoccupied state, E_{f}, is determined by the conservation of energy, as seen in (11.3) below,

$$E_{\mathrm{i}} - E_{\mathrm{f}} - h\nu = 0 \,. \tag{11.3}$$

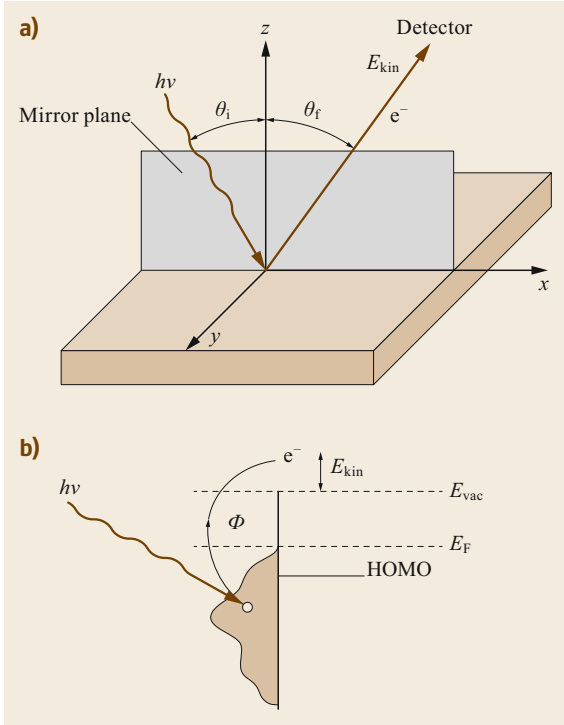

Fig. 11.1a,b Ultraviolet photoemission spectroscopy. **(a)** The photon with energy $h\nu$ with the incident angle θ_{i} with respect to the surface normal impinges on the surface of the sample. Then, the photoelectron with kinetic energy E_{kin} is emitted with an angle θ_{f}. **(b)** Sketch of the photoemission process (Reprinted from [11.13], with permission from Elsevier)

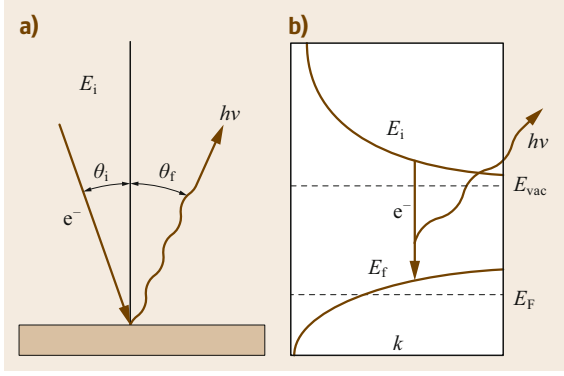

Fig. 11.2a,b Inverse photoemission spectroscopy. **(a)** An electron with energy E_{i} with the incident angle θ_{i} with respect to the surface normal impinges on the surface of the sample. Then, a photon with energy $h\nu$ is emitted with an angle θ_{f}. **(b)** Sketch of the inverse photoemission process (Reprinted from [11.13], with permission from Elsevier)

The Theory of Photoemission

Let us consider the transition probability per unit time between the initial state, Ψ_i, and the final state, Ψ_f, given by time-dependent perturbation theory, both for the photoemission process and the inverse photoemission process. Recall that the transition probability rate describes the likelihood of transitioning from one energy eigenstate to another under the influence of some perturbation. Assuming a small perturbation $H'(t)$ due to the incident photon, the photoemission transition rate ω is calculated by Fermi's golden rule

$$\omega \propto \frac{2\pi}{\hbar} \left|\langle \Psi_\mathrm{f} \left| H' \right| \Psi_\mathrm{i} \rangle\right|^2 \delta\left(E_\mathrm{f} - E_\mathrm{i} - \hbar\nu\right) . \tag{11.4}$$

The Hamiltonian of an electron in an external electromagnetic field is

$$H = H_0 + H' = \frac{1}{2m}\left(\boldsymbol{p} + \frac{e\boldsymbol{A}}{c}\right)^2 - eU - e\phi \ , \tag{11.5}$$

where $\boldsymbol{A}$ and ϕ are the vector and scalar potentials, respectively, and $\boldsymbol{p}$ is the momentum operator where $\boldsymbol{p} = \mathrm{i}\hbar\nabla$. Thus, the perturbation Hamiltonian $H'(t)$ is given as

$$\begin{aligned} H'(t) = {} & \frac{e}{2mc}\left(\boldsymbol{A}\cdot\boldsymbol{p} + \boldsymbol{p}\cdot\boldsymbol{A}\right) \\ & + \frac{e^2}{2mc^2}\boldsymbol{A}\cdot\boldsymbol{A} - e\phi \ . \end{aligned} \tag{11.6}$$

By choosing the appropriate condition such that the scalar potential is zero, $\phi = 0$, and neglecting $\boldsymbol{A}\cdot\boldsymbol{A}$, which represents the two photon process, which is unlikely and complicated, and is usually small compared to $\boldsymbol{p}\cdot\boldsymbol{A}$ terms, i.e., $\boldsymbol{A}\cdot\boldsymbol{A} \ll \boldsymbol{p}\cdot\boldsymbol{A}$, (11.6) becomes

$$H'(t) = \frac{e}{2mc}\left(\boldsymbol{A}\cdot\boldsymbol{p} + \boldsymbol{p}\cdot\boldsymbol{A}\right) . \tag{11.7}$$

Now, using the commutation relation, $\boldsymbol{A}\cdot\boldsymbol{p} + \boldsymbol{p}\cdot\boldsymbol{A} = 2\boldsymbol{A}\cdot\boldsymbol{p} + \mathrm{i}\hbar\left(\nabla\cdot\boldsymbol{A}\right)$ and setting $\nabla\cdot\boldsymbol{A} = \boldsymbol{0}$, because the photon wavelength is much larger than the atomic dimensions, we have

$$H'(t) = \frac{e}{mc}\boldsymbol{A}\cdot\boldsymbol{p} \ . \tag{11.8}$$

In ultraviolet photoemission spectroscopy, one can adopt the dipole approximation to treat the vector potential $\boldsymbol{A}$ as a constant $\boldsymbol{A_0}$, because the wavelength of the incident photon is much larger than the radius of the atom. Therefore, the perturbation Hamiltonian $H'(t)$ is finally written as

$$H'(t) = \frac{e}{mc}\boldsymbol{A_0}\cdot\boldsymbol{p} \ . \tag{11.9}$$

Now, we should make some approximation to analyze the transition matrix elements $\langle \Psi_\mathrm{f} \left| H' \right| \Psi_\mathrm{i} \rangle$. In the photoemission process, the irreducible representation of the initial state, Ψ_i, is considerably different from that of the final state, Ψ_f, after one electron is ejected by a photon. Unless it is a hydrogen atom, the systems under study have many electrons with many degrees of freedom mutually interacting with each other. However, we can adopt an assumption of a one-electron view for the initial and final wavefunctions instead of the complicated many-body theory to deal with the photoemission analysis [11.3, 24–29]. When photoelectrons are created by photoionization of the various orbitals the initial wavefunction, $\Psi_\mathrm{i}(N)$, is described as the product of a wavefunction of a single electron which is to be photoemitted, $\varphi_{\mathrm{i},k}$, and the wavefunction of the remaining $(N-1)$-electrons, $\Psi_\mathrm{i}^k\,(N-1)$, provided that the system has N number of electrons. Thus, the N-electron initial state, $|\Psi_\mathrm{i}(N)\rangle$, is

$$|\Psi_\mathrm{i}(N)\rangle = |\varphi_{\mathrm{i},k}\rangle |\Psi_\mathrm{i}^k(N-1)\rangle \ . \tag{11.10}$$

Similarly, the final wavefunction, $\Psi_\mathrm{f}(N)$, is written as the product of a wavefunction of the emitted electron, $\varphi_{\mathrm{f},E_\mathrm{kin}}$, with kinetic energy equal to E_kin and the wavefunction of the rest of the electrons, $\Psi_{\mathrm{f},s}^k\,(N-1)$. Here, s denotes the number of excited states the remaining $(N-1)$-electrons have, since the final $(N-1)$-electron states should, in general, be different from the initial one due to energy relaxation. Thus, the N-electron final state $|\Psi_\mathrm{f}(N)\rangle$ is

$$|\Psi_\mathrm{f}(N)\rangle = |\varphi_{\mathrm{f},E_\mathrm{kin}}\rangle |\Psi_{\mathrm{f},s}^k\,(N-1)\rangle \ . \tag{11.11}$$

Then, the transition matrix element becomes

$$\begin{aligned} \langle \Psi_\mathrm{f} | H' | \Psi_\mathrm{i} \rangle = {} & \langle \varphi_{\mathrm{f},E_\mathrm{kin}} \left| H' \right| \varphi_{\mathrm{i},k} \rangle \\ & \times \left\langle \Psi_{\mathrm{f},s}\,(N-1) \left| \Psi_\mathrm{i}^k\,(N-1) \right\rangle \right. . \end{aligned} \tag{11.12}$$

Therefore, the photoemission transition rate ω finally yields

$$\begin{aligned} \omega \propto {} & \frac{2\pi}{\hbar} \left|\langle \varphi_{\mathrm{f},E_\mathrm{kin}} \left| H' \right| \varphi_{\mathrm{i},k} \rangle\right|^2 \\ & \times \sum_s \left|\left\langle \Psi_{\mathrm{f},s}\,(N-1) \left| \Psi_\mathrm{i}^k\,(N-1) \right\rangle \right.\right|^2 \\ & \times \delta\left(E_\mathrm{kin} + E_s\,(N-1) - E_0(N) - h\nu\right) , \end{aligned} \tag{11.13}$$

where $E_0(N)$ is the ground state energy of the N-electron system.

While the classical vector potential $\boldsymbol{A}$ for the photoemission process generates mostly the same results,

as it is treated quantum mechanically, the inverse photoemission process requires the vector potential $\boldsymbol{A}$ to be quantized as

$$\boldsymbol{A}(\boldsymbol{x},t) = \sum_{\boldsymbol{q}}\sum_{r}\left(\frac{\hbar c^2}{2V\omega_{\boldsymbol{q}}}\right)^{\frac{1}{2}} \times \boldsymbol{\varepsilon}_r(\boldsymbol{q})\left[a_r(\boldsymbol{q},t)\,\mathrm{e}^{\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{x}} + a_r^{\dagger}(\boldsymbol{q},t)\,\mathrm{e}^{-\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{x}}\right], \tag{11.14}$$

where $\omega_{\boldsymbol{q}} = c|\boldsymbol{q}|$ [11.30, 31]. This is due to the fact that the inverse photoemission process is an excited electron system without an electromagnetic field, which causes the transition matrix elements of the dipole operator to become zero in the semiclassical expression [11.13]. Similar to the initial and final states of photoemission, for inverse photoemission, the initial state comprises an electron within a continuum state with no photons and is expressed as $|\psi_{\mathrm{i}}, n_{h\nu} = 0\rangle$, and the final state comprises an electron in a bound state and a photon with wave vector $\boldsymbol{q}$ and is expressed as $|\psi_{\mathrm{f}}, n_{h\nu}(\boldsymbol{q}) = 1\rangle$ [11.13].

Symmetry and Dipole Selection Rules

Exploiting symmetry and dipole selection rules gives us a very useful insight to analyze the transition matrix element presented as (11.12). Table 11.1 shows the character table for the C_{2v} point group which consists of the four symmetry operations, E, C_2, σ_v, σ_v'. The left column lists the name of the irreducible representations A_1, A_2, B_1, B_2, known as Mulliken symbols, and the two columns on the right-hand side of the table comprise basis functions for the irreducible representations. Since these basis functions also correspond to the symmetry of the atomic or molecular orbitals, dipole selection rules predict, without the direct calculation of the transition matrix element, which transition is allowed or not allowed using the symmetry properties of the initial and final states in solids and the electric dipole operator of the perturbed Hamiltonian described in (11.9), especially if polarized light is used. In photoemission experiments, one can use p- and s-polarized light from a synchrotron radiation source, which is highly plane (linearly)-polarized. p-polarized light has its vector potential $\boldsymbol{A}$ parallel to the plane of the sample surface (the incident beam is perpendicular to sample surface), and s-polarized light has its vector potential $\boldsymbol{A}$ normal to the plane of the sample surface (the incident beam is parallel to the sample surface, at a shallow angle of incidence). As an integral for an odd function will necessarily be zero, the transition matrix element vanishes if the product of the functions in $\langle\Psi_{\mathrm{f}}|\,\boldsymbol{A}\cdot\boldsymbol{p}\,|\Psi_{\mathrm{i}}\rangle$ is orthogonal, which occurs when functions belong to different irreducible representations of a group. In other words, the direct product of the representations of the initial and final state wavefunctions should contain the representation of the dipole operator $\boldsymbol{A}\cdot\boldsymbol{p}$ [11.13, 32]. The initial state must be symmetric (even) if the vector potential $\boldsymbol{A}$ is parallel to the mirror plane, and the initial state must be antisymmetric (odd) if the vector potential $\boldsymbol{A}$ is normal to the mirror plane.

If we consider a face-centered-cubic (fcc) metal as an example, then the normal emission along the Σ direction of the Brillouin zone (the principal direction [110] at $k_{||} = 0$), as depicted in Fig. 11.3, has C_{2v} symmetry. Table 11.2 is a result of implementing group theory to the dipole matrix element [11.32]. For p-polarized light, parallel to the Σ direction, the allowed transitions are of the type $\Sigma_1 \rightarrow \Sigma_1$. For s-polarized light, perpendicular to the Σ direction and also parallel to the x direction, the allowed transitions are of the type $\Sigma_1 \rightarrow \Sigma_3$, whereas for s-polarized light, they are perpendicular to the Σ direction and also parallel to

Table 11.1 C_{2v} character table. The Mulliken symbols A_1, A_2, B_1, B_2, are the irreducible representations of the C_{2v} point group, the row with E, C_2, σ_v, σ_v' represents the symmetry operations of the group, and the two columns on the right-hand side of the table represent the basis functions of the irreducible representations

C_{2v}	E	C_2	$\sigma_v(xz)$	$\sigma_v'(yz)$		
A_1	1	1	1	1	z	x^2, y^2, z^2
A_2	1	1	−1	−1	R_z	xy
B_1	1	−1	1	−1	x, R_y	xz
B_2	1	−1	−1	1	y, R_x	yz

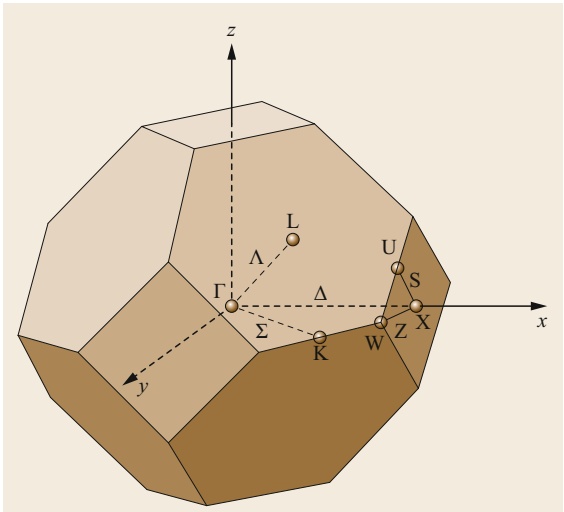

Fig. 11.3 Brillouin zone of the face-centered-cubic (fcc) lattice. The high-symmetry points and lines are indicated (Reprinted with permission from [11.32] Copyright (1980) by the American Physical Society)

Table 11.2 C_{2v} dipole transitions along the Σ line of the Brillouin zone of the fcc crystal. (+) stands for the vector potential $\boldsymbol{A} \parallel \Sigma$, (0) stands for $\boldsymbol{A} \perp \Sigma$ and $\boldsymbol{A} \parallel x$, and ($X$) stands for $\boldsymbol{A} \perp \Sigma$ and $\boldsymbol{A} \parallel y$

C_{2v}	Σ_1	Σ_2	Σ_3	Σ_4
Σ_1	+	⋯	0	X
Σ_2	⋯	+	X	0
Σ_3	0	X	+	⋯
Σ_4	X	0	⋯	+

the y direction; the allowed transitions are of the type $\Sigma_1 \rightarrow \Sigma_4$. Here, Σ_1, Σ_2, Σ_3, and Σ_4 correspond to the irreducible representation A_1, A_2, B_1, and B_2, respectively. Therefore, A_1 (includes atomic orbitals s, p_z, $d_{z^2-r^2}$), B_1 (this includes atomic orbitals p_x, d_{xz}), and B_2 (this includes atomic orbitals p_y, d_{yz}) atomic or molecular orbitals can be observed depending on the light polarization, but orbitals with A_2 symmetry cannot be observed.

The derivations above are obtained by nonrelativistic dipole selection rules. Taking into account the effect of spin–orbit coupling suggests the use of relativistic dipole selection rules [11.33, 34].

As can be seen from the previous example, assignment of the irreducible representation can be done easily once the point group of the system is determined by looking at how the state in question behaves physically under the symmetry operations of the group. Consider (11.13), as mentioned above, if the direct product of the irreducible representation of $\boldsymbol{A} \cdot \boldsymbol{p}$ on the irreducible representation of ψ_i does not cast the initial state into the same irreducible representation of the final state, there will be no intensity as $|\langle \psi_f | \psi_i \rangle|^2 = 0$. Again, it is important to understand that the final state in all photoemission is that of the free electron being measured by the energy analyzer, which has the irreducible representation $\boldsymbol{A}_1$. Thinking of the electron as a geometric sphere, the free electron is fully symmetric under all symmetry operators of *any* point group which, in general, are forms of mirror and rotation operations (C_n, σ_v, σ_h, i, etc.). The forms of these symmetry operators can be found elsewhere [11.37, 38]. In terms of the vector potential for the geometries of diatomic molecules bonded upright from the surface, if the vector potential $\boldsymbol{A}$ is parallel to the molecular axis (along z in Fig. 11.4), $\boldsymbol{A} \cdot \boldsymbol{p}$ typically belongs to the A_1 representation [11.13]. If the vector potential $\boldsymbol{A}$ is perpendicular to the molecular axis (parallel to x–y plane in Fig. 11.4), $\boldsymbol{A} \cdot \boldsymbol{p}$, depending on surface geometry, belongs to the irreducible representations B_1, B_2, E_1, or E_2 [11.13]. While the final state is well defined in general, it is the initial state which is complicated; here we turn to molecular orbital theory.

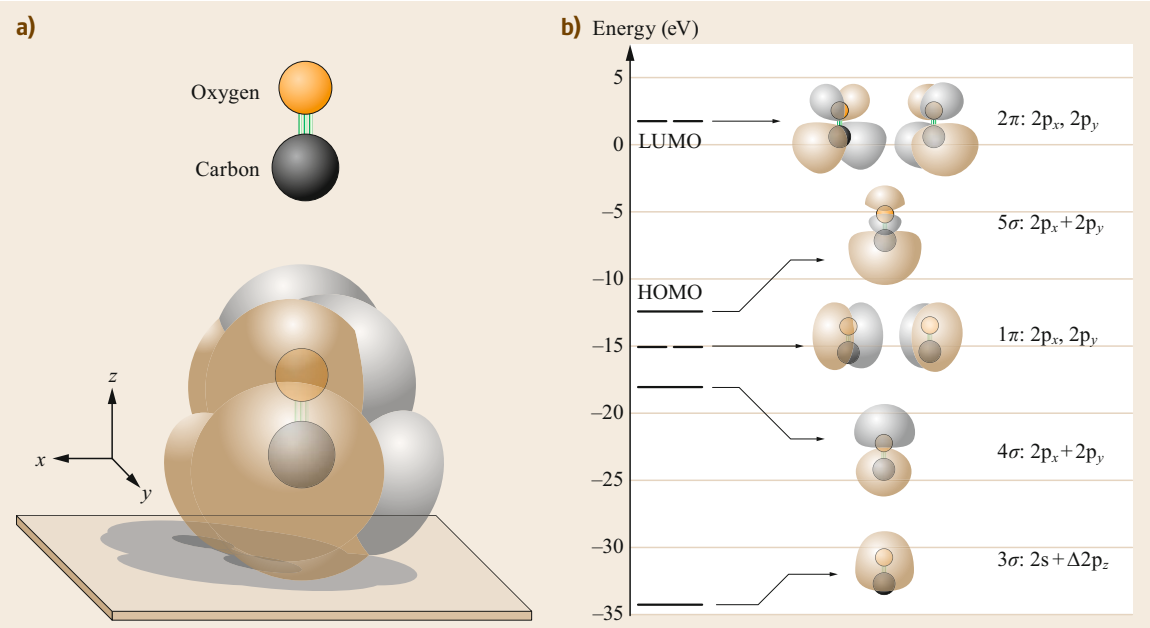

Fig. 11.4a,b Schematic of the CO molecule. **(a)** CO molecule without molecular orbitals (*top* of **(a)**) and with molecular orbitals (*bottom*); **(b)** 3σ, 4σ, 1π, 5σ, and 2π orbitals and corresponding energy levels calculated using a density functional calculation based on the global hybrid generalized gradient approximation, with the B3LYP functional, and the 6-31G* polarization basis set in the Spartan 16′ software package [11.35, 36]

In molecular orbital theory, we gain the structure of the molecular orbitals in terms of energy and contributions from atomic orbitals, and from this we can form the wavefunction of the orbitals and assign symmetry. As with homonuclear molecules (N_2) the equal energy atomic orbitals produce molecular orbitals that have *vertical* mirror symmetry, as each atomic orbital equally contributes to each molecular orbital, and this feature is clearly lacking in the CO molecule. As is shown in Fig. 11.4, the molecular orbitals of CO all have some apparent symmetry; however before the assignment of irreducible representation of each we must know which symmetry group the system belongs to, and interestingly this is different for gas phase and adsorbate phase, as we will see in the following examples.

Gas Phase Carbon Monoxide. Gas phase carbon monoxide belongs to the symmetry group $C_{\infty v}$, due to the molecule containing infinite rotational symmetry (C_∞) about the molecular axis in addition to infinite planes of mirror symmetry (σ_v) parallel to the rotational axis while lacking a dihedral mirror plane, as illustrated in Fig. 11.5. The assignment of symmetry groups quickly becomes complicated for larger molecules and systems, and the methodology of this assignment can be found elsewhere [11.37]. Now that the gas phase carbon monoxide system has been assigned a symmetry group, we may allot irreducible representations to the molecular orbitals, as shown in Fig. 11.4, by using the character table for the symmetry group shown in Table 11.3.

From the character table, we can note that the 3σ, 4σ, and 5σ occupied molecular orbitals (Fig. 11.4) belong to the A_1 irreducible representation, as they are symmetric under the identity operator (E), have infinite rotation (C_∞), and have infinite mirror planes $(\sigma_v) : (1,\ 1,\ \ldots,\ 1)$. We also note that the 1π occupied orbital belongs to the E_1 irreducible representation due to a lack of infinite mirror plane symmetry: $(2,\ 2\cos(\varphi),\ \ldots,\ 0)$. While assignment of symmetry and irreducible representations can be done by using a mathematical representation of the state in question, it is far easier to think of or use a physical model and apply the symmetry operations. Once the irreducible representation is known, one can determine the necessary configuration of the vector potential $\boldsymbol{A}$ from the direct product table for the symmetry group, as provided in Table 11.4. Using (11.13) together with the knowledge that the final state free electron is of representation A_1, in order to access the 3σ, 4σ, and 5σ occupied molecular orbitals requires $\boldsymbol{A}\cdot\boldsymbol{p}$ to be of the form A_1 (along z), as given by $|\langle A_1|A_1|A_1\rangle|^2 = |\langle A_1|A_1\rangle|^2 \neq 0$. Similarly, to access the 1π occupied orbital requires $\boldsymbol{A}\cdot\boldsymbol{p}$ to be of form of E_1 (parallel to x–y plane), as the resulting direct product has some A_1 characteristic $|\langle A_1|E_1|E_1\rangle|^2 = |\langle A_1|A_1\rangle|^2 + \cdots \neq 0$. Hence, the problem of gas phase carbon monoxide is seemingly solved; if we pick the appropriate polarization of light, we access different molecular orbitals. Overall, this process is more easily done without consideration of mathematical complexity; it is simply a short and easy tool to find selection rules. However, so far, we have only considered a single molecule of carbon monoxide. In the real gas phase, the orientation of the carbon monoxide molecules is random, such that there are portions of the gas that are perpendicular to one another; hence there is no polarization dependence for photoemission in the free gas phase. Regardless of polarization, we will have some portion of the gas in which the vector potential falls along A_1 or E_1 in relation to the molecules, enabling access to all molecular orbitals given the correct incident energy.

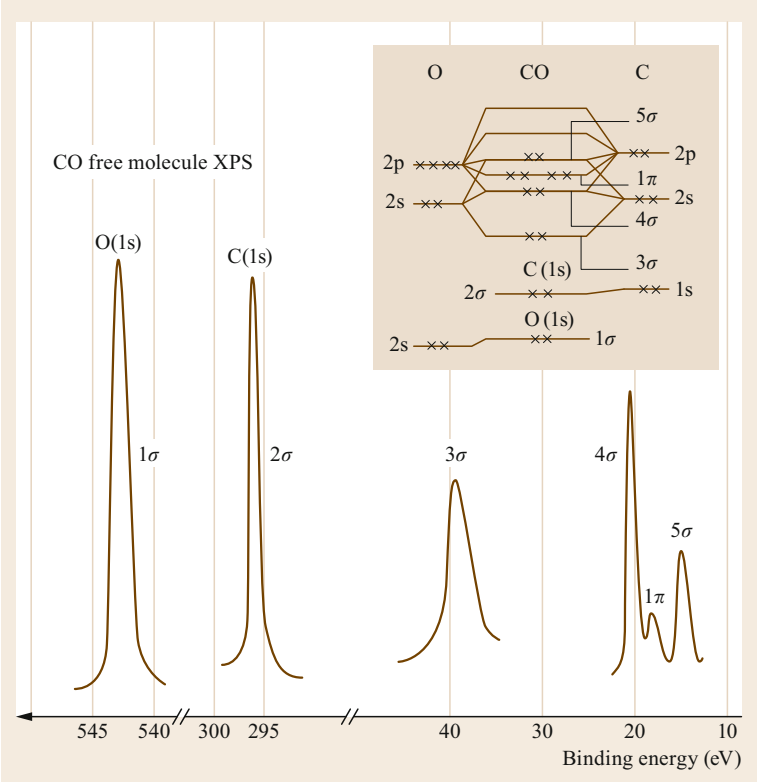

Fig. 11.6 Photoemission spectra of gas phase carbon monoxide; all molecular orbitals are accessed with the same polarization of light (From [11.39])

The phenomenon of polarization independence is evident from Fig. 11.6 for a free carbon monoxide molecule where there is no indication of light source polarization, in comparison to Fig. 11.7 which shows polarization dependent photoemission spectra of carbon monoxide on Ni(100). When the molecules are all oriented in the same direction, we will have polarization dependence, as is the case with carbon monoxide on metal surfaces, which is also the next example.

Adsorbate Phase Carbon Monoxide. As discussed with gas phase carbon monoxide, the symmetry group of the system is vital when determining the irreducible representations of the molecular orbital. The polarization dependence of the molecular orbital will develop a framework for polarization-dependent photoemission selection rules. Recall that we determined that gas phase carbon monoxide is of $C_{\infty v}$ symmetry. Adsorbate phase carbon monoxide is slightly different in that with the adherence of an adsorbate to a substrate, the system takes on the symmetry of the lowest symmetry component. Understandably, $C_{\infty v}$ has a very high degree of symmetry, thus in the interaction of CO with surfaces, the system symmetry is based on that of the surface. A good example of this is the difference in symmetry from different planes of fcc nickel where Ni(100) is C_{4v} or fourfold rotationally symmetric with four corresponding planes of vertical mirror symmetry, or Ni(111), which is C_{6v} or sixfold rotationally symmetric with six corresponding planes of vertical mirror symmetry, as shown in Fig. 11.8.

There must now be a quick discussion of the effects of the bonding of the carbon monoxide onto the surface. While the symmetry reduction is purely geometrical, the chemical process of bonding must have influence on the molecular orbitals. Interestingly, as can be seen in Fig. 11.9, the process of bonding with the surface pushes the 5σ to higher binding energy through electron donation to the metal, while also making 2π the highest occupied molecular orbital of the CO through backbonding and electron contribution of the metal to the $2\pi^*$ orbital [11.39].

If a CO molecule is adsorbed on Ni(100), we know that the system follows the symmetry operations of the C_{4v} group. If the molecular axis of the CO is along z, from Fig. 11.9 and Table 11.5, the 3σ, 4σ, and 5σ occupied molecular orbitals are of A_1 representation, as they are fully symmetric about the z-axis, both rotationally and along mirror planes: (1, 1, 1, 1, 1). Hence to access the 3σ, 4σ, and 5σ orbitals in photoemission, following Table 11.6, we need $\boldsymbol{A}\cdot\boldsymbol{p}$ to be of the form A_1 (along z), as (11.13) allows $|\langle A_1|A_1|A_1\rangle|^2 =$

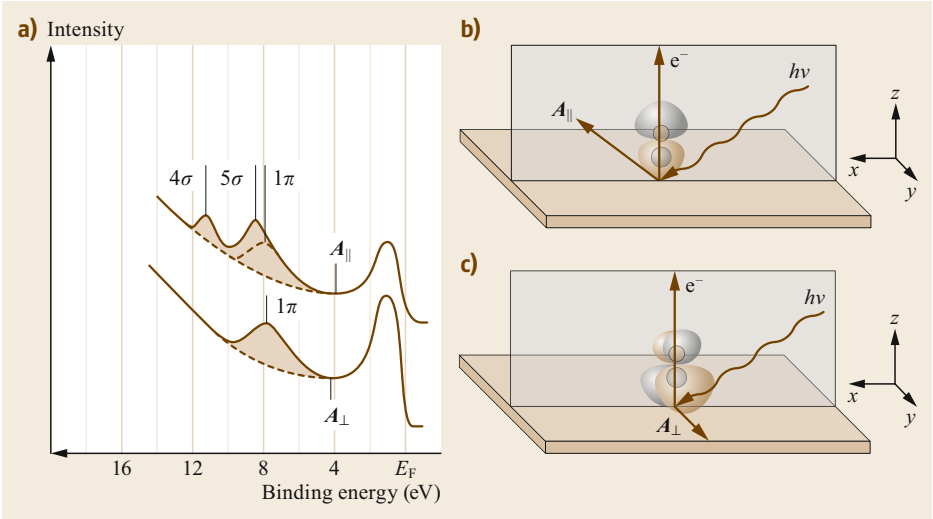

Fig. 11.7a–c **(a)** Photoemission spectra of carbon monoxide on Ni(100), geometry of the experiment indicating in **(b)** the 4σ molecular orbital of carbon monoxide with the polarization vector parallel to the molecular axis (z axis) and in **(c)** the 1π molecular orbital of carbon monoxide with the polarization vector perpendicular to the molecular axis (parallel to x–y plane) (**(a)** from [11.39])

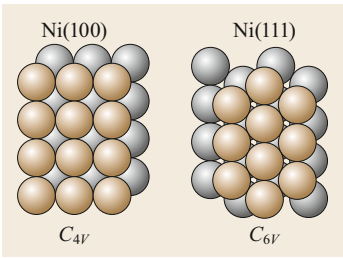

Fig. 11.8 Ni(100) and Ni(111) surfaces with C_{4v} and C_{6v} symmetry, respectively

$|\langle A_1|A_1\rangle|^2 \neq 0$. Likewise, the 1π occupied orbital belongs to the E representation due to the lack of C_4 rotational symmetry about the z-axis. This implies that to access the 1π state $\boldsymbol{A}\cdot\boldsymbol{p}$ needs to be of the form E (parallel to the x–y plane), as again from Table 11.4, $|\langle A_1|E|E\rangle|^2 = |\langle A_1|A_1\rangle|^2 + \ldots \neq 0$. Subsequent application of this methodology can be applied to the C_{6v} case of Ni(111). Here, we find that the 3σ, 4σ, and 5σ occupied molecular orbitals are again of A_1 representation (Table 11.7) due to being fully symmetric about the z-axis for rotational and mirror operations, which according to Table 11.8 would require $\boldsymbol{A}\cdot\boldsymbol{p}$ to be of the form A_1 (along z) to observe photoemission. Assignment of the 1π occupied orbital falls under the E_1 representation in Table 11.7, due to loss of C_6 rotational symmetry about the z-axis, requiring $\boldsymbol{A}\cdot\boldsymbol{p}$ to be of the form E_1 (parallel to x–y plane) for photoemission (Table 11.8). Unlike the gas phase carbon monoxide, the adsorbate phase has ordering and alignment of carbon monoxide on particular metal surfaces. Due to this ordering, we observe polarization-dependent photoemission (Fig. 11.7) for the C_{4v} Ni(100) case, where we do not for the gas phase (Fig. 11.6). The 4σ and 5σ of the CO/Ni(100) are accessed through parallel polarized light, and 1π is accessed through perpendicular polarized light as predicted from symmetry arguments (Fig. 11.7b,c).

ARPES and ARIPES at a Glance

ARPES can be used to explore the occupied molecular orbital band structure of molecular crystals and ordered molecular adlayers, while ARIPES can be used to explore the unoccupied molecular orbital band structure. The band structure can be defined as the energy dependence of the electron states as a function of the wave vector [11.13]. The measured band structure is resolved in reciprocal space, i.e., momentum space, and as such is useful for investigating the wave-like nature of the electron. As the band structure is represented in reciprocal space, it helps to define the Brillouin zone (BZ) of the material under study. Before diving into experimental examples, it is instructive to briefly discuss band dispersion.

Electronic band dispersion in the case of ARPES (ARIPES) refers to the relationship between the kinetic energy of the emitted electron (photon) and the wave vector $\boldsymbol{k}$. As the kinetic energy is directly related to the binding energy, the band dispersion can be viewed as a variation of the molecular orbital binding energy as a function of the wave vector [11.8–11, 13, 40–45]. It is important to note that the wave vector also heavily influences the allowed irreducible representation, and any changes in the wave vector could change the symmetry of the point group [11.13].

We can follow the derivation from *Dowben* et al. [11.13] where the one-dimensional periodic wavefunction is just a linear combination of wavefunctions at each lattice site m, which can be represented by the following equation

$$\psi_{\boldsymbol{k}} = \sum_m \mathrm{e}^{\mathrm{i}\boldsymbol{k}ma}\xi_m \,. \tag{11.15}$$

When $\boldsymbol{k}=0$ the wavefunction becomes,

$$\psi_{\boldsymbol{k}=0} = \sum_m \xi_m \,. \tag{11.16}$$

When $\boldsymbol{k}=\pi/a$, at the BZ boundary the wavefunction becomes,

$$\psi_{\boldsymbol{k}=\pi/a} = \sum_m (-1)^m \xi_m \,. \tag{11.17}$$

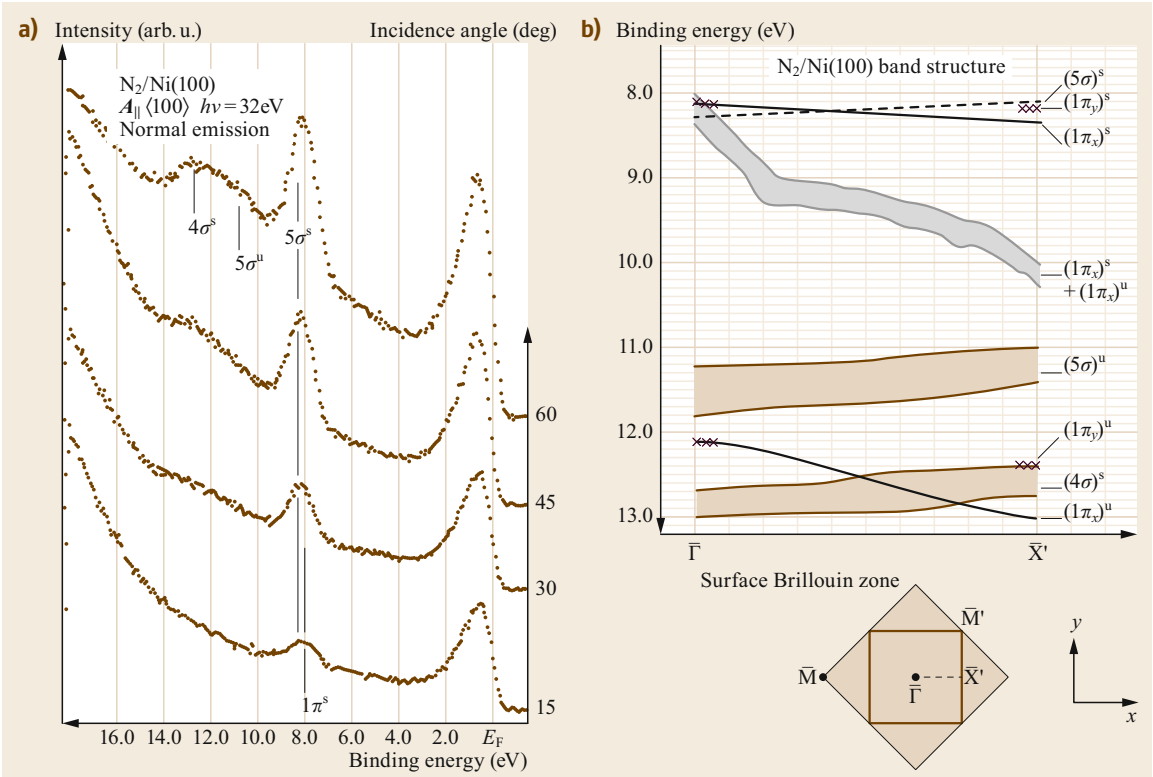

Fig. 11.10 **(a)** Incidence angle dependence of the photoemission spectra for Ni(100)c(2×2)-N_2. The features are assigned with orbital contributions using dipole selection rules and **(b)** the band dispersion of the N_2 molecular orbital taken from $\overline{\Gamma}$ to $\overline{X}'$ (Reprinted from [11.46], with permission from Elsevier)

The dependence on the wave vector influences the overall wavefunction and the observed binding energy [11.8, 9, 11, 13, 41, 43]. If we apply the law of conservation of momentum to the physical process of ARPES (ARIPES), then the energy band dispersion relation, as it relates to the wave vector $\boldsymbol{k}$, can be determined. Consider the process of ARPES (ARIPES): in the UV energy range, an incident photon (electron) strikes the surface of the ordered material and emits an electron (photon). The momentum of the incident (emitted) photon is negligible compared to the emitted (incident) electron, thus we can neglect the momentum of the incident (emitted) photon [11.47]. The momentum is conserved in the direction parallel to the surface, and as such the wave vector component parallel to the surface, $k_{\parallel}$, is conserved. On the other hand, the momentum is not conserved in the direction perpendicular to the surface, and as such the wave vector component perpendicular to the surface, $k_{\perp}$, is not conserved. The momentum is not conserved in the perpendicular direction because of the cutoff at the crystal surface [11.13]. The kinetic energy can be written as,

$$E_{\mathrm{kin}} = \frac{\hbar^2}{2m}\left(k_{\parallel}^2 + k_{\perp}^2\right). \tag{11.18}$$

This leads to the following expression for the parallel component of the wave vector,

$$k_{\parallel} = \sqrt{\frac{2m}{\hbar^2}E_{\mathrm{kin}}}\sin\theta\,, \tag{11.19}$$

where θ is the emission angle of the photoelectron with respect to the surface normal or the incident angle of the electron in IPES.

Now that we have discussed the electronic energy band dispersion in terms of the wave vector we can take a closer look at an experimental example, specifically the study performed by *Dowben* et al. on molecular N_2 on Ni(100) [11.46]. In this experiment, molecular nitrogen adsorbs onto the surface of clean Ni(100) in an ordered overlayer. Following N_2 deposition, ARPES was performed using an s-polarized ultraviolet light

source, where $\boldsymbol{A}$ is parallel to the surface. The incidence angle dependent photoemission spectra are shown in Fig. 11.10a, which indicates two features: one at 8 eV and the second at 12 eV binding energy. As N_2 has $C_{\infty v}$ symmetry (although, realistically, the symmetry is reduced to the C_{4v} symmetry of the Ni(100) surface), the feature observed at 8 eV is generally attributed to the 1π and 5σ orbitals, while the broad feature around 12 eV is considered the 4σ orbital contribution [11.48–51]. If one considers screened and unscreened final state effects, the details of which will be discussed later in the chapter,then there are six possible features that may show up in the final state photoemission spectrum for N_2 due to the screened and unscreened 4σ, 5σ, and 1π orbitals [11.50, 52]. *Dowben* et al. [11.46] argue that the N_2 molecule is oriented on Ni(100) with the molecular axis perpendicular to the Ni(100) surface, as there are only two features observed with s-polarized light at the $\overline{\Gamma}$ point of the BZ. The two features observed at $\overline{\Gamma}$ are assigned as $1\pi^{s}$ and $1\pi^{u}$ at 12.1 and 8.1 eV, respectively. Here, the superscripts s and u stand for screened and unscreened, respectively. At higher incidence angles, 45° and 60°, the σ features have the same orientation as the N_2 molecule, such that the molecular axis of N_2 is perpendicular to the Ni(100) surface. Dowben et al. use *Messmer*'s [11.52] cluster calculations to assign the features at 8.3, 11.4, and 12.8 eV to the $5\sigma^{s}$, $5\sigma^{u}$, and $4\sigma^{s}$ orbitals of N_2, respectively.

Dowben et al. [11.46] also measured dispersion curves from $\overline{\Gamma}$ to $\overline{X'}$ in the BZ for N_2 on Ni(100), which are shown in Fig. 11.10b. The main point to take away from the dispersion curves is that at $\overline{\Gamma}$ the σ orbitals are in bonding configurations, while the π orbitals are in antibonding configurations. As the dispersion moves from $\overline{\Gamma}$ to $\overline{X'}$, we can see that the bonding configuration changes, rather at $\overline{X'}$ the σ orbitals are now in antibonding configurations, while the π orbitals have changed to bonding configurations.

11.2 Chemical Shifts in XPS

11.2.1 Initial and Final State Effects and Screened and Unscreened Final States

This section will deal with the possible effects that may be observed and identified from photoemission and inverse-photoemission spectra due to changes in the chemical environment of adsorbates on both metallic and organic substrates. To describe screened and unscreened final states we must first discuss initial and final state effects in general, and the influence these play in spectroscopic data.

To begin with, initial state effects within the combined inverse and photoemission spectra arise from changes in the electrostatic potential of the core associated with the Madelung energy, charge transfer, and chemical bonding [11.53]. On the other hand, final state effects arise from screening via charge transfer from the bulk material to the adsorbate or vice versa. Another way to phrase this difference is that in the XPS process, our incident x-ray is absorbed by the material, whereby the latter is ionized; the characteristics of the ionization process are dependent on the chemical environment of the material as stated above, and this is our initial state effect. Once in the ionized state, the relaxation of a core-hole from the excited state produces an Auger photoelectron whose kinetic energy is measured and, in turn, provides the binding energy of states within the material. However, if during this relaxation process there is charge transfer from the bulk, as contributed by final state effects, then there exists a partial charge that screens the hole produced from the ionization. Depending on the direction of the charge transfer, the binding energy of the state moves accordingly.

Now we should discuss how initial and final state effects can shift spectral features. As is apparent from studies on gadolinium thin films [11.53], the shifting of the HOMO (highest occupied states of the molecular orbital) and the LUMO (lowest unoccupied states of the molecular orbital) structures within valence band (occupied states) and conduction band (unoccupied states) spectra for initial and final states appears vastly different. The central point introduced by *Ortega* et al. is that changes in spectra from initial state effects result in a shifting of the band gap, more so that both the HOMO and LUMO are rigidly shifted higher or lower in binding energy [11.53]. This is obvious when considering a change in chemical environment surrounding atoms within the substrate; the addition of an adsorbate with higher electronegativity will have a tendency to remove electron density from the substrate. This depletion of electrons forces the HOMO and LUMO to lower energy as the filling of the energy levels within the substrate with less electron density results in the highest occupied state to be a lower bound state than before, and similarly the lowest unoccupied state shifts to lower energy in response. If these states are shifted to lower values, for photoemission spectroscopy PES this requires a greater photon energy to ionize and, thus, results in a higher (more negative) binding energy. Similarly, for IPES, an incident electron of lower kinetic energy may absorb into the LUMO and, thus, we would observe both the HOMO and LUMO to have greater binding energy.

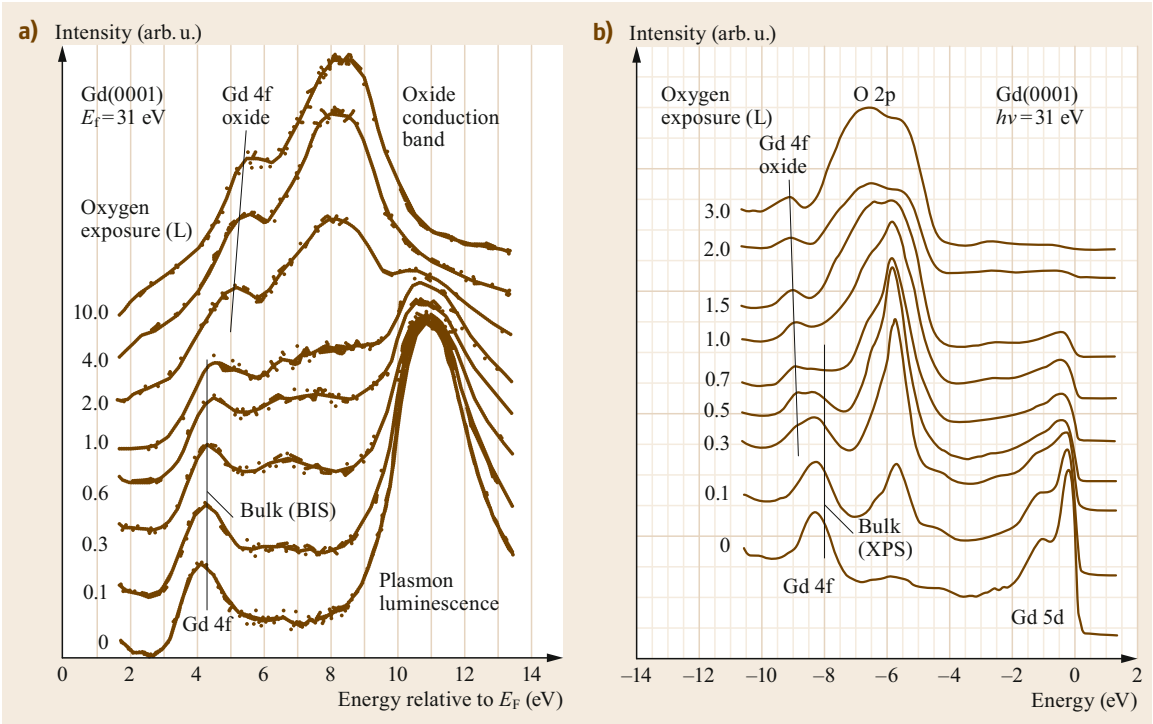

Fig. 11.11 **(a)** IPES and **(b)** PES plots of Gd(0001) with increasing levels of oxygen exposure (Reprinted from [11.53], with permission from Elsevier)

In contrast to these observed initial state effects, there are the final state effects wherein the HOMO and LUMO shift toward or away from one another. This phenomenon can be visualized on the basis of screened and unscreened final states or charge transfer where there exists a sign change in the induced charge when transitioning from a hole in the occupied core level to an extra electron in the empty core level [11.53]. Thus, for a system where there is charge transfer of electron density from an adsorbate to the substrate (screened final state), this appears as a decrease in binding energy of the HOMO within PES due to electron transfer screening the core-hole and producing a repulsive potential with respect to the photoelectron and, hence, increasing the kinetic energy of the ejected photoelectron. Screening effects also produce an increase in the LUMO binding energy within IPES, as the incident electron experiences an attractive potential due to the sign change in the charge transfer from the adsorbate requiring an electron with less kinetic energy for the absorption process and, thus, in turn produces a higher (more negative) binding energy of the LUMO. Hence, screened final states overall reduce the HOMO–LUMO gap found within spectra. On the other hand, it is in unscreened final states where there is a lack of net charge transfer. In this case, within PES the photoelectron experiences only the attractive potential of the core-hole with no reduction from screening and, hence, the photoelectron will have less kinetic energy, forcing the HOMO to have higher binding energy. Within IPES, the absorbed electron does not experience the attractive potential seen within screening and, hence, requires an incident electron with greater kinetic energy, producing a LUMO with lower (less negative) binding energy than in the presence of screening. Hence, unscreened final states lacking a net charge transfer act in such a way to increase the HOMO–LUMO gap.

Central to understanding the differences between the aforementioned effects, we should discuss the case of *Ortega* et al.'s oxygen coverage-dependent spectroscopy of Gd(0001) [11.53]. For the situation where screened final states are dominant, as seen in Fig. 11.11, at lower oxygen coverages, the Gd 4f peak in both PES and IPES shifts to lower binding energy due to the adsorbed oxygen pulling electron density away from the Gd and, thus, reducing the binding energy of both (initial state effect). At higher oxygen coverages it is apparent that unscreened final state effects dominate as the Gd 4f peaks move farther apart. In this situation the strong electronic pull of the oxygen does not allow for screening or results in reduced screening of the core-hole.

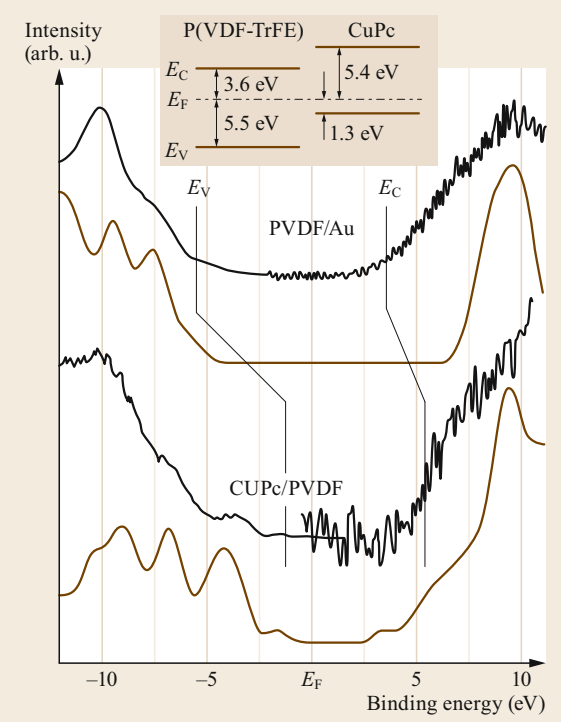

Fig. 11.12 IPES and PES band structure of CuPc/PVDF and PVDF/Au with theoretical band structure given in *brown* (P(VDF-TrFE)—poly(vinylidenefluoride-co-trifluoroethylene)) (Reprinted from [11.54], with the permission of AIP Publishing)

We may also observe systems where both initial and final state effects are congruent, as in the systems of PVDF/Au and CuPc/PVDF [11.54]. PVDF stands for polyvinylidene fluoride, which is a type of fluoropolymer, and Pc stands for phthalocyanine, which is a type of organic compound. Initial state effects can be observed in the two PVDF-based systems, for example as can be seen in Fig. 11.12, in the PVDF/Au system with the addition of Au, the band structure becomes n-type, as HOMO and LUMO rigidly shift to higher (more negative) binding energy. However, in the CuPC/PVDF system with the addition of the CuPc on PVDF, the system becomes p-type as HOMO and LUMO rigidly shift to lower (more positive) binding energy. Both of the shifts in the Au/PVDF and CuPc/PVDF systems are in response to a change in the chemical environment. Additionally, some final state effects are present as the HOMO–LUMO gap has widened or compressed due to an adlayer, as can be seen in the insert of Fig. 11.12. Although final state effects can be observed in both the PVDF/Au and CuPc/PVDF systems, *Xiao* et al. conclude that final state effects are negligible as the rigid shift in the band edges are far greater than the change in the HOMO–LUMO gap [11.54]. Thus, in a system where both effects are present, it is clear that the initial state effects are dominating, and the final state effects are not large enough to change either system from insulating to conductive in character, in other words, changing a large band gap to a small band gap.

It is instructive to consider another example where *Xiao* and *Dowben* studied CoPc, NiPc, and CuPc on PVDF [11.55]. In these systems Co, Ni, or Cu, serve as the metal centers of a phthalocyanine organic compound. Again, within each system variable coverages of the phthalocyanines produce small changes in the size of the band gaps. However, the more interesting comparison is the change in band gaps when comparing phthalocyanines with different metal centers. As illustrated in Fig. 11.13, the simple change in chemi-

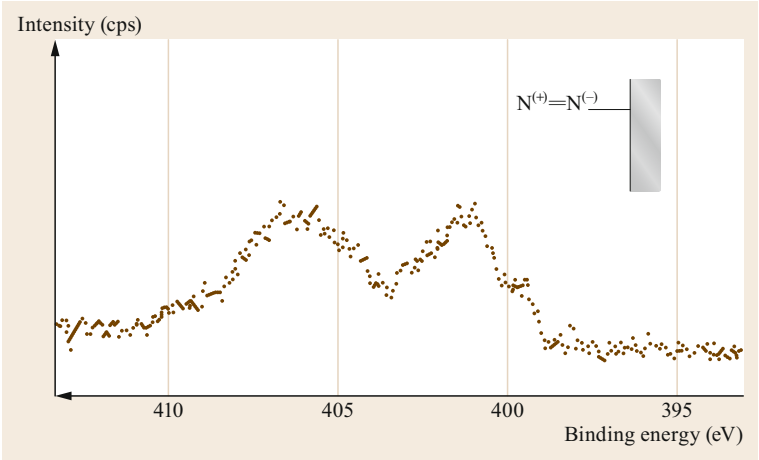

Fig. 11.14 N 1s spectra of N_2 on Ni(110) (Reprinted from [11.56], with permission from Elsevier)

cal environment from the contribution of the Co^{2+} $3d^7$, Ni^{2+} $3d^8$, and Cu^{2+} $3d^9$ orbitals within these phthalocyanines vastly changes the characteristics of the valence band [11.55]. Still, the initial state effects from varying the metal II centers greatly overshadow any final state effects present.

While the previous cases show initial state effects dominating the final state effects, we may also observe initial state effects causing splitting of final state spectra peaks as is the case with N_2 on Ni [11.46, 56]. As illustrated in Fig. 11.14, the higher binding energy peak within the N 1s spectrum is that of the unscreened final states, and the lower binding energy peak belonging to that of screened final states is further split by the separate chemical states of the nitrogen adsorbed on the surface [11.56].

The initial state effects and screened and unscreened final states effects may be further described in terms of bonding and antibonding orbitals and in conjunction with photoemission selection rules as well as the HOMO–LUMO position to determine adsorbate orientation [11.46, 54]. Such further analysis and identification is, indeed, complicated and better suited to be described in more detail elsewhere. However, understanding how initial state and final state processes affect spectroscopic data creates a good foundation for deeper investigation.

11.2.2 Surface-to-Bulk Core Level Shift

It is apparent from the above discussion that the core level binding energies are heavily influenced by the chemical environment of the atom from which the electron is emitted. The core level binding energies can experience a shift to either higher or lower binding energies for several reasons. One type of peak shift observed in XPS spectra is a core-level shift known as a surface-to-bulk core level shift, which has an extensive experimental history [11.57, 58] and is supported by many theoretical studies [11.59–63]. The surface-to-bulk core level shift is observed because surface atoms have different chemical environments than their bulk atom counterparts. If we consider how the neighboring atoms differ for a bulk atom versus a surface atom, it is apparent that the coordination number (number of bonds) of surface atoms is reduced compared to that of bulk atoms. The reduced coordination number leads to a narrowing of the valence band due to charge redistribution, which causes a change in potential and effectively results in a shift of the surface state as observed in the XPS spectra [11.58, 64]. The shift can be toward higher or lower binding energy, depending on the degree of filling of the valence band.

As is appropriate when introducing any new concept, an example of the surface-to-bulk core level shift will help to illustrate what is observed in an experimental setting. As the first example let us consider the study performed by *Wooten* et al. on $Li_2B_4O_7(110)$ [11.65]. The Li atom can exist in only one oxidation state, which suggests that the observation of a surface-to-bulk core level shift can be attributed to a large difference in the electronic structure of surface versus bulk positions. Wooten et al. used ARPES to identify the Li 1s surface-to-bulk core level shift. As shown in Fig. 11.15, the bulk Li 1s core level binding energy was measured at -56.5 ± 0.4 eV for a geometry where the electron undergoes normal photoelectron emission. Furthermore, note there is a broad bump at lower binding energy, -53.7 ± 0.5 eV, which is attributed to a surface component. By increasing the emission angle from 0° to 20°, the intensity of the lower binding energy component increases, as is expected for a surface component of the core level [11.57, 58]. The large separation in binding energy between the bulk and surface peaks suggests that

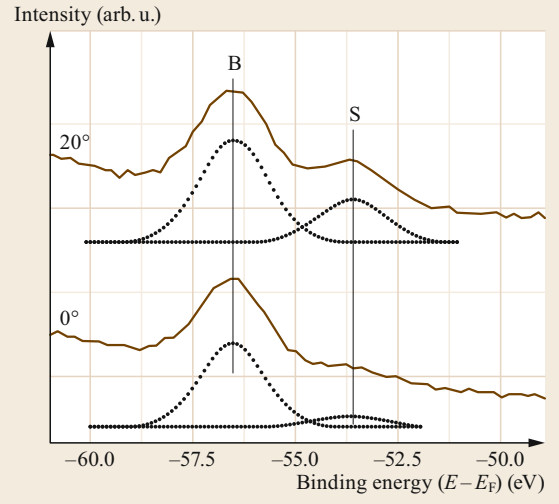

Fig. 11.15 ARPES spectra of $Li_2B_4O_7(110)$ in the region of the Li 1s core level, for photoelectron emission angles 20° and 0°. B denotes the bulk component and S the surface component (Reprinted from [11.65], with permission from Elsevier)

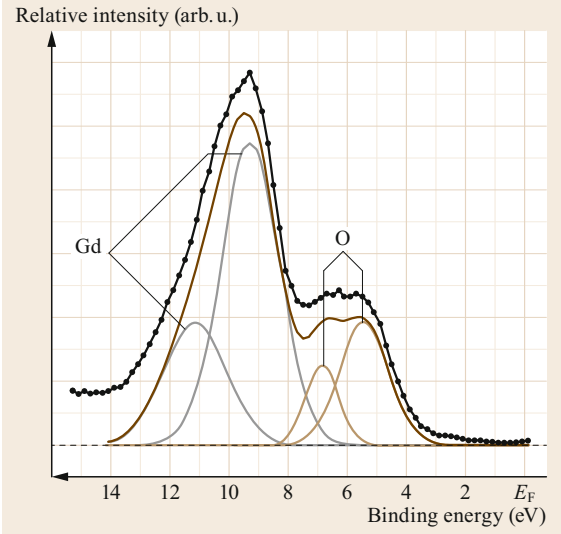

Fig. 11.16 The photoemission spectrum of the valence band of $Gd_2O_3(\bar{4}02)$ with Gd and O contributions labeled (Reprinted from [11.66]. © IOP Publishing. Reproduced with permission. All rights reserved)

the surface electronic structure is vastly different from the bulk [11.65].

As an additional example let us consider the n-type Gd_2O_3 studied by *Losovyj* et al. [11.66]. In their study, the x-ray emission spectroscopy spectra of Gd-doped HfO_2 and Gd_2O_3 are compared to one another with respect to the Gd 4f states. Here, we focus on the observed surface-to-bulk core level shift of Gd_2O_3, as it is absent in the Gd-doped HfO_2 system. It is apparent from the photoemission spectrum of the valence band, as is shown in Fig. 11.16, that there are two major contributions to the band structure, one due to Gd and the other due to O. The Gd contribution can be fit with two peaks roughly centered at 9.5 and 11.5 eV. Using resonant photoemission at various energies, *Losovyj* et al. [11.66] observe a change in intensity of the Gd contribution, as shown in Fig. 11.17a. The intensity of the resonant photoemission spectra is plotted versus the photon energy in Fig. 11.17b, taking into consideration the two peaks located at 9.5 and 11.5 eV. *Losovyj* et al. [11.66] determine that the two Gd 4f contributions at binding energies of 9.5 and 11.5 eV are due to bulk and surface states, respectively. Their separation is roughly 2 eV and may be ascribed to the oxide environment.

The two examples considered above show how the surface state can appear at higher or lower binding energy, depending on the system under investigation. The physics behind the surface-to-core level shift is rich and complicated, and for interested readers a more thorough review and analysis of surface core level spectroscopy can be found in a perspective by *Spanjaard* et al. [11.57].

11.2.3 Core Level Satellites

In XPS spectroscopy, there are sometimes additional signals or peaks at higher binding energy (lower kinetic energy), besides the main peak(s). These additional higher binding energy peaks are called satellite peaks. In principle, there are two types of processes that can cause satellite structures. The first source of satellite peaks can be understood if we consider the photoemission process. When an electron is excited from a core level as it travels to the surface, it will have a tendency to interact with the other electrons due to Coulomb and exchange interactions. These excited electrons, in turn, provide excitation to others in the systems, and these interactions cause the system to make a transition from the ground state to an excited state. Since extra energy is needed in this process, the corresponding signal will be at lower kinetic energy and as such appear as a peak at a higher binding energy in the spectrum with respect to the main peak. The second source of satellite features can be attributed to inelastic collisions. As the photoexcited electron makes its way to the surface it passes through the space that is occupied by the other electrons, so the likelihood of experiencing an inelastic collision and thus exciting the system is large. Since this excitation energy affects the kinetic energy of the outgoing electron, this means the signal will appear at

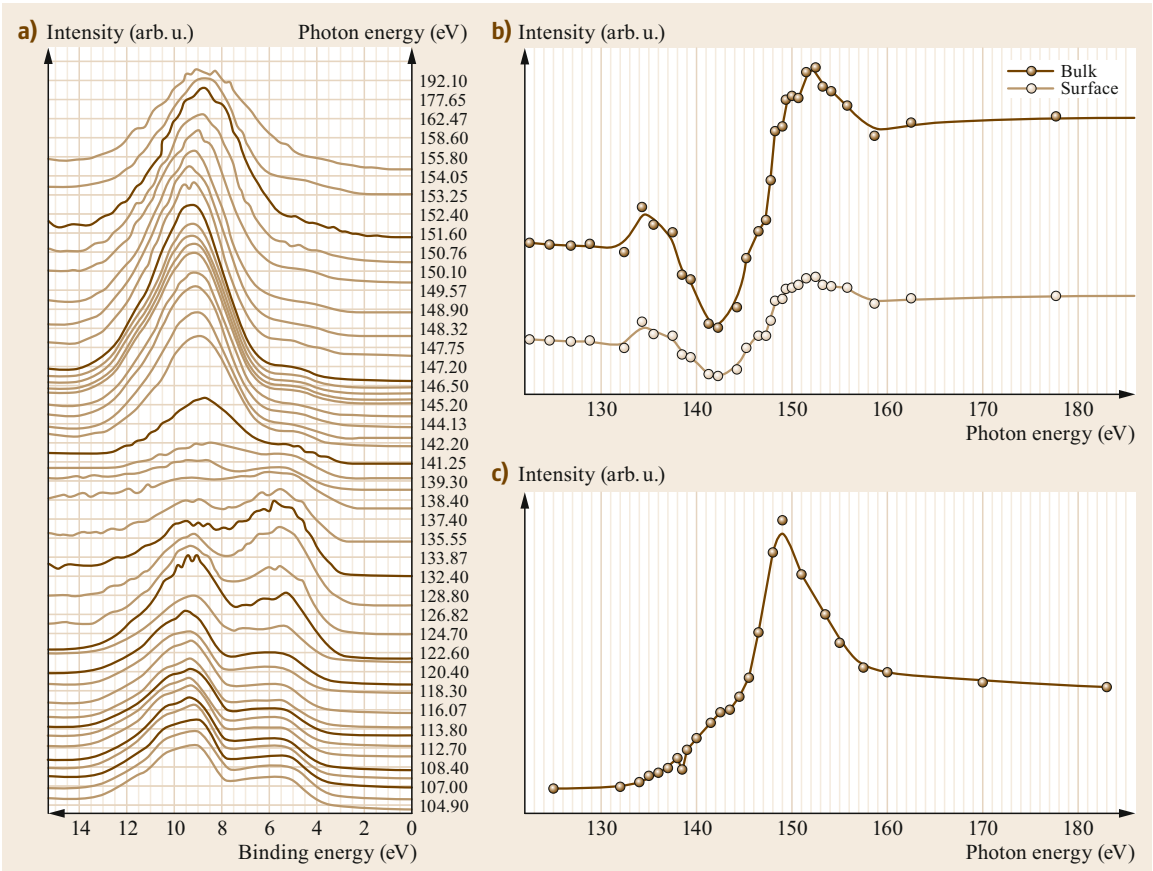

Fig. 11.17 **(a)** The resonant photoemission spectra for photon energies through the 4d → 4f resonance for Gd_2O_3 and the resonant photon intensity of the bulk versus the surface contributions plotted against photon energy for **(b)** Gd_2O_3 and **(c)** Hf-doped Gd_2O_3 (Reprinted from [11.66]. © IOP Publishing. Reproduced with permission. All rights reserved)

higher binding energy in the spectrum. No matter which case occurs, the system will have excited states that are close to the ground state. The ground state appears as the main peak, and the excited states appear as satellite peaks slightly higher in binding energy with respect to the main peaks. The intensity of these peaks is proportional to the overlap integral of their initial and final state wavefunctions [11.39].

Generally, a satellite will occur if there exist more than one final state during the photoemission process. The main peaks and satellite peaks contain different screening situations in the final state, but the analysis of those satellite features still remains difficult in most cases. Let us consider a simple case as a first example.

Transition metals possess the ability to exist in a number of different oxidation states. Furthermore, they experience what is known as multiplet splitting, a type of satellite-like feature. Multiplet splitting is caused by a coupling between the core level vacancy left behind by the photoemitted electron and the unpaired electrons in the valence state. This coupling also results in an excited state and is quite difficult to interpret. The energy separation and the shape of the multiplet peaks in combination with the main peaks can be used to determine the oxidation state of transition metals [11.67–74]. In particular, Fe compounds have been heavily investigated using XPS techniques [11.67–72, 74]. The Fe cation can take on a 2^+ oxidation state, ferrous (Fe^{2+}), or a 3^+ oxidation state, ferric (Fe^{3+}). The position of the satellite peaks in core level Fe $2p_{1/2}$ and Fe $2p_{3/2}$ spectra are sensitive to the oxidation states, and this, in turn, allows for a way to qualitatively analyze the chemical states of Fe. It has been shown that the $Fe^{2+}(2p_{3/2})$ and $Fe^{3+}(2p_{3/2})$ shake-up satellites are found at 714.5 and 719 eV, respectively, about 5–8 eV higher in binding energy than the main core $2p_{1/2}$ and $2p_{3/2}$ lines, as shown in Fig. 11.18 [11.68]. This effect, along with the separation between the multiplet splitting peaks allows one to determine the oxidation state of Fe [11.70].

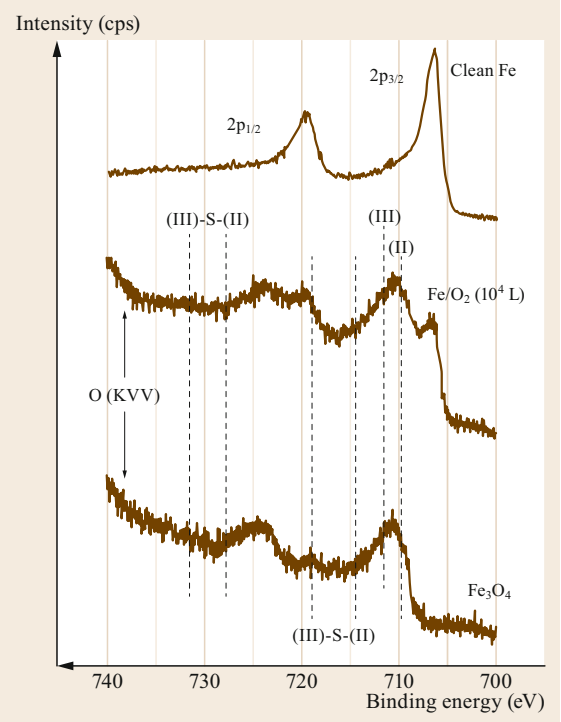

Fig. 11.18 XPS of Fe(2p) spectra for clean Fe, oxidized Fe by 10^4 L of O_2 exposure and Fe_3O_4 powder sample. (S = shake-up satellite, II and III indicate the oxidation state of Fe.) (Reprinted from [11.68], with permission from Elsevier)

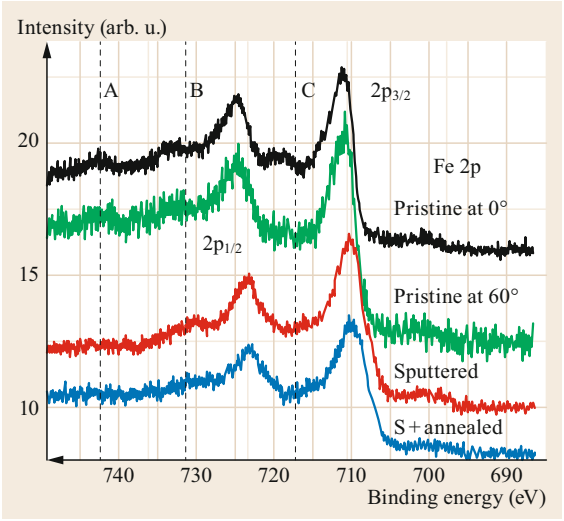

Fig. 11.19 XPS spectra for the Fe 2p core level electron structure in h-$LuFeO_3$ for pristine (both at 0° and 60° take-off angle), sputtered only, and sputtered and annealed samples taken at 0° take-off angle (Reprinted from [11.70]. © IOP Publishing. Reproduced with permission. All rights reserved)

As a second example let us take a look at the Fe 2p spectra of h-$LuFeO_3$ shown in Fig. 11.19 [11.70]. There are two main peaks ($2p_{3/2}$ and $2p_{1/2}$) with three satellites labeled by A, B, and C in Fig. 11.19. In the pristine sample, satellite C is located at 719 eV, which indicates an Fe^{3+} valance character. This feature does not change when the sample angle is changed with respect to the normal along the detector optical path, so both the surface and the bulk Fe correspond to Fe^{3+} states. However, after sputtering and annealing, the satellite moves to a lower binding energy, and the separation of energy between the satellite and the main $2p_{3/2}$ peak becomes smaller. This indicates that the oxidation state changes from Fe^{3+} to Fe^{2+}, so the local environment of Fe changes after sputtering and annealing, and it is due to the decrease of electron density around Fe by oxygen deficiencies [11.70].

The previous examples are just a couple well-studied cases of satellite features, and they are by no means exhaustive. Obtaining a thorough understanding of all the information involved with satellite transitions is still challenging and requires precise measurements coupled with extensive modeling.

11.3 Concluding Remarks

While photoemission is often used as a method to *fingerprint* molecules adsorbed on surfaces, this valuable tool has much more to offer for the understanding of the complicated nature of these systems. Photoemission can be used to identify molecular orientation, and in this sense it is complementary to near edge x-ray absorption spectroscopy. For ordered molecular adlayers, photoemission and inverse photoemission (if angle resolved) can be used to determine the extent of intermolecular interaction from the dispersion of the occupied (photoemission) and unoccupied (inverse photoemission) molecular orbitals. The often complex interactions between adsorbate and substrate can be probed through study of the photoemission spectra and asking questions such as: are there satellite features? Are screening effects present and which ones? The insight that one should gain from this brief overview is to be aware that photoemission is multifaceted and often quite complex. This means that interpreting photoemission spectra often needs caution and diligence to understand all the subtlety and value that photoemission and related spectroscopies have to show. This

chapter has shown how powerful a tool photoemission can be when used together with appropriate physical principles. It is hoped that the above discussions will provide assistance to those beginning their journey in photoemission measurement techniques and help to divulge some of the deeper physics hidden in our world.

Acknowledgments. We would like to thank the Department of Energy for supporting this research, specifically; DOE Grant DE-FG02-07ER15842. We would also like to thank Professor Peter A. Dowben for his long discussions about the physics of photoemission and his guidance with our interpretations. Prof. Dowben is truly a source of inspiration and we are eternally grateful.

Andrew J. Yost

Oklahoma State University
Stillwater, OK, USA
andrew.yost@okstate.edu

Dr Yost received his PhD in Condensed Matter Physics from the University of Wyoming in 2017. He was a Postdoctoral Research Associate at the University of Nebraska-Lincoln from 2017 to 2019. Dr Yost is currently an Assistant Professor at Oklahoma State University. Dr Yost has expertise in scanning tunneling microscopy and angle resolved photoemission spectroscopy. His research interests involve multiferroic oxides, 2-D materials, organic and inorganic solar cell materials, nanoparticle solar cell materials, spin crossover molecules on molecular ferroelectric thin films, and topological materials.

Prescott E. Evans

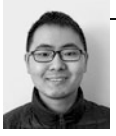
Lincoln, NE, USA
prescott.evans@huskers.unl.edu

Prescott received his PhD in Physics from the University of Nebraska-Lincoln in 2020 under the guidance of Professor Peter A. Dowben. His research focuses on heterogeneous catalyst systems with an emphasis on surface chemistry tunability.

Iori Tanabe

Lincoln, NE, USA
iori.tanabe@ni.edu

Dr Tanabe studied the electronic structures of two-dimensional semiconducting materials with Professor Peter A. Dowben and received his PhD in Physics at the University of Nebraska-Lincoln in May 2017. Dr Tanabe is currently working as an application engineer for National Instruments Japan.



Guanhua Hao

Lincoln, NE, USA
guanhuahao@huskers.unl.edu

Guanhua received his MSc in Physics from the University of Nebraska-Lincoln in 2017 and is currently in Professor Peter A. Dowben's group in Physics at the University of Nebraska-Lincoln. His research area includes spin crossover molecules and surface science.

Simeon Gilbert

Lincoln, NE, USA
simeon.gilbert@outlook.com

Simeon received his BSc in Physics from South Dakota State University in 2015. He is currently studying the electronic structure of two-dimensional materials and pursing his PhD at the University of Nebraska-Lincoln under the guidance of Professor Peter A. Dowben.

Takashi Komesu

Lincoln, NE, USA
tkomesu2@unl.edu

Dr Komesu received his PhD in Physics from the University of Nebraska-Lincoln (UNL) in 2002. Dr Komesu is currently Research Associate Professor. Dr Komesu has been working in solid-state physics, especially electronic structure measurements on magnetic thin films, 2D materials, and organo-metal compounds. Dr Komesu has expertise in spin polarized inverse photoemission spectroscopy (SPIPES), investigating the spin-polarized unoccupied electronic structure, which can only be done at UNL.

12. Electronic States of Vicinal Surfaces

J. Enrique Ortega, Aitor Mugarza, Frederik Schiller, Jorge Lobo-Checa, Martina Corso

Vicinal surfaces are crystal planes oriented a few degrees off from a high symmetry direction. Such a small deviation (called miscut) from a high symmetry axis leads to a characteristic periodic roughness at the nanoscale, namely atom-height step arrays that separate atomically-flat terraces. The alternating series of "terraces" and "steps" makes electronic properties of vicinal surfaces very peculiar, distinct from those of atomically-flat surfaces. On the one hand, terraces and steps feature atoms with distinct coordination and complex and varied elastic relaxations, influencing their core-level energies. We show how core levels at a vicinal surface exhibit a miscut-dependent stress release, as well as fine structural relaxations, such as faceting. On the other hand, atomic steps create a periodic modulation of the crystal potential, affecting two-dimensional (2-D) surface states of metals. This leads to Bloch scattering of surface electrons by the step lattice, and eventually, to one-dimensional (1-D) quantization by confinement at terraces or step edges. We discuss the occurrence and observation of superlattice scattering and 1-D confinement at a vicinal surface, the importance of the atomic nature of the surface state wave function, the dependence on the lattice constant of the step array, and the rich scattering phenomenon that arises in faceted structures and spin-textured bands.

12.1 General Considerations About Vicinal Surfaces

Vicinal surfaces have been always fundamental in technologically relevant fields, such as catalysis [12.1] and crystal growth [12.2], and are more recently becoming very attractive as growth templates for nanostructure research [12.3]. Cutting a crystal at a vicinal angle results in a regular pattern of atomic steps that delimit high-symmetry mini-facets called *terraces*. Such an ideal, periodic monatomic step-terrace structure is sketched in Fig. 12.1a. The surface plane is defined by the (high index) crystallographic orientation (e.g., (557) in Fig. 12.1a), or simply by its macroscopic deviation (miscut α) from the high-symmetry plane of the terrace ((111) in Fig. 12.1a). Beyond the periodic atomic discontinuities at steps, the vicinal surface is characterized by varied atomic coordination. For the face centered cubic (fcc) crystal shown in Fig. 12.1a, the atomic coordination varies from bulk $B = 12$, to terrace $T = 9$ and step $S = 7$, whereas the corner C depends on the orientation of the miscut, as depicted in Fig. 12.1b. For A-type steps with {100}-like pack-

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-46906-1_12

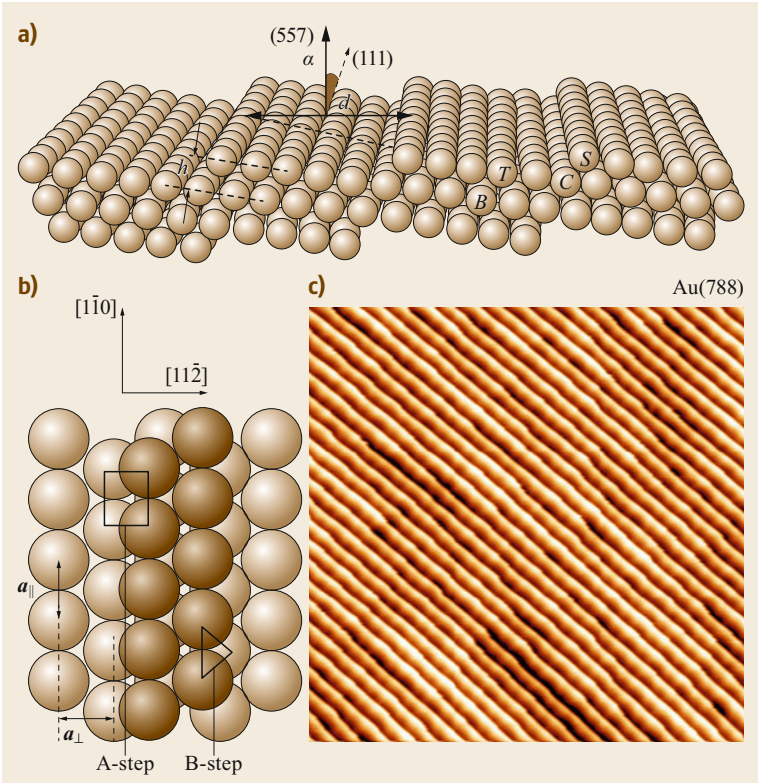


Fig. 12.1a–c Atomic structure of a vicinal surface: **(a)** the (557) surface ($\alpha = 9.5°$), which is vicinal to the (111) high-symmetry surface. Miscut angle α, terrace size d, and monatomic step height h are the characteristic magnitudes describing these step arrays. B, C, T, and S indicate the atomic sites with different coordinations. **(b)** Top-view description of the different A-type and B-type steps found in (111) vicinals of fcc crystals. **(c)** STM image ($100\,\mathrm{nm}^2$) of a Au(788) surface ($\alpha = 3.5°$), featuring straight monoatomic steps with a low density of kinks and reconstructed terraces

ing at step edges (Fig. 12.1b, square), we find $C = 10$, whereas for B-type with {111}-like packing (Fig. 12.1b, triangle), $C = 11$. Changing the miscut α will change the periodicity of the step lattice, i.e., the step modulation of the surface potential, but also the relative abundance of T, S, and C atoms, and consequently, all physical and chemical properties of the surface.

Real vicinal surfaces deviate from perfect step arrays. Ideal step and terrace networks exhibit fine structural properties that influence the electronic states. Such characteristic features are best observed in scanning tunneling microscopy (STM) images. In Fig. 12.1c, we show the case of the Au(788) vicinal plane, imaged by STM at 300 K. Terraces show atomic reconstructions, whereas monatomic steps occasionally contain kinks, i.e., step edge atoms with a missing neighbor, and hence with the coordination further reduced to 6. The terrace reconstruction may substantially vary as a function of the miscut angle α [12.4], whereas the density of kinks depends on the *in-plane* orientation (azimuth) of the step array. However, the most important property observed in Fig. 12.1c is the randomly varying width of the terraces around the nominal d value. Such a phenomenon affects any vicinal surface irrespectively of the miscut or azimuth. It is linked to the thermal excitation of kinks that leads to a temperature-dependent terrace width distribution (TWD). As we shall see in this chapter, the shape of the TWD reflects the elastic equilibrium of the vicinal surface, which in turn is fundamental to understanding subtle variations in its spectrum of electronic states.

Due to the step corrugation and the varied atomic coordination, electron energy levels at a vicinal surface are different from those of the high symmetry plane. In Fig. 12.2a, we sketch the fundamental features that can be expected at two different energy ranges, i.e., near the Fermi energy in 2-D surface states and at the deeply lying core levels. Delocalized surface electrons will sense the periodic perturbation of the crystal potential at step edges, affecting their in-plane, 2-D dispersion. Such step-edge potential is connected to the spill-out charge or charge smoothing around step atoms that leads to a net step dipole [12.7]. Figure 12.2b shows the case of Au(788). Due to the step dipole potential, the vicinal surface effectively becomes a periodic superlattice, at which the 2-D Shockley state scatters. As a result, the otherwise free-electron-like parabolic dispersion is broken up into subbands separated by mini-gaps, whose size determines the step dipole barrier strength [12.5, 8]. The step dipole also leads to a local reduction of the

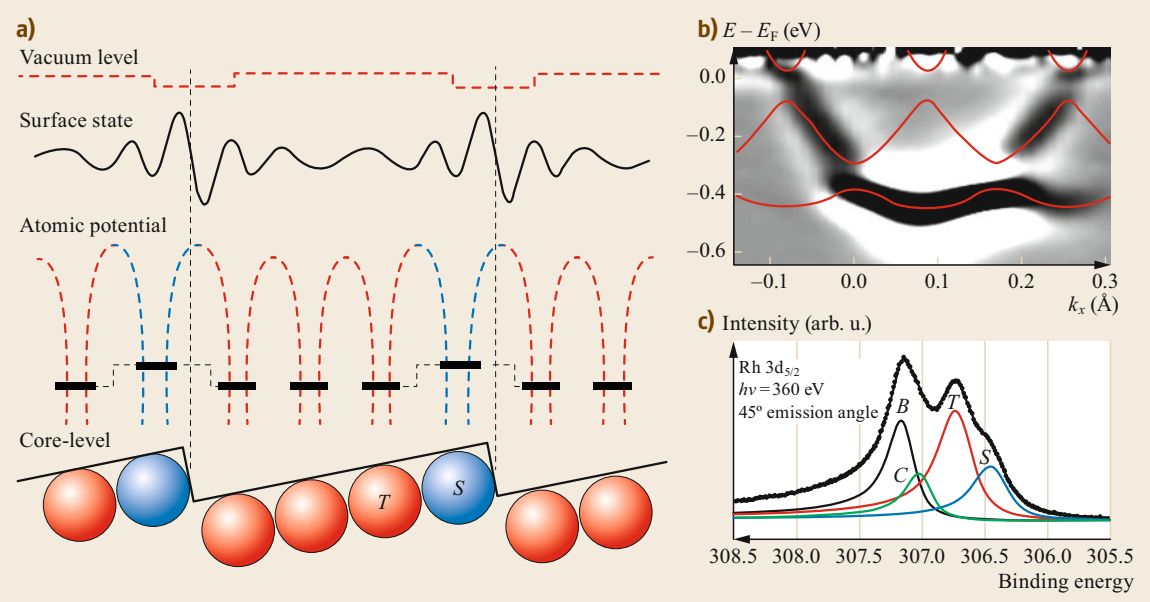

Fig. 12.2a–c Electronic states at a vicinal surface: **(a)** the surface potential (*dashed lines*) at a vicinal surface. Core levels exhibit energy shifts due to different coordinations of surface atoms at step (*S*) and terraces (*T*). Surface states scatter at step edges modulating their wave functions. **(b)** The Shockley state in Au(788), showing step superlattice bands and gaps [12.5]. **(c)** 3-D core-level emission from Rh(335), showing distinct *B*, *C*, *T*, and *S* features. (Figure reprinted with permission from [12.6]. Copyright 2003 by the American Physical Society)

work function in the proximity of the step edge. This has been shown to affect 2-D image states of vicinal surfaces, which also become superlattice states, where a 1-D step-edge state may eventually split off [12.9, 10]. On the other hand, changes in surface atomic coordination, e.g., from *S* to *T* will influence core-level energies. This is shown in Fig. 12.2c for the vicinal Rh(335) surface, where the Rh $3d_{5/2}$ core-level peak appears split into four different contributions, i.e., at the highest binding energy, the peak of bulk atoms in subsurface layers, followed by the small contribution from corner atoms below step edges, and by the terrace and step atom emission from the vicinal surface plane [12.6].

Step density, type, azimuthal orientation, as well as terrace reconstructions can be readily selected through the macroscopic miscut, allowing one to tune surface bands and core-level energies. Step type and azimuthal orientation (kink density) lead to different average dipole potentials, and hence to different scattering strengths for 2-D surface states. The step density changes the superlattice parameter, but also the relative abundance of *T* and *S* atoms, and hence the physical–chemical response of the vicinal surface. The miscut angle can be chosen to modify reconstruction patterns in terraces or to achieve complex hill-and-valley step superlattices. As a result, the electronic states are modified. In the case of Au(111) vicinal surfaces, the electronic properties at the surface are even more perturbed by the tendency to form herring-bone patterns at (111) terraces. In Au(21 23 23), monatomic steps and fcc/hexagonal close packed (hcp) patches of (111) terraces define a square pattern of quantum wells that confines surface electrons, as shown in Fig. 12.3a,b [12.11]. In contrast, the Au(9 9 11) vicinal surface undergoes a faceting transition, resulting in a periodic superstructure formed by one wide (reconstructed) and two narrow (unreconstructed) (111) terraces, which, respectively, bind the $n = 1$ (confined) and $n = 2$ (propagating) superlattice states (Fig. 12.3c), as probed by angle-resolved photoemission (ARPES, Fig. 12.3d [12.5], see also Sect. 12.2).

The rich variety of structures and electronic states that arise as a function of miscut and azimuth can be systematically explored with curved crystal samples. Although distinct macroscopic shapes have been historically tested, the $\alpha = 30°$ cylindrical sections shown in Fig. 12.4a are gaining popularity, since they are compatible with standard techniques and setups utilized in surface science [12.4, 8, 12–16]. On such surfaces, steps are aligned parallel to the cylinder axis, whereas the step density smoothly varies across the perpendicular,

The resulting square pattern of potential wells leads to the surface state wave function modulation shown in **(b)**. (Reprinted by permission from MacMillan Publishers Ltd.: [12.11]). **(c)** Faceted structure in Au(9 9 11), defined by bunches of unreconstructed $d_n = 13$ Å terraces separated by a single reconstructed $d_w = 39$ Å terrace. **(d)** Schematic wave functions (*top*) and measured Shockley bands (*bottom*) of Au(9 9 11); d_w-related 1-D quantum-wells appear under the d_n-modulated 2-D superlattice state [12.5]

curved direction. For example, the Au, Cu, and Ag samples of Fig. 12.4a were designed to have both A-type and B-type steps separated by the (111) high-symmetry plane at its center, as sketched in Fig. 12.4b. The use of small ($< 100\,\mu$m) size probes allows one to scan the different crystallographic orientations, such as to test, e.g., the characteristic miscut-dependent Shockley state shift (terrace shift) shown in Fig. 12.4c. In the latter, the presence of the reference (111) plane in the same sample and the smooth variation of the miscut with the surface position allows us to accurately determine the strength of the dipole potential at step edges [12.8].

In this chapter, we review the state-of-the-art in experiments and theory of electronic states at vicinal surfaces. Much general understanding has been gained through recent experiments performed on curved surfaces [12.4, 8, 13–16]. These have neatly demonstrated the subtle, but important variations in the spectrum of surface electronic states as the miscut is varied. Such an understanding will pave the way towards the rational choice of vicinal surface planes for technology and research applications, namely for catalysis, electron scattering problems, and nanostructure growth.

12.2 Structural Properties of Vicinal Surfaces

The electronic properties of a vicinal surface are connected not only to the local atomic structure of terraces and steps, but also to the particular way steps self-arrange at the nanoscale level. At the local scale, the fundamental feature is the variety of atomic coordinations and their corresponding core-level energies, although one will need to be aware of relaxation effects, which lead to subtle core-level energy shifts as a function of the miscut. Elastic relaxation also explains the shape of the TWD at thermal equilibrium, and the occurrence of step bunching and faceting, i.e., the rearrangement of the step lattice at the nanoscale that further shapes surface electronic bands.

12.2.1 Atomic Relaxations Around Surface Steps

After bond breaking and creation of the surface, tensile stress appears at the topmost crystal plane. Such surface stress can be relieved through local atomic rearrangement, i.e., by terrace reconstructions, but also through a characteristic crystal lattice relaxation in the vicinity of steps. Ab-initio density functional theory (DFT) calculations performed for slabs with vicinal orientations reveal the displacement of surface atoms with respect to the expected position in the bulk lattice. This is shown in Fig. 12.5 for the case of the Au(233)

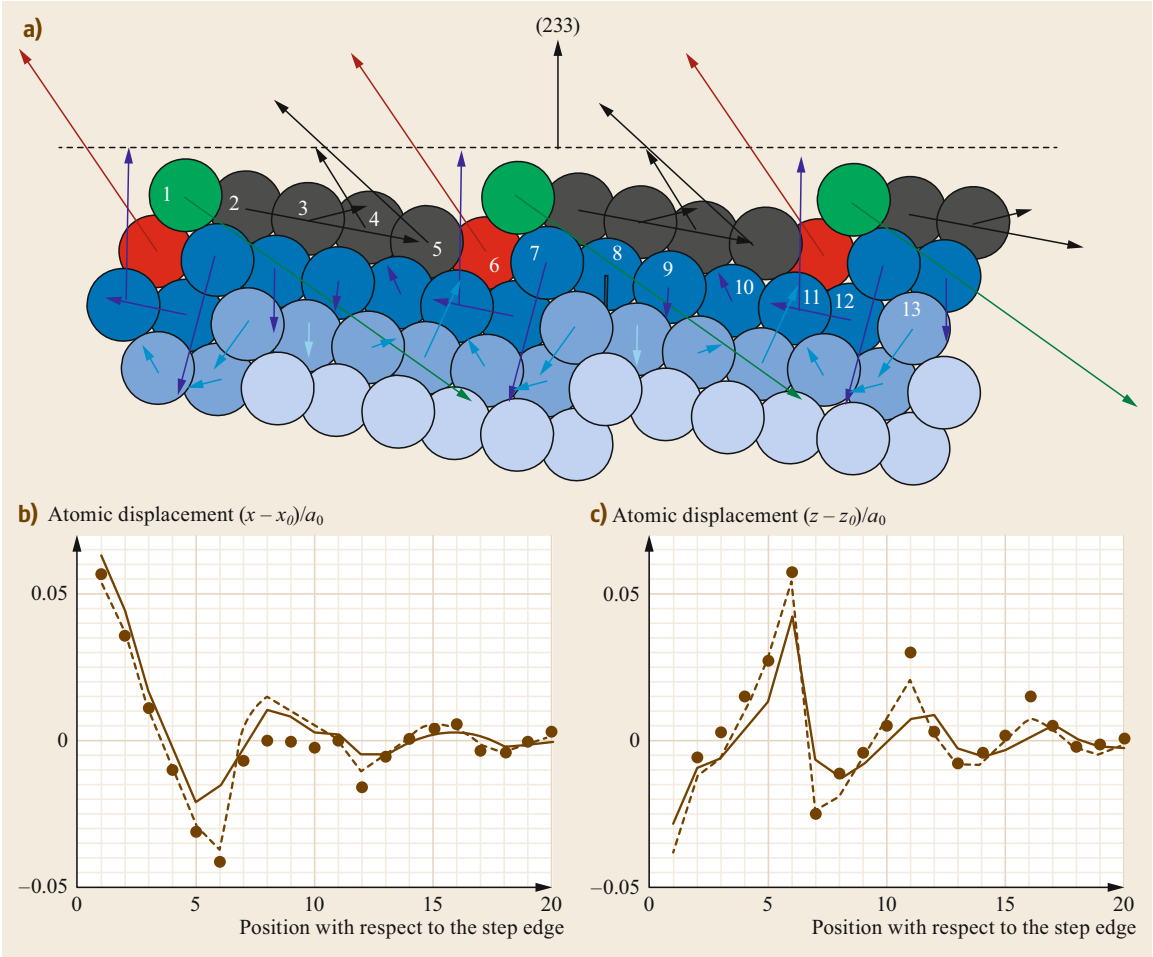

Fig. 12.5a–c Crystal lattice relaxation at a vicinal surface: **(a)** DFT calculations of atomic displacements at the Au(233) surface. *Arrows* indicate the relative magnitude and direction of the atomic relaxation with respect to the fcc bulk crystal position. **(b,c)** Damping of the atomic relaxation away from the steps, parallel (see atom numbering in **(a)**) and perpendicular to the surface, respectively. *Solid lines* fit the DFT data (*dots*) assuming a force-dipole potential model to calculate atomic relaxations. *Dashed lines* fit x-ray diffraction data (not shown) using the same force-dipole model. (Figures reprinted with permission from [12.17]. Copyright 2010 by the American Physical Society)

crystal [12.17], and analogous results are obtained for other surfaces [12.18, 19]. In the side-view sketch of Fig. 12.5a, the arrows indicate the direction in which atoms relax with respect to the ideal fcc lattice, and their length represents the relative magnitude of such atomic displacement, affecting all atoms at several outer layers. The maximum displacement corresponds to the top and the bottom atom at the step edge (*S* and *C* in Fig. 12.1), which effectively move inwards and outwards of the nominal fcc lattice. The relaxation effect damps away from the step in both the surface and the bulk direction with a similar decay constant, as shown in Fig. 12.5b,c. In particular, when looking at all *T* atoms as a whole in Fig. 12.5a, we note that they move away from the step edge and against one another, i.e., the terrace becomes laterally compressed. This leads to the characteristic core-level shift that will be discussed in Sect. 12.3.

The individual atomic relaxations of the vicinal surface obtained from first-principles DFT can be well reproduced assuming lines of force dipoles at step edges and then calculating the linear elastic response of the atomic lattice. Note that a net torque is exerted at the step edge, which explains the opposite displacements shown for *S* and *C* atoms in Fig. 12.5a. Solid and dotted lines in Fig. 12.5b,c, respectively, fit DFT results (dots) and grazing incidence x-ray diffraction (GIXD) data from vicinal crystals, using the step-force dipole as a fitting parameter. The latter allows one to experimentally

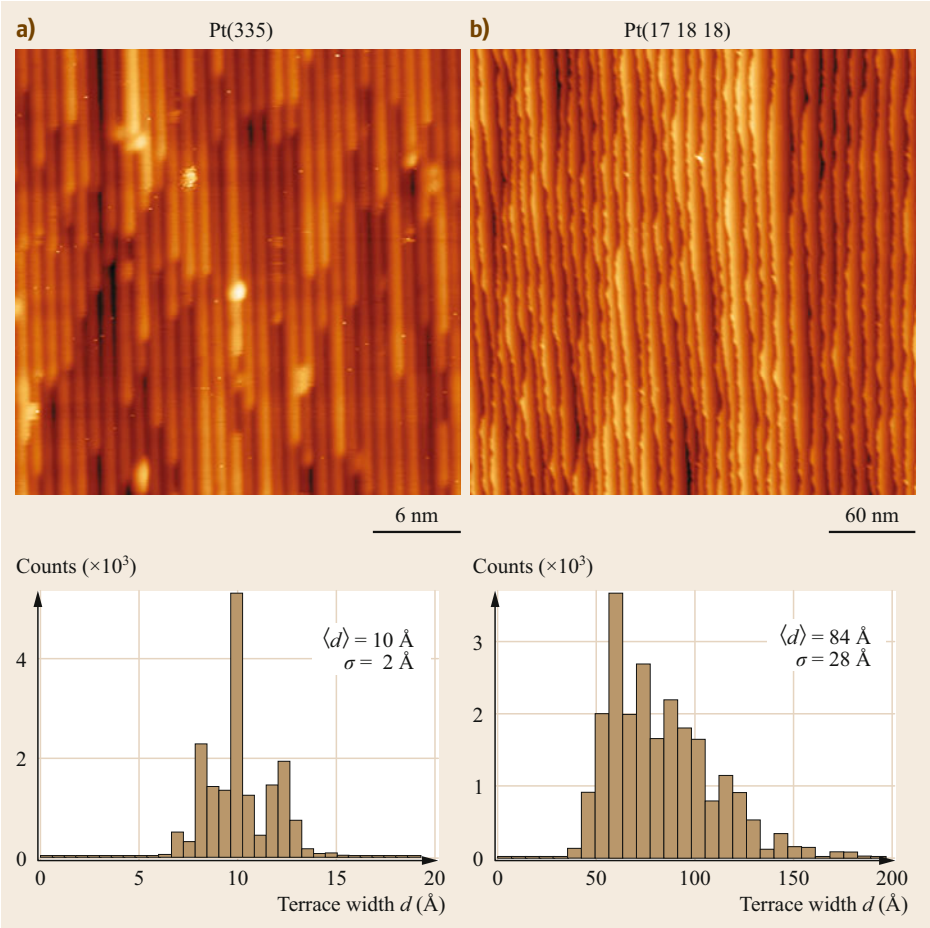

Fig. 12.6a,b Terrace width distribution (TWD) for vicinal Pt(111): characteristic STM images of **(a)** Pt(335) and **(b)** Pt(17 18 18), with their respective histogram analysis of the TWD. The TWD is symmetric for narrow, $\langle d\rangle = 10$ Å terraces in Pt(335) and broad and asymmetric for wide $\langle d\rangle = 84$ Å terraces in Pt(17 18 18) [12.14]

estimate the strength $\tilde{A}$ of the repulsive step–step elastic interaction $U(d) = \tilde{A}/d^2$, which arises in the classical elastic approach of the vicinal surface [12.20, 21].

12.2.2 Step–Step Interactions and Terrace Width Distribution

In the continuum model, the equilibrium shape of the surface is driven by the minimum free energy γ. In the case of vicinal planes with monatomic steps, γ can be expressed in terms of the miscut α and as a function of the temperature T as [12.21, 22]

$$\gamma(\alpha) = \gamma_0 + \beta\frac{|\tan\alpha|}{h} + \frac{B(T)}{a_{\|}h^3}|\tan\alpha|^3\,, \qquad (12.1)$$

where γ_0 represents the surface energy per unit area of the terraces, β the step energy per unit length, h the step height, $a_{\|}$ the lattice constant at the surface (Fig. 12.7b), and $B(T)$ the step interaction term. The latter includes the so-called entropic interaction $g(T)$ and the elastic step–step interaction. The entropic term $g(T)$ arises due to the inability of two contiguous steps to cross as they *meander* on the surface. Step wandering is activated through thermal excitation of kinks, and hence it is the key ingredient to explain the TWD that characterizes all vicinal surfaces at thermal equilibrium. In Fig. 12.6, we show the case of Pt(335) and Pt(17 18 18), namely two Pt(111) vicinals with A and B-type steps, respectively, and different α angles. The bottom panels show the TWD in each case, resulting from the statistical analysis performed over a number of STM images such as those shown on the top panels. Such analysis immediately renders the average terrace size $\langle d\rangle$ and the standard deviation σ indicated in each panel. The TWD peaks close to the expected value for the respective ideal plane, but it shows a sizeable width and a characteristic asymmetry, which is more pronounced for the wider $\langle d\rangle = 8.4$ nm terraces of Pt(17 18 18) [12.14].

On the grounds of the elastic theory described by (12.1) and assuming step meandering through

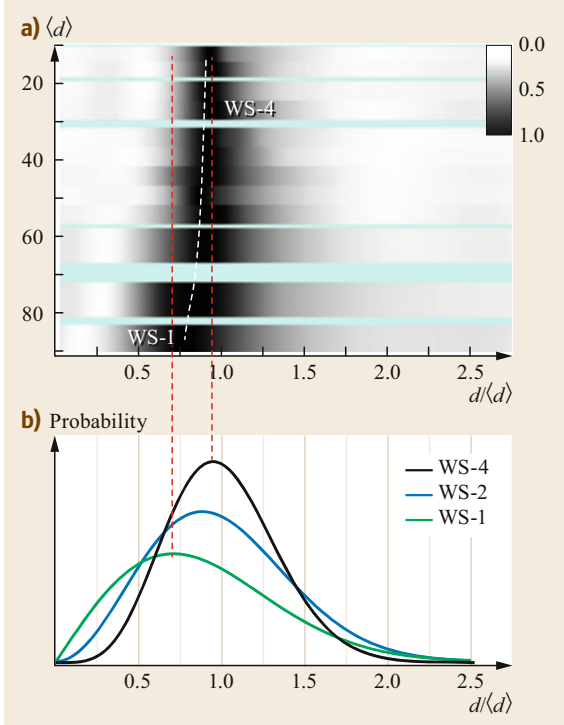

Fig. 12.7a,b Terrace width distribution variation in a curved crystal: **(a)** evolution of the TWD histogram as a function of the mean terrace width $\langle d\rangle$ measured in the A-side of a curved Pt(111) sample. *Horizontal stripes* correspond to individual histograms with the probability shown in *gray scale*. The *white dotted line* tracks histogram maxima, suggesting a gradual change of the statistical function from WS-1 at small $\langle d\rangle$ to WS-4 at large $\langle d\rangle$. The diverse WS functions are represented in **(b)** [12.14] ►

thermally activated kinks, TWDs are expressed through mathematical functions called "Wigner surmise" [12.23]. The specific d-dependent Wigner surmise is defined by the *order* parameter ϱ, depending on the nature of the step–step interactions. For elastic-like step repulsions following $U(d) = \tilde{A}/d^2$, the $\varrho = 4$ Wigner surmise should explain the TWD at all miscuts [12.23]. However, the latest experiments performed on curved crystals point to a smooth variation from $\varrho = 1$ (attractive step interaction) to $\varrho = 4$ (repulsive elastic), as a function of the miscut α [12.14–16]. In Fig. 12.7, we show the TWD for vicinal Pt(111) surfaces with A-type steps, measured by STM on a curved crystal sample [12.14]. Horizontal stripes represent the individual TWDs obtained at the indicated mean terrace width $\langle d\rangle = h/\sin\alpha$, plotted against the normalized coordinate $d/\langle d\rangle$. A clear shift of the TWD maximum from $d/\langle d\rangle \approx 0.8$ to $d/\langle d\rangle \approx 0.94$ is observed when moving from large to small $\langle d\rangle$ values. Such a shift can only be accounted for by assuming a Wigner surmise of variable ϱ. This points to the α-dependence of the step interaction term $B(T)$ in (12.1), which in turn suggests the nonlinear character of the elastic relaxation around the surface steps.

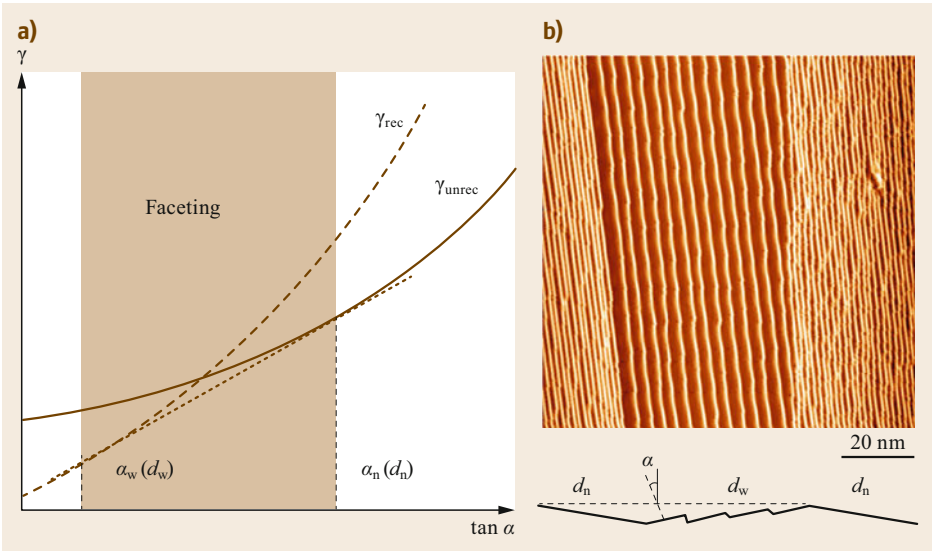

Fig. 12.8a,b Phase-competing structural model of faceting in vicinal Au(111): **(a)** the surface free energy for reconstructed and unreconstructed Au(111) surfaces. The *dotted line* joins inflexion points in both curves, defining a region (*shaded area*) at which phase segregation into d_w and d_n phases is energetically optimal. **(b)** STM image of the Au(566) surface showing large d_w and d_n phases [12.4]

12.2.3 Faceting

Vicinal surfaces with terrace reconstructions, such as the herringbone in Au(111), generally exhibit faceting or step bunching instabilities at critical miscuts [12.20, 22]. This can also be explained through (12.1), by assuming the existence of two competing phases, i.e., vicinal surfaces with reconstructed terraces of γ_0^{rec} and step-formation energy β^{rec}, versus a second phase defined by strained, unreconstructed terraces with $\gamma_0^{\mathrm{unrec}} > \gamma_0^{\mathrm{rec}}$ and low step energy $\beta^{\mathrm{unrec}} < \beta^{\mathrm{rec}}$. As is schematically represented in Fig. 12.8a, the surface free energy in each case will generally exhibit a local minimum, or inflection point at distinct α_{w} (corresponding to reconstructed d_{w}-wide terraces) and α_{n} (corresponding to unreconstructed d_{n} terraces). Therefore, for a macroscopic $\alpha_{\mathrm{w}} < \alpha < \alpha_{\mathrm{n}}$, the minimum free energy is achieved through a weighted sum of d_{w} and d_{n} phases (facets), as is schematically depicted in the bottom of Fig. 12.8b, and, in fact, observed in Au(566) (Fig. 12.8b, top). This phenomenon, which strongly affects vicinal Au(111) surfaces with both A and B type steps, will dramatically influence the electronic states, as discussed below.

12.3 Surface Core-Level Shifts at a Vicinal Surface

Core-level spectroscopy is widely utilized to assess changes in the chemical environment of atoms through energy shifts. The simplest case is that of the crystal surface, where the reduced atomic coordination with respect to the bulk manifests in its characteristic surface core-level shift (SCLS). Although many-body (also called final state) effects are also important [12.24], the SCLS is generally explained by the different filling of electron bands at the surface with respect to the bulk, which in turn is caused by the band narrowing associated to the lower atomic coordination. If the band is nearly filled, its center of gravity is below the Fermi energy. Therefore, band narrowing leads to further electron filling (reduction), and the surface core level will shift to a lower binding energy. If the band is nearly empty, band narrowing will lead to electron depletion (oxidation), and hence to a SCLS towards higher binding energy. The central panel of Fig. 12.9 displays the Pt 4f core-level spectrum measured from Pt(111) with high-resolution photoemission. Pt possesses an almost filled d-shell, and hence band narrowing leads to the observed surface peak (T) shifted by ≈ 0.4 eV to lower binding energy with respect to the bulk peak (B).

At a vicinal surface, new atomic coordinations appear at step sites, namely the corner C and step S (Fig. 12.1b), which are thus expected to lead to distinct SCLSs. In practice, core-level emission from both C and S atoms has been resolved in W and Rh vicinals only [12.6, 25]. Both W and Rh have the d-band center below E_{F}, and hence a progressive shift to a higher binding energy is consistently observed from B to C, T, and S (Fig. 12.2c). A notable feature that is common to all vicinal surfaces examined so far is the subtle shift observed in the surface T peak when going from flat

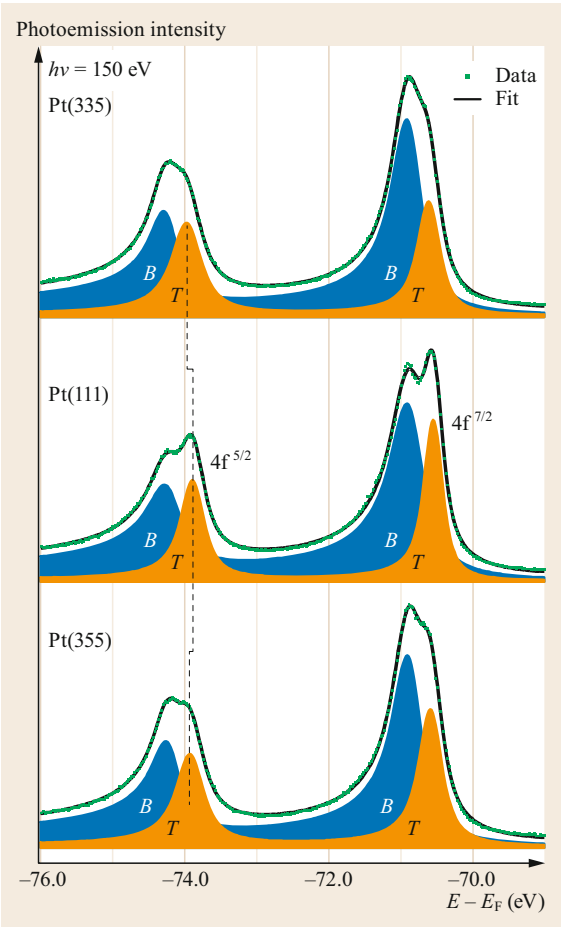

Fig. 12.9 Surface core-level shift in flat and vicinal Pt(111) surfaces: Pt 4f core-level photoemission spectra from Pt(111) (*center*), as compared to spectra measured from Pt(335) (*top*) and Pt(355) (*bottom*). *Dotted lines* mark the emission from T surface atoms, which shifts towards the bulk B line at the vicinal surface [12.14] ►

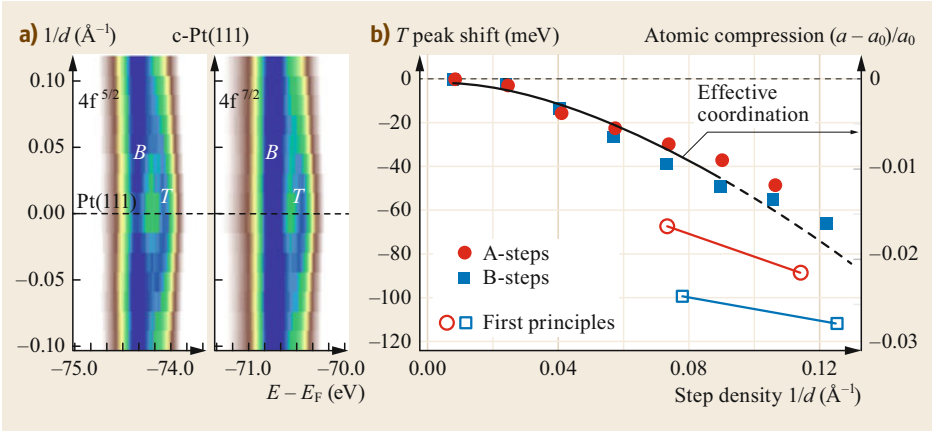

Fig. 12.10a,b Pt 4f peak scan across curved Pt(111) (α-scan): **(a)** Pt 4f core-level emission intensity plot represented against the step density $1/d$, as measured in a c-Pt(111) crystal. The surface peak shows a characteristic $1/d$-dependent shift to higher binding energy (positive T-shift), reflecting that the tensile stress at the vicinal surface, in average, is being relieved. **(b)** Average compressive strain of surface atoms as deduced from the T peak shift (*filled symbols*) and using an effective coordination model (*solid-dashed line*). Results are compared to DFT calculations (*open symbols*) [12.14]

to vicinal surfaces [12.6, 14, 25]. The case of Pt(111) vicinals is shown in Fig. 12.9. The Pt 4f T emission of Pt(335) and Pt(355) reveals a ≈ 50 meV shift with respect to the T peak in the Pt(111) surface. This small effect has been investigated in more detail using a curved Pt(111) crystal, in which the density of steps is smoothly varied. The result is shown in the core-level scan of Fig. 12.10a. The image is made of 15 different spectra, systematically recorded across the curved surface (α-scan). Taking the center of the crystal as a reference, the α-scan allows one to visualize a consistent and symmetric shift to a higher binding energy in both Pt $4f^{5/2}$ and Pt $4f^{7/2}$ surface core-level lines as a function of the step density $1/d$. Since the main contribution to this peak originated from terrace T atoms, this $1/d$-dependent shift is called a terrace shift.

The terrace shift is the spectroscopic signature of the surface layer relaxation of the vicinal surface sketched in Fig. 12.5. Such relaxation becomes more pronounced as the density of steps $1/d$ increases, such that the T peak shifts towards the bulk B peak. This connection between core-level energy and relaxation has been proven in first-principles calculations [12.14]. Substantial core-level energy variations appear in the terrace T atoms depending on the local degree of strain with respect to the fcc lattice. The T peak in Figs. 12.9 and 12.10 is thus made by contributions from the differently-relaxed T atoms of Fig. 12.5. As discussed earlier, steps allow terrace T atoms to partially relieve their tensile stress by compressing against each other. Such compression results in the larger overlap of wave functions with neighboring atoms, and hence to an effectively enhanced coordination [12.26]. Since the compression is larger for T atoms closer to step edges (Fig. 12.5), this explains the shift of the T peak towards the B peak as the step spacing d decreases. Moreover, an effective coordination model can be utilized to directly determine the average compressive strain of T atoms from the measured T core-level energy [12.14, 26]. The result is shown in Fig. 12.10b. It agrees with the lattice strain determined in both first-principles calculations and surface x-ray diffraction experiments (Fig. 12.5b,c).

The evidence that surface core-level energies mirror lattice strain variations at the surface can be of great help to investigate relevant processes in which substrate stress is a key parameter, such as catalytic reactions [12.27]. Although the expected core-level energy shifts are small, experiments on curved crystals may facilitate their accurate determination. In Fig. 12.11a, we show the α-scan of the C 1s for the CO-saturated c-Pt(111) surface. The T_{top} C 1s line for CO adsorbed on top of terrace atoms exhibits a terrace shift, although it goes in the opposite direction to that of the Pt 4f in Fig. 12.10, i.e., toward low binding energy. In reality, both shifts originate from the same stress-relief effect of surface steps, but their opposite direction indicates that the Pt(111) surface stress has changed sign upon CO saturation, that is, the negative shift of Fig. 12.11a indicates that the CO saturated Pt(111) terrace is submitted to compressive stress [12.28], in contrast to the tensile stress of the clean Pt(111) surface.

Changes in the lattice strain also occur during the spontaneous relaxation of high symmetry planes, e.g., in Au(111), where the (111) surface atomic plane forms a herring-bone reconstruction, characterized by a 4%

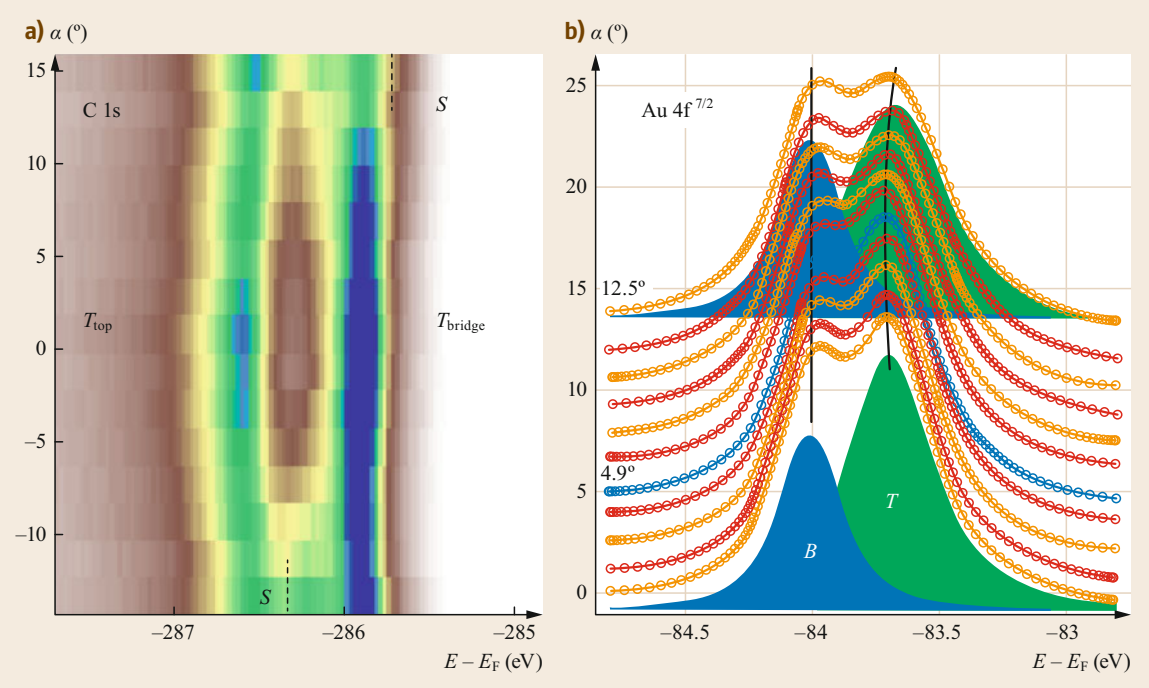

Fig. 12.11a,b Core-level α-scans for CO-covered c-Pt(111) and faceted c-Au(111): **(a)** α-scan of the C 1s level for a c-Pt(111) crystal saturated with CO. The negative T_{top} shift suggests that compressive stress diminishes from the CO-covered (111) plane to the CO-covered vicinal surface [12.14]. **(b)** Negative T shift in the Au $4f^{7/2}$ α-scan performed on a c-Au(111) surface. This is explained by the reduction of the atomic density in unreconstructed (111) terraces that progressively appear beyond $\approx 4°$

larger atomic density with respect to the bulk (111) plane. In vicinal Au(111), (111) terraces exhibit herringbone-like patterns at low miscut angles, but the reconstruction is progressively suppressed across the 4–10° faceting transition. In Fig. 12.11b, we show the α-scan of Au $4f^{7/2}$ performed on the B-step side of the c-Au(111) surface (Fig. 12.8b). From the high-symmetry (111) surface and for small miscuts, the T peak exhibits a subtle shift to higher binding energies as a function of α, similar to c-Pt(111), due to the stress-relief effect of the steps. However, the terrace shift is reversed around 3.5–5° at the threshold of the faceting transition shown in Fig. 12.8b. In fact, beyond $\approx 4°$, wide, densely-packed reconstructed terraces are smoothly replaced by narrow, unreconstructed Au(111) terraces with lower atomic density. The lower binding energy T shift is mostly due to the increasing presence of this second phase featured with terraces of higher tensile stress.

12.4 Surface States at Vicinal Noble Metal Surfaces

The (111) surface of noble metals is characterized by a projected bulk band gap that binds 2-D surface electronic states. These can be derived in a very intuitive, yet accurate way assuming a 1-D quantum well (QW) in the bulk z-direction [12.29]. As depicted in Fig. 12.12, such a 1-D QW is defined by the bulk band gap on one side and the vacuum potential barrier on the other. QW energy levels correspond to a series of 2-D electronic states located, according to their expected value $\langle z \rangle$, at an increasing distance from the surface, which makes them sensitive to surface scatterers at a different degree [12.30]. The $n = 0$ QW level, also called the intrinsic or Shockley state, is located close to the outermost atomic layer, and hence it is highly sensitive to surface impurities or structural defects such as atomic steps. As we move to higher lying states of the series, the so-called image potential states ($n \geq 1$) are located farther away from the surface, being perturbed only by the possible distortion of the vacuum level around such defects (Fig. 12.2a [12.31, 32]).

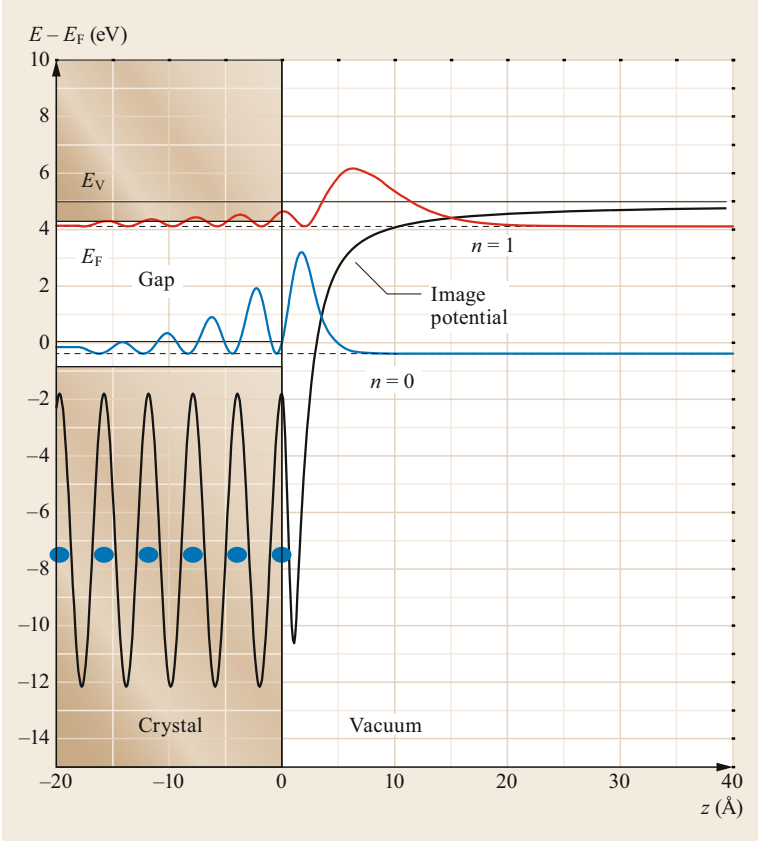

Fig. 12.12 Surface and image states: potential and probability density for the surface ($n = 0$) and image states ($n = 1$) in Cu(111). Surface electrons are trapped between the vacuum barrier (image potential) and the crystal projected bulk band gap [12.29]

The step superlattice in a vicinal surface represents an additional nanoscale potential that adds to that of the atomically flat surface. The dipolar fields originated at the undercoordinated edge atoms give rise to fully anisotropic, 1-D rows of periodic potential barriers. Understanding the effect of such periodic potential barriers on surface electrons is relevant from two different perspectives: on the one hand, it will affect electron-mediated phenomena such as adsorbate interactions, [12.33, 34] self-assembly, [12.35, 36] and chemical reactions [12.37–39]. Even the superlattice stability itself can be entangled to the final electronic structure either via electronic step–step interactions, [12.40, 41] or the induction of energy gaps at the Fermi level [12.42]. On the other hand, the combination of a 2-D nearly free electron gas in the presence of a 1-D superlattice potential grid provides a perfect scenario for modeling electronic confinement and superlattice band engineering.

The following subsections are focused on the interaction of Shockley states of (111) noble metal surfaces with monatomic steps, gradually increasing complexity from isolated pairs of steps, to simple step arrays, faceted vicinals, and, finally, to heterogeneous superlattices.

12.4.1 Electron Confinement in Isolated Step Resonators

Quantum electron confinement on metallic surfaces was elegantly demonstrated in pioneering atomic manipulation experiments performed by STM [12.43, 44]. The possibility of fabricating quantum corrals of different geometry and chemical nature by moving atoms one by one boosted research on electron confinement phenomena, providing simple model cases for quantitative studies of the QW resonator parameters, [12.44, 45] and for the exploration of more exotic phenomena such as the quantum mirage and invisibility [12.46, 47].

Similar quantum resonators can also be fabricated in a pristine surface using the intrinsic potential barriers of monatomic steps. Indeed, atomic and vacancy islands constitute effective 2-D resonators, similar to atomic quantum corrals, as shown in Fig. 12.13 [12.48]. An advantage of using steps instead of adatoms is that one can build simple 1-D resonators out of parallel steps, which can be simulated with analytical multiple scattering models. *Bürgi* and coworkers exploited this concept by artificially inducing straight parallel steps by controlled tip crashes and using the Fabry–Pérot model

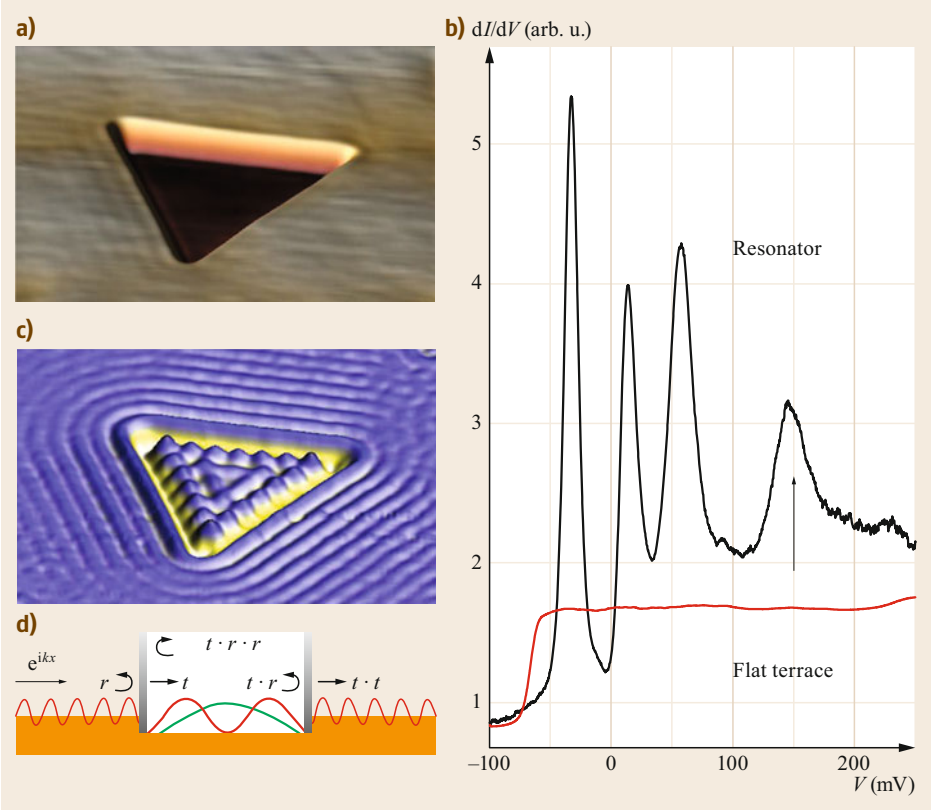

Fig. 12.13a–d Electron confinement inside a step resonator: **(a)** topographic STM image of a triangular, monatomic vacancy island on an Ag(111) surface. The length of the edges is 20 nm. **(b)** $\mathrm{d}I/\mathrm{d}V$ spectra acquired on the flat terrace (*red*) and at the center of the island (*black*). Quantization of the Shockley band gives rise to sharp peaks in the latter. **(c)** $\mathrm{d}I/\mathrm{d}V$ map acquired at the energy of the quantum-well state at +172 mV, marked with an *arrow* in **(b)**. **(d)** Multiple scattering that gives rise to quantum-well states inside the resonator

to analyze resonances [12.49]. The scattering coefficients extracted from this analysis indicated that steps in isolated resonators behave as quasi-infinite hard walls with negligible transmission. Reflection was shown to be significantly reduced by scattering into bulk states, which in the model appeared as an effective absorption. The results also revealed strongly asymmetric potential barriers that led to larger reflection coefficients for the step descending direction.

A weakness of the Fabry–Pérot model is that transmission depends on the wave function phase shift at the resonator barriers. This is determined by fitting the tail of the resonance in this region, which can be hindered by step-related local-density-of-states (LDOS) features and uncertainties in the precise barrier position. In order to directly address transmission coefficients, *Yazdani* and co-workers designed a different experiment consisting in measuring the energy-dependent LDOS modulation of the continuum electron gas outside the resonator [12.50]. For leaky barriers, transmission antiresonates at the QW energies, resulting in dips in the LDOS outside the resonator. Then, an analytical multiple scattering model can be applied to relate the energy modulation of the LDOS with the transmission coefficient [12.50].

In Fig. 12.14, this method is applied to investigate the transmission of Shockley states across steps on the Ag(111) surface [12.13]. The topographic image shows a step resonator that consists of a $d = 57$ Å wide terrace, surrounded by two larger terraces. Transmission measurements are carried out on the right terrace. Its width, $d = 1220$ Å, is well above the coherence length of Shockley states near the Fermi level, [12.51] the maximum distance where phase coherence of incoming and scattered waves permits quantum interference. Quantization effects can, therefore, be excluded here. Conductance ($\mathrm{d}I/\mathrm{d}V$) spectra acquired along a line that crosses the resonator reveal the different LDOS corresponding to the resonator and the semi-infinite terrace: coherent scattering at the two steps results in discrete

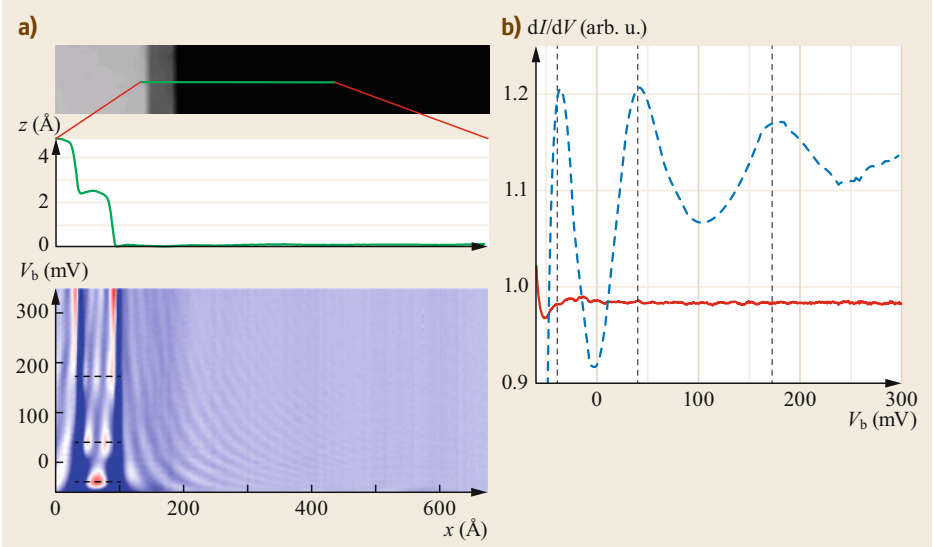

Fig. 12.14a,b Transmission across isolated steps: **(a)** topographic image of a step resonator of $d = 57.5$ Å (*top*), profile along the *green line* (*center*), and color scale dI/dV spectra acquired along the *same line* (*bottom*). **(b)** dI/dV spectra spatially averaged over the resonator (*blue*) and over the large terrace on the *right* (*red*). A background spectrum acquired at the center of a large terrace has been subtracted to all spectra in order to remove features related to the DOS of the infinite terrace and the tip [12.13]

electronic levels (dashed lines) separated by forbidden energy gaps in the resonator terrace. Outside the resonator, scattering at a single step gives rise to quasiparticle interferences that spatially modulate the LDOS over the continuum of energy. Energy modulations due to such interferences are best detected by getting rid of spatial modulations, either averaging spectra in real space or by performing the Fourier transform. Figure 12.14b shows the spatial average on the resonator (dashed lines) and on the right terrace (solid lines). The curves have been normalized by subtraction of a reference spectrum obtained far away from scatterers, in order to remove the density-of-states (DOS) onset of the noninteracting surface state and any contribution from the tip DOS. The normalized dI/dV curve is flat, without any sizeable dip at the resonant energies of the QW states (dashed vertical lines), indicating that transmission of Shockley states across isolated steps is negligible, in agreement with the Fabry–Pérot analysis [12.49]. An upper limit of $T < 0.3$ (i.e., $|T|^2 < 0.1$) can be estimated by fitting the normalized fast Fourier transform (FFT) intensity with the analytical function developed in [12.50] (not shown here).

In summary, STM studies of surface electron confinement within isolated step resonators on Ag(111) reveal that monatomic steps lead to asymmetric upwards/downwards scattering with negligible lateral transmission and significant absorption via coupling to bulk states. Similar studies on quantum corrals built by adatoms of different nature on other noble metal surfaces suggest that this is a general behavior, i.e., insensitive to the type of scatterer [12.52–54].

12.4.2 Superlattice Bands in Coupled Step Resonators

A vicinal surface can be conceived as a self-assembled periodic array of step resonators. Depending on the electron coupling strength between contiguous resonators, the resulting surface electronic structure will consist of either an array of noninteracting QW states or of propagating superlattice bands. Both cases are schematically depicted in Fig. 12.15a.

In strong contrast to the total electron confinement probed by STM on isolated step resonators, a vast number of studies demonstrate that surface electrons on vicinal surfaces propagate across steps and behave as superlattice states [12.4, 5, 8, 13, 42, 55–66]. These are mainly based on the analysis of ARPES measurements, where band perturbations such as energy shifts, backfolding and gap opening can be readily observed. Such parameters can be related to the step-barrier strength, periodicity, and scattering coefficients by fitting the bands, e.g., with the periodic Kronig–Penney potential model (Fig. 12.15b) [12.5, 64, 67]. Figure 12.15c is an illustrative example of the electronic structure of a vicinal Au surface, Au(788), where the free electron-like parabola of the flat (111) terrace is split into subbands

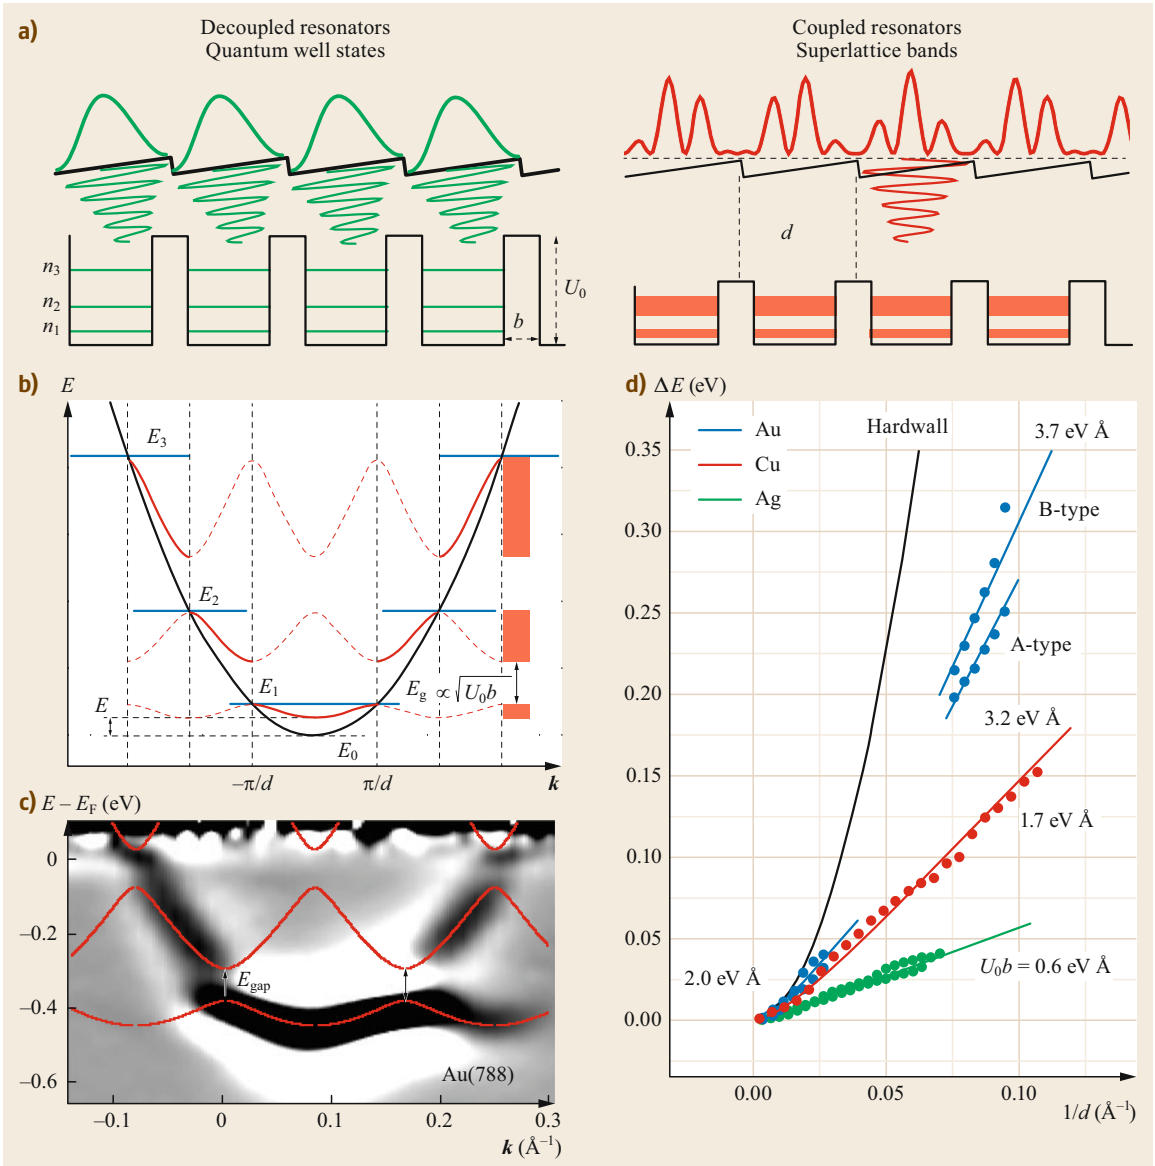

Fig. 12.15a–d Surface states at vicinal surfaces: **(a)** decoupled and coupled resonators confining QW states and giving rise to superlattice bands, respectively. Kronig–Penney potentials with barrier strength $U_0\,b$ and periodicity d are depicted below each case. **(b)** 1-D band structure of a free electron gas (*black*), superlattice states (*red*), and QW states (*blue*). **(c)** ARPES data of a Au(788) vicinal surface, with $d = 39$ Å, exhibiting superlattice bands, in inverted gray scale. The second derivative of the photoemission intensity is used to enhance the peak maxima, which explains the (bright) depression around the band. **(d)** Energy shift of the band bottom as a function of superlattice periodicity obtained from the ARPES data measured on curved Au, Cu, and Ag crystals [12.8]. *Colored lines* are fits of the data with the Kronig–Penney model (12.2), and the *black line* represents the hard-wall case

separated by small gaps. The red curves are a fit of the Kronig–Penney bands, from which the step-barrier strength $U_0\,b$ and periodicity d can be derived. The spectral weight of each subband is dominated by the zero-order Bloch component that follows the nonperturbed parabolic dispersion, minimizing the contribution of the $n = 2$ and $n = 3$ folded subbands in the first Brillouin zone [12.68].

A more reliable way of obtaining $U_0\,b$ resides on varying the miscut angle of the vicinal surface to ana-

Fig. 12.16a–c Analysis of the Fourier components of the surface states through k_x–k_z diffraction plots: **(a)** The *bottom part* sketches the exponential decay of the surface state wave function towards the bulk for QW states confined in (111) terraces (*green*) and superlattice states propagating along the macroscopic plane (*red*). In the k_x–k_z plot on the *top*, corresponding rods represent the momentum distribution of the decaying waves, peaking at the L points. For QW states, Fourier components spread along the [111] direction, whereas for superlattice states, vertical rods locate at $k_x = (2n+1)\pi/d$ (n integer), i.e., the superlattice zone edge boundaries. **(b)** Photon-energy-dependent band dispersions for a curved crystal at a position where $d = 71$ Å. *Vertical lines* mark zone-boundary edges of the step superlattice. Free-electron-like dispersion curves (*red*) that fit data are included. **(c)** k_x–k_z diffraction plots for several points of a curved Au crystal. *Red* data belong to lattices that exhibit split bands, where band minima are determined by parabolic fitting and the point size correlates with the ARPES intensity. *Blue data points* correspond to lattices where a double band cannot be resolved, and k_x data are determined from intensity maxima. In this case, split rods are not perfectly resolved around the intermediate k_z values, although alignment along the [111] direction never occurs [12.13] ►

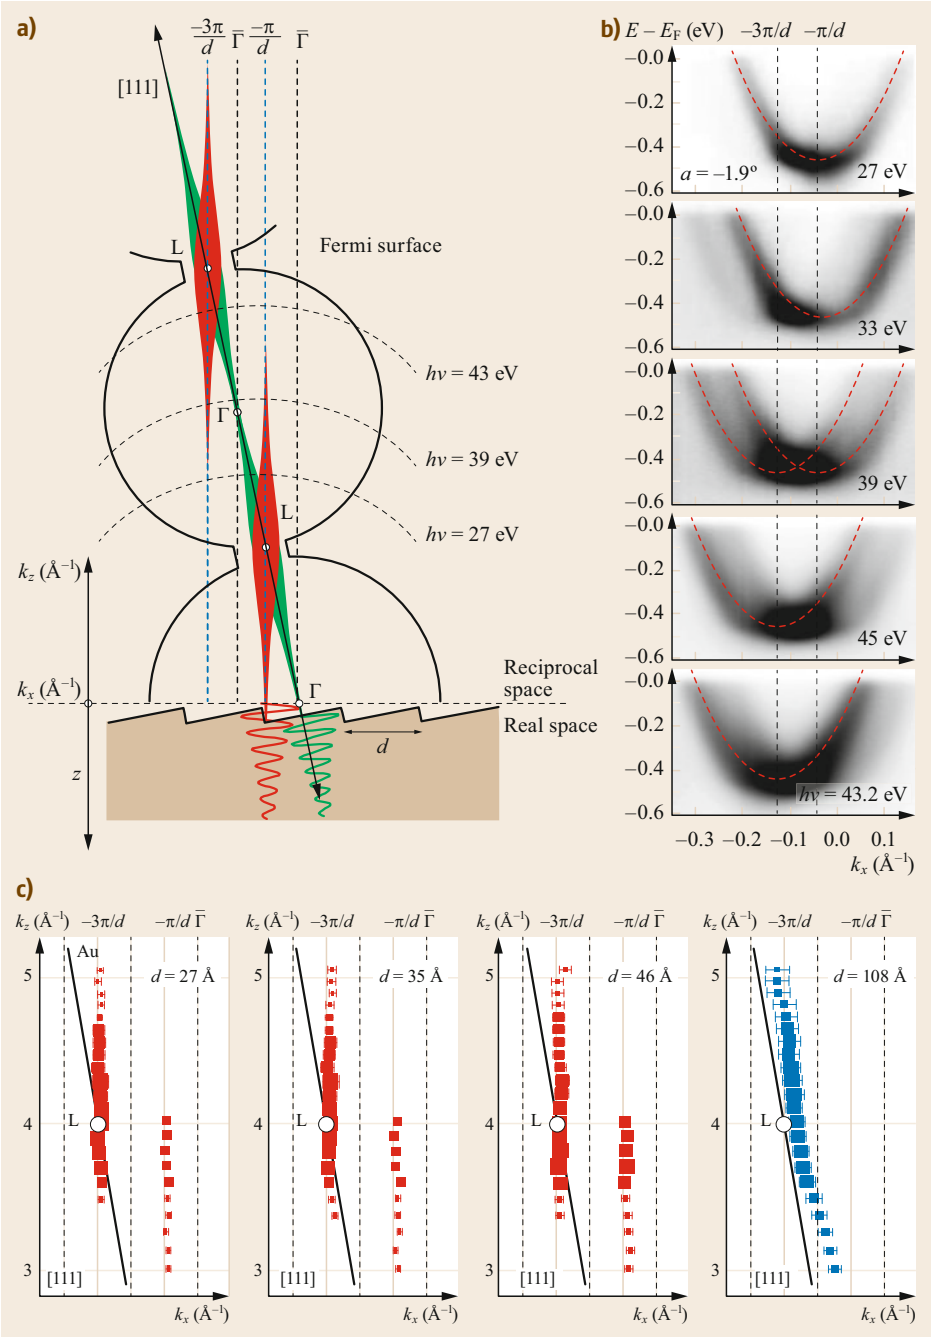
lyze the band bottom energy shift with respect to that of the flat surface, namely the terrace shift as a function of d: $\Delta E(d) = E(d, k = 0) - E_0$. For that purpose, the continuous tunability of d offered by curved surfaces turns out to be extremely useful, enabling the acquisition of systematic, high data density plots such as the one shown in Fig. 12.15d [12.8]. Here, $\Delta E(d)$ obtained for the Shockley state on curved Au(111), Cu(111), and Ag(111) crystals are plotted and fitted to the Kronig–Penney relation [12.8]

$$\Delta E = \frac{2\hbar^2}{m^*}\frac{1}{d^2}\left[\tan^{-1}\left(\frac{q_0}{q}\right)\right]^2 , \qquad (12.2)$$

where $q_0 = (m^*/\hbar^2)U_0\, b$ and $q = \sqrt{(2m^*/\hbar^2)(E - E_0)}$. Both E_0 and m^* are obtained from fitting the parabolic dispersion on the flat region of the crystal, whereas $U_0\, b$ is left as the only fitting parameter in (12.2). A single value $U_0\, b$ holds for each crystal at all d regimes, except in Au, where the interplay between steps and the surface reconstruction results in complex relaxations and faceted regions (Sect. 12.2.3). The largest barrier strengths correspond to Au, ranging from 2.0 to 3.7 eV Å depending on step density and type, then Cu with 1.7 eV Å, and Ag presents barriers as low as 0.6 eV Å. Such differences can be scaled with variations in the step dipole moment of each crystal, as suggested by partial comparative measurements in surface-vacuum [12.63] or surface-electrolyte interfaces, [12.69] supporting the electrostatic origin of the step barrier.

An alternative proof of the superlattice nature of the wave functions in the whole energy region explored with curved crystals is provided by the direction of the plane that defines its 2-D character, also called modulation plane. QW states are terrace modulated, i.e., with the bulk decaying tail perpendicular to the (111) direction, whereas superlattice bands are step modulated, i.e., propagating along the macroscopic surface plane and hence exhibiting a decaying tail perpendicular to it (Fig. 12.15a). In reciprocal space the oscillatory damping towards the bulk, with fundamental frequency $k_L = \sqrt{3}\pi/a$, gives rise to a broad spectral momentum distribution along the decaying direction that peaks at the L points [12.13]. Taking the parallel direction to the vicinal surface plane and perpendicular to the steps as the x-direction, the two cases are represented as cigar-shaped rods in the k_x–k_z cut of Fig. 12.16a, also called k_x–k_z diffraction plot for its resemblance with the low-energy electron diffraction (LEED) analysis of vicinal surfaces [12.70]. The spectral rods of terrace-modulated states spread along the [111] direction, whereas those of step-modulated states appear vertically aligned at $k_x = (2n+1)\pi/d$ (integer n), the superlattice zone edges. This spectral distribution can be elegantly probed by scanning the photon energy in ARPES measurements, i.e., by sweeping the Ewald sphere across the reciprocal space. The latter is shown in Fig. 12.16b for the curved Au crystal at a position of $d = 71$ Å. By a parabolic fitting of the data, disregarding superlattice minigaps for simplicity, one can extract the position and intensity of the band bottom. These are represented in the diffraction plots of Fig. 12.16c, the dot size being proportional to the intensity. The vertical umklapp rods indicate that the Shockley state is clearly step modulated for periodicities as large as $d = 108$ Å, and similar results are obtained with the curved Ag crystal for values of d up to 180 Å [12.13]. The slight deviations found for some points at the largest d values (blue points) appear to be a consequence of the terrace width distribution (TWD, see Sect. 12.2.2), which is expected to lead, in analogy to LEED, to broadening and effective overlap of contiguous reciprocal lattice rods $(2n+1)\pi/d$. One can, therefore, conclude that Shockley states on vicinal surfaces behave as propagating superlattice states all the way from rather small periodicities ($d \approx 10$ Å) up to the largest values that can be reliably probed in ARPES ($d = 100$–200 Å), i.e., up to the limit set by natural TWD broadening in step arrays.

The above scenario is not compatible with the transitions from superlattice to QW states proposed in previous studies on single-miscut vicinals. Those were



attributed to different mechanisms, such as a transition from deeper lying surface resonances to true surface states, [12.5] the depopulation of surface states, [12.72] or lattice disorder at the proximity of the Fermi nesting period $d = \lambda_F/2$ [12.42]. The fundamental role of lattice disorder in the induction of confined states was recently confirmed at the local scale by STM measurements in regions with significant disorder, revealing the coexistence of 1-D QW states and superlattice 2-D bands, as can be seen in Fig. 12.17 [12.71, 73]. In general, as we vary the miscut angle, complex electronic phenomena may emerge, in parallel to the also complex structural variations that real vicinal surfaces exhibit. However, all experiments in curved

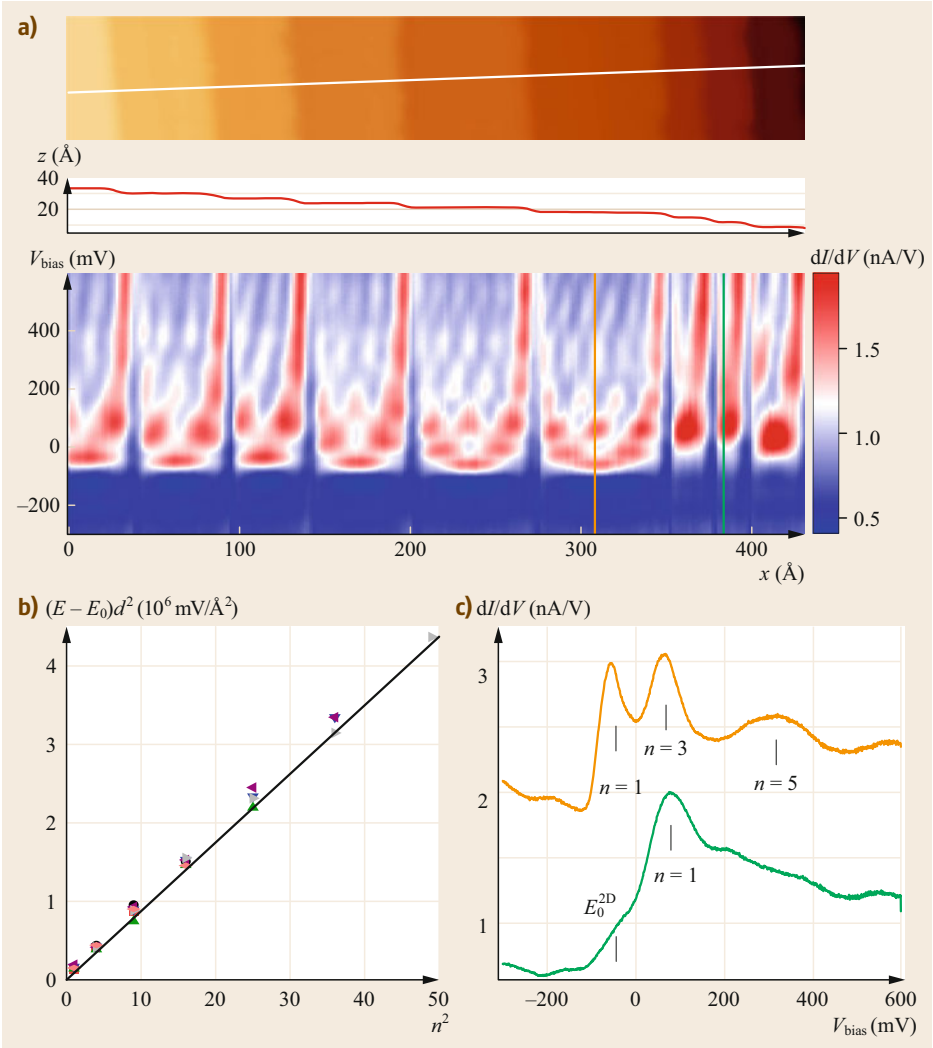


Fig. 12.17a–c Coexistence of 1-D QW states and 2-D superlattice bands: **(a)** dI/dV spectra acquired by STM along the *white line* indicated in the topographic image displayed at the *top* (the topographic profile is added right below it). **(b)** Energy shift (normalized by d^2) of the lateral 1-D resonances, obtained by fitting the spectra in **(a)** with Lorentzian peaks. Data are compared to the 1-D hard-wall potential expectation (*line*). Values obtained at different terraces are plotted in *different color*. **(c)** Individual dI/dV spectra extracted from the set of **(a)** (*vertical lines*). Both spectra exhibit clear 1-D resonant peaks. The onset of the dispersing 2-D state (E_0^{2D}) is only visible in the spectra of the smaller terrace (*green curve*), where it does not overlap with the 1-D resonant peaks [12.71]

crystals with reasonably ordered, coherent step lattices exhibit Shockley bands that can be interpreted within a simple Kronig–Penney model, using a single value of the step barrier for all miscut angles at experimental reach. Interestingly, this step barrier can be manipulated by decorating the step superlattice with metallic and molecular wires and stripes. One can tune the step-barrier strength and even invert the sign from repulsive, [12.74] switch from macroscopic to (111) terrace modulation plane [12.75], or passivate the dipole to make the step transparent [12.76].

12.4.3 Electronic States in Faceted Surfaces

The surface electronic structure becomes rather complex at vicinal surfaces that exhibit periodic faceting. As discussed above, faceting is triggered by the reconstruction of the high-symmetry plane of the terraces. This is the case of vicinal Au(111) surfaces with miscut

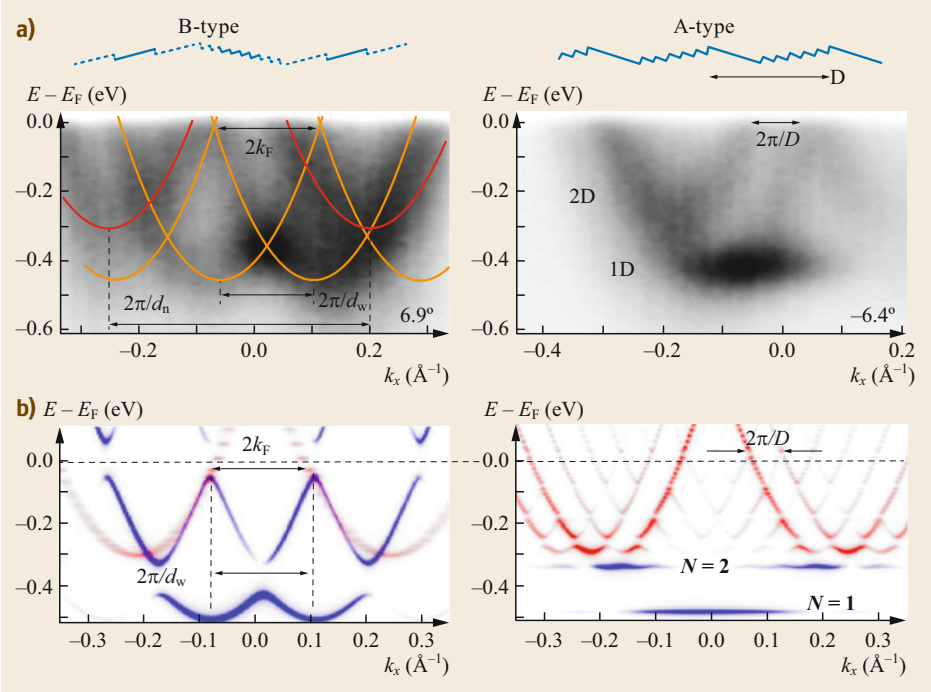

Fig. 12.18a,b Shockley bands in faceted Au(111) surfaces: **(a)** photoemission intensity maps measured with 43 eV photon energy in the B-type side (*left panel*) of the c-Au(111) surface at 6.9° miscut angle; d_w and d_n surface bands appear superimposed. *Solid lines* are guide-to-the-eye parabolic functions that agree to the periodic faceting. The *right panel* corresponds to bands at the A-side of the crystal measured at 6.4° miscut angle. The surface band splits into a quasi-1-D state (low energy) and a 2-D band (high energy). **(b)** Calculated photoemission intensity maps for B- and A-type faceted surfaces (*left* and *right panels*). For the B-side we assume 30 small $d_n = 14$ Å terraces embedded between two facets made up of 30 large $d_w = 30$ Å terraces. For the A-side we consider a periodic succession of six small $d_n = 14$ Å terraces and a single $d_w = 40$ Å terrace [12.4]

angles between $\approx 4°$ and $\approx 10°$, which exhibit periodic faceting that results in a hill-and-valley structure of wide ($d_w = 31–41$ Å) and narrow ($d_n = 13–14$ Å) terraces. As shown in Fig. 12.3c, for A-type steps, the d_w phase is characterized by a single terrace, while the d_n phase consists of several steps [12.4, 5, 77]. Therefore, a periodic superstructure with lattice constant $D = d_w + m \times d_n$ arises, where m depends on the local miscut angle. For B-type steps, bunches of terraces are formed in both d_w and d_n phases, resulting in much larger D periodicity (Fig. 12.8b). Due to faceting, Au(111) Shockley states split into low ($E_B = 0.45$ eV) and high ($E_B = 0.29$ eV) energy bands for d_w and d_n phases, respectively. For B-type steps, with large d_w and d_n phases, d_w and d_n states are decoupled, whereas the single d_w terrace in A-type faceting allows d_w and d_n bands to hybridize, leading to a complex band structure [12.5]. Such A/B faceting differences are readily observed when monitoring the evolution of the Shockley state on the curved Au(111) sample [12.4, 12]. At the upper and lower onsets of faceting, both A and B exhibit free-electron-like bands folded with $g_w = 2\pi/d_w$ (as in Fig. 12.2b) and $g_n = 2\pi/d_n$ umklapp vectors, respectively. In Fig. 12.18a, we show the characteristic spectra taken at α miscuts within the faceting region in both A and B sides (−6.4° and 6.9°). At the B side, with no d_w–d_n interactions, independent d_w and d_n bands appear superimposed. In contrast, on the A-side the d_w–d_n interaction leads to a coherent band structure, made of 2-D (dispersing) band features with the characteristic 2-D $\Delta k_x = 2\pi/D$ umklapps near E_F, plus a (weakly dispersing) 1-D quantum-well-like state split-off at $E_B = 0.4$ eV [12.4, 5].

Despite the apparent complexity of band structures of Fig. 12.18, these can be well reproduced within the same free-electron-like plus step-barrier-potential framework discussed for simple step lattices. However, the photoemission matrix element must be accounted for in order to disentangle experimental observations [12.4]. The simulated photoemission intensity maps shown in Fig. 12.18b were calculated within the dipolar approach, assuming free-electron waves as final

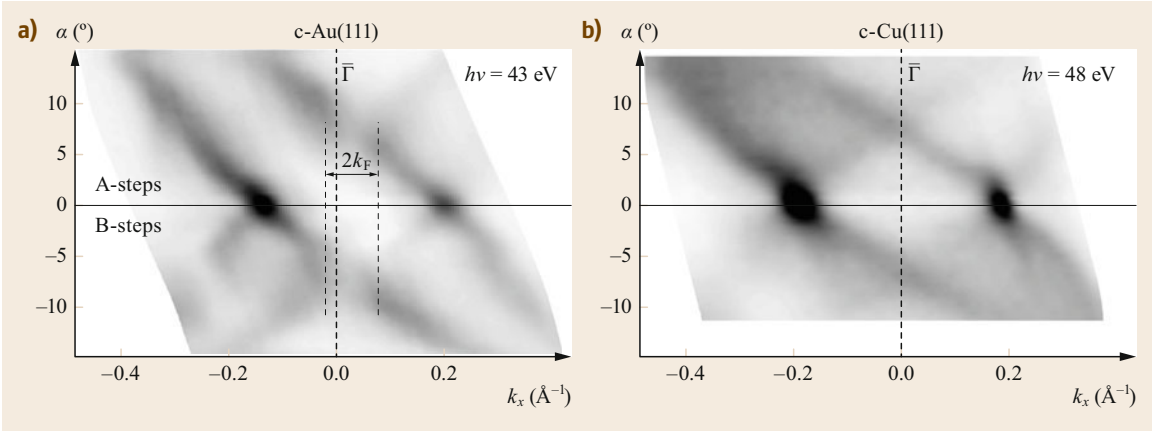

Fig. 12.19a,b ARPES α-scan at the Fermi level on c-Au(111) and c-Cu(111) surfaces: photoemission intensity map measured at E_F for the curved Au(111) surface as a function of the miscut angle α and the wave vector k_x perpendicular to the step array on the local surface plane for **(a)** c-Au(111) and **(b)** c-Cu(111) surfaces. Differences stand out at a critical $\approx 5-7^\circ$ miscut range. In c-Au(111), faceting occurs with a characteristic k_F oscillation in both d_w and d_n phases. In c-Cu(111), no apparent instabilities are observed at E_F

states and Shockley states as initial states [12.78]. The latter are free-electron-like parallel to the steps, while in the k_x-direction they scatter with a periodic 1-D step potential that mimics the faceted superstructure. Using the step-barrier potential width $U_0 = 2$ Å and height $b = 1$ eV (in agreement with Fig. 12.15d), effective mass $m^* = 0.27\,m_e$, and reference energies of terraces $E_0(d_w) = -0.53$ eV and $E_0(d_n) = -0.42$ eV, the model fits the experimental bands in the top panels for both A and B-like superlattices. Blue and red colors are assigned to electronic states with higher probability at d_w and d_n facets, respectively. The simulation validates the wave function model for the A-type superstructure sketched in Fig. 12.3. The weakly dispersing quantum well state at $E_B = 0.4$ eV appears connected to electron confinement into single d_w terraces, whereas the higher-lying 2-D band manifold corresponds to wave functions that are strongly modulated within d_n nanofacets [12.4, 5].

A closer look at ARPES experiments and simulations of Fig. 12.18 reveals the existence of peculiar Shockley state modulations near E_F. At the lower $\approx 4^\circ$ onset, we notice that d_w bands nest at the Fermi energy with $k_F = \pi/d_w$ vectors. In fact, a superlattice gap opens up for d_w bands around E_F, as shown in the model calculation for B-type steps. In this panel, we also observe that, despite their different energy and periodicity, Shockley bands of both d_n and d_w phases exhibit the same Fermi wave vector $k_F = \pi/d_w$. Such k_F coincidence for d_n and d_w phases appears as a characteristic property for Au faceting, since it is also present in the more coherent A-type faceted superstructure. This can be readily visualized in the α-scan of the Shockley state for the c-Au(111) crystal, which is compared with the corresponding α-scan of the c-Cu(111) crystal in Fig. 12.19. Each image represents the photoemission intensity at E_F, at fixed $k_y = 0$, along k_x (perpendicular to the steps), and across the curved surface. The two dark spots at $\alpha = 0$ mark $\pm k_F$ values of the Shockley state in the (111) surface, which are similar for both Au(111) and Cu(111). The pair of oblique k_F-lines that split from each $\alpha = 0$ point are superlattice umklapps. For a regular step array with a linearly-dependent step density $1/d$, such as that of c-Cu(111), opposite k_F lines cross at a critical ($\approx 7^\circ$) miscut, where the 1-D Fermi surface is nested with step-lattice vectors. On Au(111), however, the faceting transition prevents the k_F line crossing, i.e., the nesting of the Fermi surface in the k_x-direction. Instead, a $2k_F$-wide neck-like feature opens up at $\bar{\Gamma}$ and across the faceting region, for both steps A and B.

Although it is clear that the herringbone reconstruction of the Au(111) plane is the driving force in faceting, specific d_w and d_n values might be partly explained by the interplay with the electronic states [12.4]. The $2k_F$ neck of Fig. 12.19 indicates that both d_w and d_n phases share a characteristic Fermi wavelength. This property appears to be rather intriguing. In reality, the photoemission data and the model shown in Fig. 12.18 indicate that the step superlattice gap lies at the Fermi energy for the d_w phase in B-type faceting. This may, in fact, suggest that a charge-density wave-like instability with critical π/d_w wavelength may occur around d_w, as discussed long ago [12.81]. Such a possibility has been evaluated by comparing elastic (12.1) and electronic energy variations in vicinal noble metal surfaces as a function of miscut [12.8]. The size of the step su-

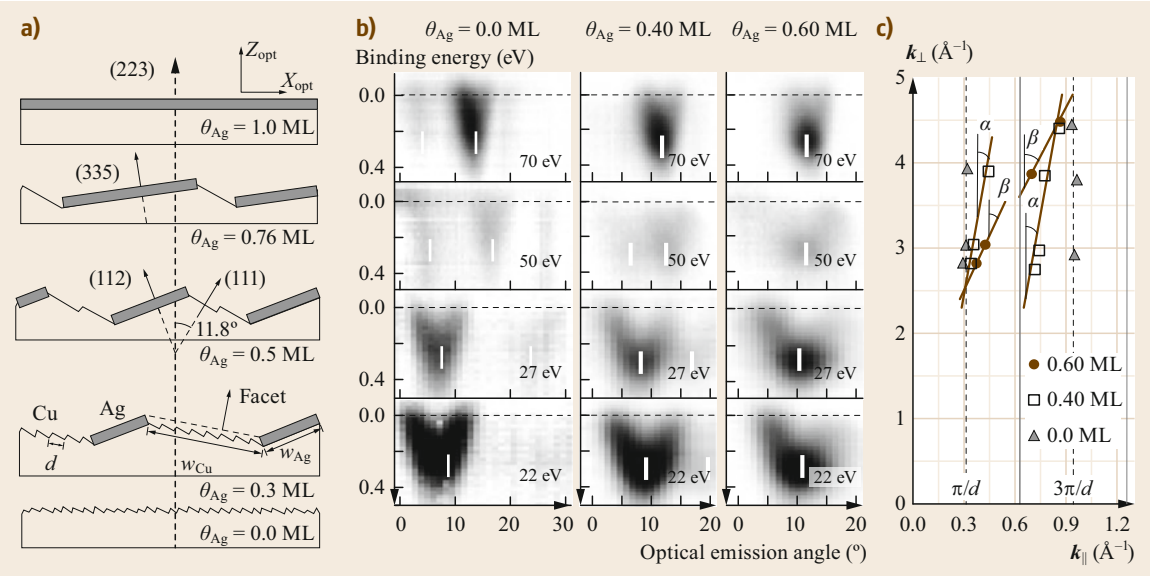

Fig. 12.20a–c Electronic structure modification of the Ag/Cu(223) system: **(a)** graphical representation of the evolution of Ag/Cu(223) with increasing Ag coverage (θ_{Ag}). Ag stripes (gray overlayers on the Cu substrate) grow in width (w_{Ag}), creating a step-bunching effect underneath them. The depletion of steps at neighboring clean Cu stripes increases the average terrace size inside the stripe, changing the local nanofacet orientation. **(b)** Photoemission gray scale plots (*darker color* corresponds to more intense features) of the surface states as a function of photon energy for pristine Cu(223) (*left*), 0.40 ML Ag (*middle*), and 0.60 ML Ag (*right*). The *white vertical lines* mark the center minima of the states. For best visualization, the Fermi step has been removed from the data and the photoemission intensity scaled to a common range. **(c)** k_x–k_z diffraction plots for the three cases shown in **(b)**. Data points line up at different angles, α and β, which correspond to the average direction in the respective Ag-free Cu nanofacet (α for 0.4 ML and β for 0.6 ML) [12.79, 80]

perlattice gap, i.e., the strength of the step dipole barrier becomes a key property. For Ag(111), where the barrier is too small, electronic energy variations are not significant, but for Au(111) and Cu(111), electronic energy instabilities are much larger. On Au(111), these can stabilize a particular lattice spacing (d_w) around the faceting transition. On Cu(111), nesting and gapping of the Shockley state could, in fact, explain the TWD instabilities observed around the $\approx 7°$ critical miscut [12.8].

Surface reconstructions can generally be induced by small amounts of adsorbates. Therefore, adsorption on a vicinal surface may also lead to a faceting transition, i.e., to the segregation of adsorbate-covered (reconstructed) and adsorbate-free facets. This option opens the way to the observation of complex surface electronic states with potential tunability, by simply modifying the coverage of the adsorbate in the submonolayer range. This is the case of Ag on vicinal Cu(111) [12.5, 65, 79, 80, 82]. By varying the Ag coverage, the surface morphology presents structural tunability due to Ag-induced periodic faceting of the Cu substrate. In particular, Ag close-packed stripes have a preference for the (112) orientation, since this allows substrate/adsorbate lattice matching, providing an efficient way to relieve the surface stress. Ag-covered and clean Cu self-assembled nanostripes appear aligned along the step directions, generating coverage-dependent hill-and-valley structures (Fig. 12.20a). By increasing the Ag coverage the clean Cu facets are progressively depleted of steps, until Ag-free Cu areas become (111)-oriented nanostripes. Consequently, the Ag coverage has a direct influence on both the Ag and Cu stripe widths and on the local, vicinal angle of the clean Cu facet.

Laterally-modulated Ag and Cu phases are both featured with Shockley states. However, in contrast to the electronic coupling between phases observed in faceted Au(111), in the Ag/Cu nanostripe system, the Shockley state appears confined within each nanofacet. However, Shockley states still reflect the coverage-dependent changes of the structure (Fig. 12.20b). In particular, the binding energy as well as the photoelectron emission angle from Ag and Cu nanostripes mirror both the nanostripe size [12.5, 65] and its local surface orientation [12.5, 65, 79, 80]. Figure 12.20b shows that for Ag/Cu(223) the emission angle of the Cu nanostripe state varies strongly with Ag coverage and photon energy. The white lines that mark the mini-

mum position of the Cu-like surface state show smaller separations between umklapps (two are visible for pristine and $\theta_{Ag} = 0.4$ ML). Indeed, the angular separation between the parabolas decreases with increasing coverage, as expected from the progressive increase in terrace size inside the Ag-free Cu nanofacet. Indeed, when the coverage approaches $\theta_{Ag} = 0.6$ monolayers (ML) only (111) terraces remain, so no splitting is observed. The photon-energy dependence allows a quantitative k_x–k_z diffraction plot analysis of the Fourier space for each superstructure (Ag coverage), in a similar way as performed for curved crystals (Fig. 12.16). This plot is shown in Fig. 12.20c. The average (223) direction is taken as the common k_x reference for all the data, i.e., for the band minima of the selected coverages in Fig. 12.20b. Separate pairs of lines fit each set of data, showing different line spacings and inclinations. Spacing and inclination angle correspond, respectively, to the step density and orientation of the local Cu nanostripe, evidencing that electrons photoemitted from the Cu facets are referred to its local facet direction [12.79].

12.5 Quantum Well States in Stepped Thin Films

In past decades, QW states of metal thin films became widely popular, due to their connection to quantum size effects in heterostructures, such as magnetic coupling in multilayers [12.83]. Such *vertical* QWs arise when a strong reflection of electron waves at the substrate interface is produced, resulting in electron confinement in the perpendicular direction of the film, in contrast to the *lateral* confinement of Shockley QWs discussed in Sect. 12.4.1. Therefore, the basic requirement for a metallic QW to exist is the presence of an electronic band gap in the crystal substrate at the right energy and momentum, whereas the film thickness (Θ) is the fundamental structural parameter that defines its energy spectrum [12.83, 84]. Laterally nanostructured thin-film/substrate systems that exhibit vertical QWs, such as those that can be grown on vicinal surfaces, may have potential interest in technology applications [12.2, 3]. Although QWs are bulk-like, their electron wave function may have an important weight at the surface or the interface, and hence be influenced by the presence of surface scatterers such as steps. Thus, the question arises whether and to which extent vertical QWs undergo, as Shockley states do, lateral scattering by a surface/interface step potential.

The Ag/Au(111) thin-film system exhibits smooth layer by-layer growth and abrupt Ag/Au interface, both resulting in sharp QW spectra in ARPES [12.85]. This is the perfect scenario to test the existence of (potentially small) lateral quantum size effects on vertical QWs. The spectrum of QWs of Ag films grown on vicinal Au(111) surfaces is thoroughly probed in ARPES experiments using a curved Au(111) sample (ϑ-axis) and a Ag wedge (Θ-axis, 7–12 ML) grown on top, as sketched in Fig. 12.21a. Figure 12.21b shows the $n = 1$ QW spectrum evolution by scanning the Ag wedge at the Au(111) surface, in the center of the curve. In a Θ-scan, one can observe the characteristic upward energy shift as a function of the Ag layer thickness in the $n = 1$ QW state. Figure 12.21c shows the in-plane 2-D band dispersion of the $n = 1$ QW state at 11.4 ML thickness, together with the Shockley band emission from the surface of the film and near E_F. Both the upward shift and the dispersion undergo strong variations at the stepped part of the film, as is shown in Fig. 12.22.

The Shockley band of the clean Au(788) surface ($\alpha = 3.5°$) is again displayed in Fig. 12.22a, in order to be directly compared with the electronic states for the 15 ML Ag film at the same α miscut. In the latter, the intense emission at ≈ 50 meV below E_F corresponds to the Shockley state at the surface of the vicinal Ag(111) film. At higher binding energies, one can observe the entire dispersion of two QW states ($n = 1$ and $n = 2$) and traces of $n = 3$. The momentum scale is referred to the local surface normal $\alpha = 3.5°$ away from the [111] direction. The dashed lines mark the minima of QW bands, which coincide with those of surface states of both the Au(788) substrate and the Ag film surface. Umklapp bands for both surface and QWs have minimum energies at π/d and $3\pi/d$ zone centers, suggesting that both undergo a similar process of scattering by the step lattice.

To qualitatively assess the strength of the step scattering in the Ag QW, constant energy cuts are compared for surface states of the Au(788) substrate and the $n = 1$ QW in a 9 ML film in Fig. 12.22c,d. The k_y–k_x intensity maps displayed were acquired at $E - E_F = -0.36$ eV for the surface state and at 120 meV above the $n = 1$ band minimum for the QW, i.e., the energies at which surface state and $n = 1$ QW umklapps, respectively, nest. Constant energy surfaces in both cases consist of a double ring structure (dashed lines are added as a guide for the eye) with a depleted intensity around the $\bar{\Gamma}$-points, indicating the presence of a superlattice gap. Figure 12.22e illustrates a typical α-scan (equivalent to the ϑ-scan in Fig. 12.21a) for a 7 ML film. For the sake of comparison, the zero in the momentum scale refers to the normal emission with respect to the local surface plane in each case. A single $n = 1$ QW band is observed,

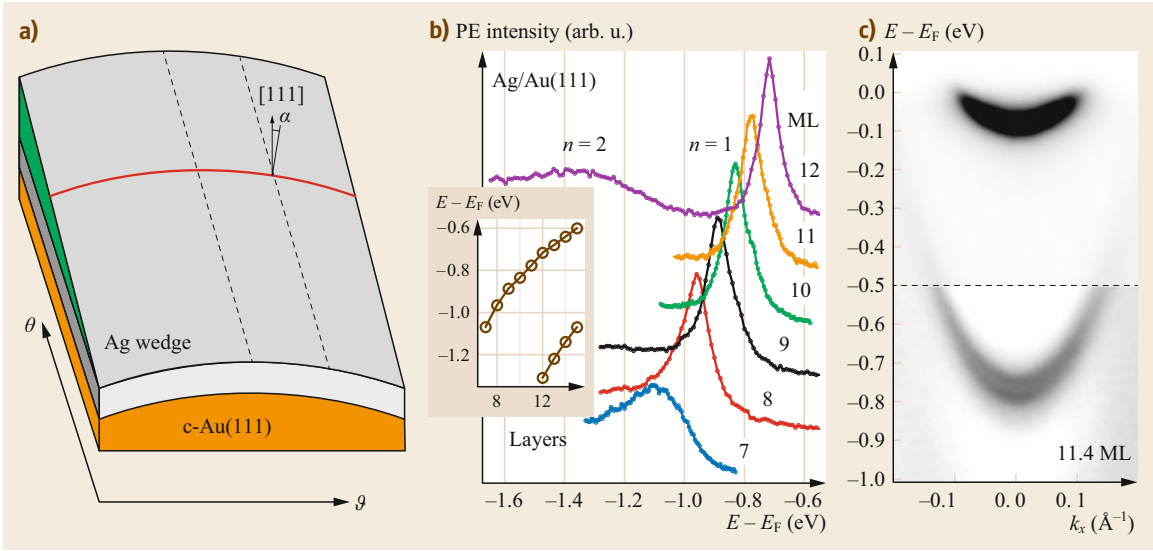

Fig. 12.21a,b Quantum well states on thin Ag films on c-Au(111): angle-resolved photoemission from Ag QWs on vicinal Au(111) surfaces, after creating a Ag wedge over a curved Au(111) surface ($h\nu = 21$ eV). **(a)** The thickness of the film is selected along the grown wedge in the Θ direction, whereas the miscut α varies along the ϑ direction. **(b)** Film thickness-dependent shift of QWs for a 7–12 ML wedge at $\alpha = 0$. **(c)** 2-D band dispersion of the $n = 1$ and the Shockley state for the 11.4 ML film at $\alpha = 0$ [12.71]

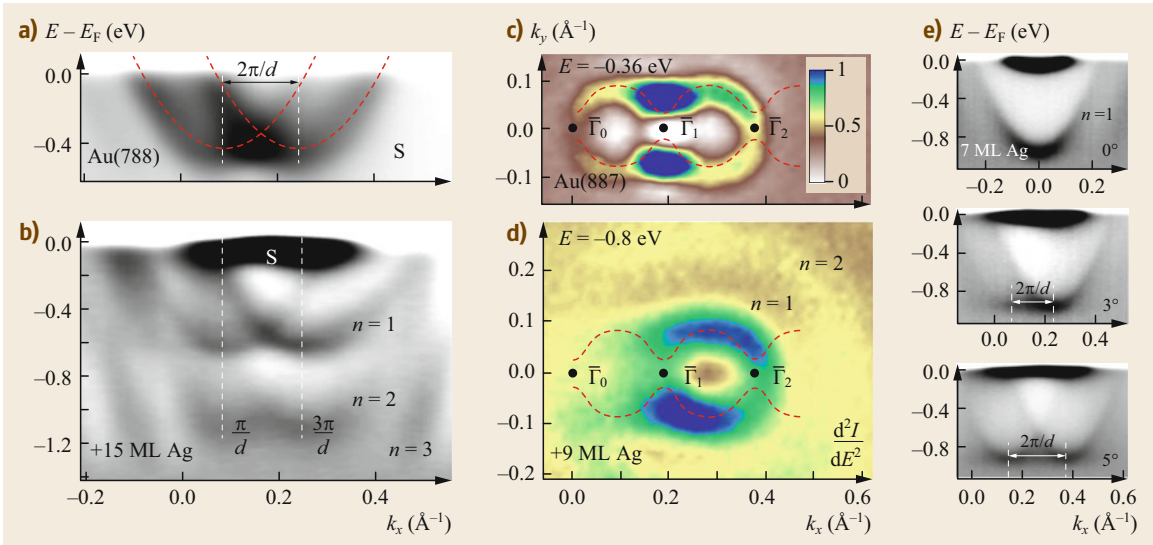

Fig. 12.22a–e Photoemission intensity plots of Ag films on c-Au(111) ($h\nu = 41$ eV): **(a)** clean c-Au(111), showing the surface state and **(b)** 15 ML Ag/c-Au(111), both at $\alpha = 3.5°$. This miscut corresponds to the (788) surface orientation. Three QW bands with step-lattice umklapps appear in the latter, which are aligned with the surface state at zone boundaries π/d and $3\pi/d$. **(c,d)** Constant energy surfaces (second derivative) at –0.36 eV, for the surface state of the Au substrate, and at 0.12 eV above the $n = 1$ QW band minimum (at 0.8 eV), for the 9 ML film, both at $\alpha = 3.5°$. The crossing of the two umklapp rings at $\bar{\Gamma}$ defines a region of lower intensity, revealing a similar gap in both surface and QW states. **(e)** 7 ML Ag/c-Au(111) QW bands in a ϑ-scan, showing the d-dependent splitting of the $n = 1$ QW bands [12.71]

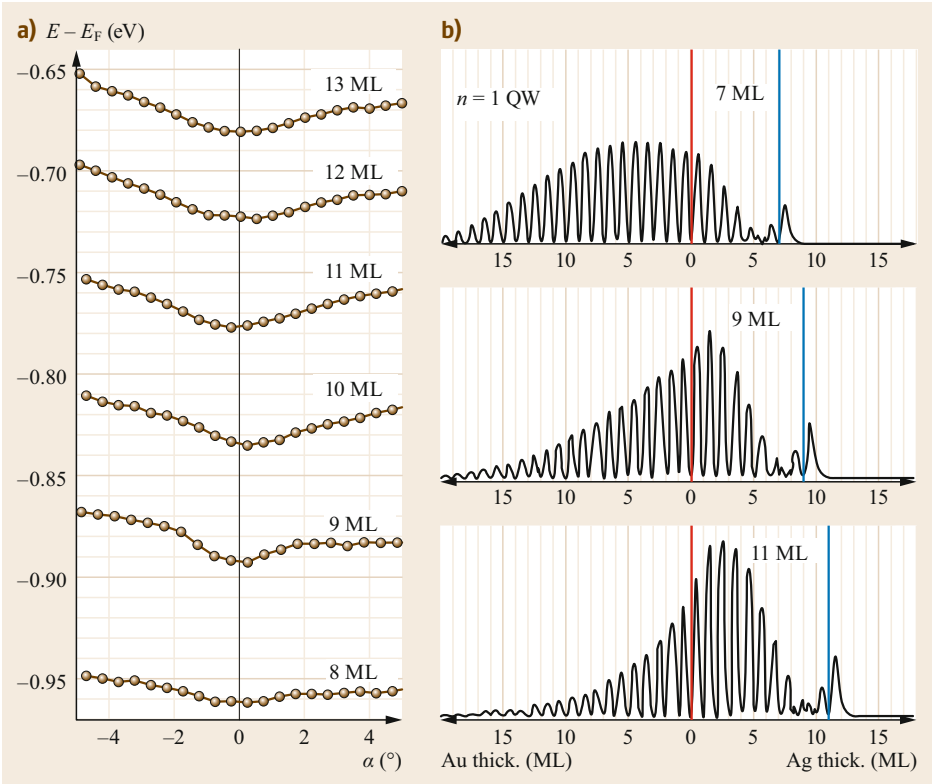

Fig. 12.23a,b Terrace size effect in QW states of stepped films: **(a)** $n = 1$ QW state energy (band minimum) measured in a full θ–ϑ-scan from a 8–13 ML wedge. The upwards shift from $\alpha = 0$ demonstrates a lateral quantum size effect. **(b)** QW wave functions in Ag films of different thicknesses grown on Au(111). *Blue* and *red lines* mark the surface and the interface position, respectively [12.71]

which exhibits the miscut-dependent $2\pi/d$ umklapp characteristic of curved surfaces [12.8]. The quantitative analysis of the step-scattering effect in QWs of the Ag/Au(111) system is shown in Fig. 12.23a. The series represents the energy minimum of the $n = 1$ QW band at different Ag film thickness and as a function of the miscut in the A (negative miscut) and B (positive miscut) sides of the curved crystal. Only small α angles below the faceting transition in the Au substrate are considered. We observe the characteristic upward (≈ 20 meV at $\alpha = 5°$) terrace energy shift, which barely depends of the film thickness in the whole 8–13 ML range.

The terrace shift and the superlattice effects (umklapp and gaps) shown in Figs. 12.22 and 12.23 prove the existence of lateral step scattering in metallic (vertical) QWs, quantitatively and qualitatively similar to that observed in surface states. This is a surprising result, since QW states are expected to have a much smaller probability in the surface plane compared to surface states, and hence are unlikely to sense the surface step dipole. However, it has been discussed that the terrace shift in QWs could result from an equally intense double contribution, i.e., a pure step-scattering effect, due to the sizeable probability density located at the surface/interface, plus a topological effect, arising from the tilt in the bulk-band quantization axis of the film, which is observed to switch from the [111] direction in flat films to the vicinal crystal direction in stepped Ag layers [12.71].

12.6 Spin-Textured Surface Bands at Vicinal Surfaces

In the absence of spin–orbit interaction (SOI), electron bands are spin degenerated and, hence, any scattering vector can connect a pair of states with the same spin and give rise to the quasiparticle interferences observed by STM (Fig. 12.24a). A very different scenario arises when the spin–orbit interaction lifts the spin degeneracy, resulting in nonconventional spin-textured bands. These occur in metals where the 2-D electron gas is affected by a sizable Rashba interaction, [12.86] or in the surfaces of topological insulators, [12.87] both depicted in Fig. 12.24b.

The Rashba effect is a consequence of the breaking of the 3-D translational symmetry at the surface or at the interface of materials with different atomic lattices.

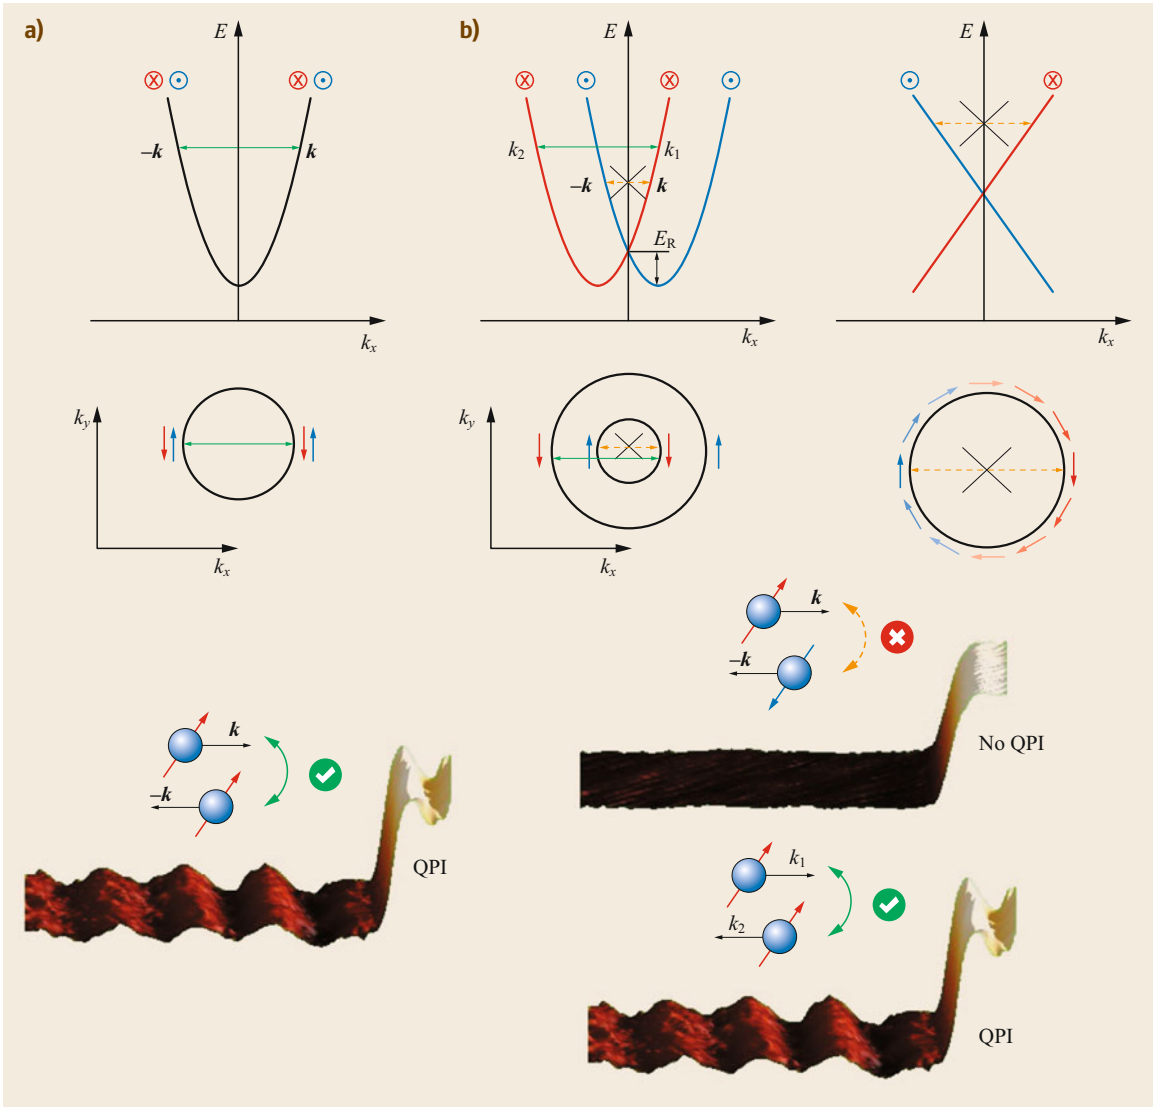

Fig. 12.24a,b Scattering within spin-textured bands: spin-polarized 1-D band structure (*top*) and 2-D constant energy cut (*bottom*) of **(a)** a free electron gas with no SOI and **(b)** an ideal Rashba system (*left*) and topological insulator (*right*). The spin polarization is represented in *blue/red* color code. Examples of forbidden/allowed scattering transitions are illustrated by *orange/green arrows*. *Bottom images* show a pictorial description of incoming and outgoing electrons scattering from a step, with their *red/blue arrows* representing their spin. In the absence of SOI, backward scattering between k and $-k$ give rise to quasiparticle interferences (QPI). In the presence of SOI, the orthogonal spins of k and $-k$ states cannot give rise to QPIs. These, however, can be formed by intraband scattering between k_1 and k_2 states

In the presence of SOI, this symmetry rupture lifts the degeneracy of a 2-D electron gas by a momentum splitting of bands with opposite spin. In an ideal Rashba system, the SOI locks the spin to the momentum of the 2-D electron gas, confining it at the surface plane, always at 90° with respect to the momentum. This particular entanglement gives rise to the helical spin texture depicted in Fig. 12.24b. In this scenario, the scattering between k and $-k$ states is forbidden by the lifting of Kramers degeneracy (only orthogonal states with opposite spin exist at k and $-k$). Other scattering events, such as the intraband transition highlighted in Fig. 12.24b by a green arrow, can still be allowed by spin conservation rules.

A more exotic spin texture is that of topological surface states, characterized in the ideal case by a spin-

polarized Dirac cone dispersion. In one dimension, the only scattering events connect orthogonal Kramers pairs, i.e., states with opposite momentum and spin, leading to an effective quenching of backscattering. Signatures of reduction of backscattering have indeed been detected by several STM quasiparticle interference experiments using randomly distributed impurities, [12.88, 89] and also monatomic steps [12.50].

In the field of spintronics, spin-momentum locking that is responsible of the unconventional spin textures of these materials represents a novel and effective strategy for controlling spins with charge currents [12.90]. It is, therefore, crucial to understand spin-dependent scattering mechanisms, and how steps may act as structural defects that filter or enhance the spin signal, or even trigger new spin textures. In this respect, vicinal surfaces might pave an exciting route towards spin-texture engineering, spin-polarized confinement, or anisotropic charge and spin transport.

A model example of a nondegenerated spin texture is that of the Shockley state in Au(111). A sizeable Rashba-type interaction in this surface gives rise to the splitting of the spin-degenerated band into two parabolic 100% spin-polarized subbands, shifted in momentum by $0.026\,\text{Å}^{-1}$ with respect to each other, as measured in high-resolution ARPES [12.91–93]. The resulting momentum distribution close to the Fermi level consists of two concentric rings with spin polarization vectors lying in-plane and tangential to the circular shape (Fig. 12.25). According to ab-initio calculations, the largest contribution to spin-splitting on Au(111) originates from its topmost atomic layer [12.94], making it susceptible to modifications in the presence of steps.

Vicinal Au(111) surfaces may, therefore, be utilized to investigate the interplay between spin–orbit coupling and scattering. This is done in Fig. 12.25 for Au(788) and Au(223). High-resolution ARPES measurements reveal an intact pair of Rashba-split Shockley bands propagating parallel to the steps, [12.96], but the broadening induced by both the reduced lifetime and the TWD hinders the observation of any split bands perpendicular to the steps (Fig. 12.25b) [12.60]. Only dedicated experimental techniques, such as spin-resolved ARPES (SR-ARPES) are able to detect the subtlety of the expected changes [12.95, 97]. The top panels of Fig. 12.25c, corresponding to a momentum distribution curve (MDC) perpendicular to the steps (direction marked with dashed lines in the top sketch in Fig. 12.25a), are obtained using SR-ARPES [12.95]. They show that spin textures persist in the presence of different step densities, indicating that neither scattering within the step superlattice nor the disorder introduced by the TWD destroy the overall spin structure. The number of peaks used for the data fitting match the expected components from the top sketch, each presenting its own spin vector. In consequence, the main and umklapp subbands still exhibit 100% polarization and maintain the spin helicity of the Au(111) surface. The spin textures observed closely relate to the flat case independently of the presence of the herringbone reconstruction. The main difference is found in the high step density Au(233) surface, where an increase of spin splitting, Δk, is observed. The cause of this has been interpreted in terms of an effective increase of one of the parameters that determine the strength of Rashba interaction, namely the out-of-plane potential gradient that the electron wave functions experience, as also illustrated by the dependence observed on the Miller indices of the surface, [12.98] the presence of adsorbates, [12.99] or the buckling of the surface layer [12.100].

Rashba interaction on vicinal Au surfaces does not seem to lead to qualitatively different electron scattering behavior due to an efficient spin-conserving intraband transition (Fig. 12.24b) [12.101, 102]. This is reflected on the value of its step-barrier, even higher than for Ag, with negligible SOI, and the endurance of the helical spin texture. Such an analogy of spin-degenerated systems is expected in model Rashba systems, where each Shockley subband is 100% spin polarized and, hence, momentum conserving intraband scattering is allowed. However, the scenario becomes more entangled in other materials with mixed orbital and spin texture. This is the case of the monolayer-thick $BiAg_2$ surface alloy grown on Ag(111), which is characterized by surface bands with record-high Rashba splitting [12.103, 104].

Highly-perfect $BiAg_2$ surface alloy domains can be grown by simply depositing 0.33 ML of Bi on Ag(111), followed by a soft annealing. The electronic structure of the surface alloy near the Fermi level consists of various sets of split parabola, all with negative effective mass, and each one with different spin and orbital composition (Fig. 12.26b) [12.100, 105]. The hybrid p_x–p_y band above the Fermi level is particularly interesting, since its spin–orbital texture is far from the 100% of ideal Rashba systems. In fact, the pair of initial and final states that leads to the spin-conserving intraband scattering observed in Au(111), exhibit spin polarization of opposite sign in $BiAg_2$ (dashed line on the right panel of Fig. 12.26a). Such a scattering process would not be allowed in a spin-conserving process. However, quasiparticle interference measurements performed near an individual step reveal strong interference patterns related to such intraband scattering transitions, as can be seen in Fig. 12.26a [12.100, 105]. Here, we show $\mathrm{d}I/\mathrm{d}V$ spectra acquired along a line perpendicular to

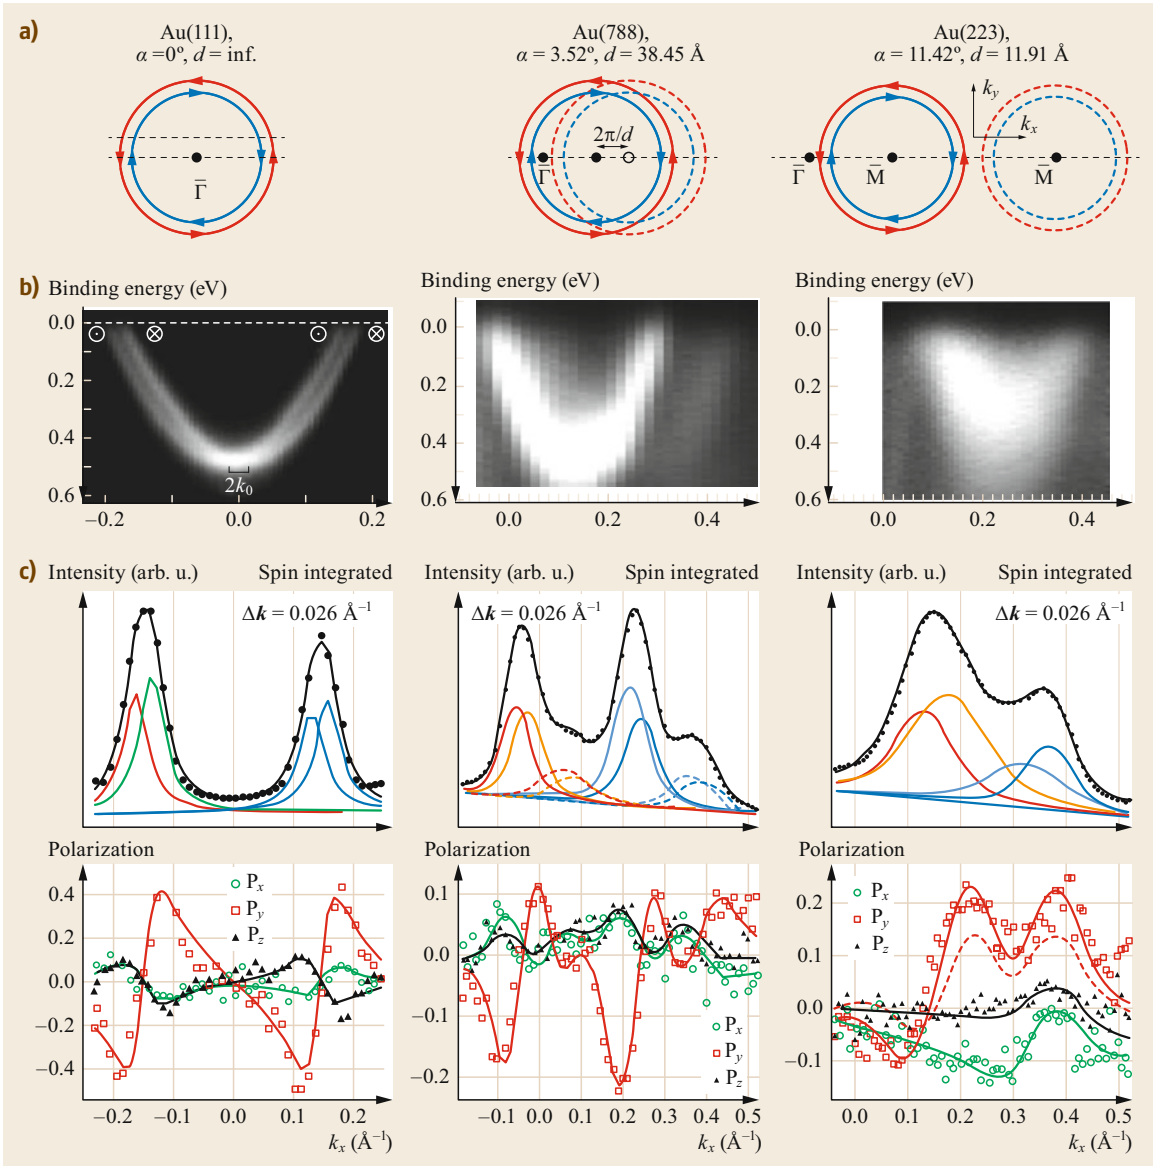

Fig. 12.25a–c Spin-resolved ARPES for Au(111), Au(788) and Au(223). For each surface, rows from *top* to *bottom* consist of: **(a)** graphical representation of the Fermi surface maps for the different miscuts indicating main (*solid circles*) and umklapp states (*dotted circles*); **(b)** spin-integrated band dispersions perpendicular to the steps, taken with $h\nu =$ 21 eV photon energy. Rashba splitting is resolved in the Au(111) surface, but in step arrays of Au(788) and Au(223) TWD broadening effects masks spin splitting; **(c)** spin-resolved MDCs acquired at $E - E_F = -50$ meV with $h\nu = 23$ eV. The *upper graphs* show the spin-integrated intensities that include the necessary peaks to fit the data and directly below the corresponding spin polarization curves for the three spatial directions [12.95]

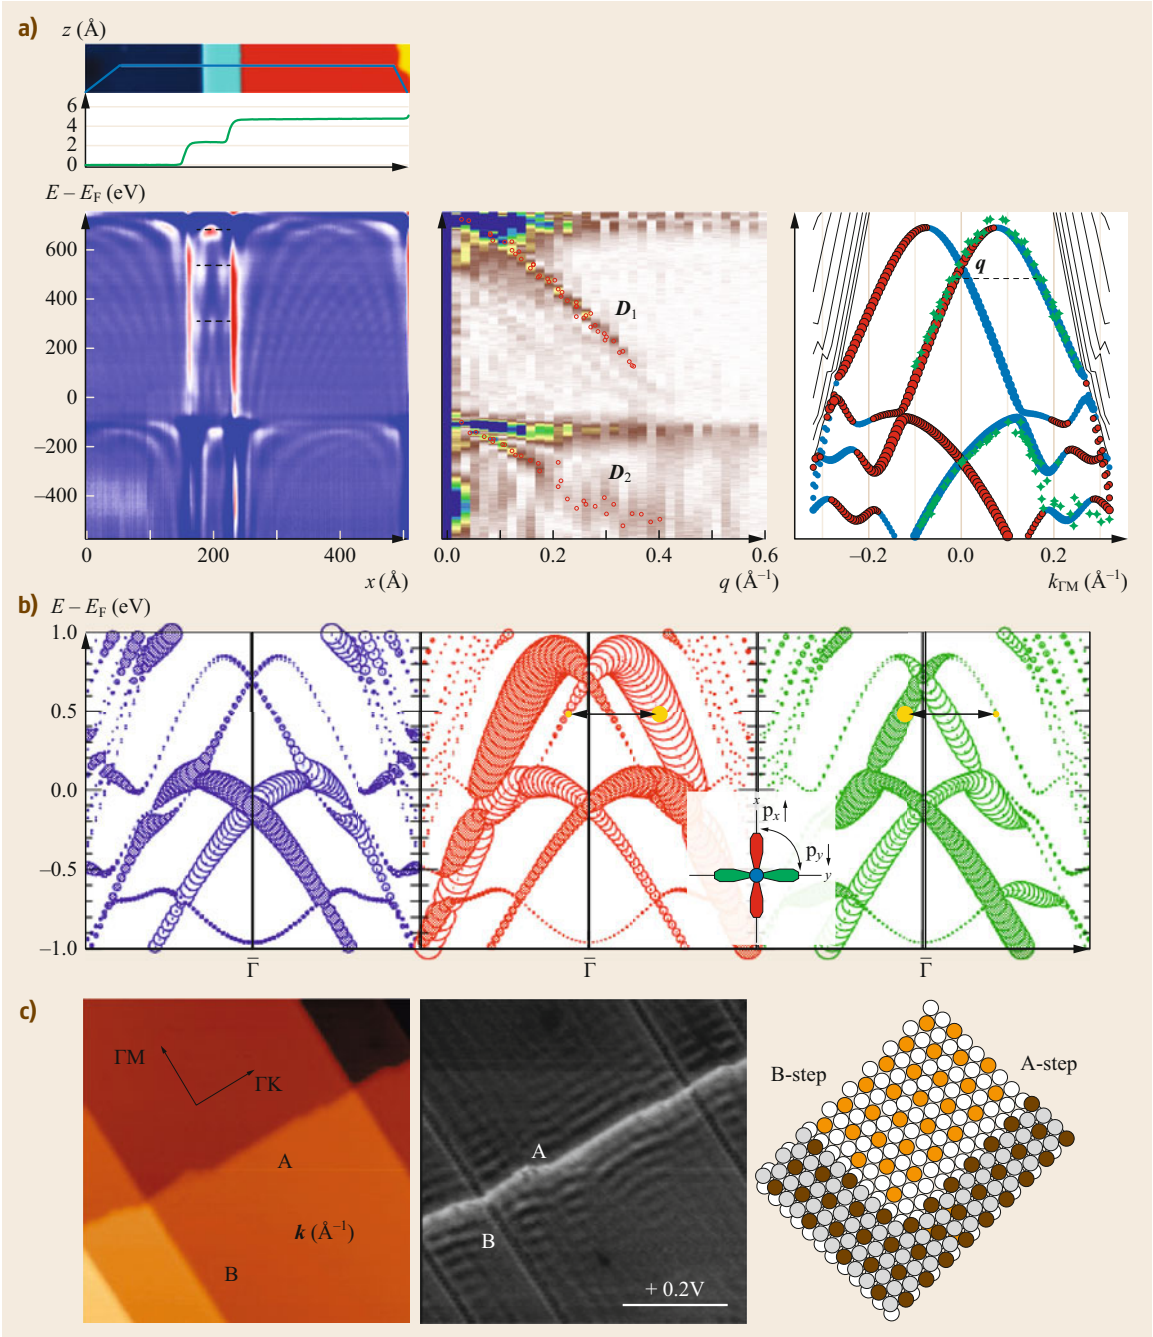
several steps. The energy-dependent quasiparticle interferences found in real space are converted into scattering wavevectors by an FFT transformation along the x-axis (central panel), resulting in two clear branches labeled $\boldsymbol{D}_1$ and $\boldsymbol{D}_2$.

We focus on the $\boldsymbol{D}_1$ branch, which very nicely fits intraband transitions of the unoccupied split bands, as is shown in the right panel of Fig. 12.26a, by making use of the band structure obtained by ab-initio calculations. This can only be explained by considering



that the spin–orbit interaction in the scattering enables combined orbital and spin flips that conserve the total momentum. That is, p_x orbitals of a given spin scatter into p_y orbitals of opposite spin and vice versa (see the inset in Fig. 12.26b). Electron confinement studies on step resonators built on the surface alloy demonstrate that this spin-flip scattering mechanism can be as effective as the conventional spin conserving one in noble metals, leading to negligible transmission [12.105]. The effectiveness of this spin–orbit-dependent scattering mechanism, nevertheless, depends on the presence of Bi, and hence varies with the chemical composition of the step (Fig. 12.26c). The different scattering properties of each step type can be visualized in the

Fig. 12.26a–c Electronic scattering on the $BiAg_2$ surface alloy. **(a)** *Left*: a series of dI/dV spectra acquired along a line crossing a pair of A-steps (see **(c)**). The line is displayed in the topographic image on top. QW states can be observed in the small terrace, whereas larger terraces show oscillations in the continuum DOS. *Center*: Fourier transform of the spectra along the x-coordinate, showing two different branches of scattering vectors $\boldsymbol{D}_1$ and $\boldsymbol{D}_2$. *Right*: ab-initio calculation of the Rashba split bands, with initial and final scattering states resulting from vectors $\boldsymbol{D}_1$ and $\boldsymbol{D}_2$ superimposed as *green diamonds*. The color and size of the points in the band structure correspond to the sign and magnitude of spin polarization in the $\boldsymbol{k}_\parallel \times \boldsymbol{z}$-direction [12.105]. **(b)** Orbital and spin decomposition of the ab-initio band structure. The size of the symbols indicates the Bi p_z (*left*), p_x (*middle*), and p_y (*right*) contribution to the state. Opposite spin directions are shown by *full* and *empty symbols*. *Inset*: combined spin and orbital flip occurring in the scattering between the states marked by the *yellow dots* in the graph (same as the *green arrows* in **(a)**) [12.105]. **(c)** Topography (*left*) of a region with different step types and simultaneously acquired dI/dV map (*right*) displaying interference patterns from scattering at steps. The standing waves parallel to A-steps are clearly more pronounced. The chemical composition of each step type is illustrated on the *right schematics* ◄

spectroscopic map of Fig. 12.26c, where A-type steps induce significantly more pronounced standing waves than B-type steps, where the Bi concentration is more dilute.

The experiment discussed above was carried out utilizing individual steps on the flat $BiAg_2$ surface grown on Ag(111). However, in contrast to the more challenging case of topological insulators, the growth of stepped $BiAg_2$ alloys can be envisioned by deposition of Bi on vicinal Ag(111) surfaces. In fact, exciting phenomena may arise when combining spin–orbit interaction with real stepped surfaces, as experimentally demonstrated for several high Miller index bismuth surfaces, namely Bi(441) and Bi(114). With, respectively, 45° and 56° of miscut, they cannot be considered vicinal to the (111) surface, and thus their electronic structure cannot be described in terms of the 2-D states of the (111) surface under a periodic step potential. In fact, the STM to-

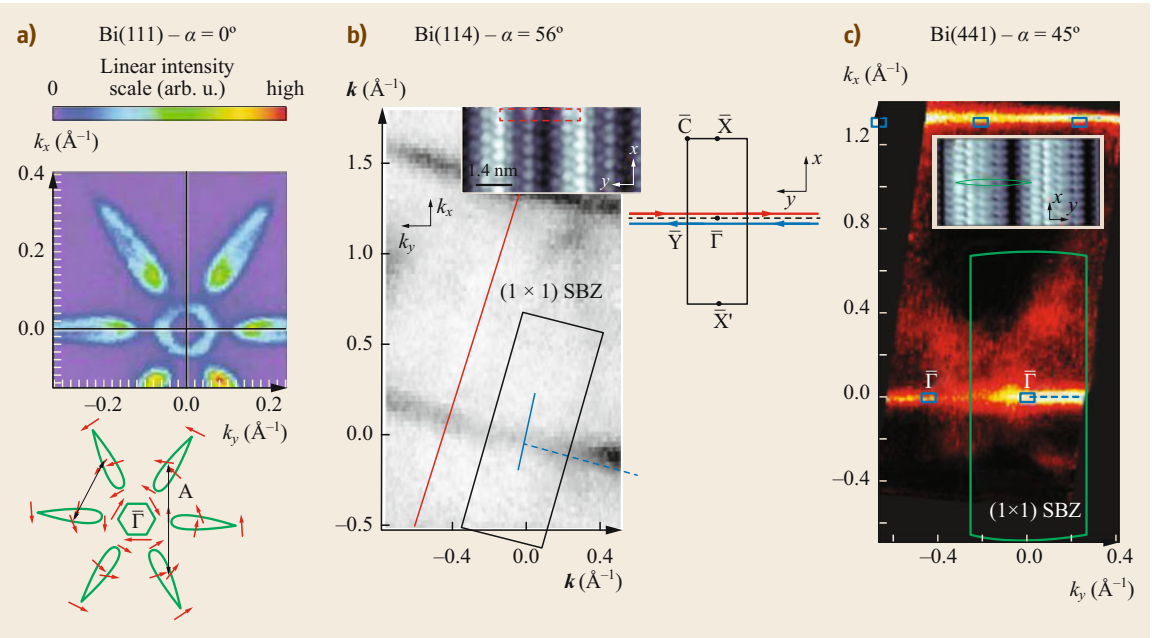


Fig. 12.27a–c Fermi surface of Bi(111), Bi(114), and Bi(441): the **(a)** Bi(111) flower-like contour presents a definite spin texture (sketched at the *bottom*) that transforms into dominant 1-D-like streaks in the direction perpendicular to the steps for both vicinal surfaces. Adapted from [12.106], with permission from Elsevier. **(b)** Bi(114) [12.107] and **(c)** Bi(441). Adapted from [12.108], with permission from the American Physical Society. These 1-D states are nondegenerate and give rise to Fermi contours consisting of two narrowly separated parallel lines with mainly in-plane opposite spin vectors, as schematically shown in the Bi(114) and Bi(441) graphs. Such small spin splitting cannot be resolved with spin-integrated ARPES. The complex atomic structure of these vicinal surfaces is shown in the STM images of the *insets* (**(a)** and **(c)** adapted from [12.106, 108])

pographic images show strong surface reconstructions where the terraces lack single (111) planes separated by monatomic steps. Figure 12.27 compares the Bi(111) surface states with those of Bi(114) and Bi(441). The flat surface exhibits a flower-like Fermi contour with oppositely rotating in-plane spin directions, a signature of the spin–orbit interaction in this material (Fig. 12.27a). In the stepped surfaces, the 2-D contour is replaced by extended 1-D streaks in the direction perpendicular to the steps, a signature of 1-D localization in such directions (Fig. 12.27b,c). Interestingly, the 1-D states are also spin-split, as demonstrated by SR-ARPES measurements [12.107, 108]. Constant energy surfaces in the vicinal planes consist of two narrowly separated parallel lines mainly featuring in-plane opposite spin vectors, as shown in the sketch in Fig. 12.27b,c. These, together with the Dirac-like dispersion along the steps, make these spin-polarized states analogous to the quantum spin Hall states of topological insulators [12.108]. Similar one-dimensional topological states have also been observed at the edges of bulk Bi islands [12.109] and isolated Bi bilayers [12.110].

12.7 Summary and Outlook

Vicinal surfaces are characterized by a varied atomic coordination and by a nanoscale step-edge corrugation, both leading to significant changes in surface electronic states. All electron wavefunctions are affected, from deep core levels to surface states, thereby influencing the variety of physical-chemical phenomena that occur at the surface–vacuum interface, such as chemical reactions and epitaxial growth. From this perspective, selecting different vicinal planes by simply changing miscut angle and azimuthal orientation, opens vast possibilities. To this aim, the use of curved surfaces with a smooth variation of the miscut are crucial, not only to choose the optimal vicinal plane for practical applications, but also, as shown in this chapter, to understand the subtle electronic effects that characterize vicinal surfaces and their relation to its structural properties, such as the atomic relaxation occurring around surface steps.

Future research based on curved crystals will surely be aimed at three different directions: nanostructure growth, chemical reactions and catalysis, and electron scattering. The growth of low-dimensional structures using vicinal surfaces, such as nanowires and nanoribbons [12.111], can notably gain from the use of curved surfaces, since they can speed up the choice of the appropriate surface template. The combined use of curved crystals and surface-sensitive techniques that operate in real conditions, such as ambient-pressure core-level photoemission, may considerably help the advance in heterogeneous catalysis research [12.112]. For example, to investigate the balance between more active (step) to less active (terrace) sites, which determines the optimal mass flow of reactants, or to directly visualize different active sites (steps and kinks) on the same sample, i.e., under the same reaction conditions [12.15].

An important amount of research is still necessary to shed light upon the fundamental scattering processes at single steps and vicinal surfaces. Crucial spectroscopic magnitudes connected to the very nature of the step-potential barrier, such as the lifetime, have barely been investigated. In this sense, pump–probe techniques, such as two-photon photoemission are best suited. Early results on image potential states of Cu vicinals validated key properties, such as the existence of quasi-elastic intraband and interband decay channels [12.113], the asymmetric inelastic decay for electrons moving up and down the steps [12.63], and the change in the modulation plane across the image-state series [12.55]. The use of curved surfaces could foster more systematic, accurate investigations. This also applies to research on spin-dependent scattering at steps, in both single-crystal and epitaxial systems [12.114], in combination with spatially averaging spectroscopic techniques, such as SR-ARPES. The early experiments on vicinal Au(111) and stepped Bi surfaces discussed in this chapter reveal complex and intriguing spin-dependent properties. In this particular field, as demonstrated by the impact of quantum well research on magnetic recordings in past decades [12.115], the knowledge obtained has the prospect of becoming key to future devices in the field of spintronics.

J. Enrique Ortega

Departamento Física Aplicada I
Universidad del País Vasco
San Sebastian, Spain

Centro de Física de Materiales
CSIC/UPV-EHU-Materials Physics Center
San Sebastian, Spain
enrique.ortega@ehu.es

J. Enrique Ortega received his PhD (1990) in Physics at the Autonomous University of Madrid. Ortega became known during the 1990s for his seminal works on metallic quantum wells. He later pioneered the study of electronic states of stepped metal surfaces. He has been paving the way to the use of curved crystals on physical-chemical research of surface phenomena linked to atomic steps. He has coauthored over 140 peer-reviewed publications.

Aitor Mugarza

Institut Catalá de Nanociencia i Nanotecnologia (ICN2)
Bellaterra–Barcelona, Spain

Aitor Mugarza received his PhD in Physics at the University of the Basque Country (2002). He was appointed Group Leader of the Atomic Manipulation and Spectroscopy Group (2013) and ICREA Research Professor (2015) at ICN2. He has carried out pioneering studies on the use of stepped surfaces for electron confinement and band engineering. He has coauthored over 50 peer-reviewed publications.

Frederik Schiller

Centro de Física de Materiales
CSIC/UPV–EHU–Materials Physics Center
San Sebastian, Spain

Donostia International Physics Centre
San Sebastian, Spain
frederikmichael.schiller@ehu.eus

Frederik Schiller (Zwickau, Germany, 1971) received his PhD in Physics at the Technische Universität Dresden. He moved to Spain in 2003 and became a permanent staff member of the Spanish Research Council in San Sebastian. He has coauthored more than 50 peer-reviewed publications. His research is focused on the magnetic and electronic structure of low-dimensional systems and catalytic reactions at stepped surfaces and curved crystals with varying density of steps.

Jorge Lobo-Checa

Instituto de Ciencia de Materiales de Aragón (ICMA)
CSIC–Universidad de Zaragoza
Zaragoza, Spain
Departamento de Física de la Materia Condensada

Universidad de Zaragoza
Zaragoza, Spain

Jorge Lobo-Checa obtained his Doctoral Degree in Physics in 2004 from the Autonomous University of Madrid. He moved to CFM (San Sebastian, 2012–2015) and established at the Material Science Center of Aragon (Zaragoza, Spain) in 2015. He has coauthored more than 50 publications. His research interests lie in the investigation of the electronic and physical-chemical properties of low dimensional systems, focusing on projects related to curved crystals, porous organometallic networks, and on-surface synthesis reactions.

Martina Corso

Centro de Física de Materiales
CSIC/UPV–EHU–Materials Physics Center
San Sebastian, Spain

Martina Corso received her PhD from the University of Zürich (Switzerland 2006). She occupies a Tenured Scientist position at the Spanish Research Council CSIC in the Centro de Física de Materiales in San Sebastián. Her research has been devoted to the study of physical-chemical properties of low-dimensional nanostructures grown in-situ on crystal surfaces. She has contributed to 41 publications in peer-reviewed scientific journals.

13. Imaging at the Mesoscale (LEEM, PEEM)

Alessandro Sala

The capability to display images containing chemical, magnetic, and structural information and to perform spectroscopy and diffraction from a μm-sized area makes cathode lens electron microscopy one of the most used and reliable techniques to analyze surfaces at the mesoscale. Thanks to its versatility, LEEM/PEEM systems are currently employed to study model systems in the fields of nanotechnology, nanomagnetism, material science, catalysis, energy storage, thin films, and 2-D (two-dimensional) materials. In this chapter, we will present a brief but complete review of this class of instruments. After a historical digression in the introductory section, we will first show the basic operating principles of a simple setup and then the elements that can be added to improve performance. Later, two sections will be dedicated to LEEM and PEEM, respectively. In both cases, a theoretical discussion on the contrast mechanisms will prelude to a showcase of the operating modes of the instrument, with clear examples that will show the best performance available today. Finally, a brief discussion about the future developments of cathode lens electron microscopy will close the chapter.

Cathode lens electron microscopy is a technique that uses slow electrons as information carriers [13.1]. Differently to the case of scanning or transition electron microscopy, in this system electrons interact with the probe at very low kinetic energy, below a few hundred electronvolts (eV). In such a range, the inelastic mean free path (IMFP) ensures a probing depth of just a few atomic layers, making cathode lens microscopy a surface-sensitive technique. It is therefore not surprising that its history parallels the history of surface science since the early years. The first example of an emission microscope with slow electrons goes back to 1932, a few years after the *Davisson* and *Germer* experiment [13.2], when *Brüche* and *Johansson* produced the first thermionic emission microscope [13.3, 4]. They used coils as magnetic lenses to produce magnified images of a hot cathode's surface on a fluorescent screen. Glass enclosures and diffusion pumps provided the vacuum system, necessary to avoid dispersion of the electrons. One year later, *Brüche* built the first prototype of the photoemission electron microscope (PEEM) [13.5], using a cold cathode illuminated by UV light (Fig. 13.1a). These milestones and the rise of theoretical electron optics gave birth to a flourishing scientific community. Several theoretical calculations concerning magnification, chromatic and spherical aberration of magnetic lenses, electrostatic mirrors and einzel lenses, were made available [13.6–9]. It was soon understood [13.10] that resolution performance could be enhanced well above that of light microscopy if electrons travel through the lens system at relatively high energies—tens of keV. The suggested setup was then to place the sample on a negative bias, i.e., using it as a cathode, in order to accelerate electrons after take-

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,

off. This basic principle is still used today for modern microscopy. The development of electron optics then suffered a sudden pause during the 1940s, not only because of World War II, but also because of the technological limitations of that age.

The *renaissance* period of the 1960s coincides with the development of UHV technology: several new solutions, such as ion pumps, Cu gaskets, valves and sample transfer systems, boosted surface science and hence the creation of more sophisticated instruments. In 1962, *Ernst Bauer* conceived the low-energy electron microscope (LEEM) [13.12, 13], which uses elastically backscattered electrons as a probe (Fig. 13.1b). In this system, electrons generated by a gun are decelerated to a few eV before interaction with the surface. Once backscattered, the outgoing electron beam is separated from the incoming one by a magnetic field, and then processed by the lens system. In the same period, emission electron microscopy reached a period of maturity, when the demonstrated resolution of $\approx 10\,\text{nm}$ made explicit new limitations, such as lens aberration and astigmatism, energy dispersion, electron detection, surface stability and cleanness. The attention of the microscopy community was then gradually driven away by the success of transmission electron microscopy (TEM); during the 1970s the LEEM project was frozen, while the few PEEM systems were mainly dedicated to investigation of biologic systems [13.14] and test additional light sources, such as lasers and synchrotron radiation [13.15]. Only in the following decade did cathode lens electron microscopy manifest itself as one of the principal surface science tools. Many up-

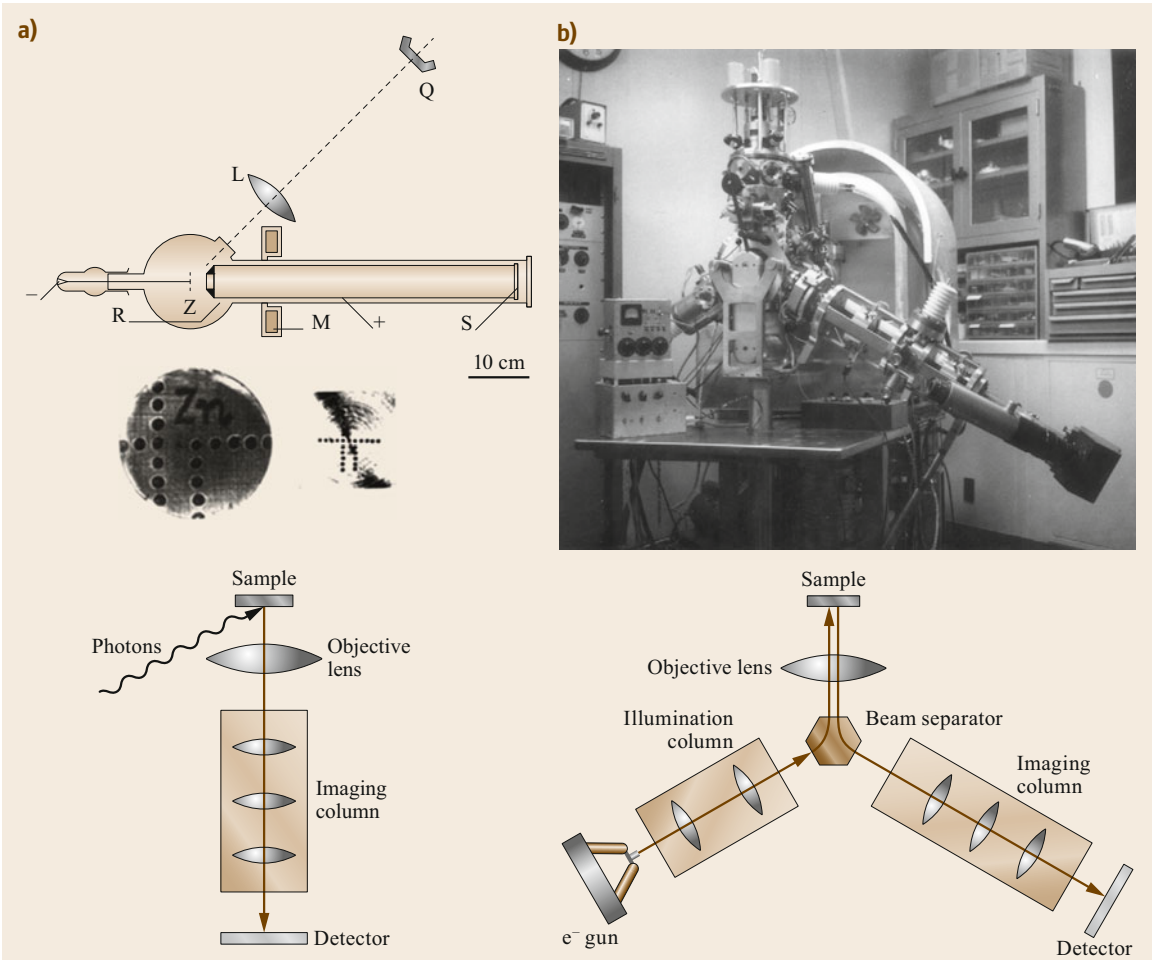

Fig. 13.1 (**a**) *Top*: schematic of Brüche's first PEEM system and the first PEEM image of a scraped Zn plate with holes (Reproduced from [13.5] with permission, copyright 1933 Springer Science + Business Media). *Bottom*: scheme of an ideal PEEM system. (**b**) *Top*: picture of the original LEEM instrument in the 1960s (Reproduced from [13.11] with permission, copyright 2012 Elsevier). *Bottom*: scheme of an ideal LEEM system with 120° deflection

grades were introduced, enhancing the versatility and the power of such systems in the investigation of surfaces at the mesoscale. The microscopy approach was combined with other investigation methods such as spectroscopy and diffraction, already known for their successful application in surface science. In 1981, low-energy electron diffraction (LEED) patterns were displayed in LEEM systems using the backfocal plane of the objective lens [13.16–18], giving the possibility to spatially select the probing area. *Tonner* et al. demonstrated the feasibility of PEEM with synchrotron radiation in the late 1980s [13.19], while *Ertl*'s group at the Fritz Haber Institute increased interest in the chemistry community for PEEM showing the oscillatory behavior of gas adsorption on active surfaces during catalytic reactions [13.20]. A few years later, the first cathode lens system equipped with a hemispherical energy analyzer (spectroscopic photoemission and low-energy electron microscope, SPELEEM) was planned and later hosted at BESSY and Elettra synchrotrons. The first x-ray PEEM (XPEEM) image, i.e., made with core-level electrons photoemitted by x-rays, was published in 1998 [13.21]. In the same years, two LEEM systems were equipped with a spin-polarized electron gun [13.22, 23], pioneering magnetic imaging. Magnetic contrast was achieved also in PEEM using circular and linear dichroism of polarized light [13.24]. The development of new operation modes continues today, with the construction of aberration-free systems towards the ultimate spatial resolution [13.25–27], the use of pulsed light to enable time-resolved dynamic microscopy [13.28], and the design of special sample holders to modify the mechanic, electric, and magnetic properties of the probe in operando [13.29]. Moreover, firms started to create commercial versions of LEEM and PEEM systems. The most notable examples are Elmitec GmbH in 1995 (based on Ernst Bauer's design) and SPECS GmbH (based on Ruud Tromp's design) [13.30, 31].

Although the cost of such systems is relatively high compared to other microscopes, the openness of the labs to external users, e.g., at the synchrotron endstations, helped to create a vast and heterogeneous user community. Nowadays, cathode lens microscopy is widely appreciated by surface scientists. Thanks to its multidisciplinarity and to the interplay between microscopy, spectroscopy and diffraction, it has become an essential technique for the overall comprehension of surface phenomena.

13.1 Cathode Lens Microscopy

13.1.1 Operating Principles

The first optical element electrons run into after takeoff from the sample surface is also the most important. The cathode lens, often integrated with other refocusing elements and called the objective lens, must both accelerate the electrons emitted from the sample and form a first magnified image. To do so, the sample is placed at negative potential V of about 10−50 kV to act as a cathode. The first electrode is grounded and attracts the electrons towards its central aperture, where they pass through the other magnetic or electrostatic elements of the objective lens. An equipotential plot of a lens is displayed in Fig. 13.2a. The overall focal length is determined by two opposite contributions, one divergent generated by the anode aperture and one convergent generated by the other elements of the lens [13.32, 33]. Figure 13.2b helps to explain the relevant physics in detail.

When electrons are emitted from the surface at a distance L from the entrance aperture of the microscope with kinetic energy E_0 and angle θ_0, the acceleration in the quasihomogeneous electric field in the cathode lens imposes a parabolic traj>ectory (in blue). This real situation can be converted to a virtual frame, in which electrons assume a linear trajectory and appear to have originated from a virtual image plane located at a distance $2L$ from the anode (green trajectory). Since in the real case the anode aperture distorts the electric field, the optical effect is to create a thin diverging lens with focal length $-4L$, called the *aperture lens* [13.35]. The final virtual image is then placed at a distance $4L/3$ from the anode (red trajectory), magnified by a factor $2/3$. After the aperture, the field of the other elements of the objective lens magnifies the electron beam by a factor of M_M.

This conversion can be defined as a change of relative coordinates, from real spatial and angular coordinates at takeoff (x_0, θ_0,) to virtual coordinates (x, θ) [13.36]. Given the overall lateral magnification of the objective lens M and defining the immersion factor as $k = E/E_0$, one has the following relations

$$M = \frac{2}{3} M_M \,, \qquad M_A = \left(k^{\frac{1}{2}} M\right)^{-1} \,,$$

$$\frac{x}{x_0} = M \,, \qquad \frac{\theta}{\theta_0} = M_A \,, \quad \frac{q_0}{q} = M \,,$$

where $q_0 = \theta_0/\lambda_0$ and $q = \theta/\lambda$ are the spatial frequencies parallel to the surface in the real and virtual plane respectively, and M_A is the angular magnification. In the case of low-energy electrons, i.e., if E_0 is just a few eV,

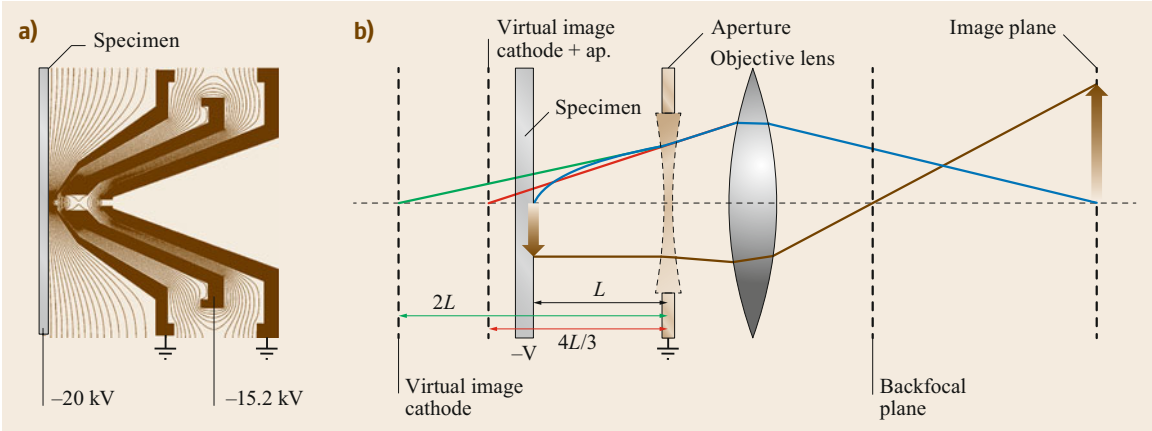

Fig. 13.2 (a) Field contour plot of a tetrode objective lens. The equipotential lines are 1250 V apart (Reproduced from [13.34] with permission, copyright 2002 AIP Publishing). subfigref Scheme of the cathode immersion lens

the application of a potential of a few tens of kV guarantees a large immersion factor.

In the simplest configuration, the objective lens displays the magnified image to the electron detector, e.g., a phosphorescent screen. In this case, only a limited magnification can be reached: the overall lateral magnification of the modern objective lens ranges typically between 15 and 40. To increase the performance of the microscope, a series of magnetic and electrostatic lenses can be added, to constitute the so-called *imaging column*. The focal length of the lenses can be controlled by changing the current of magnetic lenses, or the potential of electrostatic lenses. Electrons travel through the imaging column with kinetic energy equal to $E = E_0 + eV$. Since usually electrons can escape from a surface with different E_0 simultaneously, their trajectory in the imaging column can differ considerably from the optimum one. To guarantee that electrons with a selected initial kinetic energy pass through the lenses along the optimal trajectory, a tunable bias must be subtracted from the potential V between sample and aperture. The bias value, also called *start voltage* (V_0), imposes the optimal trajectory and speed to only the electrons with initial kinetic energy $E_0 = eV_0$. For them, the final kinetic energy will be $E = eV$. Electrons with different kinetic energy still pass through the objective lens, but can be easily filtered at a later stage due to their different trajectories. Moreover, the fixed trajectory and speed of the electrons allow the lenses of the imaging column to be set once and for all. This not only improves the usability of the instrument, but permits apertures and slits to be placed to mold the image in a convenient plane.

The advantage of having an imaging column is twofold. Besides the improved magnification, it gives access to the angular distribution of the emitted electrons. In optics, for objects a finite distance away, rays that leave the object with a given angle (Fig. 13.2b, brown trajectory) cross at a precise point in the backfocal plane of the objective lens. There, the image maps the distribution of electrons as a function of their emission angle, i.e., in the reciprocal space. In the case of electrons backscattered or photoemitted from a crystalline surface, this plane contains the diffraction pattern. The imaging column can then be set to display a magnification of the backfocal plane on the screen instead of the image plane.

At the end of the imaging column, it is possible to place an *energy filter* that excludes electrons with different kinetic energy. By knowing the displacement as a function of energy, one can filter out the electrons by placing a slit of given size. Typically, the energy analyzer is optically neutral, i.e., the entrance plane is displayed in the dispersive plane at the exit with unit magnification. Finally, another series of lenses project the desired plane onto the detector.

In conclusion, three different operation modes can be defined:

- In the *Microscopy* mode (Fig. 13.3a) the image plane is displayed on the screen. In the imaging column, the backfocal plane is reproduced and an aperture (called *contrast aperture*) can be inserted to limit the acceptance angle of the electrons. If an energy analyzer is installed, the imaging column is set to display the reciprocal plane at its entrance. The energy slit is placed at the dispersive plane and only lets electrons with a selected kinetic energy pass. The projector displays the image plane back onto the detector. Since the apertures are inserted on diffraction planes, the real image is still fully available.

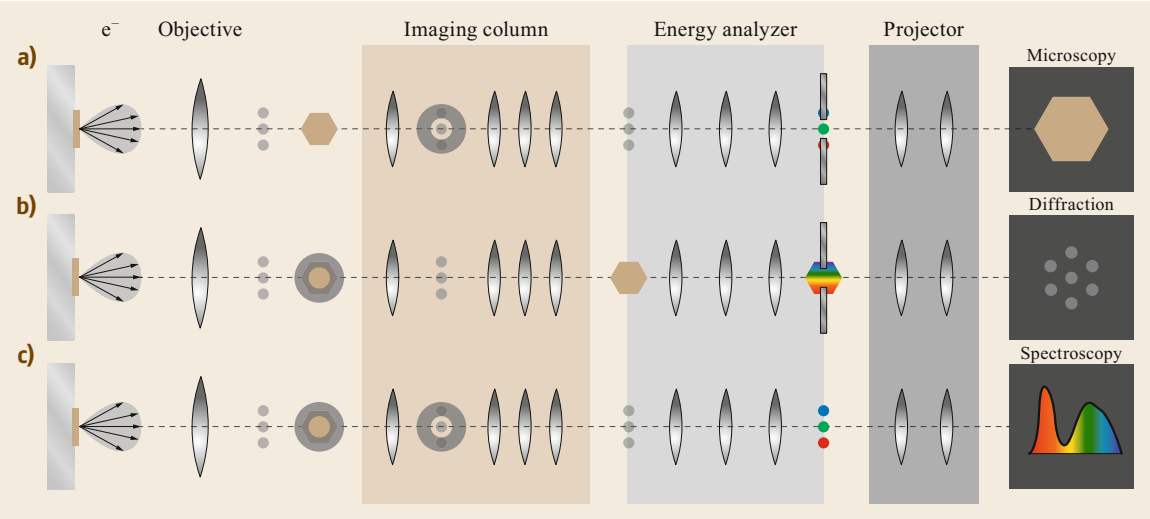

Fig. 13.3a–c Scheme of PEEM optics with energy filtering. Three main operational modes are presented: **(a)** microscopy mode, **(b)** diffraction mode, **(c)** spectroscopy mode. The *hexagon* represents the image plane, while the *gray dots* represent the diffraction plane. *Rainbow colors* symbolize the dispersive plane. The *gray ring* indicates the presence of an aperture

- The *Diffraction* mode (Fig. 13.3b) displays the distribution of electrons in the reciprocal space. In this case, no contrast aperture has to be placed. Nonetheless, an aperture in the image plane of the objective lens, called the *field limiting aperture*, can filter the electrons in the real space: the diffraction image is then made only from electrons emitted in a particular area. The imaging column transfers the image plane to the entrance of the energy filter: the slit at the dispersive plane does not influence the reciprocal image. The projector converts the image plane at the exit of the analyzer to the diffraction plane.
- In the *Spectroscopy* mode (Fig. 13.3c) the projector magnifies the dispersive plane at the end of the energy filter. In this case, both the contrast aperture and the field-limiting aperture can be inserted, to limit conveniently the acceptance angle and the probed area. The reciprocal plane is usually displayed at the entrance of the energy analyzer. The dispersive plane then looks like a line with modulated intensity. The intensity line profile over the spread electron beam reveals the energy distribution of the electrons.

The easy switch between the three operational modes is at the origin of the versatility of cathode lens microscopy. In addition, the insertion of apertures and slits in the convenient planes allows microscopic, spectroscopic, and diffraction information to be combined in a single experiment: the active filtering in real space, reciprocal space, and kinetic energy can be simultaneously activated to obtain a unique characterization of the probed surface.

13.1.2 Instrumentation

The simplest setup, with objective lens, imaging column and electron detector, is already capable of performing microscopy and diffraction measurements on surfaces. Over the years, cathode lens microscopes have become more sophisticated, with the addition of multiple optical elements. This section will show the most common components available today, with a brief discussion on the working principles and the experimental advantages introduced.

Beam Separator

The beam separator is a magnetic element that imposes different trajectories to electron beams with opposite direction by using the Lorentz force. While in standard PEEM it has no practical use, it is an essential element in LEEM and in aberration-corrected instruments equipped with an electrostatic mirror. The decoupling between incident and reflected electrons allows a separate treatment of the two beams, i.e., in LEEM a full-field detection of the illuminated area, with no shadows cast by the electron gun (like for standard LEED optics). The beam splitter is usually placed after the objective lens, so apertures and slits can be introduced along the incident or the reflected path separately.

The first separator installed in the original LEEM was a simple *Archard–Mulvey* type with 10° deflection [13.39]. Very soon it became clear that the magnetic field strongly impacts the image quality [13.16], therefore more sophisticated and multipolar MPAs were developed. Over the years, two geometries emerged as standard: 120° deflection (Bauer/Elmitec) and 90° de-

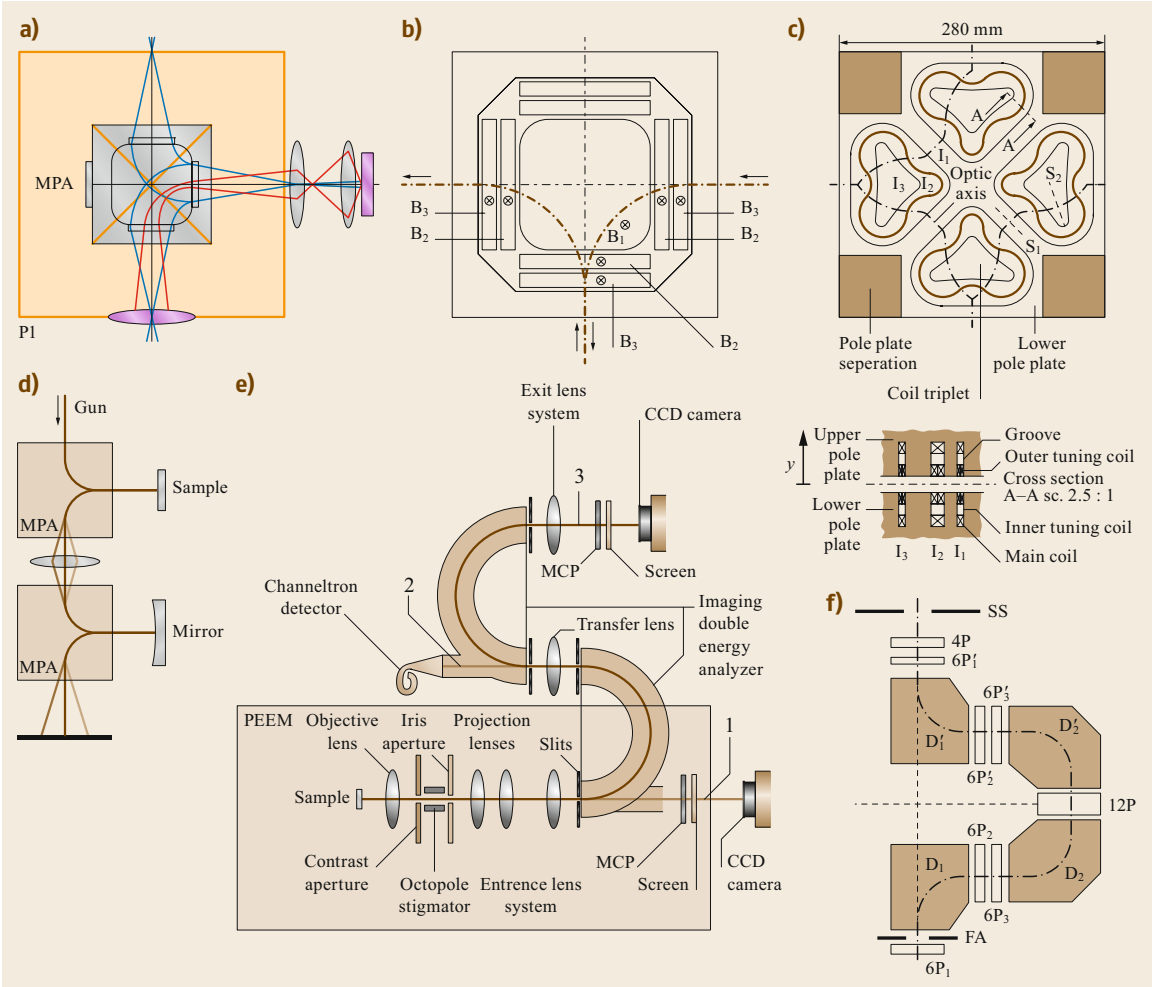

Fig. 13.4a–f Scheme of beam separators **(a–c)** and energy filters **(d–f)** used in cathode lens microscopy. **(a)** Diagram of the magnetic prism array (MPA) used in Tromp's IBM LEEM-II system. The *orange boxes* around the MPA indicate the position of diffraction planes. Intermediate image planes are located on the MPA diagonals (Reproduced from [13.26] with permission, copyright 2010 Elsevier). **(b)** Layout of Mankos' magnetic prism array with four pairs of rectangular sectors (Reproduced from [13.37] with permission, copyright 2007 Elsevier). **(c)** Midsection view of the twofold-symmetric beam separator that equips SMART microscope. The induced dispersion is depicted with *light brown lines* (Reproduced from [13.26] with permission, copyright 2010 Elsevier). **(e)** Schematic layout of the NanoESCA instrument equipped with the imaging double energy analyzer. The three electron paths are indicated: (1) PEEM mode, (2) selected-area spectroscopy, and (3) energy-filtered imaging (Reproduced from [13.38] with permission, copyright 2005 IOP Science). **(f)** Schematic layout of the Omega filter equipping SMART. Dipoles (D), quadrupoles (4P), hexapoles (6P), and dodecapoles (12P) are highlighted. The introduction of a field aperture (FA) and a selection slit (SS) enables the filtering (Reproduced from [13.25] with permission, copyright 1997 Elsevier)

flection (Tromp/SPECS, SMART, PEEM3, and others). For the first case, unfortunately no detailed information has been published. In the other case, several solutions have been employed. In the square MPA used by *Tromp* (Fig. 13.4a) a large central squared and four rectangular magnetic field segments provide the deflection and a stigmatic refocus of the electron beam [13.26, 40], so that the images produced at the entrance and exit plane are equivalent. The lenses of the microscope are set to display the focused incoming electron beam and the

outgoing diffraction plane at the entrance planes. With this geometry, the image plane is created on the diagonal plane of the MPA. The contrast aperture is then displaced in the exit plane of the MPA, together with the first projective lens. A similar design, but with more elements, is used in a LEEM with dedicated optics for high-throughput performance (Fig. 13.4b; [13.37]). In this case, four pairs of smaller rectangular sectors, in which the magnetic field is about three times stronger, surround the central squared magnetic field. The advantage to have a pair of independent coils per side is that the same 90° deflection can be achieved with different pairs of flux density values, favoring a more precise alignment of the device and allowing a larger field of view without significant distortions.

It is worth noting that the Lorentz force imposes different deflection to electrons with different kinetic energy, i.e., the MPA displays a chromatic dispersion on the exit plane. As will be discussed in Sect. 13.1.2, *Energy Analyzers*, the beam deflector can be used as an energy filter. Moreover, the four sectors can be independently set to deploy different magnetic field strengths, so as to deflect electron beams when the incoming and outgoing electrons have different kinetic energy. This is the case of secondary electron microscopy (SEM) and Auger electron microscopy (AEM), which use slow secondary electrons or Auger electrons as information carriers. In both cases, the kinetic energy of the emitted electrons is lower than the one of the electrons used for illumination: the beam separator must then be set to deflect properly both beams along the optimum trajectory.

The performance of beam separators became more crucial with the advent of aberration-corrected instruments. In LEEM/PEEM systems, the compensation of aberrations is made with the introduction of a particular electrostatic mirror along the electron path (Sect. 13.1.2, *Aberration Correctors*). Its application requires a second deflection that separates entering and reflected beams. The beam separator used for this purpose needs not only to be stigmatic and distortion-free, but also with no chromatic dispersion. To do so, two solutions have been employed. The first is to use two identical deflectors, one in front of the objective lens and one for the electrostatic mirror, connected by transfer optics. In this case, most of aberrations and the chromatic dispersion are canceled out by symmetry. Rose and Preikszas proposed a second solution with the development of a highly symmetric four-quadrant beam separator (Fig. 13.4c; [13.41]), used successfully by SMART and PEEM3 instruments [13.25, 27, 42]. Each quadrant contains a coil triplet that produces two regions with opposite magnetic field. Electrons pass through the field of two coils for every 90° deflection. The shape of the triplet is such that the fields are axially symmetric and point symmetric about the diagonal planes of the beam separator (S_1) and the bisector plane of the coil triplet (S_2). This double symmetry ensures automatic compensation of deviations and dispersion up to second order. Since the Rose deflector has four quadrants, it can be used for both deflections required by the objective lens and the mirror.

Energy Analyzers

As seen in Sect. 13.1.1, the energy filtering of electrons activates a third, scientifically very important operating mode of cathode lens microscopy. The most logical way to filter electrons with different kinetic energy is to exploit their different trajectories along the optical path and to cut them out with an aperture. The energy window ΔE around the pass energy E required to perform active spectroscopy of photoemitted electrons is typically below 200 meV; since E is some tens of keV, the order of magnitude of the resolving power $E/\Delta E$ must be considerable, about 10^5. The simplest device that acts as an energy filter is the beam separator. The brightest example of this kind is the aberration-corrected LEEM developed by *Tromp*, equipped with two identical deflectors (Fig. 13.4d; [13.26]). In this setup, the MPAs are connected by a transfer lens, which resends the dispersed image at the exit of MPA1 to MPA2. This double pass guarantees an achromatic image on the electrostatic mirror. After a second pass through MPA2, the newly formed dispersive plane is used to filter electrons on a narrow energy window with a slit. The low dispersion of the beam separator, 6 µm/eV, allows a proved energy resolution of 250 meV.

To achieve better resolution performance, a dedicated energy analyzer with larger dispersion is necessary. The fact of having a separate device to filter electrons has a few further advantages. In fact, despite the more complicated setup, it allows full control over the energy window and the pass energy. Moreover, it enables active filtering in the *diffraction* mode if the image plane is projected at its entrance, as mentioned in Sect. 13.1.1. The first spectroscopic instrument, the SPELEEM [13.21, 43], was equipped with an electrostatic hemispherical deflector analyzer (HDA), a common solution for filtering in photoelectron spectroscopy. In the analyzer electrons travel through the space between two concentric hemispheres held at different potentials. The electrostatic field disperses the electrons depending on their kinetic energy around an optimal trajectory, given by particles with a well-defined *pass energy*. The resolving power $E/\Delta E$ of an HDA is typically 10^3–10^4; therefore for cathode lens microscopy it is necessary to slow down electrons with a dedicated retarding lens from E (few tens of keV) to a pass energy of 1 keV or less. Such deceleration

is a critical parameter, since the resulting immersion factor expands the angular spreading of the electron beam and degrades the lateral and the energy resolution via spherical aberrations. In the first version of SPELEEM the pass energy in HDA was 1800 eV and the demonstrated energy resolution was 0.5 eV. The optimized commercial version by Elmitec lowered the pass energy to 900 eV to obtain a reported energy resolution of 110 meV in *spectroscopic* mode and about 150–200 meV in the other modes [13.44]. The passage through an HDA induces second-order aberrations at the exit plane. Their correction can be achieved with the introduction of a second twin HDA (Fig. 13.4e). This configuration, called the imaging double energy analyzer (IDEA), equips the NanoESCA PEEM [13.38, 45]. The path symmetry forces the electron trajectories to coincide after the double passage, thus generating an achromatic image at the exit plane. The energy filtering in *imaging* and *diffraction* mode is obtained with the introduction of a slit in the dispersive plane placed between the HDAs. This system is capable of a demonstrated energy resolution of 12 meV with pass energy 15 eV. Higher pass energies, more suited for core-level spectroscopy and imaging, degrades the resolution to 50–100 meV. Remarkably, NanoESCA can also work as a single-pass photoelectron energy analyzer and as a classic PEEM with no energy filtering.

Another filtering solution with large dispersion factors is the so-called *Omega filter* that was originally developed for TEM [13.46] and that now equips the SMART instrument (Fig. 13.4f; [13.25, 42]). It is made by four magnetic 90° deflectors, arranged in a way that the resulting optic axis resembles the Greek capital letter Omega. The symmetry of the path and the placement of a quadrupole, six hexapoles, and a dodecapole on convenient planes allow correction of all second-rank aberrations. The pass energy of this instrument is 15 keV, i.e., no retarding field is required, and the designed resolving power is 150 000. The calculated dispersion at the exit plane, 35 μm/eV, is large enough to display a window of ≈ 10 eV in *spectroscopy* mode with a demonstrated energy resolution better than 180 meV [13.47].

Aberration Correctors

In optics, aberration is the deviation from the nominal image raised by defects of the optical system. Such deviation can depend on geometrical factors (rays with different initial trajectories can be refocused on different planes—*spherical aberration*) or physical factors (the refraction index of the lens changes with the wavelength of the ray—*chromatic aberration*). In light optics, an easy way to correct aberrations is to combine convex and concave lenses conveniently, since the two types produce aberrations of opposite sign and the overall effect can cancel out. In electron optics, this circumstance is prohibited by *Scherzer*'s theorem [13.48]:

> The chromatic and spherical aberrations of an electron microscope with round lenses, real images, static fields, no space charge and a potential and its derivative without discontinuities, are always positive.

The resolution of a cathode lens microscope is then dominated by chromatic and spherical aberrations, mainly resulting from the objective lens. In the ideal case of an aberration-free system, the image of a point-like source is again a point. The blur induced by aberrations transforms the point image into a disk with a width d_0. Since effects like coma and field distortion are negligible in a LEEM/PEEM system, d_0 can be expressed as a Gaussian convolution of the contributions given by chromatic aberration, spherical aberration, and the diffraction limit [13.49, 50]. Given the acceptance angle α, the energy width ΔE, and the start energy E_0, one has that

$$d_0 = \sqrt{d_\mathrm{d}^2 + d_\mathrm{s}^2 + d_\mathrm{c}^2}\,,$$

with

$$d_\mathrm{d} = \frac{0.61\sqrt{\frac{1.5}{E_0}}}{\sin\alpha}\,,$$

$$d_\mathrm{s} = C_0 \sin\alpha + C_\mathrm{s}\sin^3\alpha + C_\mathrm{ss}\sin^5\alpha\,,$$

$$d_\mathrm{c} = C_\mathrm{c}\frac{\Delta E}{E_0}\sin\alpha + C_\mathrm{cc}\left(\frac{\Delta E}{E_0}\right)^2\sin\alpha + C_\mathrm{sc}\frac{\Delta E}{E_0}\sin^3\alpha\,.$$

Here, d_d is the radius of the confusion spot due to diffraction at the smallest aperture. The other components d_s and d_c are the radii of the confusion disc due to spherical and chromatic aberration, expressed to the lowest orders of a Taylor series. In standard experimental conditions d_d is less than 1 nm, thus the resolution is mainly determined by spherical and chromatic aberrations. The effect of the first one is predominant at higher kinetic energy, while the second is more significant at lower kinetic energy.

The constraints of Scherzer's theorem can be circumvented in many ways: some solutions were already known in the early years of theoretical electron optics, but were not implemented before the 1970s [13.51, 52]. Historically, the field of aberration correction was pioneered by the TEM community [13.53, 54], while its

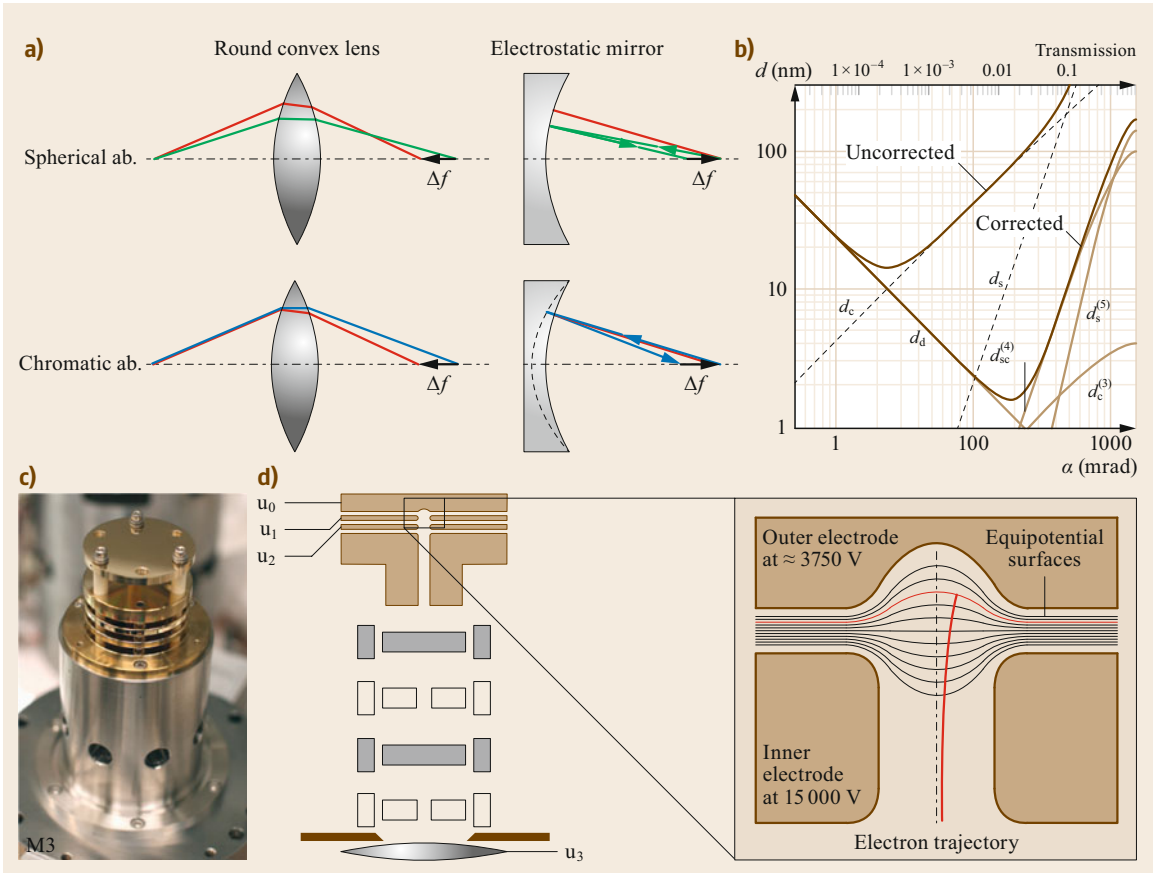

Fig. 13.5 **(a)** Schematics of the effect of spherical and chromatic aberration on a round convex lens and on an electrostatic mirror. **(b)** Resolution limit as a function of the acceptance angle α for uncorrected and corrected SMART in the case $E_0 = 10\,\text{eV}$ and $\Delta E = 2\,\text{eV}$. The dominating aberration components are added: *dashed line* for the uncorrected and *thin solid lines* for the corrected case (Reproduced from [13.49] with permission, copyright 2002 World Scientific). **(c)** Photograph of the electron tetrode mirror assembly used in IBM LEEM-II and **(d)** scheme of the tetrode mirror that equips SMART. The equipotential surfaces in the latter mirror stage are highlighted (Reproduced from [13.26] and [13.25] with permission, copyright 2010 and 1997 Elsevier)

development in cathode lens microscopy started much later. Among the multiple methods already tested in TEM, the most convincing one for cathode lens microscopy is the use of an electrostatic mirror [13.41, 55–57]. The principle how a mirror can compensate spherical and chromatic aberrations is shown in Fig. 13.5a. In the first case, an electrostatic mirror and a round convex lens with the same radius produce focal displacements ΔF of equal magnitude and opposite of sign. In the second case, the electrostatic mirror deflects more the trajectory electrons with higher kinetic energy, compensating the focal displacement ΔF induced in the round convex lens. The electrostatic tetrode mirror can compensate the aberration effect by reducing simultaneously the lower order coefficients C_s and C_c to zero. The effect on resolution and transmission calculated for the SMART instrument is presented in Fig. 13.5b. The cancelation of low-order aberration coefficients can improve the resolution by an order of magnitude. Moreover, since the acceptance angle can now be broadened without loss of resolution, the transmission of the microscope results are enhanced as well, with sensible reduction of the acquisition time.

The mirror is currently employed in several aberration-corrected systems. The first in chronological order is a pure PEEM microscope equipped with a hyperbolic mirror with only two electrodes, capable of compensating simultaneously spherical and chromatic aberrations only for one magnification and one energy [13.58, 59]. The maximum flexibility is obtained with a tetrode mirror (Fig. 13.5c), currently employed in several instruments (SMART, PEEM3,

Tromp/SPECS, Elmitec) [13.25–27]. While the first electrode is at ground potential, the potential of the three others can be varied. They modify the shape of the equipotential surfaces that act as a mirror for the incoming electrons, thus determining the focal length, the chromatic aberration, and the spherical aberration. The mirror is then set conveniently with the operation mode and kinetic energy to cancel out the primary aberration coefficients induced by the lens system. The C_s and C_c coefficients of the mirror can be calculated in a reasonable amount of time for a given E_0, so that standard values of the electrodes can be easily set. Furthermore, the aberration coefficients of the system can be directly evaluated with a series of routine measurements, thus enabling fine correction. PEEM3 reported a lateral resolution of 5.4 nm for PEEM images of biological samples with a 233-nm laser as photon source [13.59]. The first aberration-corrected LEEM image of SMART visualized nanometer surface structures such as the herringbone reconstruction of the Au(111) surface with a lateral resolution of 2.6 nm [13.60]. Both the Tromp/SPECS and Elmitec systems report now an ultimate lateral resolution below 2 nm in LEEM [13.26]. Better results are still theoretically possible, but are very difficult to achieve for long periods of time due to the intrinsic instability of the corrected state, which constrains the lifetime of the corrected state to just a few minutes [13.61]. Nonetheless, it should be remarked that the gain in transmission guaranteed by the aberration corrector is of great help for measurements, e.g., with x-ray photoemitted electrons, where the exposure time and the weakness of the photon source can be a crucial issue for the success of the experiment [13.62].

Electron and Photon Sources

The electron source in LEEM is an electron gun capable of emitting electrons with high brilliance and narrow energy distribution. Over the years, several kinds of emitters have been used. The most frequent electron source is a LaB_6 or CeB_6 crystal with conical shape showing the (100) surface on the flat tip. Once heated by a filament, electrons leave the crystal via thermionic emission from the tip, because of the low work function of the (100) surface. A Wehnelt aperture placed in front of the tip with negative potential suppresses the emission from other faces of the crystal [13.63]. These thermionic emitters have a long lifetime and can draw a very high current with an energy width larger than 0.7 eV [13.64]. The use of thermionic emitters is not recommended for high-resolution microscopes: cold field emitters and Schottky emitters can generate electron beams with a narrower energy spread (0.3 eV), thus reducing the influence of chromatic aberrations, at the cost of lower brilliance and shorter lifetime [13.65–67]. Rarer, but with very interesting applications, are the spin-polarized electron sources. The interaction between spin-polarized electrons and the specimen in LEEM systems provides unique information on magnetic phenomena with lateral resolution (Sect. 13.2.3, *Spin-Polarized LEEM*). The most common one uses the photoemission of electrons from III–V semiconductors with circularly polarized light [13.68–71]. Under particular conditions of strain, the photocathode can generate an electron beam with polarization ≈ 0.9, while the selection of the light polarization switches easily the polarization vector of the beam.

The photon sources employed in PEEM span over a broad range of photon wavelengths and time duration of the pulses, enabling a wide variety of surface science experiments. The easiest way to produce photoemission is with continuous UV illumination by discharging lamps. The first PEEM systems used a Hg short-arc lamp emitting UV light at 4.9 eV (254 nm). The low energy of the photons restricted its application to samples with low work function and low electron affinity. Higher photon energy can be provided by a He gas discharge lamp: the HeI emission mode (21.6 eV) is still used for energy-filtered angle-resolved photoemission diffraction measurements of valence band electrons.

Laser sources have been used to stimulate photoemission in PEEM since the 1970s [13.72]. Pulsed lasers can provide very short flashes of light along a wide wavelength spectrum and are currently used for time-resolved studies in pump-probe mode and for multiphoton photoemission. Several systems are suited for LEEM, such as Nd:YAG and Ti:sapphire, and are often used with higher harmonic photon generation [13.73–75]. The high throughput of lasers concentrated in a single pulse is the major limitation to their employment in PEEM measurement. The dense bunch of photoemitted electrons experience a reciprocal Coulomb repulsion while they travel to the detector, causing a general degradation of the carried information (the so-called *space-charge* effect—Sect. 13.3.2). This phenomenon can be mitigated with a high pulse repetition rate and with a low energy per pulse, so that PEEM experiments with a dynamic timescale of some tens of fs and good lateral resolution are now possible [13.76].

The most successful photoelectron source for PEEM is synchrotron radiation. Since the first installation of SPELEEM in Elettra, Italy, it was clear that the tunable, intense light provided by insertion devices in the third-generation synchrotron is the most versatile and powerful complement to cathode lens systems [13.21]. For example, the SPELEEM beam-

line [13.44, 81] is equipped with two Sasaki Apple II undulators that provide elliptically polarized light (circular left and right, linear horizontal and vertical) in a spectral range between 40 and 1000 eV. The light is monochromatized by two variable line space plane gratings with a resolving power $E/\Delta E = 4000$ at 400 eV. The beamline flux exceeds 10^{13} photons at 150 eV and is above 10^{12} photons in an energy range between 50 and 600 eV. These numbers permit to develop a great variety of experiments with valence band and core-level photoemitted electrons and with state-of-the-art lateral and energy resolution. The only technical limitation arises through the pulsed structure of the synchrotron radiation: space-charge effects limit again the lateral resolution of XPEEM images with core-level electrons to about 20 nm [13.62, 82]. This restriction could be overcome not only with photon intensity reduction, but also with an intelligent placement of apertures to cut away electrons not used for imaging. Nowadays, about 20 synchrotron endstations are equipped with a PEEM, with energies ranging from near-UV to hard x-rays (HAXPEEM), supplying the greatest contribution to the growth of the cathode lens microscopy user community.

13.1.3 Performance

At this point it is useful to summarize the performance of the various imaging techniques of cathode lens microscopy, highlighting the advantages and underlining the limitations. The list in Table 13.1 incorporates some of the state-of-the-art results, as well as routine performance achievable with good quality samples. The purpose of this section is to help the nonexpert reader in choosing the technique that correctly fits their needs, with no claim to being exhaustive. It must be remarked that the state-of-the-art results are obtained in very controlled and stable environmental conditions, with flat and conductive samples and cannot be achieved in every measurement of that kind. A charging and nonatomically flat sample can degrade performance easily by an order of magnitude. In this sense, the routine values are more significant, as they give a more realistic expectation for a generic experiment.

Table 13.1 Performance for the various operating modes of cathode lens microscopy

Resolution	Operation mode	Performance	References
Lateral resolution	LEEM		
	Nonaberration corrected	Routine: 20 nm Best: 4.1 nm (LEEM) (SPLEEM)	[13.26]
	Aberration corrected	Routine: 5–10 nm Best: 2.6 nm 2.0 nm 2.0 nm	[13.26, 30, 60]
	PEEM		
	Nonaberration corrected	Routine: 40–100 nm Best: 7.0 nm	[13.33]
	Aberration corrected	Routine: 40 nm Best 5.4 nm (UVPEEM) 18 nm (XPEEM) 2.6 nm (laser)	[13.59, 62, 77]
Energy resolution	PEEM		
	With MPA energy filter	Routine: 1–2 eV Best: 0.25 eV (spectroscopy) 1.7 eV (imaging)	[13.31]
	With HDA energy filter	Routine: 0.7 eV Best: 0.11 eV (spectroscopy) 0.2 eV (imaging)	[13.30, 44]
	With double HDA	Routine: 0.1 eV Best: 0.01–0.05 eV	[13.78]
Angular resolution	With HDA	Best: 0.047 A^{-1}	[13.44]
	With double HDA	Best: 0.005 A^{-1}	[13.78]
Time resolution	Laser	Routine: tens of fs (lateral resolution 20–50 nm) Best: 200 as (lateral resolution 200 nm)	[13.79, 80]
	Synchrotron	Few ps (single bunch width)	

13.2 Low-Energy Electron Microscopy

LEEM uses backscattered electrons as information carriers. Unlike scanning microscopy, electrons are collected simultaneously from an illuminated area of several tens of μm. The image formed by the magnification lenses can then be acquired even in video-rate (down to 1 ms/frame), depending on the detector quality and the signal intensity. The image contrast depends on how electrons interact with the surface: the higher or lower reflectivity can depend on several factors, e.g., morphology, crystallinity, and quantum effects. It is therefore important to understand how electrons interact with the surface and how the image is formed. Elastic and inelastic scattering of electrons on solids is a well-studied subject in condensed matter physics. Herein, only the most important concepts will be presented, leaving a more complete description to other textbooks [13.83].

13.2.1 Basic Image Contrast

The simplest conceptual case from where to start is the *single scattering* frame, i.e., an electron scattered only once by a surface atom. Here, the scattering amplitude is given by the atomic scattering factor $f_n(\boldsymbol{s})$, where $\boldsymbol{s} = \boldsymbol{k}_{\text{out}} - \boldsymbol{k}_{\text{in}}$ is the momentum transfer between incident and diffracted plane wave with wave vectors $\boldsymbol{k}_{\text{in}}$ and $\boldsymbol{k}_{\text{out}}$, respectively. Considering now a monoenergetic electron beam, represented by a plane wave with amplitude

$$\psi_{\text{in}} = \psi_0 \mathrm{e}^{\mathrm{i}\boldsymbol{k}_{\text{in}}\cdot\boldsymbol{R}} ,$$

the amplitude of a diffracted beam is represented by

$$\psi_{\text{out}} = \psi_0 \left[\sum_n \alpha f_n(\boldsymbol{s}) \mathrm{e}^{\mathrm{i}\boldsymbol{s}\cdot\boldsymbol{R}_n} \right] \mathrm{e}^{\mathrm{i}\boldsymbol{k}_{\text{out}}\cdot\boldsymbol{R}} .$$

Here $f_n(\boldsymbol{s})$ is the atomic scattering factor for the n-th atom at position $\boldsymbol{R}_n$. For an elastic scattering, the kinetic energy E_0 must be preserved, i.e.,

$$E_0 = \frac{\hbar^2}{2m} |\boldsymbol{k}_{\text{in}}|^2 = \frac{\hbar^2}{2m} |\boldsymbol{k}_{\text{out}}|^2 .$$

The contribution of atomic scattering factor and the diffraction effects generate image contrast in LEEM. In fact, areas with different composition, stoichiometry, and crystal structure will have a different electron reflectivity and will appear in LEEM as brighter and darker areas.

For a complete description of electron reflection, inelastic effects and multiple scattering must be taken into account. When traveling inside solids, electrons have a certain probability to experience an inelastic event. Therefore, their probability to be reflected with no losses depends on how deep the scattering center is placed into the bulk. To model this behavior, one can introduce a mean free path expressed by an imaginary component of the electron–surface interaction potential, such that the scattering amplitude decays exponentially in the direction of wave propagation. In general, the electron mean free path is energy dependent and relatively independent of the material, so that its value follows a *universal curve*. Such a universal curve has a V-shape, i.e., presents a minimum for energies around 30–100 eV: in this range the mean free path is so small (few Å) that elastic electrons come from only the top-most atomic layers. LEEM and PEEM performed in this range are then surface sensitive. Electrons with higher kinetic energy can probe the sample in more depth, while at very low energy (≈ 10 eV) the IMFP can show large deviations in accordance with the density of states of the material: at a few eV, organic thin films with very low density of states can show a mean free path of 10 nm, while transition metals with dense d or f bands above the Fermi energy can damp scattered electrons already at a depth of 0.5 nm. The surface sensitivity can be used in LEEM to achieve image contrast even between samples with the same stoichiometry and different surface reconstruction.

At very low kinetic energy, another quantum phenomenon can affect the elastic backscattering of electrons from thin films. When electron wavelength and penetration depth are comparable to film thickness, i.e., at very low kinetic energy, the confinement imposed by the vacuum boundary and the film-substrate interface induces a one-dimensional quantum well condition [13.84]. This so-called quantum size effect (QSE) rises from the interference between electron waves reflected at the surface and at the film-substrate interface. In first approximation, for a film of thickness d, the phase shift induced by the different path length is

$$\phi = \frac{2d}{\hbar} \sqrt{2m(E_0 + V_{\text{i}})} , \tag{13.1}$$

where V_{i} is the inner potential of the thin film. The electron reflectivity is then subject to periodic oscillations as a function of electron kinetic energy and film thickness. QSE is extensively used to measure directly the thickness of thin films: significant examples will be given in Sect. 13.2.3.

13.2.2 Image Formation

The reflection of plane waves is also influenced by the morphology of the surface: atomic steps, kinks, domain boundaries, and defects create interference and modulate the electron reflectivity. To better understand how to interpret the features in a LEEM image, it is necessary to address the theory of image formation. Over the last two decades, several approaches have been used to calculate the image formation in LEEM. The first is from *Chung* and *Altman* [13.22, 85], who developed a wave-optical model to describe the step contrast in ideal and real conditions, i.e., taking into account instrumental broadening and beam coherence. Later the model was improved by a Fourier optics formalism [13.36], which elucidates the image formation for objects with different scattering amplitude and phase and incorporates aberration effects of the objective lens, diffraction cut-off by a contrast aperture, lens defocus, energy spread of the electron beam, and instabilities in lens current and voltage. In parallel, *Jesson* and coworkers [13.86, 87] proposed an alternative approach, based on the definition of a contrast transfer function (CTF), into which flow all the effects of the imaging system on the transfer from real object to image. *Schramm* et al. [13.88] integrated this method with fifth-order aberrations, making it suitable for aberration-corrected instruments. The CTF formalism is attractive for its low computational cost and its universal treatment of arbitrary phase, amplitude, or mixed amplitude-phase objects. In the following, a brief excursus on the CTF formalism is depicted.

Consider having an object illuminated by a monoenergetic plane wave, as in Sect. 13.2.1. It has been shown that the reflection causes variation of wave amplitude and phase. In general, the reflected wave is given by

$$\psi_{\text{out}} = \psi_{\text{in}}\psi_{\text{obj}}$$

with

$$\psi_{\text{obj}}(\boldsymbol{R}) = \sigma(\boldsymbol{R})\mathrm{e}^{\mathrm{i}(\boldsymbol{k}_{\text{out}}-\boldsymbol{k}_{\text{in}})\cdot\boldsymbol{R}}\mathrm{e}^{\mathrm{i}\phi(\boldsymbol{R})} .$$

Here $\sigma(\boldsymbol{R})$ is the amplitude modification factor, while the phase modification factor $\phi(\boldsymbol{R})$ incorporates the phase difference between outgoing and incoming waves induced by the surface morphology. Supposing that the surface is the plane xy at $z = 0$, its morphology can be modeled by a surface height function $h(\boldsymbol{R}_0)$ expressed in unit of step height a_0. $\boldsymbol{R}_0$ is then a two-dimensional position vector spanning over the surface plane. In case of normal incidence, only the vertical component of the wave vector matters, i.e., $\boldsymbol{k} = |\boldsymbol{k}|\hat{z}$. Given $|\boldsymbol{k}| = 2\pi/\lambda_0$, the phase shift defining the surface is given by

$$\phi(\boldsymbol{R}_0) = 2\frac{2\pi}{\lambda_0}a_0 h(\boldsymbol{R}_0) .$$

The phase object function includes the effects of surface morphology on the reflected wave, assuming no significant modification of the accelerating electric field.

The reflected wave is then modified by the cathode immersion lens. First of all, the acceleration from kinetic energy E_0 to E imposes the change of coordinates as in Sect. 13.1.1, from takeoff coordinates in real ($\boldsymbol{R}_0$) and reciprocal space (q_0) to respective virtual coordinates ($\boldsymbol{R}$ and $\boldsymbol{q}$). The transfer from virtual object to magnified image can be described in real or reciprocal space. In real space, the response of the system is described by the point spread function (PSF) $T(\boldsymbol{R})$, which models the blurring of an ideal point object. The final image $\psi(\boldsymbol{R})$ is then the convolution of the outgoing wave ψ_{out} and the PSF,

$$\psi(\boldsymbol{R}) = (\psi_{\text{out}} * T)(\boldsymbol{R}) .$$

Using the fact that convolution in real space corresponds to multiplication in the Fourier space,

$$\psi(\boldsymbol{R}) = \mathcal{F}^{-1}\{\mathcal{F}[\psi_{\text{out}}(\boldsymbol{R})]\,\mathcal{F}[T(\boldsymbol{R})]\} .$$

$T(\boldsymbol{q}) = \mathcal{F}[T(\boldsymbol{R})]$ is the CTF of the LEEM imaging system and it is modeled as the product of all relevant contributions imposed by the optical system, i.e., the frequency cutoff imposed by the contrast aperture, chromatic and spherical aberration, defocus, and instrument-related instabilities. One can model $T(\boldsymbol{q})$ as follows

$$T(\boldsymbol{q}) = M(\boldsymbol{q})W(\boldsymbol{q}, \Delta f)\mathcal{E}(\boldsymbol{q}, \Delta E) .$$

Here, $M(\boldsymbol{q})$ incorporates the effect of a round contrast aperture placed in the backfocal plane, where the reciprocal space is displayed. Its effect is to filter high spatial frequencies

$$M(\boldsymbol{q}) = \begin{cases} 1 & \text{if } |\boldsymbol{q}| < q_{\max} \\ 0 & \text{if } |\boldsymbol{q}| \geq q_{\max} . \end{cases}$$

$q_{\max}$ corresponds to the maximum spatial frequency imposed by the aperture size and it is equal to $\alpha_{\max}/\lambda$, with $\alpha_{\max}$ being the maximum angle accepted. It should be noted that the contrast aperture acts downline of the acceleration stage, therefore the electron wavelength is calculated from the final kinetic energy E.

The wave-aberration contribution $W(\boldsymbol{q})$ refers to deviations of the wave path from the ideal one, induced

by defocus Δf and by spherical aberrations, which may be expressed by Taylor series coefficients as in Sect. 13.1.2, *Aberration Correctors*

$$W(\boldsymbol{q}, \Delta f) = \exp\left[\frac{\mathrm{i}\pi}{2}\left(C_\mathrm{s}\lambda^3 q^4 + \frac{C_{\mathrm{ss}}}{3}\lambda^5 q^6 - 2\Delta f \lambda q^2\right)\right].$$

The defocus Δf also takes into account the unintentional focus oscillations caused by voltage and current fluctuations in lenses and high-voltage supplies.

Finally, the chromatic aberration damping envelope $\mathcal{E}(\boldsymbol{q}, \Delta E)$ comes from an integration over the weighted contribution of the different energies within the Gaussian energy distribution with FWHM ΔE. Limiting the expression of chromatic aberration to the first-order coefficient, one has that

$$\mathcal{E}(\boldsymbol{q}, \Delta E) = \exp\left[-\frac{\left(\pi C_\mathrm{c}\lambda q^2\right)^2}{16\ln 2}\left(\frac{\Delta E}{E}\right)^2\right].$$

The final LEEM image is an intensity distribution of the reflected wave modified by the lens system, so it can be calculated as

$$I(\boldsymbol{R}') = \frac{1}{M^2}\left|\psi(\boldsymbol{R})\right|^2,$$

with $\boldsymbol{R}'$ being the two-dimensional coordinates at the detector plane.

The CTF approach is currently used to produce simulation of LEEM images for a surface with arbitrary height map $h(\boldsymbol{R}_0)$ and given scattering amplitude. It has been used not only to prove well-known surface features, like atomic steps [13.86], but also to construct valuable morphology models of peculiar surfaces, as in the case of corrugated MnAs layers on GaAs(001) [13.89] or sub-surface line dislocations in magnetite thin films [13.90]. Moreover, the CTF algebra helps to figure out how to achieve the best performances from a cathode lens microscope. It is now clear the effect of the contrast aperture, which on one side deteriorates the image by acting as a low-pass filter and on the other side limits the acceptance angle and therefore the blurring induced by spherical aberration. The energy distribution of electrons coming, e.g., from the electron source, act together with the chromatic aberration, while the voltage and current instability can be modeled as an additional defocus. This knowledge has proven to be crucial in the case of aberration-corrected systems, where the lifetime of fully-corrected state has observed to be just a few minutes. After a correct estimation of every contribution, *Schramm* et al. [13.61] concluded that the stability of power supplies, the active damping of vibrations, good electromagnetic shielding and improved detectors are the crucial factors for maintaining the corrected state, and that more accurate monitor and correction systems must be developed to prolong its lifetime and make it usable for complex experiments.

13.2.3 Imaging Mode

LEEM and LEEM-IV

The first operating mode of LEEM corresponds to the magnified image plane displayed on the detector. Typically, the camera interconnects with the microscope software to capture single images or videos on varying the start voltage, the sample temperature, the lens settings, and so on. In this way, several in situ experiments and diagnostic procedures can be performed. In principle, the LEEM image is the intensity distribution of electrons on the image plane. The local intensity is then converted to a gray-scale image, where the contrast depends on how the objects modify the reflected electron plane wave in phase and amplitude. In the following, we will show topical examples of how phase and amplitude objects are displayed in LEEM.

The simplest phase object giving contrast in LEEM is an atomic step on an elsewhere flat, crystalline surface. The uniform, regular distribution of atoms, as in the case of a terrace, gives no contrast in LEEM, since the electron beam is backscattered everywhere in the same way. Plane waves coming from two adjacent terraces have different phases, so that at the terrace edges the interference between them degrades the reflected intensity. Figure 13.6a shows a LEEM image of a clean, stepped Si(111) surface with (7×7) reconstruction: monoatomic steps are displayed as dark lines with a faint, brighter decoration on one side [13.85]. This appearance is confirmed by simulation performed with CTF formalism [13.86]. In this case, the surface height function $h(\boldsymbol{R}_0)$ is expressed as a simple step function of height $a_0 = 0.31$ nm (Fig. 13.6b, brown line). The simulated intensity line profile (Fig. 13.6b, black line) displays a minimum in the vicinity of the step and a maximum on one side. In general, the presence of minima and maxima is related to the phase shift, i.e., the electron kinetic energy and the step height: For $\phi(\boldsymbol{R}_0) = 2n\pi$ the contrast is almost absent, while in the complete out-of-phase condition $\phi(\boldsymbol{R}_0) = (2n+1)\pi$ the line profile is symmetric (no bright decoration). The asymmetric maximum is observed at the intermediate phase conditions and is most pronounced at $\phi(\boldsymbol{R}_0) = (2n+1)\pi/2$. The relative position of maxima and minima can be inverted periodically as a function of the phase shift. CTF formalism can be readily extended to

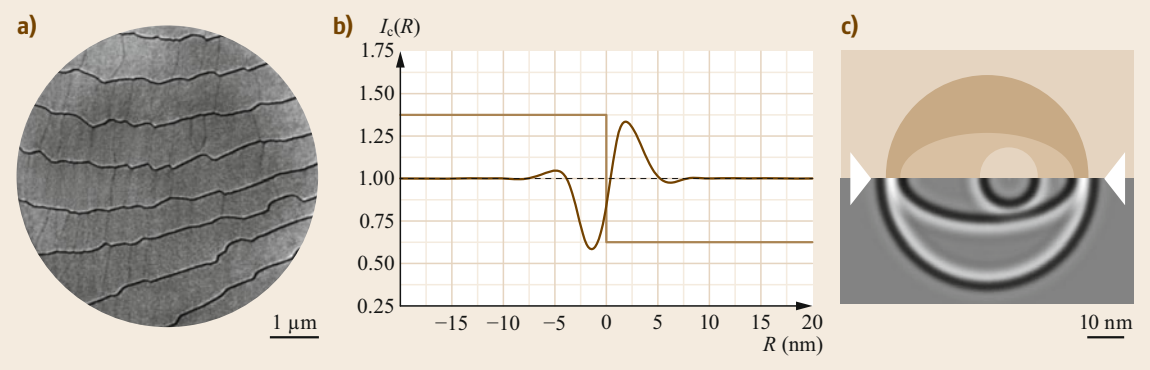

Fig. 13.6a–c Imaging with phase contrast. **(a)** Underfocus LEEM image of monoatomic steps on the Si(111)-(7×7) surface. two spatial dimensions: Fig. 13.6c shows the simulation of how an ideal Si(111) surface with monolayer-step-height circular and elliptical terraces (top) appear in LEEM for a given phase shift. It should be noted that more complicated interference patterns could be produced when steps were closer together, e.g., in the region highlighted with white arrows. The correct interpretation in such cases must pass through an extensive simulation of model surfaces in different conditions of focus, electron kinetic energy, and morphology.

The amplitude contrast is produced between two adjacent areas that have different scattering amplitude. This case is quite common during an experiment: any area with a different composition, stoichiometry, crystal structure, and even surface reconstruction gives amplitude contrast. The exact calculation from first principles of how crystalline surfaces diffract electron beams in LEEM is derived from kinematic and dynamic LEED theory developed already in the late 1960s [13.83] and will not be discussed here in detail. An example of amplitude contrast is given in Fig. 13.7a, displaying a LEEM image of a Pt(111) surface covered with a graphene (Gr) layer of variable thickness [13.91]. In this particular case, the contrast is given not only by changes in amplitude, as between monolayer and bilayer Gr, but also by the quantum size effect. The difference is more evident by looking at the *I–V* characteristics obtained from a stack of LEEM images with increasing start voltage (Fig. 13.7b). The *I–V* curve for ML Gr reflects the particular morphology of the system, where the carbon sheet rests 3.30 Å upon the Pt substrate. The other reflectivity curves appear quite similar to one another at kinetic energies above 20 eV, since the Gr thickness becomes bigger than the IMFP and no contribution from substrate atoms is present. Nonetheless, pronounced oscillations due to quantum size effects can be observed at lower kinetic energies (Fig. 13.7c). In particular, the number of minima of these oscillations scales with the number of layers. This characteristic has been observed not only on 2-D materials, but also on epitaxial thin films on metal substrates, and therefore can be used as a universal fingerprint to estimate the film thickness. Moreover, one can plot the phase shift from (13.1) as a function of the energies at which interference maxima or minima are observed (Fig. 13.7d) and determine accurately the film thickness and the inner potential with a fit. In this particular case, the analysis confirms that Gr stacks thicker than three layers have identical layer separation to graphite.

Brightfield and Darkfield LEEM

Up to now, we have only considered the case in which incoming and reflected electron beams are perpendicular to the sample surface. Even with a perpendicular incoming beam, the outgoing electrons distribute over the solid angle to form a diffraction pattern in the back-focal plane of the objective lens. Then, the contrast aperture limits the acceptance angle in order to only let electrons pass that are emitted in the neighborhood of the zero-order diffraction spot. This configuration is called *brightfield* and is schematized in Fig. 13.8a. However, it would be interesting to build the LEEM image also with nonperpendicular electrons, i.e., with higher or fractional order diffraction spots; in this way the crystallographic information contained in the diffraction pattern can be transferred to the real space and generate a crystallographic map of the sample. This case is called *darkfield* and can be achieved in

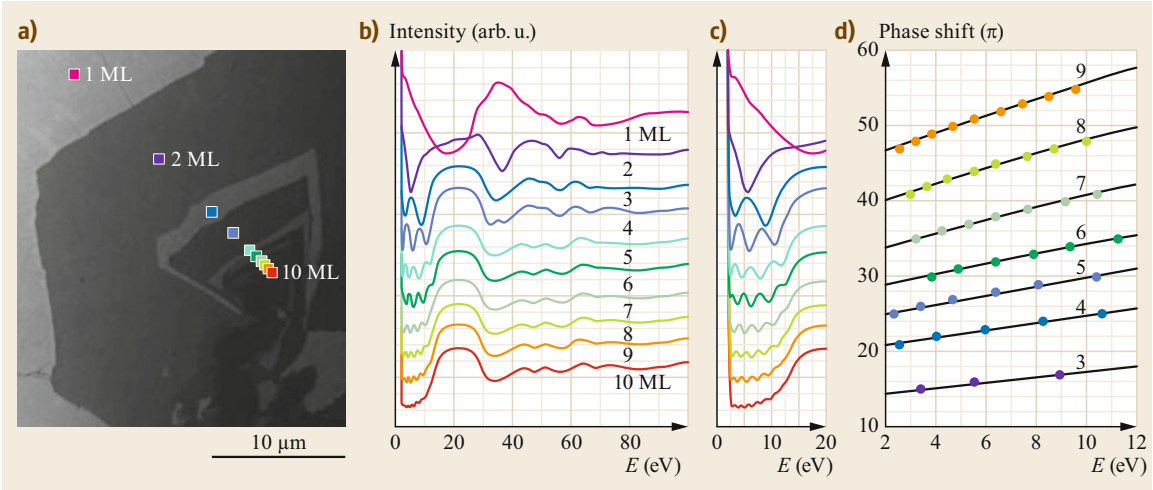

Fig. 13.7a–d Imaging amplitude objects. **(a)** LEEM image (electron energy 4.4 eV) of a few-layer Gr stack nucleated at a boundary between rotationally misaligned ML Gr domains. *Markers* denote areas with coverage between one and ten Gr layers. **(b)** *I–V* characteristics obtained from a stack of LEEM images with electron energy from 2 to 100 eV at the locations marked in **(a)**. **(c)** Higher magnification of the same data set at electron energies below 20 eV, showing fringes due to interference of electrons backscattered from the Gr surface and Gr/Pt interface. **(d)** Phase shifts for constructive and destructive interference (fringe maxima and minima in **(c)**) as a function of electron energy. *Black lines* are theoretical fits calculated assuming a free-electron propagation model. Fig. 13.8a–d Scheme of brightfield **(a)** and darkfield **(b–d)** LEEM operation. Darkfield can be performed by displacing the contrast aperture **(b)**, tilting the sample **(c)**, and deflecting the incident electron beam **(d)**. The zero-order diffraction spot is depicted in *brown*, while the higher order ones are in *gray*

different ways. The simplest way is (i) to move the contrast aperture and accept electrons with a nonzero emission angle, e.g., from a first-order diffraction spot (Fig. 13.8b). This method has the disadvantage that the selected electron trajectory is far from the optical axis and therefore the spherical aberrations may blur the image. A way to overcome this limitation is (ii) to incline the sample tilt by a certain angle α to let the selected diffraction feature with emission angle 2α pass through the contrast aperture along the optical axis (Fig. 13.8c). In this case the incident electron beam is not perpendicular to the surface, so one should take into account

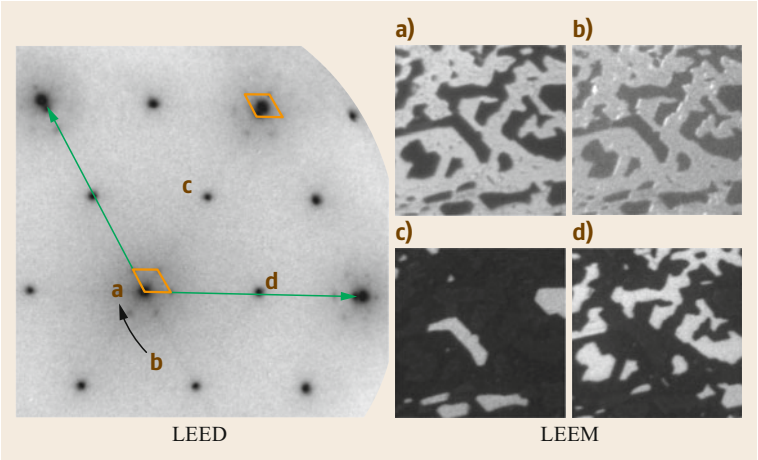

Fig. 13.9a–d LEED (*left*) and LEEM (*right*) images of a strongly dewetted $Fe_3O_4(111)$ thin film. In LEED ($E_0 = 88\,eV$) the reciprocal vectors of a $Fe_3O_4(111)$ unit cell and FeO(111) moiré pattern are highlighted in *green* and *orange*, respectively. The labels in LEED mark the selected diffraction spots used for LEEM ($E_0 = 24\,eV$): **(a)** brightfield, **(b)** darkfield with FeO(111) moiré, **(c)** and **(d)** darkfield with (2×2) inequivalent spots of $Fe_3O_4(111)$ (Reproduced from [13.92] with permission, copyright 2012 American Physical Society)

the different atomic scattering factor $f(\boldsymbol{s})$, as it depends on the momentum transfer $\boldsymbol{s} = \boldsymbol{k}_{out} - \boldsymbol{k}_{in}$. This approach does not need a dedicated alignment of the lens system, but lacks accuracy and reliability due to mechanical limitations of the sample manipulator. The most convenient method to produce darkfield LEEM is (iii) to leave the sample untouched and tilt the incoming electron beam with deflectors placed in the illumination column (Fig. 13.8d). It is optically equivalent to the previous case, but with the advantage that the sample holder and the lens system are untouched, and deflectors can be remotely controlled and accurately calibrated, enabling fast switching between brightfield and darkfield.

The contrast mechanism in darkfield LEEM measurement adds substantial information on the crystal structure of the sample. Electrons forming a particular spot in the diffraction pattern are emitted only from areas with a certain crystal structure. Thus, a LEEM image produced with these electrons shows as bright the area from where they were emitted, and as dark the areas with another structure. By studying the area distribution in darkfield LEEM for several diffraction spots, one can reveal if a LEED pattern is produced from a single phase over the entire surface or is a superposition of two or more contributions. Images over a large field of view offer a direct measurement of the relative coverage of the phases. Moreover, domains with the same crystal structure but rotated orientation can be distinguished. Even if the domains give the same LEED pattern geometry, the intensity of same-order spots differs, thus resulting in an amplitude contrast among rotational domains. An example of both occurrences is given in Fig. 13.9. The system is a dewetted $Fe_3O_4(111)$ thin film of thickness larger than 7 nm, grown on a Pt(111) surface [13.92]. The film holes do not expose a clean Pt surface, but are decorated by a single bilayer of FeO(111) [13.93, 94]. The corresponding LEED pattern, obtained with illumination over a large area, is a superposition of two distinct patterns: the (2×2) superstructure over the $Fe_3O_4(111)$ spots (unit cell in green) and the moiré pattern of FeO(111) surrounding the Pt(111) spots. Brightfield LEEM (Fig. 13.9a) shows areas with different reflectivity, but at a first glance one cannot distinguish which is Fe_3O_4 and which is FeO/Pt. Darkfield LEEM performed with electrons from the moiré (Fig. 13.9b) shows as bright the FeO(111) areas, leaving the rest as dark. The contrast inverts when one of the $Fe_3O_4(111)$ (2×2) spots is used, but while the FeO patches appear dark, only one rotational domain of Fe_3O_4 enlightens (Fig. 13.9c). The other rotational domain, rotated by 180°, emerges on darkfield LEEM by using the inequivalent (2×2) spot (Fig. 13.9d). It should be noted that the FeO darkfield image corresponds to the sum of the two Fe_3O_4 darkfield images when the contrast is inverted, thus excluding the presence of a third crystalline phase. Moreover, the amplitude contrast between rotational domains is achieved only at some kinetic energies, for which two inequivalent LEED spots with the same order have a different intensity. Other energies can eliminate or invert the contrast.

Mirror Electron Microscopy

It has been shown that in LEEM the reflectivity of electrons changes with the momentum transfer $\boldsymbol{s}$ occurring during backscattering. Such reflectivity is always less than unitary, i.e., part of the electrons is lost due to inelastic scattering, bulk absorption, surface and quantum effects. The only way to achieve total reflection is to decrease the start voltage until all electrons are reflected above the sample surface, turning the cathode immersion lens into an electrostatic mirror. However, the equipotential surface in front of the specimen is still influenced by field inhomogeneities determined by the surface morphology, work function changes,

contact potentials, and magnetic fields. As electrons decrease speed and reverse direction, their trajectories are deviated by such perturbations, thus giving contrast to the electron image. This imaging technique is called mirror electron microscopy (MEM) and has the advantage of probing surfaces without direct impact, giving access to nonconductive specimens and imaging phenomena in a nonperturbative way. The contrast mechanism in MEM has been discussed and modelized over the years [13.95–97], in order to extract quantitative information regarding morphology and microfields. Although the algebra is in some cases quite similar to the CTF approach described in Sect. 13.2.2, it will not be discussed here. In general, the lateral resolution in MEM is worse than standard LEEM imaging on the same surface, ranging around several tens of nm. Nonetheless, the high sensitivity to height variations and equivalent surface potentials gives a remarkable depth resolution of about 1 nm. Like in LEEM, the intensity line profile of features in different focus conditions can be simulated and reverted to quantitative real-space models. $I(V)$ spectra of different areas through the LEEM-MEM threshold can be used to extrapolate a map of the local potential, owed to work function changes, charge states, or application of external fields.

Spin-Polarized LEEM

Spin is a degree of freedom of the incident electron beam that can be used to achieve imaging of magnetic states of the specimen surface. As shown in Sect. 13.1.2, *Aberration Correctors*, spin-polarized sources such as III–V semiconductor photocathodes can provide beams with a high degree of polarization $\boldsymbol{P}$. In SPLEEM, the usual image contrast is augmented by magnetic contrast generated by the exchange interaction between incident spin-polarized electrons and spin-polarized electrons in the magnetic material [13.98–101]. This exchange contribution to the scattering is proportional to $\boldsymbol{P}\cdot\boldsymbol{M}$, with $\boldsymbol{M}$ being the magnetization vector of the target material. In a magnetic material $\boldsymbol{M}$ results from the difference between the number of electrons with parallel and antiparallel spin contained in the occupied states of majority and minority bands, respectively (Fig. 13.10a; [13.102]). The two electronic populations produce nonequivalent exchange-correlation potentials, so that electron beams with different polarization are scattered differently. Moreover, the minority spin band offers more unoccupied states for an inelastic event, thus minority electrons are more effectively scattered than majority electrons and the IMFP decreases. This leads to a larger reflectivity for majority electrons. The intensity difference between parallel ($I_{1\uparrow}$) and antiparallel ($I_{1\downarrow}$) configurations, normalized to the sum of the intensities, i.e.,

$$A = \frac{I_{1\uparrow} - I_{1\downarrow}}{I_{1\uparrow} + I_{1\downarrow}} ,$$

is called exchange asymmetry and is proportional to $\boldsymbol{P}\cdot\boldsymbol{M}$, weighted with the damping caused by the different IMFP. It should be noticed that the difference at the numerator cleans the resulting image from nonmagnetic diffraction and topological features resulting from conventional LEEM imaging, leaving only contrast from magnetic features. The effect of spin on exchange correlation potential and IMFP decreases rapidly as the kinetic energy of incident electrons increases. For this reason, the best magnetic contrast in SPLEEM is obtained at energy typically below 20 eV.

The photocathode electron gun delivers electron beams with a fixed spin polarization vector that can be eventually flipped by changing the sense of the circular polarized light. The spin polarization vector can be subsequently changed with a spin manipulator, where electrostatic and magnetic deflectors and a magnetic rotator lens give three degrees of freedom on the spin orientation. This allows complete characterization of the sample magnetization direction in both in- and out-of-plane geometry, and tilted directions in between. An example of SPLEEM asymmetry images with different polarization orientation is given in Fig. 13.10b. Here, two epitaxial Fe ribbons produced by deposition of 5 ML of Fe on a W(110) surface and annealing at 650 K are displayed with the polarization vector in-plane and parallel to [001] (1) and [1$\bar{1}$0] (2) crystallographic direction, respectively [13.103]. The magnetic state of the ribbons is primarily determined by the interplay between exchange and stray-field energy, which prefers magnetization along the [001] axis, and the surface/-magnetoelastic energy, whose minimization produces states with magnetization along [1$\bar{1}$0]. The consequent multidomain state can be extracted by the intensity pattern in the SPLEEM asymmetry image: brightest areas have a parallel magnetization vector, darkest have an antiparallel one, while neutral gray are oriented perpendicularly. By combining images with different polarization vectors one can construct a consistent domain model, as presented on the sides for the marked regions.

SPLEEM has been used to address phenomena such as domain wall structures in thin magnetic films, micromagnetic configurations in surface-supported nanostructures, spin reorientation transition, magnetic coupling in multilayers, phase transitions, and finite-size effects. Its application has several advantages, such as real-time observation and the possibility to combine crystallographic and magnetic information. The surface

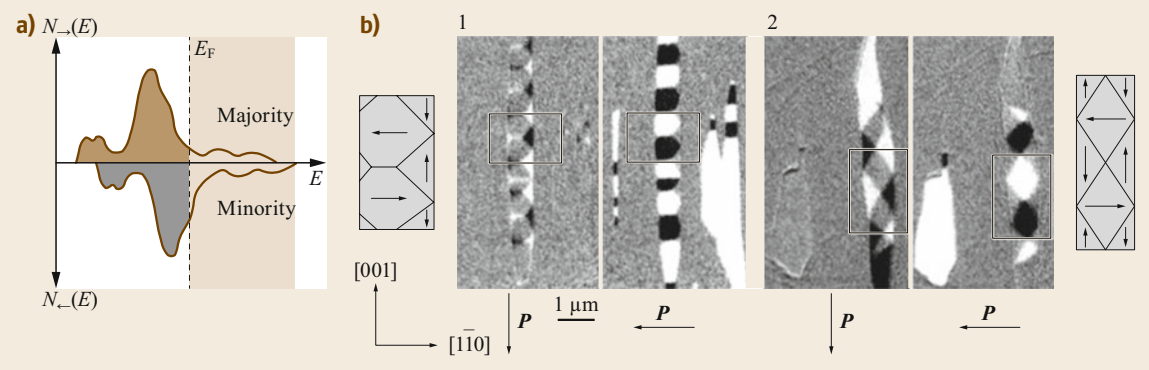

Fig. 13.10 **(a)** Density of states in a ferromagnetic metal. Because of the spin interaction, the electronic band can be conceived as a superposition of a majority (*brown*) and minority (*gray*) population. **(b)** Domain structure of epitaxial Fe ribbon crystals on W(110). The image pairs were taken with the polarization vector of the electrons parallel to the [001] (1) and [1$\bar{1}$0] (2) directions, respectively. The magnetization distribution in the *marked regions* is indicated on the sides (Reproduced from [13.103] with permission, copyright 2006 John Wiley & Sons)

sensitivity limits its usefulness to samples prepared in situ or grown elsewhere and protected by a removable capping layer. The main disadvantage in the use of SPLEEM is its strong sensitivity to applied magnetic fields, which distress the trajectory of electrons and degrade the image quality. Modest fields of few hundred gauss can be applied only in the surface normal direction, so that the Lorentz force is geometrically minimized. This limitation affects important fields of research, such as dynamics on domain walls and exotic magnetic states of matter.

Electron Energy Loss Microscopy

LEEM systems equipped with an energy filter have the possibility to use inelastic electrons for imaging with opportune detuning of the energy analyzer [13.81, 105]. Electrons can lose some kinetic energy during the scattering process and the energy distribution of all inelastically scattered electrons provides information about the local physical and chemical properties of the specimen. The low-loss region (< 50 eV) of this energy spectrum contains valuable information about the band structure and the dielectric properties of the material, e.g., electron–phonon interaction, band gaps, and surface plasmons [13.106, 107]. Such inelastic electrons can pass through the energy analyzer with optimal trajectory if a supplementary bias is applied. The usual slit at the exit plane selects only electrons with a certain energy loss. Electron energy loss microscopy (EELM) images typically have very low intensity and contrast, but can be used to display the surface distribution of plasmons and to distinguish between surface areas with different phononic and plasmonic properties [13.108]. For example, this is the case when Gr and hexagonal boron nitride (h-BN) patches rest one aside the other upon a surface [13.104]. Figure 13.11a shows

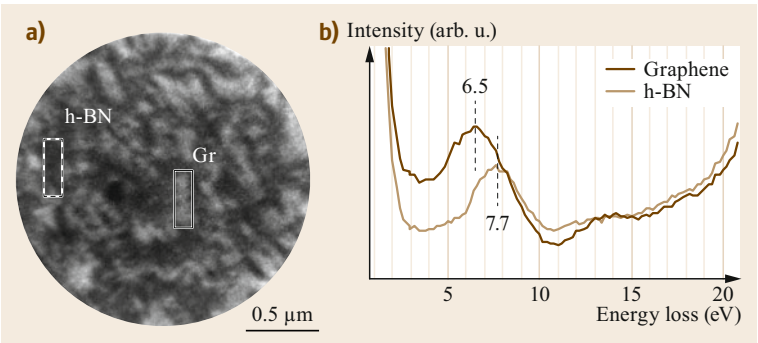

Fig. 13.11 **(a)** EELM image of Gr and h-BN coplanar flakes on Pt(111) collected with electron energy $E_0 = 32$ eV and a loss of 6.5 eV. Graphene (Gr) patches appear brighter than h-BN due to the plasmonic excitation. **(b)** Electron energy loss spectra of Gr and h-BN extracted from a stack of EELM images at different energy losses. The spectrum measured in region Gr shows a π-plasmon loss at 6.5 eV; the spectrum measured in region h-BN shows a π-plasmon loss at 7.7 eV (Reproduced from [13.104] with permission, copyright 2015 Wiley-VCH Verlag)

an EELM image of adjacent Gr and h-BN flakes grown on a Pt(111) surface from a single molecular precursor, dimethylamine borane (DMAB). The simultaneous presence of B, C, and N atoms obtained from dissociation of DMAB at 1000 K is a very efficient way to obtain a continuous, almost free-standing layer mostly made of Gr and h-BN, with only a low percentage of impurities. Gr and h-BN flakes have a different plasmon energy loss and therefore display a contrast for particular electron loss energies. Local integration over a stack of EELM images allows the collection of size-selected electron energy loss spectra (Fig. 13.11b). It is shown that in the bright areas in EELM the collective excitation of the electrons is found at 6.5 eV, whereas in the dark areas a peak centered at 7.7 eV is found. These spectroscopic features are assigned to π-plasmon energy loss in slightly doped Gr and h-BN, respectively [13.109, 110].

The use of energy loss microscopy in LEEM systems can provide additional information on the dielectric nature of surfaces and thin films. However, its accuracy cannot be compared to a dedicated apparatus. In LEEM the monochromaticity of the incident electron beam, a few tenths of eV, is not enough to resolve vibrational states of molecules and adatoms. Despite this aspect, EELM is ideal to characterize inhomogeneous surfaces, showing the lateral extent of every species with different plasmonic signature with a resolution of some tens of nm.

13.2.4 Diffraction Mode

μ-LEED

The second operating mode in LEEM is the so-called diffraction mode, i.e., when the backfocal plane of the objective lens is displaced on the detector. This mode gives access to the angular distribution of backscattered electrons, which forms a diffraction pattern in the case of crystalline surfaces. The use of LEEM systems for diffraction studies has many advantages with respect to standard LEED optics:

- The operation conditions of the electron gun and the illumination angle are fixed, while the kinetic energy at the interaction is governed by the start voltage. This ensures beam stability and constant current, even for dynamic measurements.
- The backfocal plane is displayed for electrons traveling at a kinetic energy E, independently of their takeoff energy E_0. This means that the displayed reciprocal space has the same lateral extent for every start voltage, so the diffraction spots do not move during an energy scan. The calibration of the reciprocal space can be calculated by looking at the linear expansion of the Ewald sphere with increasing start voltage, or through the position of the diffraction spots for a known surface, e.g., Gr, Si(111)-7×7 or oxidized W(110).
- The probed region can be inspected in LEEM and selected by placing an opportune aperture in the image plane. Commercial LEEM systems can reduce the illuminated area to a diameter of 250 nm [13.30].
- The electrons can be filtered in energy and the background of secondary electrons can be removed.
- The zero-order diffraction spot can be easily detected, as the magnetic beam splitter separates the incoming and outgoing electron beams.

The collection of LEED measurements from a selected region is often referred to as micro-LEED or μ-LEED. Figure 13.12 shows how microscopy and diffraction can be combined to obtain structural information on surfaces and nanostructures under particular conditions. The LEEM image in Fig. 13.12a presents cerium oxide microparticles grown on a Ru(0001) surface saturated with oxygen [13.111, 112]. This system is a model catalyst, used to study the interplay between oxide and metal under reaction conditions. A 500-nm wide illumination aperture can be introduced and placed on a large CeO_2 particle (as indicated by the red circle), so that electrons are backscattered from only this single object. The transfer lens setup is then changed to display the LEED pattern. The real-time observation of the diffraction pattern was used to investigate how the reduction of ceria particles influences their atomic surface structure. LEED patterns were acquired in real time while dosing up to 4800 L of molecular hydrogen at a substrate temperature of 700 K (Fig. 13.12b). Before hydrogen exposure, only the (1×1) integer spots of CeO_2 are visible. After dosing 500 L of H_2 at 5×10^{-7} mbar, additional spots emerge as a consequence of the local ordering of oxygen vacancies induced by H_2 dissociation and surface reduction. At this moment, the superstructure spots exhibit a periodicity of 2.6 with respect to the integer spots of CeO_2. A further dose of H_2 at higher pressure leads to larger periodicities in the diffraction pattern, notably (3×3) at 1900 L and (4×4) at 4800 L, as well as slight in-plane lattice expansion, detectable from the contraction of first-order spots. The structural changes observed in LEED, together with other LEEM analysis not shown here [13.111], helped the authors to conclude that under reducing conditions three stable phases of reduced ceria exist, which coexist for intermediate oxidation states.

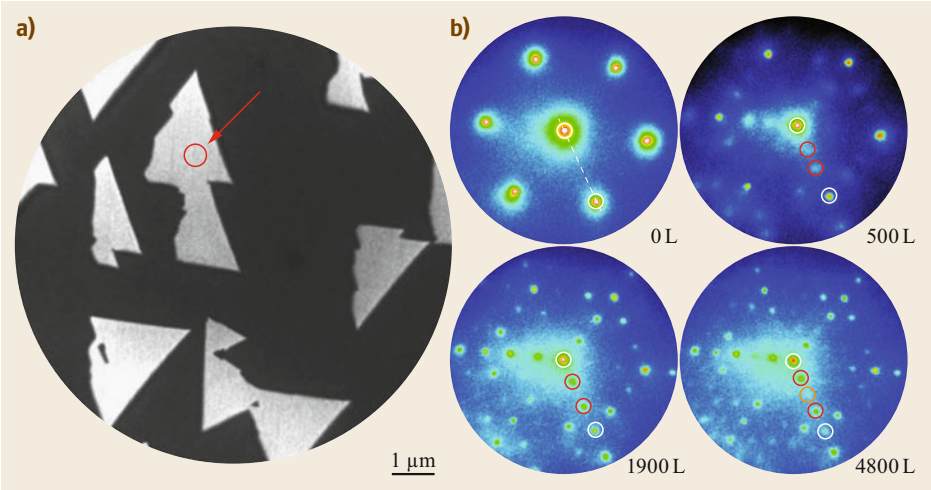

Fig. 13.12 **(a)** LEEM image recorded at 16.3 eV of ceria microparticles (*bright*) on the Ru(0001) support (*dark*). The *red circle* highlighted with an *arrow* illustrates the electron beam spot size and position during µ-LEED. **(b)** µ-LEED image series obtained during reduction of a single ceria microparticle in hydrogen at 700 K. *White circles* indicate the reflections of CeO_2. *Red* and *orange circles* indicate the positions of the superstructure spots (Reproduced from [13.111] with permission, copyright 2015 Wiley-VCH Verlag)

Spot Profile Analysis and LEED-IV

The real-time observation of an energy-filtered, stable LEED pattern is a valuable tool to investigate inhomogeneous surfaces under changing conditions. The quality of LEED images taken in LEEM is such that other analysis methods are made available. For example, the intensity line profile of a particular diffraction spot along a selected crystallographic direction can reveal many details in relation to surface morphology and roughness, such as step distribution and the presence of defects and ordered superstructures [13.113]. The sampling frequency of the profile is determined by the magnification of the backfocal plane and the number of pixels of the detector. The sharpness limit for LEED spots is determined by the transfer width of the electron beam at the surface and depends on the type of electron source and other instrumental effects of the LEEM apparatus.

Figure 13.13a gives an example of a LEED spot profile analysis (SPALEED) performed with LEEM optics on an $Fe_3O_4(111)$ thin film grown on a Pt(111) substrate [13.92]. Magnetite films are used both as a model catalyst and a support for catalytically active nanoparticles. Its surface termination, deeply connected with its functional and catalytic properties, changes with the preparation conditions. In this case, the film was grown with subsequent cycles of Fe deposition and oxidation at 900 K. After the last oxidation performed at 1000 K, if the sample is cooled in an oxygen atmosphere, the zero-order diffraction spot presents a shoulder-like broadening. Such broadening disappears after flashing at 900 K in UHV. The (0,0) spot profile can be fitted with a superposition of a Gaussian peak, accounting for the instrumental broadening, and a shoulder that can be described as a sum of three Lorentz$_{3/2}$-like functions of different half-widths [13.114].

$$I(\boldsymbol{k}) = I_{\mathrm{Gauss}}(\boldsymbol{k}) + I^{(1)}_{\mathrm{Lor3/2}}(\boldsymbol{k}) + I^{(2)}_{\mathrm{Lor3/2}}(\boldsymbol{k}) + I^{(3)}_{\mathrm{Lor3/2}}(\boldsymbol{k}) \,.$$

The prominent broadening is described by the first part, $I^{(1)}_{\mathrm{Lor3/2}}(\boldsymbol{k})$. The weakly modulated background, ascribable to small clusters or adsorbates on the surface, is described by $I^{(2)}_{\mathrm{Lor3/2}}(\boldsymbol{k})$ with a FWHM as large as the first Brillouin zone (FBZ). The third component, $I^{(3)}_{\mathrm{Lor3/2}}(\boldsymbol{k})$, has a FWHM slightly larger than the Gaussian one and can be related to the presence of atomic steps. The spot profile has then been collected over an energy range between 40 and 200 eV, in order to highlight the changes in the relative intensities of the components. It has been found that the FWHM of the components increased linearly with the perpendicular component of $\boldsymbol{k}$, indicating that the surface has a mosaic structure with a calculated angular spread of 0.2°. Moreover, the ratio G between integral intensities of $I_{\mathrm{Gauss}}(\boldsymbol{k})$ and $I^{(3)}_{\mathrm{Lor3/2}}(\boldsymbol{k})$ spot components,

$$G = \frac{I_{\mathrm{Gauss}}}{I_{\mathrm{Gauss}} + I^{(3)}_{\mathrm{Lor3/2}}} \,,$$

revealed a periodic exchange between the two intensities with a period linearly related to the perpendicular

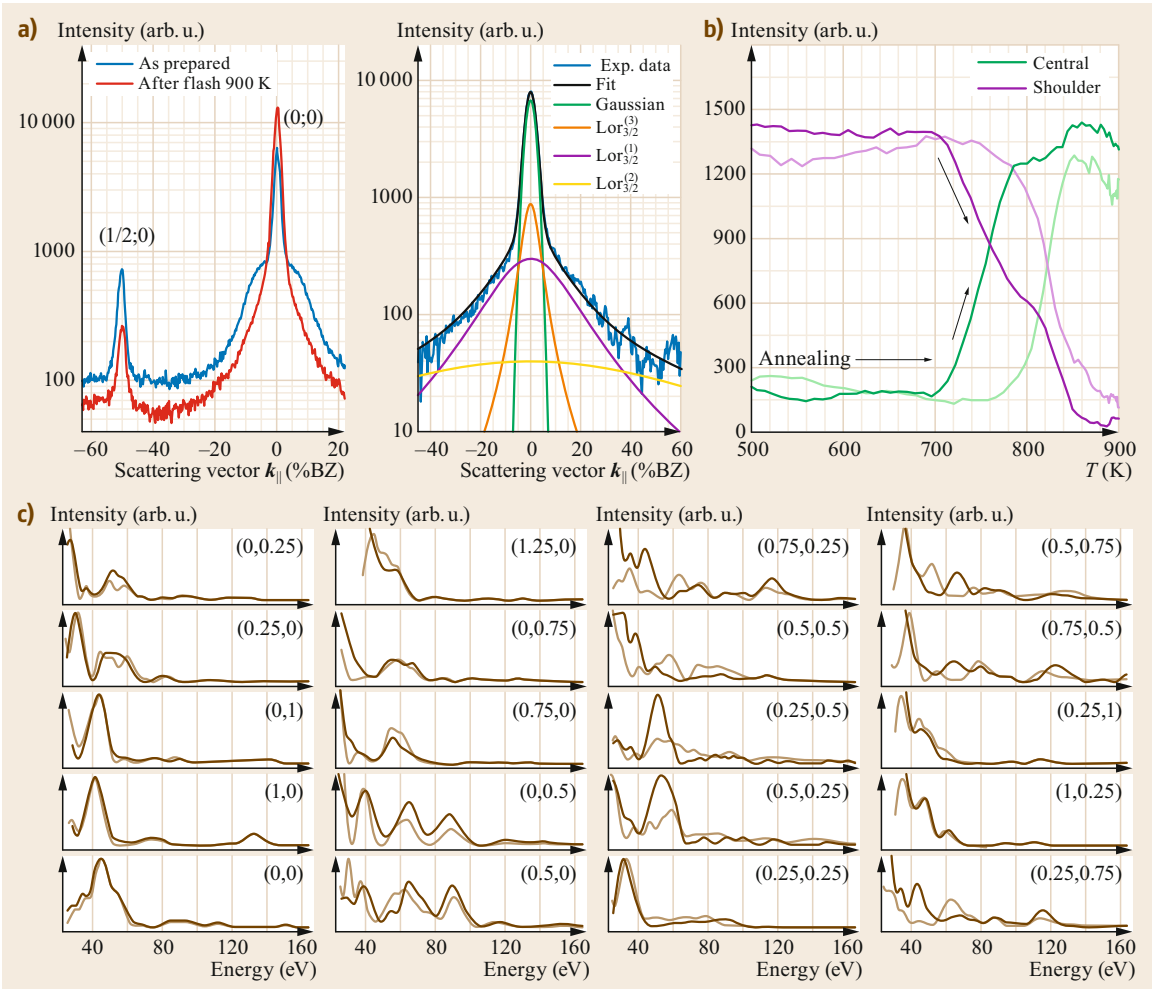

Fig. 13.13 **(a)** Spot profile analysis of $Fe_3O_4(111)$ LEED pattern along the (1,0) vector for the as-prepared surface and after a final annealing at 900 K. The preparation conditions for the $Fe_3O_4(111)$ thin film are described in the main text. The fit of the (0,0) LEED spot profile on the *right* shows a narrow central Gaussian peak in green, two $Lorentz_{3/2}$ peaks in *orange* and *purple* for the shoulder-like broadening, and a very broad $Lorentz_{3/2}$ peak in *dark yellow*. **(b)** Integral intensity of the central Gaussian and the shoulder during cooling in oxidation conditions. The formation of surface inhomogeneities is influenced by the cooling rate, $\approx 4\,K/s$ for *dark lines* and $\approx 1\,K/s$ for *light lines* (**(a)** and **(b)** reproduced from [13.92] with permission, copyright 2012 American Physical Society). **(c)** Comparison of experimental *I–V* curves (*dark brown*) taken with μ-LEED and best-fit calculated curves (*light brown*) for the (4×4) diffraction structure of oxidized Ag(111) (Reproduced from [13.115] with permission, copyright 2007 American Institute of Physics)

component of $\boldsymbol{k}$. Such behavior is consequent to the periodic constructive and destructive interference between two adjacent terraces separated by an atomic step [13.113]. By fitting this periodicity one can calculate the step height: in this case, it was found to be 4.79 ± 0.09 Å, in fair agreement with the height of the magnetite unit cell (4.84 Å).

The nature of the objects giving the shoulder-like broadening was then clarified with real-time acquisition of the LEED pattern under dynamic conditions. Figure 13.13b shows the intensities of the Gaussian and the first $Lorentz_{3/2}$-like spot components during formation under cooling in an oxygen atmosphere for two different cooling rates. The broadening in the zero-order diffraction spot and its behavior during cooling under oxidation conditions suggest that the prepared surface is roughened by oxygen-related objects smaller than the lateral resolution in LEEM [13.92]. Such objects can

expose atoms with different coordination and charge states with respect to the ideal surface and therefore influence the catalytic behavior of the system [13.116].

As in the case of LEEM, the collection of LEED patterns over a broad energy range gives access to structural information. The intensity modulation of diffraction peaks can be simulated with full dynamic calculations. The calculation packages available today allow the comparison of calculated and experimental *I–V* curves to find the most probable atomic configuration of the surface. The acquisition of LEED-IV spectra in a LEEM system starts with the collection of a stack of LEED images with variable start voltage. The intensity of a single peak can be extracted with proper fitting of the line profile, as in the case of SPALEED, or with direct integration over a rounded region of interest of the image. In both cases, a background subtraction is required. To perform a reliable dynamic analysis, the data set, calculated as the sum of the energy widths for every inequivalent diffraction spot, must be in the range of thousands of eV [13.83, 117]. The *I–V* curves must then be smoothed by a convolution with a Lorentzian curve of width 1−2 eV to reduce the noise [13.118]. The first successful *I–V* analysis performed with LEEM optics related to the (4×4) superstructure created by surface oxidation of Ag(111) [13.115]. The comparison of experimental *I–V* curves and calculated ones for the best fit model is shown in Fig. 13.13c. In this experiment, the data set was compared with one recorded with a conventional LEED system. It is shown that LEED acquisition with LEEM optics offers a much better signal-to-noise ratio (some faint diffraction spots were visible in LEED/LEEM and undistinguishable from background in conventional LEED) and a larger energy range for every spot.

The combination of LEED and LEEM gives another advantage with respect to conventional LEED optics [13.90, 92]. In the latter one, the illuminated area is very large, of the order of several hundreds of μm. In the case of a surface with rotational domains, some inequivalent spots from different domains of unknown relative abundance can superpose which forces the researcher to average spectra of spots of the same diffraction order and makes the detection of separated spectra impossible. In LEED/LEEM systems the active selection of the illuminated area can solve this problem. The probed region can be inspected with darkfield LEEM using an inequivalent diffraction spot and the relative abundance p of the domains can be calculated. Then, the disentangled *I–V* spectra can be extracted as follows. Assuming that the experimental LEED pattern is a weighted, incoherent superposition of the rotated LEED patterns, in the case of two rotational domains one can write that

$$I_{\text{total}}(\boldsymbol{k}_{xy}, k_z) = (1-p)I_+(\boldsymbol{k}_{xy}, k_z) + pI_-(\boldsymbol{k}_{xy}, k_z) \,,$$

where $I_+(\boldsymbol{k})$ and $I_-(\boldsymbol{k})$ are the intensity of two inequivalent spots of the same order, produced by two domains with abundance $(1-p)$ and p, respectively. The symmetry condition between rotational domains imposes an equivalency between same-order spots. In the case of two domains with 180° symmetry,

$$I_+(\boldsymbol{k}_{xy}, k_z) = I_-(-\boldsymbol{k}_{xy}, k_z) \,.$$

As a consequence, one can separate the two contributions

$$I_+(\boldsymbol{k}_{xy}, k_z) = \frac{1-p}{1-2p} I_{\text{total}}(\boldsymbol{k}_{xy}, k_z) - \frac{p}{1-2p} I_{\text{total}}(-\boldsymbol{k}_{xy}, k_z) \,.$$

With this method, *I–V* spectra of inequivalent spots become accessible, thus improving the data set quality and the reliability of its dynamic analysis.

13.2.5 Spectroscopy Mode

μ-EELS

If the LEEM apparatus is equipped with an energy filter, its dispersive plane can be displayed on the detector and spectroscopy over a selected area can be performed. The energy spectrum of reflected low-energy electrons presents a very intense peak of elastically scattered electrons, a weaker tail due to inelastic events and the secondary yield. In a region close to the elastic peak, one can perform electron energy loss spectroscopy from a micrometer-sized area (μ-EELS) and detect the electrons that interact with the specimen via creation of plasmons and phonons, in the same fashion as Fig. 13.11b. Although the direct measurement of the dispersive plane offers a better energy resolution and signal-to-noise ratio than the spectrum extrapolation from EELM images, the performance is still too low compared to a dedicated EELS apparatus [13.106, 107]. Other loss features at higher energies, such as ionization edges of core-level electrons, are poorly visible from an apparatus optimized for low-energy electrons. For these reasons, the spectroscopy mode in a LEEM system is used marginally and only as a complement to other investigation techniques. Its counterpart with emitted electrons is much more scientifically valuable, therefore a more complete technical review of the mode can be found in Sect. 13.3.5.

13.3 Photoemission Electron Microscopy

PEEM is equipped with a photon source that illuminates the specimen with ultraviolet and x-ray photons. Electrons emitted via photoelectric effect are collected by the cathode immersion lens and used as information carriers. The image formed on the detector can be acquired in real time as in LEEM, but the acquisition time of a single frame can vary considerably as a consequence of the electron beam intensity: while video-rate is still possible with secondary electrons for intermediate magnification, the collection of a single XPEEM image with core-level electrons requires minutes. The nature of image contrast in PEEM is different from the case of LEEM and is governed mainly by the physics behind the photoemission process and the chemical state of the probed matter. Here only a general discussion will be presented, followed by a more detailed examination of space-charge phenomena that affect PEEM with pulsed light sources.

13.3.1 Basic Image Contrast

The main difference in image formation between PEEM and LEEM is the electron coherence. The photoemitted electrons are in general incoherent in time and space, although for delocalized valence-band electrons some coherence can be seen in reciprocal space. As a consequence, the intensity distribution of the image is the convolution of the intensities of the phase object and the CTF (while in LEEM, i.e., under coherent conditions, the intensity is the square modulus of the convolution) [13.88]. Following the definitions given in Sects. 13.2.1 and 13.2.2 leads to

$$I(\boldsymbol{R}) = \left|\psi_{\mathrm{obj}}(\boldsymbol{R})\right|^2 * \left|T_{\mathrm{inco}}(\boldsymbol{R})\right|^2 \ .$$

The incoherent process modifies the definition of the CTF. In the coherent case, the chromatic damping envelope $\mathcal{E}(\boldsymbol{q}, \Delta E)$ comes from an integration over the weighted contribution of the different energies within the Gaussian energy distribution of the incoming beam. For PEEM, the temporal incoherence imposes a different algebra. *Schramm* et al. [13.88] have modeled the square modulus of the PSF $|T_{\mathrm{inco}}(\boldsymbol{R})|^2$ as the Fourier transform of the square modulus of the CTF for the monochromatic case weighted over the energy distribution $N(E)$,

$$\left|T_{\mathrm{inco}}(\boldsymbol{R})\right|^2 = \mathcal{F}^{-1}\left[\int_{-\infty}^{\infty} \left|H_{\mathrm{mono}}(\boldsymbol{q}, E)\right|^2 N(E)\mathrm{d}E\right] \ .$$

The electron incoherence implies that only amplitude objects give contrast: in PEEM phase objects like atomic steps and other morphologic features are generally invisible. Figure 13.14a reports one of the first images taken in 1934 with an improved version of Brüche's first PEEM [13.119, 120] and shows a polycrystalline Pt foil annealed at high temperature. The contrast is given by the work function difference among the facets and the grain boundaries. The lateral resolution for amplitude objects depends on the kinetic energy of the electrons and their energy and angular distribution. In UVPEEM, a standard Hg short-arc lamp induces photoemission of valence band electrons with a $\cos\theta$ angular distribution over an energy window ΔE larger than 1 eV. In this case, it has been calculated that the best lateral resolution should be about 7 nm for noncorrected instruments and less than 4 nm for the aberration-corrected case [13.88]. Similar values can be expected also in energy-filtered XPEEM

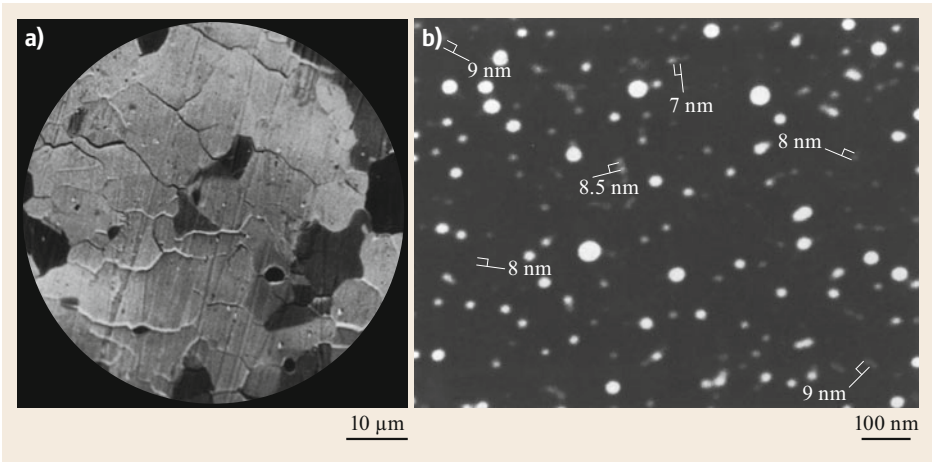

Fig. 13.14
(a) Brüche's PEEM image of a polycrystalline Pt foil after annealing at high temperature (Reproduced from [13.119]). **(b)** PEEM image of colloidal silver demonstrating 7-nm resolution (Reproduced from [13.33] with permission, copyright 1992 Elsevier)

for low start voltages [13.49], while for higher take-off energies the performance gets worse. Such limits were partially reached when PEEM systems with UHV technology were made available. *Gertrude Rempfer* and coworkers demonstrated in the late 1980s a lateral resolution of 7 nm with a nonaberration-corrected UVPEEM [13.33]. Figure 13.14b shows a photoelectron micrograph of colloidal silver particles taken with her instrument. Aberration-corrected instruments lowered the limit for UVPEEM to about 5 nm.

13.3.2 Space-Charge Effects

The lateral resolution in XPEEM is a particular case that deserves a dedicated discussion. The use of monochromatic synchrotron radiation to excite core-level electrons and employ them for imaging has brought huge advantages in terms of flux and versatility, but its pulsed time structure has a worsening effect on both lateral and energy resolution. When a pulsed light beam illuminates the sample, the photoemitted electrons are packed in a small volume. During the flight the cloud density is such that electrons experience reciprocal Coulomb repulsion, thus degrading the transported information [13.121]. This effect, called space charge, has been broadly studied for electron sources and influences both the energy distribution (Börsch effect [13.122]) and the trajectory displacement (Löffer effect [13.123]). Fewer studies addressed the problem in x-ray photoelectron spectroscopy (XPS) [13.124] and specifically in PEEM, not only using synchrotron radiation [13.62, 82] but also fs-laser [13.75, 125].

In the specific case of synchrotron radiation, the photon beam used for XPEEM delivers typically $\approx 10^{13}$ photons/s of variable energy on a small area of a few tens of μm^2. The photon flux is not constant in time, but is organized in pulses. Every pulse has a duration of a few tens of ps and hosts about 20 000 photons. The number of photoelectrons emitted during a single pulse depends on the total photoionization quantum yield: in the case of photoemission from transition metals, this can be estimated as about 400–600 electrons. However, just a few of them are core-level electrons used directly in XPEEM, while the overwhelming majority ($\approx 97\%$) are secondary electrons emitted by inelastic events and filtered away in a second moment by the energy analyzer. In order to understand the magnitude of the space-charge effect, *Locatelli* et al. [13.82] showed LEEM and XPEEM images of the same surface at different photon flux. In LEEM the continuous flow of incident electrons ensures a photocurrent density three orders of magnitude lower than the one in XPEEM, producing a space-charge free image. The latter was then compared to secondary electron ($E_0 = 4$ eV) XPEEM images acquired with the same alignment and configuration of the microscope, but for different photon fluxes (Fig. 13.15a). The lateral resolution in secondary XPEEM increases linearly with the photon flux, from 35 nm with 2.0×10^{12} photons/s to 180 nm with 5.5×10^{13} photons/s. Such degradation is visible also in imaging with core-level electrons. Figure 13.15b shows LEEM and XPEEM images of the same surface, using backscattered electrons and W $4f_{7/2}$ core-level electrons at a kinetic energy of 147 eV, respectively. Again, the XPEEM image blurs as the photon flux rises. The lateral resolution ranges from 31 nm with 2.0×10^{12} photons/s to 82 nm with 5.9×10^{13} photons/s, a degradation smaller than the case of secondary PEEM. An analogous effect can be seen on the energy resolution. *Locatelli* et al. reported a broadening of the Fermi level on a Au(100)-hex surface in a series of spectroscopy measurements with increasing photon flux. At high fluences, the broadening induced by the space-charge effect dominated over the contribution of the energy analyzer.

Space-charge effects occur also when PEEM is performed with a femtosecond laser. *Nakagawa* et al. [13.75] proved that the laser light from a Ti:sapphire laser with pulses of 100 fs produces blurred PEEM images with worse resolution than using a non-pulsed, continuous wave (CW) laser. Figure 13.15c shows images of the same surface acquired with photons of energy 3.1 eV and increasing incident laser power, from 0.2 to 7.8 mW. In this case, the photon flux is much higher than the one with synchrotron light, 8×10^{10} photons per pulse. Again, the lateral resolution is inversely proportional to the laser power, forcing the power output to be greatly reduced and the integration time to be increased to obtain good lateral resolution. Similar results were found by *Buckanie* et al. [13.125] using a Ti:sapphire laser with comparable pulse length and lower photon flux. Such evidence demonstrates how space-charge effects are the biggest restriction for the implementation of pump-probe experiments in PEEM, forcing users to work at low power output, with high repetition rates and long acquisition times.

In order to overcome the resolution limitation induced by space-charge effects, it is important to understand in more detail the evolution of the electron beam from emission to detection. From observation, it is clear that the space-charge effect is determined by the number of photons per time per emitting surface. X-ray photoemission with pulsed light produces a large majority of low-energy secondary photoelectrons and a small amount of core-level electrons with high energy, all taking off from the sample surface in a time range equal to the pulse length. Then, the high volt-

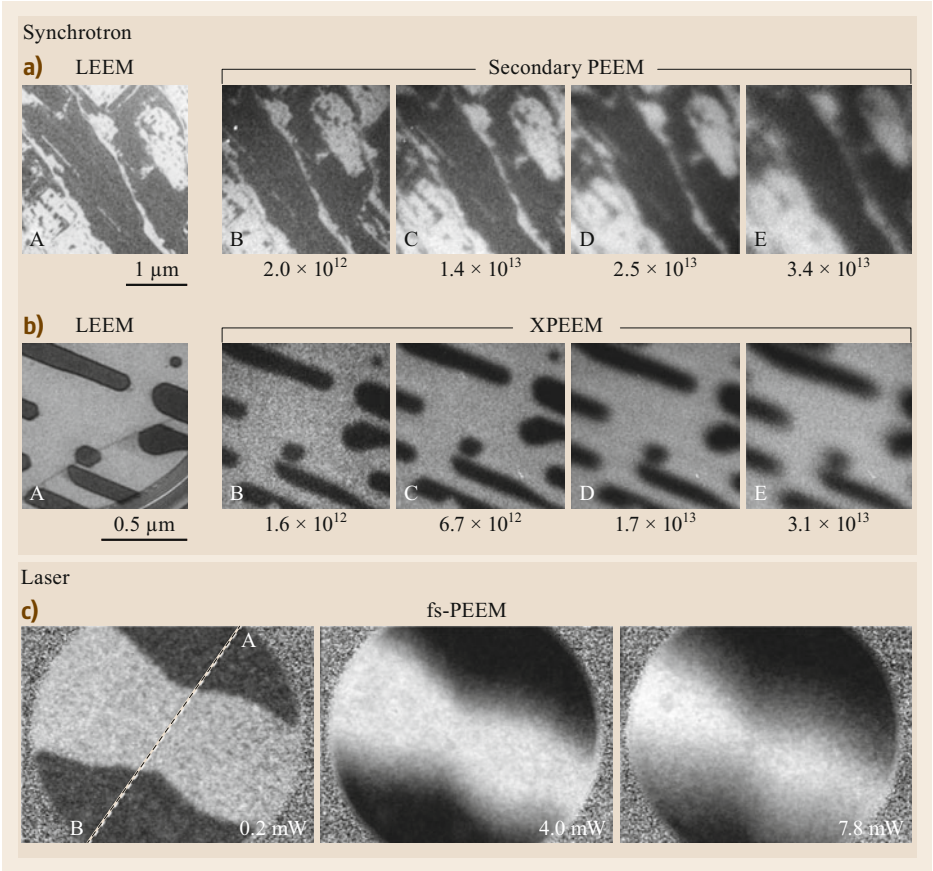

Fig. 13.15 **(a)** LEEM and secondary XPEEM images of 1-ML-thick Au islands on Ir(001). $E_0 = 4\,\text{eV}$. **(b)** LEEM and W $4f_{7/2}$ XPEEM images of thick Fe islands on W(110). $E_0 = 147\,\text{eV}$. Both series of XPEEM images illustrate the degradation of the microscope lateral resolution with increasing photon flux, which is indicated below each image (in photons/s). Photon energy: 182 eV. The operating conditions of the microscope were the same in LEEM and XPEEM (Reproduced from [13.82] with permission, copyright 2010 Elsevier). **(c)** Magnetic circular dichroism fs-PEEM images at increasing laser power of 12 ML Ni deposited on Cu(001) and covered by Cs to reduce the work function. The photon source was a femtosecond laser with a photon energy of 3.1 eV. The lateral resolution was evaluated along the A–B cross section (Reproduced from [13.75] with permission, copyright 2009 IOP Science)

age between sample and objective lens accelerates the electron cloud. The lens system of the microscope induces several crossovers of the electron beam along the path, i.e., where the diffraction and image planes are placed. The first crossover is located in the back-focal plane of the objective lens, while the second is the first intermediate image plane. The magnification induced by the objective lens implies that the lateral size of the crossovers is larger than the initial size of the electron cloud at takeoff. Therefore, no special point with significantly large space-charge density may cause local image blurring, i.e., the blurring occurs along the entire electron path. Moreover, simple kinematic calculations show that the strong overlap between secondary and core-level electrons within one single pulse decays with time due to their different flight speeds. For the SMART microscope, core-level electrons with a takeoff energy of 100 eV are separated from the secondary electron bunch after 70 cm of flight. Behind this point the electron–electron interaction can be neglected for XPEEM measurements. The best strategy to reduce space-charge blurring is then to remove non-necessary electrons as soon as possible along the electron path. In particular, *Schmidt* et al. demonstrated that the insertion of a small field-limiting aperture that cuts away electrons emitted outside the field of view reduces the electron beam intensity behind that point and improves the lateral resolution. This, together with accurate photon flux reduction, led to a demonstrated lateral resolution of 18 nm in XPEEM [13.62]. This

limit is still far from the analogue result in LEEM, but there are reasons to think that a future, dedicated instrument could bridge the gap, at least partially. In particular, such an instrument should be equipped with apertures at the backfocal plane in order to cut non-necessary electrons with different emission angles, and at the first dispersive plane inside the beam separator, to roughly filter away secondary electrons. Highly efficient detectors and improved illumination optics would also help to obtain good quality images with lower photon flux. These measures to reduce the space-charge effect will result in higher resolution.

13.3.3 Imaging Mode

PEEM and XPEEM

The imaging mode with photoemitted electrons displays a magnified real-space image of the probed surface. Such an image contains valuable information on the physical and chemical state of the specimen. The contrast mechanism in PEEM has already been discussed: in the case of low-energy photons, areas can emit a different number of electrons as a function of the local work function and of the local density of states of the valence band. In the case of energy-filtered XPEEM with core-level electrons, the amplitude contrast can also be given, in first approximation, by the relative local abundance of the particular element. The photon energy is often selected in order to maximize the image intensity, in agreement with the atomic cross section of the selected emission line and the brilliance of the photon source. The resulting kinetic energy of the photoemitted electrons typically ranges between 50 and 200 eV, so that the small probing depth due to the IMFP influences the contrast. Figure 13.16 shows a direct example of XPEEM images with chemical contrast. In this case, an Ir(100) surface is partially covered by single and multilayer Gr [13.126]. XPEEM images using Ir $4f_{7/2}$ photoemitted electrons (Fig. 13.16a) shows areas with different intensity. The attenuation of the signal is due to the screening from Gr layers of different thickness. This is confirmed by XPEEM images taken with C 1s electrons (Fig. 13.16b), where the intensity is proportional to the Gr thickness.

The screening effect can be evaluated quantitatively by changing the start voltage and extracting the I–V curve, with the same procedure seen for LEEM. In this case, the collected intensity curve is the local spectro-

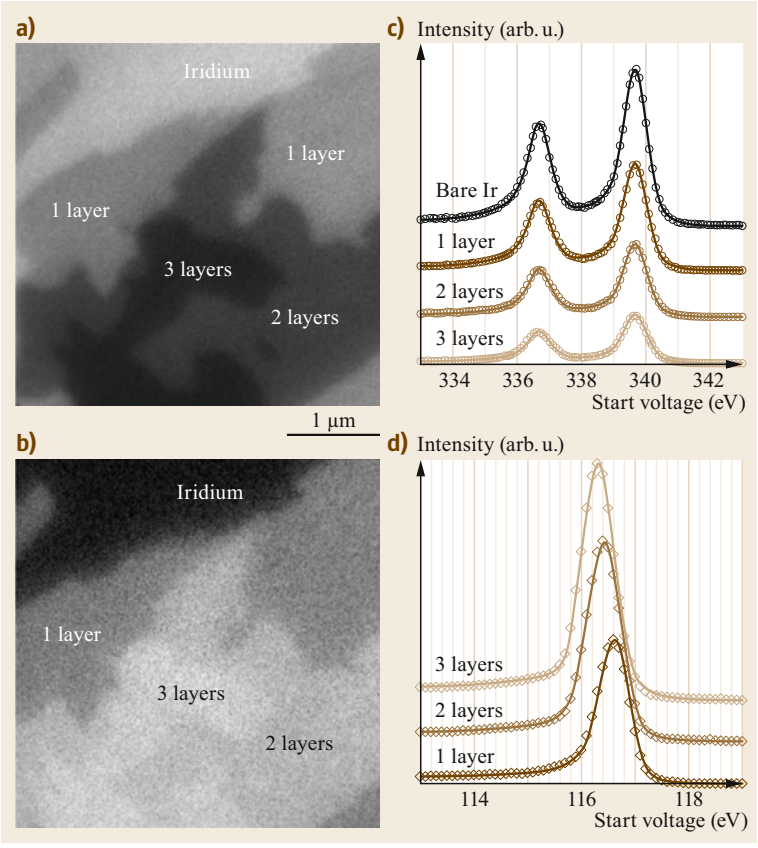

Fig. 13.16 **(a)** XPEEM Ir $4f_{7/2}$ image of a multithickness Gr island. The start voltage corresponds to the kinetic energy of the photoemitted electrons. A photon energy of 400 eV was used in the experiment (Reproduced from [13.126] with permission, copyright 2014 Elsevier)

scopic photoemission peak, i.e., a stack of XPEEM images gives access to local XPS spectra. Figure 13.16c,d displays, respectively, the Ir 4f and C 1s core-level emission spectra, obtained by integration over selected regions of interest over a stack of XPEEM images at different start voltages. The intensity drop in the Ir 4f photoemission line follows the exponential damping factor $e^{-d/\lambda_{gr}(E_0)}$, where d is the layer separation and $\lambda_{gr}(E_0)$ is the kinetic-energy-dependent effective attenuation length [13.127]. The intensity growth of the C 1s core-level shows a similar behavior, although it does not increase linearly with thickness. This deviation is given by the screen effect of the outermost Gr layers that diffract the photoelectrons emitted from buried C atoms. This example demonstrates how the intensity evaluation of XPEEM imaging provides an alternative method of assigning thin film thickness.

Brightfield and Darkfield PEEM

The ordinary microscope setup in PEEM includes the insertion of a contrast aperture to limit the acceptance angle in order to reduce spherical aberration and enhance contrast and resolution. Usually, the aperture selects only electrons with normal emission, i.e., limits the diffraction pattern to a neighborhood of the Γ point of the FBZ. As in the case of LEEM, it would be convenient to build PEEM images with electrons coming from other regions of the FBZ [13.129, 130]. The methods for implementing darkfield measurement have already been reviewed in Sect. 13.2.3, *Brightfield and Darkfield LEEM* and schematized in Fig. 13.8. In the case of emitted electrons, only the first two are available, i.e., (i) to position the contrast aperture around the desired k-point of the reciprocal space and (ii) to incline the sample tilt by a certain angle. In addition, it is possible to deflect the emitted beam after the objective lens. Among the three, the second offers the best advantages in terms of PEEM image quality, since it is the one that lets the electrons travel along the optical axis. It should be remarked that the required tilt inclination is reduced by the change of coordinates due to the accelerating field of the cathode immersion lens. It is sufficient to incline the tilt angle by less than 2° to obtain a consistent shift of the reciprocal image in the backfocal plane of the objective lens and to get to the edge of the FBZ of most materials. The best procedure to select the desired diffraction feature for imaging is to display the backfocal plane and to modify the sample tilt mechanically until the selected point is positioned at the center. Once the contrast aperture is placed, the microscope can be shifted to imaging mode, whereas the intensity is proportional to the local density of states at the selected k-point.

Darkfield PEEM is very powerful tool for probing the local electronic properties of heterogeneous surfaces. For example, it has been employed on Gr grown on Ni(111), a model case for the study of interfacial interactions that can play a key role in tailoring the magnetic [13.131] and chemical [13.132] properties of 2-D materials. In particular, darkfield PEEM has been used to determine the lateral extension of epitaxial and rotated monolayer Gr grown on Ni(111), and to identify particular areas in which the rotated Gr is metallic due to the formation of an interstitial carbide layer [13.128]. Brightfield LEEM image of the system (Fig. 13.17a) reveals the presence of three coexisting phases with different gray levels. Characteristic I–V reflectivity curve and μ-LEED measurements (not shown here) assigned the brighter area in the upper right side to epitaxial Gr (labeled EG), while the neutral gray area and the dark gray patches are rotated Gr (labeled RG). Local XPS measurement on the C 1s core-level performed with the method addressed in the previous Section proved that the dark patches are small areas in which the monolayer Gr rests upon a Ni-carbidic interface layer (labeled RGC) [13.133]. Darkfield PEEM was then performed with electrons photoemitted from Gr's π-band. When the reciprocal space K-point of the epitaxial Gr is selected, only the upper right area becomes bright (Fig. 13.17b). When the equivalent point of the rotated Gr is used, the contrast shows a dependence on the selected start voltage. The RGC phase

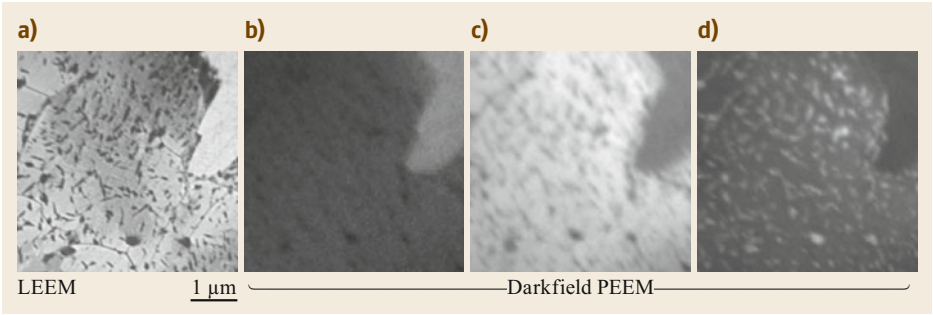

Fig. 13.17 **(a)** LEEM and **(b–d)** darkfield PEEM of: **(b)** EG on Ni(111); **(c)** RG flakes grown on Ni(111); **(d)** RGC patches on a Ni-carbide interstitial layer (Reproduced from [13.128])

exhibits a high density of states at a binding energy of 0.2 eV (Fig. 13.17c), while the RG phase shows the same behavior only at 2.2 eV (Fig. 13.17d; [13.134]). This demonstrated that the π-band of RGC Gr has the Dirac point very close to the Fermi energy, i.e., shows an almost metallic state, while in EG and RG it undergoes a severe hybridization with the substrate states. This result, together with the angular-resolved photoelectron spectroscopy measurement, demonstrated that the presence of the interstitial carbide layer decoupled the monolayer Gr from the substrate.

XAS–PEEM and Magnetic PEEM Imaging

It has been shown that when x-rays illuminate a sample, the displayed intensity of slow secondary electrons exceeds by orders of magnitude the one of photoemitted electrons. It is therefore convenient to use them for imaging, enabling even video-rate acquisition. Moreover, imaging with secondary electrons is particularly useful in the presence of tunable x-ray sources such as synchrotron beamlines. Direct secondary PEEM imaging during photon energy scans reveals intensity variations due to the x-ray absorption process, i.e., the characteristic curve for a selected region of interest corresponds to the local x-ray absorption spectrum (XAS) [13.135, 136]. Compared to XPS, the XAS has a bigger signal-to-noise ratio and uses electrons with a larger IMFP, thus enabling a larger probing depth. Moreover, it can be performed even without active energy filtering, as the photoemitted electrons give a negligible contribution to the overall intensity. The possibility to select a desired photon polarization also gives access to magnetic characterization of materials [13.102]. In the case of circular polarized light, one can use the x-ray magnetic circular dichroism (XMCD) to obtain magnetic contrast in PEEM. In XMCD the angular momentum of circular polarized light is used to impose selection rules over the photon absorption process [13.137]. In ferromagnetic materials, the valence and the conduction band are split in two electron populations, a majority with spin parallel to the magnetization vector and a minority with spin antiparallel. In the photon absorption process, Fermi's Golden Rule imposes that the transition probability of an electron from the initial core-level to an unoccupied state depends on their density of states. Therefore, the different final density of unoccupied states in the majority and minority population determines two distinct absorption probabilities for left and right circular polarized light. The magnetic dichroism is defined by convention as the intensity difference between the two absorption spectra, $I_{\mathrm{XMCD}} = I_{\uparrow\downarrow} - I_{\uparrow\uparrow}$ and is directly proportional to the scalar product between the magnetic moment of the sample and the photon polarization vector. XMCD can be performed in PEEM by taking two images with opposed circular polarization at the absorption photon energy and subtracting one from the other, thus extracting the exchange asymmetry image, as in the case of SPLEEM,

$$I_{\mathrm{XMCD}} = \frac{I_{\uparrow\downarrow} - I_{\uparrow\uparrow}}{I_{\uparrow\downarrow} + I_{\uparrow\uparrow}} \,.$$

The XAS-PEEM imaging process is illustrated in Fig. 13.18a, where Fe nanowires on a W(110) surface

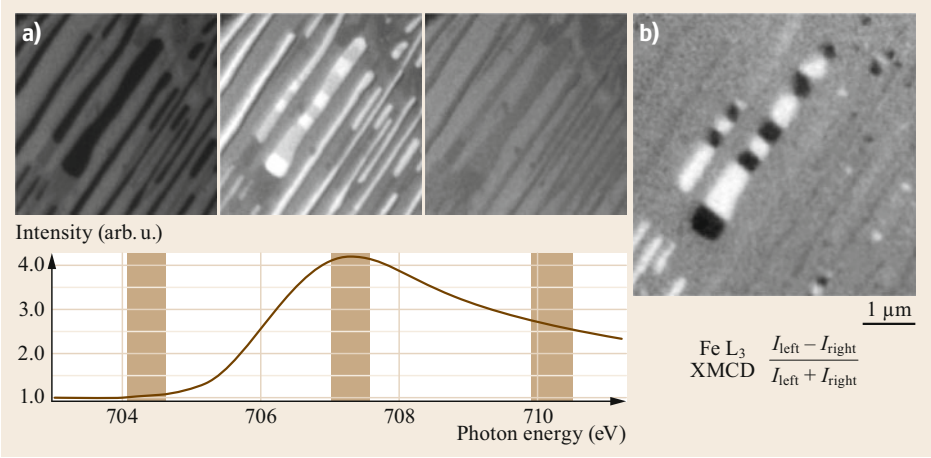

Fig. 13.18 **(a)** Illustration of imaging spectroscopy in XAS mode. Fe nanowires on W(110) appear dark on the *left panel* at a photon energy of 704.5 eV. At the Fe L_3 threshold, the wires become much brighter (*middle panel*). The XAS spectrum *below* is extracted from the largest nanowire in the center. **(b)** Illustration of XMCD-PEEM imaging. The photon energy is tuned to the L_3 maximum. The field of view is 5 µm. The start voltage is 3 eV in order to collect secondary electrons. Within the image plane, the x-ray direction is perpendicular to the nanowire axis (Reproduced from [13.44])

are displayed [13.44]. When the photon energy is set to be off-resonance (left), the contrast is given simply by the different secondary yield. Once the photon energy is set to the Fe absorption L_3 edge (center), the nanowires become brighter whereas the clean W(110) surface in between shows no change. The contrast reduces again for higher, above-resonance photon energies (right), although it is changed also as the new Fe $2p_{3/2}$ photoemission channel enhances the Fe secondary yield. The entire absorption spectrum of an individual nanowire (below) can be extracted from local integration over a stack of PEEM images at different photon energy. Then, XMCD imaging is obtained by tuning the photon energy to the Fe L_3 adsorption edge and taking the difference between two secondary PEEM images with opposed circular polarization (Fig. 13.18b). The wires with magnetization perpendicular to the polarization direction appear gray as the scalar product reduces the XMCD signal to zero. The black and white regions in the central wires are dipolar domains with magnetization parallel and antiparallel to the beam direction, respectively. Note that the strong magnetic contrast in the case of highly magnetic materials is visible even at the single XAS image acquired with one circular polarization. The most advanced PEEM systems are then capable of acquiring magnetic images at video rate, thus enabling dynamic studies of the magnetic domain evolution in nonequilibrium conditions.

In particular samples, magnetic imaging can also be performed using x-ray magnetic linear dichroism (XMLD). The sum rules are similar to those for XMCD [13.102], so the technical implementation mimics the one already discussed. Its main application field is the study of antiferromagnetic materials and their interfaces with ferromagnetic materials, as well as multiferroics. In conclusion, it should be noted that in a synchrotron beamline equipped with insertion devices, the polarization vector could be varied only in the plane perpendicular to the photon beam propagation direction. Therefore, XMCD-XMLD contrast can be achieved only for selected geometries. PEEM systems with perpendicular illumination can characterize only out-of-plane magnetization states, while grazing photon incidence gives its best with in-plane states.

13.3.4 Diffraction Mode

μ-ARPES and μ-XPD

As in the case of μ-LEED, the diffraction operation mode of a PEEM system gives access to the angular distribution of energy-filtered photoemitted electrons. The convenient placement of a field-limiting aperture on an intermediate image plane selects a probed region down to 1 μm in size. ARPES is one of the most important methods to study the band structure of solids [13.138, 139]. The direct display of the entire angular spectrum in a single image gives PEEM systems the possibility to acquire ARPES spectra over a large energy range in a very short amount of time without any mechanical movement of the sample. The same operation mode is then capable of detecting XPD spectra, when the angular distribution of photoemitted core-level electrons is displayed. Although the energy resolution is not comparable to a dedicated ARPES machine, its fast acquisition and the possibility to conjugate it with microscopy measurement makes PEEM systems ideal for studies on dynamic and/or heterogeneous systems [13.140].

ARPES spectra are usually collected at relatively low photon energy. Typical photon sources are lasers under high harmonic generation (the fourth harmonic of a Ti:sapphire laser delivers 6 eV photons), He discharging lamps (HeI emission line at 21.2 eV) and synchrotrons (10−100 eV). The latter is more indicated to highlight surface states, because of the smaller IMFP of photoemitted electrons. Among others, μ-ARPES has been employed to access the π-band of Gr and to quantify the local doping induced by foreign species and/or interaction with the substrate [13.142]. In particular, the local probing in diffraction mode was crucial to determine the doping level of 2-D heterojunctions created with selected-area low-energy irradiation of a monolayer Gr with N_2^+ ions at room temperature [13.141]. Figure 13.19a shows a LEEM image of the boundary region between irradiated and nonirradiated Gr grown on an Ir(111) surface. The first appears notably darker than the second due to the development of corrugations and defects. Microprobe ARPES measurements were performed separately on the two areas (Fig. 13.19b). The reciprocal space image, taken with photon energy of 40.5 eV and at a binding energy of 0.45 eV, displays a large density of states around the *K*-point due to the Gr band structure, while the background modulation resembles the surface states of the Ir(111) substrate. While in the nonirradiated area the circular feature around the *K*-point corresponds to a slice of the Dirac cone, the irradiated area showed no band splitting at this point. The entire band structure can be depicted if one extracts the intensity line profile along a high-symmetry direction over a stack of ARPES images at different kinetic energy. Figure 13.19c shows the momentum distribution curve (MDC) along the normal to Γ-K direction on the *K*-point for both areas. The nonirradiated Gr presented a linear dispersion of the π-band centered at the Dirac point $E_D = 0.08 \pm 0.03$ eV, corresponding to a slight p-doping due to the interaction with the substrate. The irradiated Gr showed a large shift of the Dirac point towards higher binding energies, quantified as $E_D = -0.45 \pm 0.07$ eV. This n-doping was induced by the implantation of N atoms in the C mesh

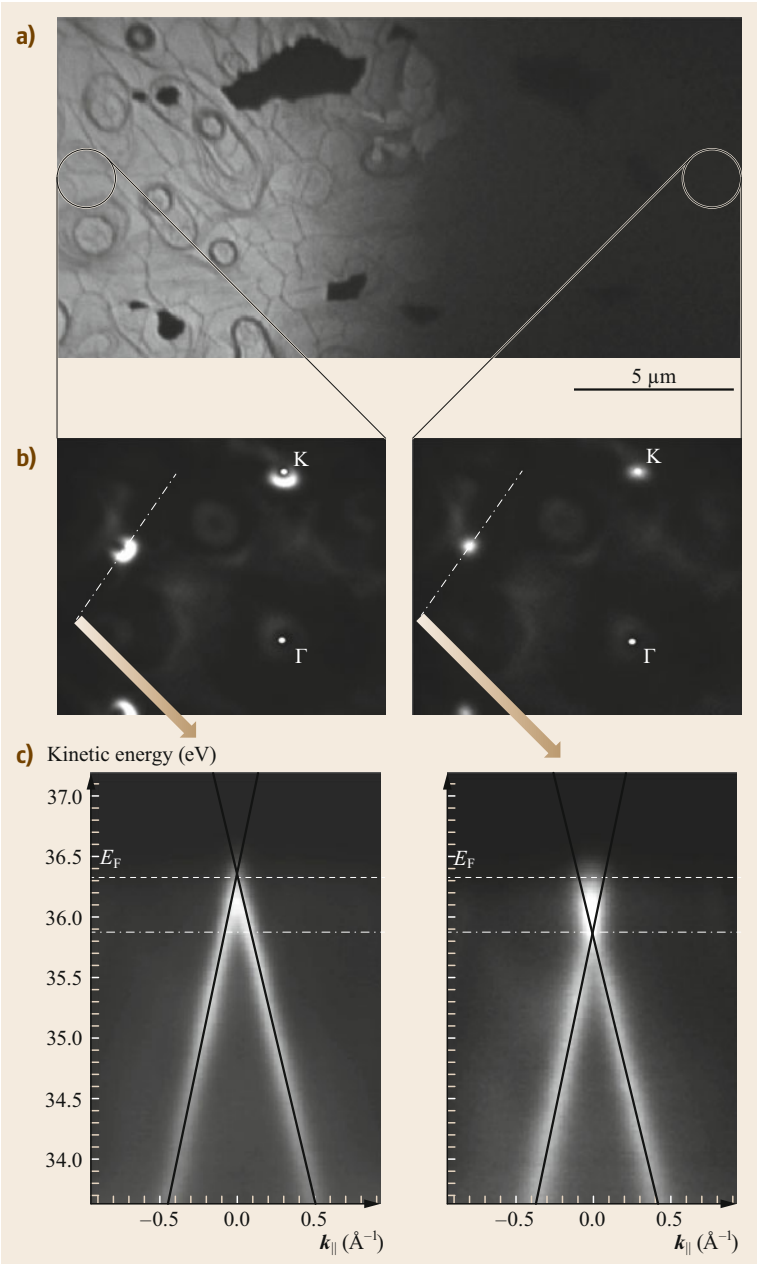

Fig. 13.19 **(a)** LEEM image ($E_0 =$ 7 eV) of the boundary between N_2^+ irradiated (*dark*) and nonirradiated graphene (*bright*) grown on Ir(111). **(b)** μ-ARPES patterns of nonirradiated (*left*) and irradiated (*right*) epitaxial graphene on Ir(111) before annealing. The image was acquired 0.45 eV below the Fermi level. The *dash-dot line* passing through the *K*-point identifies the high symmetry direction perpendicular to ΓK; $h\nu = 40.5$ eV. **(c)** Intensity cut in the plane passing through K along ΓM. The MDCs demonstrate linear dispersion of the π-band close to the Fermi energy E_F (*left*). On the *right*, the same intensity cut for an N_2^+ irradiated sample (3 min at $p_{N_2} = 2 \times 10^{-5}$ mbar, ion current 0.14 μA). The Dirac energy was estimated by fitting the MDC and determining the intersection of the resulting *solid lines*. $E_D = -0.45 \pm 0.07$ eV. The Fermi energy E_F is highlighted by the *dashed line*, while the *dash-dot line* represents the energy of the images in **(b)** (Reproduced from [13.141] with permission, copyright 2015 Wiley-VCH Verlag)

of Gr [13.143]. This example shows clearly how microprobe ARPES in PEEM systems has the power to characterize the electronic states of micrometer-sized regions.

The SPELEEM microscope used in these measurements is an energy-filtered LEEM/PEEM station dedicated to the probe of surfaces with backscattered electrons and synchrotron radiation. The lens setup is designed to guarantee good performance overall, but is not devised for state-of-the-art measurement in every single operational mode. The provided energy resolution, 330 meV, was adequate to accurately detect the shift of the Gr π-band, but was insufficient to determine whether a small band gap has been opened by the substitutional implantation of N [13.142]. PEEM stations specifically designed for high performance in ARPES, e.g., NanoESCA [13.45, 140], forgoes the lateral resolution for a better energy and angular resolution. Such systems are often labeled as momentum microscopes or *k*-PEEM.

13.3.5 Spectroscopy Mode

μ-XPS

The spectroscopy analysis of photoemitted electrons is a major tool in surface science. Since its first development by Kai Siegbahn in 1957, Electron Spectroscopy for Chemical Analysis showed how the accurate measurement of photoemitted core-level electrons allows the retrieval of information on the chemical structure and bonding, the elemental composition, and the surface state of atoms [13.144]. PEEM systems equipped with an energy analyzer are capable of performing photoemission spectroscopy (PES) from a selected area of the sample, much smaller in size than a standard PES machine [13.145]. The probed area can be selected by strong demagnification of the illuminating photon beam and insertion of a field-limiting aperture in the first intermediate image plane. The best PEEM systems available worldwide for PES measurements make use of synchrotron radiation and take advantage of its high brilliance and energy tunability. The access to the dispersive plane in PEEM enables direct measurement of the photoemission spectrum from a localized area and is often called microprobe XPS (μ-XPS).

The standard setup for a PEEM in dispersive mode includes the insertion of the field-limiting aperture at the intermediate image plane and the contrast aperture at the diffraction plane (Fig. 13.3), limiting conveniently the probed area and the acceptance angle. The dispersive plane is then projected on the detector and appears as a thin line with modulated intensity. Electrons with initial kinetic energy equal to the bias value eV_0 are projected at the center. The width of the energy window depends on the final magnification of the dispersive plane and the construction constraints, and can be as wide as $\pm 5\,\mathrm{eV}$. The energy spectrum around the bias value is then revealed with an intensity line profile after opportune background subtraction and response function division. The photoemission spectrum collected in dispersive mode has a better energy resolution and a more favorable signal-to-noise ratio than the one extracted from a stack of XPEEM images over a start voltage range. In several cases the signal-to-noise ratio is sufficiently high to enable fast image acquisition up to video rate. This opens the gates to the microprobing of dynamic processes in real time, such as catalytic reactions, thin film growth, deposition of atoms and molecules on surfaces, and testing in changing conditions of temperature and pressure. The data quality is well visible in the XPS data measured for the heterogeneous system already presented in Sect. 13.3.4. In Fig. 13.20a,b N 1s and C 1s core-level photoemission spectra are depicted, respectively, of a monolayer Gr grown on Ir(111) and locally irradiated with low-energy N_2^+ ions at room temperature [13.141]. It has already been shown with μ-ARPES that the ion irradiation induces a negative doping on the Gr sheet. The XPS N 1s spectrum of the irradiated Gr describes in great detail the film stoichiometry and the atomic arrangement of N atoms in the C mesh. The photoemission peak can be fitted with four Doniach–Šunjic line profiles [13.142, 143, 146], later assigned to pyridine-like, twofold coordinated nitrogen (N1), pyrrole-like, threefold coordinated nitrogen (N2) and substitutional nitrogen (N3 graphitic and N4 secondary graphitic) on the basis of their binding energy. By evaluating the areas of the various components, one can establish the relative abundance of the defects and obtain that 43% of the N is in substitutional configuration. The N 1s spectrum of nonirradiated graphene confirms that no N atoms are detected few μm aside. The analysis of the C 1s spectra shows a notable broadening for the irradiated area at higher binding energies with respect to the main emission line (the only component in the nonirradiated area). This is consistent with the picture of Gr functionalized with N. The irradiated spectrum was fitted considering the different contributions of sp^2 and sp^3 carbon, vacancies and carbon species bonded with nitrogen [13.147, 148]. The evaluation of peak areas allows a vacancy abundance of 1.7% of a ML to be estimated, evidencing the little damage suffered by Gr. Moreover, from the comparison of N 1s and C 1s peak areas one can estimate the overall N coverage. Since both core-levels have the same number of electrons and were measured at the same photon energy ($h\nu = 500\,\mathrm{eV}$), the N/C peak area A ratio can be normalized with the *Yeh* and *Lindau* photoionization cross section σ [13.149] and the energy-dependent transmission of the microscope, which in the case of SPELEEM is proportional to the kinetic energy E_0 of the photoemitted electrons. In the case of coplanar species, no IMFP correction is needed (as in Sect. 13.3.3), therefore the nitrogen abundance is equal to

$$\theta_\mathrm{N} = \frac{A_\mathrm{N1s}}{A_\mathrm{C1s}} \frac{\sigma_\mathrm{C1s}}{\sigma_\mathrm{N1s}} \frac{E_0^\mathrm{N1s}}{E_0^\mathrm{C1s}} \,.$$

The stability test of locally implanted nitrogen took full advantage of the real-time capability of μ-XPS. Annealing in UHV up to a temperature of 800 °C followed probing the N 1s photoemission line every 2 s. The intensity of the various components, as determined in a fit, is presented in Fig. 13.20c. As can be seen, both N2 and N4 components decrease steadily with increasing temperature, reaching negligible intensity at high temperature. The N1 component, associated with in-

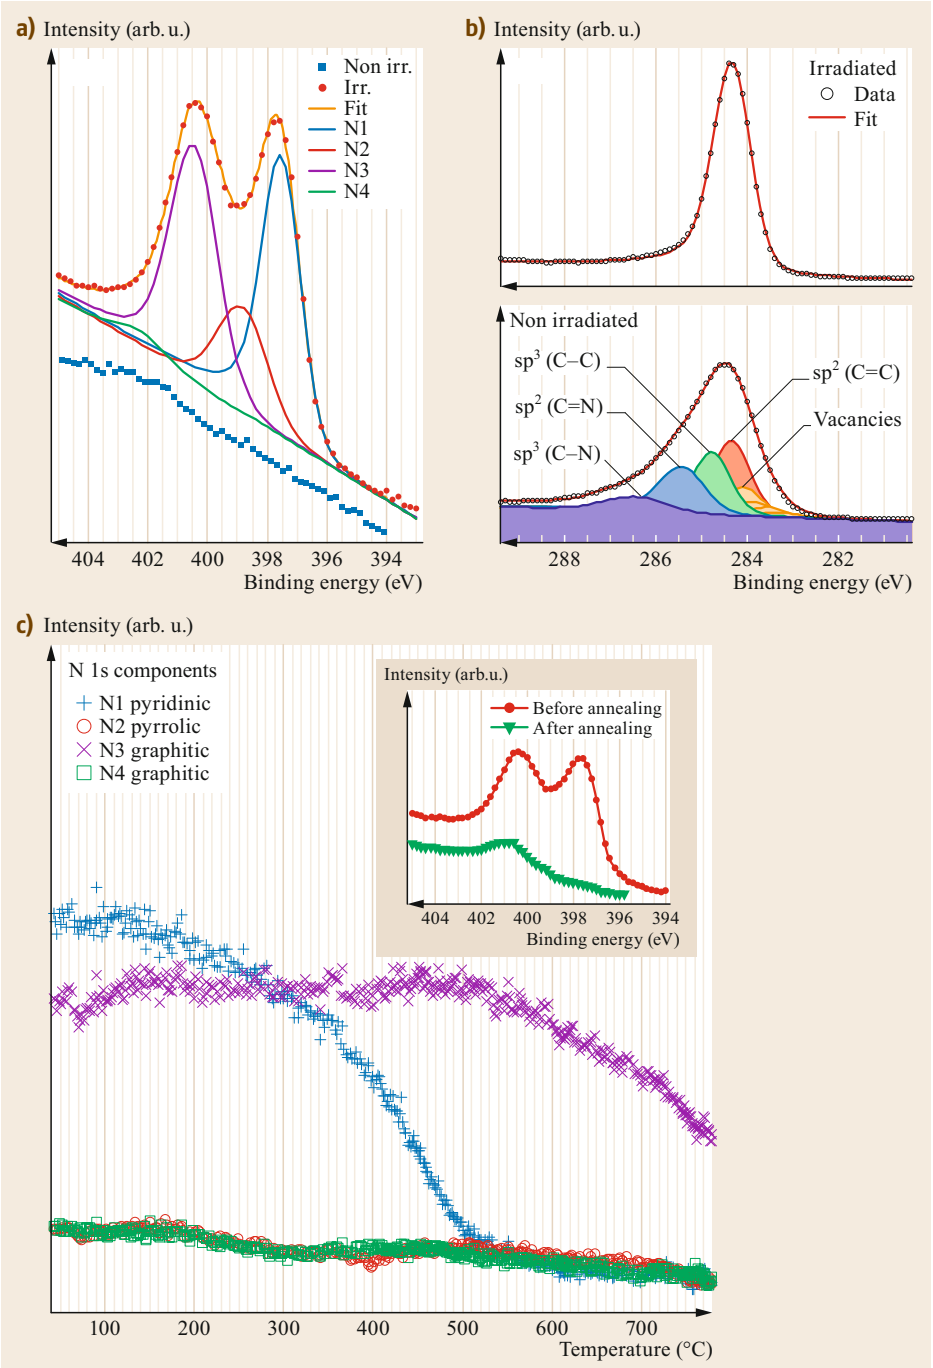

Fig. 13.20 **(a)** N 1s spectra and **(b)** C 1s spectra obtained from the nonirradiated and N_2^+ irradiated graphene on Ir(111). The best fit to the experimental data is also shown: the simulated curve for the irradiated Gr is shown as the sum of different components, each with a Doniach–Šunjic line profile. **(c)** Evolution of the intensity of the N 1s components, N1–N4, plotted as a function of the annealing temperature. In the *inset* the N 1s spectra of ion-irradiated Gr before and after annealing at 800 °C are compared; $h\nu = 500$ eV (Reproduced from [13.141] with permission, copyright 2014 Wiley-VCH Verlag)

tercalated, pyridine-like nitrogen, decreases moderately up to 430 °C and suddenly decays above this temperature. The N3 component, related to graphitic nitrogen, remains constant up to 500 °C and decays moderately with annealing temperature. After annealing, the overall nitrogen coverage decreased from 0.07 to 0.04 ML. The real-time μ-XPS highlighted the different evolution of each defect species during annealing, giving highly valuable information on the stability of doping level for annealed heterostructures embedded in a single Gr sheet.

The dispersion mode can probe photoemitted electrons at any given start voltage. Therefore, it is suitable to probe not only core-level electrons, but also valence band electrons and even secondary electrons. It should be noted that the size of the contrast aperture determines the angular acceptance, i.e., the probed region in the reciprocal space. Usually the neighborhood of Γ in the FBZ is selected, but one can use the methods introduced for darkfield measurement (Sect. 13.3.3) to filter another region of *k*-space. Very often, core-level XPS measurement is combined with valence band measurement up to the Fermi edge, in order to use it as reference for zero binding energy. The Fermi edge of conductive surfaces at low temperature is frequently used to test on the go the energy resolution of the instrument. The edge of the secondary yield can also be probed to measure the work function differences among separate areas.

13.4 Perspectives

More than 80 years after the first PEEM image, cathode lens microscopy continues to be one of the most used techniques in surface science. The ability to conjugate microscopy, spectroscopy, and diffraction in a single instrument is the key to its successful application in several fields. The increasingly high level of sophistication led to the construction of systems with many specializations, such as magnetic imaging, pump-probe photoemission, synchrotron endstations, momentum microscopes, and more. The growing user community shares its findings and perspectives in many dedicated workshops; among others, the LEEM-PEEM biennial gathering reviews the status of LEEM, PEEM, SPLEEM, XPEEM and related techniques, promotes applications of cathode lens microscopy to a broader audience and highlights the most recent scientific advances and instrumental developments.

After the advent of synchrotron radiation, spin-polarized electron guns and pulsed laser in the attosecond domain, cathode lens microscopy can be defined as a mature and well-established technique. In more recent years, much of the technical effort has been spent addressing three main problems, here reviewed briefly:

- *Reduction of space-charge effect:* its inevitability imposes the creation of a system expressly designed to circumvent it. Such apparatus must have particular filters in the backfocal plane, in the first intermediate image plane and in the first dispersive plane, all of them placed very close to the objective lens. Moreover, it must be equipped with a state-of-the-art detection system. The new generation of SMART microscope, called SMART 2, is currently (2017) under construction and implements most of the strategies discussed to give full advantage of aberration correction in XPEEM. This development is needed for advances in pump-probe experiments.
- *Resolution improvement:* in principle, aberration correction via an electrostatic mirror pushes LEEM towards the ultimate resolution, i.e., the diffraction limit. Several groups, with particular mention of Ruud Tromp's team, have investigated theoretical and experimental aspects of aberration correction. They discovered that the correct state is intrinsically unstable due to the performance of electronics. The creation of more stable devices and a dynamic feedback system that prolongs the lifetime of the correct state remains a serious challenge.
- *Pressure gap:* in a standard cathode lens microscope, the high electrostatic field of the accelerating stage limits the pressure in the main chamber so that it is lower than $\approx 10^{-5}$ mbar. The direct observation of surfaces under near-ambient pressures is highly desirable, e.g., in the field of catalysis. In principle, the implementation of high-pressure cathode lens microscopy can take profit from the technical development of near-ambient pressure XPS systems, which have been available since the late 2000s. These systems are equipped with a pressure cell that maintains high pressure in a small volume in front of the sample and lets photoemitted electrons escape through nozzles and membranes towards the detector placed under UHV conditions. The design of a high-pressure cell that works with the strong electrostatic fields required in cathode lens microscopy is a very difficult task that may require years of research and development. A successful breakthrough in the pressure problem can breathe new life into the cathode lens microscopy user community and ensure a bright future for this technique.

Dr Alessandro Sala is currently Research Fellow at the University of Trieste and CNR-IOM, Trieste, Italy. His research fields in surface science are low-dimensional materials, biomimetic molecules, and model catalysis. He has worked with LEEM/PEEM systems since 2008, first on the SMART project at the Fritz-Haber-Institute, Berlin, Germany, then at the SPELEEM equipping Nanospectroscopy Beamline at Elettra Sincrotrone Trieste, Italy.

14. Scanning Photoelectron Microscopy: Past, Present and Future

Matteo Amati, Alexei Barinov, Luca Gregoratti, Hikmet Sezen, Maya Kiskinova

Adding submicrometer lateral resolution to the analytic capabilities of photoelectron spectroscopy was a milestone that opened up new opportunities to access lateral fluctuations in the chemical composition and electronic and magnetic structure of surfaces and interfaces and to explore exotic properties of nanostructured matter. To achieve a high spatial resolution while preserving the spectral resolution of this technique requires the very intense photon flux that has become available with the advent of third-generation synchrotron storage rings. The high spatial resolution of x-ray photoelectron microscopes, operated at synchrotron facilities, is achieved by either: (i) magnifying the image of the irradiated surface area using a suitable electron optical imaging system; or (ii) demagnifying the incident photon beam using x-ray photon optics. The contrast mechanisms in both instruments are based on photon absorption and the photon-induced electron emission is used to obtain spectroscopic information encoding the composition and electronic structure of the sample under investigation.

This paper offers a brief overview of the history, operational principles and potential of scanning photoelectron microscopes where the imaging is performed by scanning the sample with respect to the focused beam.

14.1 X-Ray Microscopy—A Brief Overview

The trend of modern nanotechnology is to fabricate nanostructured and composite materials with improved structural, chemical, electric, magnetic and optical properties that relate directly to the performance of energy harvesting, storage media, catalysts and a variety of electronic devices and applications. It is also well known that the nanoscale confinement leads to new properties, feeding vanguard technologies to improve device functionalities, for example in the fields of communications, chemical sensing and biomedical appliances. Understanding the properties of such exotic functional materials requires experimental techniques that allow access to their structure and composition at proper length and depth scales. Much progress in nanoscience and nanotechnology has been made thanks to the availability of sophisticated methods such as electron microscopy and scanning probe microscopy, in addition to standard techniques such as x-ray and neutron diffraction, x-ray scattering, and other spectroscopies. Other techniques that have flourished in the recent three decades with the construction of third-generation synchrotron light sources are encompassed in so-called x-ray microscopy [14.1, 2]. The contrast mechanisms in the x-ray microscopes are based on photon absorption,

phase shift and photon-induced x-ray or electron emission. Depending on the detection mode, the chemically specific information is provided by x-ray absorption spectroscopy (XAS) [14.3], fluorescence spectroscopy (FS) or photoelectron spectroscopy (PES) [14.4].

Many of the complex functional materials playing an essential role in technology advancements involve interfaces that call for understanding and control at submicron length scales, in particular for the correlation between the surface and near-surface properties and elementary processes such as adsorption, chemical reactions, growth and processing. When these phenomena are investigated, the advantage of the electron detection mode in x-ray microscopes is the limited escape depth the emitted electrons that provides high surface sensitivity. Using PES the energy filtered electrons emitted from atomic core and valence levels as a result of interaction with monochromatic photons provide the most straightforward quantitative compositional information and are also excellent fingerprints for the chemical state and the structural and chemical environment of the emitting atoms. More specific electronic and structural information can be obtained by angle-resolved measurements of the valence band and through photoelectron diffraction. Angle-resolved photoelectron spectroscopy (ARPES), is a direct experimental technique to observe the distribution of the electrons (more precisely, the density of single-particle electronic excitations) in the reciprocal space of solids. The technique is a refinement of ordinary photoemission spectroscopy, studying photoemission of electrons from a sample achieved usually by illumination with soft x-rays. ARPES gives information on the direction, speed and scattering process of valence electrons in the sample being studied (usually a solid). This means that information can be gained on both the energy and momentum of an electron, providing detailed information on band dispersion and the Fermi surface. This technique is also known as angle-resolved ultraviolet photoelectron spectroscopy (ARUPS) since ultraviolet light is more commonly used to generate photoemission. The XAS spectra exhibit resonant electronic transitions from core levels into unfilled valence states, governed by well-established selection rules. Using circularly or linearly polarized photon beams the element specific XAS can also provide information on the average magnetic moment and symmetry of the chemical bonds, called x-ray magnetic circular or linear dichroism (XMCD or XMLD).

The sample probing depth in PES-related techniques is determined by the kinetic energy of the photoemitted electrons and can be varied from less than ten to hundred angstrom. In XAS, measured by detecting low-energy secondary electrons, the information can originate from a sample depth up to a few hundred angstroms.

There are two distinct approaches to x-ray microscopy using synchrotron radiation, called full-field imaging and scanning. In the full-field imaging method a magnified image of the irradiated sample area is obtained by tailoring the transmitted photons or photoemitted electrons using appropriate photon or electron optical elements. In the scanning method photon optics demagnify the monochromatized photon beam to a small spot onto the sample, and an image is acquired by collecting emitted or transmitted photons or emitted electrons while scanning the sample with respect to the microprobe provided by the focused beam.

In the scanning approach the spatial resolution is achieved by reflective, glancing or near-normal-incidence mirror systems or diffractive circular grating optical elements, called zone plate (ZP) lenses [14.5]. Today ZPs can cover the wide photon energy range 100–15 000 eV [14.6, 7]. The grazing geometry (generally defined as Kirkpatrick–Baez (K–B)) system consists of two crossed mirrors for separated focusing in the vertical and horizontal planes. Only in the recent decade has advanced K–B fabrication technology reached sub-100 nm microprobes [14.8] but this is still not easily achievable using soft x-rays. The advantage of K–B optics is that they are achromatic and allow for easy x-ray absorption near edge spectroscopy (XANES) measurements keeping the optics–sample distance invariant. Another optical system optimized for the focalization of low-energy photons is based on a set of two spherical multilayer mirrors with a normal incidence (Schwarzschild objective, SO), which have been demonstrated to provide submicrometer resolution, but since the reflectivity drops very rapidly with increasing photon energy this optical system works well only at very soft x-rays (< 200 eV) [14.9].

The full-field imaging microscopes based on detection of photoelectron emission are a special class of microscopes. They were called photoelectron emission microscopes (PEEM) and date from the early 1930s when they used a laboratory UV photon source. They use a suitable electrostatic or magnetostatic electron optical imaging system for a magnified projection of the emitted electrons and dispersive elements for their energy discrimination. It was decades before synchrotron sources provided sufficiently high x-ray fluxes to operate PEEMs as XPEEMs; it happened in mid-1990s and today at least one instrument operates at each main synchrotron facility. The great potential of the XPEEM direct imaging approach is that one can follow dynamics with temporal resolution down to nanoseconds, depending on the signal level. Today XPEEMs are very popular instruments for the characterization of antifer-

romagnetic and ferromagnetic samples using XMLD and XMCD, taking advantage of the time structure of the synchrotrons for applying dynamic pump-probe measurements as well. Another notable advantage of XPEEM is that by adding an electron source it can become a multifunctional instrument providing complementary structural information at the same time via low-energy electron microscopy (LEEM). Details of the working modes and the applications capabilities of XPEEM, and XPEEM combined with LEEM, can be found in [14.10–13].

The present review article is intended to introduce the reader to the capabilities of the scanning photoelectron microscopes (SPEM) for characterization of matter, which is either laterally inhomogeneous at micro-to-nano length scales or consists of nanostructures that need to be probed individually. The major strength of SPEM is for exploiting processes occurring at solid surfaces in contact with gas and recently also ambient liquid, relevant to operation of technologically important materials where issues of complexity at microscopic length scales, such as lateral inhomogeneity in the stoichiometry and/or morphology, should be faced and understood. It should be noted that SPEM dedicated to μ-ARPES became very attractive more recently, when the discovery of graphene and other appealing two-dimensional (2-D) materials, as semiconductors with direct gap, topological insulators, Weyl semimetals etc. have opened up new unexplored scientific fields. These exotic materials have called for adequate characterization methods of small devices demanding sophisticated microscopic tools capable of harvesting important information about their electronic structure as well. In this respect μ-ARPES is becoming a unique tool for band structure determination especially for 2-D materials since the interpretation of results is rather straightforward with precisions of the order of few meV and below $0.01\,\text{Å}^{-1}$ in k-space [14.14–16]. If compared to full-field instruments, the scanning instruments, where the x-ray beam is focused to a microprobe, provide a flexible and adaptable sample environment and an optimal performance in terms of spectral, spatial and variable depth information.

Here we will present in more details the recent achievements with SPEMs using SO and ZP optical systems, referred as SO-SPEM and ZP-SPEM respectively. The review is divided in three sections: the first part illustrates the construction principles of SPEM including focusing optical elements, which determine the microprobe, detectors and possible operation modes. The second part uses selected results obtained with the microscopes operated at the Elettra Laboratory to demonstrate the new information provided by combining chemical sensitivity with submicron spatial resolution. The third section reports on the most recent developments of experimental setups in ZP-SPEM for breaking the pressure gap and studying materials near to the realistic operation conditions.

14.2 Operation Principle of SPEM

The general setup of a SPEM instrument operated at a synchrotron light source is schematically shown in Fig. 14.1. The drawing is for ZP-based SPEMs but, except for the optics providing the microprobe, all x-ray beamlines hosting SPEM include the following components: a photon source (usually an undulator) and suitable photon transport and tailoring optics (mirrors, gratings and slits) in order to meet the requirements of the focusing optics (ZP, SO or K–Bs) providing the microprobe onto the sample.

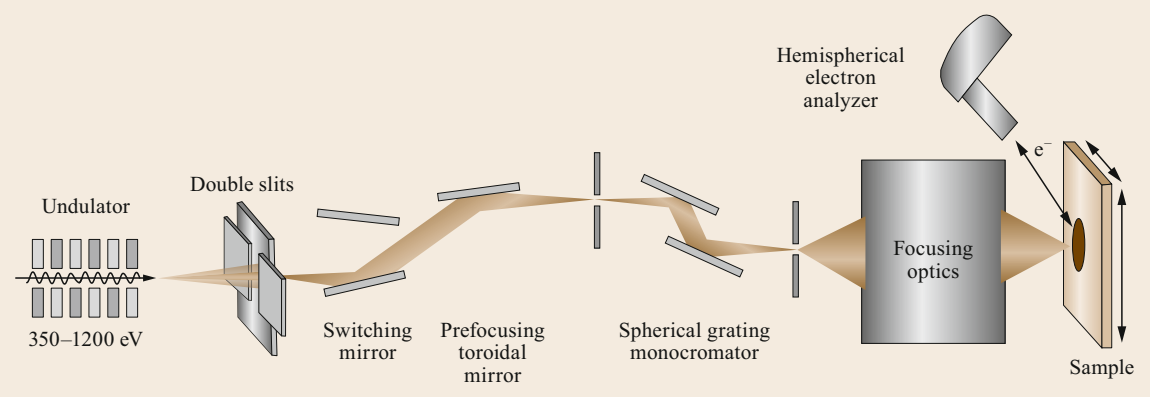

Fig. 14.1 General setup of a SPEM instrument operated at a synchrotron light source

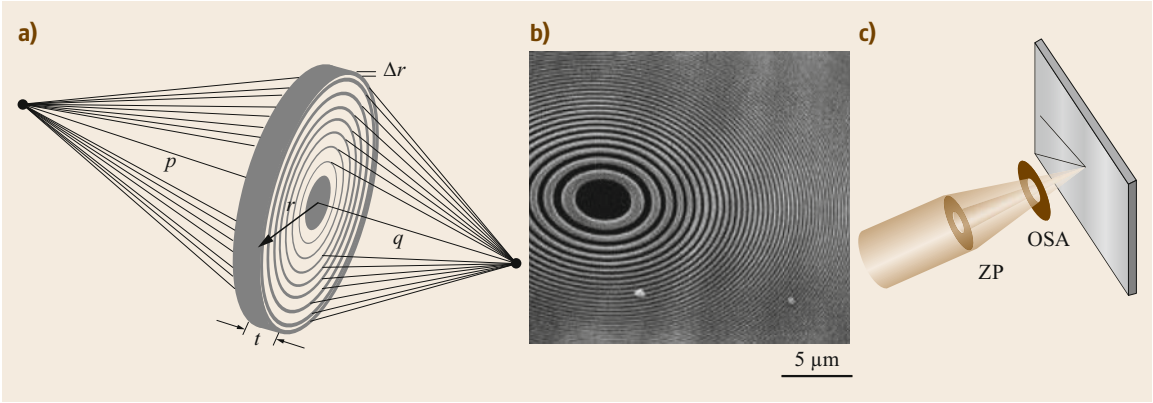

Fig. 14.2 **(a)** Schematic drawing of a ZP used to form an image of a source point onto the image plane with p and q as object and image widths respectively. The ZP has radius r, outermost zone width Δr, and thickness t. **(b)** Scanning electron microscopy (SEM) image of the inner structures of a ZP used for focusing soft x-rays [14.2]. **(c)** Typical arrangement of the ZP and OSA in front of the sample

As noted above the microprobe in the SPEMs hosted at the ESCAmicroscopy and Spectromicroscopy beamlines at Elettra is provided by a zone plate (ZP) and normal incident Schwarzschild objectives (SOs), respectively [14.17, 18].

14.2.1 Zone Plate Optics

The high-resolution ZPs that today can reach 10 nm resolution in the soft x-ray range are circular diffraction gratings with a radially increasing line density (Fig. 14.2). They obey the visible light lens rule $1/f = 1/p + 1/q$ [14.6], where f denotes the focal length, p the source distance and q the image width. The basic relation between the focal length in the m-th diffracted order, f_m, photon wavelength, λ (or energy, E, in eV), ZP radius, r, and the outermost zone width, Δr, is expressed as [14.5]

$$f_m = \frac{2r\Delta r}{m\lambda} \approx \frac{2r\Delta r}{1240m}E\ (\mathrm{eV})\,. \qquad (14.1)$$

This equation shows that, as with any diffraction gratings, the ZPs are highly chromatic optics with an infinite number of diffraction orders. The first-order diffraction is the most commonly used one in SPEM and, as shown in Fig. 14.2, a central stop and order-sorting aperture (OSA) are needed to cut the undesired orders. For a ZP with a numerical aperture $\mathrm{NA} \approx \lambda/(2\Delta r)$ the depth of focus (DOF) is described by the following (14.2)

$$\mathrm{DOF} = \pm\frac{\lambda}{2(\mathrm{NA})^2} \approx \pm\frac{\Delta r}{\mathrm{NA}} \approx \pm\frac{2(\Delta r)^2}{\lambda}\,. \qquad (14.2)$$

The spatial resolution is not only a function of the diffraction-limited resolution $\delta_i = 1.22\Delta r/m$ (applying the Rayleigh criterion), but also of the light monochromaticity. In order to avoid chromatic aberrations, δ_m, which reduce the spatial resolution the source monochromaticity has to exceed $E/\Delta E \geq Nm$, where N is the number of zones [14.19].

Another important parameter of the ZP is the diffraction efficiency ϵ_m, which is the fraction of the incident light focused in the m-th diffraction order. It can be calculated using the scalar diffraction theory introduced by *J. Kirz* [14.20] and the complex refractive index $\eta = 1 - \delta - \mathrm{i}\beta$, tabulated for most elements by *Henke* and coworkers [14.21], which are at the base of (14.3)

$$\varepsilon_m = \frac{1}{(m\pi)^2}(1 + \mathrm{e}^{-2k\phi} - 2\mathrm{e}^{-k\phi}\cos\phi)\,, \qquad (14.3)$$

where $k = \beta/\delta$, and $\Phi = 2\pi\delta t/\lambda$ denotes the phase shift of diffracting structures with height t. Equation (14.3) is valid for rectangular zone shapes and not too high aspect ratios of the zone structures [14.22]. In the case of $k \to 0$, i.e., dominating phase shift, the maximum first-order diffraction efficiency of $4/\pi^2 \approx 40\%$ can be achieved, while for $k \to \infty$ or high absorption, the first-order efficiency is limited to $1/\pi^2 \approx 10\%$. An important and limiting factor in the fabrication process is the aspect ratio (height/width of zone structures), which lowers the diffraction efficiency to real values below 20%.

The ZPs used in the ZP-SPEM at Elettra have diameters ranging from 200–250 μm and minimum outermost zone width of 50 nm. They are selected to have good compromise between spatial resolution in microspectroscopy and sufficient signal to get good spec-

tral resolution. Depending on the photon energy used for the experiments for these ZP parameters the typical focal distances in the first-order diffraction range should be from 4 to 15 mm and one should consider that also there is the OSA (a pinhole) placed between the sample and the ZP. It has to be noted that, although the size of the focused beam becomes smaller using higher diffraction orders ($\delta_i \approx 1/m$), it is almost not applicable for SPEM because the diffraction efficiency scales with $1/m^2$ and when using soft x-rays the sample–OSA/ZP distance becomes very short, obstructing the emitted electrons.

The monochromaticity of the ZP optics imposes the requirement for moving the sample when scanning the photon energy in order to preserve the spot size since the focal distance varies with the photon energy. This requirement impedes easy implementation of micro-XAS in total electron yield but recently interferometer controlled sample movements have been implemented in ZP-SPEMs to solve the problem [14.23]. The optical system ZP/OSA generating the x-ray microprobe is mounted on appropriate stages, which enable independent positioning of the ZP and OSA in x-, y- and z-directions.

14.2.2 Schwarzschild Objectives

SO with multilayered primary and secondary spherical mirrors is the final focusing element of the SO-SPEM hosted at the Spectromicroscopy beamline used to provide the microprobe on the sample. The high reflectivity ($\approx 50\%$ per mirror) for the selected energy by multilayer spacing on the energy line secures a high photon flux in the microprobe, which is essential to satisfy the requirements of the photon-hungry μ-ARPES. Compared to the soft x-ray ZP described in the previous subsection the SO has a much longer working distance (12.5 cm), which eases the movements of the internal electron analyzer around the sample in order to perform angular resolved measurements. In fact, for photon energies less than 100 eV used for ARUPS the ZPs are not suitable due to the reduced focal distance and transmission. A SO system is schematically shown in Fig. 14.3.

The major disadvantage of the SO is the constraint imposed by using multilayer pairs of mirrors that perform only at a preselected photon energy. Currently two SOs are installed at the SO-SPEM at Elettra; they can be easily selected without vacuum break. They work at photon energies of 27 and 74 eV that fit well to the ARUPS measurements. Indeed, compared to ZPs the spatial resolution achievable with SO are ≈ 250 nm considering that the diffraction limit for such types of optics is 120 nm. However, due to aberrations caused by figure errors of the objective's mirrors, the realistic spatial resolution in microspectroscopy is ≈ 500 nm.

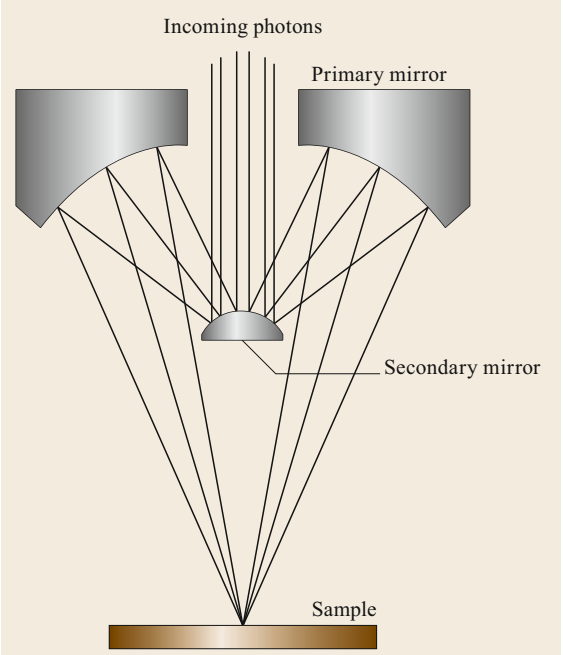

Fig. 14.3 Schematic view of a SO system. The incoming photons are first focused by the secondary mirror onto the primary mirror and then projected to the focal spot at the sample surface

14.2.3 Sample Environment and Detection Systems

The SPEM optics-sample-analyzer setup is sketched in Fig. 14.4. The samples are mounted on a scanning stage manipulator, which allows for quick XYZ positioning, controlled by stepper motors and a fine $X-Y$ piezoelectric stage that holds and scans the sample with respect to the microprobe for obtaining two-dimensional images. In the ZP-SPEM the sample temperature can be varied between 150 and 1300 K and also there are possibilities for applying potentials in the range of several volt that have been used for in situ studies of electrochemical energy devices [14.24]. The research performed using SO-SPEM also requires cooling so the sample temperature can be varied within the range of 35–400 K by combination of liquid helium or liquid nitrogen cooling and a sample heater.

Since in both types of SPEM the microprobe hits normal to the sample surface the emitted photoelectrons are detected and energy filtered by an electron analyzer positioned at a grazing angle. The ZP-SPEM working in the 400–1200 eV photon energy range is dedicated

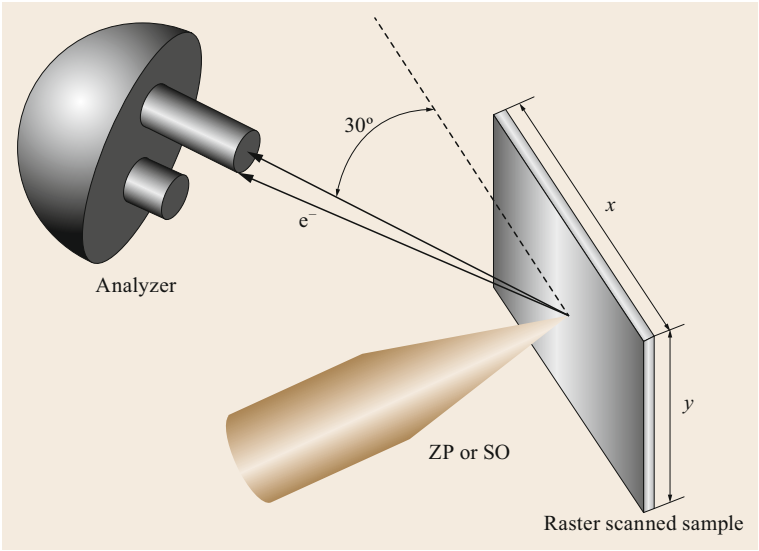

Fig. 14.4 Typical optics-sample-analyzer setup of a SPEM

exclusively to core-level spectroscopy and uses a classical type hemispherical electron analyzer (HEA) where the electron detection is based on a delay-line technology developed at Elettra [14.25]. The SO-SPEM for μ-ARUPS has a movable HEA designed and constructed in-house. It is mounted on a goniometer inside the vacuum chamber that can face the sample from different directions within a section of sphere covering $50° \times 50°$ [14.18]. The relatively long distance between the sample and the analyzer entrance slit (73 mm) has allowed the placing of a five-element electrostatic lens system designed to transform the cone of photoelectrons up to 16° to an entrance slit preserving their angular dispersion. The photoelectrons are further dispersed in energy between the hemispheres of the analyzer and detected by multichannel plates mounted on a delay-line setup, where the X–Y position of the electron pulse is monitored. By combining stacks of 2-D k–E (E being the energy) dispersion images from the detector while rotating the goniometer one can obtain the three-dimensional (3-D) band structure of a considerable part of the Brillouin zone. We would like to note that thanks to the high reflectivity of SO this electron analyzer, although small, operates at low pass energies reaching spectral and angular resolutions better than 50 meV and ±0.3° maintaining reasonable count rates.

Both SO-SPEM and ZP-SPEM at Elettra use in-house designed detectors based on the delay-line technology. The detector of the ZP-SPEM is a one-dimensional (1-D) array configured as a multichannel sensor, which reduces substantially the time necessary for getting chemically specific information and handles topography effects as well. In multichannel detection, the number of images collected simultaneously is equal to the number of the channels, where each channel corresponds to a specific kinetic energy, defined by the selected energy window. The multichannel imaging allows not only mapping of different chemical states and the background with a single scan of the sample, but also reconstruction of the spectrum corresponding to the energy window, so-called spectra imaging, as described in the next section. The SO-SPEM uses a 2-D array with working area $20 \times 20\,\mathrm{mm}^2$.

14.2.4 Imaging and Spectroscopy Acquisition Modes

The main advantage of the scanning photoemission microscopes is that imaging and microspot spectroscopy are independent modes. This allows optimization of each mode accounting for the required spectral and lateral resolution and acquisition time. In the imaging mode, one can map element concentration, element chemical state, Fermi band structure etc. by scanning the sample and simultaneously collecting the photoelectrons within a selected kinetic energy window that defines the property under investigation. The microspot spectroscopy (termed μ-spectroscopy) uses the whole analytical power of PES, providing detailed information on the composition and local electronic structure of the probed microscopic area. However, as illustrated below the imaging mode can also offer sufficient spectral information when the multichannel detection system is properly exploited.

In imaging mode the contrast map visualizes the lateral distribution of a particular sample constituent. Figure 14.5 illustrates the advantages of mapping, including spectral imaging by using a 48-channel detector

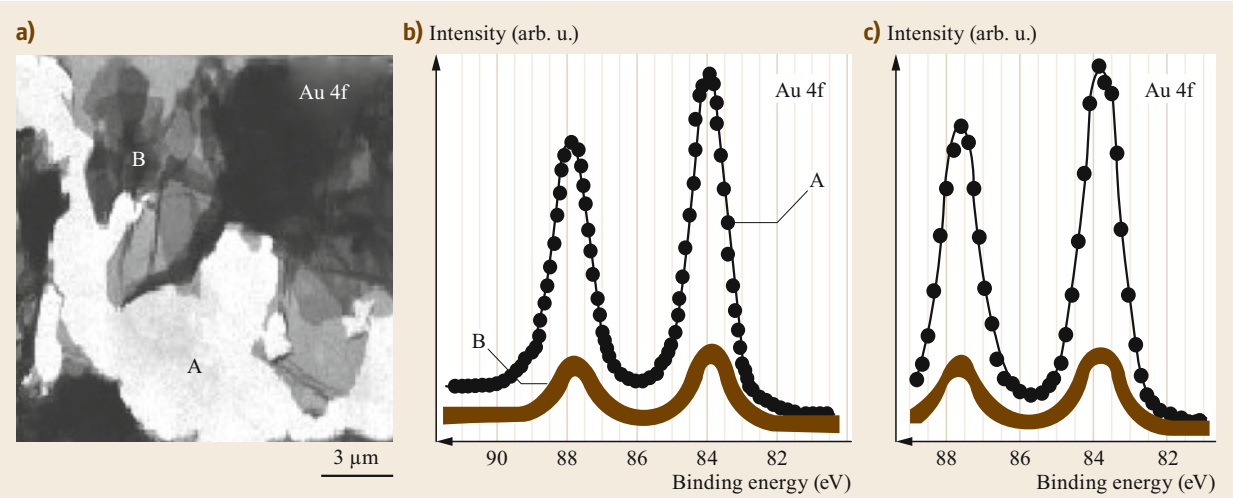

Fig. 14.5 **(a)** Au $4f_{7/2}$ map ($15 \times 15\,\mu m^2$) illustrating areas partially covered by graphene flakes. **(b)** Au 4f spectra measured in µ-spectroscopy mode from the positions, marked as A and B in **(a)**. **(c)** Reconstructed Au 4f spectra from the same A and B areas. The similarity with conventional µ-spectra is evident

in the ZP-SPEM. The example is an Au surface partially covered by graphene flakes, where the Au 4f signal shows significant intensity variations as a function of the local graphene thickness. The contrast level in the Au 4f map (Fig. 14.5a), obtained by summing the signal from all 48 channels covering the Au $4f_{7/2}$ energy window, reflects the lateral variations of the graphene thickness. This is confirmed by comparing the intensity of the high-resolution Au 4f spectra taken in $0.01\,\mu m^2$ spots A and B (Fig. 14.5b) indicating thicker graphene overlayer in position B that strongly attenuates the signal. From the Au map we reconstructed the Au 4f spectra corresponding to the indicated selected areas (Fig. 14.5c). One can clearly see striking similarity achieved using spectral imaging, despite the lower spectral resolution due to the higher pass energy used in the imaging mode. Furthermore, by selecting a few channels corresponding to a specific photoelectron energy that is a fingerprint of a chemical or electronic state one can visualize its lateral distribution or can account for the topographic contributions, as described below. It should be noted that by increasing the number of parallel counting channels the pass energy of the analyzer can be increased accordingly, accepting a much wider energy range of the emitted photoelectrons while maintaining the same energy resolution on each channel.

Since SPEM operates with a grazing angle detection this enhances the topography contributions to the signal intensity. Topography affects the intensity of the detected signal in each pixel and its contribution depends on the angle between the sample surface and the axis of the HEA lenses. This contribution can be expressed by the following equation:

$$I = I_0 e^{\frac{-d}{\lambda \cos\theta}} , \tag{14.4}$$

where I_0 is the photoelectron yield from the top atomic layer, d is the probing depth, λ is the inelastic mean free path for the specific material and θ is the angle between the surface normal and the HEA lenses axis. For the ZP-SPEM at Elettra θ is 60° with respect to the surface normal, a geometry that increases the surface sensitivity, as evidenced by (14.4), but also favors stronger topographic effects, represented by an enhancement of the signal from the side of the feature facing the HEA due to locally smaller θ and attenuation from the opposite side due to shadowing of the emitted electrons.

Although the topography contribution obscures the quantitative information, in many cases it is also useful to look for possible correlations between topography and chemical or electronic properties. However, in order to get quantitative information the topographical contribution should be removed using proper processing approaches [14.26]. The most common one is based on the application of rather simple algorithms such as

$$I = \frac{I_{pk}}{I_{bg}} ,$$
$$I = \frac{(I_{pk} - I_{bg})}{I_{bg}} , \tag{14.5}$$

where I_{pk} is the intensity recorded at the maximum of a photoemission core level, while I_{bg} is the measured background signal at the lower binding energy region of the core level.

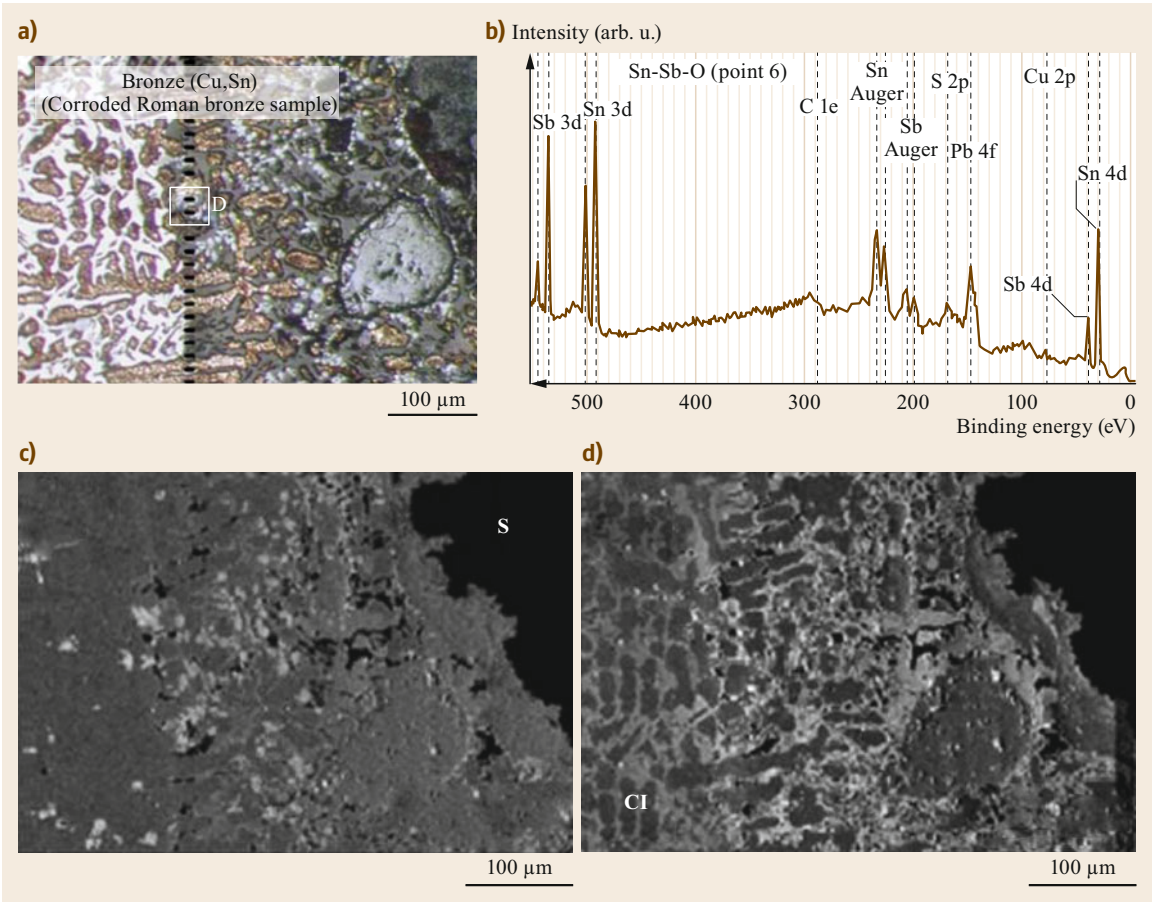

Fig. 14.6 **(a)** Optical image of an ancient bronze coin after thousands of years of environmental degradation. **(b)** Survey XPS spectrum revealing the main coin constituents: Sb, Sn, S, Cl, C and Cu. **(c,d)** Processed S 2p and Cl 2p images after applying (14.5) where the topographic contribution to the contrast is removed, leaving the pure lateral variations of the S and Cl content

An example of the processing procedures for getting quantitative information from the SPEM images is reported in Fig. 14.6 using results obtained in studies of an ancient bronze coin after thousands of years of exposure to environmental degradation. The optical image in Fig. 14.6a clearly reveals the surface topography with colored regions of different heights. The survey XPS spectrum in Fig. 14.6b shows the average elemental content, namely Sb, Sn, S, Cl, C and Cu. By applying (14.5) we were able to visualize the lateral elemental distribution quantitatively. This is illustrated by the S 2p and Cl 2p maps in Fig. 14.6c,d showing that S is generally homogeneously distributed with few microscopic areas where the S concentration appears higher (bright) or lower (dark), while Cl appears concentrated in specific confined regions that correlate with the topographic features of the optical map.

A detailed analysis of the ancient coin Sn chemistry is reported in Fig. 14.7 where the high resolution XPS spectra in Fig. 14.7a taken in different regions contain components characteristic of different Sn chemical states: the yellow vertical band represents the energetic position of the metallic Sn while the light blue one covers the energy position of Sn oxides. The images in Fig. 14.7b–d are obtained by selecting channels covering different energy windows. The variations in the entire Sn surface content are represented by Fig. 14.7b, obtained by integrating the whole Sn energy window. By selecting the specific energy ranges as indicated by the two bands in Fig. 14.7a and removing the topographical contribution we get the images shown in Fig. 14.7c,d, which reveal the distribution of the metallic and oxidized tin. More details about the characterization of the ancient coin can be found in [14.27].

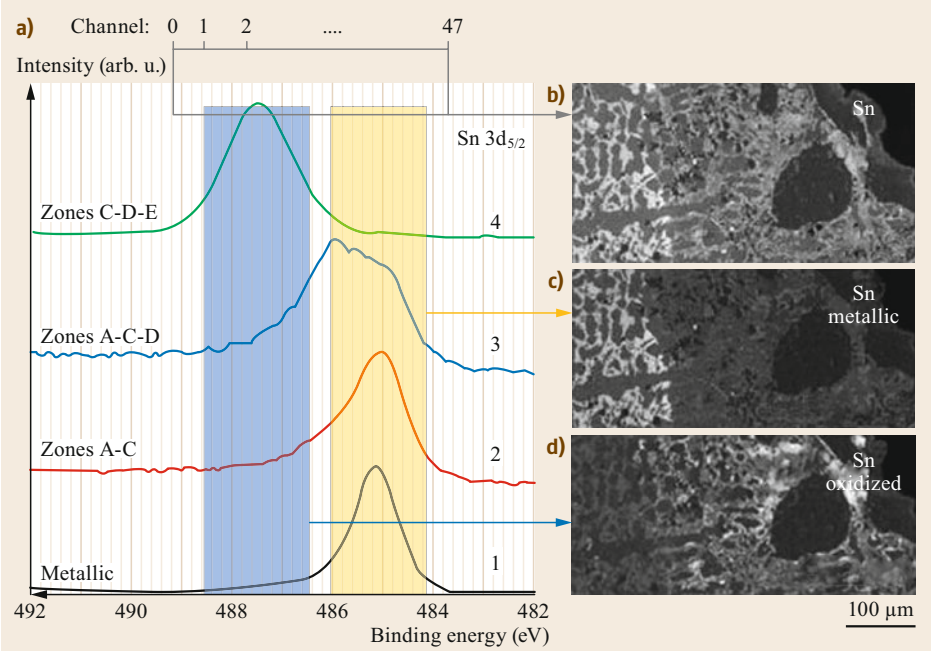

Fig. 14.7 **(a)** Sn $3d_{5/2}$ core-level spectra acquired in different regions of the coin shown in Fig. 14.6a; the *yellow vertical band* represents the energetic position of the metallic Sn while the *light blue* one covers the energy position of Sn oxides. **(b)** SPEM Sn image obtained by integrating the whole Sn 3d energy window where the contrast indicates variations in the Sn surface content. **(c,d)** Sn metallic and oxide maps obtained by selecting the corresponding energy widows components after removal of topographic contribution showing inhomogeneous oxidation

14.3 Some Representative Examples of Systems Studied with SPEMs

14.3.1 Surface Reactivity of Metals Used as Catalysts

Several early SPEM studies were focused on the lateral variation in the surface reactivity that has been well evidenced in exploiting the initial oxidation states of single-crystal transition metals, such as Ru and Rh [14.28–31]. In both cases a distinct feature of the initial oxidation is a laterally nonuniform oxide growth, which was evidenced by the SPEM images tuned to the selected transition metal core level and the O 1s spectra. From both spectra we were able to follow the evolution of oxidation based on the core-level shifts and relative intensities of oxide and metallic components. A representative example of such experiments is reported in Fig. 14.8 where the lateral variations in the contrast of the O 1s and Rh_{ox} $3d_{5/2}$ (Rh_{ox} means that the oxidized related energy window is selected to produce the map) images and the spectra taken in selected spots clearly evidence inhomogeneity in the Rh oxidation state. Close inspection of the two images shows that there is no correlation between the bright and dark regions, as one expects considering single stoichiometry of the oxidation state. On the contrary, most of the brighter areas in the O image appear darker in the Rh_{ox} image, with some exceptions, e.g., region (3). This can only be explained supposing that the inhomogeneity is due to spatial variations in the local density of the Rh and O atoms in the oxide film. In fact, we obtained numbers corresponding to the existing two Rh bulk oxides, the rutile RhO_2 and the corundum Rh_2O_3 from the Rh_{ox}(dark)/Rh_{ox}(bright) and O(bright)/O(dark) and Rh/O intensity ratios, evaluated from the maps and the spectra. The appearance of regions type (1) (dark in Rh_{ox} and bright on O maps) resembles the step bunches observed often on the Rh(110) surface that indicates that structural defects and irregular structures may act as more effective centers for O_2 dissociation that stabilize the RhO_2-like film, which requires a higher O density. Similar nonuniform ox-

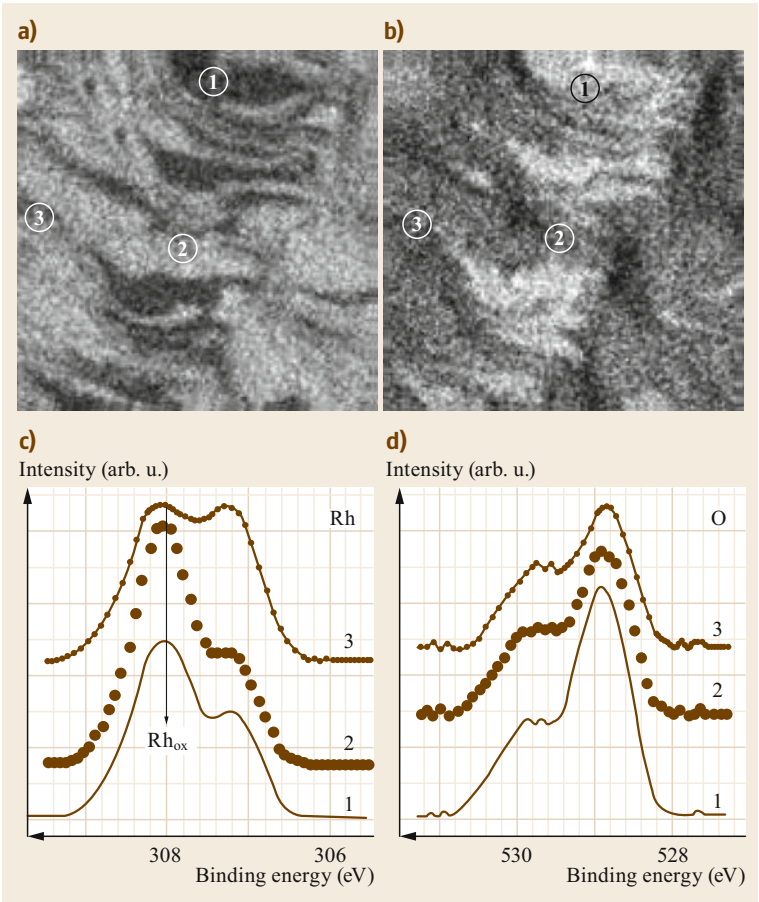

Fig. 14.8 **(a,b)** Rh_{ox} and O 1s images ($12.8 \times 12.8\,\mu m^2$) taken after exposure of Rh(110) to 1.2×10^5 L O_2 at 750 K. **(c,d)** Rh $3d_{5/2}$ and O 1s spectra reconstructed from the regions marked as 1, 2, and 3 in the images, where the component corresponding to the Rh oxides and used for taking the Rh_{ox} map in **(a)** is indicated by an *arrow*. The lower energy Rh components contain contributions from the metallic and interfacial Rh below the thin oxide film

ide growth is observed during the initial oxidation of Ru(0001) carried out under comparable oxidation conditions where not only the stable bulk oxide, RuO_2, can exist; the coexistence of ordered oxide and disordered precursor phases were evidenced in the transient oxidation stages [14.28, 29].

14.3.2 Degradation Mechanism of Light-emitting Diodes

The simultaneous information about the surface topology and chemical composition at local microscales provided by SPEM has made it possible to shed light on degradation mechanisms in organic light-emitting diodes (OLEDs) consisting of InSn oxide (ITO) anode organic emitters, electron transport layers and Al cathodes [14.32–34]. Comparing the results obtained from the characterization of the degraded microscopic areas of the Al cathode, occurring in OLEDs operated and exposed to different ambient conditions, has revealed that in all cases the final degradation state is similar. Degraded surfaces show small fractures usually with swollen regions in the vicinity. As illustrated in Fig. 14.9 these morphology changes are apparently created by eruptions and are clearly encoded as a distinct dark hole in the Al 2p map where the swollen regions are outlined by the topography-related enhancement.

The morphology highlighted by the In 3d map is very similar to that of Al, but distinct features comparing both images are the hole areas and those in the vicinity of the hole: (i) there is some In 3d emission from the hole and (ii) the surrounding regions appear brighter in the In maps and darker in the Al maps. Since the contrast level is a measurement of the element presence and concentration this indicates removal of the organic layers in the hole location and deposition of In on top of the Al surface around it. This is confirmed by the spectra in Fig. 14.9b, measured within the hole and in the areas in the hole vicinity. The spectra from the dark hole, created by the eruption, are very similar to the ITO spectra, with the exception of the presence of very weak C 1s and small Si 2p peaks, originating from organic film residues and from the ITO glass support. Consider-

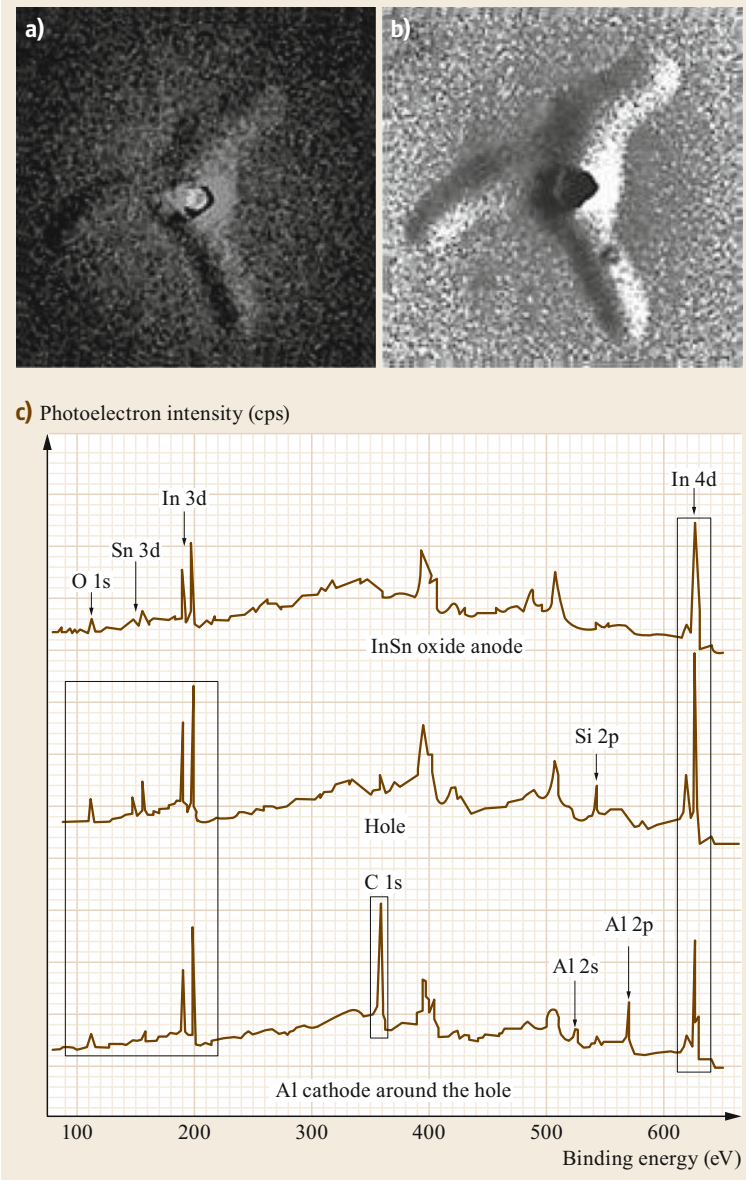

Fig. 14.9 **(a)** In 3d and **(b)** Al 2p maps centered in the hole created after operating the device in UHV and increasing the voltage to 32 V. **(c)** XPS survey spectra taken in the hole and in the vicinity of the hole. For the sake of comparison the ITO spectrum is shown as well

ing the small photoelectron probing depth the presence of Si 2p indicates that the ITO film thickness below the hole has been dramatically reduced due to material loss. The presence of In and C in the spectrum taken from the areas surrounding the hole point to local decomposition of the ITO anode and organic layer, resulting in deposition of volatile products on the Al surface, including In_xO_y and organic fragments. Since this final state of fractured OLEDs was observed even when they were fabricated and operated under ultrahigh vacuum (UHV) [14.32, 33], this suggests that the degradation is due to spikes resulting in local temperature rises sufficiently high to decompose the organic layers and ITO film. The pressure burst of the released volatile products causes delamination and fracture of the Al cathode. The conclusion was that the main reason for such local electrical shorts is intrinsic imperfections in structure, topography or chemical composition at ITO electrode surfaces and that the environment where the OLED is assembled only promotes the degradation. This feedback has pushed for improvements in the technology for fabrication of more perfect defect-free ITO films.

The silicon substrate on the *left* appears *dark gray* (secondary photoelectron emission), whereas the vacuum around the CNTs appears *dark*. **(b)** O 1s spectra taken in the spots indicated in the C 1s images. For this experiment atomic oxygen was used. Oxygen doses for the three images in **(a)** are from bottom to top: 0.5×10^{17}, 2.7×10^{17}, 8.1×10^{17} atoms/cm^2

14.3.3 Free-standing Nanostructures

Using SPEM we were able to explore the properties of individual free-standing nanotubes, nanowires and nanostructures [14.35–42]. In one of the studies we followed and compared the evolution of multiwall carbon nanotubes (CNT) during oxidation, one of the most common methods used for purification and tailoring their properties by introducing oxygenated groups in the C cage [14.36]. The C 1s images of the aligned CNT and the O 1s spectra, taken at selected microspots, are reported in Fig. 14.10a. Comparing the initial and advanced stages of CNT oxidation one can clearly see the morphological and chemical changes occurring as a result of the interaction of carbon with oxygen. It is clear that the oxidation and consumption via gasification starts from the more reactive tips of the CNTs and also that the oxidation rate varies when comparing the evolution of the individual CNTs. The different oxidation rate was attributed to the fact that it depends on the density of defects in the C cage, a characteristic property for each single CNT. The O 1s spectra contain features corresponding to different oxygenated groups, ether epoxy and carbonyl, which evolve with advancement of oxidation, and the carbonyls, which are those preceding gasification. It has been revealed that the major reason for the different oxidation rate of single CNTs is that the type and abundance of the oxygenated functional groups is controlled by the presence and type of the vacancy defects in the C cage, which is encoded in the C 1s spectrum of each CNT [14.35]. Since the introduction of a selected oxygenated func-

tional group can be used to tailor the physical, chemical or electronic properties of the CNTs, the obtained results suggest that controlled introduction of defects can be used to favor a desired modification. In this respect SPEM can be used as an excellent characterization tool.

14.3.4 Graphene Microstructures

This last example demonstrates the potential of μ-ARPES in mapping the band structure of graphene grown on an Ir(111) single crystal by vapor deposition (few cycles of methanol exposure and annealing to ≈ 1270 K). This growth procedure results in the formation of microsized flakes with different rotations. Apparently, such samples cannot be characterized with the traditional ARPES instruments since they require not only high spectral and angular resolution but also a sub-micrometer spatial resolution. The image of the graphene rotational domains taken with SO-SPEM is shown in Fig. 14.11, where the contrast variations are provided by different rotations of the flakes on the Ir surface. In order to obtain this image the analyzer was set to exclusively collect electrons emitted from the domains appearing brighter while the photoelectrons from other domain bands were only partially collected and these domains appear darker.

A standard low-energy electron diffraction pattern (Fig. 14.11b) demonstrates the diffraction peaks from such incommensurate domains. However, incommensurability and concomitant rotations complicate considerably interpretation of such space-averaging measurements. The constant energy slice at the Fermi level (E_f) shows the Fermi surface of Ir(111) and in blue the Brillouin zone of graphene is schematically shown for the case in which graphene orientation coincides with the substrate. Analysis of the ARPES measured for each individual domain allows clear interpretation of domain rotations, understanding their thickness and electronic structure. The rotation angles of particular domains, i.e., position of their K points with respect to the aligned graphene Brillouin zone (Fig. 14.11c) can be evaluated from constant energy slices below E_f, at which the

graphene π bands have a truncated triangular profile, as indicated by dashed lines in Fig. 14.11d centered at the K point. In Fig. 14.11d,e, showing fragments of Brillouin zones around the K point, such profiles are shown for two types of domains, rotated by $R = -6°$ and 1.2° with respect to the Ir substrate. Analysis of the angle-energy dispersions k–E (not shown) has also indicated that the domains are graphene bilayers with only the top layer rotationally misaligned and nondoped while the first layer exhibits p-type doping and has the same orientation as the substrate.

However, it should be recognized that the μ-ARPES technique although promising has limits to shedding light on new physics at the nanoscale; spatial resolution better than 50 nm is still a desire for the future. The main advantage and applicability of μ-ARPES today is in exploiting the physics of operative microsized devices, i.e., for the samples produced ex situ. However, also here the application is not trivial and many aspects should be considered for rational sample design, i.e., beam-induced effects, cleanness of the transfer of 2-D materials of interest and the choice of the substrate. For example, historically the graphene flakes were placed on thick SiO_2 substrate allowing them to be aligned in an optical microscope. Therefore, for several years these were also the first-choice samples studied with ARUPS. There have been a few attempts to measure the electronic structure of ex situ prepared devices as well but the obtained band widths were large, i.e., with quite modest resolution not allowing the use of the full potential of our μ-ARPES because of intrinsic complications in the sample design and sample degradation under the photon beam. For example, in the works reported in [14.43, 44] the bands of MoS_2 monolayer on Si oxide are broad, while for a bilayer they look better and the bulk one is comparable to other average ARPES measurements. A real breakthrough for such types of measurements was achieved only recently with proper device design combining dry transfer of monolayers, right choice of the substrate and encapsulation by an inert monolayer i.e., by graphene [14.45] or boron nitride (BN). In this case, the spectral resolutions we obtained are comparable to standard ARPES measurements and hence can provide quantitative access to many important parameters such as small spin orbit couplings, band alignments between different monolayers etc. This first achievement opens up further new possibilities, e.g., for exploiting the electronic structure of contacted devices, including applications exploring the gate potentials as well.

14.4 Near-ambient Pressure (NAP) Experiments with SPEM

Overcoming the pressure gap limits can be considered as the most significant recent development opening up the route for in operando SPEM experiments. We would like to note that soft x-ray SPEM cannot use the classical near-ambient pressure XPS approach with a differentially pumped analyzer, since the geometrical arrangement with ZP focusing optics in front of the sample does not allow for placing of the sample very close to the entrance aperture of the analyzer.

In this section, which can also be considered as an outlook, we will present the current state of different approaches developed in recent years aimed at exploiting with submicron spatial resolution the functional materials in their natural ambient environment. At present many of the obtained results are still a proof of principle for the performance of developed setups. Nevertheless, the implementation of new technical solutions is moving ahead extremely rapidly making these methods more reliable and user friendly.

14.4.1 The Dynamic High-pressure Setup

The dynamic high pressure (DHP) system developed at Elettra uses a highly collimated gas jet, as a supersonic jet expansion into a vacuum chamber, to confine the gases into a narrow beam pointing to the sample surface illuminated by x-rays. By using a pulsed jet instead of a continuous one the space volume containing the high-pressure gas is limited to a small region near the sample. This particular setup is also adopted in other research fields to control the amount of injected gas [14.46]. The schematic view of the DHP setup is reported in Fig. 14.12a: a gas jet is generated in the region around a sample by a thin needle oriented to avoid any interference with the x-ray optic system and the electron analyzer. It should be noted that to run the DHP no particular upgrades were necessary for the SPEM chamber pumping system, except for an additional differential pumping of the HEA electron detector section. The plot of the pressure time profile on the sample is shown in Fig. 14.12b. A pulsed valve produces a series of gas jet shots at a fixed repetition time. Each shot generates a short burst of pressure in a small and confined volume near the sample, which, expanding through the entire volume of the vacuum chamber, induces an increase of the background pressure. If the duration of shots is properly tuned, the injected gas is efficiently diluted into the large chamber volume to keep the back-

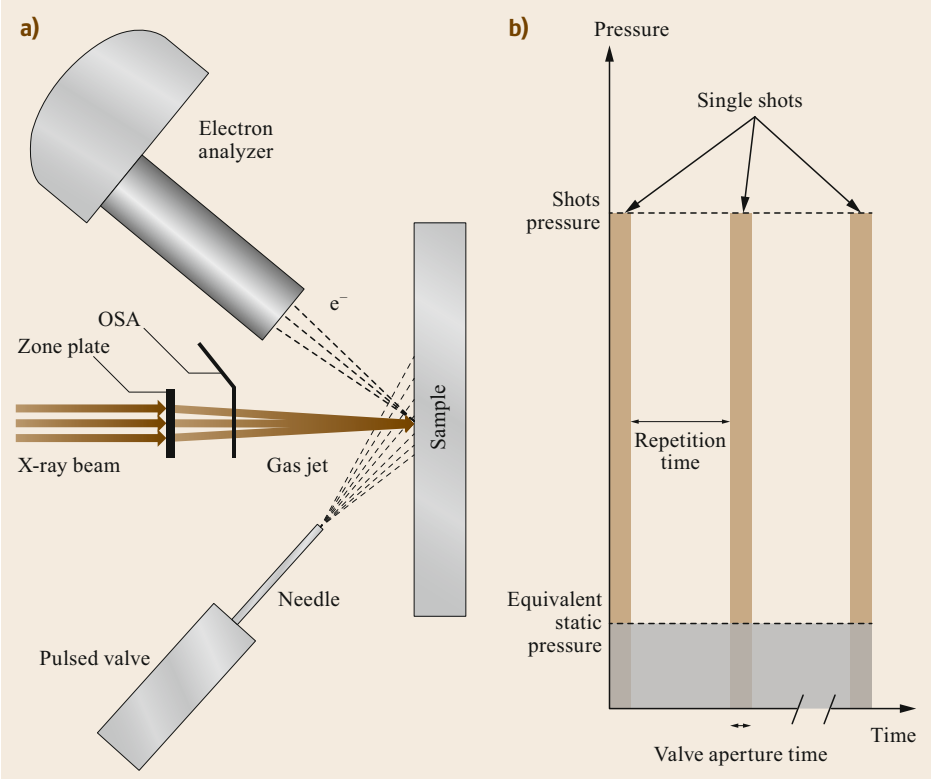

Fig. 14.12
(a) Schematic view of the DHP setup; a commercial pulsed valve has been used. This valve, which can operate in a UHV environment, provides high repeatability and response operation as fast as 160 μs and the peculiar design of the valve outlet gas section avoids dead volumes as well. **(b)** Plot of the pressure time profile on the sample with time

ground pressure low enough to not exceed the limits for XPS measurement, set to 1×10^{-5} mbar in the electron detector region. After each shot the background pressure rapidly recovers to the initial UHV condition.

Due to the geometrical constraints existing in the SPEM chamber (sample and optics stages, HEA) the DHP system is mounted with a grazing angle geometry as shown in Fig. 14.12a. Both the pulsed valve and the needle are mounted inside the SPEM vacuum chamber while the gases are supplied through a feedthrough from the air side of the chamber. The whole DHP system is mounted on a precision three-axis manipulation stage to allow a fine alignment of the gas jet with the focused x-ray beam and electron analyzer focal position. More details about the setup are given in [14.46].

The single shot pressure time profiles at the sample surface as a function of the pulsed valve aperture time are shown in Fig. 14.13. The distance between the sample and the needle tip were fixed to 2 mm while the valve inlet gas pressure was set to 3.5 bar. An aperture time of the valve ranging from 3.2 to 3.8 ms produces a burst of pressure at the sample surface in the range of few tenths of mbar; small changes of the aperture time generate significant variations of the outgoing jet pressure as clearly visible in the figure. The inset in Fig. 14.13 shows the time evolution of the pressure in the electron detector region of the HEA for a 3.2 ms-long pulse corresponding to a 10 mbar shot at the sample; the pressure in the most critical zone of the SPEM chamber does not overcome the pressure limit ($\approx 1\times10^{-5}$ mbar) and can be considered the upper limit for the valve aperture. The injected amount of gas by each jet corresponds to an equivalent dosage of 10^3-10^4 mbar s. As shown in Fig. 14.13, the time needed to recover a UHV condition in the SPEM chamber is a couple of seconds. For a prolonged use of the DHP we have found that pulses repeated with a frequency of 0.35 Hz with a 3.2 ms aperture time never exceed the background pressure limit. The system has demonstrated a high level of reproducibility of the parameters over long periods (> 7 h) of operation.

No significant changes in the performance of the system have been observed by changing the valve inlet gas pressure by ±0.5 bar. Due to the gas jet profile an alignment between the x-ray beam and the gas jet with a precision of 0.5 mm is required to maximize the shot pressure in the analyzed area of the sample surface.

The DHP setup was first used in the in operando study of a self-driven MnO_2 cathode/YSZ/NiO anode cell exposed to H_2 and CH_4+O_2 reactant mixture, where we were able to detect the current generated by

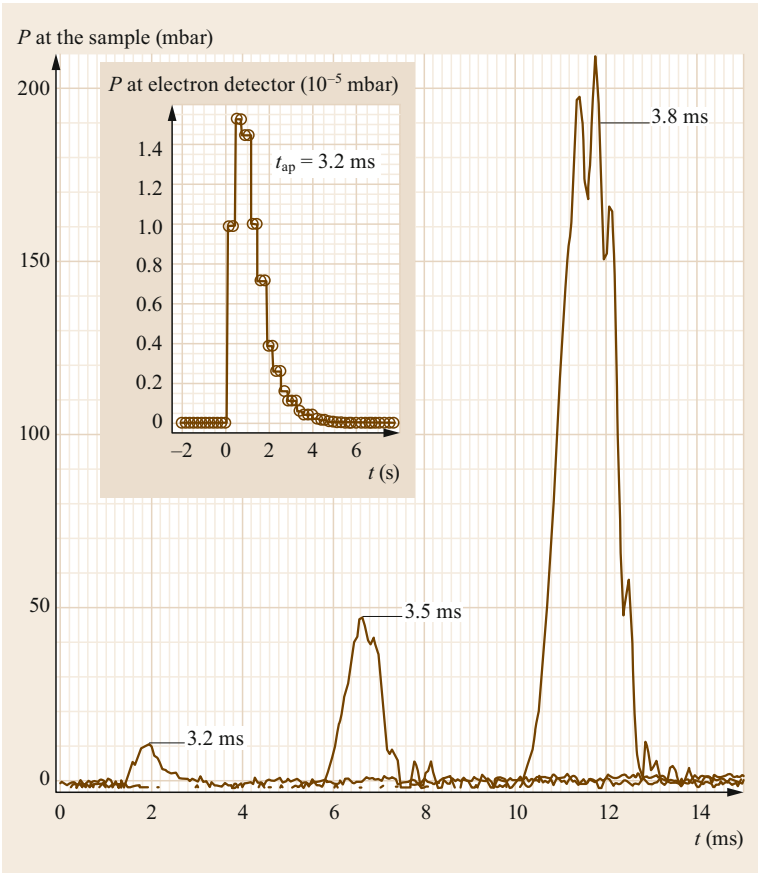

Fig. 14.13 Single shot pressure time profiles at the sample surface as a function of the pulsed valve aperture time. The *inset* shows the time evolution of the pressure in the electron detector region of the HEA for a 3.2 ms-long pulse corresponding to a 10 mbar shot at the sample

the electrochemical processes [14.24, 47]. By collecting Ni 2p maps of the electrode in the vicinity of the electrolyte we took advantage of the lateral and spectral resolution of SPEM to monitor both the evolution of the chemical state of the anode and the current-induced spectral shift that is a direct measure of the created local overpotential. Using the Ni $2p_{3/2}$ energy window both for imaging and microspot spectroscopy covering the oxide and metallic Ni components we were also able to follow the evolution after starting the reaction. The duration of each vertical scan and the time required for collecting a microspot spectrum determined the time resolution (better than 60 s), which allowed us to follow the growth of the metallic Ni^0 component at the expense of the oxide Ni^{2+} one and the overpotential shift (Fig. 14.14a).

The time evolution of the oxidation state and local potential of the working Ni anode are exemplified by the Ni $2p_{2/3}$ spectra in Fig. 14.14a, measured close to the Ni/YSZ interface (three-phase boundary), i.e., the most electrochemically active region. Immediately after switching to $H_2 + O_2$ the Ni $2p_{2/3}$ spectrum undergoes a rigid energy shift. Since in the initial state the Ni electrode is oxidized, the shift is better evidenced by the Ni^{2+} component that is present in all spectra. The energy shift of the spectra is a measure of the overpotential resulting from the current flow generated by the hydrogen oxidation that starts on the NiO electrode; this process is anodic so the shift is to higher binding energy (lower kinetic energy). As illustrated by the plots in Fig. 14.14b and c under the applied reaction conditions, starting from a NiO, the steady chemical state resulting from the concurrence between anodic oxidation and chemical reduction is achieved after 30 min; the same time is needed to reach the steady-state overpotential of 0.8 eV. These results have shed light on competing electrochemical and chemical processes occurring in real electrochemical devices generating electrical current. They demonstrate the great potential of the used advanced experimental approach to gain insight into electrochemical and chemical processes taking place in energy conversion systems, which could guide the design of next-generation devices with improved performance.

14.4.2 Compact Near-ambient Pressure Cells

The development of compact cells to enable PES at near-ambient pressure started several years ago [14.48]; to tackle the problem of replacing samples in UHV systems it is necessary to have retractable cells versatile enough to offer the desired reaction conditions (e.g., a sample heating system). Moreover, in order to achieve a certain flexibility to attain nearly realistic in operando conditions a sophisticated design of the differentially pumped HEA is required. However, to date the possibility to use these cells for laterally resolved photoemission studies has remained a dream; the main obstacle in the case of ZP-based SPEMs is the severely constrained space available around the sample where focusing optics, HEA nose, and sample scanners are located.

The cell designs for SPEM have exploited the advantage of using a focused x-ray beam. The first SPEM reaction cell had a small pinhole of 2 μm diameter on the front plate and was vacuum sealed using electron transparent graphene or graphene oxide membranes to separate the sample environment from the UHV without requiring any differential pumping. The graphene sealed setups have already been described in detail in several reports [14.49–51]. Indeed, the great advantage of the sealed cells is that they can also be used for studies of reaction in liquids, but this requires fabrication of very high quality defect-free membranes, very well-developed and reliable sealing technology and a long-term resistance of the graphene membranes to intense x-ray radiation. The graphene-sealed cells have already found wide applications in electron microscopes as well and are really the only means to study events in ambient gas pressures and liquid environments using electron detection. Attempts to design electrochemical cells where the graphene window can also act as a working electrode have already been made and the first results demonstrating electrochemical deposition from an electrolyte are promising [14.51].

Recently, the team of the Escamicroscopy beamline at Elettra succeeded in developing a retractable near ambient pressure cell (NAPCell) capable of performing XPS sample analysis with the typical spatial resolution of the ZP-SPEM (≈ 100 nm) at pressures as high as 0.1 mbar without using a sealing membrane. Indeed, this novel approach works only in gas ambient environments but it does use membranes that also attenuate the intensity of the emitted photoelectron signal. As noted above the x-ray microprobe used in SPEM allows the use of small-dimension pinholes as photon in/photoelectron out apertures. Since the gas leak through such pinholes is very weak this avoids the use of differ-

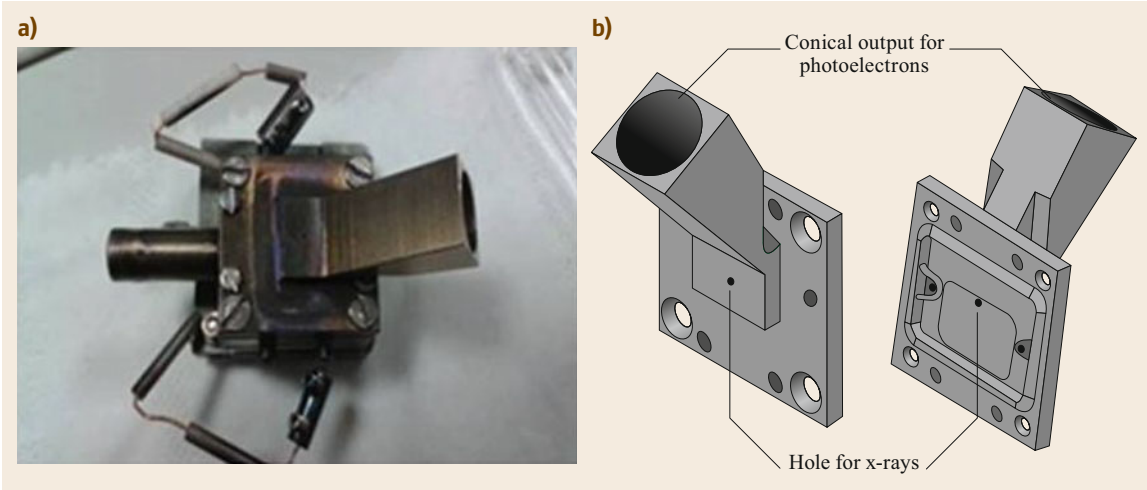

Fig. 14.15 **(a)** Picture of the compact NAPCell. The material used to build the current version is stainless steel. **(b)** CAD drawings showing the top plate (front and back side); the holes for the incoming x-rays in the center and the conical output for the photoelectrons have been indicated

entially pumped HEA, barely adaptable in a SPEM. As described below this much simplified approach has made SPEM a unique microscope for both UHV and near-ambient pressure experiments.

The SPEM NAPCell, illustrated in Fig. 14.15, is vacuum sealed. It is provided with two pinholes: one of 500 μm diameter on the front plate providing an entrance port of the focus x-ray beam and a second one of the same size that laterally extends in a conical shape pointing to the HEA (i.e., with an angle of 60° with respect to the x-ray beam) through which the photoelectrons generated on the surface sample will escape and reach the HEA. The dimension of the first pinhole defines also the accessible area of samples while the size of the lateral pinhole with the outer cone has been selected to provide the same maximum acceptance angle of the HEA.

The reactive gases are delivered into the cell via a mechanically flexible part of the dosing line inside the SPEM chamber and a complimentary external part connecting to the atmosphere side. The gas pressure can be adjusted by means of dosing valves and a Pirani pressure gage. An external pumping stage is attached to the NAPCell to pump the dosing line and the cell. The NAPCell is also constantly pumped through the pinhole by the vacuum provided by the main chamber pumping system. The pumping power of the SPEM chamber and the size of pinholes enable pressures up to 0.1 mbar to be achieved inside the cell and below 10^{-5} mbar inside the SPEM chamber, which is the upper safe pressure limit for performing photoelectron spectroscopy without any failure on the electron detection system and the beamline. An encapsulated heater, placed on the back of the sample, allows varying of the sample temperature in the range 300–720 K. Additional electrical contacts are available for the thermocouple connection and/or biasing of sample. All parts of the cell, including the heater and the thermocouple feedthroughs, were made of UHV-compatible materials to avoid undesirable degassing especially at elevated temperatures.

The following example reports on the oxidation and reduction of a Rh metal surface. It represents the first experiment performed with the NAPCell in the mbar pressure range. The evolution of Rh 3d and O 1s core levels acquired from an unpolished polycrystalline Rh foil under successive exposures of oxygen and hydrogen at 670 K was characterized by acquiring core-level photoemission spectra and maps.

Figure 14.16a shows a small-scale Rh $3d_{5/2}$ map of the foil inside the NAPCell. The image represents the lateral variations of the selected photoelectron emission signal, including the background as well. These well-resolved structures prove that the typical submicron resolution of the ZP-SPEM instrument is preserved, i.e., the cell setup does not deteriorate the SPEM spatial resolution. The performance of the high-pressure cell was examined by investigating the oxidation and reduction of the Rh metal surface.

The lineshape of the top Rh $3d_{5/2}$ spectrum A in Fig. 14.16b is typical for a sample being exposed to air before being introduced into the cell, where it was annealed at 570 K in the ambient air of 0.1 mbar of $H_2(g)$ for 60 min in order to recover its metallic state. The spectrum, which has been deconvoluted by using Doniach–Sunjich functions (colored solid lines), reveals a dominant metallic Rh component centered

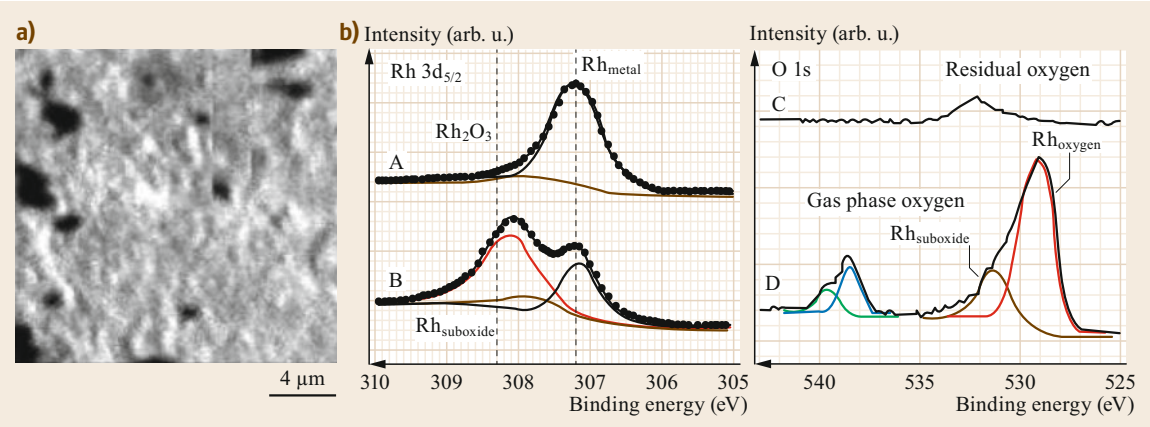

Fig. 14.16 **(a)** $20 \times 20\,\mu m^2$ Rh map acquired with the ZP-SPEM during the exposure to 0.1 mbar O_2. As it is visible the characteristic spatial resolution of the ZP-SPEM is kept also in this environment. **(b)** Rh $3d_{5/2}$ and O 1s core-level XPS spectra acquired before and after the oxidation. The presence of the gas phase O 1s peak should be noted in spectrum D

at 307.2 eV binding energy (eV) and a minor additional contribution at 307.8 eV, indicative for the presence of residual substoichiometric surface oxides. These values are in fair agreement with previous experiments [14.52]. This result provides clear evidence that the annealing at 0.1 mbar H_2 exposure had effectively reduced the surface and also removed the C contaminants (not shown), which is not possible for H_2 exposures of maximum allowable pressure level of 1×10^{-5} mbar by backfilling of the SPEM chamber. The same surface was then exposed to 0.1 mbar O_2 for 30 min, keeping the temperature of the sample at 670 K. After the oxygen treatment the measured Rh $3d_{5/2}$ spectrum (B in the Rh $3d_{5/2}$ panel of Fig. 14.16b) is dominated by a new peak situated at 308.2 eV BE, corresponding to Rh_2O_3 [14.52, 53]. These results show an uneven reactivity of the Rh surface at the length scale reachable with the SPEM.

The observed changes in the Rh 3d and O 1s spectra after oxidation are in good agreement with previous results for oxidized Rh films and Rh polycrystalline foils at ambient pressures, where the observed two components were attributed to Rh_2O_3 and RhO_2/RhOOH species [14.54, 55].

A clear proof that the sample inside the cell is exposed to O_2 pressure at the mbar level are the O 1s core-level spectra, recorded before and during exposure of the Rh foil to O_2. The spectrum C, measured after the initial treatment in H_2, appears as a broad feature peaked at $\approx$ 532–533 eV, well matching residual suboxides reported in literature [14.52]. The presence of this residual oxygen component is also in agreement with the existence of a small high BE component of the Rh $3d_{5/2}$ in the spectrum A. As for the Rh $3d_{5/2}$ also the O 1s spectrum undergoes an evident change during the 0.1 mbar O_2 exposure. In spectrum D two new distinct O 1s doublet spectral features appear. The most intense doublet is dominated by a component located at $\approx$ 529.3 eV and the second weaker one at $\approx$ 531.3 eV belonging to O 1s of Rh_2O_3 and $Rh_{suboxide}$ phases respectively. The second nicely resolved doublet within the $\approx$ 538.5–539.6 eV range corresponds to the gas phase oxygen molecules inside the cell, directly ionized by the x-ray photon beam. The presence of a well-resolved O 1s spectral feature from the gas phase oxygen also validates that the high-pressure cell allows mbar pressure levels to be reached, so the Rh undergoes oxidation that cannot occur under high vacuum conditions.

14.5 Conclusions

In this short review we hope that we were able to introduce the reader to the growing ability of SPEM in the last decade to characterize the surface and interfacial properties and the events occurring at gas-surface interfaces, where the microprobe added the missing lateral resolution. Looking to the future, we expect further advances to fully overcome the material and in operando gaps, which means pushing further lateral resolution, time resolution and the performance of real in operando studies. These are the only viable routes in the attempt to optimize the fabrication processes or reveal the chemical states and all possible desired and undesired events that determine the performance of the complex functional materials.

Hikmet Sezen received his PhD (2012) in Chemistry from Bilkent University (Ankara, Turkey). He worked as a postdoc at Karlsruhe Institute of Technology (Germany) between 2012 and 2014 and at Elettra, ESCAmicroscopy beamline (Italy) between 2014 and 2017. He currently has a scientist position at Helmholtz-Zentrum Berlin, at the Slicing Femtospex Molecules and Surface Endstation and High Harmonic Laser Laboratory (Germany).

Maya Kiskinova

Elettra – Sincrotrone Trieste SCpA
Trieste, Italy
maya.kiskinova@elettra.eu

Maya Kiskinova received her PhD in 1977 and her ScD in 1989 in Physical Chemistry. She has worked at research centers and universities in Bulgaria, USA, and Germany and, since 1991, at Elettra, where she is presently Research Coordinator. She received Italian citizenship for scientific merits in 2002 and the Distinguished Humboldt Grant in 2005. Her research focuses on properties and transient states of functional materials. http://www.elettra.eu/PEOPLE/index.php?n=MayaKiskinova.HomePage

15. Natural Topological Insulator Heterostructures

S. V. Eremeev, Igor P. Rusinov, Evgueni V. Chulkov

A topological insulator is a state of quantum matter that, while being an insulator in the bulk, hosts metallic topologically protected electronic states at the surface. These states open the way for realizing a number of new applications in spintronics and quantum computing. In order to take advantage of their unique properties, topological insulators should be tuned in such a way that isolated Dirac cones are located within the topological transport regime, without any scattering channels.

This chapter is devoted to natural topological heterostructures composed of different sublattices, at least one of which is a topological insulator. We demonstrate that these systems show diverse electronic properties and, depending on the structure and composition, can be topological insulators supporting Dirac surface states whose dispersion essentially depends on the surface termination, topological Weyl semimetals, or trivial band insulators.

The chapter is organized in five sections. Section 15.1 provides computational details. In Sect. 15.2, we discuss the crystal structure and electronic states in the $(C^{IV}B^{VI})_{n=1}(A^{V}_2B^{VI}_3)_{m>1}$ superlattices. Section 15.3 is devoted to the peculiarities of the topologically protected electronic states in the $(C^{IV}B^{VI})_{n>1}(A^{V}_2B^{VI}_3)_{m=1}$ compounds. Temperature-driven topological phase transitions in the $Ge_2Sb_2Te_5$ phase-change materials are addressed in Sect. 15.4. Finally, we end with a summary and conclusions in Sect. 15.5.

Part C | 15

Over the past decade, the strong impact of topology on the electronic structure of numerous materials and related properties such as novel spin textures, surface and edge Dirac states, magnetic properties in two- and three-dimensional topological insulators, spin and charge transport, and exotic superconducting states have been actively discussed [15.1–4]. This research work resulted in the introduction of a topological classification based on topological order parameters. The most decisive contribution in this context is the definition of a class of topological insulators (TIs) based on $\mathbb{Z}_2$ classification. A topological insulator differs from a conventional band insulator (semiconductor) in that it features a nontrivial topological invariant in its bulk electronic wave functions.

Among the various formulations for the computation of the $\mathbb{Z}_2$ topological invariants, the Fu–Kane approach [15.5] is most suitable for analyzing band structures of crystals with inversion symmetry. In this approach, $\mathbb{Z}_2$ invariants can be determined from the matrix elements of Bloch wave functions at time-reversal invariant momentum (TRIM) points in the Brillouin zone (BZ). The three-dimensional (3-D) materials with inversion symmetry are classified according to four $\mathbb{Z}_2$ topological invariants, ν_0; $(\nu_1\nu_2\nu_3)$, which can be determined by the parity $\xi_m(\Gamma_i)$ of occupied bands at eight TRIM $\Gamma_{i=(n_1,n_2,n_3)} = (n_1\boldsymbol{b}_1 + n_2\boldsymbol{b}_2 + n_3\boldsymbol{b}_3)/2$ of the 3-D Brillouin zone, where $\boldsymbol{b}_1, \boldsymbol{b}_2, \boldsymbol{b}_3$ are primitive reciprocal lattice vectors, and $n_j = 0$ or 1 [15.5, 6]. The $\mathbb{Z}_2$ invariants are determined by

$$(-1)^{\nu_0} = \prod_{i=1}^{8} \delta_i$$

and

$$(-1)^{\nu_k} = \prod_{n_k=1;n_{j\neq k}=0,1} \delta_{i=(n_1n_2n_3)} ,$$

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-46906-1_15

where $\delta_i = \prod_{m=1}^{N} \xi_{2m}(\Gamma_i)$ [15.6]. The strong time-reversal symmetry-driven topological insulators, which we will deal with in this chapter, are determined by a nontrivial topological invariant $\nu_0 = 1$. In the case of $\nu_0 = 1$, the topological invariants ν_1, ν_2, ν_3, provided that at least one of them is nonzero, indicate weak topological insulators.

The 3-D topological insulators are characterized by an inverted energy gap at an odd number of symmetry points of the bulk Brillouin zone due to strong spin–orbit coupling (SOC). The intriguing property of topological insulators is the formation of unique topologically protected metallic surface/edge states in spite of bulk insulating behavior [15.1, 6–11]. The surface state protection is provided by a combination of time-reversal symmetry and spin–orbit coupling [15.1, 6, 8, 9]. As a result, any nonmagnetic surface perturbation, such as surface passivation or doping, does not eliminate this surface state [15.5, 12–15].

The topological surface states (TSS) possess a range of properties that allow us to employ topological insulators in spin-based electronics (spintronics) [15.6, 8–10, 16]. First, these states demonstrate a linear dispersion forming a Dirac cone with a crossing (Dirac) point at/close to the Fermi level, which leads to high charge carrier mobility, similar to the case of graphene. Also, these carriers are spin-polarized, and a manipulation of spin-currents is an essential requirement for spintronics. In the search for efficient materials for spintronics, some studies have proposed topological insulators [15.7, 17–19] that possess a surface state for which the effects of spin–orbit coupling are maximal in the sense that an electron spin orientation is fixed relative to its propagation direction. Additionally, there are several exotic effects that exist on the surfaces of topological insulators that are based on half-quantized conductivity. A half-quantum Hall effect can be observed in TI surfaces with an odd number of Dirac cones and with time-reversal symmetry breaking induced by out-of-plane magnetization, as well as in thin films under external magnetic perturbation or magnetic doping [15.20]. Such an effect is a common feature for massless states like Dirac cones in TIs or graphene [15.9, 21–23]. The topological magnetoelectric effect is also the consequence of the half-quantization and results in an increase in the Hall current along the surface. This current is directed perpendicular to the applied electric field and is an intrinsic property of TIs that is independent of the system details [15.21, 24]. A related scenario has been found when the TI surfaces are radiated by linearly polarized light [15.25]. The possible existence of an image magnetic monopole in the proximity of the charge close to the surface of the topological insulator has also been reported. In this case, the system can be considered with additional charge both inside the topological insulator and in the imaginary magnetic monopole [15.26].

Among the currently known strong TIs, the layered binary compounds Bi_2Te_3, Bi_2Se_3, and Sb_2Te_3 have been widely investigated both experimentally [15.16, 27–29] and theoretically [15.30–33]. Realization of many of the predicted topological phenomena requires tuning of the conduction properties of topological insulators when they are in contact with magnetic semiconductors or superconductors and modification of the topological state by doping [15.14, 15, 26, 34–42]. The realization of topological properties also necessitates the search for new families of topological insulators. A particularly promising method for designing new TI materials with tunable surface electronic properties relies on the fact that pseudo-binary systems $(C^{IV}B^{VI})_n(A_2^VB_3^{VI})_m$, where A^V are elements of group V = Bi, Sb; B^{VI} are elements of group VI = Te, Se; and group IV elements C^{IV} = Ge, Sn, Pb, contain homologous series of ternary compounds. These include a wide variety of mixed-layer materials that have a more complex crystal structure than their parent TIs and can be characterized as natural topological insulator heterostructures.

The structurally simplest systems $(n = 1, m = 1)$, i.e., $C^{IV}A_2^VB_4^{VI}$ compounds, are composed of septuple-layer (SL) hexagonally ordered blocks stacked along the c-axis and separated by van der Waals (vdW) spacings. The SL building block can be obtained from the original quintuple-layer (QL) block of $A_2^VB_3^{VI}$ compounds by introducing the $C^{IV}B^{VI}$ bilayer in the middle part of the QL. These compounds, $PbBi_2Te_4$, $SnBi_2Te_4$, $SnSb_2Te_4$ and others, were predicted to be 3-D $\mathbb{Z}_2$ TI [15.43] with a single Dirac cone in the bulk energy gap, which was subsequently confirmed experimentally [15.29, 44].

The $(C^{IV}B^{VI})_n(A_2^VB_3^{VI})_m$ compounds, where $n = 1$ and $m > 1$, have tetradymite-like layered structures but with distinct many-layered slabs stacked along the c-axis of the hexagonal unit cell. The bonding within the slabs is ionic-covalent, whereas the slabs are linked by weak van der Waals forces. In contrast to $A_2^VB_3^{VI}$ and $C^{IV}A_2^VB_4^{VI}$ topological insulators, the structures of which are formed by quintuple and septuple layers, respectively, the $(n = 1, m > 1)$ compounds are built of alternating QLs and SLs; in other words, they are natural superlattices consisting of blocks of different topological insulators.

Another type of $(C^{IV}B^{VI})_n(A_2^VB_3^{VI})_m$ system is that with $n > 1$ and $m = 1$. Unlike the previous structures in these compounds for C^{IV} = Sn, Pb, the $(C^{IV}B^{VI})_n$ sublattice is built in the middle part of the $A_2^VB_3^{VI}$ QL, and thus their crystal structure is formed by unique, nonalternating building blocks composed of two different

sublattices. As we will later show, the surface spectrum strongly depends on the material of the $C^{IV}B^{VI}$ sublattice, e.g., SnTe, which is topological crystalline insulator, or PbTe—the trivial insulator.

A special case of ($n > 1$, $m = 1$) systems corresponds to compounds with C^{IV} = Ge, which belong to the class of phase-change materials. An example is $Ge_2Sb_2Te_5$, i.e., the $(GeTe)_{n=2}(Sb_2Te_3)_{m=1}$ system, which can adopt four different hexagonal layered structures. At low temperature, it has a nonuple-layer (NL) structure similar to the related compounds with Sn and Pb, while in other phases, GeTe and Sb_2Te_3 sublattices are separated and alternate along the c-axis as in ($n = 1$, $m > 1$) structures. We later show that stable crystal structures of $Ge_2Sb_2Te_5$ possess different topological quantum phases: a topological insulator phase, realized in its low-temperature structures, and a Weyl semimetal phase, characteristic of the stable high-temperature structure. Since the structural phase transitions are caused by the temperature factor, the switching between different topologically nontrivial phases can be driven by variations in temperature.

15.1 Computational Methods

For structural optimization and electronic calculations, for most of the compounds we use the Vienna Ab Initio Simulation Package (VASP) [15.45, 46] with a generalized gradient approximation (GGA) [15.47] for the exchange correlation potential. The interaction between the ion cores and valence electrons is described by the projector-augmented wave method [15.48, 49]. Relativistic effects, including SOC, are taken into account. The atomic positions of bulk compounds are optimized. DFT-D3 van der Waals corrections [15.50] are applied for accurate structure optimization. For slab calculations, we use over 40 atomic layers, and a vacuum space of ≈ 20 Å is included to ensure negligible interaction between opposite surfaces. The k-point meshes of $7 \times 7 \times 7$ and $11 \times 11 \times 1$ are used for the bulk and slab calculations, respectively. Total-energy convergence of better than 1.0×10^{-6} eV is obtained.

To treat the disordered phase in the case of a $Ge_2Sb_2Te_5$ phase-change material, we employ a virtual crystal approximation (VCA) as implemented in the ABINIT code [15.51], where the averaged potential of a virtual atom occupying a site in the Ge/Sb sublattice is defined as a mixture $V_{VCA} = xV_{Ge} + (1-x)V_{Sb}$ of Ge (V_{Ge}) and Sb (V_{Sb}) pseudopotentials. In ABINIT calculations, we use GGA-PBE (Perdew–Burke–Ernzerhof) Hartwigsen–Goedecker–Hutter (HGH) relativistic norm-conserving pseudopotentials, which include the SOC [15.52]. For surface electronic structure calculations, first, the results of DFT calculations are used in the WANNIER90 code [15.53] to construct a tight-binding model. The chosen basis consists of six spinor p-type orbitals for each atom: $|p_x^{\uparrow}\rangle$, $|p_y^{\uparrow}\rangle$, $|p_z^{\uparrow}\rangle$, $|p_x^{\downarrow}\rangle$, $|p_y^{\downarrow}\rangle$, $|p_z^{\downarrow}\rangle$. The low-lying s orbitals are not taken into consideration. The surface tight-binding model is derived from the bulk model with inclusion of band-bending effects obtained from direct surface calculations within DFT. The surface spectrum is calculated using the surface Green function approach [15.54, 55].

The $\mathbb{Z}_2$ invariant is calculated from the parity of occupied electronic states at the time-reversal invariant points of the bulk Brillouin zone [15.6].

15.2 $(C^{IV}B^{VI})_n(A_2^VB_3^{VI})_m$ Superlattices ($n = 1$, $m > 1$)

The crystal structure of the $(C^{IV}B^{VI})_{n=1}(A_2^VB_3^{VI})_{m=2}$ compounds belongs to the hexagonal group $P3m1$, and the unit cell contains alternating QL and SL blocks formed by alternating anion and cation layers, B^{VI}-A^V-B^{VI}-A^V-B^{VI} and B^{VI}-A^V-B^{VI}-C^{IV}-B^{VI}-A^V-B^{VI}, respectively [15.56]. Each block consists of strongly bonded ionic-covalent atoms, whereas the bonding between blocks is determined by vdW forces. Ternary compounds of this series with $m = 3$ also have a hexagonal crystal structure, but it differs from that with $m = 2$ in that it is built of alternating SL and *two* QL blocks along the hexagonal c-axis. As an example, the crystal structures of parent Bi_2Te_3 (QL-structured) and $PbBi_2Te_4$ (SL-structured) compounds and of the superlattices based on them, $PbBi_4Te_7$ ($m = 2$) and $PbBi_6Te_{10}$ ($m = 3$), are shown in Fig. 15.1. Compounds such as $SnBi_4Te_7$, $SnSb_4Te_7$ ($m = 2$) and $SnBi_6Te_{10}$, $SnSb_6Te_{10}$ ($m = 3$) have similar crystal structures.

The Dirac cone in binary TIs such as Bi_2Te_3, Sb_2Te_3, and Bi_2Se_3 originates from the inversion of the bands forming the gap edges: the conventional sequence of the energy levels is inverted by strong spin–orbit coupling [15.6, 13]. In binary compounds, the bottom of the conduction band in the vicinity of

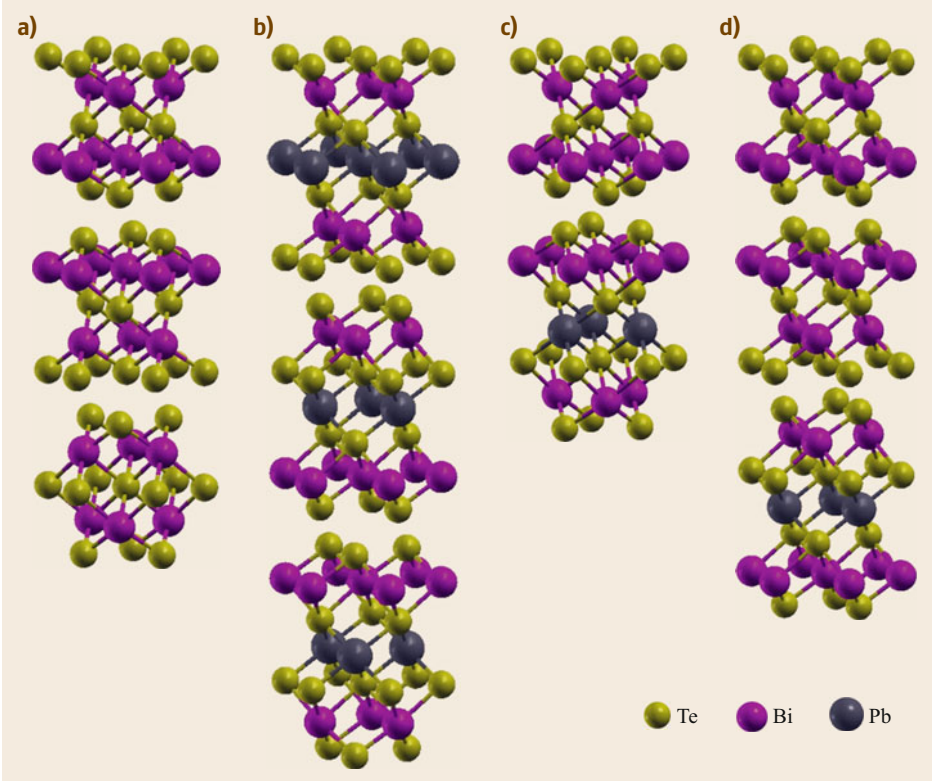

Fig. 15.1a–d Atomic structure of Bi_2Te_3 and Pb-based ternary compounds $(C^{IV}B^{VI})_{n=1}(A_2^VB_3^{VI})_{m\geq 1}$: **(a)** Bi_2Te_3; **(b)** $PbBi_2Te_4$ ($m = 1$); **(c)** $PbBi_4Te_7$ ($m = 2$); and **(d)** $PbBi_6Te_{10}$ ($m = 3$)

the Γ point is derived predominantly from the states localized at the outermost QL chalcogen atoms, whereas the top of the valence band is formed by the pnictogen atoms. A similar band inversion is found in ternary SL-structured TIs, with the only difference being that the top of the valence band is occupied by both A^V and C^{IV} [15.57].

A more complicated SOC-induced band structure is found in compounds with alternating QL and SL slabs. For example, the $SnSb_4Te_7$ compound is a narrow-bandgap semiconductor that demonstrates a direct gap of ≈ 70 meV at the A point (Fig. 15.2a). As can be seen in Fig. 15.2b, left-hand side, the bands forming the gap edges have a *normal* band order, i.e., the valence band edge is predominantly formed by the anionic (Te) orbitals, while the conduction band minimum is mainly determined by the cationic (Sb, Sn) orbitals. The inclusion of the SOC in the calculation leads to a significant modification of the gap (Fig. 15.2a), which becomes indirect, with a width of ≈ 100 meV. At the A point, the SOC induces a complicated inversion of the gap edge states (Fig. 15.2b, right-hand side): the Te states reveal themselves in the conduction band, whereas the top valence band is basically formed by Sb and Sn orbitals of the SL block, while Sb states of the QL block appear in the second top band (Fig. 15.2b, right-hand side). A similar band inversion is characteristic of isostructural compounds $SnBi_4Te_7$ and $PbBi_4Te_7$.

Another feature of band-inverted insulators $C^{IV}A_4^VB_7^{VI}$, whose crystal structure consists of alternating SL and QL building blocks, is that the surface can be formed by SL or QL building blocks, which we define as 7L and 5L terminations, respectively.

The surface band structures of the 7L and 5L terminations of $SnSb_4Te_7$ and $SnBi_4Te_7$ compounds are shown in Fig. 15.3. The spectrum of 7L-terminated $SnSb_4Te_7$ demonstrates a strictly linear dispersion of the Dirac state, which is spatially localized within both surface SL and subsurface QL building blocks. The dispersion of the Dirac state on the 5L termination in the vicinity of the Dirac point (DP), where it is also localized within two building blocks (surface QL and subsurface SL) is also linear. However, at higher energies, above the Fermi level, the state changes its spatial distribution, which becomes predominantly localized in the surface QL block, and the dispersion of the TSS changes. The Dirac cone at the 7L termination of $SnBi_4Te_7$ is warped near the conduction band simi-

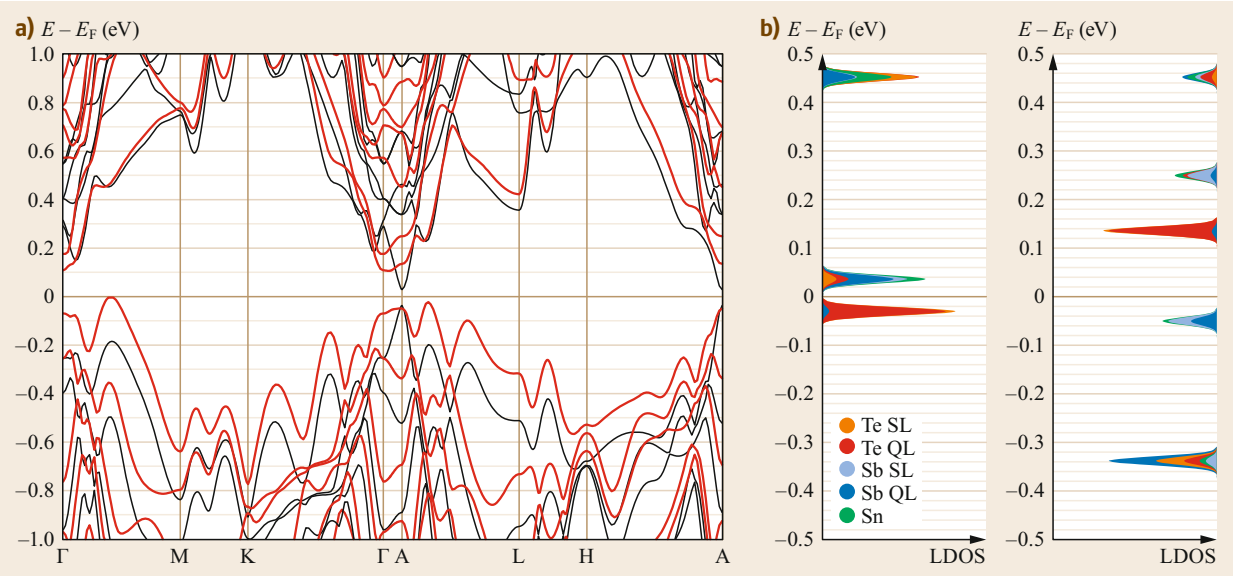

Fig. 15.2 **(a)** Bulk band spectra of $SnSb_4Te_7$ along the high symmetry lines in the Brillouin zone. *Red/black lines* correspond to results with/without SOC included. **(b)** Local density of states (LDOS) calculated without (*left-hand side*) and with (*right-hand side*) SOC included at the vicinity of the A point. *Colors* in the LDOS correspond to different atomic contributions

lar to that in the parent Bi_2Te_3. In contrast to $SnSb_4Te_7$, the TSS at the 7L-terminated $SnBi_4Te_7$ surface is completely localized within the surface SL block, as in the case of $PbBi_4Te_7$ [15.43]. The Dirac state at the 5L termination of $SnBi_4Te_7$ also demonstrates a change in the dispersion above the DP, which is attributed to its inhomogeneous spatial localization.

Another feature of the 5L-terminated surface spectra of both $SnSb_4Te_7$ and $SnBi_4Te_7$ compounds is the occupied Dirac state that lies in the valence bandgap at the $\overline{\Gamma}$ point at −0.15 eV (−0.25 eV). The dispersion and localization of this Dirac state is similar to that of the parent $Sb(Bi)_2Te_3$ compounds and is associated with complicated bulk bandgap inversion in $C^{IV}A_4^VB_7^{VI}$ crystals when the inverted QL states appear inside the valence band, which in turn allows the original TSS of the parent binary TI to survive in the $C^{IV}A_4^VB_7^{VI}$ heterostructure.

It should be noted that at the real crystal surface, owing to the presence of both QL- and SL-surface terminations, both Dirac states should appear simultaneously at the $\overline{\Gamma}$ point, as shown in the example of the $PbBi_4Te_7$ compound in Fig. 15.4. These two Dirac cones have been successfully resolved in the angle-resolved photoemission spectroscopy (ARPES) spectrum [15.58].

Ternary compounds SnX_6Te_{10} (X = Sb, Bi) differ from SnX_4Te_7 in that they are built of alternating SL and *two* QL blocks along the hexagonal *c*-axis. Calculations of the $\mathbb{Z}_2$ topological invariant have shown that it is nonzero for $SnBi_6Te_{10}$, whereas it is zero for $SnSb_6Te_{10}$. The nonzero $\mathbb{Z}_2$ in $SnBi_6Te_{10}$ is provided by the band gap inversion at the Z point of the bulk Brillouin zone. In the calculation with SOC excluded, the Z point gap is above > 300 meV. The switching on of the SOC leads to substantial narrowing of the gap at Z. Similar to the $C^{IV}A_4^VB_7^{VI}$ systems, the band inversion has a complicated character when the orbitals of the atoms constituting different building blocks contribute to the gap edges. However, because of the more complicated crystal structure of $SnBi_6Te_{10}$, the gap inversion is more complicated as well. The lowest conduction band is formed by the orbitals of Te atoms faced to each other at the vdW spacing between neighboring QLs (marked as Te QL/QL in Fig. 15.5b, right-hand panel), whereas two upper bands are composed of orbitals of Te atoms lying at the van der Waals spacing between neighboring QL and SL blocks (marked as Te QL/SL and Te SL). The top valence band, as in the case of $C^{IV}A_4^VB_7^{VI}$, is formed in the main part by the states of the SL building block, and the next two, deeper, bulk valence bands are determined by the orbitals of Bi atoms of the QL blocks.

The $C^{IV}A_6^VB_{10}^{VI}$ crystals, and in particular $SnBi_6Te_{10}$, have two nonequivalent cleavage planes: between SL and QL blocks, and between two neighboring QLs. Such cleavages give rise to three different surface terminations. Two of these, 5L with surface QL and subsurface SL blocks, and 7L with the opposite sequence of the surface and subsurface building blocks,

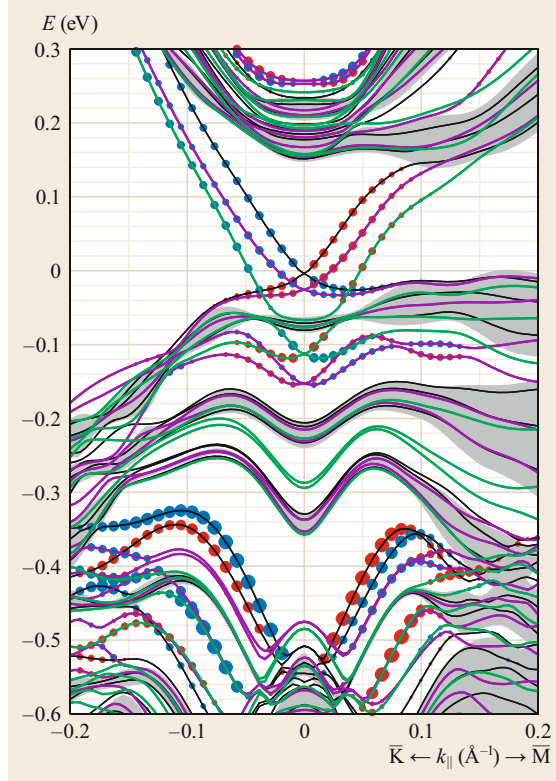
are the same as in the $SnSb(Bi)_4Te_7$ crystals discussed earlier. The third termination that can be obtained by the cleavage of the $SnBi_6Te_{10}$ crystal is the surface in which both the surface and subsurface blocks are QLs. We will call this surface termination the 5-5L termination.

Figure 15.6 shows the surface band spectra of $SnBi_6Te_{10}$ with all types of terminations. The dispersion of the Dirac state at the 7L- and 5L-terminated surfaces is similar to that at the respective terminations of $SnBi_4Te_7$. The spatial charge distributions of the TSS on these terminations are also akin those in $SnBi_4Te_7$.

However, on the 5-5L termination, the TSS forms an exotic cone with a Dirac point in the local gap of the valence bulk band. This unusual behavior can be understood from the fact that the occupied states localized at the Bi atoms of the QL block are not at the gap edge, but below the Bi and Sn states of the SL block, which for this termination lies deep in the bulk and forms the top of the bulk valence band. In particular, the Dirac point is located in the local gap of the bulk valence band. As a result, this Dirac cone possesses two segments: located in the local and in the fundamental bandgap. However, the charge density of the TSS in both segments is mostly localized in the surface QL block.

The dispersion of the Dirac cones at the 7L, 5L and 5-5L surfaces of $SnBi_6Te_{10}$ is similar to



the respective surfaces of $PbBi_6Te_{10}$ [15.43]. As in the case of compounds with simpler structure $(C^{IV}B^{VI})_{n=1}(A_2^VB_3^{VI})_{m=2}$, here different surface terminations, which should be present inevitably in a real crystal due to the stepped morphology of the surface, result in the presence of multiple coexisting Dirac states, as shown in the example of the $PbBi_6Te_{10}$ compound in Fig. 15.7, where spectra for three surface terminations are superposed. Three Dirac cones have been found in this material experimentally [15.59], in accord with the prediction. In particular, as can be seen in Fig. 15.7, the 7L surface shows a rather linear dispersion close to its DP_{7L}, which lies ≈ 60 meV above the $\overline{\Gamma}$ valence band edge, in agreement with the experimental value of ≈ 80 meV [15.59]. The Dirac point of the 5L TSS lies at ≈ 40 meV lower than DP_{7L}, closer to the bulk valence states, consistent with the estimated experimental value of 120 meV. At the same time, the 5L TSS deviates markedly from the linear dispersion, approaching the Dirac point. The Dirac point of the 5-5L termination ($DP_{5\text{-}5L}$) emerges below (≈ 15 meV) the first valence band, so that the Dirac cone loses its localized character passing through the narrow energy region of the first valence band and becomes localized (and spin-polarized) again in the local gap between the first and second bulk valence bands.

15.3 $(C^{IV}B^{VI})_n(A_2^VB_3^{VI})_m$ Compounds ($n > 1$, $m = 1$)

Different $(C^{IV}B^{VI})_n(A_2^VB_3^{VI})_m$ systems, containing layers of $A_2^VB_3^{VI}$ topological insulators and $C^{IV}B^{VI}$ materials like SnTe and PbTe, are formed when $n > 1$ and $m = 1$. In contrast to the compounds of the $(n = 1, m > 1)$ series containing alternating QL and SL structural units, the $(n \geq 1, m = 1)$ compounds are formed of unique, nonalternating building blocks. The simplest system ($n = 1$, $m = 1$), e.g., $SnBi_2Te_4$, is composed of SL hexagonally ordered blocks stacked along the c-axis and separated by van der Waals spacings. The SL building block (Fig. 15.8b) can be obtained from the original QL block of Bi_2Te_3 (Fig. 15.8a) by introducing the SnTe bilayer in the middle part of the QL. The $SnBi_2Te_4$ compound was earlier predicted to be 3-D $\mathbb{Z}_2$ TI [15.43]. The heterostructure with a larger n index, $Sn_2Bi_2Te_5$ ($n = 2, m = 1$), is formed by NL building blocks [15.60]. The NL block (Fig. 15.8c) can be obtained from the SL block by the introduction of an additional SnTe bilayer in the middle of the SL. Another experimentally confirmed structure $(SnTe)_n(Bi_2Te_3)_m$, which is also built from the ionic-covalent bonded Bi_2Te_3 and SnTe atomic layers, is $Sn_3Bi_2Te_6$ ($n = 3, m = 1$), see Fig. 15.8d [15.60]. The compounds with C^{IV}=Pb have similar crystal structures. However, it should be noted that PbTe is a trivial insulator, while SnTe [15.61, 62] belongs to the class of topological materials in which the topological surface states are protected by the crystal mirror symmetry [15.63]—so-called topological crystalline insulators (TCI).

The bulk band structures of $Sn_2Bi_2Te_5$ have been calculated without (Fig. 15.9a) and with (Fig. 15.9b) SOC included. In the calculated spectrum without SOC, a direct energy gap of 0.32 eV exists at Γ. The switching on the SOC transforms it into an indirect gap of 0.11 eV (Fig. 15.9b). This value is in good agreement with the experimental gap of 0.09 eV [15.60].

The time-reversal invariant momenta in the bulk Brillouin zone are the Γ, A, and triply degenerate M and L points. We found that the parity inversion of bulk bands occurs at the Γ point, which leads to $\mathbb{Z}_2$ invariants 1;(000) as in the parent TI Bi_2Te_3. In spite of this similarity, the band inversion at Γ is an entanglement of two different inversions corresponding to each sublattice, Bi_2Te_3 and SnTe. Thus, in Bi_2Te_3, the SOC inverts the top valence band state (predominantly of p_z character) of Te atoms lying in the outer layers of the QL (Te_o) and the Bi p_z-state of the bottom conduction band. A similar band inversion occurs in the bulk SnTe, where Sn and Te orbitals are inverted in the L point of the cubic Brillouin zone. In the case of the $Sn_2Bi_2Te_5$ heterostructure, both Bi and Sn states form the bottom of the conduction band, while the states of the Te_o atoms and Te atoms of the central layer of the NL (Te_c) lie in the top valence band of the spectrum calculated without SOC (Fig. 15.9c,d). Switching on the SOC results in an inversion of Bi and Te_o states and Sn and Te_c states. However, in contrast to the parent systems, this inversion has a more complex character. As can be seen in Fig. 15.9e, after switching on the SOC, the Te_o states become dominant in the conduction band while the Bi states occupy the second valence band. The SOC-inverted Sn states lie in the highest valence band, and Te_c states appear in the second conduction

Fig. 15.7 Calculated band structure of $PbBi_6Te_{10}$ surfaces along the $\overline{K}$-$\overline{\Gamma}$-$\overline{M}$ direction with the 7L, 5L, and 5-5L terminations (*black*, *violet*, and *green lines*, respectively); the size of the *colored circles* represents the weights of the states in the surface layers; *red* and *blue colors* denote the sign of in-plane spin components (positive and negative, respectively), and the *shaded area* identifies the bulk-projected bands ◄

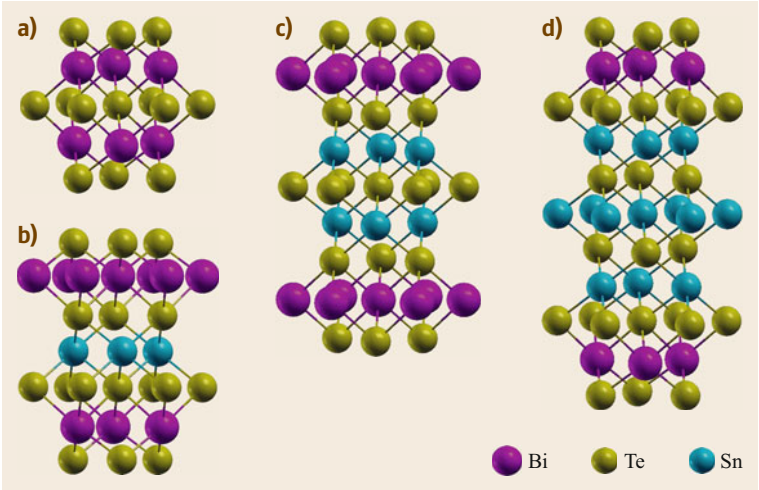


Fig. 15.8a–d Building blocks of Bi_2Te_3 **(a)**, $SnBi_2Te_4$ **(b)**, $Sn_2Bi_2Te_5$ **(c)**, and $Sn_3Bi_2Te_6$ **(d)**

band (Fig. 15.9f). Additionally, the SOC-inverted Sn states (with smaller weight) appear in the second valence band. Thus, the $Sn_2Bi_2Te_5$ TI has a competitive bulk band inversion, which comprises the inversion of the states belonging to different sublattices, SnTe and Bi_2Te_3, so that the valence band edge is formed mainly by Sn states and the conduction band edge occupied by Te_o states, i.e., inverted gap edges are formed by the orbitals of atoms belonging to different sublattices.

The superposition of the SOC-induced bulk band inversions in the SnTe and Bi_2Te_3 sublattices of the $(SnTe)_2(Bi_2Te_3)_1$ heterostructure results in the formation of two topological surface states at the $\overline{\Gamma}$ point. The upper TSS lies in the bandgap (see light pink rectangle in Fig. 15.10a), while the lower TSS (light green rectangle in Fig. 15.10a) resides in the valence band (hereafter referred to as bandgap and valence band TSSs, respectively). The valence band TSS, residing in the local valence bandgap, has typical Dirac dispersion, similar to that in Bi_2Te_3. In contrast, the bandgap TSS displays nonlinear dog-leg dispersion. It has two linear sections, near the band crossing (Dirac point) and below the conduction band, which connect to each other in the middle part of the gap with the formation of shoulders in the spectrum. As in other TIs, the TSSs in $Sn_2Bi_2Te_5$ are localized within the surface building block. However, in this case, the building block has SnTe and Bi_2Te_3 sublattices, and the localization of the TSS is affected by the peculiarities in the bulk band inversion. The Bi and Sn orbital weights are shown in Fig. 15.10b,c for the band gap and valence band topological surface states, respectively. As can be seen, the valence band TSS has dominant Bi weights that reflect its dominant localization in the outer Bi-Te layers of NL, i.e., in the Bi_2Te_3 sublattice. Comparing the dispersion of this state with the dispersion of the Dirac cone in Bi_2Te_3 [15.33] (Fig. 15.10e), one can conclude that the two bands are almost identical. In the lower linear section near the band crossing of the bandgap TSS (Fig. 15.10b), the Sn contribution dominates, and thus the state is mainly localized in the SnTe sublattice. Approaching the shoulders, the Sn contribution disappears rather quickly, and above the band shoulders the TSS becomes mostly localized in the Bi-Te layers. Thus, the band shoulders in the TSS spectrum are associated with the change in the TSS localization from the SnTe to Bi_2Te_3 sublattice. It is worth noting that the dispersion of the upper linear section of the bandgap TSS (at $k_\parallel > 0.1\,\text{Å}^{-1}$) is comparable to the slope of the Bi_2Te_3 Dirac cone (Fig. 15.10d), while that of the lower linear section ($k_\parallel < 0.05\,\text{Å}^{-1}$) differs notably from both Bi_2Te_3 and SnTe(111) [15.64] Dirac states.

The linear fitting of the lower and upper sections in the bandgap TSS gives $E/k_\parallel$ slopes of 2.22 and 1.13 eV Å, respectively. Between these linear sections, at $0.05 < k_\parallel < 0.1\,\text{Å}^{-1}$, two inflection points exist that limit the almost flat section in the TSS spectrum. Owing to slightly negative dispersion of the TSS in the shoulder region, the system can pass from one velocity mode in the lower linear section to the other velocity mode in the upper linear section through the three surface Fermi pockets at energy of ≈ 50 meV (Fig. 15.10f).

The spin texture of the bandgap TSS is demonstrated in Fig. 15.10g,h. Figure 15.10g shows spin-resolved constant energy contours (CECs) for the lower (inner contour) and upper (outer contour) linear sections of the TSS, at energies of 25 meV below and above the shoulders, respectively. Both contours demonstrate the in-plane clockwise spin polarization. In addition, the outer contour indicates the presence of the out-of-plane spin component S_z, which is zero along $\overline{\Gamma}$-$\overline{M}$ and reaches a minimum (maximum) value in the $\overline{\Gamma}$-$\overline{K}$ di-

rections. Such a spin texture is an intrinsic feature of the spin-polarized states at hexagonal surfaces. At the same time, S_z for the inner contour is very small. The dependence of absolute values for $S_\parallel$ and S_z on $k_\parallel$ along $\overline{\Gamma}$-$\overline{K}$ is shown in Fig. 15.10h. The in-plane spin polarization having a maximum near the Dirac point rapidly decreases approaching the shoulder. At $k_\parallel > 0.1$ Å^{-1}, i.e., in the upper linear section, it increases with $k_\parallel$ until it reaches the region of the bulk states. In contrast, the out-of-plane spin polarization increases with $k_\parallel$ in both linear sections of the TSS, having a kink at the band shoulder.

Let us consider the $(C^{IV}B^{VI})_{n>1}(A_2^VB_3^{VI})_{m=1}$ heterostructure with a larger n index. The increase in the index up to $n = 3$ corresponds to the addition of a SnTe bilayer in the building block and leads to the formation of the $Sn_3Bi_2Te_6$ compound. As can be seen in Fig. 15.11a, in this case two TSSs are also present in the surface spectrum, and a dog-leg dispersion is the feature of the bandgap surface state. The difference from the $Sn_2Bi_2Te_5$ case is that the band shoulders lie closer to the bulk valence band, making the lower section of the TSS very short and half as steep.

Another system of the $(C^{IV}B^{VI})_{n=2}(A_2^VB_3^{VI})_{m=1}$ series is a heterostructure, where the $A_2^VB_3^{VI}$ sublattice is Sb_2Te_3. As can be seen in Fig. 15.11b, the surface spectrum of $Sn_2Sb_2Te_5$ also holds two TSSs with dog-leg dispersion in the bandgap TSS. However, in contrast to the case of $Sn_2Bi_2Te_5$, the band shoulders arise near the conduction band.

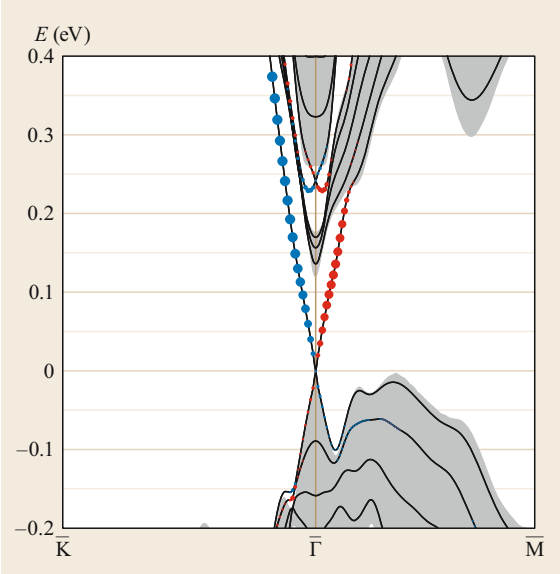

Fig. 15.12 Spin-resolved surface electronic structure of $Pb_2Bi_2Te_5$

On the other hand, if the $(C^{IV}B^{VI})_{n>1}(A_2^VB_3^{VI})_{m=1}$ heterostructure is built of a Bi_2Te_3 topological insulator and trivial insulator sublattices, as in the case of the $Pb_2Bi_2Te_5$ compound, the only one band inversion, provided by the Bi_2Te_3 sublattice, occurs in the bulk spectrum. As a result, in this case a single Dirac state with linear dispersion arises in the surface spectrum (Fig. 15.12).

15.4 Phase-Change Materials

The $Ge_2Sb_2Te_5$ compound is regarded as a prototype conventional phase-change material (PCM) [15.65–67]. It is known that this compound, i.e., $(GeTe)_{n=2}(Sb_2Te_3)_{m=1}$ heterostructure, can adopt four different hexagonal layered structures [15.68]. Experimentally, the most stable phase of $Ge_2Sb_2Te_5$ is the so-called Kooi structure [15.69], which is formed by nonuple-layer building blocks, where GeTe bilayers are incorporated into the Sb_2Te_3 QL, i.e., it has the same structure as in $(C^{IV}B^{VI})_{n=2}(A_2^VB_3^{VI})_{m=1}$ systems with C^{IV} = Pb, Sn. Other crystal phases are the Petrov structure [15.70], in which the $(GeTe)_2$ blocks are sandwiched between Sb_2Te_3 QLs with a Ge-Te-Te-Ge sequence within the block; the inverted-Petrov structure, with a Te-Ge-Ge-Te sequence; and the so-called Ferro structure, in which the atomic layer sequence in the $(GeTe)_2$ block has the order Ge-Te-Ge-Te, i.e., as in ferroelectric bulk GeTe.

The stability of these four structures is dependent on temperature. It was shown by means of calculations of enthalpy as a function of temperature [15.71] that the Kooi phase has the lowest enthalpy at 0 K, in agreement with earlier DFT results [15.68] and experiments [15.69]. However, upon raising the temperature, the enthalpy of the Kooi structure increases, and above $\approx$ 125 K the Ferro phase becomes the most stable structure [15.71]. It has been established that the metastable Petrov and inverted Petrov phases are involved in the atomic mechanism of the crystal phase transformation from the Kooi to Ferro structure [15.71].

For the low-temperature Kooi structure, the narrow-gap band insulator phase has been obtained theoretically [15.68, 72, 73]. This is in contrast to the related compounds $Ge_2Bi_2Te_5$ and $Sn_2Sb(Bi)_2Te_5$, which were shown to be topological insulators [15.73, 74]. The $(GeTe)_n(Sb_2Te_3)_m$ compound with indices $n = 1$ and $m = 2$ has also been predicted to be TI [15.43]. At the same time, the DFT calculations for Ferro and Petrov structures predicted the trivial band insulator phase, while another metastable structure, the inverted Petrov structure, was shown to possess the Dirac semimetal phase [15.68]. We will deal with the electronic structure of stable low-temperature Kooi and high-temperature Ferro structures, whose equilibrium crystal structures are shown in Fig. 15.13.

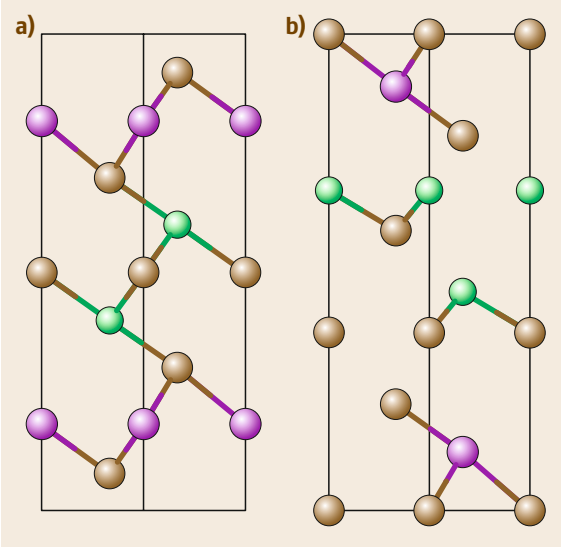

Fig. 15.13a,b Unit cells of the (a) low-temperature Kooi and (b) high-temperature Ferro phases of $Ge_2Sb_2Te_5$

The calculated bulk band structure of the Kooi phase demonstrates the insulating state with a gap of 25.2 meV in the middle of the Γ-A direction (Fig. 15.14a, red lines), which gives a trivial band insulator according to the $\mathbb{Z}_2$ topological invariant calculation. This result is in agreement with earlier calculation data [15.68, 72, 73]. The small bandgap value obtained may be an indication that the system is close to the topological quantum phase transition (TQPT) and can be converted into the topological phase by applying hydrostatic pressure, as was shown for the Sb_2Se_3 band insulator [15.75, 76], or by increasing the spin–orbit interaction strength. We checked the possibilities and found that, with the increase in the hydrostatic pressure (contraction of the cell volume), the gap gradually shifts toward the A point, decreasing in magnitude, and at $\approx$ 10% volume contraction (corresponding to pressure of 6.3 GPa), the A-gap closes and a bulk Dirac cone with linear dispersion is formed. With a further increase in the pressure, when the system has gone through the critical point of the TQPT, the A-point gap reopens with inverted order of the bands; however, under these conditions, the spectrum is metallic, and

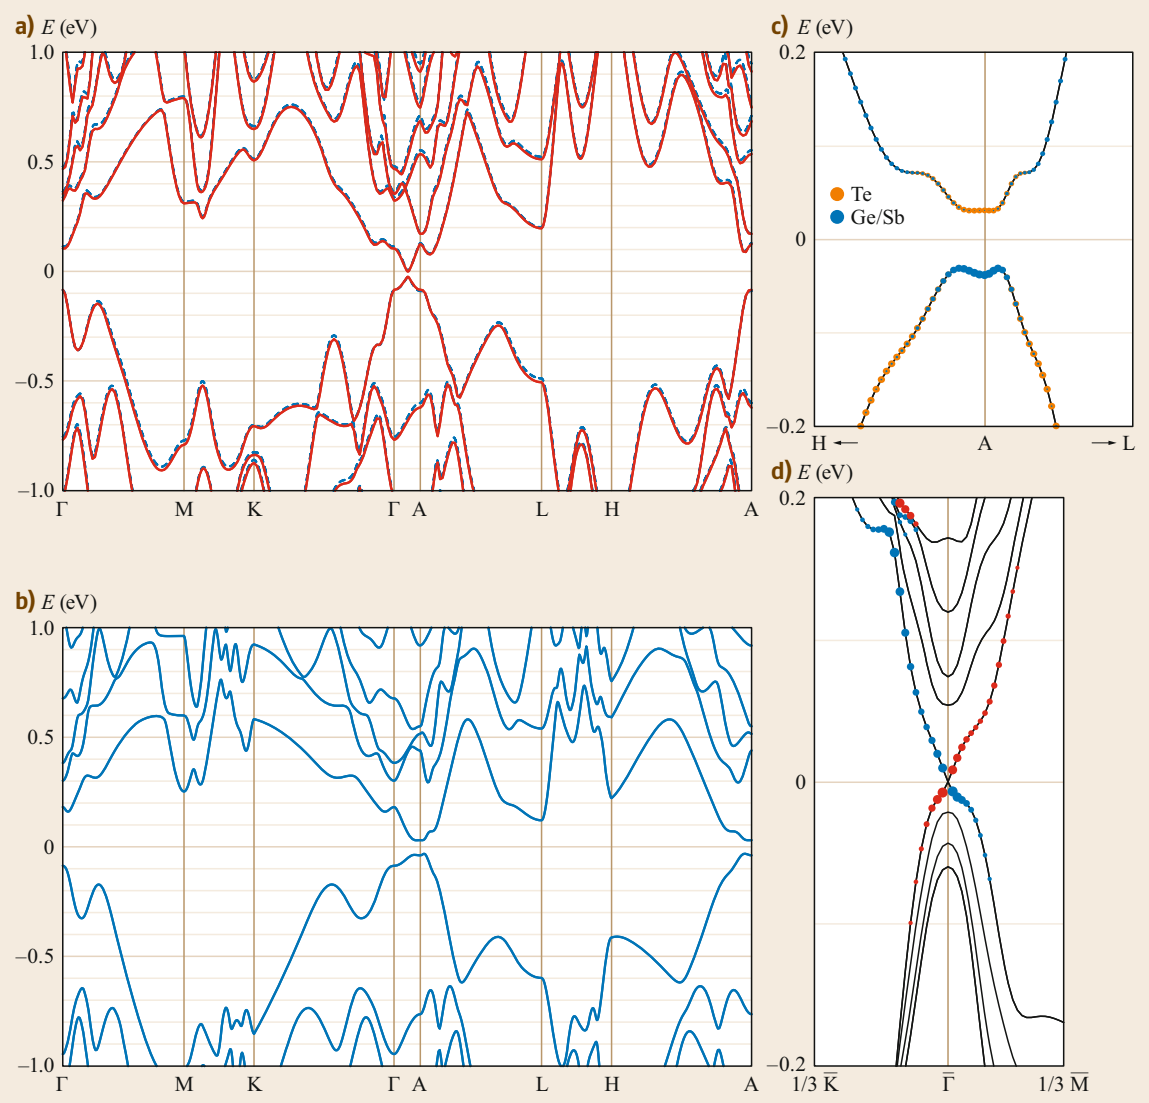

Fig. 15.14 **(a)** Bulk band structure of ordered Kooi phase with equilibrium crystal structure parameters (*red solid lines*, VASP calculation; *blue dashed lines*, ABINIT calculation). **(b)** Band structure of Kooi-$Ge_2Sb_2Te_5$ with Ge/Sb mixing (VCA-ABINIT calculation) and **(c)** its magnified view near the A-gap, with indication of the weights of Te and Ge/Sb p_z orbitals (VCA-ABINIT calculation). **(d)** Surface electronic spectrum for Kooi-$Ge_2Sb_2Te_5$ with Ge/Sb mixing. *Red* and *blue circles* denote the positive and negative sign of the in-plane spin, respectively

hence the system can be characterized as a topological metal. We also artificially increased the spin–orbit interaction strength λ in the ordered equilibrium structure and found that, as in the case of hydrostatic pressure, it leads to a shift of the gap toward the A point, along with its narrowing. Upon a further increase in the spin–orbit interaction strength, the gap becomes inverted, achieving at $\lambda/\lambda_0 = 1.4$ a width of 76 meV at the A point. This result is in line with the fact that the TI phase was predicted for $Ge_2Bi_2Te_5$ [15.73], in which the atomic spin–orbit coupling strength is larger owing to the larger atomic mass of Bi as compared with Sb.

However, it is known from experiments that the stable $Ge_2Sb_2Te_5$ contains mixed Ge/Sb atomic layers [15.77]. This mixing has been taken into account in the calculations within the virtual crystal approximation using the ABINIT code. The band structure for the ordered phase with ABINIT code is in good agreement with the VASP result (Fig. 15.14a, dashed blue lines). The calculated spectrum has a gap of 29.5 meV

in the middle of the Γ-A direction. Next, according to the experiment [15.77], we constructed $Ge_{0.56}/Sb_{0.44}$ and $Ge_{0.44}/Sb_{0.56}$ virtual atoms for the outer and inner Ge/Sb layers of NL, respectively. We find that in the case of the mixed Ge/Sb atomic layers, a minimum gap of 61 meV appears at the A point (Fig. 15.14b) and, being inverted (Fig. 15.14c), results in the nontrivial topological invariant $\mathbb{Z}_2 = 1$. This signifies that the Kooi structure possesses the TI quantum phase. Therefore, Ge/Sb mixing in the $Ge_2Sb_2Te_5$ Kooi structure effectively increases the spin–orbit interaction. The surface band structure for $Ge_2Sb_2Te_5$ with mixed Ge/Sb layers is shown in Fig. 15.14d. As can be seen, the surface spectrum of the Kooi structure holds the topological surface state with the Dirac point at the Fermi level.

The distinctive feature of the Ferro structure of $Ge_2Sb_2Te_5$ (Fig. 15.13b) is the lack of inversion symmetry. It results in the spin–orbit splitting of the bulk energy spectrum (Fig. 15.15a), which resembles the Rashba-like band splitting in the bulk GeTe [15.78]. The presented spectrum has a small gap of 11 meV in the A-H direction at $k_x \approx 0.1\,\text{Å}^{-1}$ away from the A point. Near the gap, the spin texture differs from the Rashba spin-helical picture and demonstrates almost collinear spin alignment perpendicular to the A-H (k_x) direction, with a sizable S_z component of the same sign both below and above the gap (Fig. 15.15b). Away from the H-A-L plane at $k_z = \pi/c \pm 0.015\,\text{Å}^{-1}$ (where $k_z = \pi/c$ is the H-A-L plane), the gap closes, forming a pair of Weyl nodes (Fig. 15.15c), which is a distinctive feature of the topological Weyl semimetal (TWS) phase.

The TWS can be realized by breaking either time-reversal or inversion symmetry in a topological Dirac semimetal [15.17]. In this regard, the appearance of the TWS quantum phase in the $Ge_2Sb_2Te_5$ with Ferro structure can be understood from the comparison with the intermediate inverted Petrov structure. The inverted Petrov structure predicted to be a Dirac semimetal differs from the Ferro structure only in the atomic layer sequence within the $(GeTe)_2$ block, so that the latter is inversion-asymmetric.

The Weyl topological phase is predicted to provide a realization of the chiral anomaly, giving rise to a negative magnetoresistance under parallel electric and magnetic fields, the semi-quantized anomalous Hall effect, unusual optical conductivity, and nonlocal transport and local nonconservation of the current [15.79–85]. At the surface, the bulk band topology should result in the formation of unusual surface states that form disjoint Fermi arcs connecting the projections of the Weyl nodes onto the surface Brillouin zone [15.86, 87]. The Fermi arcs are predicted to show unconventional quantum oscillations in magneto-transport, as well as unusual quantum interference effects in tunneling spectroscopy [15.87–90].

The $Ge_2Sb_2Te_5$ compound with a Ferro structure can adopt six different surface terminations depending on the Sb_2Te_3 QL and GeTe bilayer sequence near the cleavage plane. The geometries of the terminations are shown schematically in the insets in Fig. 15.16. The calculated surface electronic spectra (Fig. 15.16, odd columns) demonstrate that all surface terminations hold the trivial Rashba-split surface states resulting from splitting off from bulk bands due to the band-bending effect, which is negative for QL-GeTe-GeTe, GeTe-GeTe-QL, and GeTe-QL-GeTe terminations (first column in Fig. 15.16) and positive for terminations shown in the third column. Besides these states, as can be seen in the Fermi surface maps (Fig. 15.16, even columns), each surface termination holds the Fermi arcs connecting the Weyl pairs. In most cases, the arcs connect the Weyl nodes within each $\overline{\Gamma}$-$\overline{K}$ pair, while in the case of the TeGe-QL-TeGe termination, the arcs connect points of neighboring pairs via the hole-like Rashba surface state, which crosses the Fermi level twice in the $\overline{\Gamma}$-$\overline{M}$ direction, but once in $\overline{\Gamma}$-$\overline{K}$, and touches the Weyl nodes on the conduction band side. A similar effect of Weyl node reconnection was recently observed in the TWS phase arising in BiTeI under pressure [15.91].

15.5 Conclusions

In this chapter we have demonstrated the diversity of electronic states in natural topological heterostructures. These ternary compounds, with the general formula $(C^{IV}B^{VI})_n(A_2^VB_3^{VI})_m$, where A^V are elements of group V = Bi, Sb; B^{VI} are elements of group VI = Te, Se; and group IV elements C^{IV} = Ge, Sn, Pb, have layered hexagonal crystal structures with two distinct sublattices, one of which is the well-known topological insulator $A_2^VB_3^{VI}$ such as Bi_2Te_3, and another sublattice can be a strong topological insulator, topological crystalline insulator, or trivial insulator. Depending on the elemental composition and stoichiometry, these heterostructures can possess a van der Waals superlattice structure, may take the form of built-in sublattices within unique structural blocks, or can demonstrate phase-change behavior with temperature. Such a wealth of structures results in a wide variety of topological surface states in these materials.

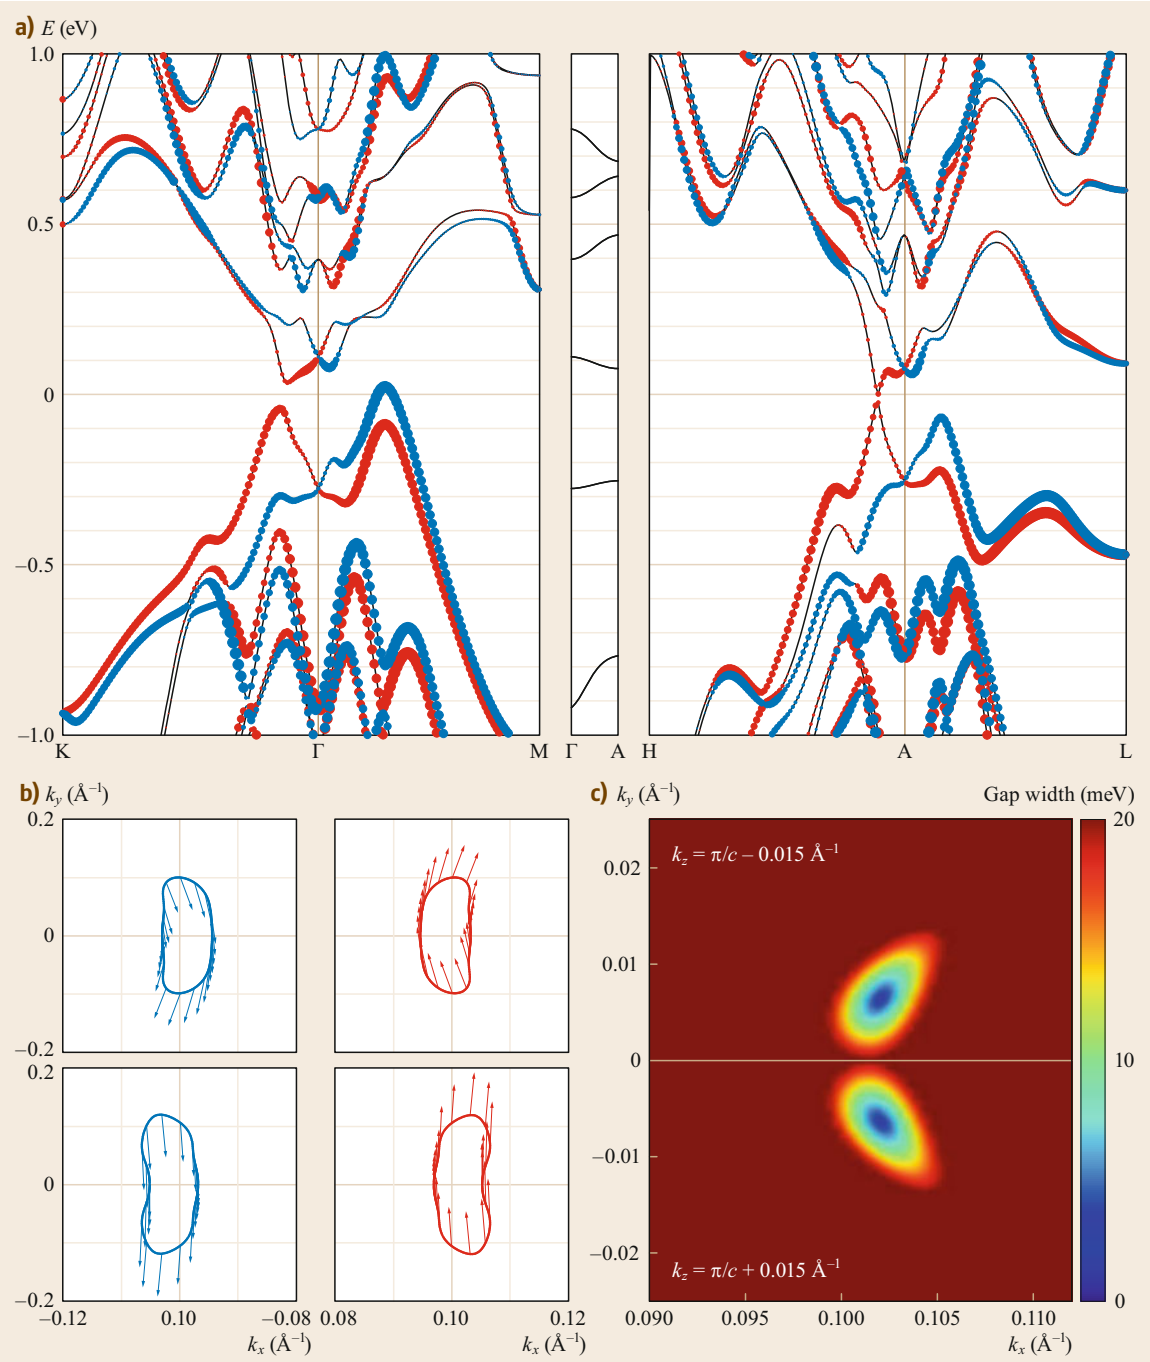

Fig. 15.15 **(a)** Bulk band spectrum of the high-temperature Ferro-$Ge_2Sb_2Te_5$ structure; *red/blue circles* indicate the positive/negative sign of the in-plane $S_\parallel$ spin components. **(b)** Spin-resolved constant energy contours taken below and above the gap (*left-* and *right-hand panels* for the H-A and A-H directions, respectively); here, *arrows* show the in-plane spin direction, and the *red/blue color* corresponds to the positive/negative sign of S_z. **(c)** The dependence of the gap width on $k_\parallel$ at $k_z = \pi/c - 0.015$ and $k_z = \pi/c + 0.015$ Å^{-1}; the zero-gap points correspond to the Weyl nodes

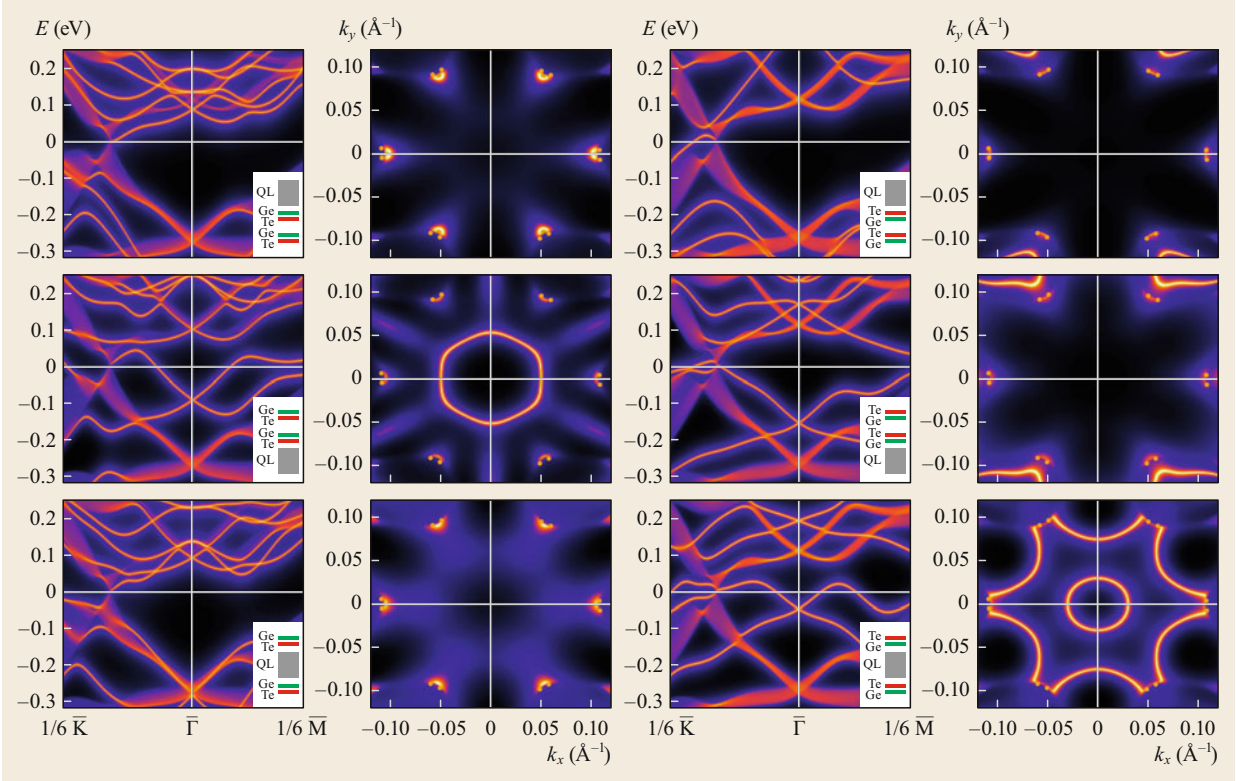

Fig. 15.16 Surface electronic structure for different Ferro-$Ge_2Sb_2Te_5$ surface terminations (*odd columns*), whose structure is shown in the insets, and corresponding Fermi surfaces (*even columns*). *Small red points* on the Fermi surfaces mark positions of the Weyl nodes. k_x- and k_y-axis directed along $\overline{\Gamma}$-$\overline{K}$ and $\overline{\Gamma}$-$\overline{M}$, respectively

In particular, most of the $(C^{IV}B^{VI})_{n=1}(A_2^VB_3^{VI})_{m>1}$ superlattices, including $PbBi_4Te_7$, $PbSb_4Te_7$, $PbBi_6Te_{10}$, $SnBi_4Te_7$, and $SnBi_6Te_{10}$ and others, are 3-D $\mathbb{Z}_2$ topological insulators [15.43], while some of them, like $SnSb_6Te_{10}$, are trivial insulators. The topological insulator superlattices exhibit a more complicated surface electronic structure and spin behavior than their parents, thus providing an efficient way to manipulate both the spin structure and the spatial localization of the conducting state. They demonstrate strong differences in the dispersion of the topological surface state and its spin polarization depending on the cleavage surface. Since in a real cleavage surface the different surface terminations are present due to the stepped morphology of the surface, the multiple coexisting Dirac cones centered at the $\overline{\Gamma}$ point of the reciprocal space arise in the ARPES spectra [15.58, 59]. These findings aid in understanding the diversity of topological surface states in TI superlattices and may pave the way for the application of topological insulators to real spintronic devices.

The $(C^{IV}B^{VI})_{n>1}(A_2^VB_3^{VI})_{m=1}$ heterostructures contain layers of $A_2^VB_3^{VI}$ topological insulator and $C^{IV}B^{VI}$ materials like SnTe and PbTe. The compounds with the trivial band insulator sublattice PbTe, such as $Pb_2Bi_2Te_5$, demonstrate a linear Dirac state in the surface spectrum similar to that in the parent binary TI. On the other hand, heterostructures with a SnTe sublattice (a material that is a topological crystalline insulator in bulk phase), such as $(SnTe)_{n=2,3}(Bi(Sb)_2Te_3)_{m=1}$ compounds, are $\mathbb{Z}_2$ topological insulators. In these TIs, two spin-helical topological surface states arise at the $\overline{\Gamma}$ point. These states reside in the bandgap and in the local gap of the valence band. The latter TSS, lying deep below the Fermi level, has a dispersion similar to that in the Bi_2Te_3 TI, while the bandgap TSS demonstrates an exotic dog-leg dispersion with two linear sections of different slope and a very low-velocity shoulder section between them. In $Sn_2Bi_2Te_5$, the shoulders are located in the middle of the gap, and the velocities of carriers in the lower and upper linear sections differ by a factor of two. Thus, in contrast to all hitherto known TIs, where the slope of the spin-helical TSS is linear or varies smoothly with energy, the bandgap TSS in the $(SnTe)_{n=2,3}(Bi_2Te_3)_{m=1}$ compounds shows an abrupt switch of the velocity of topological carriers

with a change in the Fermi surface topology in the narrow energy range (shoulder section), where the spin and charge current should be blocked. This novel finding paves a way for the efficient control of the group velocity with sufficiently large spin-current density by tuning the chemical potential.

Another type of $(C^{IV}B^{VI})_{n>1}(A_2^VB_3^{VI})_{m=1}$ heterostructures comprises materials with a GeTe sublattice, like the $Ge_2Sb_2Te_5$ compound, which is a phase-change material. The $(GeTe)_{n=2}(Sb_2Te_3)_{m=1}$ system can adopt four different hexagonal layered structures. At low temperatures it has a nonuple-layer structure similar to the related compounds with Sn and Pb, while in other phases the GeTe and Sb_2Te_3 sublattices are separated and alternate along a c-axis as in ($n = 1$, $m > 1$) structures. Thus, the temperature-induced structural phase transformation is accompanied by a quantum topological phase transition from the TI phase in the low-temperature Kooi crystal structure to the topological Weyl semimetal phase in the high-temperature Ferro structure. Together with the earlier predicted Dirac semimetal phase for the intermediate metastable inverted Petrov structure, the TI and Weyl semimetal phases form a rich topological family realized in the same material. The Dirac surface states of TI, with potential for spintronic applications, and the exotic bulk and surface electronic states of TWS, providing an ideal platform for many novel physical phenomena including negative magnetoresistance, anomalous quantum Hall effect, and chiral magnetic effect, can be realized in $Ge_2Sb_2Te_5$, substantially expanding the application potential of this material.

Evgueni Chulkov is Professor at the University of the Basque Country, San Sebastian, Spain, and a head of the laboratory of electronic and spin structure of nanosystems at Saint Petersburg University. He received his PhD from Tomsk State University in 1980. His work focuses on electronic structures in materials with strong spin-orbit interactions and electronic properties of topological insulators.

16. Energetic Ground State Calculations, Electronic Band Structure at Surfaces

Gian Paolo Brivio, Guido Fratesi

Ground-state properties and electronic band structures at surfaces are a very important field of research in surface science not only for catalysis, but more recently for organic electronics where several sensitive experimental techniques have been developed. Nowadays, a joint theoretical and experimental effort based on exceptionally improved computer power/algorithms and experimental advances is successful in describing adsorption sites, geometry, reconstruction, and many-body properties. In the first section, we focus on density functional theory (DFT) including its historical improvements: generalized gradient approximation, self-interaction correction, hybrid functionals (orbital-dependent functional), and phenomenological treatments of van der Waals (vdW) interaction. After examining the methods to compute band structures, we present organic classes of molecules. Polycyclic aromatic hydrocarbons have attracted significant interest for organic electronic devices, and are presented through examples of pentacene on silicon, noble metals, and aluminum. Charge rearrangement/dipoles/spin distributions induced by adsorption complete this chapter.

16.1 Preliminary Remarks

Energetic ground-state calculations and electronic band structure at surfaces have been important fields of research in surface science since crystallographic surfaces were grown under ultrahigh vacuum conditions and several surface-sensitive techniques were developed. Currently clean, almost two-dimensional (2-D) periodic surfaces can be obtained even after adsorbing complex organic molecules.

Adsorption is a very relevant phenomenon and well known are its implications for corrosion, heterogeneous catalysis, and more recently for organic electronics. But the understanding of such processes requires an understanding of bonding of atoms and molecules at solid surfaces. Nowadays, a joint experimental and theoretical effort, based on first-principles calculations, strongly propelled by the enormously increased computer power, is often successful in determining adsorption sites, geometry, possible surface reconstruction, orientation of molecules, potential energy barriers, wavefunctions, vibrations, and more recently in a few cases many-body properties such as plasmon, polariton on metals, magnons, etc. The density of states of the clean surface and of the surface bands projected onto the molecular eigenstates now enjoy clearer pictures.

M. Rocca, T.S. Rahman, L. Vattuone (Eds.), *Springer Handbook of Surface Science*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-46906-1_16

We can distinguish surface-projected bulk states, resonant surface ones, and also localized surface electronic states. Refined two-photon photoemission experiments or inverse photoemission experiments have detected image potential states determined by the long-range Coulomb tails of the surface potential. Quantum well states localized between an adsorbate overlayer and the surface are also important. Surface states can be used as a tool to monitor adsorption but may also occur as a consequence of such phenomena.

The study of molecule–surface interaction boasts a great variety of systems and of physical and chemical properties. Large binding energy implies chemisorption. This is often the case of open-shell atoms, while inorganic molecules may form strong bonds or dissociate by unsaturated states on the surface. In this respect, alkali adatoms are benchmark systems of which the state of knowledge is not only remarkable but reveals unexpected phenomena such as the *vertical diffusion* probed by ^{3}He scattering. Physisorption is relevant in the simpler noble gas–solid interaction but often also dictates coupling both in an overlayer or in a thin film of organic molecules. Adsorption of organic molecules has opened up new research perspectives. In fact, such moieties display an almost infinite possibility of combining atoms to the required functionalization. Studies have in particular focused on hybrid interfaces in which an organic overlayer is adsorbed on an inorganic one, in view of applications to photovoltaics and electronic devices. Here molecular π and σ states may couple to the substrate and the vdW interaction often plays a crucial role.

16.2 Density Functional Theory at Surfaces

Reliable theoretical models of the electronic properties of surfaces are paramount to interpreting measurements, to account for the molecule surface interaction, and to suggest new routes to the experimental activity. In this respect, density functional theory (DFT) is currently the most popular method because, first, it is an ab initio approach and second, on the basis of Hohenberg–Kohn–Sham theorems, it provides a quantum description capable of handling several hundreds of atoms. Its main limitation is related to an approximate treatment of the exchange-correlation functional which is essentially semilocal in common implementations. A pairwise vdW interaction damped at shorter distances, is usually added to remedy such an incomplete correlation. Apart from the computationally very expensive methods of theoretical chemistry, the study of ground states by DFT is sometimes implemented by many-body perturbation theory. However, the size of the system to be treated limits most of calculation to density functional theory (plus a phenomenological addition of the vdW coupling). Kohn–Sham (KS) eigenstates are found to provide an approximate yet useful description of electronic bands even though these lie outside the realm of DFT being a ground-state theory.

16.2.1 Theoretical Framework

Density functional theory currently constitutes the only practical ab initio method for calculating the electronic properties of condensed matter systems that allow one to deal with a few thousand electrons (hundreds of atoms) [16.1]. Consequently, it is the best approach to deal with a realistic description of adsorbate systems where the interaction between molecules and the surface requires consideration of several layers. The DFT formalism is based on the Hohenberg–Kohn theorem which states that there is a one-to-one correspondence between the charge density $n(\boldsymbol{r})$ of an N interacting electron system and an external potential (up to a constant) $v_{\text{ext}}(\boldsymbol{r})$ [16.2]. In practice, a condensed matter system is fully identified by the electron–nuclei potential

$$v_{\text{ext}}(\boldsymbol{r}) = -\sum_a \frac{Z_a}{|\boldsymbol{r}-\boldsymbol{R}_a|}\,, \tag{16.1}$$

where Z_a and $\boldsymbol{R}_a$ are the atomic number and coordinate, respectively, and atomic units are used throughout. The ground-state charge $n(\boldsymbol{r})$ can be obtained by minimizing the total energy functional

$$E[n] = \int \mathrm{d}\boldsymbol{r}\; v_{\text{ext}}(\boldsymbol{r})n(\boldsymbol{r}) + F[n]\,, \tag{16.2}$$

with respect to variations of $n(\boldsymbol{r})$ over the possible ground-state charge densities. The functional $F[n]$ is the Hohenberg–Kohn functional which is independent of the system.

However, the explicit form of $F[n]$ is not known. For this reason Kohn and Sham resorted to constructing a viable set of single-particle equations by affirming that for any electron problem one can make fictitious single particle equations, subject to an external potential $v_{\text{eff}}(\boldsymbol{r})$, such that the interacting system ground-state density equals that of the noninteracting

one $n_{\text{eff}}(\boldsymbol{r})$ [16.3]

$$n(\boldsymbol{r}) = n_{\text{eff}}(\boldsymbol{r}) \,. \tag{16.3}$$

The auxiliary problem equations, the so-called Kohn–Sham (KS) equations, read as

$$\left[-\frac{\nabla_r^2}{2} + v_{\text{eff}}(\boldsymbol{r})\right]\varphi_i(\boldsymbol{r}) = \varepsilon_i\varphi_i(\boldsymbol{r}) \,, \tag{16.4}$$

and

$$n(\boldsymbol{r}) = \sum_{i=1}^{N} |\varphi_i(\boldsymbol{r})|^2 \,. \tag{16.5}$$

The KS equations can be worked out from the Hohenberg–Kohn variational principle which ensures that the functional $E[n]$ is stationary for small variations of the charge density from the one which guarantees the minimum energy, i.e., $n_{\text{eff}}(\boldsymbol{r})$ [16.3, 4]. One can find that

$$v_{\text{eff}}(\boldsymbol{r}) = v_{\text{ext}}(\boldsymbol{r}) + v_{\text{H}}([n], \boldsymbol{r}) + v_{\text{xc}}([n], \boldsymbol{r}) \,, \tag{16.6}$$

where $v_{\text{H}}(\boldsymbol{r})$ and $v_{\text{xc}}(\boldsymbol{r})$ are the Hartree and the exchange-correlation potential, respectively.

The KS approach is exact: its limitations are in regard to the approximated choice of the exchange-correlation potential defined as the functional derivative of the exchange-correlation functional,

$$\frac{\delta E_{\text{xc}}[n(\boldsymbol{r})]}{\delta n(\boldsymbol{r})} = v_{\text{xc}}(\boldsymbol{r}) \,. \tag{16.7}$$

Here $E_{\text{xc}}[n]$ includes the electron–electron functional minus the Coulomb classical one plus the kinetic energy functional difference between the (unknown) correct one and the single particle expression [16.4]. Approximations to $E_{\text{xc}}[n]$ will be discussed in the following section.

Finally, we wish to remark on some important points of the KS equations: (i) They can be solved self-consistently; (ii) they allow for a magnetic solution; (iii) differently from the Hartree–Fock (HF) approach their eigenvalues cannot be associated to ionization energies, since the Koopmans' theorem does not hold. Only the highest occupied KS eigenvalue is exactly the chemical potential of the system [16.5]. The KS eigenstates cannot be interpreted as one-electron orbitals since the sum of the squared magnitudes of the occupied orbitals, i.e., the charge density, is the fundamental quantity in DFT. However, both eigenfunctions and eigenvalues may often be considered as one-electron orbitals and energies with a good accuracy.

The Local Density Approximation

The local density approximation (LDA) functional can be defined by that of the exchange-correlation one for the homogeneous electron gas. Though a very simplified expression the LDA provides a useful guess for $E_{\text{xc}}[n(\boldsymbol{r})]$ of several condensed matter systems [16.3]. In a spin-polarized form the LDA exchange-correlation functional can be generalized to the local spin density approximation (LSDA) to be written as

$$E_{\text{xc}}[n]^{\text{LSDA}}[n_\uparrow, n_\downarrow] = \int n(\boldsymbol{r})\varepsilon_{\text{xc}}(n_\uparrow(\boldsymbol{r}), n_\downarrow(\boldsymbol{r}))\mathrm{d}\boldsymbol{r} \,, \tag{16.8}$$

where $n(\boldsymbol{r}) = n_\uparrow(\boldsymbol{r}) + n_\downarrow(\boldsymbol{r})$, and ε_{xc} is the exchange-correlation energy per particle for a homogeneous electron gas depending on its spin. Despite its simple expression the L(S)DA has produced many relevant results [16.6]. For example, the bulk constants, cohesive energies, and bulk moduli have been computed for C, Si, Ge with very small differences with respect to the experimental data, namely $\simeq 1\%$ for the bulk constants, $\simeq 4\%$ for the cohesive energies, and $\simeq 5\%$ for the bulk moduli. A detailed LDA-DFT study has demonstrated that the diamond structure is the most stable one for Si among several plausible ones [16.7]. The success of L(S)DA for systems with rapid changes in $n(\boldsymbol{r})$ can be explained by recalling a fundamental property of the exchange-correlation hole $n_{\text{xc}}(\boldsymbol{r}, \boldsymbol{r}')$, defined as [16.8]

$$n_{\text{xc}}(\boldsymbol{r}, \boldsymbol{r}') = \frac{n_2(\boldsymbol{r}, \boldsymbol{r}')}{n(\boldsymbol{r})} - n(\boldsymbol{r}) \,, \tag{16.9}$$

where $n_2(\boldsymbol{r}, \boldsymbol{r}')$ is the diagonal second-order density matrix, which represents the conditional probability of finding an electron in $\boldsymbol{r}'$ if there is one in $\boldsymbol{r}$. In an exact theory

$$\int n_{\text{xc}}(\boldsymbol{r}, \boldsymbol{r}')\mathrm{d}\boldsymbol{r}' = -1 \,. \tag{16.10}$$

The theorem in (16.10) is satisfied by the exchange-correlation hole in L(S)DA. We also observe that while the function $n_{\text{xc}}(\boldsymbol{r}, \boldsymbol{r}')$ is poorly estimated by L(S)DA, the corresponding exchange-correlation functional $E_{\text{xc}}^{\text{LSDA}}$

$$\begin{aligned} E_{\text{xc}}^{\text{LSDA}} &= \frac{1}{2}\int \mathrm{d}\boldsymbol{r}\, n(\boldsymbol{r}) \int \mathrm{d}\boldsymbol{r}' \frac{1}{|\boldsymbol{r}-\boldsymbol{r}'|} n_{\text{xc}}(\boldsymbol{r}, \boldsymbol{r}') \,, \\ &= \frac{1}{2}\int \mathrm{d}\boldsymbol{r} \int_0^\infty R^2 \mathrm{d}R \frac{1}{R} \int \mathrm{d}\Omega\, n_{\text{xc}}(\boldsymbol{r}, \boldsymbol{R}) \end{aligned} \tag{16.11}$$

only depends on the spherical average of $n_{\text{xc}}(\boldsymbol{r}, \boldsymbol{R})$ so that $E_{\text{xc}}^{\text{LSDA}}$ is often a reliable approximation to the

exchange correlation energy, since such a functional displays only a weak dependence on the exact shape of the exchange correlation hole [16.9].

The Generalized Gradient Approximation

Though being a very useful approximation, the L(S)DA is often unable to supply quantitatively correct predictions of physical quantities, e.g., it overestimates dissociation energies by $\approx 1\,\mathrm{eV}$ and determines inaccurate molecular atomization energies which turn out to be about 1 eV smaller than the real ones [16.10]. All these errors are much above the chemical accuracy of 43.36 meV. To amend such discrepancies it seemed rather obvious to introduce a semilocal exchange-correlation functional also dependent on the charge density. This expression is named the generalized gradient approximation (GGA) in which the exchange correlation functional $E_{\mathrm{xc}}^{\mathrm{GGA}}$ is given by

$$E_{\mathrm{xc}}^{\mathrm{GGA}} = \int f\big(n_{\uparrow}(\boldsymbol{r}), n_{\downarrow}(\boldsymbol{r}), \nabla n_{\uparrow}(\boldsymbol{r}), \nabla n_{\downarrow}(\boldsymbol{r})\big)\mathrm{d}\boldsymbol{r}\,. \tag{16.12}$$

Note that (16.12) is called the generalized gradient approximation because $E_{\mathrm{xc}}^{\mathrm{GGA}}$ does not simply include a gradient expansion of the exchange-correlation functional as occurs in the gradient expansion approximation. Such an approach does not fulfill some fundamental properties of the exchange-correlation hole leading to results worse than those by L(S)DA. The merit of the GGA is to describe the exchange correlation hole more realistically than a sheer expansion in the density. To this aim real-space cutoffs are introduced, and in analogy to L(S)DA the exchange hole is never positive, while the exchange and correlation holes integrate to minus one and zero, respectively [16.9, 11–13].

In [16.14] the GGA is extensively applied to several systems with consistent improvements in the calculated properties. First ionization energies of 30 atoms and atomization ones of simple hydrocarbons agree with the experimental ones within a 10% error. For three metals (Al, Na, Cs) studied with the stabilized jellium model very good estimates of the work function and the surface energy have been worked out [16.15]. The GGA functional unlike the L(S)DA is not unique and may contain empirical parameters. Among the most successful ones we recall the functional by Perdew and Wang (PW91) [16.11–14] by which the above-mentioned results were computed; and the subsequent Perdew, Burke, and Ernzerhof (PBE) [16.9, 16] and the revised PBE (revPBE) ones [16.17, 18]. The PBE functional is based on the PW91 one, but it exhibits a simpler and more transparent form, only satisfies physically important conditions, provides a precise account of the linear response of the homogeneous electron gas, and it scales correctly in the low- and high-density limit. For all these reasons, the PBE functional is routinely preferred to the PW91. As a detail the revPBE functionals substitute the value of the empirical parameter κ in the exchange functional with one which best matches the exchange function of the first-row atoms, which allows obtaining better chemisorption energies [16.17, 18].

Failures of the DFT-GGA Method

Despite the very good results outlined in the previous section, the GGA functional exhibits three important drawbacks:

(i) The presence of a spurious self-interaction [16.19];
(ii) The lack of discontinuities in the derivatives of the total energy at N integer number of particles [16.8, 20];
(iii) The erroneous exponential long-range decay interaction of an electron with a metal surface, for which an example is given in Fig. 16.1, and the inability to treat realistically the vdW interaction between two molecules or a molecule and a surface [16.21].

This last topic will be addressed later in this section. (i) We recall that in the Hartree–Fock method the self-interaction is correctly zero since for the same electron the Hartree and the exchange term cancel out. For an extended system of N electrons the right number of pair interactions is given by $N(N-1)/2$ and largely overcomes that of the self-interaction proportional to N. But for an atom or a small molecule the self-interaction correction (SIC) is a relevant one. For this reason, a modified functional to subtract spurious terms has been suggested which corrected very well the ionization energies of atoms [16.19]

$$E^{\mathrm{SIC}} = E^{\mathrm{approx}}[n^{\uparrow}, n^{\downarrow}] - \sum_{\alpha,\sigma}\left(J[n_{\alpha,\sigma}] + E^{\mathrm{approx}}[n_{\alpha,\sigma}, 0]\right)\,. \tag{16.13}$$

The expression E^{approx} is a conveniently approximated classical plus exchange-correlation functional, while J is the classical Coulomb one and hence the sum represents the SIC summed over all orbitals (α, σ). In (16.13) the self-interaction is subtracted for each orbital and creates an effective potential which is orbital dependent in the KS equations. We shall come back to this problem later.

(ii) It is well known that the variational formulation of DFT with the constraint of a fixed number of particles and external potential v_{ext} is expressed via the

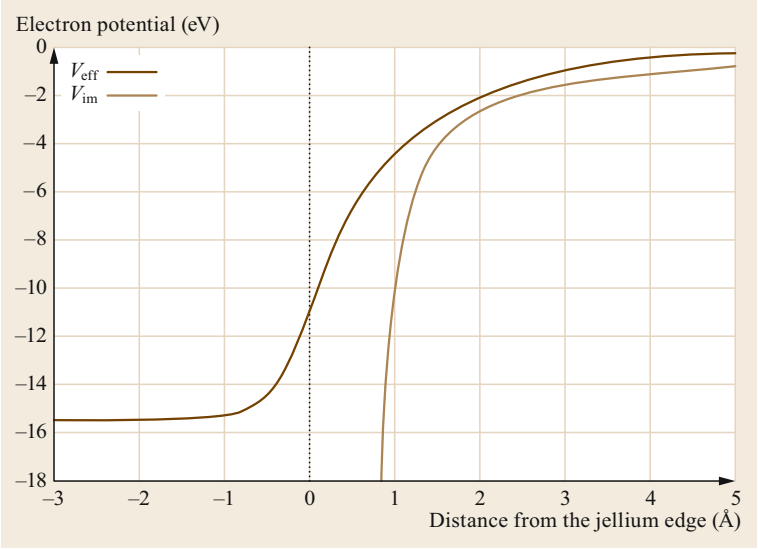

Fig. 16.1 Effective KS LDA potential at the surface of a jellium model having the aluminum density (*dark brown*). This curve shows an erroneous exponential decay towards vacuum following the one (correct) of the charge density. Hence, it misses the interaction of an electron with its image charge (whose potential is depicted by the *light brown line*)

Lagrange multiplier μ by

$$\delta\left(E[n]-\mu\int n(\boldsymbol{r})\mathrm{d}\boldsymbol{r}\right)=0\,, \tag{16.14}$$

which implies

$$\frac{\delta E[n]}{\delta n(\boldsymbol{r})}=\mu\,. \tag{16.15}$$

Following [16.22] (16.15) can be extended to a noninteger number of particles N by considering a mixture of pure states with fractional occupancy as an average. By assuming that $n_N(\boldsymbol{r})$ is the solution of (16.14) with particle number N the corresponding energy is $E_N = E[n_N]$ and

$$\frac{\partial E}{\partial N}=\mu(N)\,. \tag{16.16}$$

So the Lagrange multiplier μ is the exact chemical potential [16.4, 23].

By using fractional occupancy one can get the ground-state energy of the system on varying the particle number N. Such an energy is formed by piecewise segments joining with discontinuous derivatives at integer N and allows one to get the first ionization I and affinity energies A. For an atom with nuclear charge Z [16.4]

$$I=E(Z-1)-E(Z)\,, \tag{16.17}$$

$$A=E(Z)-E(Z+1)\,. \tag{16.18}$$

This behavior is described correctly by the exact DFT. Instead LDA and GGA calculate such fractional energies $E(Z)$ with an unphysical curvature and wrong minima at fractional occupancies. Such incorrect results are associated to the spurious self-interaction of fractional electrons introduced in the system and may be amended by adding a Hubbard-like term U to the LDA energy functional [16.20]: this approach is the so-called LDA+U method. We finally point out that occupancies entering the LDA+U functional are expressed as projections of the KS orbitals on a suitable localized basis set. For this reason and like SIC this functional is orbital dependent and nonlocal.

Orbital-Dependent Functionals

As pointed out in the previous section, orbital-dependent functionals could be a useful implementation to DFT. But we stress that in the KS equation the potential $v_{\text{eff}}(\boldsymbol{r})$ must be local and the same one for all orbitals to satisfy the Hohenberg–Kohn theorem [16.2]. So the orbitals to evaluate the exchange term must be KS orbitals which are generally different from the Hartree–Fock (HF) ones and generate an exchange energy other than the HF one and consequently two different correlation energies (i.e., the total energy, equal in all exact theories, minus the HF one) are determined in the two methods. Note that the KS orbitals depend on the charge density and are obtained solving the Schrödinger equation by a local multiplicative potential, while those computed by orbital-specific potentials are not. This is an important problem [16.10, 24] and much work has been devoted to it outside the scope of this review. We only remind the reader that in the optimized effective potential formalism it has been demonstrated that at first order in the density the energy functionals coincide when the variation between the KS potential and an orbital-dependent one is taken into account [16.10, 24]. Moreover, *Gilbert*'s theorem [16.25] established

that a nonlocal external potential determines uniquely the first-order density matrix, but from a known ground-state wavefunction the external potential v_{ext} is not given in a sole way [16.25].

A very popular class of orbital-dependent functionals are the hybrid ones which incorporate part of the exact exchange term from HF. First *Becke* realized that the adiabatic connection formula [16.26, 27] could be the correct tool to obtain rigorously the exchange correlation energy E_{xc} in the KS formalism and suggested the following expression [16.26]

$$E_{\text{xc}} \simeq \frac{1}{2}E_{\text{x}} + \frac{1}{2}E_{\text{xc}}^{\text{LSDA}} , \tag{16.19}$$

where E_{x} is the exchange energy of the KS orbitals. Such half exchange plus half LSDA contributions was improved into a three-parameter formula

$$E_{\text{xc}}^{\text{hyb}} = E_{\text{xc}}^{\text{LSDA}} + a_0\left(E_{\text{x}} - E_{\text{x}}^{\text{LSDA}}\right) + a_{\text{x}}\Delta E_{\text{x}}^{\text{GGA}} + a_{\text{c}}\Delta E_{\text{c}}^{\text{GGA}} , \tag{16.20}$$

where $\Delta E_{\text{x}}^{\text{GGA}}$ and $\Delta E_{\text{c}}^{\text{GGA}}$ are exchange and correlation gradient corrections to their respective L(S)DA expressions [16.10, 27]. A popular expression for the exchange correlation functional is that by *Becke*, Lee, Yang, and Parr (B3LYP) constituted by several terms with constants referred to thermochemical data. Such terms are: the LDA and HF exchange [16.28]; the gradient exchange correction by *Becke*; the Lee, Yang, Parr correlation [16.29]; the coefficients of local and gradient correlation functionals by Vosko, Wilk, and Nusair [16.30]. With this functional one obtains excellent atomization energies for the G2 set of molecules [16.31], and standard enthalpies of formation, ionization, affinity energies of the G3/99 set [16.32]. For these reasons such a semiempirical functional is widely used especially in the chemical scientific community [16.10]. Several other hybrid functionals have been proposed and we refer the reader to specialized papers [16.33, 34].

The van der Waals Interaction

The vdW or London dispersion interaction is a quantum effect due to the instantaneous zero-point fluctuations of electrons determining multipole moments on a quantum system which may induce other ones in other moieties, which interact with each other. Such a coupling is usually weaker than the electrostatic one but is pervasive in materials science becoming more important for larger molecules, noble gases, and organic molecule–surface systems. The polarizability of atoms, also depending on their environment, is fundamental to estimate the magnitude of the vdW forces [16.35–37]. The vdW coupling is attractive and behaves asymptotically as R^{-6} for two atoms/molecules at distance R, R^{-3} for a molecule–surface system, R^{-2} among two metal surfaces [16.37]. Such an interaction is a many-body phenomenon included in the exact DFT, but is not accounted for correctly by the GGA and hybrid functionals since they neglect instantaneous charge density fluctuations and correlations and solely consider semilocal correlations. The rigorous treatment of the vdW interactions should grasp their nonadditive and nonlocal character but models with pairwise potentials and fitted parameters can achieve good qualitative results in systems stemming from hybrid interfaces to biomolecular compounds [16.35].

In this section, we would like to outline three methods capable of treating the vdW interaction within DFT and which are suited to molecule–surface systems. First, the Rutgers–Chalmers collaborative efforts, say vdW DF and vdW DF2, succeeded in writing a seamless exchange-correlation functional as

$$E_{\text{xc}}^{\text{DF}} = E_{\text{x}}^{\text{GGA}} + E_{\text{c}}^{\text{LDA}} + E_{\text{c}}^{\text{nl}} , \tag{16.21}$$

where $E_{\text{x}}^{\text{GGA}}$ is the exchange energy in the revPBE approach, $E_{\text{c}}^{\text{LDA}}$ the LDA correlation energy, and E_{c}^{nl} the nonlocal correlation [16.38–40]. In this method, one treats the nonlocal functional starting from the adiabatic connection formula for the exact correlation energy, [16.38, 40], and then makes an expansion in the integrand to second order in $\hat{\varepsilon}$, $\hat{\varepsilon}$ being the dielectric constant treated in the plasmon pole approximation. By this approach, results in good agreement with experiments were calculated for the interaction energies of molecular dimers (duplexes) of the S22 complex set. A comparison with quantum chemistry results of vdW DF and vdW DF2 is shown in Fig. 16.2 [16.41]. The vdW DF treatment has also been proven to be accurate enough to study adsorption of organic molecules on solids, see *n*-alkane adsorption on C(0001) deposited on Pt(111) and *n*-butane on Cu(100), Cu(111), Au(111), and Pt(111) [16.40], and to investigate adsorption of organic molecules on solids, e.g., benzene and naphthalene on graphite [16.42].

A semiempirical method was devised by Grimme in which the vdW dispersion interaction between a couple of atoms is assumed to have the well-known asymptotic pairwise form, E_{disp}

$$E_{\text{disp}} = s_6 \sum_{i=1}^{N_{\text{at}}-1} \sum_{j=1}^{N_{\text{at}}} \frac{C_6^{ij}}{R_{ij}^6} f_{\text{damp}}(R_{ij}) , \tag{16.22}$$

and we denote the total functional as

$$E_{\text{DFT-D}} = E_{\text{KS-DFT}} + E_{\text{disp}} . \tag{16.23}$$

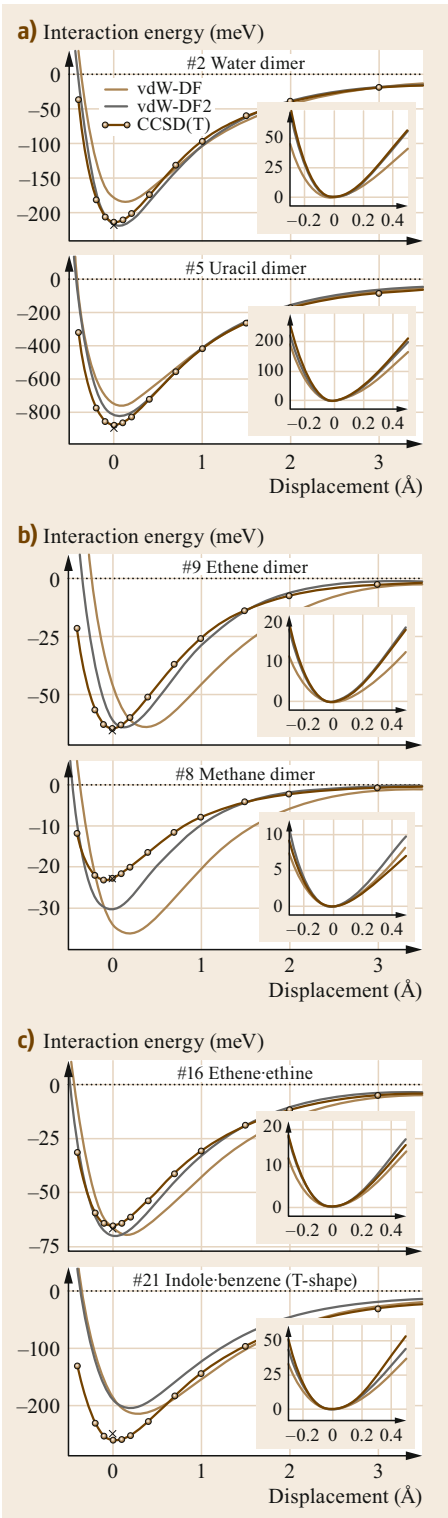

Fig. 16.2a–c Comparison between vdW DF and quantum chemistry (coupled cluster single-double and triple, CCSDT) potential energy curves, for the best and the worst case (among the S22 duplexes) of **(a)** hydrogen-bonded, **(b)** dispersion-dominated, and **(c)** mixed duplexes. *Insets* compare the shapes near the minima upon aligning to a common minimum point (Reprinted figure with permission from [16.41]. Coypright 2010 by the American Physical Society) ►

In (16.22) N_{at} is the number of atoms in the system, C_6^{ij} are the dispersion coefficients, R_{ij} the interatomic distances, s_6 is a scaling factor depending on the used approximate functional in the KS scheme. The damping function $f_{\text{damp}}(R_{ij})$ is equal to 1 for large R and becomes very small for R going to zero. In the D2 scheme the dispersion coefficients are given by a geometric mean of the atomic ones

$$C_6^{ij} = \sqrt{C_6^i C_6^j}\,. \tag{16.24}$$

As the coefficient C_6 is proportional to the ionization potential and the static dipole polarizability, it acts as a predetermined quantity which does not take into account modifications of the physical and chemical environment [16.43]. To consider such effects in the C_6 coefficients *Grimme*'s group later introduced the D3 scheme which takes into account the number of neighbors of each atom [16.44]. The larger the coordination the smaller the coefficient C_6^i of atom i, since the atom is somewhat compressed. In the numerical procedure one starts from a reference set of C_6 coefficients for each pair of atoms depending on their properties (location, hybridization). Interpolating among them by varying the number of neighbors one can obtain continuously changing C_6 values. The accuracy of this approach is confirmed by several results discussed in [16.44] and makes it a very useful tool in adsorption calculations also for organic molecules [16.45].

A different idea to take into account the environmental effects in the calculation of C_6^{ij} is to introduce the effective volume of an atom which is different from the free one. By using a Hirshfeld atomic partitioning weight $w_{\text{A}}(\boldsymbol{r})$ for atom A, the coefficient C_6^{AA} for an atom inside a molecule or a solid is scaled by the squared ratio of its volume in the molecule/solid and in the free atom within a self-consistent procedure. Then an equation for the coefficient between two atoms C_6^{AB} is provided in terms of C_6^{AA}, C_6^{BB} and the static atomic polarizability. Finally, the dispersion interaction is written as a pairwise summation like (16.22) [16.46]. This is often named the Tkachenko–Scheffler PBEvdW

method. Another approach within an atomic pair summation is the so called vdW-surf approach, which is more recent [16.47]. In this treatment many-body effects are taken into account by employing the Lifshitz–Zaremba–Kohn theory [16.48] to write the dispersion coefficient which includes the polarizability of the atoms and the dielectric constant of the solid. For a realistic calculation of adsorption energies one has also to take into account rapid variation of C_6^{AB} near the surface which may be described by a varying effective dimensionless volume, V^i_{eff}, to be determined via the Hirshfeld method. The effective $C^{ii}_{6,\text{eff}}$ coefficient attains the final form $C^{ii}_{6,\text{eff}} = [V^i_{\text{eff}}]^2 C^{ii}_{6,\text{bulk}}$ [16.47]. Accurate estimates of geometries and adsorption energies of perylene-3,4,9,10-tetracarboxylic dianhydride (PTCDA) on noble metals and Xe and benzene on transition metal surfaces have been worked out [16.47, 49]. For an up to date review on vdW interaction for adsorption of organic molecules at metals see [16.50].

Finally we wish to recall that both for a more accurate description of the ground state, and for excited ones, time dependent (TD) DFT and many-body perturbation theory are started being used with more stringent limitations of size [16.51].

16.2.2 Model Geometries

Cluster

The cluster model was introduced for the study of catalysis describing the system, i.e., a nanoparticle or a surface with an adsorbate, by a cluster of atoms plus the admolecule. Among the advantages of such an approach the treatment of localized effects, the convenient usage of computational chemistry methods. Difficulties may arise for the convergence of results with the cluster size and unwanted surface effects since the cluster displays several surfaces not just the one on which the adsorbate is located. This determines a large number of uncoordinated atoms and possibly surface charges to be compensated. The cluster model has proven successful, e.g., in evaluating the optical absorption spectra of adsorbed dyes [16.52] and, with suitable embedding techniques, in relation to the free energy of proton abstraction from water at $TiO_2(110)$ [16.53], but its relevance has historically decreased in favor of the slab approach. For recent reviews on the cluster model see [16.54, 55].

Slab

The slab approach describes the surface plus the adsorbate as a film of a few 2-D periodic layers accounting for the solid plus an adsorbate overlayer usually deposited on one of the two surfaces. On the 2-D periodic surface, for which the surface parallel momentum $\boldsymbol{K}$ is a good quantum number, by using Bloch waves as a linear combination of a set of localized orbitals l at lattice site i, say $\{\varphi_{\alpha i}\}$, the electronic energies can be obtained by the following secular equation for the wavefunction coefficient $c_{\beta j}$ [16.8]

$$\sum_{\beta j} \left(H_{\alpha i,\beta j} - E_{\boldsymbol{K}} S_{\alpha i,\beta j}\right) c_{\beta j} = 0 \,, \tag{16.25}$$

where $H_{\alpha i,\beta j}$ are the matrix elements of the KS Hamiltonian, while $S_{\alpha i,\beta j}$ represent the overlap ones. A way to recover three-dimensional (3-D) periodicity in the direction $\hat{z}$ normal to the surface is to repeat the slab adding a vacuum portion between replicas which has to be wide enough to avoid the spurious interaction [16.8, 56, 57]. A particularly useful basis set for this 3-D supercell geometry is represented by plane waves [16.8, 57]. If solved on a plane wave basis set, the supercell method requires a larger basis than the localized one of the 2-D slab approach but matrix elements of plane waves are easier to compute and converge. Indeed, for plane wave basis sets, the only parameter is the kinetic energy cutoff that can be increased without any bias. Practically, two kinetic energy cutoffs are chosen in representing the wavefunctions ($E_{c,\psi}$) and the charge density ($E_{c,\rho}$, with $E_{c,\rho} \neq E_{c,\psi}$ to properly describe ultrasoft pseudopotentials and ones with nonlocal core corrections). As a matter of fact the surface study within the supercell approach translates into a bulk problem but for a 2-D integration of the Brillouin zone, so the reader can be referred to textbooks on electronic structure calculation for practicalities [16.58].

The Extended Substrate

The models so far discussed provide computationally viable methods to calculate surface properties by systems that are finite in the direction orthogonal to the surface. However, one should not ignore that the thickness of the substrate in a typical experiment is several orders of magnitude larger and hence better represented by a semi-infinite one. For this reason, approaches based on Green's function accounting for the continuous spectrum of the solid were contrived. Such methods more recently formulated within DFT-KS include the Dyson equation [16.59–61], the embedded cluster [16.62–64], and Green's function matching techniques [16.65–68]. Owing to the extraordinary increase in computer performance in the last two decades, capable now of handling routine DFT simulations with several hundred atoms, the above methods have become less popular than the computationally simpler supercell approach to calculate adsorption geometries and energies. Such a technique also allows one to attain a very good description of bond structures, density of states (DOS), and spectroscopies of adsorbates. Only if the

detailed features of narrow peaks in the adsorbate projected density of states (PDOS) are required, e.g., to obtain information on the elastic linewidths of surface states, does the continuum of substrate states in the calculation appear to be beneficial [16.69]. Finally, we report that recently a Green's function approach adapted from quantum transport theory [16.70] has been successfully employed in the calculation of the lifetimes of the lowest unoccupied molecular orbital (LUMO) of organic molecules on rutile $TiO_2(110)$ [16.71] and of the LUMO of core-excited pyridine on Au(111) [16.72], via the inverse of the linewidth of this state. The former result may help in understanding charge transfer in dye-sensitized solar cells, the latter being bidirectional electron transport in femtosecond phenomena. To show the computational suitability of this approach for calculating the PDOS of molecules on solids compared to the finite size models we observe that the resolution of the LUMO PDOS of perylene compounds on a $(TiO_2)_{60}$ cluster is very approximate [16.73]. If one adopts a slab geometry, a 2-D unit cell of rutile $TiO_2(110)$ (3×1), and a required resolution of 2 meV in the PDOS for the fixed surface wavevector, one is forced to use more than 50 trilayers of semiconductor which would make the calculation very cumbersome. Instead using the above-mentioned Green's function method we can determine the PDOS on a molecular orbital of an adsorbate, Φ of energy E_Φ, by the imaginary part of the Green's function. Thus, we can fit the result with a Lorentzian function with full width at half maximum (fwhm) Γ [16.71]

$$P_\Phi \propto \frac{1}{\pi}\frac{\Gamma}{(E-E_\Phi)^2+\Gamma^2}\,. \tag{16.26}$$

16.3 Electronic States at Surfaces

Surface intrinsic electronic states, which decay exponentially both towards vacuum and bulk, may occur when 3-D bulk periodicity is broken by a surface. Traditionally, they are distinguished as *Shockley* [16.74] and *Tamm* [16.75] states. The derivation of such states is extensively described in several books [16.76, 77], which we refer the reader to for a thorough treatment. Here it suffices to outline the main properties.

16.3.1 Bulk Bands from the Surface Viewpoint

Given that bulk electronic states persist in the presence of the surface, their identification in terms of the surface symmetry is a necessary prerequisite for the description of genuine surface electronic states. This calls for obtaining the so-called *surface-projected band structure*. A 3-D wavevector $\boldsymbol{k}$ is decomposed in the components parallel and perpendicular to the surface, $\boldsymbol{k}=\boldsymbol{K}+\boldsymbol{k}_\perp$, so that bulk Block states $\epsilon_n(\boldsymbol{k})$, with n the band index, can be labeled by a joint index $(n,\boldsymbol{k}_\perp)$ and studied as a function of $\boldsymbol{K}$: $\epsilon_{n,\boldsymbol{k}_\perp}(\boldsymbol{K})$. Notice that, at variance of n, $\boldsymbol{k}_\perp$ can span a continuum of values so that energy ranges, rather than discrete values, are allowed for $\epsilon_{n,\boldsymbol{k}_\perp}(\boldsymbol{K})$.

As an example we consider a simple cubic solid within the tight-binding model, having a single band with analytic form $\epsilon(\boldsymbol{k})=-V[\cos(k_x a)+\cos(k_y a)+\cos(k_z a)]$, and derive the (001) surface band structure. Namely, we are interested in the energy ranges accessible at fixed $\boldsymbol{K}=(k_x,k_y)$ as a function of k_z in the interval $[-\pi/a,\pi/a]$. These ranges, evaluated at the high-symmetry points of the surface Brillouin zone, are $[-3V,-V]$ for $\boldsymbol{K}=\bar{\Gamma}$, $[-V,V]$ for $\boldsymbol{K}=\bar{\mathrm{X}}$, and $[V,3V]$ for $\boldsymbol{K}=\bar{\mathrm{M}}$. Overall, the band structure depicted in Fig. 16.3 is obtained.

As a more realistic example we consider the case of a face-centered-cubic metal, Cu(111). In practical ab initio calculation a bulk conventional unit cell with three atoms following the *ABC* stacking of atomic planes along the (111) direction can be constructed, and the bands plotted for different values of $\boldsymbol{k}_\perp$. One obtains a *spaghetti plot* becoming denser with a finer sampling of $\boldsymbol{k}_\perp$, that is reported in Fig. 16.4 as a gray area. Especially interesting is the presence of bulk-forbidden energy regions (surface-projected band gaps) where surface electronic states can exist. Such plots can be compared to the electronic structure in the presence of the surface. To that purpose, in Fig. 16.4 the states of a 30-atom-thick Cu(111) slab are reported, corresponding to 30 possible values of $\boldsymbol{k}_\perp$. There, additional features emerge, in the surface-projected band gaps or overlapping with bulk bands, that originate from the surface modification of the electronic potential and are discussed in the next paragraphs.

16.3.2 Shockley and Tamm States

In a simple picture of Shockley states we consider a periodic solid described by the nearly free electron model. Even if the lattice potential is treated as a small perturbation, its effect is to open up gaps in the band structure in which localized states may exist near the surface. Within the gap no solution is found for real wavevector $\boldsymbol{k}$. Formally, we look for wavefunctions with complex $\boldsymbol{k}$ and imaginary part $k_\mathrm{I}>0$. Assume that the lattice periodic potential is interrupted

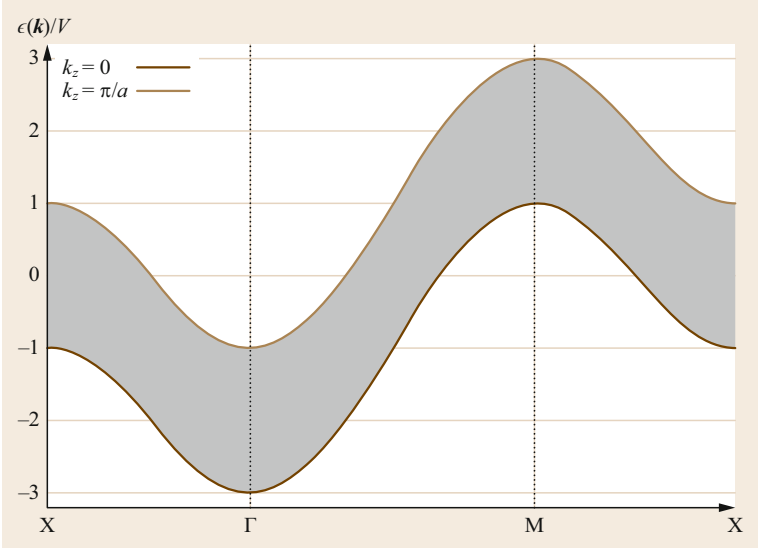

Fig. 16.3 Surface band structure of a tight-binding model of a simple cubic crystal with an s-like band

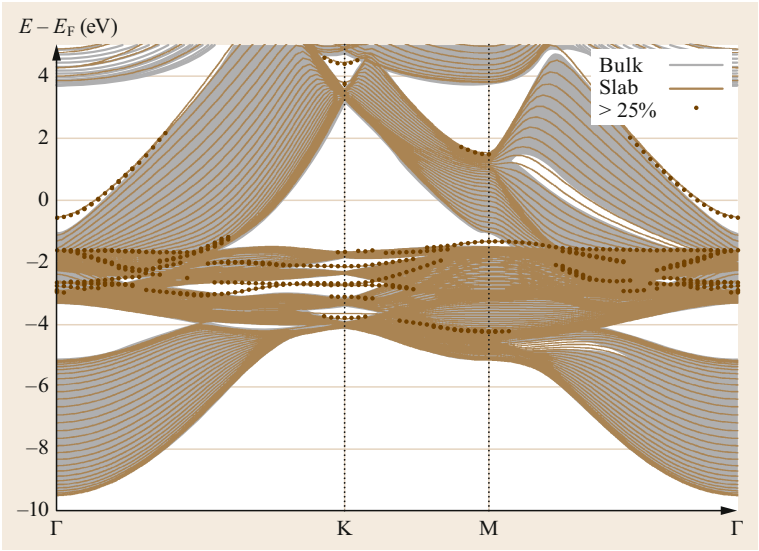

Fig. 16.4 Band structure of a slab consisting of 30 Cu(111) layers, calculated at the KS PBE level of theory in the absence of surface relaxations. *Brown circles* mark states whose weight on the first/last Cu layers is > 25%. The *gray shaded area* is the surface-projected band structure

at $z = z_0$ (z being the direction normal to the surface so that $\boldsymbol{r} \equiv (\boldsymbol{R}, z)$) by a step function of height W_0, a surface is created at $z = z_0$ and vacuum extends in the semi space $-\infty < z < z_0$. The complex wavefunction involves a factor $\exp(-k_I z)$ decreasing exponentially for positive and diverging for negative z_0, respectively. The latter solutions are incorrect for infinite bulk but are acceptable for a semi-infinite solid if they can be matched to decaying waves in vacuum of the form $\psi_{\text{out}} \propto \exp(\kappa z)\exp(\mathrm{i}\boldsymbol{K}\cdot\boldsymbol{R})$, where κ is real and positive and equal to

$$\kappa = \left[2\left(W_0 - E + \frac{K^2}{2}\right)\right]^{1/2} . \tag{16.27}$$

By equating the logarithmic derivatives of the wavefunctions, ψ_{in}, decaying into bulk, with ψ_{out} we obtain κ. Such a state localized at the surface is named the Shockley state.

An alternative way to describe surface states is to make use of the tight-binding method which is useful when the extension of the atomic orbitals in the solid is less than the interatomic spacing and so applicable to the study of narrow bands of transition metals and actinides. In this framework consider the slab model with infinite periodic atomic planes, identical atoms, and one atom per unit cell. In (16.25) one can write

$$c_{\alpha i(p)}(\boldsymbol{K}) = \exp(\mathrm{i}\boldsymbol{K}\cdot\boldsymbol{R}_i)c_{\alpha p}(\boldsymbol{K}) , \tag{16.28}$$

where $\boldsymbol{R}_i$ is a 2-D lattice vector while p labels the atomic plane of atom i. If P is the number of planes one solves a secular equation like (16.25) of dimension $lP \times lP$.

An elegant approach to compute the system bands is to avail oneself of a continued fraction technique within the single-particle Green's function. If we consider a linear chain in the Hückel approximation, i.e., there is a single non-zero resonance integral only for non nearest neighbors, with value β (with $\beta > 0$), while overlap is zero for orbitals in different sites, and modify the atomic orbital, say α_s for the first atom in the chain, two localized orbitals occur, that are named Tamm states. One with energy above that of the band for $\alpha_s > \beta$ and one below it for $\alpha_s < -\beta$. To take into account a simple solid with a chemisorbed atom Grimley also changed the resonance integral between the adatom and its nearest neighbor. According to the parameters one or two localized states may exist, which lying outside the band describe the formation of a localized bond [16.78]. A well-known example of Shockley and Tamm states is provided by the noble metal surfaces. For Cu(111) angle-resolved photoemission spectroscopy (ARPES) and DFT calculations [16.79–81] determined a fairly parabolic (sp) Shockley state, crossing the Fermi level, ε_F, along the $\bar{\Gamma}\bar{M}$ and $\bar{\Gamma}\bar{K}$ paths, with a minimum about 0.5 eV below ε_F. A d-like fairly dispersionless Tamm state was measured and computed just above the projected bulk d band around $\bar{M}$ and at about -2.0 eV below ε_F. See also Fig. 16.4. Along the direction $\bar{\Gamma}\bar{M}$ this state merges into the d band and becomes a surface resonant state, defined as a state which preserves an enhanced amplitude at the surface but propagates into bulk like a Bloch wave [16.82].

16.3.3 Quantum Well States

If we deposit ultrathin layers of atoms or molecules on the surface constituted of a different material one-dimensional (1-D) potential wells could be formed in the $\hat{z}$-direction. Such systems may display localized quantized states typical of a particle in a box and hence are named quantum well (QW) states. Several examples of such states are found in semiconductor heterostructures and metal atoms on metal surfaces. For a review on the latter systems see [16.83].

16.3.4 Image States

Together with Shockley and Tamm surface states a free surface exhibits surface states generated by the image potential (IP). In classical physics if an electron is at distance z from a metal, the electron–surface interaction can be calculated by replacing it with the interaction of an electron of charge e with a positive charge $-e$ (image charge) at position z inside the metal. One obtains

$$V_{\text{image}}^{\text{class}}(z) = -\frac{e^2}{4z} \,. \tag{16.29}$$

In a microscopic quantum treatment in which the metal is described by a semi-infinite jellium the distance z is substituted by that with reference to a plane with coordinate z_{image} which is the center of gravity of the metal polarization charge [16.85]. At large enough distances from the surface one can write

$$V_{\text{image}}(z) = -\frac{e^2}{4(z - z_{\text{image}})} \,. \tag{16.30}$$

The combination of the potential formed by the surface repulsive barrier (that occurs if a gap is present in the surface-projected bulk band structure) and of $V_{\text{image}}(z)$ generates weakly bound states with wavefunctions mainly located outside the surface [16.86]. They constitute a Rydberg-like series with energies E_n

$$E_n = \frac{-0.85}{(n+a)^2} \text{ eV} \,. \tag{16.31}$$

The constant a depends on the surface, the width of the energy gap, and its position with respect to vacuum. Inverse (IPES) and two-photon (2PP) photoemission spectroscopy are the experimental techniques of choice to investigate IP states (IPS). Finally, we remark on a new effect for IPS due to the spin–orbit Rashba effect [16.87]. Measurements performed with 2PP and circular dichroism coupled to DFT calculations with the phenomenological addition of the IP and based on the Green function embedding approach of *Ishida* [16.67] have shown that the spin–orbit interaction splits up the IPS with $n = 1$ on Au(001). Namely the energy splitting is zero at $\boldsymbol{K} = 0$ and increases along the $\bar{\Gamma}\bar{X}$ direction being larger than 20 meV for $\boldsymbol{K} = 0.25$ Å^{-1} [16.88].

16.3.5 Lifetimes of Surface States

The study of lifetimes of excited electron (or holes below the Fermi level) states is very important in physics. Their knowledge allows one to ascertain the duration and the extent of the influence of an excitation and they are strictly related to the dynamics of charge and energy transfer and of screening including the effect of surface vibrations. For a free metal surface, even when the elastic lifetime is infinite, other effects are present, namely the electron–electron interaction (inelastic lifetime) and the phonon one (vibrational lifetime). The former phenomenon leads to lower energy surface or bulk electrons together with the creation of an electron–hole pair. A nice schematic picture of such processes

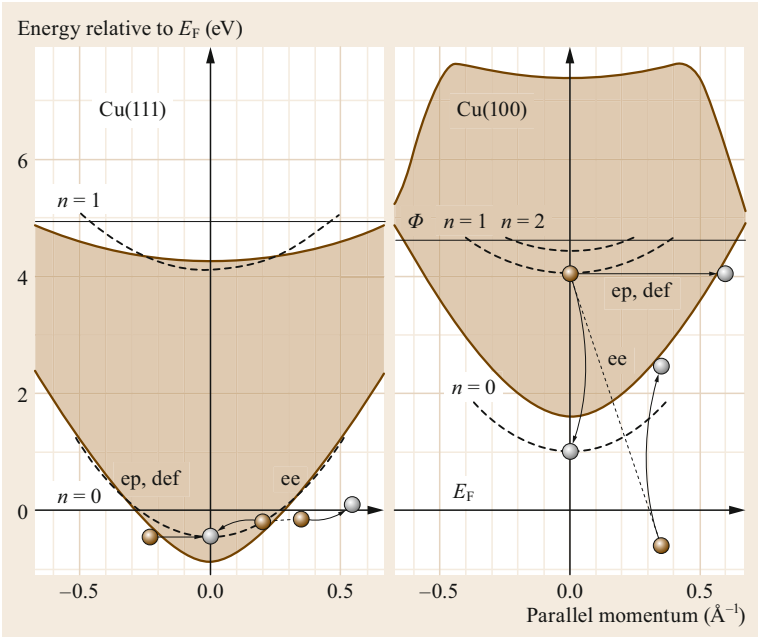

Fig. 16.5 Schematic projected bulk band structure (*shaded areas*) for the Cu(111) and Cu(100) surfaces with intrinsic surface-state bands ($n = 0$) and image-potential bands ($n \geq 1$). *Arrows* indicate possible electron–electron (ee), electron–phonon (ep), and defect (def) scattering processes (Reprinted with permission from [16.84] with permission from Elsevier)

for the Shockley state on Cu(111) and Cu(100) and IP bands is provided by [16.84, Fig. 1] which is repeated here (Fig. 16.5). While ARPES is limited to measuring lifetimes of hole states, scanning tunneling spectroscopy (STS) can explore those of states above and below the Fermi level. The interaction of an electron with the metal bands is described by the GW method using the random-phase approximation (RPA) or by time-dependent density functional theory (TDDFT) [16.89]. Results for the lifetimes, τ, of the (111) face of noble metals worked out by theory including the phonon contribution and STS experiments were found in excellent agreement. For Cu(111) at the band edge of the Shockley state both theory and experiments predict $\tau \approx 21$ meV [16.90].

16.3.6 Recent Results for Organic Adsorbates

Over the last 40 years several investigations have dealt with the modification of surface states by adsorption [16.91–93]. In this review we concentrate on very recent results regarding the effects of adsorption of organic molecules on surface states. To obtain a thorough understanding of the properties of the interface between an organic semiconductor and a metal, research has addressed by 2PP experiments the electronic states of hexa-cata-hexabenzocoronene (HBC), a promising photovoltaic material, on Cu(111) [16.94]. It is shown by increasing the coverage Θ from 0 to 2 ML (monolayers) that the Shockley state is quenched and the work function Φ of the HBC/Cu system decreases due to a combination of push back and electron transfer. New states appear at larger HBC coverage and are interpreted as IPS modified by the molecular layer on the metal. An interesting behavior of the Shockley state is found for NTCDA (1,4,5,8-naphthalene tetracarboxylic dianhydride) on Au(111) [16.95]. It is known that by deposition of a low amount of alkali atoms (Na) on noble metals an increase of the binding energy of the Shockley band occurs. The Shockley state is also sensitive to the presence of an organic film which displaces it upwards. In [16.95] the two effects are combined. First one covers Au(111) with a small amount of Na shifting down the Shockley state and then one deposits a monolayer of NTCDA: the Shockley state modifies its energy which appears very similar to that on clean Au(111) and suggests a very weak interaction between NTCDA and the metal. So this work outlines the importance of the behavior of Shockley states and the effect of alkali adatoms in controlling organic molecule adsorption and charge transfer. Among a variety of applications, scanning tunneling microscopy (STM) has been demonstrated to be able to induce nonlocal manipulations leading to molecular desorption [16.96]. The experiment considered chlorobenzene molecules on Si(111)-(7 × 7) and showed that charge injection from an STM tip with positive voltage V can cause molecular desorption once V reaches the desorption threshold. The effect decreases exponentially ($\simeq 100$ Å) from the location of the injected charge. From the electronic

point of view charge is transferred from the STM tip to a new surface state predominantly located at faulted rest and unfaulted rest atoms which is the threshold surface state for nonlocal desorption and hints at new ways of long-range surface manipulation via surface states [16.97].

16.4 Adsorption of Simple Atoms and Molecules

Adsorption is a phenomenon by which the surface of a solid links molecules from a gas or a liquid. It is generally a spontaneous one which is accompanied by a decrease of the free energy of the system and of entropy. The process is exothermic and the released heat is called heat of adsorption. Chemical adsorption or chemisorption requires a higher production of heat and often needs to overcome a barrier of activation energy. Physical adsorption or physisorption always occurs and asks for a lower energy of adsorption. Chemisorption does not always occur, but couples to physisorption when the molecules are closer to the surface and chemical bonds are formed.

The variety of adsorption phenomena, the possibility of covering only a small fraction of the solid surface (in percentage), a full layer or overlayer, from few to several layers, the enormous amount of different adsorbates from the simplest, hydrogen, to molecules with hundreds of atoms opens up an incredible number of new effects. This somewhat limits our treatment to prototypes of the main classes of adsorption.

16.4.1 Chemisorption of Simple Atoms and Molecules

The modern age of chemisorption started with *Grimley* [16.98] and later *Grimley* [16.99] and *Newns* [16.100] who independently adapted the Anderson model for magnetic impurities to chemisorption. They pointed out that the energy of an orbital of a chemisorbed atom is equal to $\varepsilon_{A\pm\sigma} = E_A + J_A n_{A\mp\sigma}$, where J_A is the Coulomb repulsion. So the effective energy of an orbital depends on its occupancy by an electron of opposite spin. Contrarily the occupancy of an orbital $n_{A\pm\sigma}$ depends on the distance of an orbital of opposite spin $\varepsilon_{A\mp\sigma}$ from the Fermi level. This indeed shows that chemisorption cannot be treated in a one-electron picture. We have seen how DFT progressed to supply a realistic tool to calculate the energetic and often with the help of experimental data the exact position of adsorbed molecules also with several atoms. Following Grimley and Newns, *Hammer* and *Norskov* [16.101] provided simple models to interpret the results by DFT which well account for the main trends of chemisorption and in which a fundamental role is played by the local density of states (LDOS). Take oxygen chemisorption on metals; we can imagine that this process occurs in two steps. First, the adsorbate 2p state interacts with the wide sp metal band and causes a single resonance. Its interaction with the narrower d band (strong coupling in the Grimely–Newns' model) splits it into two states: one bonding and the other one antibonding, below and above the d band, respectively. The adsorption energy can be written as $E_{ads} = E_0 + E_{hybr}$. Although the larger energy is the sp contribution, this is practically constant for all metals while the second term allows one to distinguish between different values of adsorption energy. In the case of Cu, Ag, and Au the antibonding band is completely filled and repulsive, while if we move on the left of the periodic table the antibonding state becomes depopulated as the d band shifts upwards and chemisorption becomes increasingly stronger: $\simeq -0.6$ eV (Ag); $\simeq -0.9$ eV (Pd); $\simeq -2.8$ eV (Ru); $\simeq -3.5$ eV (Tc); $\simeq -4.00$ eV (Mo); -4.2 eV (Nb), with the d band center roughly increasing from -4.0 to 2.0 eV, correspondingly.

To examine the molecular adsorption consider as a benchmark system the adsorption of CO. Experimental and theoretical studies suggest that electron donation from the CO 5σ filled orbital to the sp and d bands and backdonation from these bands to the 5π empty orbital is mainly the origin of this chemisorption phenomenon. The interaction with the sp band of the metals determines a downshift and broadening of 5σ and $2\pi^*$ orbitals, and with the d band, two bonding and two antibonding states below and above the pristine states. In conclusion, the d band contribution to the adsorption energy E_{d-ads} can be expressed in the form of a hybridization gain for the 5σ orbital and an orthogonalization cost for the 2π one. Analogously to oxygen if we move from noble metals to the right of the periodic table we span from dissociated CO (from Ag to Rh) to about -3.0 eV CO chemisorption for Nd.

Another fundamental question in chemisorption regards bond-making and breaking. For H dissociation bonding and antibonding states similar to atomic adsorption display a bond which is a little stretched. In this case, bonding and antibonding states similarly to atomic adsorption occur, while for stretched bonds the electronic structure of the molecule is alike that of the final state.

Very recently a sophisticated calculation was provided by *Schimka* et al., who abandoned the most recent functionals for alternative methods based on the many-

electron approach with the RPA [16.51]. In fact even for a small molecules like CO on Pt(111) the usual semilocal functionals tend to overestimate chemisorption energy and not provide the correct monoxide site. When exact Hartree–Fock exchange is combined with RPA we observe that the adsorption energy decreases which is due to interaction of the two frontier orbitals of CO, the 5σ and the $2\pi^*$ with the metal states. The 5σ orbitals are partially filled above ε_F determining a strong interaction in the atop site. The RPA also restores the correct order in energy for the most critical cases lowering the binding energy by 350−550 meV: −0.42 eV (adsorbed on Cu(111) in the top site) < −0.32 eV (Cu, face-centered cubic site, fcc); −1.31 eV (Pt top) < −1.23 eV (Pt fcc); and −1.43 eV (Rh top) < −1.28 eV (Rh, hexagonal close packed, hcp). Another example is benzene on ferromagnetic Ni(111). In the RPA the experimentally observed hollow site is favored while the total adsorption energy is instead lowered by RPA (−0.95 meV) compared to PBE (−0.65 meV) owing to a strong vdW bond.

Alkali Atoms on Metals

Among atomic adsorbates, alkali metal adsorbed on metal surfaces have been the subject of intense investigations in order to clarify fundamental issues in adsorption phenomena, as well as for their technological relevance as workfunction modifiers and surface dopants. Early description of this prototypical system dates to about 80 years ago with the Langmuir–Gurney model [16.102, 103]. The knowledge of this apparently simple system has remarkably improved during the last three decades showing the occurrence of various nontrivial phenomena overcoming the Langmuir–Gurney model, as reviewed by several authors in the past [16.104, 105] and more recently [16.106].

One example of peculiar phenomena lies in the correlated *vertical diffusion* motion observed for Na atoms on copper. Measurements of surface diffusion based on helium atom scattering for Na/Cu(001) have proven to be unable to explain an observed coverage dependence of the 2-D motion [16.107]. By high-resolution ^{3}He spin-echo, *Alexandrowicz* et al., [16.108] could demonstrate that experimental findings are accurately reproduced upon introducing an explicit dependence of the Na coordinate on the local adsorbate concentration, that is a time-dependent quantity at finite temperature, hence leading to a confined motion also along the surface normal, occurring on the same timescale as the diffusive motion. However, a coverage dependence of the Na–surface bond length is not expected [16.105]. DFT simulations [16.109] could eventually clarify this puzzle demonstrating that, while the Na−Cu bond is minimally affected by adsorbate concentration, the extent of the electronic density towards vacuum is modified considerably because of the dipole electric field induced by the other adsorbates. As the adsorbate distribution is inhomogeneous and time-dependent, this translates into a time evolution of the turning point for the scattered probe atoms. Related (yet static) electronic effects occur in emphasizing the corrugation of quasi-1-D structures observed by helium atom scattering (HAS) for Li and Na on Cu(001) as coverage approaches saturation, where changes in the atomic height are irrelevant. We will return to this case when discussing adsorption dipoles (Sect. 16.5.2).

Alkali atoms are also prototypical effects for the study of surface diffusion phenomena. Considering again Na on copper, the effects of step on surface diffusion have been studied by adopting a vicinal Cu(115) surface [16.110]. Motion is anisotropic and occurs prevalently parallel to the step edges, following intuition. Additionally, Na−Na collective effects described above are also anisotropic, pointing to a screened interaction for adsorbates on different terraces.

16.4.2 Physisorption of Noble Gases on Metals

Adsorption of noble gases is for several reasons an important topic in surface science. Already about 50 years ago *Scoles* et al. [16.111] and *Boato* et al. [16.112] performed the first experiments of diffraction of light noble atoms on solid surfaces. This technique has been extensively applied by *Toennies* et al. [16.113] and other scientists to obtain a detailed dispersion relationship of phonons on several surfaces. More recently, *Allison* et al. have employed beams of the fermion isotope ^{3}He to check the diffusion of alkali adatoms (Chap. 15) [16.114]. Ar, Kr, and Xe have been used for microscopic tribological models for perspective technological applications.

Being atoms with closed-shell systems, noble gases interact with a surface mainly with vdW or London dispersion forces by instantaneous dipoles. For this reason their bond to the surface is a physisorption one where we have already observed that DFT with semilocal corrections is not sufficient. The weakness of the interaction between the atom and the surface introduces the main complication since the adsorption energy is strongly dependent on correlation so that a local (semilocal) qualitative estimate, sufficient at shorter distances for a chemical bond, is insufficient to yield vdW energies, in which the polarizability of the probe and the long-wavelength dielectric constant are missing. Still LDA/GGA DFT treatments have supplied important information. A general property, validated by GGA-DFT, independent of the functional, is that the

equilibrium distance from the surface increases from Xe to Ar and it correlates with the adsorption energy that varies from a few meV for He to −320/−360 meV for the heaviest one, Xe. The results of *Da Silva* and *Stampfl* [16.115], confirmed by low-energy electron diffraction (LEED) measurements, found that Xe adatoms preferentially bind to low-coordination top sites instead of the highly coordinated hollow sites on metals because when charges of the atom and of the metal begin to overlap, Pauli repulsion is present and electrons are transferred more easily from atoms adsorbed on top sites than on hollow sites getting the atom closer on top. Nonlocal vdW DF functionals showed later that the hollow sites for Xe are maxima and the atop site a true minimum [16.51]. This phenomenon holds for close-packed surfaces, i.e., Pt(111), Pd(111), Cu(111) for Xe. However, a potential curve of a noble gas atom is erroneous when calculated by GGA-DFT. It is clear that a many-body seamless solution, as a function of distance from the surface, would be desirable for correct results.

A more subtle effect of He interacting with transition metal surfaces and the Cu(111) one, is the so-called anticorrugating effect. In fact elastic scattering measurements of He performed by *Rieder* et al. [16.116] on Rh(110) and Ni(110) showed intensities in the measured diffraction scans that can be reproduced by models in full disagreement with intuition: In order to explain their data, these authors had to assume that the corrugation profile seen by He is off phase with respect to the surface lattice atom positions, and that the classical turning point of the interaction potential is farther away at the short bridge position than at the top one, for a fixed kinetic energy of the impinging atom. GGA-DFT calculations by *Scheffler*'s group [16.117], which produce reasonable results at this atom–surface distance since the He surface potential is in its repulsive part, show that the property of s for He and p for Ne wavefunction facing the d metal ones at top and bridge position determine the anticorrugating effect. In a later paper on Cu(111), which explains very satisfactorily the anomalies of phonon spectra, anticorrugation was accounted for in terms of the relative kinetic energy ΔK of the electrons between top and bridge sites for the same impinging He kinetic energy. In other words, $\Delta K(\text{bridge}) > \Delta K(\text{top})$ and overcomes the electrostatic difference $\Delta U(\text{top}) > \Delta U(\text{bridge})$, with the exchange correlation term being negligible. Conversely, for a simple metal He/Al(111) the standard corrugation is observed and $\Delta K(\text{bridge}) < \Delta K(\text{top})$ [16.118].

Surface Properties Studied by Adsorption Phenomena

While the emphasis of adsorption studies may be more frequently on adsorbates, absorption and diffusion phenomena are also a tool to investigate surface properties. One obvious example is given by atom-scattering experiments. We would also like to mention a less direct example, where the observed atomic diffusion at a surface can be linked to the substrate approaching a structural transition [16.119]. Bulk cobalt is characterized by a hexagonal close-packed structure at ambient temperature and pressure, but thin Co films can be stabilized epitaxially on top of Fe(001) which acts as a template with square symmetry. Hence, a metastable body-centered-tetragonal structure is obtained up to about ten Co layers (after which the film transforms into hcp crystallites). Despite the fact that the atomistic structure of the surface remains unaltered, the diffusivity of Co adatoms has been shown to depend dramatically on film thickness: the process gradually evolves from an activated one, with a barrier of about half an eV on clean Fe(001), to being practically barrierless already at a thickness of 5 ML. Experimentally, this was determined by a statistical analysis of Co island size distributions, from which the diffusion coefficient was extracted, as a function of thickness and temperature. Density functional theory simulations then identified the transition state in the diffusion mechanism as a Co adatom occupying the bridge site, and that such site is stabilized by deformations in the substrate that increase in magnitude with film thickness. These deformations locally recover a structure in closer resemblance to the hexagonal one, so their energy cost drops to zero as the film approaches the structural transition.

16.5 Adsorption of Organic Molecules

The flexibility offered by natural and synthetic organic chemistry leads to a great deal of possible options in the choice of organic adsorbates. Example of classes of molecules having attracted significant interest in the literature for fundamental aspects and applications are self-assembled monolayers (SAMs), porphyrins, and polycyclic aromatic hydrocarbons (PAHs). Some examples are depicted in Fig. 16.6. Although the definition strictly applies to a wide class of molecules, with the SAM acronym one customarily denotes a specific class of self-assembled adsorbates where molecules are composed of a chemisorbed head group, a tail, and a functional termination. A prototypical case consists of *n*-alkanethiols where the anchoring group is a sulfur

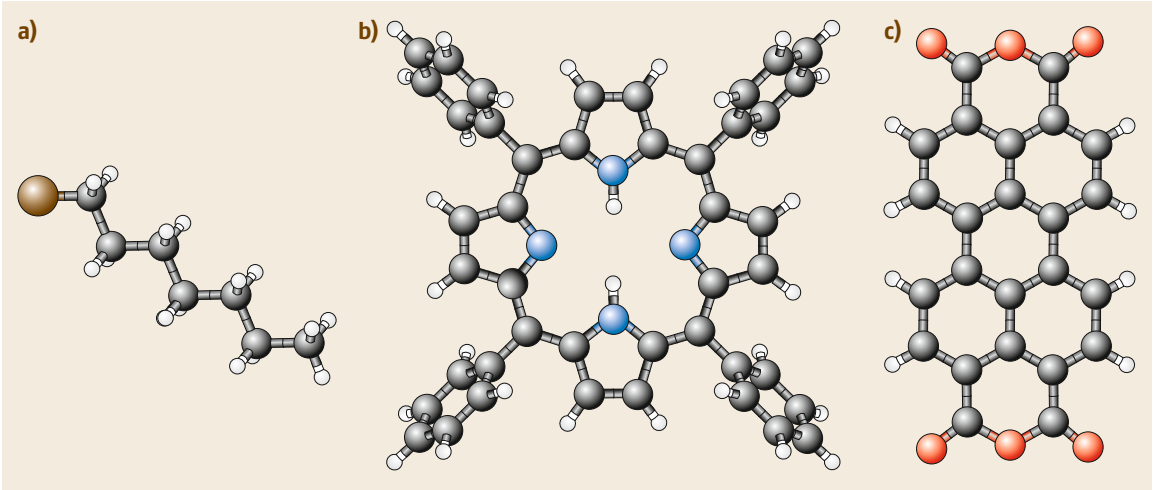

Fig. 16.6a–c Ball-stick model of example molecules for **(a)** SAM, showing an alkanethiol, **(b)** a porphyrin, here tetraphenylporphyrin, **(c)** a PAH, here PTCDA. *Gray*, *red*, *blue*, *smaller white*, and *larger brown balls* represent C, O, N, H, and S atoms, respectively

atom and the tail a $(-CH_2-)_n$ chain, see Fig. 16.6a, but many more configurations are possible [16.120]. These molecules find various applications in surface coatings. Porphyrins are molecules with enormous significance in biology and interesting catalytic properties. The case of tetraphenylporphyrin is shown in Fig. 16.6b. They can incorporate different metal centers which can be adjusted for tailored applications, and their properties and functionalities are characteristically influenced by interfacial interactions [16.121, 122].

Polycyclic aromatic hydrocarbons have attracted significant interest for organic electronic devices [16.123]. In the following, we will focus on this latter subset to select a few test cases for additional discussion. A popular molecule in surface science studies is PTCDA, which is shown in Fig. 16.6c.

16.5.1 Aromatic Molecules on Semiconductors and Metals: Configurations, Electronic and Spectroscopic Properties, π and σ Bands

Pentacene on TiO_2

The performance of an electronic device depends on a diversity of factors, including the structural, electronic, and spectroscopic properties of the very first layer of molecules at the hybrid interfaces within the device. The arrangement of the first molecules may steer the crystalline ordered growth of an organic active layer, [16.124] which is especially important since high quality of the organic crystal is required [16.125]. Also, the mobility within organic materials, also when high molecular ordering can be achieved, is optimal only for the directions maximizing intermolecular couplings [16.126]. Additionally, the ultimate transfer at a contact depends on the overlap of the molecular wavefunctions with the substrate ones.

An especially interesting and prototypical case that we take here as an example is constituted by pentacene ($C_{22}H_{14}$). This aromatic hydrocarbon is characterized by very high hole and electron mobility [16.127, 128] that exceeds that of amorphous silicon. The adsorption of pentacene on different substrates has therefore been widely studied both experimentally and theoretically. We select a few examples here to describe how different levels of interaction influence the growth.

The anisotropy of a weakly interacting substrate has proven effective to gently influence the molecular adsorbates, without affecting too strongly their electronic and spectroscopic properties. One such example is the case of pentacene on the rutile $TiO_2(110)$ surface. This surface is characterized by the formation of rows of protruding O atoms along the [001] crystal azimuth; rows are spaced ≈ 6.5 Å along $[1\bar{1}0]$ and atoms protrude by ≈ 1 Å with respect to surface Ti [16.129, 130], forming an ideal template to accommodate planar molecules as found for pentacene (other examples are perylene and its derivatives [16.131]). Submonolayer phases of pentacene on $TiO_2(110)$ have been studied by STM, HAS, and near-edge x-ray absorption fine structure (NEXAFS). These experiments have demonstrated the formation of a very ordered phase [16.132] with molecules adsorbed in a nearly planar geometry (tilt angle $\approx 25°$) and aligning along

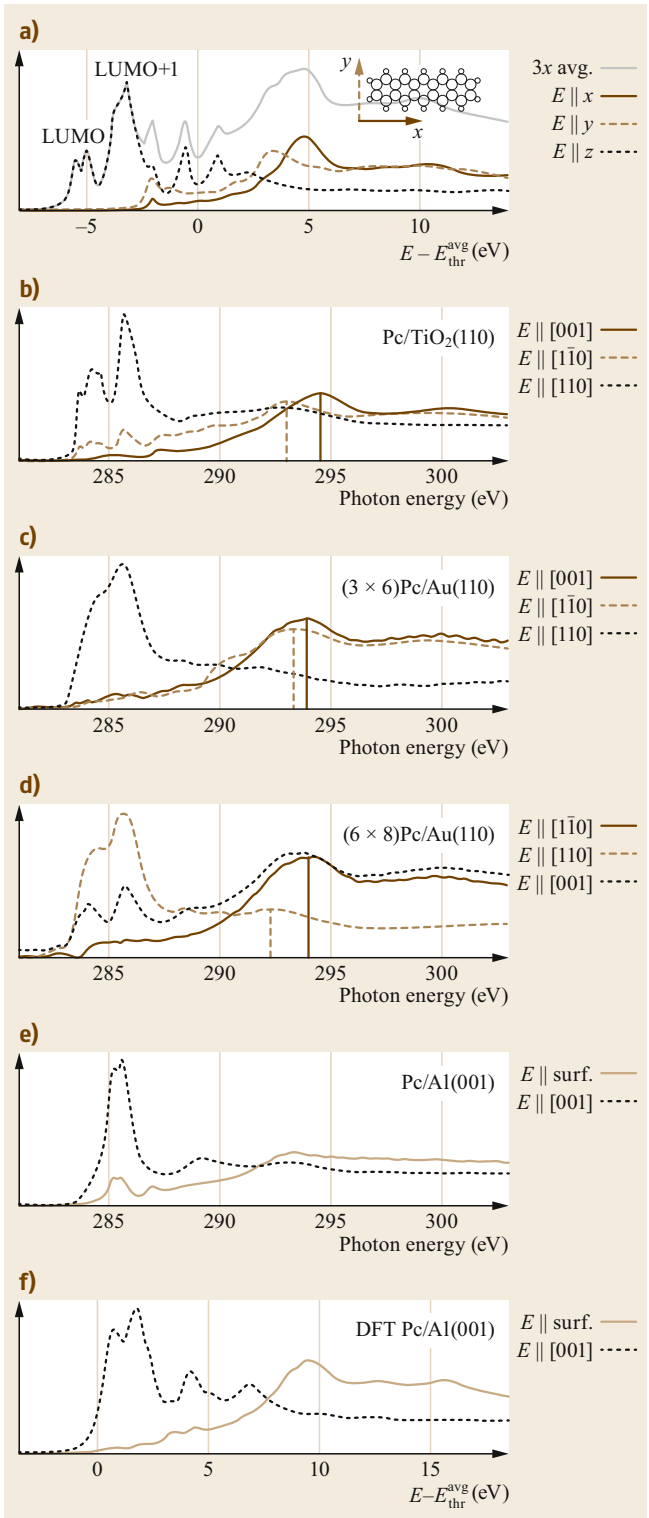

Fig. 16.7a–f NEXAFS spectrum of pentacene: **(a)** theoretical result for the gas phase [16.134]; **(b)** measured on TiO_2 [16.132]; **(c,d)** measured on Au(110) [16.135]; **(e)** measured and **(f)** computed for pentacene on Al(001) [16.136] ►

the $[1\bar{1}0]$ crystal azimuth with intermolecular distance dictated by coverage, and approaching that of the organic crystal at monolayer completion. In the other surface azimuth ([001]) intermolecular π–π attraction stabilizes stripes of pentacene. The NEXAFS spectrum of these molecules is reported in Fig. 16.7a for the gas phase (calculations shown as a reference) and in Fig. 16.7b for pentacene/TiO_2. It exhibits several characteristics testifying that the interaction with the substrate, although sufficiently strong as to drive the ordered phase, has only a minor influence on the molecular orbitals: molecular features are clearly resolved, not showing a hybridization-induced broadening present in other cases (see the other panels, discussed below); the spectra at monolayer coverage already resemble those of a thin overlayer and, once spherically averaged, gas-phase ones [16.133]. The ordered phase allows unprecedented analysis of the symmetry of the molecular orbitals that is only possible for stabilized molecules, and that is fully rationalized by theoretical simulations of the spectra based on the transition-potential approach [16.134] (Fig. 16.7a). One can identify the first unoccupied resonances as due to transitions to final bound states (LUMO, LUMO+1 and higher states) having π symmetry. For final unbound states $\approx 5\,\mathrm{eV}$ higher energy than that threshold, transitions to σ states emerge. Given the asymmetry of pentacene and the uneven length of its C–C bonds, the energy of σ states differ according to the dominant contribution of in-plane orbitals along the long or short molecular axis. Such an effect identifies an azimuthal dichroism in the spectra that can be used to resolve in-plane molecular orientation by NEXAFS, as was done to validate a model of perylene ($C_{20}H_{12}$) adsorption on the same surface, with the molecular axis along $[1\bar{1}0]$ where a rounded appearance of the molecules in the STM images could not be conclusive [16.131].

Pentacene on Silicon

The case of pentacene on silicon surfaces exhibits a completely different behavior. On this semiconductor, the molecule is found to strongly chemisorb. Several studies have highlighted possible configurations on Si(001)-(2 × 1). A work by the *Yates* group [16.137], combining STM with slab simulations at the PW91 level, revisited previous assignments and pointed out

the formation of six to eight Si−C covalent chemical bonds, and an adsorption energy of up to 128 kcal/mol. This is realized for a nearly flat molecule bridging between adjacent rows of Si dimers. Other configurations include strongly distorted pentacene with sp^3 hybridized C atoms. Consequently, a NEXAFS spectrum of pentacene on Si(001)-(2×1) reveals lost conjugation and missing contributions by peripheral C atoms at the otherwise expected $1s \rightarrow$ LUMO transition energy [16.138]. Chemisorption also occurs on Si(111)-(7×7). This strong interaction of pentacene with a silicon surface can be reduced by passivating the substrate with H [16.139] or by organic adsorbate functionalization [16.140].

Pentacene on Noble Metals

Adsorption of pentacene on metal surfaces also raised significant interest because of the occurrence of organic/inorganic interfaces at potential contacts. Among the noble metal surfaces, Au(111) is supposedly the one exhibiting the smallest interaction with the adsorbate. There, pentacene adsorbs in a mostly planar configuration. However, the interaction is still appreciable in inducing a weak bending of the molecule [16.141]. On Au(110) [16.135] different structures are observed: a (3×6) one, Fig. 16.7c, with planar molecules having their long axis along [001], exhibiting a significant broadening of the LUMO peaks and significantly smaller azimuthal dichroism than the one of free molecules. At higher coverage, a (6×8) structure forms where planar molecules coexist with ones having the long axis along the surface normal. The spectra of the two intermixed phases can be distinguished thanks to a different dependence on the experimental geometry in Fig. 16.7d. For example, π transitions are excited with $E \parallel [110]$ for flat-lying molecules and $E \parallel [001]$ for standing ones. Their comparison at about 285 eV in Fig. 16.7d testifies the dependence on adsorption angle of the electronic coupling of the π system with the substrate orbitals, with standing molecules leading to better resolved features and larger azimuthal dichroism. By increasing the interaction strength, silver and copper surfaces also present mostly planar molecules, with upwards bending of the molecule along its short axis. The mixing of the molecular and substrate electronic states becomes more relevant, featuring the filling of the lowest unoccupied molecular orbital on Ag(111) [16.142], Ag(110) [16.143], Cu(111) [16.144], Cu(001) [16.145], and Cu(110) [16.146]. Consequences of the LUMO filling are the possibility to detect such orbitals in photoemission experiments normally accessing the molecular states up to the highest occupied molecular orbital (HOMO) [16.143], and their reduced intensity or disappearance in NEXAFS.

Pentacene on Aluminum

As another metal of interest for device research, aluminum presents a stronger interaction that leads to a peculiar scenario. The adsorption of pentacene on Al(001) was studied by a combination of experimental and theoretical techniques [16.136]. It was found by reflection high-energy electron diffraction (RHEED) and STM that adsorption induces a reconstruction on the substrate, which appears as a rippling of Al rows along [100] having a corrugation of 30 pm in the STM images taken in exposed surface areas. The periodicity of these rows across $[1\bar{1}0]$ is 1.6 nm, the same as molecular stripes also identified in STM that extend along [100] with molecules having the long axis along [110]. From the theoretical point of view, the adsorption is somewhat intermediate between chemisorption and physisorption. If a DFT description with a semilocal functional is used, molecules are barely bound with GGA, whereas an adsorption energy of ≈ 2 eV is obtained with LDA showing an upward curvature (similarly to adsorption on Cu) [16.147]. The inclusion of vdW correction, there at the Grimme level, has a major impact on the GGA results. Of the possible adsorption sites compatible with the experimental orientation, all of them but one still present a mostly flat molecule with adsorption energy up to 1.50 eV. The other one, which is centered on a bridge site with the central C atoms on top of two Al atoms, is the most stable with an energy of 2.20 eV and features a V-shaped molecule. This configuration is depicted in Fig. 16.8 and is characterized by a V-angle at the center of 155° and a difference in C heights of 1.35 Å, with a deformation that costs, in the gas phase, an energy of 1.35 eV. This structure is stabilized by the optimal matching of the central C atoms with two Al ones, with a C−Al distance as small as 2.20 Å. This is only made possible, however, by the inclusion of dispersion forces: these allow a shorter distance between the aromatic rings and the surface, eventually allowing for the direct C−Al anchoring. Spectroscopic and microscopic properties simulated for molecules adsorbed in the V-shape are in very good agreement with the observations and corroborate this result. In particular, NEXAFS spectra reported in Fig. 16.7e (experiments) show that the molecules lie mostly face-on, with an effective tilt angle of the aromatic planes of $(28\pm5)°$ with respect to the surface, which takes into account molecular deformation and defect sites. Given the hybridization with metal states, a broadening of the molecular features could be expected similarly to the case of pentacene on Au(110). Differently from the gas phase, the signature of transitions to π^* orbitals is much narrower both in measured and computed (Fig. 16.7f) spectra, suggesting also in this case that filling of the LUMO takes place hence

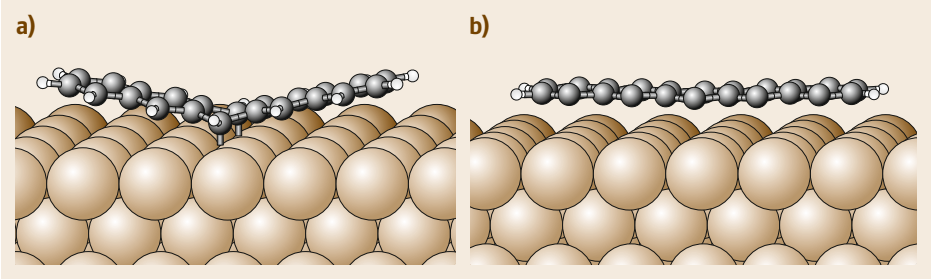

Fig. 16.8a,b Adsorption configuration of pentacene on Al(001) [16.136]. **(a)** Most-stable V-shaped configuration in the bridge site. **(b)** Flat-lying on a top site. *Balls* of *increasing size* denote H, C, and Al atoms

removing it from the unoccupied manifold of possible final states.

Band Symmetry and Spectroscopy

An effective tool for a rational analysis of spectra of adsorbed molecules is the identification of the molecular energy levels in the DOS and surface band structure of the system; Fig. 16.4 shows an example of a clean substrate. In this respect, many ab initio codes implement the possibility to project the surface bands onto the molecular eigenstates, typically computed by a separate calculation for the free molecule. As a result, one can visualize *fat bands*, where the color or size of the symbols in the *spaghetti plot* is proportional to the molecular contribution. Alternatively, a ***K***-resolved DOS (projected onto molecular orbitals) can be used and possibly superimposed as a color map on the usual surface band plot. The two approaches are conceptually equivalent and while the former may be more convenient to represent regions where only few bands appear, the latter is advantageous for high density of states and is the natural framework to describe the continuous spectrum of an extended substrate. The ***K***-resolved DOS is reported in Fig. 16.9 for thymine molecules forming rows of π-stacked molecules deposited on Si(001) [16.148]. In this case, the dispersion of HOMO- and LUMO-derived states (see insets) can be identified, allowing the distinction of molecular features and molecule-induced substrate ones in optical reflectance spectra.

16.5.2 Adsorption-Induced Charge Rearrangements/Induced Dipoles/Induced Spin Distributions

Induced Charge Rearrangements

Out of the various adsorption-induced phenomena, such as substrate relaxations, reconstructions, surfactant effects, etc., one of the most relevant and possibly easily visualized is the displacement of the electron density

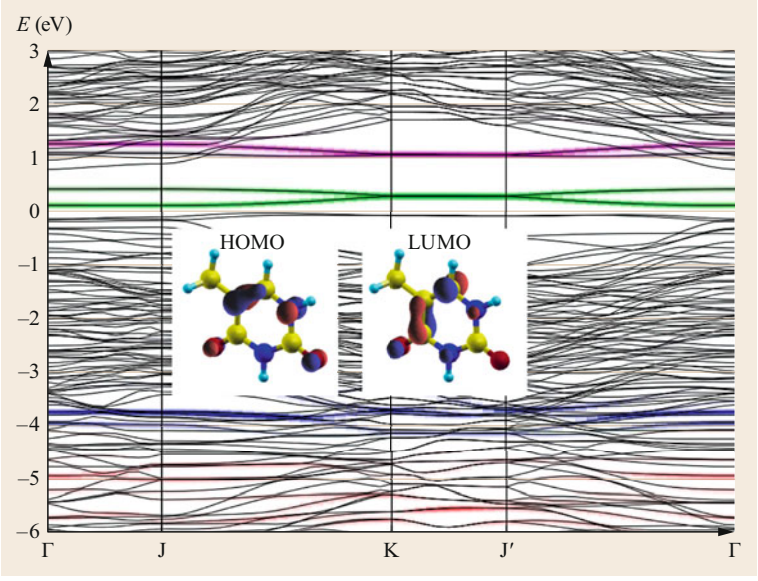

Fig. 16.9 Surface band structure of thymine molecules on Si(001) in the *dimer-bridge* configuration at half coverage [16.148] with molecular contributions shown as a color map of the ***K***-resolved DOS. HOMO and LUMO of gas-phase thymine are shown in the *insets*

of the combined system when that of the summed fragments is taken as a reference. That quantity, $\Delta\rho_{ads} = \rho_{mol/surf} - \rho^{gas}_{mol} - \rho^{clean}_{surf}$, is in principle exactly accessible by DFT where $\rho_{mol/surf}$, ρ^{gas}_{mol}, and ρ^{clean}_{surf} are the ground-state charge densities of the full system, of the free molecule, and of the clean substrate, respectively (the latter two commonly taken at the same coordinates they attain upon adsorption).

Let us take again as an example the case of adsorbed pentacene. A strong electronic charge reorganization at the interface occurs for various metals, see, e.g., [16.146] (also recall the filling of the LUMO of pentacene on a variety of substrates as presented in Sect. 16.5.1). The case of pentacene on Al(001) may serve as a tool to identify the relation between adsorption configurations and different charge displacements. To that purpose, in Fig. 16.10 the quantity $\Delta\rho_{ads}$ is reported for the two configurations, B chemisorbing with a V-shape (Fig. 16.10a,b) and T physisorbing nearly planar (Fig. 16.10c). The red color indicates regions of higher electron density and blue ones of lower density. By plotting in Fig. 16.10a the isosurfaces corresponding to an isovalue of $\pm 0.04\, e/\text{Å}^3$, accumulation of electron density in the C−Al bond formed at the center of the molecule can be seen. A corresponding charge depletion is instead observed in the vicinity of that bond at a smaller isovalue ($\pm 0.01\, e/\text{Å}^3$) in Fig. 16.10b. The net electron transfer from Al to the molecular region was estimated to amount to $0.56e$ [16.149]. To visualize any effect of electron density rearrangement in the physisorbed case, one has to take a lower isovalue $0.005\, e/\text{Å}^3$ in Fig. 16.10c.

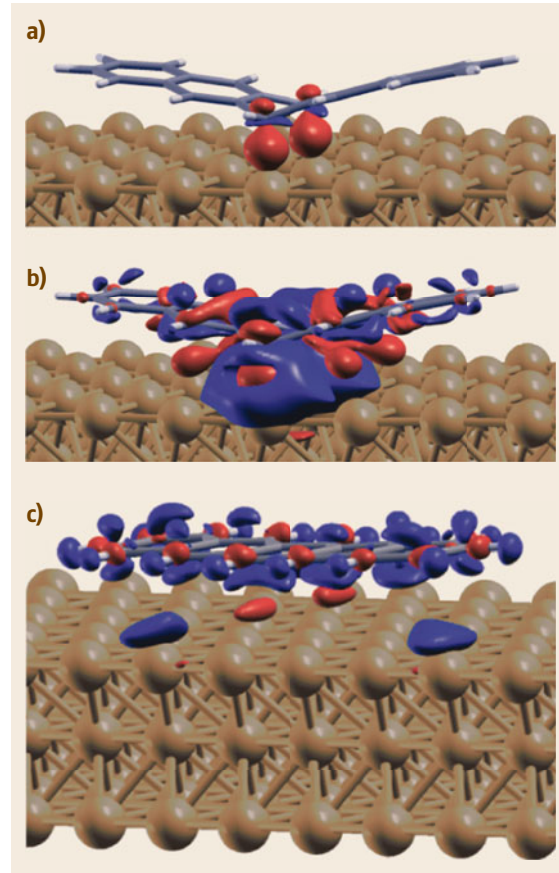

Fig. 16.10a–c Adsorption charge of pentacene on Al(001). **(a)** and **(b)** pentacene on the bridge site, showing surfaces at adsorption charge isovalues of **(a)** $\pm 0.04\, e/\text{Å}^3$ and **(b)** $\pm 0.01\, e/\text{Å}^3$. **(c)** Pentacene on the top site, with isovalues of $\pm 0.005\, e/\text{Å}^3$

Induced Dipoles

In relating the adsorption density rearrangements to workfunction changes one is tempted to express the dipole moment per adsorbed species at a given coverage as the product of the displaced charge (as estimated by Bader or related approaches) times an adsorption distance. However, as pointed out by *Bagus* and coworkers [16.150], several and often canceling terms contribute to the interface dipole so that the above expression is only formally valid. So one may have negatively charged adsorbates, like I/Cu(111), that decrease the surface workfunction contrary to expectations.

Also in the most simple and prototypical case of alkali atoms on a metal, several interesting phenomena may emerge.

For example, the charge displacement induced by adsorption of Cs on Cu(001) is depicted in Fig. 16.11a where we subtract from the electron density of the full system that of neutral Cs and of clean Cu(001). The first and more obvious feature is the transfer of electrons from the Cs region (diffuse red region centered at Cs) to the metal (see the blue region mostly located just above the surface layer). However, one can also appreciate: a localized polarization around the nearest Cu atoms that goes beyond earlier treatments by the jellium model [16.69]; a charge displacement in the region closer to the Cs nucleus, with negative/positive charge at larger/smaller distances, hence producing a dipole moment opposite to the total one. The latter effect corresponds to the polarization of the inner shell and reduces the total dipole moment especially for the heavier alkalis (by 11% for Cs, reducing dipole–dipole repulsions by 20%). The total dipole moment, as computed by DFT-PBE [16.151], produces a variation of the workfunction that at 0.06 ML coverage amounts to 1.97 eV, in excellent agreement with the measured value of 2.0 eV [16.152]. Lighter alkalis show qualitatively similar results, although reduced in magnitude [16.151].

It is noted that the surface dipole is a determined self-consistently. In particular, the experimental saturation of the workfunction change at a given coverage demonstrates the coverage dependence of the adsorption dipole as the overlayer is increasingly denser. Inhomogeneous changes in the local adsorbate density, while keeping the total coverage constant, also lead to interesting phenomena. For example, the dipole–dipole repulsion of adsorbed Na atom pairs on Cu(001) is modified from a pure R^{-3} law (R being the Na−Na distance) because of the reduction of the dipole moment as they come closer: neglecting this effect overestimates the repulsion energy by 20 meV when Na atoms are two Cu unit cells apart [16.153]. Reduction in the adsorption dipole induced by local density increases contributes to the stability of quasi-1-D structures observed and computed for Li/Cu(001) [16.154, 155] and Na/Cu(001) [16.156, 157] as saturation coverage is approached. Atom-scattering experiments demonstrate a 1-D corrugation of the probe–surface interaction that, linked to the surface electron density through the effective medium theory, is actually due to larger extension of the density towards vacuum, as the workfunction is locally reduced because of the increased density of dipoles. As an example, the electron density displacement for a high-coverage structure of Li/Cu(001) [16.155] is reported in Fig. 16.11b, where we show the difference between the adsorption charge density $\Delta\rho_{ads}$ for the full structure and a reference adsorption charge calculated by summing independent contributions by individual Li atoms at lower coverage. The accumulation of electron density in the red *pipe*-shaped region, probed by the experiments, indicates depolarization of the alkali–surface bond (see the blue region underneath) in favor of a metallic-like bond within Li atoms.

Induced Spin Distributions

Adsorption phenomena also have an interplay with spin-dependent phenomena. Cases of magnetic substrates where molecules can attain magnetic properties as a consequence of hybridization are reported (see, e.g., C_{60}/Fe_3O_4 [16.158] or pentacene on Co islands on copper [16.159]) or, conversely, ones of adsorbed magnetic molecules (e.g., porphyrins incorporating magnetic centers). The combination of a magnetic molecule with magnetic substrates [16.160] also raises significant interest for molecular spintronic devices.

However, it is intriguing to observe that adsorption can induce spin-polarization also for nonmagnetic molecules on nonmagnetic substrates. A case that has attracted particular interest is the one of covalent adsorption on graphene. Perfect clean graphene is spin-compensated and several techniques have been proposed to induce magnetic moment. *Casolo* and coworkers [16.161] already demonstrated that the adsorption of an H atom induces a net magnetic moment of $1\mu_B$ by effectively removing one p_z orbital from the π band of graphene: that, by Lieb's theorem for bipartite lattices, translates into the observed magnetism. The unpaired electron occupies a spin-polarized state (called *mid-gap state*) occurring right at the Dirac cone which is localized in space around the adsorbate given the vanishing substrate density of states, although periodic calculations show the appearance of bands in a small, size-dependent, energy gap. This effect is intimately related to modifications in the graphene lattice, rather than on the properties of the adsorbate, and was therefore extended to more general cases of covalently bonded organic molecules on graphene [16.162, 163] and carbon nanotubes [16.164]. The interested reader is referred to the review by *Martinazzo* for more details [16.165].

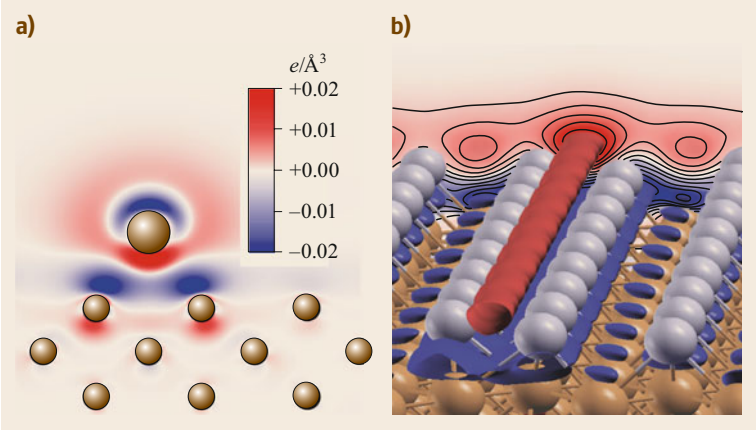

Fig. 16.11 (**a**) Side view of the adsorption charge for Cs/Cu(001). *Large* and *small circles* mark the position of Cs and Cu atoms, respectively. (**b**) Charge redistribution in forming 0.6 ML structures of Li/Cu(001), as compared to the individually adsorbed Li atoms. *Red regions* mark increased electron density. Isosurfaces are depicted at ± 0.01 Å^{-3}

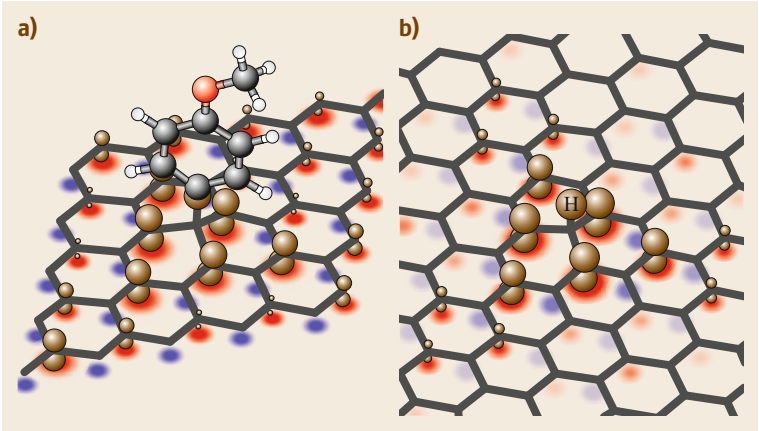

Fig. 16.12a,b Electron spin density $n_\uparrow - n_\downarrow$ for **(a)** methoxybenzene and **(b)** hydrogen adsorbed on graphene. The *red* isosurface corresponds to the value of $0.05\,e/\text{Å}^3$. *Red* and *blue shades* underneath are a false-color plot for values cut through a plane passing 0.65 Å below graphene and saturate at $\pm 0.02\,e/\text{Å}^3$

We recall few experimental facts. Observations of individual atoms and molecules on graphene are possible by the transmission electron microscope [16.166]. Hydrogen adsorption can be used to open a highly demanded band gap, as shown for H/graphene/Ir(111) [16.167]. Also, at low coverage hydrogen can induce a three-order-of-magnitude enhancement of the spin–orbit interaction in graphene [16.168]. Eventually, magnetic properties for organically functionalized graphene samples were measured showing the occurrence of antiferromagnetic domains [16.169].

The spin polarization of graphene with a covalent adsorbate is represented in Fig. 16.12 where we report the spin density $n_\uparrow - n_\downarrow$ for an adsorbed molecule (methoxybenzene, $CH_3OC_6H_5$) and atomic hydrogen, the latter computed for a larger (10×10 unit cell). We start by describing the case of anisole [16.163] in Fig. 16.12a. Upon covalent adsorption on a C atom belonging to one sublattice (A), that atom is lifted out of the carbon plane by 0.42 Å undergoing $sp^2 \rightarrow sp^3$ rehybridization. (This structural deformation costs 0.96 eV, which is subtracted from the adsorption energy leading to a final energy gain of only 0.32 eV despite the additional C–C bond.) The occupied mid-gap state is only minimally contributed directly by the adsorbate. Rather, it is mostly located at the nearest C atoms of the other sublattice (B), as evidenced by the spin density. A smaller and opposite spin polarization at the A sublattice can also be identified. As anticipated, very similar findings occur for adsorbed H, which is presented as a comparison in Fig. 16.12b.

Ultrafast Phenomena

We conclude this section by mentioning that adsorption-induced charge rearrangements and spin distributions can exhibit ultrafast time dependence (on the femtosecond timescale) in response to excitations. As an example, the adsorption charge of a core-excited adsorbed molecule is altered so as to accommodate an additional electron. This results in specific decay channels in de-excitation spectra [16.170] that are explained in terms of a modified $\Delta\rho_{\text{ads}}$ taking into account a filled LUMO orbital [16.72] injected from the substrate within a few fs to screen the perturbation. Returning to covalently functionalized graphene, a core-level excitation in the adsorbate is shown to disrupt the adsorption-induced magnetism on the fs time scale [16.171].

16.6 Conclusions

In this Chapter we have reviewed the progress made in adsorption and band structures in recent years. Adsorption energies have benefited from increased computer power and from new functionals and vdW implementation. Accuracies of maximum 200–300 meV in bonding have been accomplished. For surface bands a new area has opened up with the topic of adsorbed organic molecules. Especially with the help of synchrotron radiation methods and DFT approaches, the bands of organic adsorbates have been determined with great precision, including their orientation, tilting angle, and the formation of metal–semiconductor overlayers of particular interest for organic electronic devices and photovoltaics. In this respect, scanning tunneling microscopy and spectroscopy have also been of great help. New effects such as distance-surface manipulation of surface states have been foreseen.
