Springer

Handbook of Mechanical Engineering

Grote
Hefazi
Editors

2nd Edition

Springer

Springer Handbook of Mechanical Engineering

Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical and applied sciences. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of scientific and technical information.

The volumes are designed to be useful as readable desk book to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Springer Handbook of Mechanical Engineering

Karl-Heinrich Grote, Hamid Hefazi (Eds.)

2nd. Edition
With 1481 Figures and 381 Tables

Preface

The Springer Handbook series is an essential resource for scientists and practicing engineers, as well as students during all phases of their studies.

The first edition of the *Springer Handbook of Mechanical Engineering* was published in 2008 and was very well received by the mechanical engineering community worldwide. As early as 2015, the publication of an updated second edition of the handbook was discussed with Springer, based on suggestions from authors and readers to include new developments in mechanical engineering. Finalizing the publication took a while, and the mechanical engineering handbook team is now more than happy to present the second edition of the *Springer Handbook of Mechanical Engineering*".

Mechanical engineering is a broad and complex field within the world of engineering and has close relations to many other fields. This handbook provides a broad overview of many areas of the discipline. Springer, however, recommends supplementing this handbook with other editions of Springer Handbooks, such as the Springer Handbook of Robotics, the Springer Handbook of Metrology and Testing, the Springer Handbook of Experimental Solid Mechanics, the Springer Handbook of Experimental Fluid Mechanics, and the Springer Handbook of Materials Data, as well as other specialized literature as references.

Mechanical engineering is also an important economic factor for all industrialized countries, as well as for the global market. Rapid developments in the field allow for a wide range of international competition for products and processes in mechanical engineering. In order to stay on top of the scientific findings and to apply existing knowledge, it is important to renew and continuously update existing information.

We have been privileged to work with approximately 100 authors from all around the world to gather selected and useful information about the discipline. The book can not claim to cover all and every aspect in all areas where mechanical engineers contribute their expertise and knowledge towards solving major societal challenges. However, this handbook will be a valuable guide for all who design, develop, manufacture, operate, and use mechanical artefacts. Compared to the first edition, many chapters, including those about machine elements, electronics, materials in mechanical engineering, and transportation, have been completely rewritten or substantially revised. We also hope to initiate interest in the field of mechanical engineers in others. For example, high-school students can get a first glance and learn about options in engineering and possible career choices.

As with all books of this kind, the individual authors are responsible for their chapters, and questions should be directly addressed to them.

Since Dr Erik Antonsson has entered a new challenging career path, the continuing editor Dr Karl-Heinrich Grote welcomed Dr Hamid Hefazi as coeditor. Furthermore, Dr Werner Skolaut thankfully came out of retirement again to also join the team.

We would like to express our gratitude and thanks to all of the authors of this handbook, who each devoted a considerable amount of time to this project. We would like to thank them for their patience and cooperation during the seemingly ever-lasting preprinting process, and we hope for a long-lasting partnership in this ambitious project. We would also most sincerely like to thank our managers and friends at Springer and le-tex: Dr Judith Hinterberg and others at Springer who were always most cooperative and supportive of this handbook, Petra Möws and the team at le-tex, who did a wonderful job in preparing the diagrams and graphics to meet the high standards of the Springer Handbook series. The printer has done a fantastic job – as always – in printing and binding. We would also like to thank all the people we worked with in the departments, universities, and industry who supported the time and effort spent on this book.

Finally, we know that there is always room for improvement – with this handbook as with engineering products and approaches. We, as well as the other authors, welcome your constructive hints, comments, and criticism. We would also like to draw your attention to what has been accomplished in and with this Springer Handbook of Mechanical Engineering, for the benefit of the engineering world and our society – done by engineers worldwide!

About the Editors

Dr Karl-Heinrich Grote German and US citizen, is Full Professor in the Department of Machine Design at the Otto-von-Guericke University in Magdeburg, Germany. He received his "Diploma in Engineering" (Master's of Science in Mechanical Engineering) in 1979 and his "Dr-Ing" in Engineering) in 1984, both from the Technical University in Berlin, Germany. From 1984 to 1986 he was postdoctoral researcher in Long Beach, USA and returned to Germany to become the Technical Chief Manager for Engineering Design at the "Ingenieurgesellschaft für Auto und Verkehr, IAV" in Berlin (Engineering Group for Automotive and Transportation, Berlin). From June 1995 to October 2020, he was Chair and Director of the Department of Machine Design at the Otto-von-Guericke University in Magdeburg, Germany, where he was also Vice President for Academic Affairs from 1989 to 2001. Since 1997 he has been serving as Chair of the Scientific Advisory Board of the Experimental Factory in Magdeburg. From 2002 to 2004 he was Visiting Full Professor of Mechanical Engineering at the California Institute of Technology (Caltech), Pasadena, USA. From 2005 to 2017 Professor Grote was the Dean of the College of Mechanical Engineering at the Otto-von-Guericke University, Magdeburg, Germany. In 2013, he joined the Department of Mechanical and Marine Engineering of HVL, Western Norway University of Applied Science, Bergen, Norway, as Professor II. Dr Grote´s research interests are all mechanical aspects within the practical engineering area and new technologies of creating and manufacturing design solutions for state-of-the-art products and new ideas. Over 330 publications as author/co-author and advising more then 90 dissertations cover his research projects and results in mechanical engineering since 1990.

In 1995, Dr Grote became editor of the "DUBBEL- Taschenbuch für den Maschinenbau" (Handbook of Mechanical Engineering) – the standard handbook for the German-speaking engineering community, with over 1 million copies sold and in 2002 co-author/editor of the book "Pahl/Beitz: Engineering Design" (all books published by Springer). Dr Grote is the 1993 recipient of the Ring of Honor (Young Engineers Award) from the German Society of Professional Engineering (VDI) and the 1993 recipient of the "Thomson-Ramo-Wooldridge (TRW) Excellence Award" in the USA and in 2015 the recipient of an Honorary Doctors Degree (Dr. h.c.) from Kiev Institute of Technology.

Dr Hamid Hefazi is Professor and Chair of the Mechanical Engineering Department at the State University of New York (SUNY) – Korea located in Incheon, Republic of Korea. He received his PhD in Aerospace Engineering from the University of Southern California in 1985. He has extensive teaching and research experience in aerodynamics and the design and optimization of aerospace systems. He has been involved in a broad range of teaching and research topics in fluid mechanics, aeroacoustics, and aerodynamics. His more recent research has been focused on hydrodynamics, advanced multidisciplinary design and optimization (MDO) methods, and their applications to naval engineering. He has authored more than 75 journal publications and 4 book chapters. Dr Hefazi has been the principal investigator for more than 100 externally funded research projects, including projects sponsored by the US National Science Foundation, NASA, the US Office of Naval Research, and the Boeing Company, among others. He has organized several national conferences and taught many short courses for industry. Dr Hefazi has worked extensively as a consultant for wind-energy companies and holds a patent on an innovative vertical axis wind turbine. Dr Hefazi served as the Director of the "Boeing Technology Center", at California State University, Long Beach, for 12 years. The center worked on high priority research and development projects of interest to the aerospace industry. He is the recipient of many awards, including the Boeing Company's Silver Eagle award for innovation and the US Department of Defense's Nunn-Perry Award for 2005 and 2006 for his work with Northrop Grumman Space Technology. He is an associate fellow of the American Institute of Aeronautics and Astronautics.

List of Abbreviations XXI

Part A Fundamentals

1 **Introduction to Mathematics**
Gnana Bhaskar Tenali 3
1.1 Linear Algebra 4
1.2 Differential Equations 8
1.3 The Laplace Transform 13
1.4 Fourier Analysis 16
1.5 Complex Analysis 19
References 23

2 **Mechanics**
David C. Fleming, Hen-Geul Yeh, Hsien-Yang Yeh, Shouwen Yu 25
2.1 Statics of Rigid Bodies 26
2.2 Dynamics 39
References 59

3 **Thermodynamics**
Peter Stephan, Frank Dammel, Jay M. Ochterbeck 61
3.1 Scope of Thermodynamics and Definitions 61
3.2 Temperatures and Equilibria 63
3.3 First Law of Thermodynamics 66
3.4 Second Law of Thermodynamics 69
3.5 Exergy and Anergy 71
3.6 Thermodynamics of Substances 73
3.7 Changes of State of Gases and Vapors 93
3.8 Thermodynamic Processes 97
3.9 Ideal Gas Mixtures 109
3.10 Heat Transfer 114
References 127

Part B Materials

4 **Atomic Structure and Microstructure Characterization**
Jens Freudenberger, Martin Heilmaier, Ulrich Wendt 131
4.1 Order in Solid State 132
4.2 Microstructure Characterization 152
References 162

5 **Mechanical Properties**
Vivek Srivastava, Martin Heilmaier 165
5.1 Mechanical Properties 165
5.2 Physical Properties 178
References 182

6 **Corrosion and Corrosion Resistance**
Thomas Böllinghaus, Michael Rhode, Thora Falkenreck 185
6.1 Fundamental Aspects 185
6.2 Electrochemical Corrosion 186
6.3 Chemical Corrosion and High-Temperature Corrosion 207
6.4 Corrosion Testing 212
References 212

7 **Nondestructive Inspection (NDI)**
Gerhard Mook, Islam Shyha 215
7.1 Principles of Nondestructive Inspection 216
7.2 Acoustic Methods 217
7.3 Potential Drop Method 219
7.4 Magnetic Methods 220
7.5 Electromagnetic Methods 224
7.6 Thermography 225
7.7 Optical Methods 226
7.8 Radiation Methods 228
7.9 Health Monitoring 229
References 231

8 **Engineering Materials and Their Properties**
Ulrich Wendt 233
8.1 Iron-Based Materials 234
8.2 Aluminum and Its Alloys 258
8.3 Magnesium and Its Alloys 262
8.4 Titanium and Its Alloys 265
8.5 Ni and Its Alloys 269
8.6 Co and Its Alloys 273
8.7 Copper and Its Alloys 275
8.8 Polymers 278
8.9 Glasses and Ceramics 285
8.10 Composite Materials 289

List of Abbreviations

A

A.M.	algebraic multiplicity
ABWR	advanced boiling water reactor
AC	alternating current
ACES	automated, connected, electrified, shared/services
ACI	austempered cast iron
ACM	polyacrylate rubber
ADAS	advanced driver-assistance system
ADI	austempered ductile cast iron
AES	atomic emission spectroscopy
AGR	advanced gas reactor
AGSC	automatic guided straddle carrier
AGV	automated guided vehicle
AI	authorized inspector
AMS	automated miniload system
AND	airplane nose down
ANG	absorbed natural gas
APB	antiphase boundary
APWR	advanced pressurized water reactor
AR	augmented reality
AS/RS	automated storage and retrieval system
ASL	loss due to hot ash or slag
AT	all-terrain
ATC	automatic train control
ATS	air transport system
AVAS	acoustic vehicle alerting system
AVS	angle of vanishing stability
AW	antiwear
AWJ	abrasive waterjet

B

bcc	body-centered cubic
bct	body-centered tetragonal
BD	balanced draft
BDC	bottom dead center
BEV	battery electric vehicle
BiW	body in white
BM	beam machining
BMEP	break mean effective pressure
BOM	bill of materials
BS	British standard
BSE	backscattered electron
BSFC	brake specific fuel consumption
BTL	biomass-to-liquid
BV	Bureau Veritas
BWB	blended wing body
BWR	boiling water reactor

C

CAD	computer-aided design
CAES	compressed air energy storage
CAM	computer-aided manufacturing
CANDU	Canada Deuterium Uranium
CAS	computer-aided styling
CBN	cubic boron nitride
CC	combustion chamber
CCD	charge-coupled device
CCGT	combined cycle gas turbine
CCT	continuous cooling transition
CD	continuous dressing
CDC	crank dead center
CDP	car development process
CF	corrosion fatigue
CFC	chlorofluorocarbon
CFD	computational fluid dynamics
CFRP	carbon fiber reinforced plastic
CGI	compacted graphite iron
CHP	combined heat and power
CI	compression-ignition
CIFI	cylinder-individual fuel injection
Class NK	Nippon Kaiji Kyokai
CMM	coordinate measuring machines
CMOS	complementary metal–oxide–semiconductor
CMP	chemical-mechanical planarization
CN	coordination number
CNC	computer numerical control
CNG	compressed natural gas
CODAP	code français de construction des appareils à pression
CP	critical point
CPI	central-point injection
CPP	controllable pitch propellers
CPT	critical pitting temperature
CPU	central processing unit
CR	chloroprene rubber
CRSS	critical resolved shear stress
CRT	cathode ray tube
CSM	chlorosulphonyl polyethylene rubber
CT	compact tension
CTE	coefficient of thermal expansion
CTEM	conventional transmission electron microscopy
CTL	coal-to-liquid
Cu-DHP	deoxidized copper
CVD	chemical vapor deposition
CVM	comparative vacuum monitoring
CVN	Charpy V-notch

D

DAB	dialkylbenzenes
DBTT	ductile to brittle transition temperature
DC	direct current
DCA	double-circular arc
DCF	duty cycle factor

DEGL	dry exhaust gas losses
DEM	dust extinction moisture
DET	distortion energy theory
DFE	design for the environment
DFM	design for manufacturability
DI	direct injection
DIC	differential interference contrast microscopy
DKD	German calibration service
DLC	dual-load carrier
DME	dimethyl ether
DMIS	dimensional measuring interface specification
DMU	digital mock-up
DPF	diesel particulate filter
DPH	diamond-pyramid hardness number
DRAM	dynamic random-access memory
DSC	differential scanning calorimetry
DWT	deadweight

E

E-GAS	synthetic methane
EAC	environmentally assisted cracking
EAM	European approval of material
EAS	equivalent airspeed
EBM	electron beam machining
EBSD	electron backscatter diffraction
ECDD	evanescent coupling display device
ECDM	electrochemical-discharge machining
ECG	electrochemical grinding
ECM	electronic control module
ECU	electronic control unit
EDG	electro-discharge grinding
EDM	electro-discharge machining
EDX	energy-dispersive x-ray spectrometer
EELS	electron energy-loss spectroscopy
EEOI	energy efficiency operation index
EGR	exhaust gas recirculation
EHD	elastohydrodynamic lubrication
EHL	elastohydrodynamic lubrication
EIS	entry into service
ELI	extralow interstitial
ELID	electrolytic in-process dressing
EMC	electromagnetic compatibility
EN	European Standard
EP	extreme pressure
EPDM	ethylene-propylene diene monomer
EPIWRC	synthetic coated independent wire rope core
EPMA	electron probe microanalysis
ERP	enterprise resource planning
ERS	energy recovery system
ESCA	electron spectroscopy for chemical analysis
ESEM	environmental SEM
ESP	electrostatic precipitator
ESR	essential safety requirement
EYL	effective yield locus

F

F	freshwater
FAME	fatty acid methyl ester
FBC	fluidized-bed combustor
FBR	fast breeder reactor
FC	fiber core
fcc	face-centered cubic
FCEV	fuel cell electric vehicle
FCV	fuel cell vehicle
FD	forced draft
FEA	finite element analysis
FEGT	furnace exit gas temperature
FEM	finite element method
FF	flow function
FFKM	perfluoroelastomer
FFT	fast Fourier transform
FGD	flue gas desulfurization
FIB	focused ion beam
FIFO	first-in first-out
FKM	fluoroelastomer
FLD	forming limit diagram
FMEA	failure mode and effects analysis
FN	ferrite number
FPM	fluorocarbon rubber
FPO	future project office
FRP	fiber-reinforced plastic

G

G.M.	geometric multiplicity
GA	general arrangement
GDI	gasoline direct injection
GDOES	glow-discharge optical emission spectroscopy
GDP	gross domestic product
GHG	greenhouse gas
GIDAS	German In-Depth Accident Study
GMAW	gas metal arc welding
GNC	guidance navigation and control
gt	gross tonnage
GTAW	gas tungsten arc welding
GTL	gas-to-liquid

H

HAC	hydrogen-assisted cracking
HASCC	hydrogen-assisted stress corrosion cracking
HAZ	heat-affected zone
HCFC	hydrochlorofluorocarbon
hcp	hexagonal close-packed
HDC	head dead center
HDPE	high-density polyethylene
HE	heat exchanger
HEDE	hydrogen-enhanced decohesion
HELP	hydrogen-enhanced localized plasticity
HEM	high-efficiency machining
HEV	hybrid electric vehicle

HFID	heated flame ionization detector
HHV	higher heating value
HIL	hardware-in-the-loop
HIP	hot isostatic pressing
HP	high pressure
HPCC	high-pressure combustion chamber
HPDI	high-pressure direct injection
HPT	high-pressure turbine
HRC	hardness Rockwell cone
HRSG	heat recovery steam generator
HSC	high-speed cutting
HSLA	high-strength low-alloy
HSM	high-speed machining
HSS	high-speed steel
HTA	heavier than air
HTHA	high-temperature hydrogen attack
HVACR	heating, ventilation, air-conditioning, and refrigeration

I

I/O	input/output
IAS	indicated airspeed
IBC	international building code
IBM	ion beam machining
IC	integrated circuit
ICL	incomplete combustion loss
ID	induced draft
IDD	interferometric display device
IDI	indirect diesel injection
IE	Erichson index
IFR	instrument flight rules
IGBT	insulated-gate bipolar transistor
IGC	intergranular corrosion testing
IGCC	integrated gasification combined cycle
IISE	ion-induced secondary electron
IoT	Internet of Things
IP	intermediate pressure
ITO	indium tin oxide
IVP	initial value problem
IWRC	independent wire rope core
IYL	instantaneous yield locus

K

KOH	potassium hydroxide

L

LA	lead acid
LAM	laser-assisted machining
LB	laser beam
LBM	laser beam machining
LC	laser cutting
LCA	life cycle analysis
LCB	longitudinal center of buoyancy
LCF	longitudinal centre of flotation
LCG	longitudinal center of gravity
LCI	life cycle inventory
LDPE	low-density polyethylene
LE	leading edge
LED	light-emitting diode
LHV	lower heating value
LIFO	last-in first-out
LMTD	log-mean temperature difference
LNG	liquefied natural gas
LP	low pressure
LPCC	low-pressure combustion chamber
LPG	liquefied petroleum gas
LPT	low-pressure turbine
LRO	long-range order
LTA	lighter than air
LU	loading unit
LYS	lower yield stress

M

m.a.c.	mean aerodynamic chord
MAM	motorized air cycle machine
MAP	main air pipe
MBS	multibody simulation
MC	molecular weight of carbon
MCA	multi-circular arc
MCAL	losses due to moisture in the combustion air
MCD	monocrystalline diamond
MCO	molecular weight of CO
MCTC	moment to change the trim by one centimeter
MDT	mean downtime
MEMS	microelectromechanical system
MEP	mean effective pressure
MHD	magnetohydrodynamic
MIC	microbiologically induced corrosion
MLC	multiload carrier
MLW	maximum landing weight
MMC	metal matrix composites
MOF	metal-organic framework
MOS	metal oxide semiconductor
MP-OVI	multipoint open-valve injection
MPI	magnetic particle inspection
MPS	mean piston speed
MSI	motion sickness incidence
MSS	maximum shear theory
MSW	municipal solid waste
MTBE	methyl *t*-butyl ether
MTBF	mean time between failures
MTOGW	maximum take-off gross weight
MWE	manufacturer's weight empty
MZFW	maximum zero-fuel weight

N

NA	number of atoms
NAND	not and
NBC	national building code
NBR	acrylonitrile butadiene rubber
NC	numerical control
NCAP	new car assessment program
ND	normal direction

NDE	nondestructive evaluation
NDI	nondestructive inspection
NDIR	nondispersive infrared
NDT	nondestructive testing
NEFZ	Neuer Europäischer Fahrzyklus
NFC	natural fiber core
NG	natural gas
NGDI	natural gas direct injection
NMOS	n-channel MOS
NPSH	net positive suction head
NR	natural rubber
NTP	normal temperature and pressure
NVH	noise–vibration–harshness

O

OCP	open-circuit potential
ODE	ordinary differential equation
ODS	oxide-dispersion-strengthened
OEM	original equipment manufacturer
OFA	over fire air
OFW	oblique flying wing
OIM	orientation imaging microscopy
OWE	operating weight empty

P

PA	polyamide
PAM	plasma arc machining
PAO	polyalphaolefines
PBM	plasma beam machining
PCBN	polycrystalline cubic boron nitride
PCC	pneumatic conveying characteristic
PCD	polycrystalline diamond
PCI	peripheral component interconnect
PD	packing density
PDF	powder diffraction file
PDM	product data management
PE	polyethylene
PE-HD	high-density polyethylene
PED	Pressure Equipment Directive
PEMS	portable emissions measurement system
PET	polyethylene terephthalate
PHE	plate heat exchangers
PHEV	plug-in hybrid electric vehicle
PHS	pumped hydro storage
PIB	polyisobutenes
PM	particulate matter
PMA	particular material appraisal
PMMA	polymethylmethacrylate
PMOS	p-channel MOS
PN	particulate number
PP	polypropylene
PPS	polyphenylene sulfide
PQR	procedure qualification record
PREN	pitting resistance equivalent numbers
PS	polystyrene
PSB	persistent slip band
PSD	power spectral density
PTFE	polytetrafluoroethylene
PUR	polyurethane
PVC	polyvinylchloride
PVD	physical vapor deposition
PVDF	polyvinylidene fluoride
PWB	printed wiring board
PWHT	postweld heat treatment
PWR	pressurized water reactor
PWRC	parallel wire rope core

Q

QCC	quality control chart
QFD	quality function deployment
QM	quality management
QMS	quality management system
QPC	quasi-propulsive coefficient
QS	quality management system
QueSST	quiet supersonic transport

R

RA	recuperator air side
RAMS	reliability, availability, maintainability and safety
RAO	response amplitude operator
RC	rate of climb
RD	rolling direction
RDE	real-world driving emission
RG	recuperator gas side
RIE	reactive ion etching
RIT	runaway ignition temperature
rms	root-mean-square
RNG	renewable natural gas
RPV	reactor pressure vessel
RPZ	risk priority number
RT	radiographic testing
RTM	resin transfer molding
RUL	radiation and unaccounted-for losses

S

S	summer saltwater
SAM	scanning Auger electron spectroscopy
SBR	polystyrene-butadiene rubber
SC	supercritical
SCC	stress corrosion cracking
SCI	special crash investigation
SCR	selective catalytic reduction
SDD	silicon drift detector
SDOF	single degree of freedom system
SE	secondary electron
SEDM	spark electro-discharge machining
SEFI	sequential fuel injection
SEM	spark-erosion machining
SFC	synthetic fiber core
SFC	specific fuel consumption
SHM	structural health monitoring
SI	International System
SI	spark ignition

SIMS	secondary-ion mass spectroscopy
SKU	stock keeping unit
SLC	single load carrier
SLCA	streamlined life cycle analysis
SLM	selective laser melting
SLPL	space limit payload
SMAW	shielded metal arc welding
SNCR	selective noncatalytic reduction
SNG	synthetic natural gas
SOF	soluble organic fraction
SOG	speed over the ground
SOLAS	Safety Of Life At Sea
SOP	start of production
SPC	statistical process control
SPV	simple pressure vessel
SQUID	superconducting quantum interference device
SRO	short-range order
SSSF	steady-state steady flow
ST	softening temperature
STEM	scanning transmission electron microscopy
STW	speed through water
SUV	sports utility vehicle
SV	suction valve

T

T	tropical saltwater
TAS	true airspeed
TC	turbocharger
TCG	transverse center of gravity
TD	transversal direction
TDC	top dead center
TE	trailing edge
TEM	transmission electron microscopy
TEU	twenty-foot equivalent unit
TF	tropical freshwater
TGV	train à grande vitesse
TLAR	top-level aircraft requirements
TMAH	tetramethyl ammonium hydroxide
TMC	traffic message channel
TML	transportable moisture limit
TOR	top of rail
TPC	tonnes per centimeter
TQM	total quality management
TRIAC	triode for alternating current
TRIP	transformation induced plasticity
TS	tribological system
TSF	time-strain-to-fracture
TTP	time–temperature–precipitation
TTT	time–temperature transition
TWC	three-way catalyst

U

UAS	unmanned aircraft system
UAV	unmanned aerial vehicle
UBC	uniform building code
UCAV	unmanned combat air vehicle
UCL	unburnt carbon loss
UHC	unburned hydrocarbon
UHCA	ultrahigh-capacity aircraft
UHEGT	ultrahigh-efficiency gas turbine
UNS	unified numbering system
UPS	uninterruptible power supply
UPV	unfired pressure vessel
US	ultrasonic
USC	ultra-supercritical steam
USM	ultrasonic machining
UT	ultrasonic testing
UTS	ultimate tensile strength/stress
UV	ultraviolet
UYS	upper yield stress

V

VCG	vertical center of gravity
VDMOS	vertically double-diffused MOS
VE	vinyl ester resin
VHN	Vickers hardness number
VI	viscosity index
VLCT	very large commercial transport
VNA	very narrow aisle
VOC	volatile organic compound
VOF	volatile organic fraction
VPH	Vickers pyramid hardness
VPP	variable pitch propellers
VPSEM	variable-pressure SEM
VR	virtual reality
VTG	variable turbine geometry
VTOL	vertical take-off and landing

W

W	winter saltwater
WC	wire core
WDX	wavelength-dispersive x-ray spectrometer
WEDM	wire electro-discharge machining
WNA	winter North Atlantic saltwater
WPS	weld procedure specification
WSC	wire strand core
WSP	wheel-slide protection
WWI	World War I
WYL	wall yield locus

X

XPS	x-ray-exited photoelectron spectroscopy
XRD	x-ray diffraction
XRF	x-ray fluorescence spectroscopy

Y

YL	yield locus
YPE	yield point elongation

1. Introduction to Mathematics

Gnana Bhaskar Tenali

This chapter presents mathematical concepts and techniques that are fundamental for the study of problems in mechanical engineering. Precisely formulating a mathematical model of the problem at hand, using appropriate methods and techniques to solve the mathematical problem, and, finally, interpreting the solution to the real life problem are some of the important components of the process of solving problems in any engineering field. The topics covered here include linear algebra, differential equations, the Laplace transform, Fourier analysis, and complex analysis. These basic concepts essentially act as tools that facilitate the understanding of many techniques involved in different branches of mechanical engineering.

1.1 **Linear Algebra** 4
1.1.1 Vectors in $\mathbb{R}^n$ 4
1.1.2 Matrix Algebra 4
1.1.3 Eigenvalues and Eigenvectors of a Square Matrix **A** 7

Mathematical concepts and techniques play an important role in the study of problems in mechanical engineering. Precisely formulating a mathematical model of the problem at hand, using appropriate methods and techniques to solve the mathematical problem, and, finally, interpreting the solution to the real-life problem are some of the important components of the process of solving problems in any engineering field. The topics covered include linear algebra, differential equations, the Laplace transform, Fourier analysis, and complex analysis. Different branches of mechanical engineering employ ideas and techniques from these fundamental topics in mathematics. Linear algebra deals with the study of matrices and linear systems of equations. Ordinary differential equations (ODEs) arise in the study of any phenomena that involve the rate of change with respect to an independent variable. The corresponding models involve ODEs, along with suitable initial or boundary conditions. Analysis of such models requires us to obtain analytical and/or numerical solutions to such problems. Transform techniques are useful in many such settings, where the (real-world) problem may be difficult to solve in its original formulation. So, the problem is recast in a different (more easily solvable) form using a mathematical transformation, and the solution of the modified problem is then transformed using the inverse transform to obtain the solution of the original problem. We discuss the Laplace transform and the Fourier transform among such transform techniques. As a part of Fourier analysis, we also present a brief discussion on Fourier series, a very important and effective tool in representing the solutions of several problems that arise in mechanical engineering, in terms of periodic functions sine and cosine. Complex analysis deals with complex numbers, their properties, and the analysis of functions of a complex variable. This plays an important role in problems arising on potential theory.

https://doi.org/10.1007/978-3-030-47035-7_1

1.1 Linear Algebra

Linear algebra plays a crucial role in both the analytical and computational aspects of solving various mechanical engineering problems. We start this section with a brief overview of vectors in $\mathbb{R}^n$ and matrix algebra.

1.1.1 Vectors in $\mathbb{R}^n$

Let $\mathbb{R}$ denote the set of all real numbers (scalars). By $\mathbb{R}^n$ we mean the set of all ordered n-tuples of the form $(x_1, x_2, \ldots, x_n)$, where $x_i \in \mathbb{R}$. Each $\boldsymbol{x} = (x_1, x_2, \ldots, x_n)$ is also treated as an n-dimensional *row vector*, and each x_i is called a component of the vector. The zero vector is denoted by $\mathbf{0} = (0, 0, \ldots, 0)$. For $\boldsymbol{x} = (x_1, x_2, \ldots, x_n)$ and $\boldsymbol{y} = (y_1, y_2, \ldots, y_n)$ in $\mathbb{R}^n$, the addition and scalar multiplication are defined as follows

$$\begin{aligned} \boldsymbol{x} + \boldsymbol{y} &= (x_1 + y_1, \ldots, x_n + y_n) \,, \\ k\boldsymbol{x} &= (kx_1, \ldots, kx_n) \,. \end{aligned}$$

The length of a vector $\boldsymbol{x}$ is called the *norm* or *magnitude*, denoted by $\|\boldsymbol{x}\|$ and is given by $\|\boldsymbol{x}\| = \sqrt{x_1^2 + x_2^2 + \cdots + x_n^2}$. The *dot product* of the vectors $\boldsymbol{x}, \boldsymbol{y}$ is given by $\boldsymbol{x} \cdot \boldsymbol{y} = x_1 y_1 + x_2 y_2 + \cdots + x_n y_n$. For nonzero vectors $\boldsymbol{x}$ and $\boldsymbol{y}$ in $\mathbb{R}^2$, and $\mathbb{R}^3$, the angle between these vectors is given by $\cos\theta = \boldsymbol{x} \cdot \boldsymbol{y} / (\|\boldsymbol{x}\| \|\boldsymbol{y}\|)$. Vectors in $\mathbb{R}^n$ may also be represented in *column vector* form

$$\begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{pmatrix} .$$

By a linear combination of the vectors $\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_n$ in $\mathbb{R}^m$ we mean a vector of the form $c_1\boldsymbol{x}_1 + c_1\boldsymbol{x}_1 + \cdots + c_n\boldsymbol{x}_n$, where $c_1, c_2, \ldots, c_n$ are scalars.

1.1.2 Matrix Algebra

A matrix is one of the most powerful mathematical objects that represents data efficiently, and one that includes different perspectives of the data. An $m \times n$ matrix, in the most mundane definition, is simply a rectangular array of mn numbers. More elegantly, it can also be thought of as a collection of m *row vectors* in $\mathbb{R}^n$ or as a collection of n *column vectors* in $\mathbb{R}^m$. An $m \times n$ matrix $\mathbf{A}$ is denoted by $\mathbf{A} = (a_{ij})$, $1 \le i \le m$, $1 \le j \le n$. Here a_{ij} is the entry at the intersection of the i-th row and j-th column. If the number of rows in a matrix $\mathbf{A}$ is same as the number of columns, $\mathbf{A}$ is called a *square* matrix. In a square matrix $\mathbf{A}$, the entries a_{ii} are referred to as *diagonal entries*. Two matrices $\mathbf{A} = (a_{ij})$ and $\mathbf{B} = (b_{ij})$ of size $m \times n$ are said to be *equal* if and only $a_{ij} = b_{ij}$, $1 \le i \le m$, $1 \le j \le n$.

For the $m \times n$ matrices $\mathbf{A} = (a_{ij})$ and $\mathbf{B} = (b_{ij})$ the *sum* $A + B$ is the matrix of same size, whose ij-th entry is $a_{ij} + b_{ij}$. For $k \in \mathbb{R}$ and a matrix $\mathbf{A} = (a_{ij})$, $k\mathbf{A} = (ka_{ij})$.

We denote the row vectors and column vectors of an $m \times n$ matrix $\mathbf{A} = (a_{ij})$ as $\boldsymbol{r}_i$, $1 \le i \le m$, and $\boldsymbol{c}_j$, $1 \le j \le n$, respectively. Given an $n \times 1$ column vector $\boldsymbol{b} = (b_j)$, the product $\mathbf{A}\boldsymbol{b}$ is an $m \times 1$ column vector $\boldsymbol{c} = (c_i)$, where $c_i = \sum_{j=1}^{n} a_{ij} b_j = \boldsymbol{r}_i \cdot \boldsymbol{b}$, $i = 1, \ldots, m$. This column vector can also be realized as the linear combination $b_1\boldsymbol{c}_1 + b_2\boldsymbol{c}_2 + \ldots + b_n\boldsymbol{c}_n$.

If the number of columns of $\mathbf{A}$ does not equal the number of rows of $\mathbf{B}$, the product $\mathbf{AB}$ is not defined. When the product is defined, the ij-th entry of $\mathbf{C}$ is obtained by taking the dot product of the i-th row of $\mathbf{A}$ with the j-th column of $\mathbf{B}$. That is, $c_{ij} = \boldsymbol{r}_i \cdot \boldsymbol{c}_j$, $1 \le i \le m$, $1 \le j \le n$. This is shown schematically in Fig. 1.1.

Example 1.1

Let

$$\mathbf{A} = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & -1 \\ 1 & -1 & -1 \\ -1 & -1 & -1 \end{pmatrix} \quad \text{and} \quad \boldsymbol{b} = \begin{pmatrix} 1 \\ 2 \\ 3 \end{pmatrix} .$$

The product

$$\mathbf{A}\boldsymbol{b} = \begin{pmatrix} \boldsymbol{r}_1 \cdot \boldsymbol{b} \\ \boldsymbol{r}_2 \cdot \boldsymbol{b} \\ \boldsymbol{r}_3 \cdot \boldsymbol{b} \\ \boldsymbol{r}_4 \cdot \boldsymbol{b} \end{pmatrix} = 1 \begin{pmatrix} 1 \\ 1 \\ 1 \\ -1 \end{pmatrix} + 2 \begin{pmatrix} 1 \\ 1 \\ -1 \\ -1 \end{pmatrix} + 3 \begin{pmatrix} 1 \\ -1 \\ -1 \\ -1 \end{pmatrix} = \begin{pmatrix} 6 \\ 0 \\ -4 \\ -6 \end{pmatrix} .$$

For an $m \times n$ matrix $\mathbf{A} = (a_{ij})$ and an $n \times p$ matrix $\mathbf{B} = (b_{ij})$, the product $\mathbf{AB}$ is a $m \times p$ matrix $\mathbf{C} = (c_{ij})$, where

$$c_{ij} = \sum_{k=1}^{n} a_{ik} b_{kj} \,, \quad 1 \le i \le m \,, \quad 1 \le j \le p \,. \tag{1.1}$$

Example 1.2

Let

$$\mathbf{A} = \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & -1 \\ 1 & -1 & -1 \\ -1 & -1 & -1 \end{pmatrix} \quad \text{and} \quad \mathbf{B} = \begin{pmatrix} 1 & 0 \\ 2 & -1 \\ 3 & 2 \end{pmatrix} .$$

The product $\mathbf{AB}$ is a 4×2 matrix given by

$$\mathbf{A} = \begin{pmatrix} 6 & 1 \\ 0 & -3 \\ -4 & -1 \\ -6 & -1 \end{pmatrix} .$$

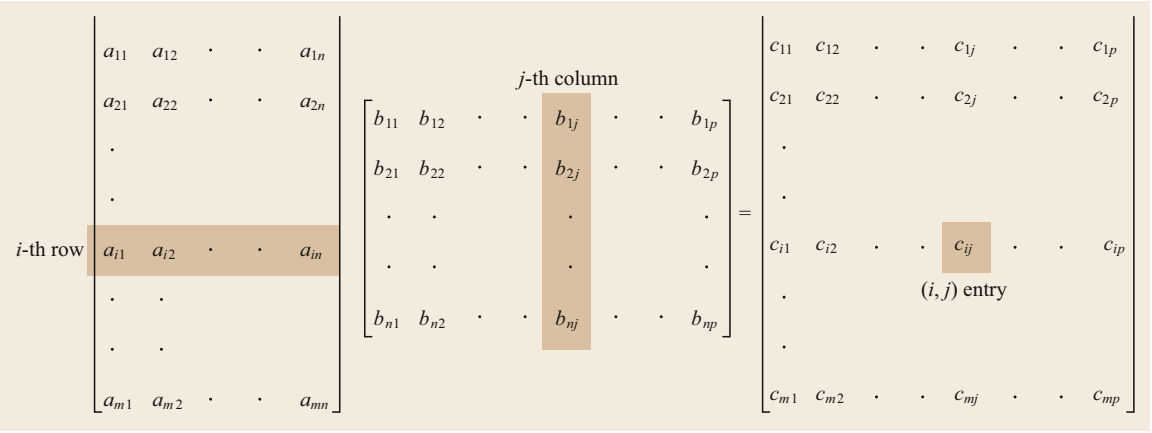

Fig. 1.1 Construction of the matrix product $\mathbf{AB} = \mathbf{C}$

In general, matrix multiplication is not commutative. That is, $\mathbf{AB} \neq \mathbf{BA}$. As can be seen in the example above, the product $\mathbf{BA}$ is not even defined.

For an $m \times n$ matrix $\mathbf{A}$, its transpose $\mathbf{A}^\top$ is obtained by making the rows of $\mathbf{A}$ into columns. That is, the i-th row of $\mathbf{A}$ becomes the i-th column of $\mathbf{A}^\top$. Given that the operations indicated are all valid, we have: $(\mathbf{AB})^\top = \mathbf{B}^\top\mathbf{A}^\top$. We use the notation $\mathbf{A}^k$ to denote the product, $\underbrace{\mathbf{AA}\ldots\mathbf{A}}_{k \text{ times}}$.

Special Matrices

A matrix is said to be *symmetric* if $\mathbf{A}^\top = \mathbf{A}$ and is *skew-symmetric* if $\mathbf{A}^\top = -\mathbf{A}$. A square matrix $\mathbf{A} = (a_{ij})$ is called *upper triangular* (*lower triangular*) if $a_{ij} = 0$ for all $i > j$ ($i < j$), that is, all the entries below (above) the diagonal are zero. The *identity matrix*, $\mathbf{I}_n$ is an $n \times n$ matrix whose diagonal entries are all 1, and the remaining entries are all zero. The *zero matrix*, $\mathbf{0}_{m\times n}$ has all its entries equal to zero.

Determinant

The determinant of a square matrix $\mathbf{A}$ is a real (unique) scalar denoted by $|\mathbf{A}|$ or $\det(\mathbf{A})$. For $n = 1$, $\mathbf{A} = (a_{11})$, and we define $\det(\mathbf{A}) = a_{11}$. For $n \geq 2$, the determinant is defined as (using the i-th row:)

$$|\mathbf{A}| = \sum_{k=1}^{n} a_{ik}(-1)^{i+k} M_{ik}, \quad i = 1, 2, \ldots, n\,. \tag{1.2}$$

or (using the j-th column)

$$|\mathbf{A}| = \sum_{k=1}^{n} a_{kj}(-1)^{k+j} M_{kj}, \quad j = 1, 2, \ldots, n\,. \tag{1.3}$$

Here, M_{ik} is the *minor* of the entry a_{ik}, defined as the determinant of the *submatrix* obtained by deleting the i-th row and the k-th column from $\mathbf{A}$. The quantity $(-1)^{i+k}M_{ik}$ is called the cofactor of a_{ik} and is denoted by C_{ik}. Thus, the determinant of a square matrix can be computed using any row or column of the matrix.

The following properties of determinants are important and useful:

- The determinant of $\mathbf{A}^\top$, the transpose of $\mathbf{A}$, is the same as the determinant of $\mathbf{A}$. That is, $|\mathbf{A}| = |\mathbf{A}^\top|$.
- If a matrix $\mathbf{A}$ has either a row (or a column) of zeros, then $|\mathbf{A}| = 0$.
- If a matrix $\mathbf{A}$ has two identical rows (or columns), then $|\mathbf{A}| = 0$.
- For a square matrix, $\mathbf{A}$ and a scalar k, $|k\mathbf{A}| = k^n\mathbf{A}$.
- For $n \times n$ matrices $\mathbf{A}, \mathbf{B}$, $|\mathbf{AB}| = |\mathbf{A}||\mathbf{B}|$.

Inverse of a Matrix

An $n \times n$ square matrix $\mathbf{A}$ is said be *invertible* if there exists an $n \times n$ matrix $\mathbf{B}$ such that $\mathbf{BA} = \mathbf{AB} = \mathbf{I}_n$. Such an inverse, when it exists, is unique and is denoted by the symbol $\mathbf{A}^{-1}$. If the inverse of $\mathbf{A}$ exists, $\mathbf{A}$ is said to be *nonsingular*, and otherwise it is said to be *singular*.

For an invertible matrix $\mathbf{A}$, the following hold:

- $\mathbf{A}$ is invertible if and only if $|\mathbf{A}| \neq 0$.
- For an $n\times n$ matrix $\mathbf{A} = (a_{ij})$, the matrix $\mathbf{C} = (C_{ij})$ is called the *cofactor matrix* of $\mathbf{A}$, and its transpose $\mathbf{C}^\top$ is called the *adjoint* of $\mathbf{A}$ and is denoted by $\mathrm{adj}(\mathbf{A})$. We have the formula

$$A^{-1} = \frac{\mathrm{adj}(\mathbf{A})}{\det(\mathbf{A})}\,. \tag{1.4}$$

- In particular, for a 2×2 matrix

$$\mathbf{A} = \begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix},$$

we have

$$\mathbf{A}^{-1} = \frac{1}{|\mathbf{A}|}\begin{pmatrix} a_{22} & -a_{12} \\ -a_{21} & a_{11} \end{pmatrix}.$$

- $(\mathbf{A}^{-1})^{-1} = \mathbf{A}$.
- $(\mathbf{A}^{\top})^{-1} = (\mathbf{A}^{-1})^{\top}$.
- For any positive integer k, $(\mathbf{A}^{k})^{-1} = (\mathbf{A}^{-1})^{k}$.
- For invertible $n \times n$ matrices $\mathbf{A}$ and $\mathbf{B}$, we have $(\mathbf{AB})^{-1} = \mathbf{B}^{-1}\mathbf{A}^{-1}$.
- $|\mathbf{A}^{-1}| = 1/|\mathbf{A}|$.

Echelon Form and Systems of Linear Equations

A matrix $\mathbf{U}$ that has the following properties is said to be in *row echelon form*:

1. If a row does not consist entirely of zeros, then the first nonzero entry is called the leading nonzero entry of the row. For two successive rows not consisting entirely of zeros the leading nonzero entry of the lower row occurs to the right of the leading nonzero entry of the row above.
2. If there are any rows consisting of only zero entries, they are grouped together at the bottom of the matrix.

Further, if a matrix $\mathbf{R}$ is in row echelon form and additionally (i) each leading nonzero entry (if any) is 1, (ii) each column containing the leading 1 has zeros everywhere else, R is said to be in *reduced row echelon form*.

Example 1.3

$$\mathbf{U} = \begin{bmatrix} 3 & 5 & 0 & -3 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 7 \end{bmatrix};$$

$$\mathbf{R} = \begin{bmatrix} 1 & 0 & 3 & 0 & 4 \\ 0 & 0 & 0 & 1 & 2 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix}.$$

There are three elementary row operations that can be performed on a matrix:

1. Interchange two rows
2. Multiply an entire row by a nonzero constant
3. Add a nonzero-multiple of a row to another row.

Two matrices $\mathbf{A}, \mathbf{B}$ are said to be *row equivalent* if each can be obtained from the other by means a sequence of elementary row operations. There exists a row echelon matrix $\mathbf{U}$ that is row equivalent to a given matrix $\mathbf{A}$. There exists a unique reduced row echelon matrix $\mathbf{R}$ that is row equivalent to a given matrix $\mathbf{A}$. An $n \times n$ matrix $\mathbf{A}$ is invertible if and only if it is row equivalent to $\mathbf{I}_n$.

The vectors $\boldsymbol{v}_1, \boldsymbol{v}_2, \ldots, \boldsymbol{v}_k$ in $\mathbb{R}^n$ are said to be *linearly independent* if the only scalars $c_1, c_2, \ldots, c_n$ that satisfy the equation

$$c_1\boldsymbol{v}_1 + c_2\boldsymbol{v}_2 + \cdots + c_k\boldsymbol{v}_k = \mathbf{0}$$

are $c_1 = 0, c_2 = 0, \ldots, c_k = 0$. If there are scalars, not all zero, that satisfy this equation, then the vectors are said to be *linearly dependent*.

Given the vectors $\boldsymbol{v}_1, \boldsymbol{v}_2, \ldots, \boldsymbol{v}_k$ in $\mathbb{R}^n$, one way to determine whether they are linearly independent or dependent is to form an $n \times k$ matrix $\mathbf{V}$ with these vectors as the column vectors and determine the associated row echelon form $\mathbf{U}$. If each column in $\mathbf{U}$ contains a leading nonzero entry, then the given vectors are linearly independent. On the other hand, if at least one of the columns in $\mathbf{U}$ does not contain a leading nonzero entry, then the vectors are linearly dependent. The (column) vectors in the matrix $\mathbf{V}$ corresponding to the columns in $\mathbf{U}$ that contain the leading nonzero entries are linearly independent. The maximum number of linearly independent column (or row) vectors in a matrix $\mathbf{A}$ is defined as the *rank* of the matrix $\mathbf{A}$. Clearly, the rank of a matrix $\mathbf{A}$ is the number of columns that contain the leading nonzero entries in its (reduced) row echelon form.

Example 1.4

Let

$$\mathbf{A} = \begin{bmatrix} 2 & 6 & 4 & 8 \\ 4 & 2 & 0 & 0 \\ 3 & 4 & 2 & 5 \end{bmatrix};$$

$$\mathbf{U} = \begin{bmatrix} 1 & 3 & 2 & 4 \\ 0 & 5 & 4 & 7 \\ 0 & 0 & 0 & 0 \end{bmatrix};$$

$\mathbf{A}$ and $\mathbf{U}$ are row equivalent; $\mathbf{U}$ is in row echelon form. The leading nonzero entries of the rows are in the first and the second columns. Columns 3 and 4 do not contain leading nonzero entries. So, the (column) vectors

$$\left\{ \boldsymbol{v}_1 = \begin{pmatrix} 2 \\ 4 \\ 3 \end{pmatrix}, \boldsymbol{v}_2 = \begin{pmatrix} 6 \\ 2 \\ 4 \end{pmatrix}, \boldsymbol{v}_3 = \begin{pmatrix} 4 \\ 0 \\ 2 \end{pmatrix}, \boldsymbol{v}_4 = \begin{pmatrix} 8 \\ 0 \\ 5 \end{pmatrix} \right\}$$

are linearly dependent. Of these four vectors, $\boldsymbol{v}_1, \boldsymbol{v}_2$ that correspond to the columns in $\mathbf{U}$ that contain the leading nonzero entries are linearly independent. Further, $\boldsymbol{v}_3, \boldsymbol{v}_4$ are linearly dependent on the first two vectors. In fact, $(-\frac{2}{5})\boldsymbol{v}_1 + \frac{4}{5}\boldsymbol{v}_2 = \boldsymbol{v}_3$ and $(-\frac{1}{5})\boldsymbol{v}_1 + \frac{7}{5}\boldsymbol{v}_2 = \boldsymbol{v}_4$.

Consider a system of linear equations, $\mathbf{A}\boldsymbol{x} = \boldsymbol{b}$, where $\mathbf{A}$ is an $m \times n$ (coefficient) matrix, $\boldsymbol{x}$ is the (unknown) vector, and $\boldsymbol{b}$ is a given vector. Let $[\mathbf{U}|\tilde{\boldsymbol{b}}]$ be the row echelon form of the augmented matrix $[\mathbf{A}|\boldsymbol{b}]$. The following statements are true:

1. If the augmented matrix $[\mathbf{U}|\tilde{\boldsymbol{b}}]$ has a row of the form $[000\ldots0|a]$, and $a \neq 0$, then the system does not have a solution.
2. If the augmented matrix $[\mathbf{U}|\tilde{\boldsymbol{b}}]$ has a row consisting entirely of zeros, then the system has infinitely many solutions. Further, if $\boldsymbol{b} \equiv \mathbf{0}$, and if r columns of $\mathbf{U}$ have leading nonzero entries, then there are $(n-r)$ number of linearly independent solutions that *span* the set of solutions of the homogeneous system.
3. If $\mathbf{A}$ is an $n \times n$ matrix and is invertible, then there exists a unique solution for $\mathbf{A}\boldsymbol{x} = \boldsymbol{b}$. If in addition, $\boldsymbol{b} \equiv \mathbf{0}$, then $\mathbf{A}\boldsymbol{x} = \mathbf{0}$ has only a trivial solution.
   Solutions to linear systems can be found using Gaussian elimination, or by the Gauss–Jordan elimination method.

1.1.3 Eigenvalues and Eigenvectors of a Square Matrix A

Eigenvalues and eigenvectors of a matrix play an important role in stress analysis and in many other areas of mechanical engineering. Let $\mathbf{A}$ be an $n \times n$ matrix. A scalar λ is called an *eigenvalue* of $\mathbf{A}$ if there is a nonzero $n \times 1$ vector $\boldsymbol{x}$ such that

$$\mathbf{A}\boldsymbol{x} = \lambda\boldsymbol{x}\,. \tag{1.5}$$

All such nonzero vectors $\boldsymbol{x}$ are called eigenvectors of $\mathbf{A}$ corresponding to the eigenvalue λ. The eigenvalues can be determined as roots of the n-th degree *characteristic polynomial*

$$\det(\mathbf{A} - \lambda\mathbf{I}) = 0\,. \tag{1.6}$$

Thus, there are exactly n eigenvalues (counting multiple occurrences). *The eigenvalues may be real or complex numbers.* For each eigenvalue λ, the corresponding eigenvectors are determined as nontrivial solutions of the homogeneous system of equations

$$(\mathbf{A} - \lambda\mathbf{I})\boldsymbol{x} = 0\,. \tag{1.7}$$

For a real matrix $\mathbf{A}$, if an eigenvalue is a complex number, say $\lambda = \alpha + \mathrm{i}\beta$, and $\boldsymbol{v}$ is the corresponding eigenvector, then $\overline{\lambda} = \alpha - \mathrm{i}\beta$ is also an eigenvalue, and the corresponding eigenvector is $\overline{\boldsymbol{v}}$.

Example 1.5

Let

$$\mathbf{A} = \begin{pmatrix} -4 & -1 \\ 2 & -1 \end{pmatrix}.$$

To find the eigenvalues consider $|\mathbf{A} - \lambda\mathbf{I}| = 0$. This results in the characteristic polynomial, $\lambda^2 + 5\lambda + 6 = 0$, and the eigenvalues are $\lambda_1 = -3, \lambda_2 = -2$. The eigenvectors corresponding to $\lambda_1 = -3$ are the solutions of the system: $(\mathbf{A} - (-3)\mathbf{I_2})\ \boldsymbol{v} = 0$. All vectors of the form

$$\begin{pmatrix} t \\ -t \end{pmatrix} \quad \text{for } t \in \mathbb{R}\,,\ t \neq 0\,,$$

are the eigenvectors corresponding to $\lambda_1 = -3$. Similarly, the eigenvectors corresponding to the eigenvalue $\lambda_2 = -2$ are

$$\begin{pmatrix} -t \\ 2t \end{pmatrix} \quad \text{for } t \in \mathbb{R}\,,\ t \neq 0\,.$$

Thus,

$$\boldsymbol{v}_1 = \begin{pmatrix} 1 \\ -1 \end{pmatrix}, \quad \boldsymbol{v}_2 = \begin{pmatrix} -1 \\ 2 \end{pmatrix}$$

are two linearly independent eigenvectors of the matrix $\mathbf{A}$.

The eigenvalues of a symmetric matrix are real, and it has n linearly independent eigenvectors. However, in general, an $n \times n$ matrix may not always have n linearly independent eigenvectors. If an $n \times n$ matrix $\mathbf{A}$ has n linearly independent eigenvectors, $\mathbf{A}$ is said be *diagonalizable*.

Two matrices $\mathbf{A}, \mathbf{B}$ are said to be *similar* if there exists a nonsingular matrix $\mathbf{S}_{n\times n}$, such that $\mathbf{B} = \mathbf{S}^{-1}\mathbf{A}\mathbf{S}$.

Let $\mathbf{P} = [\boldsymbol{v}_1, \boldsymbol{v}_2, \ldots, \boldsymbol{v}_n]$ be the $n \times n$ matrix whose column vectors $\boldsymbol{v}_i$ are the linearly independent eigenvectors of $\mathbf{A}$. Then, we have the relation,

$$\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \begin{pmatrix} \lambda_1 & & 0 \\ & \ddots & \\ 0 & & \lambda_n \end{pmatrix}.$$

The order of appearance of λ_i along the diagonal is according to the order in which the eigenvectors occur as column vectors in $\mathbf{P}$. That is, $\mathbf{A}$ is similar to a diagonal matrix.

Example 1.6
For the matrix $\mathbf{A}$ in Example 1.5, the matrix

$$\mathbf{P} = \begin{pmatrix} 1 & -1 \\ -1 & 2 \end{pmatrix},$$

and it can be verified that

$$\mathbf{P}^{-1}\mathbf{A}\mathbf{P} = \begin{pmatrix} -3 & 0 \\ 0 & -2 \end{pmatrix} = \begin{pmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{pmatrix}.$$

The *algebraic multiplicity* (A.M.) of an eigenvalue λ_i of an $n \times n$ matrix $\mathbf{A}$ is the number of times λ_i occurs as a root of the characteristic polynomial. Moreover, the number of linearly independent eigenvectors associated with the eigenvalue λ_i is called the *geometric multiplicity* (G.M.) of λ_i. In general, G.M. $\leq$ A.M. So, when, we have G.M. $<$ A.M., for an eigenvalue λ_i, we define the following. A nonzero vector $\boldsymbol{v}$ is called a generalized eigenvector of $\mathbf{A}$ corresponding to λ_i if $(\mathbf{A}-\lambda\mathbf{I})^p\boldsymbol{v} = 0$, where p is the smallest such positive integer. For more details see [1.1].

1.2 Differential Equations

Differential equations play an important role in the modeling of physical engineering systems and help analyze and understand the behavior of these systems. Ordinary differential equations (ODEs) arise when the (unknown) functions under study involve only one independent variable, whereas if there are more than one independent variable, we have partial differential equations. The order of an ODE is the order of the highest-order derivative that occurs in the ODE. So, $yy' + y^2 = 1$ is a first-order equation, whereas $y'' + y^3 = \sin x$ is a second-order ODE. The $'$ here is the derivative with respect to the underlying independent variable. Sometimes, the unknown function y may be a function of x, or in some other applications, y may be a function of t. Further, ODEs are classified as linear and nonlinear ODEs. An ODE is said to be *linear* if it does not involve any products of the dependent variable with itself nor with any of its derivatives, and it does not also contain any products of the derivatives of the dependent variable. An ODE that is not linear is said be a *nonlinear* ODE. An ODE of the form $y'' + (\cos x)y = \sin x$ is a linear ODE, whereas $yy' + y^2 = 1$ is a nonlinear ODE. In this section, we present a few methods of solving a few simple classes of ordinary differential equations that arise in the study of several mechanical engineering problems.

1.2.1 First-Order ODEs

A first-order ODE of the form $F(x, y, y') = 0$ is an *implicit* ODE. We assume that it is possible to solve for y' and obtain an explicit ODE of the form $y' = f(x, y)$ on some interval I. By a solution of such an ODE, we mean a function $y = \phi(x)$:

(i) Defined on an (open) interval $J \subset I$
(ii) With ϕ is differentiable on J
(iii) Satisfies the equation $\phi'(x) = f(x, \phi(x))$ for all $x \in J$.

Such a solution is called an explicit solution. If on the other hand, a relation involving the solution of the form $G(x, y) = 0$ is called an *implicit* solution. In general, there is a one-parameter family of solutions for the first-order ODE.

A first-order initial value problem (IVP) is given by

$$y' = f(x, y)\,, \quad y(x_0) = y_0\,, \tag{1.8}$$

where x_0 is some point in the interval I, and y_0 is a given scalar. Such an initial value is guaranteed to have a unique solution if the function f is continuous on a rectangular region R containing the point (x_0, y_0) and satisfies the *Lipschitz condition*

$$|f(x, y_1) - f(x, y_2)| \leq k|y_1 - y_2| \tag{1.9}$$

for all $(x, y_1), (x, y_2) \in R$.

Separable ODE

A first-order ODE of the form

$$f(y)y' = g(x) \tag{1.10}$$

is separable. Integrating both sides with respect to x, we obtain

$$\int f(y)\,\mathrm{d}y = \int g(x)\,\mathrm{d}x + c\,. \tag{1.11}$$

This (usually) results in an implicit solution of the ODE. The c here is an arbitrary constant.

Example 1.7
Find the solution of the IVP

$$2(y-1)\frac{\mathrm{d}y}{\mathrm{d}x} = 3x^2 + 4x + 2\,, \quad y(0) = -1\,.$$

Separating the variables, integrating, and using the initial condition, we obtain

$$y^2 - 2y = x^3 + 2x^2 + 2x + 3 \,.$$

To obtain an explicit solution, we can solve for y in terms of x. We obtain

$$y = 1 \pm \sqrt{x^3 + 2x^2 + 2x + 4} \,.$$

Only one of these two solutions satisfies the initial condition, and we obtain

$$y = 1 - \sqrt{x^3 + 2x^2 + 2x + 4} \,.$$

This is the (unique) solution of the IVP, existing on the interval $(-2, \infty)$.

A first-order ODE of the form $M(x,y)\,\mathrm{d}x + N(x,y)\,\mathrm{d}y = 0$, is said to be a *homogeneous* ODE if both functions M and N are such that $M(\alpha x, \alpha y) = \alpha^n M(x,y); N(\alpha x, \alpha y) = \alpha^n N(x,y)$ for some real number n. A homogeneous ODE can converted to a separable ODE by the transformation $y = xv(x)$.

Linear First-Order ODEs

A first-order ODE of the form $y' + p(x)y = q(x)$, $x \in I$, where p and q are continuous functions on I, is called a *linear* ODE. If $q(x) \equiv 0$, then this equation is called a *homogeneous* linear ODE, otherwise it is called a *non-homogeneous* linear ODE.

The general solution of the linear (nonhomogeneous) first-order ODE is given by

$$y(x) = \mathrm{e}^{-r(x)} \left[\int \mathrm{e}^{r(x)} q(x)\,\mathrm{d}x + c \right], \tag{1.12}$$

where $r(x) = \int p(x)\,\mathrm{d}x$.

A first-order (nonlinear) ODE of the form $y' + p(x)y = q(x)y^n$, $\in I$, for $n \neq 0, 1$ is called a Bernoulli differential equation. A Bernoulli differential equation can be transformed into a linear ODE by the substitution $v = y^{1-n}$.

Second-Order ODEs of Special Form. Second-order ODEs of the form $y'' = f(x, y')$ can be transformed into a first-order ODE by the substitution $y' = u(x)$, whereas, $y'' = f(y, y')$ can be transformed into a first-order ODE by the substitution $y' = u(y)$.

We discuss one simple example bellow, as an illustration.

Example 1.8

Solve the initial-value problem

$$y'' = y'\mathrm{e}^y \,, \quad y(0) = 0 \,, \quad y'(0) = 1 \,.$$

Let $y' = u(y)$. Then $y'' = u\mathrm{d}u/\mathrm{d}y$, and the ODE becomes $u\mathrm{d}u/\mathrm{d}y = u\mathrm{e}^y$. If $u \neq 0$, we get the separable ODE: $\mathrm{d}u/\mathrm{d}y = \mathrm{e}^y$. Solving this we get, $u(y) = y'(x) = \mathrm{e}^{y(x)} + c$. Using the initial conditions, we get $c = 0$. Thus, $y' = \mathrm{e}^y$, which again is a separable ODE. Solving this ODE, and using the initial conditions again, we get,

$$y(x) = \ln\left(\frac{1}{1-x}\right), \quad x \in (-\infty, 1) \,.$$

1.2.2 Numerical Solution of First-Order ODEs

It is not always possible to obtain the solutions of differential equations in a closed form expression. Numerical (approximate) solutions are obtained using a variety of methods. We present here one such commonly used method called *Runge–Kutta method*.

Consider the first-order ODE

$$y' = f(x,y) \,, \quad y(x_0) = y_0 \,, \quad x_0 \le x \le x_N \,. \tag{1.13}$$

Choosing a step size, $h > 0$, the approximate values for the solution $y(x)$ at the points $x_n = x_0 + nh$, $n = 1, 2, \ldots, N$, are determined using the Runge–Kutta method. The R–K scheme involves a weighted average of values of $f(x,y)$ at different points in $[x_n, x_{n+1}]$. The R–K scheme is given below

$$y_{n+1} = y_n + h\left(\frac{k_{n1} + 2k_{n2} + 2k_{n3} + k_{n4}}{6}\right),$$

where

$$\begin{aligned}
k_{n1} &= f(x_n, y_n) \,, \\
k_{n2} &= f\left(x_n + \frac{1}{2}h, y_n + \frac{1}{2}hk_{n1}\right), \\
k_{n3} &= f\left(x_n + \frac{1}{2}h, y_n + \frac{1}{2}hk_{n2}\right), \\
k_{n4} &= f\left(x_n + \frac{1}{2}h, y_n + \frac{1}{2}hk_{n3}\right).
\end{aligned}$$

1.2.3 Second-Order Linear ODEs

The motion of a mass on a vibrating spring, torsional oscillations of a shaft with a flywheel, and several other physical engineering problems are described using second and higher-order linear ODEs. Nonlinear systems arising in such applications may be treated using numerical methods such as the Runge–Kutta method.

Consider the second-order linear IVP

$$y'' + p(x)y' + q(x)y = f(x)\,, \quad x \in I\,, \tag{1.14a}$$
$$y(x_0) = y_0\,, \quad y'(x_0) = y_1\,. \tag{1.14b}$$

The existence of a unique solution for this IVP on an (open) interval I is guaranteed provided that the functions $p(x)$, $q(x)$ and $f(x)$ are continuous on I.

If $y_(x), y_2(x)$ are any two solutions of the second-order linear (homogeneous) ODE

$$y'' + p(x)y' + q(x)y = 0\,, \tag{1.15}$$

then any linear combination $c_1y_1 + c_2y_2$ is also a solution, where c_1 and c_2 are constants.

A pair of functions f_1 and f_2, defined on an internal I are said to be *linearly independent* on I if the only scalars c_1, c_2 that satisfy the equation

$$c_1f_1(x) + c_2f_2(x) = 0 \quad \text{for all } x \in I$$

are $c_1 = c_2 = 0$. If there are scalars, not both zero, that satisfy the equation, then the functions are said to be *linearly dependent* on I.

In particular, two solutions y_1, y_2 of the linear second-order homogeneous ODE are linearly independent if and only if the *Wronskian*,

$$W(y_1, y_2)(x) = \begin{vmatrix} y_1(x) & y_2(x) \\ y_1'(x) & y_2'(x) \end{vmatrix} \neq 0$$

for some $x = x_0 \in I$.

There exist two linearly independent solutions of (1.15), say $\phi_1(x), \phi_2(x)$. The general solution of $y(x)$ of linear homogeneous ODE (1.15) is given by,

$$y(x) = c_1\phi_1(x) + c_2\phi_2(x)\,,$$

where c_1, c_2 are arbitrary constants.

There are no general methods that can be used to find the general solution of (1.15), when the ODE has variable coefficients. However, it is quite easy to solve ODEs with constant coefficients.

Homogeneous Second-Order ODEs with Constant Coefficients

Consider the second-order linear ODE with constant coefficients

$$y'' + py' + qy = 0 \quad \text{on } (-\infty, \infty) \tag{1.16}$$

where p, q are (real) constants. Seeking solutions of the form $y(x) = e^{mx}$, leads to the auxiliary equation,

$$m^2 + pm + q = 0\,.$$

The following three cases arise:

1. The auxiliary equation has two real roots, say m_1, m_2. Thus, we have two linearly independent solutions $\phi_1(x) = e^{m_1x}$, $\phi_2(x) = e^{m_2x}$. Thus, the general solution of (1.16) is given by $y(x) = c_1e^{m_1x} + c_2e^{m_2x}$.
2. The auxiliary equation has repeated (real) roots. That is, $m_1 = m_2$. In this case, $\phi_1(x) = e^{m_1x}$, $\phi_2(x) = xe^{m_2x}$ are two linearly independent solutions of (1.16), and the general solution is given by $y(x) = c_1e^{m_1x} + c_2xe^{m_2x}$.
3. Complex roots for the auxiliary equation occur in pairs. That is, if $\alpha + i\beta$ is a root, then so is $\alpha - i\beta$. The two (real-valued) solutions of (1.16) are given by $\phi_1(x) = e^{\alpha x}\cos(\beta x)$, $\phi_2(x) = e^{\alpha x}\sin(\beta x)$. The general solution is given by $y(x) = e^{\alpha x}(c_1\cos\beta x + c_2\sin\beta x)$.

Nonhomogeneous Linear Second-Order ODE

The general solution of the nonhomogeneous linear ODE (1.14a) is of the form $y(x) = y_h(x) + y_p(x)$, where $y_h(x)$ is the general solution of the (1.15) homogeneous ODE, and $y_p(x)$ is a particular solution of (1.14a). We could use the *method of undetermined coefficients* in case the (1.14a) has constant coefficients, and the function $f(x)$ is of a special type – polynomial, exponential, sine and/or cosine, or a combination/products of these functions. For details on this method, see [1.2]. We outline a different method, one that applies to a large class of ODEs, including the ones with variable coefficients: the method of variation of parameters.

Given two linearly independent solutions of (1.15), $\phi_1(x), \phi_2(x)$, we know that the Wronskian $W(\phi_1, \phi_2)(x) \neq 0$. By the method of variation of parameters, a particular solution of (1.14a) is obtained in the form, $y_p(x) = c(x)\phi_1(x) + c_2(x)\phi_2(x)$, where

$$c_1(x) = \int \frac{\begin{vmatrix} 0 & \phi_2(x) \\ f(x) & \phi_2'(x) \end{vmatrix}}{W(\phi_1, \phi_2)(x)}\,\mathrm{d}x\,,$$
$$c_2(x) = \int \frac{\begin{vmatrix} \phi_1(x) & 0 \\ \phi_1'(x) & f(x) \end{vmatrix}}{W(\phi_1, \phi_2)(x)}\,\mathrm{d}x\,.$$

The following example illustrates the ideas discussed in the section.

Example 1.9

Solve

$$y'' + y = \sec x\,, \quad y(0) = 1\,,\ y'(0) = -1\,.$$

The auxiliary equation for the associated homogeneous equation $y''+y=0$, $\lambda^2+1=0$. The roots are $\lambda=\pm i$. The general solution $y_h(x)$ is, $y_h(x)=c_1\cos x+c_2\sin x$. Clearly, $W(\cos x,\sin x)\equiv 1$. Using the above formulas, we obtain

$$c_1(x)=-\int \sec x\sin x\,dx=\ln(\cos x)\,,$$
$$c_2(x)=\int \sec x\cos x\,dx=1\,.$$

So the particular solution is

$$y_p(x)=x\sin x+\cos x[\ln(\cos x)]$$

and the general solution of the nonhomogeneous equation is

$$y(x)=c_1\cos x+c_2\sin x + x\sin x+\cos x[\ln(\cos x)]\,.$$

Using the initial conditions, we can determine the constants c_1, c_2 and we get

$$y(x)=\cos x-\sin x+x\sin x+\cos x[\ln(\cos x)]\,.$$

The Cauchy–Euler Equation. A second-order ODE of the form,

$$ax^2y''+bxy'+cy=0 \quad \text{on } (0,\infty)\,, \tag{1.17}$$

is called a Cauchy–Euler equation. We seek a solution of the form $y(x)=x^m$, resulting in the auxiliary equation

$$am(m-1)+bm+c=0\,.$$

Again, we have the three following cases:

1. The auxiliary equation has two real roots, say m_1, m_2. Then, x^{m_1}, x^{m_2} are two linearly independent solutions, and the general solution is given by $y_h(x)=c_1x^{m_1}+c_2x^{m_2}$.
2. The auxiliary equation has repeated roots, say $m_1=m_2$. The two linearly independent solutions are $x^{m_1}, x^{m_1}\ln x$. The general solution is $y_h(x)=c_1x^{m_1}+c_2x^{m_1}\ln x$.
3. The auxiliary equation has (a pair of) complex roots $\alpha\pm i\beta$. Then, $x^\alpha\cos(\beta\ln x)$ and $x^\alpha\sin(\beta\ln x)$ are the two linearly independent solutions resulting in the general solution: $y_h(x)=x^\alpha[c_1\cos(\beta\ln x)+c_2\sin(\beta\ln x)]$.

The principles outlined above extend in a very straightforward manner for higher-order linear ODEs as well. So, in general, for an n-th order linear nonhomogeneous ODE,

$$a_n(x)y^{(n)}+a_{n-1}(x)y^{(n-1)}+\ldots + a_1(x)y'+a_0(x)y=f(x)\,,\quad x\in I\,, \tag{1.18}$$

the general solution is of the form

$$y(x)=c_1\phi_1(x)+\ldots+c_n\phi_n(x)+y_p(x)\,,$$

where $\phi_1(x),\ldots,\phi_n(x)$ are linearly independent solutions of associated n-th order linear homogeneous ODE

$$a_n(x)y^{(n)}+a_{n-1}(x)y^{(n-1)}+\ldots + a_1(x)y'+a_0(x)y=0\,,\quad x\in I\,, \tag{1.19}$$

and $y_p(x)$ is a particular solution of (1.18). For details on the solutions of higher-order ODE, see [1.3].

1.2.4 Systems of Linear First-Order ODEs

Systems of ODEs arise in most physical and engineering applications when there are several (unknown) dependent variables, all depending on the same independent variable. We discuss here only the first-order, linear ODE with constant coefficients

$$\begin{aligned} y_1' &= a_{11}y_1+a_{12}y_2+\cdots+c_{1n}y_n\,,\\ y_2' &= a_{21}y_1+a_{22}y_2+\cdots+c_{2n}y_n\,,\\ &\vdots\\ y_n' &= a_{11}y_1+a_{12}y_2+\cdots+c_{1n}y_n\,. \end{aligned}$$

This system is written in the matrix-vector form: $\boldsymbol{Y}'=\mathbf{A}\boldsymbol{Y}$. It has n linearly independent solution vectors, say $\phi_1(x),\phi_2(x),\ldots,\phi_n(x)$. An $n\times n$ matrix $\Phi(x)$ whose columns are these linearly independent solution vectors is called a *fundamental matrix* of the system. In particular, $\Phi(x)=e^{\mathbf{A}x}$ is the fundamental matrix with $\Phi(0)=I$, $-\infty<x<\infty$:

1. If $\lambda_1,\lambda_2,\ldots,\lambda_n$ are distinct eigenvalues of the matrix $\mathbf{A}$, and $\boldsymbol{v}_1,\boldsymbol{v}_2,\ldots,\boldsymbol{v}_n$ are the corresponding eigenvectors, the solution vectors $\phi_i(x)=e^{\lambda_i x}\boldsymbol{v}_i$, $i=1,2,\ldots,n$ are linearly independent.
2. If $\lambda_1,\lambda_2,\ldots\lambda_k$ are eigenvalues of the matrix $\mathbf{A}$, with respective multiplicities $n_1,n_2,\ldots,n_k$ with $\sum_{j=1}^k n_j=n$. Corresponding to each eigenvalue λ_j of multiplicity n_j consider the system of linear equations

   $$(\mathbf{A}-\lambda_j\mathbf{I})^{n_j}\boldsymbol{x}=0\quad (j=1,2,\ldots,k)\,.$$

   The solutions of each such linear system span a subspace $X_j\subset\mathbb{R}^n$, and for every $\boldsymbol{x}\in\mathbb{R}^n$ there ex-

ist unique vectors $\boldsymbol{x}_j \in X_j$ such that $\boldsymbol{x} = \boldsymbol{x}_1 + \boldsymbol{x}_2 + \cdots + \boldsymbol{x}_k$. Now, the (unique) solution of the initial value problem $\boldsymbol{Y}' = \mathbf{A}\boldsymbol{Y}$, $\boldsymbol{Y}(0) = \boldsymbol{\eta}$ is given by

$$\boldsymbol{\phi}(x) = \sum_{j=1}^{k} \mathrm{e}^{\lambda_j x} \left[\sum_{i=0}^{n_j - 1} \frac{x^i}{i!} (A - \lambda_j I)^i \right] \boldsymbol{v}_j \qquad (-\infty < x < \infty) \,. \tag{1.20}$$

Here, $\boldsymbol{\eta} = \boldsymbol{v}_1 + \boldsymbol{v}_2 + \ldots \boldsymbol{v}_j$, and $\boldsymbol{v}_j$ is a suitable vector in X_j.

Example 1.10

[1.3] Let us find the solution $\phi(x)$ of the IVP

$$\begin{aligned} x_1' &= 3x_1 - x_2 + x_3 \,, \\ x_2' &= 2x_1 + \quad + x_3 \,, \\ x_3' &= x_1 - x_2 + 2x_3 \end{aligned}$$

satisfying the initial condition $\phi(0) = \eta$.

It is easy to find that the eigenvalues of the coefficient matrix $\mathbf{A}$ are $\lambda_1 = 1, \lambda_2 = 2$ with $n_1 = 1, n_2 = 2$. The eigenvectors corresponding to $\lambda_1 = 1$ are

$$\begin{pmatrix} 0 \\ t \\ t \end{pmatrix}, \quad t \in \mathbb{R} \,,\ t \neq 0 \,.$$

Solutions of the system $(\mathbf{A} - \lambda \mathbf{I})^2 \boldsymbol{x} = 0$ are

$$\begin{pmatrix} t \\ t \\ s \end{pmatrix}, \quad t, s \in \mathbb{R} \,,\ t, s \neq 0 \,,$$

simultaneously. Let

$$\eta = \boldsymbol{v}_1 + \boldsymbol{v}_2 = \begin{pmatrix} \eta_1 \\ \eta_2 \\ \eta_3 \end{pmatrix} = \begin{pmatrix} 0 \\ \alpha \\ \alpha \end{pmatrix} + \begin{pmatrix} \beta \\ \beta \\ \gamma \end{pmatrix} .$$

This leads to

$$\boldsymbol{v}_1 = \begin{pmatrix} 0 \\ \eta_2 - \eta_1 \\ \eta_2 - \eta_1 \end{pmatrix}$$

and

$$\boldsymbol{v}_2 = \begin{pmatrix} \eta_1 \\ \eta_1 \\ \eta_3 - \eta_2 + \eta_1 \end{pmatrix} .$$

Substituting these vectors in (1.20), we obtain the solution.

Numerical Solution of First-Order Systems of ODEs

For most (nonlinear) systems of ODE that arise in real-world applications, obtaining numerical solutions is, often, the only choice available. In this section, we discuss two methods that can be used to solve systems of ODE numerically. For more details, see [1.4].

Consider the following initial value problem

$$\boldsymbol{Y}' = \boldsymbol{f}(x, \boldsymbol{Y}), \quad \boldsymbol{Y}(x_0) = \boldsymbol{y}_0 \,. \tag{1.21}$$

We assume that $\boldsymbol{f}$ is such that the problem has a unique solution $\boldsymbol{Y}(x)$ on some open x-interval containing x_0.

The Euler Method. For $x_j = x_0 + jh$ for $j = 1, 2, \ldots$ where h the step size h is a fixed number, define the iterates $\boldsymbol{Y}_n$ (approximate values of the solutions at x_j's) as follows

$$\boldsymbol{Y}_{j+1} = \boldsymbol{Y}_j + h\boldsymbol{f}(x_j, \boldsymbol{Y}_j) \,. \tag{1.22}$$

In terms of the components of $\boldsymbol{Y}_j$ we have, for $i = 1, 2, \ldots, n$, and $j = 1, 2, \ldots$

$$y_{i,j+1} = y_{i,j} + hf_i(x_j, y_{i,j}) \,. \tag{1.23}$$

However, the Euler method is not accurate enough for practical purposes. A more efficient method is the fourth-order Runge–Kutta method. For each step $j = 1, 2, \ldots$, we have the following four auxiliary quantities

$$\begin{aligned} \boldsymbol{k}_1 &= h\boldsymbol{f}(x_j, \boldsymbol{Y}_j) \,, \\ \boldsymbol{k}_2 &= h\boldsymbol{f}\left(x_j + \frac{1}{2}h, \boldsymbol{Y}_j + \frac{1}{2}\boldsymbol{k}_1\right) , \\ \boldsymbol{k}_3 &= h\boldsymbol{f}\left(x_j + \frac{1}{2}h, \boldsymbol{Y}_j + \frac{1}{2}\boldsymbol{k}_2\right) , \\ \boldsymbol{k}_4 &= h\boldsymbol{f}(x_j + h, \boldsymbol{Y}_j + \boldsymbol{k}_3) \,, \end{aligned}$$

and the new value (approximation of the solution $\boldsymbol{y}(x)$ at $x_{j+1} = x_0 + (j+1)h$) is

$$\boldsymbol{Y}_{j+1} = \boldsymbol{Y}_j + \frac{1}{6}(\boldsymbol{k}_1 + 2\boldsymbol{k}_2 + 2\boldsymbol{k}_3 + \boldsymbol{k}_4) \,.$$

These numerical schemes are, of course, applicable for the scalar ODE ($n = 1$) as well.

1.3 The Laplace Transform

Transform techniques are very useful in solving a variety of problems arising in engineering and physical sciences. The basic paradigm is to transform the given problem to a different domain in which the problem is recast in a form that is easier to solve or/and gives an insightful perspective of the underlying problem. Integral transforms such as the Laplace transform and the Fourier transform are the most popular among the integral transforms. Here in this section, we consider the Laplace transform, present its properties, and its use in solving initial value problems for ODE. Using the Laplace transform on such a problem results in an algebraic problem that can be solved easily in the transform domain. To obtain the solution of the original problem, one needs to use the *inverse Laplace transform* and transform the solution obtained in the transform domain back to the original domain.

The schematic diagram given in Fig. 1.2 illustrates the idea of using the Laplace transform to solve initial value problems for ODEs.

1.3.1 The Laplace Transform: Definition and Properties

For a piecewise continuous function $f : [0, \infty) \to \mathbb{R}$, we may define the *Laplace transform* of f as follows. For a suitable transform variable, say s,

$$F(s) = \mathcal{L}\{f(t)\} = \int_0^\infty f(t)\, \mathrm{e}^{-st}\, \mathrm{d}t\,, \tag{1.24}$$

provided that the integral exists. Usually, the Laplace transform of a function $f(t)$ is denoted by the same letter in uppercase as $F(s)$. Such a Laplace transform exists, for example, for a function of *exponential order*. That is, if there exist positive constants M, T, and α such that $|f(t)| \le M\mathrm{e}^{\alpha t}$ for all $t \ge T$. If $F(s)$ is the Laplace transform of a function $f(t)$, then the *inverse Laplace transform* $\mathcal{L}^{-1}\{F(s)\} = f(t)$.

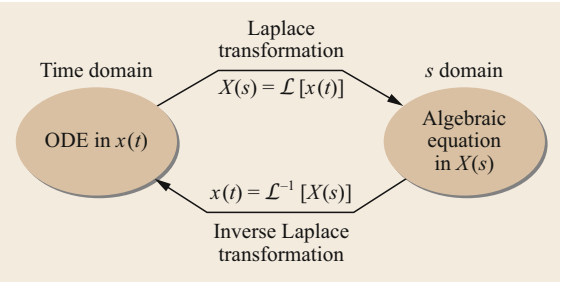

Fig. 1.2 Operations involved in the Laplace transform method

The following properties of the Laplace transform are useful in solving initial value problems:

1. Linearity: $\mathcal{L}\{af(t)+bg(t)\} = a\mathcal{L}\{f(t)\}+b\mathcal{L}\{g(t)\}$. Here a, b are constants.
2. For
$$\mathcal{U}(t-a) = \begin{cases} 1\,, & \text{if } t \ge a\,, \\ 0\,, & \text{if } t < a\,, \end{cases}$$
$$\mathcal{L}\{\mathcal{U}(t-a)\} = \frac{\mathrm{e}^{-as}}{s}\,.$$
3. Translation properties:
(i) $\mathcal{L}\{f(t)\,\mathrm{e}^{at}\} = F(s-a)$
(ii) $\mathcal{L}\{f(t)\,\mathcal{U}(t-a)\} = \mathrm{e}^{-as}\mathcal{L}\{f(t+a)\}$
(iii) $\mathcal{L}\{f(t-a)\,\mathcal{U}(t-a)\} = \mathrm{e}^{-as}F(s)$
4. $\mathcal{L}\{t^n f(t)\} = (-1)^n \mathrm{d}^n/\mathrm{d}s^n F(s)$
5. $\mathcal{L}\{f(t)/t\} = \int_s^\infty F(\sigma)\,\mathrm{d}\sigma$
6. $\mathcal{L}\{\delta(t-t_0)\} = \mathrm{e}^{-st_0}$.
Here, $\delta(t)$ is the Dirac delta function, $t_0 > 0$ is a real number.
7. If $F(s) = \mathcal{L}\{f(t)\}$, then
$$\mathcal{L}\{f'(t)\} = sF(s) - f(0)\,, \tag{1.25}$$
$$\mathcal{L}\{f''(t)\} = s^2F(s) - sf(0) - f'(0)\,. \tag{1.26}$$
In general,
$$\mathcal{L}\{f^{(n)}(t)\} = s^nF(s) - s^{n-1}f(0) - s^{n-2}f'(0) - \cdots - f^{(n-1)}(0)\,. \tag{1.27}$$
8. If $F(s) = \mathcal{L}\{f(t)\}$, then
$$\mathcal{L}\left\{\int_0^t f(\tau)\,\mathrm{d}\tau\right\} = \frac{F(s)}{s}\,. \tag{1.28}$$
9. For piecewise continuous functions f, g on $[0, \infty)$ that are of exponential order, the *convolution* of f and g is defined as
$$(f \star g)(t) = \int_0^t f(\tau)g(t-\tau)\,\mathrm{d}\tau\,. \tag{1.29}$$
We have
$$\mathcal{L}\{(f \star g)(t)\} = F(s)\,G(s)\,, \tag{1.30}$$
where $F(s) = \mathcal{L}\{f(t)\}$ and $G(s) = \mathcal{L}\{g(t)\}$.

10. A piecewise continuous function $f(t)$ is said to be a periodic function with period $T > 0$ if it is defined for all $t > 0$, and $f(t+T) = f(t)$ for all $t > 0$. For such a function,

$$\mathcal{L}\{f(t)\} = F(s) = \frac{1}{1-\mathrm{e}^{-sT}} \int_0^T f(t)\mathrm{e}^{-st}\,\mathrm{d}t\,. \tag{1.31}$$

Table of Laplace Transform Pairs

In Table 1.1, we present the Laplace transforms of several functions. The same table can also be used to find the inverse transforms as well.

Table 1.1 Laplace transform pairs

No.	$f(t)$	$F(s)$
1	Unit impulse $\delta(t)$	1
2	1 , unit step $u_s(t)$	$\frac{1}{s}$
3	t , unit ramp $u_r(t)$	$\frac{1}{s^2}$
4	$\delta(t-a)$	e^{-as}
5	$u(t-a)$	$\frac{\mathrm{e}^{-as}}{s}$
6	t^{n-1} , $n = 1, 2, \ldots$	$\frac{(n-1)!}{s^n}$
7	t^{a-1} , $a > 0$	$\frac{\Gamma(a)}{s^a}$
8	e^{-at}	$\frac{1}{s+a}$
9	$t\mathrm{e}^{-at}$	$\frac{1}{(s+a)^2}$
10	$t^n\mathrm{e}^{-at}$, $n = 1, 2, \ldots$	$\frac{n!}{(s+a)^{n+1}}$
11	$\frac{1}{b-a}(\mathrm{e}^{-at} - \mathrm{e}^{-bt})$, $a \neq b$	$\frac{1}{(s+a)(s+b)}$
12	$\frac{1}{a-b}(a\mathrm{e}^{-at} - b\mathrm{e}^{-bt})$, $a \neq b$	$\frac{s}{(s+a)(s+b)}$
13	$\frac{1}{ab}\left(1 + \frac{1}{a-b}(b\mathrm{e}^{-at} - a\mathrm{e}^{-bt})\right)$	$\frac{1}{s(s+a)(s+b)}$
14	$\frac{1}{a^2}(-1 + at + \mathrm{e}^{-at})$	$\frac{1}{s^2(s+a)}$
15	$\frac{1}{a^2}(1 - \mathrm{e}^{-at} - at\mathrm{e}^{-at})$	$\frac{1}{s(s+a)^2}$
16	$\sin \omega t$	$\frac{\omega}{s^2+\omega^2}$
17	$\cos \omega t$	$\frac{s}{s^2+\omega^2}$
18	$\mathrm{e}^{-\sigma t}\sin \omega t$	$\frac{\omega}{(s+\sigma)^2+\omega^2}$

Table 1.1 (continued)

No.	$f(t)$	$F(s)$
19	$\mathrm{e}^{-\sigma t}\cos \omega t$	$\frac{\omega^2}{s(s^2+\omega^2)}$
20	$1 - \cos \omega t$	$\frac{s+\sigma}{(s+\sigma)^2+\omega^2}$
21	$\omega t - \sin \omega t$	$\frac{\omega^3}{s^2(s^2+\omega^2)}$
22	$t\cos \omega t$	$\frac{s^2-\omega^2}{(s^2+\omega^2)^2}$
23	$\frac{1}{2\omega}t\sin \omega t$	$\frac{s}{(s^2+\omega^2)^2}$
24	$\frac{1}{2\omega^3}(\sin \omega t - \omega t\cos \omega t)$	$\frac{1}{(s^2+\omega^2)^2}$
25	$\frac{1}{2\omega}(\sin \omega t + \omega t\cos \omega t)$	$\frac{s^2}{(s^2+\omega^2)^2}$
26	$\frac{1}{\omega_2^2-\omega_1^2}\left(\frac{1}{\omega_2}\sin \omega_2 t - \frac{1}{\omega_1}\sin \omega_1 t\right)$, $\omega_1^2 \neq \omega_2^2$	$\frac{1}{(s^2+\omega_1^2)(s^2+\omega_2^2)}$
27	$\frac{1}{\omega_2^2-\omega_1^2}(\cos \omega_1 t - \cos \omega_2 t)$, $\omega_1^2 \neq \omega_2^2$	$\frac{s}{(s^2+\omega_1^2)(s^2+\omega_2^2)}$
28	$\sinh at$	$\frac{a}{s^2-a^2}$
29	$\cosh at$	$\frac{s}{s^2-a^2}$
30	$\frac{1}{a^2-b^2}\left(\frac{1}{a}\sinh at - \frac{1}{b}\sinh bt\right)$, $a \neq b$	$\frac{1}{(s^2-a^2)(s^2-b^2)}$
31	$\frac{1}{a^2-b^2}[\cosh at - \cosh bt]$, $a \neq b$	$\frac{s}{(s^2-a^2)(s^2-b^2)}$
32	$\frac{1}{3a^2}\left[\mathrm{e}^{-at} + 2\mathrm{e}^{\frac{1}{2}at}\sin\left(\frac{\sqrt{3}}{2}at - \frac{\pi}{6}\right)\right]$	$\frac{1}{s^3-a^3}$
33	$\frac{1}{3a}\left[-\mathrm{e}^{-at} + 2\mathrm{e}^{\frac{1}{2}at}\sin\left(\frac{\sqrt{3}}{2}at + \frac{\pi}{6}\right)\right]$	$\frac{s}{s^3-a^3}$
34	$\frac{1}{3a^2}\left[\mathrm{e}^{at} - 2\mathrm{e}^{-\frac{1}{2}at}\sin\left(\frac{\sqrt{3}}{2}at + \frac{\pi}{6}\right)\right]$	$\frac{1}{s^3-a^3}$
35	$\frac{1}{3a}\left[\mathrm{e}^{-at} + 2\mathrm{e}^{-\frac{1}{2}at}\sin\left(\frac{\sqrt{3}}{2}at - \frac{\pi}{6}\right)\right]$	$\frac{s}{s^3-a^3}$
36	$\frac{1}{4a^3}(\cosh at \sin at - \sinh at \cos at)$	$\frac{1}{s^4+4a^4}$
37	$\frac{1}{2a^2}\sinh at \sin at$	$\frac{s}{s^4+4a^4}$
38	$\frac{1}{2a^3}(\sinh at - \sin at)$	$\frac{1}{s^4-a^4}$
39	$\frac{1}{2a^2}(\cosh at - \cos at)$	$\frac{s}{s^4-a^4}$

1.3.2 The Inverse Laplace Transform

The inverse Laplace transform plays an important role in solving initial value problems. In general, the process of finding the inverse transform of the solution to the transformed problem to obtain the solution of the original problem often involves the use of algebraic techniques, prior to invoking the properties of Laplace transform. To determine the inverse transform of rational functions of the form,

$$F(s) = \frac{N(s)}{D(s)} = \frac{\text{polynomial of degree } m}{\text{polynomial of degree } n}\,, \quad m < n\,,$$

using the idea of *partial fractions* we can express $F(s)$ as a sum of (simpler) rational functions and find the inverse Laplace transform of each rational function using the table of transforms. There are a few scenarios that depend on the factors of $D(s)$. Factors of $D(s)$ may be linear, repeated linear, irreducible polynomial, or repeated irreducible polynomial.

Case (i): linear factors. That is,

$$D(s) = (s-a_1)(s-a_2)\cdots(s-a_k)\,.$$

Then, we express,

$$F(s) = \frac{N(s)}{D(s)} = \frac{A_1}{(s-a_1)} + \frac{A_2}{(s-a_2)} + \cdots + \frac{A_k}{(s-a_k)}\,.$$

Case (ii): repeated linear factors. If a root of $D(s)$, say, a_i, with multiplicity m, then, $D(s)$ contains the factor $(s-a_i)^m$. This factor is associated with the partial fractions of the form,

$$\frac{A_1}{(s-a_1)} + \frac{A_2}{(s-a_2)^2} + \cdots + \frac{Ak-1}{(s-a_{m-1})^{m-1}} + \frac{A_k}{(s-a_m)^m}\,.$$

Case (iii): irreducible polynomial factor. If $D(s)$ has a pair of complex (conjugate) roots, then $D(s)$ is of the form s^2+as+b. Each irreducible polynomial is associated with a single fraction of the form

$$\frac{Bs+C}{s^2+as+b}\,.$$

This term can be rewritten as

$$\frac{Bs+C}{s^2+as+b} = \frac{BS+C}{(s+\sigma)^2+\omega^2}\,.$$

This, in turn, can be written in terms of rational functions of the form

$$\frac{\omega}{(s+\sigma)^2+\omega^2} \quad \text{and} \quad \frac{s+\omega}{(s+\sigma)^2+\omega^2}\,,$$

and then the inverse Laplace transform can be determined.

Case (iv): repeated irreducible polynomial factor. That is, $D(s)$ has a factor of the form $(s^2+as+b)^m$. In this case, the fractions formed are

$$\frac{B_1s+C_1}{(s^2+as+b)} + \frac{B_2s+C_2}{(s^2+as+b)^2} + \cdots + \frac{B_ms+C_m}{(s^2+as+b)^m}\,.$$

Example 1.11

Let $F(s) = s/(s+16)^2$. Clearly,

$$F(s) = -\frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}s}\left(\frac{1}{(s^2+16)}\right).$$

Invoking property (4) of the Laplace transform listed above, we have $\mathcal{L}^{-1}\{F(s)\} = \frac{1}{8}t\sin t$.

Example: Let

$$F(s) = \frac{6s+3}{s^4+5s^2+4}\,.$$

Using the procedure outlined above in case (iv) for partial fractions, we can show that

$$\frac{6s+3}{s^4+5s^2+4} = \frac{2s}{s^2+1} + \frac{1}{s^2+1} - \frac{2s}{s^2+4} - \frac{\sin 2s}{2}\,.$$

Taking the inverse transform, we obtain $f(t) = 2\cos t + \sin t - 2\cos 2t - \frac{1}{2}\sin 2t$.

Example 1.12

Let us solve the initial value problem: $y'' + y = \sin t$, $y(0) = y'(0) = 0$. Applying the Laplace transform on the nonhomogeneous ODE and using the initial conditions, we obtain

$$Y(s) = \frac{1}{(s^2+1)^2}\,.$$

Invoking property (9) above, we obtain

$$y(t) = \mathcal{L}^{-1}\{Y(s)\} = \mathcal{L}^{-1}\left\{\frac{1}{(s^2+1)}\frac{1}{(s^2+1)}\right\} = \frac{\sin t - t\cos t}{2}\,.$$

Example 1.13
Solve

$$y'' + 4y = \sin t\,\mathcal{U}(t-2\pi)\,, \quad y(0) = 1\,, y'(0) = 0\,.$$

Applying the Laplace transform on the ODE and using the initial conditions, we obtain

$$Y(s) = \frac{s}{s^2+4} + \frac{\mathrm{e}^{-2\pi s}}{(s^2+1)(s^2+4)}\,.$$

It can be easily verified that

$$\mathcal{L}^{-1}\left\{\frac{1}{(s^2+1)(s^2+4)}\right\} = \frac{1}{3}\sin t - \frac{2}{3}\sin 2t\,.$$

Now, using the property (3)(ii) of the Laplace transform, we obtain

$$\mathcal{L}^{-1}\left\{\frac{\mathrm{e}^{-2\pi s}}{(s^2+1)(s^2+4)}\right\} = \frac{1}{3}\sin t\,\mathcal{U}(t-2\pi) - \frac{2}{3}\sin 2t\,\mathcal{U}(t-2\pi)\,.$$

Finally, finding the inverse transform, we obtain

$$y(t) = \begin{cases} \cos 2t\,, & 0 \le t < 2\pi\,, \\ \cos 2t + \dfrac{1}{3}\sin t - \dfrac{2}{3}\sin 2t\,, & t \ge 2\pi\,. \end{cases}$$

1.4 Fourier Analysis

A Fourier series represents a general periodic function in terms of an infinite series of sine and cosine functions, where the coefficients of the series are obtained by using the *orthogonality* properties of the sine and cosine functions on the interval under consideration. Fourier series are widely used in various applications involving ordinary or partial differential equations. On the other hand, the Fourier transform maps a function defined in the time domain to one in the frequency domain. We outline the most basic ideas of this vast and fascinating subject.

1.4.1 Fourier Series

Let $f(x)$ be a piecewise continuous function defined on an interval $(-c, c)$ for $c > 0$. We may extend this function to all of $\mathbb{R}$ as a periodic function of period $p = 2c$. That is, $f(x+p) = f(x)$ for all $x \in \mathbb{R}$. Such functions may be represented by the *Fourier series* of the form

$$\frac{a_0}{2} + \sum_{n=1}^{\infty}\left(a_n \cos\frac{n\pi x}{c} + b_n \sin\frac{n\pi x}{c}\right), \tag{1.32}$$

where the *Fourier coefficients* of $f(x)$ are given by the Euler–Fourier formulas, as

$$a_n = \frac{1}{c}\int_{-c}^{c} f(x)\cos\frac{n\pi x}{c}\,\mathrm{d}x\,, \quad n = 0, 1, \ldots\,, \tag{1.33}$$

$$b_n = \frac{1}{c}\int_{-c}^{c} f(x)\sin\frac{n\pi x}{c}\,\mathrm{d}x\,, \quad n = 1, \ldots \tag{1.34}$$

If the function f is piecewise smooth on $(-c, c)$, that is, both f and f' are piecewise continuous on $(-c, c)$, and $F(x)$ is the $2c$ periodic extension of f, then at each $x \in (-\infty, \infty)$, the Fourier series for f on $(-c, c)$ converges to the average value $(F(x+) + F(x-))/2$.

Each term of the Fourier series above may be written as a *harmonic*, $A\cos(n\pi x/c + \phi)$, where the *amplitude* A is $\sqrt{a^2+b^2}$, the *angular frequency* is $n\pi/c$, and the initial phase ϕ is $\tan^{-1}(b_n/a_n)$. These harmonics describe the variation of f about its average value $\frac{1}{2}a_0$.

If a function f is defined only on $(0, c)$ for $c > 0$, then we can consider the *even* ($f(-x) = f(x)$) and *odd* ($f(-x) = -f(-x)$) extensions of f onto $(-c, c)$. We thus have a *Fourier cosine series* (consisting only of the cosine terms) and a *Fourier sine series* (consisting only of sine terms) for a function f on $(0, c)$. On the other hand, the mapping $s = (2x-b-a)c/(b-a)$ maps the interval $[a, b]$ to the interval $[-c, c]$, and we can write a Fourier series for a function $f(x)$ defined on an interval (a, b) as

$$\frac{a_0}{2} + \sum_{n=1}^{\infty} a_n \cos\frac{n(2x-b-a)c}{(b-a)} + b_n \sin\frac{n(2x-b-a)c}{(b-a)}\,, \tag{1.35}$$

where

$$a_n = \frac{2}{(b-a)}\int_{a}^{b} f(x)\cos\frac{n(2x-b-a)c}{(b-a)}\,\mathrm{d}x\,, \quad n = 0, 1, \ldots\,, \tag{1.36}$$

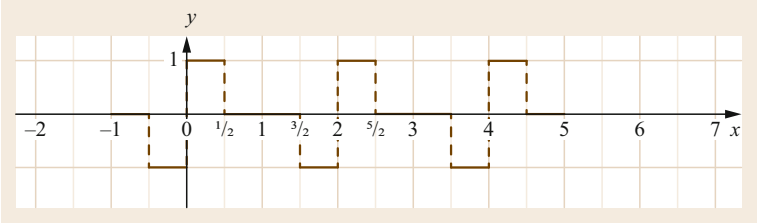

Fig. 1.3 Odd-periodic extension of $f(x)$

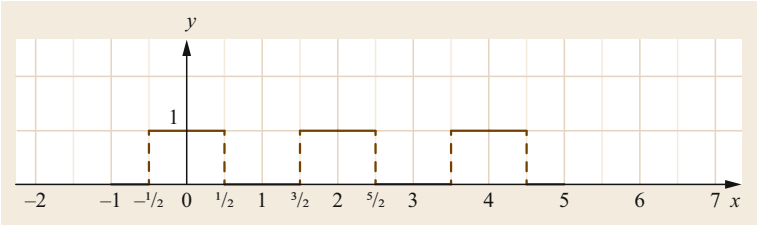

Fig. 1.4 Even-periodic extension of $f(x)$

and

$$b_n = \frac{2}{(b-a)} \int_a^b f(x) \sin \frac{n(2x-b-a)c}{(b-a)} \, \mathrm{d}x \,,$$
$$n = 1, 2, \ldots \qquad (1.37)$$

Example 1.14 gives all the three types of series for a given function.

Example 1.14

Let

$$f(x) = \begin{cases} 1 \,, & 0 < x < \dfrac{1}{2} \,, \\ 0 \,, & \dfrac{1}{2} < x < 1 \,. \end{cases}$$

Find (i) the Fourier sine series, (ii) the Fourier cosine series, and (iii) Fourier series for $f(x)$:

(i) Upon extending the function as an odd function on to $(-1, 1)$ (Fig. 1.3), we have $a_n = 0$ and

$$b_n = 2 \int_0^1 f(x) \sin n\pi x \, \mathrm{d}x$$
$$= \frac{2}{n\pi} \left[1 - \cos\left(\frac{n\pi}{2}\right) \right].$$

So, we have

$$b_1 = \frac{2}{\pi} \,, \quad b_2 = \frac{2}{\pi} \,,$$
$$b_3 = \frac{2}{3\pi} \,, \quad b_4 = 0 \,, \quad \ldots$$

Therefore, the Fourier sine series of f is

$$\frac{2}{\pi} \left(\sin \pi x + \frac{2 \sin 2\pi x}{2} + \frac{\sin 3\pi x}{3} + \sin 5\pi x 5 + \frac{2 \sin 6\pi x}{6} + \ldots \right).$$

(ii) Extending f onto $(-c, c)$ as an even function (Fig. 1.4), we have $b_n = 0$ and

$$a_n = 2 \int_0^1 f(x) \cos n\pi x \, \mathrm{d}x$$
$$= \frac{2}{n\pi} \sin\left(\frac{n\pi}{2}\right).$$

Therefore, the Fourier cosine series of f is

$$\frac{1}{2} + \frac{2}{\pi} \left(\cos \pi x - \frac{\cos 3\pi x}{3} + \frac{\cos 5\pi x}{5} - \ldots \right).$$

(iii) Consider the periodic extension of $f(x)$ of period 1 (Fig. 1.5). Applying the formulas given, we

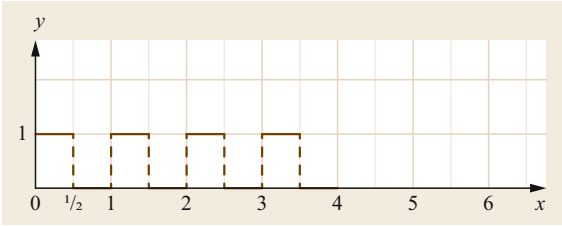

Fig. 1.5 1-periodic extension of $f(x)$

obtain

$$
\begin{aligned}
a_0 &= 1\,,\\
a_n &= 2\int_0^1 f(x)\cos(2x-1)n\pi\,\mathrm{d}x = 0\,,\\
&\qquad n = 1,2,\ldots\,,\\
b_n &= 2\int_0^1 f(x)\sin(2x-1)n\pi\,\mathrm{d}x\\
&= \frac{1}{n\pi}[(-1)^n - 1]\,,\\
f(x) &= \frac{1}{2} + \frac{2}{\pi}\left(\sin 2\pi x + \frac{\sin 6\pi x}{3}\right.\\
&\qquad \left. + \frac{\sin 10\pi x}{5} + \ldots\right).
\end{aligned}
$$

It is a coincidence that in case (iii), the coefficients a_n are all zero. Notice also that while both in case (i) and (iii) we have Fourier sine series, they are different.

1.4.2 The Fourier Transform

Let $f : \mathbb{R} \to \mathbb{C}$ be a piecewise continuous function that is absolutely integrable. That is, $\int_{-\infty}^{\infty} |f(x)|\,\mathrm{d}x < \infty$. The Fourier transform of such an f is defined as

$$
\begin{aligned}
\mathcal{F}(f)(\omega) &= \hat{f}(\omega)\\
&= \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} f(x)\mathrm{e}^{-\mathrm{i}\omega x}\,\mathrm{d}x\,. \qquad (1.38)
\end{aligned}
$$

The inverse Fourier transform is defined as

$$
f(x) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} \hat{f}(\omega)\mathrm{e}^{\mathrm{i}\omega x}\,\mathrm{d}\omega\,. \qquad (1.39)
$$

In fact, the Fourier transform exists for a more general class of functions, for example, such as square integrable functions on $\mathbb{R}$. That is, $\int_{-\infty}^{\infty} |f(x)|^2\,\mathrm{d}x < \infty$. The following can be easily verified:

1. $$\mathcal{F}(\mathrm{e}^{-|x|}) = \sqrt{\frac{2}{\pi}}\frac{1}{1+\omega^2}\,.$$

2. For $b > 0$,
$$
f(x) = \begin{cases} 1\,, & -b \le x \le b\,,\\ 0\,, & \text{otherwise}\,, \end{cases}
$$
$$\mathcal{F}(f)(\omega) = \frac{\sin\omega b}{\omega\pi} = \mathrm{sinc}(b\omega)\,.$$

3. $$\mathcal{F}(\mathrm{e}^{-x^2}) = \sqrt{\frac{2}{\pi}}\mathrm{e}^{-\frac{\omega^2}{4}}\,.$$

The following properties of the Fourier transform are useful. We assume that the Fourier transform of the functions mentioned in these properties exists:

1. (Linearity) for $a, b \in \mathbb{C}$,
$$\mathcal{F}[af + bg](\omega) = a\mathcal{F}[f](\omega) + b\mathcal{F}[g](\omega).$$

2. $$\mathcal{F}[f](-\omega) = \overline{\mathcal{F}[f](\omega)}\,.$$

3. For $a, b \in \mathbb{C}$, $a \neq 0$, and $g(x) = f(ax + b)$, we have
$$\mathcal{F}[g](\omega) = \frac{1}{|a|}\mathrm{e}^{\frac{\mathrm{i}\omega b}{a}}\mathcal{F}[f]\left(\frac{\omega}{a}\right).$$

4. For $c \in \mathbb{R}$,
$$\mathcal{F}[\mathrm{e}^{\mathrm{i}cx}f(x)](\omega) = \mathcal{F}[f](\omega - c)\,.$$

5. $$\mathcal{F}[f'](\omega) = \mathrm{i}\omega\mathcal{F}[f](\omega)\,.$$

6. $$\mathcal{F}[xf(x)](\omega) = \mathrm{i}\frac{\mathrm{d}}{\mathrm{d}\omega}\mathcal{F}[f](\omega)\,.$$

7. For $(f \star g)(x) = \int_{-\infty}^{\infty} f(x-y)g(y)\,\mathrm{d}y$,
$$\mathcal{F}[f \star g](\omega) = \mathcal{F}[f](\omega)\cdot\mathcal{F}[g](\omega)\,.$$

1.5 Complex Analysis

The study of the functions of a complex variable is very fascinating, and such functions arise in a variety of application areas. We begin this section with a brief introduction to complex number algebra.

1.5.1 Complex Numbers

A complex number z may be represented as $z = x + \mathrm{i}y$, where $\mathrm{i} = \sqrt{-1}$ and $x, y \in \mathbb{R}$ are called the real part and the imaginary part of z, respectively, and are denoted by $x = \mathrm{Re}(z)$ and $y = \mathrm{Im}(z)$. Two complex numbers are said to be equal if and only if their real and imaginary parts are equal. For $z_1 = x_1 + \mathrm{i}y_1$, $z_2 = x_2 + \mathrm{i}y_2$,

$$z_1 + z_2 = (x_1 + x_2) + \mathrm{i}(y_1 + y_2) \tag{1.40}$$

and

$$\begin{aligned} z_1 z_2 &= (x_1 + \mathrm{i}y_1)(x_2 + \mathrm{i}y_2) \\ &= (x_1 x_2 - y_1 y_2) + \mathrm{i}(x_1 y_2 + x_2 y_1) \,. \end{aligned} \tag{1.41}$$

For $z_2 \neq 0$,

$$z = \frac{z_1}{z_2} = \frac{x_1 x_2 + y_1 y_2}{x_2^2 + y_2^2} + \mathrm{i}\,\frac{x_2 y_1 - x_1 y_2}{x_2^2 + y_2^2} \,. \tag{1.42}$$

Complex numbers may be represented as points in a plane, in which the x-axis is called the real axis, and the y-axis is called the imaginary axis. Thus, complex numbers may also be represented as *ordered pairs*. That is, the complex number $x + \mathrm{i}y$ is identified with the (unique) point (x, y) in the complex plane.

The magnitude of a complex number $z = x + \mathrm{i}y$ is defined as

$$|z| = \sqrt{x^2 + y^2} \,. \tag{1.43}$$

The *complex conjugate* $\bar{z}$ of a complex number $z = x + \mathrm{i}y$ is defined by $\bar{z} = x - \mathrm{i}y$. It can be easily verified that $\mathrm{Re}(z) = x = \frac{1}{2}(z + \bar{z})$, $\mathrm{Im}(z) = x = \frac{1}{2\mathrm{i}}(z - \bar{z})$. Geometrically, a complex number and its conjugate are reflections of one another about the real axis (Fig. 1.6).

Polar Representation of Complex Numbers

The polar form of complex numbers, as suggested by its name, uses the polar coordinates to represent complex numbers in the complex plane. We know that $x = r\cos\theta$ and $y = r\sin\theta$, where r is the radial coordinate, and θ is the angular coordinate. Invoking Euler's formula,

$$\mathrm{e}^{\mathrm{i}\theta} = \cos\theta + \mathrm{i}\sin\theta \,,$$

we can represent a complex number

$$z = x + \mathrm{i}y = r\mathrm{e}^{\mathrm{i}\theta} \,.$$

Here, the magnitude of z is $r = |z|$ and the phase (or argument) of z is

$$\theta = \arg z = \tan^{-1}\left(\frac{\mathrm{Im}(z)}{\mathrm{Re}(z)}\right) = \tan^{-1}\left(\frac{y}{x}\right) .$$

The angle θ is measured from the positive real axis and, by convention, is regarded as positive in the counterclockwise direction (Fig. 1.7). It is measured in radians, and the specific value of θ that lies in the interval $(-\pi, \pi]$ is called the principal value of $\arg z$ and is denoted by $\mathrm{Arg}\, z$. The following properties of complex numbers are useful:

1. For complex numbers z_1, z_2, the triangle inequality holds

$$|z_1 + z_2| \leq |z_1| + |z_2| \,.$$

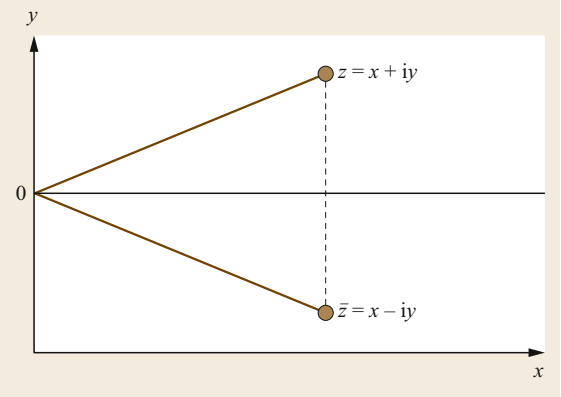

Fig. 1.6 A complex number and its conjugate

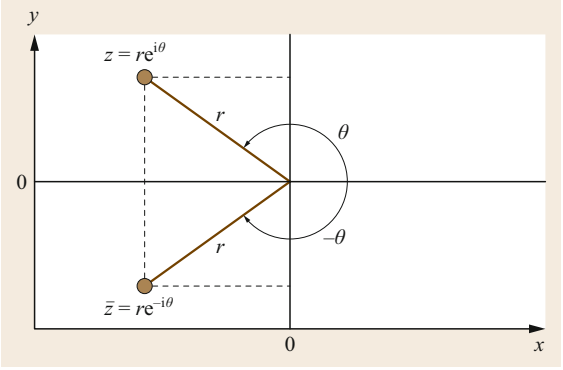

Fig. 1.7 Relation between the rectangular and polar forms of a complex number

2. The product of complex numbers z, and its conjugate, is a positive, real number, equal to the square of its magnitude. That is, $z\bar{z} = |z|^2$.
3. For $z = e^{i\theta}$, $z_1 = r_1 e^{i\theta_1}$ and $z_2 = r_2 e^{i\theta_2}$, we have:

   a) $z_1 z_2 = r_1 r_2 e^{i(\theta_1+\theta_2)}$ and $|z_1 , z_2| = |z_1||z_2|$
   and $\arg(z_1 z_2) = \arg(z_1) + \arg(z_2)$
   (up to a multiple of 2π)
   b) $z_1/z_2 = r_1/r_2 e^{i(\theta_1-\theta_2)}$.
   So, $|z_1/z_2| = |z_1|/|z_2|$,
   and $\arg(z_1/z_2) = \arg(z_1) - \arg(z_2)$
   (up to a multiple of 2π).
   c) $\bar{z} = re^{-i\theta}$.
   d) $z^n = (re^{i\theta})^n = r^n e^{in\theta} = r^n(\cos n\theta + i \sin n\theta)$.

Example 1.15

Let

$$z = \frac{8}{-2+2i} = -2-2i\,.$$

Clearly, z is located in the third quadrant of the complex plane. The phase of z is

$$\theta = \tan^{-1}\left(\frac{-2}{-2}\right) = 45^\circ = \frac{\pi}{4}\,\text{rad}\,.$$

This only tells us that the (smallest) angle between OA and the real axis is 45°. Since z is in the third quadrant, its actual phase is $180^\circ + 45^\circ = 225^\circ$ ($\pi + \pi/4 = 5\pi/4$ rad) in the counterclockwise direction or -135° ($-3\pi/4$) in the clockwise direction. So, the polar form of z can be written as

$$z = -2-2i = \sqrt{8}e^{i(\frac{5\pi}{4})}\,.$$

Thus, the phase of z is $5\pi/4$.

Roots of a Complex Number. For a complex number, $z \neq 0$, and a positive number n, the n-th root of z, denoted by $\sqrt[n]{z}$, is *multivalued*, namely n-valued. The n values of $w = \sqrt[n]{z}$ can be obtained as follows.

For $z = r(\cos\theta + i\sin\theta)$ and $w = R(\cos\phi + \sin\phi)$, we have

$$w^n = R^n(\cos n\phi + \sin n\phi) = z$$
$$= r(\cos\theta + i\sin\theta)\,. \qquad (1.44)$$

Comparing the modulus (which is determined only up to an integer multiple of 2π) and the arguments, we see that $R = \sqrt[n]{r}$ and

$$n\phi = \theta + 2k\pi\,, \quad \text{thus } \phi = \frac{\theta}{n} + \frac{2k\pi}{n}\,,$$

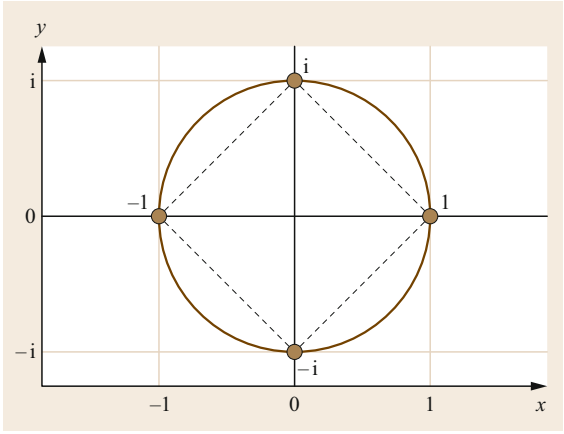

Fig. 1.8 Locations of the fourth roots of unity

where $k = 0, 1, \ldots, n-1$.

Thus, for $k = 0, 1, \ldots, n-1$,

$$\sqrt[n]{z} = \sqrt[n]{r}\left(\cos\frac{\theta+2k\pi}{n} + i\sin\frac{\theta+2k\pi}{n}\right).$$

These n values lie on a circle of radius $\sqrt[n]{r}$ with the center at the origin and constitute the vertices of a regular polygon of n sides.

For $z = 1$, we have $|z| = r = 1$ and $\text{Arg}\, z = 0$. Thus, for $k = 0, 1, \ldots n-1$,

$$\sqrt[n]{1} = \left(\cos\frac{2k\pi}{n} + i\sin\frac{2k\pi}{n}\right). \qquad (1.45)$$

These n values are called the *n-th roots of unity*.

Figure 1.8 shows the fourth roots of unity, namely $1, i, -1$ and $-i$.

1.5.2 Complex Functions

Denoting the set of all complex numbers by $\mathbb{C}$, we consider a subset $S \subset \mathbb{C}$. A function f defined on S is a rule that assigns to every $z \in S$, a $w \in \mathbb{C}$, called the *value* of f at z. We denote this by $f(z) = w$. Here, z varies in S and is called a complex variable. The set S is called the *domain* of f. For example, the domain of the function $w = f(z) = z^2$ is the entire complex plane where as the domain of the function $w = g(z) = z/z-1$ is the set of all complex numbers, except $z = 1$. The set of all values of a function f is called the *range* of f; w is a complex number as well, so we may write $w = u + iv$, and since w depends on $z = x + iy$, we write

$$w = f(z) = u(x, y) + iv(x, y)\,. \qquad (1.46)$$

Unlike the situation for real functions, we are no longer able to draw *graphs* for complex functions. This is because z is in the xy-plane, whereas w is in the uv-plane,

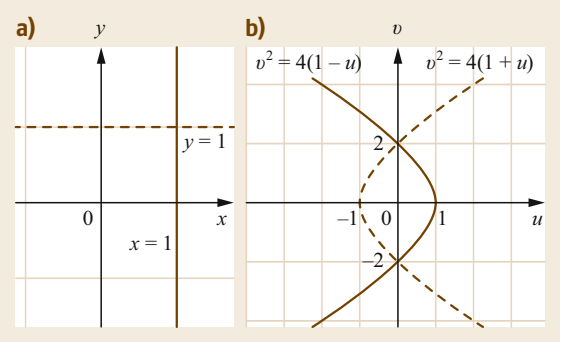

Fig. 1.9a,b The lines $x = 1$ and $y = 1$ **(a)** and their images under the mapping $f(z) = z^2$ **(b)**

and it is not possible to superimpose them onto one diagram. However, we can separately depict the *domain plane* and the *image plane* and think of a complex function f as a transformation that maps points (curves) in the xy-plane onto points (curves) in the uv-plane.

Example 1.16

Consider $f(z) = z^2 = (x + \mathrm{i}y)^2 = (x^2 - y^2) + \mathrm{i}(2xy)$.

Clearly, $u(x, y) = x^2 - y^2$ and $v(x, y) = 2xy$. So, we see that the line $x = 1$ is mapped to $u = 1 - y^2$ and $v = 2y$. Upon eliminating the variable y, we obtain the parabola, $v^2 = 4(1 - u)$, that opens to the left. On the other hand, the horizontal line $y = 2$ is mapped to parabola $v^2 = 4(1 + u)$ that opens to the right. See Fig. 1.9a,b.

Using the polar coordinate representation, we have for $z = re^{\mathrm{i}\theta}$, $w = z^2 = r^2 e^{2\mathrm{i}\theta}$. Thus, we see that circles $r = r_0$ are mapped onto circles $R = r_0^2$, and the ray $\theta = \theta_0$ is mapped onto ray $\phi = 2\theta_0$.

1.5.3 Analytic Functions

By a neighborhood of a point $z_0 \in \mathbb{C}$ we mean an open circular disk of some radius $\epsilon (> 0)$ centered at z_0. That is,

$$N_\epsilon(z_0) = \{z \in \mathbb{C} \,|\, |z - z_0| < \epsilon\} \,.$$

Differentiability at a single point is often of no practical interest. Therefore, the following important notion in defined.

A complex function $f(z)$ is *analytic* (or *holomorphic*) at a point z_0, if it is differentiable throughout some neighborhood of z_0. A function is analytic in a domain if it is analytic at all points of the domain. Analytic functions arise in fluid flows and complex potentials.

Let $f(z) = u(x, y) + \mathrm{i}v(x, y)$ be defined and continuous in some neighborhood of a point $z = x + \mathrm{i}y$ and differentiable at z itself. Then, at that point, the first-order partial derivatives of u and v exist and satisfy the Cauchy–Riemann equations

$$u_x = v_y \,, \quad v_x = -u_y \,. \tag{1.47}$$

Conversely, if two real-valued continuous functions $u(x, y)$, $v(x, y)$ of two real variables x and y have continuous first partial derivatives that satisfy the Cauchy–Riemann equations in some domain D, then the complex function $f(z) = u(x, y) + \mathrm{i}v(x, y)$ is analytic in D.

Example 1.17

Let $f(z) = \mathrm{e}^z = \mathrm{e}^x(\cos y + \mathrm{i} \sin y)$.

Here, $u(x, y) = \mathrm{e}^x \cos y$, $v(x, y) = \mathrm{e}^x \sin y$, and we have

$$u_x = \mathrm{e}^x \cos y \,, \quad v_y = \mathrm{e}^x \cos y \,,$$
$$u_y = -\mathrm{e}^x \sin y \,, \quad v_x = \mathrm{e}^x \sin y \,.$$

We see that the Cauchy–Riemann equations are satisfied. Thus, $f(z)$ is analytic for all z.

If we express a function in polar coordinates, that is, $f(z) = u(r, \theta) + \mathrm{i}v(r, \theta)$, the Cauchy–Riemann equations in polar form are given by

$$u_r = \frac{1}{r} v_\theta \,, \quad v_r = -\frac{1}{r} u_\theta \,. \tag{1.48}$$

If $f(z) = u(x, y) + \mathrm{i}v(x, y)$ is an analytic function on some domain $D \subset \mathbb{C}$, then both u and V satisfy the *Laplace equation*

$$\nabla^2 u = u_{xx} + u_{yy} = 0 \,, \quad \text{and} \quad \nabla^2 v = v_{xx} + v_{yy} = 0$$

in D and have continuous second partial derivatives in D.

Examples of Analytic Functions

1. $f(z) = \mathrm{e}^z$ is analytic on the entire complex plane $\mathbb{C}$; $\mathrm{e}^z = \mathrm{e}^x(\cos y + \mathrm{i} \sin y)$ is, clearly, a periodic function with the complex period $2\pi\mathrm{i}$.
2. The complex trigonometric functions

$$\cos z = \frac{1}{2}(\mathrm{e}^{\mathrm{i}z} + \mathrm{e}^{-\mathrm{i}z}) \quad \text{and} \quad \sin z = \frac{1}{2\mathrm{i}}(\mathrm{e}^{\mathrm{i}z} - \mathrm{e}^{-\mathrm{i}z}) \,.$$

These are analytic, again, in the entire complex plane $\mathbb{C}$. The following properties of these functions are useful:

a) $\cos z = \cos x \cosh y - \mathrm{i} \sin x \sinh y$.
b) $\sin z = \sin x \cosh y + \mathrm{i} \cos x \sinh y$.

c) $|\cos z|^2 = \cos^2 x + \sinh^2 y$
and $|\sin z|^2 = \sin^2 x + \sinh^2 y$.
This tells us that, unlike their real-valued counterparts, these functions are unbounded.

3. For $z \neq 0$, the complex logarithm function, $f(z) = \ln z = \ln r + \mathrm{i}\theta$, where $\theta = \arg z$ is multivalued. However, the *principal complex logarithm*

$$\mathrm{Ln}\, z = \ln |z| + \mathrm{i}\, \mathrm{Arg}\, z \quad (z \neq 0)$$

is single-valued and is analytic on $D = \{z = r\mathrm{e}^{\mathrm{i}\theta} | \ r > 0, -\pi < \theta < \pi\}$.
Note that $\mathrm{Ln}(-1) = \pi\mathrm{i}$ and $\mathrm{Ln}\,\mathrm{i} = \frac{\pi}{2}$.

4. The power function $f(z) = z^c = \mathrm{e}^{c\,\mathrm{Ln}\, z}$ (c complex, $z \neq 0$), is again, multivalued. The particular value $z^c = \mathrm{e}^{c\,\mathrm{Ln}\, z}$ is called the principal value of z^c.

1.5.4 Complex Integration

Curves in the complex plane may be represented parametrically by complex-valued functions of a real variable

$$z(t) = x(t) + \mathrm{i}y(t)\,, \quad a \leq t \leq b\,.$$

The curve C denoted by this function is said to be *oriented* in the increasing direction of t.

The curve C is said to be *smooth* if it can be represented by a function $z(t)$ such that $z'(t) \neq 0$ for all $t \in [a, b]$.

Suppose $C : z(t), a \leq t \leq b$ is a *piecewise smooth* curve (consisting of finitely many smooth curves joined end to end), and f is a continuous function on C. Then, the *line integral* of $f(z)$ over C is computed as follows

$$\int_C f(z)\,\mathrm{d}z = \int_a^b f(z(t))z'(t)\,\mathrm{d}t\,. \tag{1.49}$$

If the initial and terminal points of a curve C coincide, it is called a closed curve; C is *simple* if it does not intersect itself. A domain $D \subset \mathbb{C}$ is called a *simply-connected domain* if every simple closed curve (path) in D encloses only points in D. A domain that is not simply-connected is said to be *multiply-connected*.

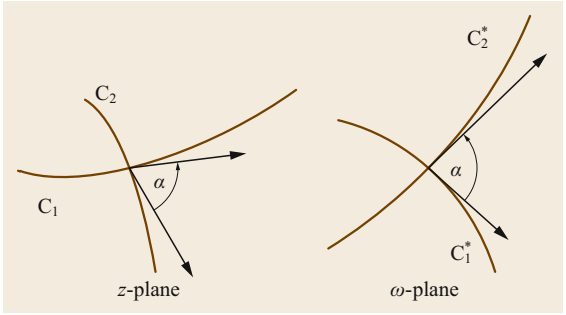

Fig. 1.10 Curves C_1 and C_2 and their respective images C_1^* and C_2^* under a conformal mapping $\omega = f(z)$ (adapted from [1.4])

The Cauchy Integral Theorem

If $f(z)$ is analytic in a simply-connected domain D, then for every simple closed curve C in D, $\oint_C f(z)\,\mathrm{d}z = 0$.

Cauchy Integral Formula

If $f(z)$ is an analytic function in a simply connected domain D, for any point $z_0 \in D$ and any simple closed path C that encloses z_0, we have

$$\oint_C \frac{f(z)}{z - z_0}\,\mathrm{d}z = 2\pi\mathrm{i}f(z_0)\,, \tag{1.50}$$

where the integration is taken in the counterclockwise direction.

1.5.5 Conformal Mappings

A mapping $w = f(z)$ is called a *conformal mapping* if it preserves angles between oriented curves in magnitude as well as in sense. The angle α ($0 \leq \alpha \leq \pi$) between two intersecting curves C_1 and C_2 is defined as the angle between their oriented tangents at the point of intersection of the curves. A mapping f is conformal means that if C_1 and C_2 are two intersecting curves in the domain plane, and C_1^*, C_2^* are their images under f, then the angle of intersection is the same in magnitude and in sense for both pairs of curves (Fig. 1.10).

Conformal mappings play an important role in applications in electrostatics, heat flow, and fluid flow.

If the mapping $w = f(z)$ is analytic, then it is a conformal mapping at all points where $f'(z) \neq 0$.

He has coauthored a research monograph on set differential equations and about 50 research papers in various refereed international journals.

2. Mechanics

David C. Fleming, Hen-Geul Yeh, Hsien-Yang Yeh, Shouwen Yu

Engineering mechanics is the study of forces and their effects on the objects to which they are applied. This chapter presents the fundamentals of the study of mechanics in the two categories of *static mechanics*, (or simply *statics*) and *dynamic mechanics*. The first section deals with statics and addresses stationary objects. Statics is based on a reduction of Newton's second law ($\boldsymbol{F} = m\boldsymbol{a}$) and the equivalent equation describing rotational motion for the special case where the accelerations are zero. This results in the equations of equilibrium, which state that the vector sum of all forces and moments acting on a static body must be zero. Equations of static equilibrium can be used to find, for example, forces generated by supports that constrain a body against externally applied loads. Principles of statics are also used to understand the internal forces in the material comprising a structure under load. Understanding these forces is fundamental to the design of structures to avoid material failure. The second section is devoted to dynamic mechanics which is concerned with the motion of bodies. It is divided into two parts, *kinematics* and *dynamics* (also called *kinetics*). Kinematics is the study of motion without consideration of the forces and moments that produce the motion. Relationships between displacement, velocity, and acceleration are part of the study of kinematics. Dynamics relates the motion of bodies to the action of applied forces and moments, and thus is fundamental to many engineering problems.

Mechanics is the study of the response of matter to forces, and is based on the concepts of time, space, force, energy, and matter. A knowledge of mechanics is needed for the study of all branches of physics, chemistry, biology, and engineering [2.1]. The subject of mechanics is logically divided into two parts: statics, and dynamics. Statics is concerned with the equilibrium of bodies under the action of forces, and hence is unconcerned with motion. Dynamics is concerned with the motion of bodies under the action of applied forces. The principles of mechanics as a science are rigorously expressed by mathematics, which therefore plays an important role in the application of these principles to the solution of practical problems [2.2]. A force is a vector

K.-H. Grote, H. Hefazi (Eds.), *Springer Handbook of Mechanical Engineering*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-47035-7_2

quantity, because its effect depends on the direction as well as on the magnitude of the action. In addition to the tendency to move a body in the direction of its application, a force can also tend to rotate a body about an axis. This rotational tendency is known as the *moment of the force*, or simply the *moment*. Like force, moment can be expressed as a vector quantity. When the resultant force and the resultant moment are both zero the body is in equilibrium and there is no acceleration of the body. This condition is described by satisfying the equations of static equilibrium. If the body is not in equilibrium, it will accelerate and the motion is analyzed using principles of dynamic mechanics.

Problems in mechanics are often defined using free-body diagrams. These are diagrams showing an object, or *body* under study and the forces acting upon it. A large number of problems in mechanics can be approximated by problems concerning the equilibrium or motion of a particle. This is done by choosing a significant particle and creating a free-body diagram showing this particle and all the forces acting on it. Particle models do not consider the effects of moments or rotation of the body; all forces are treated as acting through its center of gravity. For problems where the effects of moments or rotation are significant, the body must be represented as a two-dimensional or three-dimensional object. If deformation of the body due to the applied forces is not significant, the body may be approximated as a rigid-body problem [2.3].

Static equilibrium problems may be used to understand the forces acting on structures or other objects of interest to engineers. Principles of statics can be used to analyze many types of engineering problems including structures, mechanisms, machines, biomechanical systems, and vehicles. Specialized techniques of statics are used to analyze special cases. For example, a truss is a structure composed of (usually straight) members pinned together at their end points and loaded only at the joints. Trusses are commonly seen supporting the roofs of buildings as well as in large railroad and highway bridges [2.4]. Forces in the individual members comprising a truss are found to be either simple tension or compression forces and these forces can be found using specialized application of the principles of statics. Static equilibrium can also be used to help understand the internal forces existing in a body that hold it together.

Dynamic mechanics can be divided into two parts: (1) kinematics, which is the study of a geometry of motion and is used to relate displacement, velocity, acceleration, and time, without taking into account forces and moments as causes of the motion, and (2) dynamics, which is the study of the relation between the forces and moments acting on a body, and the mass and motion of the body; it is used to predict the motion caused by given forces and moments or to determine the forces and moments required to produce a given motion.

Kinematics is the starting point from which the analysis of the basic motion of particles and rigid bodies begins. Dynamics allows the motion of bodies to be related to applied forces and moments. Newton's laws and other principles of dynamics are introduced in this chapter followed by a review of advanced topics, such as the dynamics of systems of particles, momentum equations, Lagrange's equations, energy equations, D'Alembert's principle, and the dynamics of rigid bodies. Lagrange's equations of motion for linear systems are introduced at the end of the chapter, which can be regarded as the beginning of a study of vibration.

2.1 Statics of Rigid Bodies

Statics is a branch of classical mechanics, which is part of the foundation of physics and modern engineering technology. Statics is the study of the equilibrium of rigid bodies under the action of forces and moments. Equilibrium is defined as a condition in which all of the forces and moments applied to an object are in balance, such that the resultant force and moment vectors are zero. According to Newton's laws, if a body is in equilibrium the body must either be at rest or is in uniform motion along a straight line.

Many problems in statics can be analyzed by approximating an object as a rigid body. The size and shape of a rigid body remain constant at all times and under all loading conditions. In other words, rigid bodies are understood in statics as bodies in which the deformations are so small that the points at which force is applied undergo negligible displacement.

2.1.1 Force

A force represents the action of one body on another. Forces may be generated by a variety of phenomena including contact between objects, gravitation, electric or magnetic fields and others. Mathematically, a force is characterized by its magnitude, and direction. Thus, force is a vector quantity. The point of application of a force is also significant in statics problems. Introducing the unit vectors $\boldsymbol{i}, \boldsymbol{j}$, and $\boldsymbol{k}$, directed along the x, y,

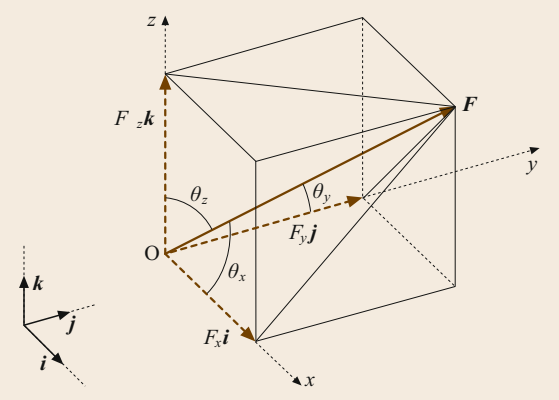

Fig. 2.1 Vector representation of a force $\boldsymbol{F}$

and z axes, respectively, the force $\boldsymbol{F}$ can be expressed in Cartesian vector notation as (Fig. 2.1a,b)

$$\boldsymbol{F} = F_x\boldsymbol{i} + F_y\boldsymbol{j} + F_z\boldsymbol{k}$$
$$\boldsymbol{F} = (F\cos\theta_x)\,\boldsymbol{i} + \big(F\cos\theta_y\big)\boldsymbol{j} + (F\cos\theta_z)\,\boldsymbol{k}\,. \quad (2.1)$$

F_x, F_y and F_z are the scalar components of the vector in the x, y and z coordinate directions, respectively. The magnitude of the force vector relates to these scalar components according to

$$F = |\boldsymbol{F}| = \sqrt{F_x^2 + F_y^2 + F_z^2}\,. \quad (2.2)$$

The orientation of a vector in three-dimensional space is sometimes described in terms of *direction angles*, which are the angles formed between each of the three positive coordinate axes and the force vector. In Fig. 2.1 direction angles are labeled as θ_x, θ_y, θ_z. Cosines of these direction angles are called *direction cosines* and relate to the scalar vector components according to $\cos\theta_x = F_x/F$, $\cos\theta_y = F_y/F$, $\cos\theta_z = F_z/F$. The direction cosines must satisfy $\cos^2\theta_x + \cos^2\theta_y + \cos^2\theta_z = 1$. When solving three-dimensional problems, it is necessary to find the x, y, and z scalar components of a force. In many cases, the direction of a force is not given in terms of direction angles. Often, the direction of a force is described either by defining two points on the line of action of the force (Fig. 2.2a), or by defining angles that orient the line of action of the force using its projection onto coordinate planes (Fig. 2.2b):

1. In Fig. 2.2a the direction of a force $\boldsymbol{F}$ is defined by the coordinates of two points $\mathrm{M}(x_1, y_1, z_1)$ and $\mathrm{N}(x_2, y_2, z_2)$, located on its line of action. Consider the vector $\overrightarrow{\mathrm{MN}}$ joining M and N and in the same direction sense as $\boldsymbol{F}$. Therefore

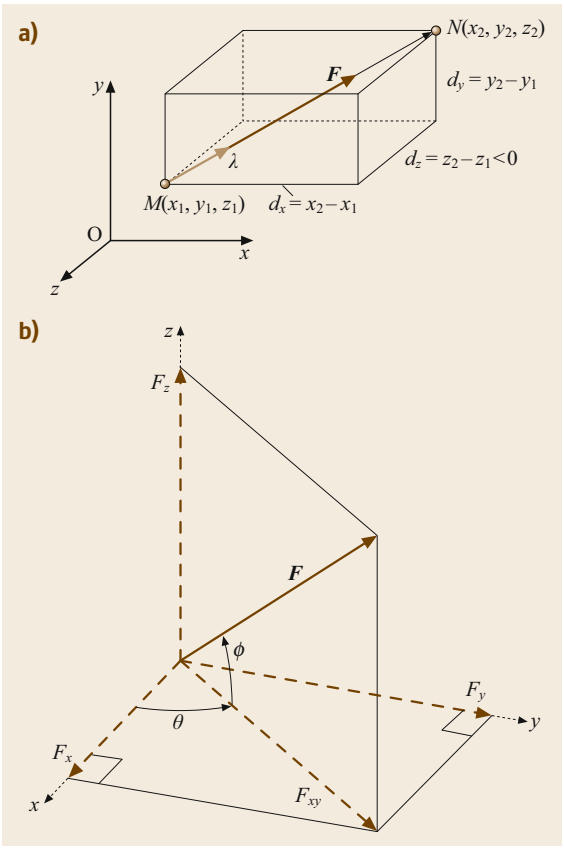

Fig. 2.2a,b Force defined by **(a)** its magnitude and two points on its line of action, or **(b)** by its magnitude and angles describing the projection of the vector onto a coordinate plane

$$\overrightarrow{\mathrm{MN}} = (x_2 - x_1)\,\boldsymbol{i} + (y_2 - y_1)\boldsymbol{j} + (z_2 - z_1)\,\boldsymbol{k}\,. \quad (2.3)$$

The unit vector $\boldsymbol{\lambda}$ along the line of action of $\boldsymbol{F}$ is obtained by dividing the vector $\overrightarrow{\mathrm{MN}}$ by its magnitude MN, thus

$$\boldsymbol{\lambda} = \frac{\overrightarrow{\mathrm{MN}}}{\mathrm{MN}} = \frac{(x_2 - x_1)\,\boldsymbol{i} + (y_2 - y_1)\boldsymbol{j} + (z_2 - z_1)\,\boldsymbol{k}}{\sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2 + (z_2 - z_1)^2}} = \frac{d_x\boldsymbol{i} + d_y\boldsymbol{j} + d_z\boldsymbol{k}}{d}\,, \quad (2.4)$$

and $\boldsymbol{F} = F\boldsymbol{\lambda}$, where F is the magnitude of the force $\boldsymbol{F}$,

$$d_x = x_2 - x_1\,, \quad d_y = y_2 - y_1\,, \quad d_z = z_2 - z_1$$

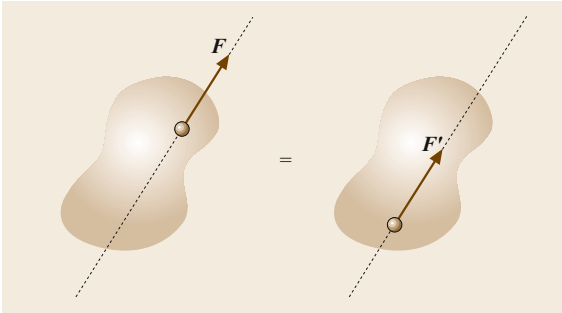

Fig. 2.3 Principle of transmissibility: either $\boldsymbol{F}$ or $\boldsymbol{F}'$ will produce the same effect on the body

and

$$d = \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2 + (z_2 - z_1)^2}\,.$$

The angles θ_x, θ_y, and θ_z that $\boldsymbol{F}$ forms with the coordinate axes can be expressed as

$$\cos\theta_x = \frac{d_x}{d}\,, \quad \cos\theta_y = \frac{d_y}{d}\,, \quad \cos\theta_z = \frac{d_z}{d}\,.$$

2. Consider the geometry of Fig. 2.2b, assuming that the angles θ and ϕ are known. F_{xy} represents the projection of $\boldsymbol{F}$ onto the xy plane. First resolve $\boldsymbol{F}$ into its horizontal and vertical components

$$F_{xy} = F\cos\phi\,, \quad F_z = F\sin\phi\,.$$

Then resolve the projection F_{xy} into x- and y-components

$$F_x = F_{xy}\cos\theta = F\cos\phi\cos\theta\,,$$
$$F_y = F_{xy}\sin\theta = F\cos\phi\sin\theta\,.$$

The quantities F_x, F_y, and F_z are the desired scalar components of $\boldsymbol{F}$.

The *line of action* of a force vector is the infinite line passing through the point of application of the force and pointing in the same direction as the force. The *principle of transmissibility* states that the conditions of equilibrium or motion of a rigid body remain unchanged if a force $\boldsymbol{F}$ acting at a given point on the rigid body is replaced by a force $\boldsymbol{F}'$ of the same magnitude and same direction, but acting at a different point on the same line of action (Fig. 2.3); $\boldsymbol{F}$ and $\boldsymbol{F}'$ are known as *equivalent forces*.

2.1.2 Addition of Concurrent Forces in Space and Equilibrium of a Particle

The resultant $\boldsymbol{R}$ of two or more forces in space is usually determined by summing their Cartesian components. Graphical or trigonometric methods are sometimes used to quickly add vectors in two-dimensional problems, but these methods are usually not practical for a systems of many forces or for three-dimensional forces in space, and these methods are not reviewed here [2.2, 3]. If forces are first expressed using Cartesian components, as described above, addition of vectors can be quickly accomplished according to the approach shown in (2.5)–(2.6), where $\boldsymbol{R}$ represents the *resultant* (or sum) of a set of vectors $\boldsymbol{F}$.

$$\boldsymbol{R} = \sum \boldsymbol{F}\,, \tag{2.5}$$

$$\boldsymbol{R} = R_x\boldsymbol{i} + R_y\boldsymbol{j} + R_z\boldsymbol{k} = \left(\sum F_x\right)\boldsymbol{i} + \left(\sum F_y\right)\boldsymbol{j} + \left(\sum F_z\right)\boldsymbol{k} \tag{2.6}$$

From which it follows that

$$R_x = \sum F_x\,, \quad R_y = \sum F_y\,, \quad R_z = \sum F_z\,. \tag{2.7}$$

The magnitude of the resultant and the direction angles of the resultant, θ_x, θ_y, and θ_z are

$$R = \sqrt{R_x^2 + R_y^2 + R_z^2}\,, \tag{2.8}$$

$$\cos\theta_x = \frac{R_x}{R}\,, \quad \cos\theta_y = \frac{R_y}{R}\,, \quad \cos\theta_z = \frac{R_z}{R}\,. \tag{2.9}$$

When a body is in equilibrium, the resultant of all the forces acting on it is zero. Therefore, for equilibrium of a body the following three scalar equilibrium equations apply

$$\sum F_x = 0\,, \quad \sum F_y = 0\,, \quad \sum F_z = 0\,. \tag{2.10}$$

2.1.3 Moment of a Force and Force Couple

In addition to the tendency to move a body in the direction of its application, a force can also tend to rotate a body. This rotational tendency is known as the *moment of the force*, $\boldsymbol{M}$ (Fig. 2.4a). The moment is a vector quantity whose magnitude is the strength of the rotational effect and whose direction describes the axis of rotation. The moment vector depends on the choice of the location O where the axis of rotation is to be considered.

A special case is found by considering the action of two equal, opposite, and non-collinear forces. This combination of two forces is called a *force couple* or, more simply, a *couple* (Fig. 2.4b). The resultant force produced by a couple is zero, and thus a couple will produce no linear acceleration of an object to which it is applied. A couple, however, produces a resultant moment. Thus, imposing a force couple on an object will

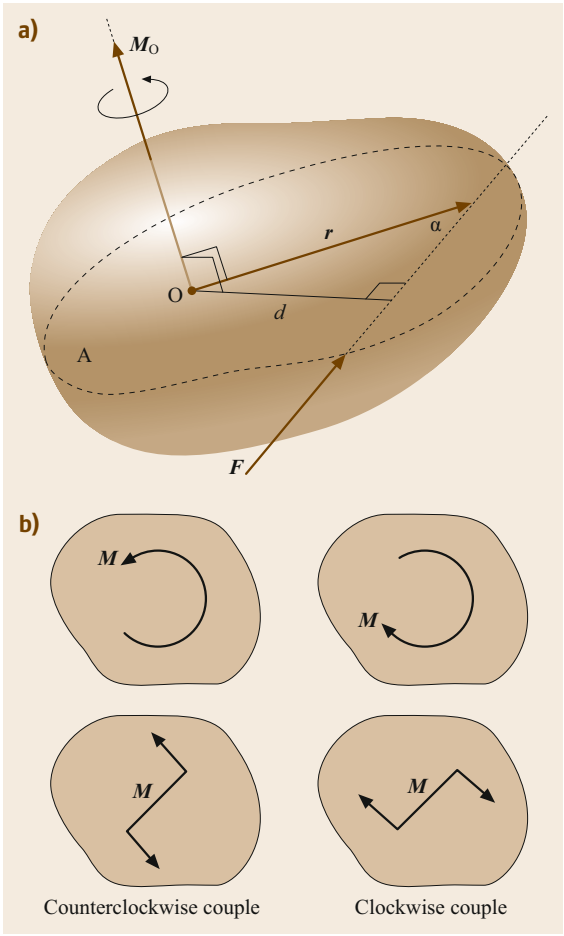

Fig. 2.4 (a) Moment of a force about a point, (b) couple

produce only a tendency toward rotational acceleration. A force couple is therefore commonly represented by showing only the resultant moment vector that the couple provides rather than showing the two force vectors (Fig. 2.4b). An important feature of a force couple is that once the magnitude of the forces comprising the couple and their positions are specified, the resultant moment vector produced by the couple will be the same regardless of where in space one choses to place the axis of rotation, O. This is unlike the moment produced by a single force vector, where the moment is directly dependent on the choice of O.

The moment produced by a single force vector about a chosen point O can be computed as follows. Consider a force $\boldsymbol{F}$ acting on a rigid body as shown in Fig. 2.4a. Define A as the plane containing both point O and the line of action of $\boldsymbol{F}$. The axis of rotation of the moment, and thus the direction of the moment vector $\boldsymbol{M}$ must be perpendicular to plane A. Its direction sense follows a right-hand rule. The moment $\boldsymbol{M}_O$ of $\boldsymbol{F}$ about O has magnitude $M_O = Fd$, where d is the perpendicular distance from O to the line of action of $\boldsymbol{F}$. For simple problems it may be possible to easily determine d and thus compute the moment. For more complex problems, particularly in three-dimensional geometries, direct geometric determination of the plane A and the distance d is difficult. In such cases a vector computation approach is preferred. Let the position vector $\boldsymbol{r}$ be any vector that originates at point O and terminates at any point on the line of action of the force $\boldsymbol{F}$. The moment of $\boldsymbol{F}$ about O can then be computed by taking the cross product between $\boldsymbol{r}$ and $\boldsymbol{F}$

$$\boldsymbol{M}_O = \boldsymbol{r} \times \boldsymbol{F} = \begin{vmatrix} \boldsymbol{i} & \boldsymbol{j} & \boldsymbol{k} \\ r_x & r_y & r_z \\ F_x & F_y & F_z \end{vmatrix} . \tag{2.11a}$$

Expansion of the determinant gives

$$\begin{aligned} \boldsymbol{M}_O = {} & \left(r_y F_z - r_z F_y\right) \boldsymbol{i} + \left(r_z F_x - r_x F_z\right) \boldsymbol{j} \\ & + \left(r_x F_y - r_y F_x\right) \boldsymbol{k} . \end{aligned} \tag{2.11b}$$

For two-dimensional problems, a scalar approach to computing the moments is often used. If the force vector and point O lie in the xy plane as shown in Fig. 2.5, then the moment vector will have only a single nonzero component in the $\boldsymbol{k}$ direction, and it is commonly drawn as in the top of Fig. 2.4b. The direction sense is indicated by the arrowhead. The magnitude of the moment may be computed using $M_O = Fd$ if d is known. Often, it is more convenient to first resolve the vector $\boldsymbol{F}$ into x and y components. The moment M_O is then found as the sum of the moments about O produced by each of the components. This approach is called the *principle of moments*. Using the example shown in Fig. 2.5b, we see that $M_O = F_x d_y - F_y d_x$. Note that the algebraic sign associated with each term has to be carefully considered based on the location of the point of application of $\boldsymbol{F}$ relative to the location of O and the chosen sign convention for M_O.

Sometimes, rather than wanting to know the complete vector moment produced by a force vector about a specified point O, one needs to know only the component of this moment vector about a specified axis direction passing through point O. The moment about such an axis can be found by first computing the moment $\boldsymbol{M}_O$ of that force about O and then using the dot product to find the projection of $\boldsymbol{M}_O$ in the desired axis direction. This process is shown in Fig. 2.6. Let OL be an axis through O. The direction of the OL axis is defined by the unit vector $\boldsymbol{\lambda}$. The moment $\boldsymbol{M}_{OL}$ of $\boldsymbol{F}$ about OL is found as the projection OC of the moment $\boldsymbol{M}_O$ onto the axes using

$$\boldsymbol{M}_{OL} = \boldsymbol{\lambda} \cdot \boldsymbol{M}_O = \boldsymbol{\lambda} \cdot (\boldsymbol{r} \times \boldsymbol{F}) , \tag{2.12a}$$

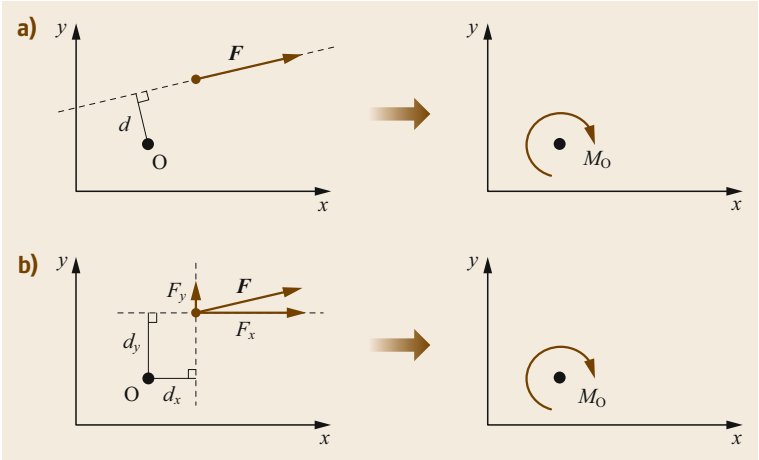

Fig. 2.5 Determination of a moment in two dimensions by scalar computations

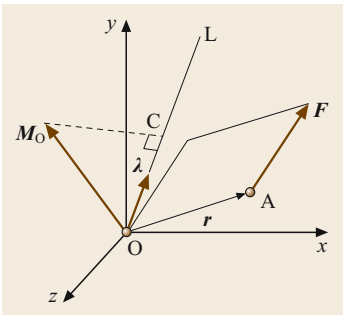

Fig. 2.6 Moment about an arbitrary axis

which shows that the moment $\boldsymbol{M}_{OL}$ of $\boldsymbol{F}$ about the axis OL is the scalar obtained by the scalar triple product of λ, $\boldsymbol{r}$, and $\boldsymbol{F}$.

Expressing $\boldsymbol{M}_{OL}$ in the form of a determinant

$$\boldsymbol{M}_{OL} = \begin{vmatrix} \lambda_x & \lambda_y & \lambda_z \\ r_x & r_y & r_z \\ F_x & F_y & F_z \end{vmatrix}, \qquad (2.12b)$$

where λ_x, λ_y, and λ_z are the direction cosines of the axis OL. x, y, and z are the coordinates of the point of application of $\boldsymbol{F}$, and F_x, F_y, and F_z are the components of the force $\boldsymbol{F}$.

2.1.4 Equilibrium Conditions

When a body is in equilibrium, the resultant effect of all forces acting on it is zero. Thus, the resultant force $\boldsymbol{R}$ and the resultant moment $\boldsymbol{M}$ acting about any point are both zero vectors, and the equilibrium equations result

$$\boldsymbol{R} = \sum \boldsymbol{F} = 0\,, \quad \boldsymbol{M} = \sum \boldsymbol{M} = \sum (\boldsymbol{r} \times \boldsymbol{F}) = 0\,. \qquad (2.13)$$

These requirements are both necessary and sufficient conditions for equilibrium.

Forces can be separated into two groups: (a) external, and (b) internal forces. External forces represent the action of other bodies on the body under consideration. Internal forces are the forces that hold together the particles forming the body. In solving a problem concerning the equilibrium of a rigid body, it is essential to consider all of the external forces acting on the body. Internal forces are typically not included in rigid body equilibrium problems because they are associated with equal and opposite force pairs according to Newton's third law, and therefore cancel each other. Section 2.1.7 describes analytical techniques for studying internal forces.

The first step in the solution of a problem should be to draw a free-body diagram of the rigid body under consideration. The free-body diagram is a diagrammatic representation of the isolated system treated as a single body. The diagram shows all forces applied to the body (Fig. 2.7). Typically, many of these forces result from mechanical contact with other bodies not included in the free-body diagram, which are imagined to be removed. An important category of forces that appear in free-body diagrams are those associated with supports that hold a structure in position. Supports constrain certain displacements or rotations of the structures at locations where the support contacts the structure. The magnitudes of these forces (and sometimes also force couples or *moments*) are typically not known in advance because their size depends on the magnitude of the other external loads applied to the system as well as the structural geometry; these forces develop in reaction to the other loads on the body, and thus are known as *support reactions*. The direction of the support reactions typically is known in advance because they correspond to the direction of the displacement or rotation components that they constrain. Examples of the reactions provided by some basic sup-

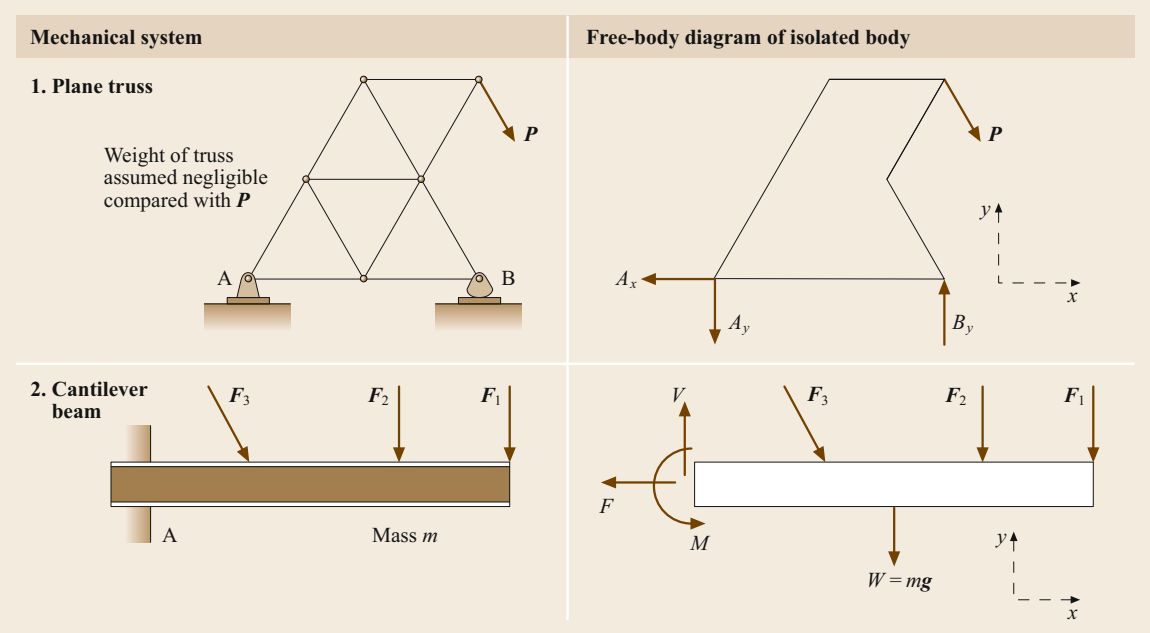

Fig. 2.7 Free-body diagrams (after [2.2]) Note the support reactions identified at points A and B in case 1 and at point A in case 2 and their correspondence to Fig. 2.8

port types is shown in Figs. 2.8 and 2.9. Note that support types that constrain rotation, such as the fixed support, produce reaction moments (force couples) in addition to reaction forces. Often, a statics problem involves determining the magnitude of support reactions as part of the solution process and it is therefore vital that the free-body diagram properly identifies the unknown reactions. Examples of free-body diagrams of simple mechanical systems are shown in Fig. 2.7.

For a two-dimensional rigid-body equilibrium problem in the xy plane, all force vectors have only two nonzero components, and all forces in the xy plane produce only moment components about the z-axis. Therefore, the vector equilibrium equations (2.13) can be reduced to a set of three scalar equations of equilibrium: $\sum F_x = 0$, $\sum F_y = 0$, $\sum M_z = 0$. A solution for unknown forces is possible provided that the number of unknown scalar quantities is three. For example, in case 1 of Fig. 2.7, if the geometry of the truss is specified and the magnitude and direction of the external force $\boldsymbol{P}$ is given then the equations of equilibrium will allow the three unknown reaction force components A_x, A_y and B_y to be determined. Similarly, for the cantilever beam in case 2 of Fig. 2.7 if the three external forces are specified as well as the mass of the beam and the location of its center of gravity then the three support reactions at A (F, V, and M) can be computed. In three dimensional problems, the equations of equilibrium are equivalent to six scalar equations, and solution is typically possible if there are six unknown scalar quantities in the free-body diagrams.

Problems whose solution is possible using only the equations of static equilibrium are called *statically determinate*. Stable bodies supported by the minimum number of constraints necessary to ensure an equilibrium configuration are statically determinate. Not all problems can be solved using static equilibrium alone. For example, if we added an additional rocker support to the plane truss in Fig. 2.7 at the joint midway between support A and support B, then an additional unknown reaction force would be required at that location in the free-body diagram, bringing the number of unknowns to four. We would still have only three equations of equilibrium and thus a solution would not be possible without providing additional information. A rigid body that possesses more external supports or constraints than are necessary to maintain an equilibrium position is called *statically indeterminate*. Supports that can be removed without destroying the equilibrium condition of the body are said to be redundant. The number of redundant supporting elements corresponds to the degree of static indeterminacy and equals the total number of unknown external forces minus the number of available independent equations of equilibrium. The solution of statically indeterminate problems typically involves consideration of the deformations of the structure un-

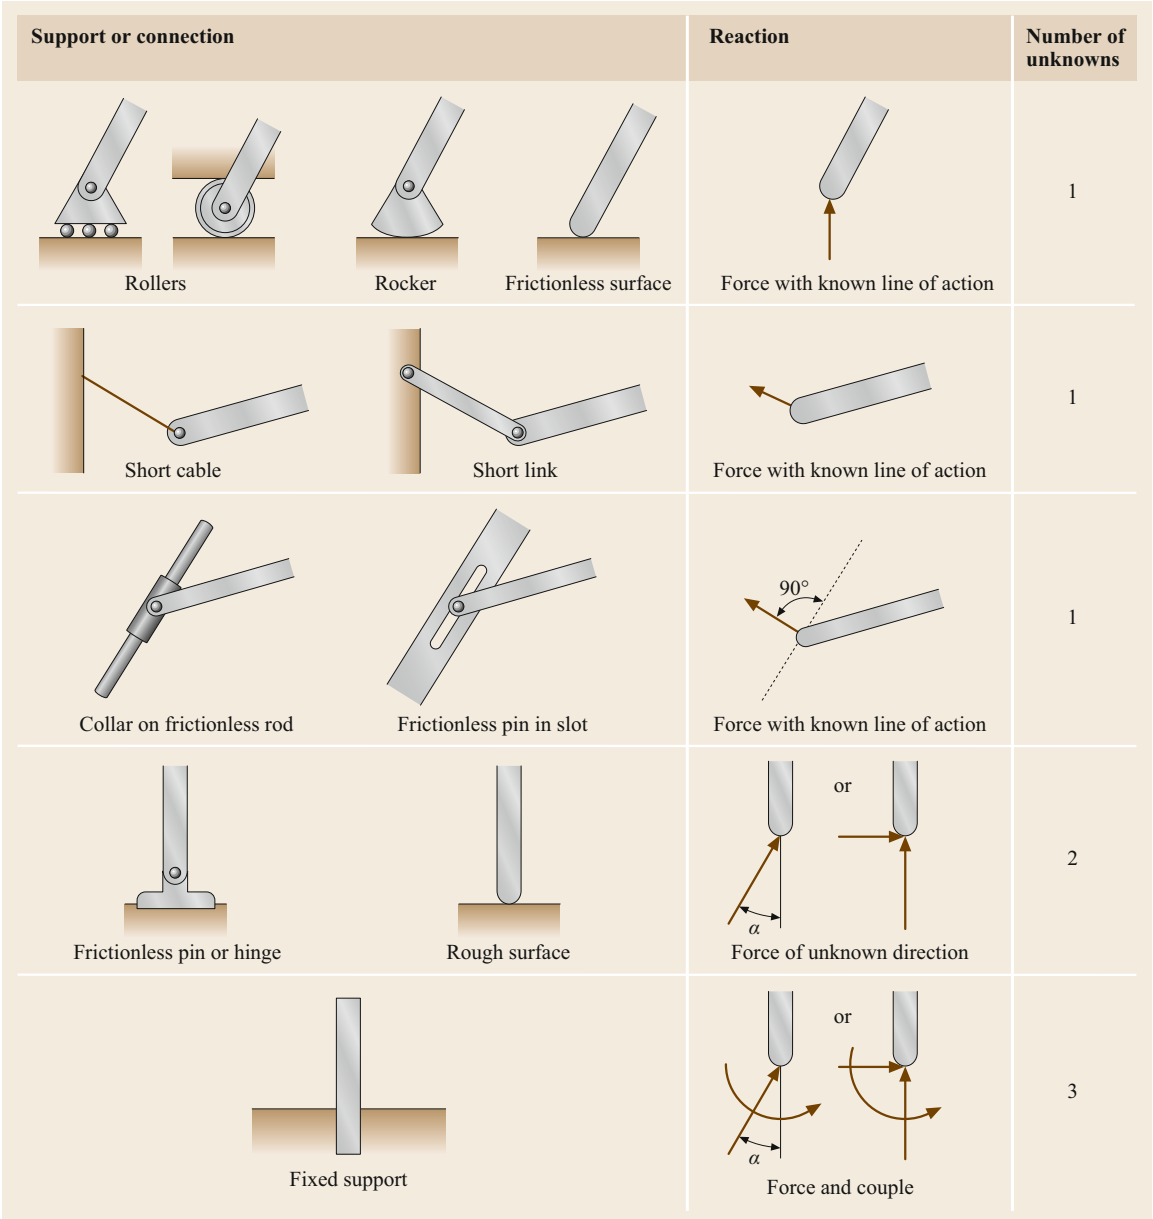

Fig. 2.8 Reactions at supports and connections for a two-dimensional structure (after [2.3])

der load. Solution of statically indeterminate structures problems is studied in detail in [2.5].

Two frequently occurring equilibrium situations permit rapid simplification of equilibrium problems: two- and three-force members. A two-force member is any body under the action of two forces only, as shown in Fig. 2.10. For a two-force member to be in equilibrium, the forces must be equal, opposite and collinear. The shape of the member does not affect this simple requirement.

A three-force member is a body under the action of exactly three forces, as shown in Fig. 2.11. For a three-force member to be in equilibrium, the lines of action of the three forces must be concurrent (or in a special case they may be parallel to each other). The principle of the concurrency of three forces in equilibrium is of considerable use in carrying out a graphical solution of the force equations. If two of the force vectors are specified, the third vector can be quickly determined using a polygon of forces, as shown in Fig. 2.11b.

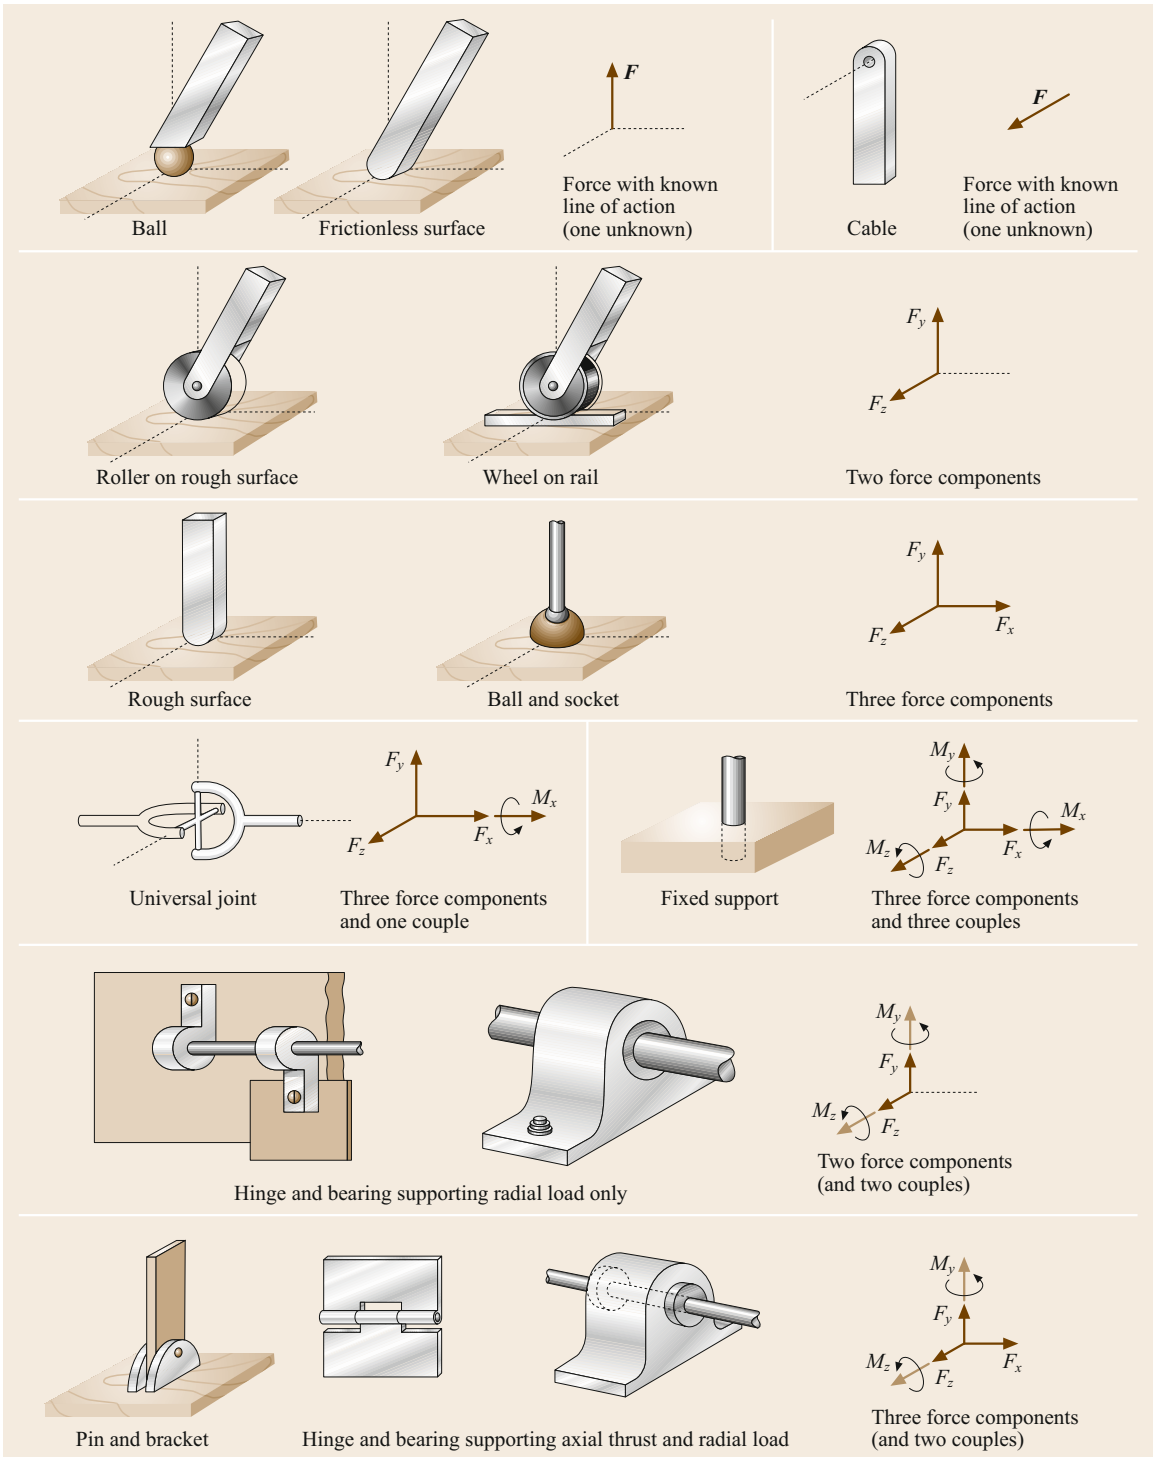

Fig. 2.9 Reactions at supports and connections for a three-dimensional structure (after [2.3])

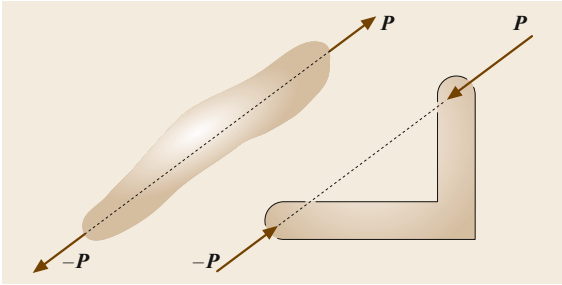

Fig. 2.10 Two-force member

2.1.5 Truss Structures

A framework composed of slender members joined at their ends to form a rigid structure is called a truss. In addition, members in a truss are typically assumed to be straight. When the members of the truss lie essentially in a single plane, the truss is called a *plane truss*. If the truss members are distributed in three-dimensions, the truss is called a *space truss*. The basic element of a plane truss is the triangle (Fig. 2.12a). Three bars joined by pins at their ends constitute a rigid truss and a larger rigid truss can be obtained by adding two new members to the first one and connecting them at a new joint as shown in Fig. 2.12b,c. Trusses obtained by repeating this procedure are called *simple trusses*. If certain simplifying assumptions are made, truss structures can be analyzed by the application of static equilibrium principles. If each member is joined to the rest of the structure at each end by frictionless pins and if we neglect the weight of the member then each member is subject to only two forces: a contact force at each end. Thus, each member in this ideal truss is a two-force member, as described in Sect. 2.1.4. The force within each truss member must be directed along the line joining the two ends of the member. The goal of truss analysis is to determine the magnitude of the force carried by each member and to indicate its directional sense. A truss member subject to loads that tend to lengthen the member are said to be in *tension*, while if the forces tend to shorten the member it is said to be in *compression*. Slender members are typically able to support much larger magnitudes of load in tension than in compression because compressive loads tend to cause a structural instability called buckling. Determining the loads in the truss members is a necessary first step toward designing a truss structure as the necessary size of the parts depends on the magnitude and direction sense of the applied forces.

Internal forces in a truss may be determined using static equilibrium principles provided the truss is statically determinate. In a simple plane truss, the total number of members m is given by $m = 2n-3$, where n is the total number of joints. If the truss is stable, such a simple plane truss is statically determinate, because two equations of equilibrium exist for each joint (providing $2n$ equations). Three unknown reaction forces are necessary to provide equilibrium of the structure, bringing the total number of unknowns, $m+3$ up to $2n$. Thus the number of equations matches the number of unknowns and

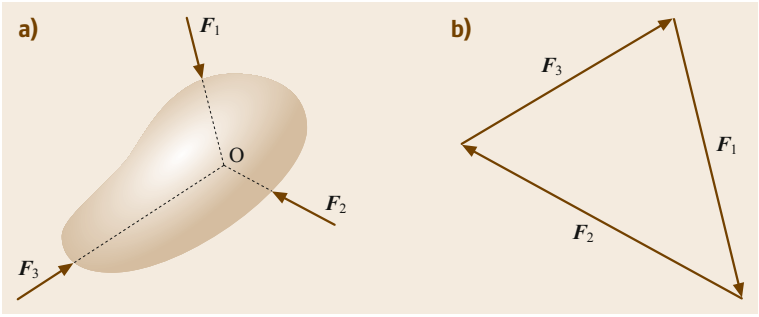

Fig. 2.11a,b Three-force member **(a)**. **(b)** Closed polygon satisfies $\sum \boldsymbol{F} = 0$

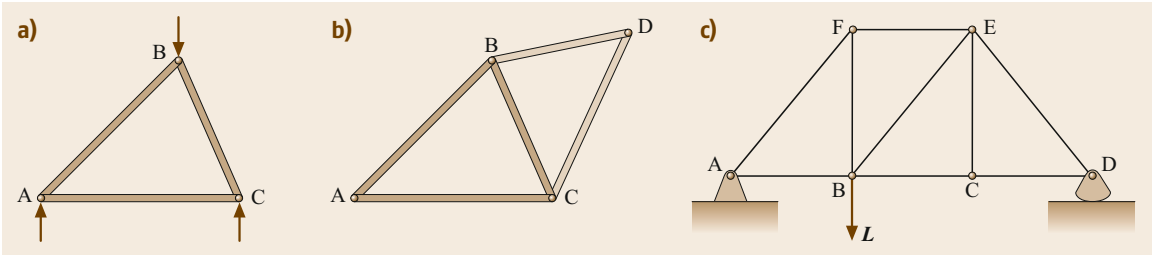

Fig. 2.12a–c Truss structures. **(a)** A basic truss element showing forces applied at the joints. **(b)** A five element truss. **(c)** A truss bridge with supports and an applied load

all unknowns may be determined. A pin-jointed plane truss with $m < 2n - 3$ members is statically indeterminate and kinematically unstable, and a pin-jointed plane truss with $m > 2n - 3$ is internally statically indeterminate, implying that there are redundant members and solutions requires additional consideration of the deformation of the truss beyond static equilibrium principles.

Two methods of analysis are typically used to find the member forces in truss structures, the *method of joints* and the *method of sections*. Before either method is applied, the reactions at the supports can be obtained by considering the entire truss as a free body.

In the method of joints, the free-body diagram of each pin is drawn, showing the forces exerted on the pin by each of the members or supports it connects. Because the members are straight two-force members, the force exerted by a member on the pin is directed along that member and only the magnitude of the force is unknown. It is always possible in the case of a simple plane truss to draw the free-body diagrams of the pins in such an order that only two unknown forces are included in each diagram. For a plane truss, these forces can be determined from the two corresponding equilibrium equations: $\sum F_x = 0$ and $\sum F_y = 0$. If the force exerted by a member on a pin is directed toward that pin, the member is in compression; if it is directed away from the pin, the member is in tension.

The method of sections is usually preferred to the method of joints when the force in only one member or very few members of a truss is desired. For example, to determine the force in member BD of the truss shown in Fig. 2.13, it is better to pass a section through members BD, BE, and CE, remove these members and use the portion ABC of the truss as a free body. Note that the internal forces F_{CE}, F_{BE} and F_{BD} are exposed by this approach because their corresponding equal and opposite reactions act on the part of the structure that is discarded to make the free-body diagram in Fig. 2.13b. If $\boldsymbol{P}_1$ and $\boldsymbol{P}_2$ are specified, equations of equilibrium based on the free-body diagram in Fig. 2.13b permit a solution for the member forces F_{CE}, F_{BE} and F_{BD}.

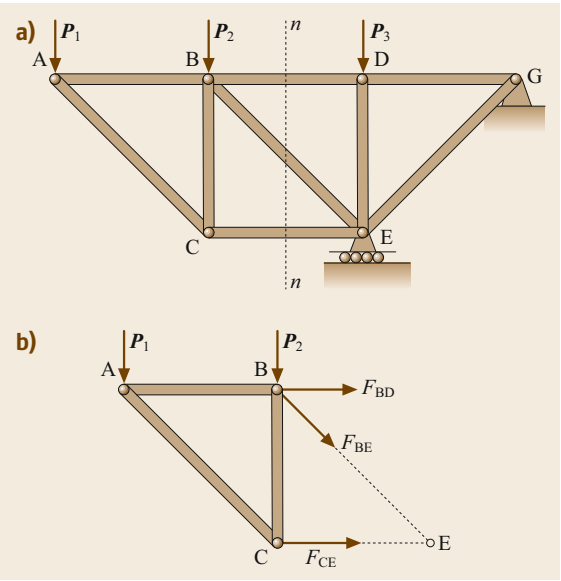

Fig. 2.13a,b Method of sections. **(a)** Complete truss. **(b)** Free body diagram using section *n–n*.

2.1.6 Frames and Machines

Many common structures do not meet the definition of truss structures. *Frames* are defined as static structures that, unlike truss structures, are not comprised solely of two-force members. *Machines* contain moving parts, and likewise are not comprised solely of two-force members. If the motion of a machine is slow enough that inertial effect are not significant, techniques of static equilibrium can be used to analyze the forces in the structure at each geometric configuration of interest. Otherwise, dynamic analysis based on Sect. 2.2 must be considered.

When analyzing frame or machine structures, specialized analysis techniques developed for truss structures, such as the method of joints described in Sect. 2.1.5, must be discarded or modified. Analysis of a frame structure typically involves separating the structure into individual members that are joined by simple connections and then using free-body diagrams and equations of equilibrium to analyze each member. For example, consider the simple frame shown in Fig. 2.14. It is comprised of three members, AB, BC and DE. Assume that joints B, D, and E are frictionless pins, and that there is a fixed support at A. We see that member BC is not a two-force member because it is acted upon by resultant forces at three locations: B, C, and E. Member DE, however, is a two-force member, experiencing only forces at pin D and at pin E. The forces at each end of this member must therefore be equal and opposite and point in the DE direction. The free-body diagram of member BC is shown in Fig. 2.14b. The pinned joint at B acts like a pinned support and thus unknown reaction components in both horizontal and vertical directions are identified at B. Because the force at E results from connection with two-force member DE, the direction of this reaction force is known to be in the DE direction and it is drawn in the free-body diagram as such. By inspection, DE will be loaded in the compression sense and the force that it imposes on member BC will be in the direction shown. Solution for the forces acting on member BC can be found by applying two-dimensional equilibrium equations to the

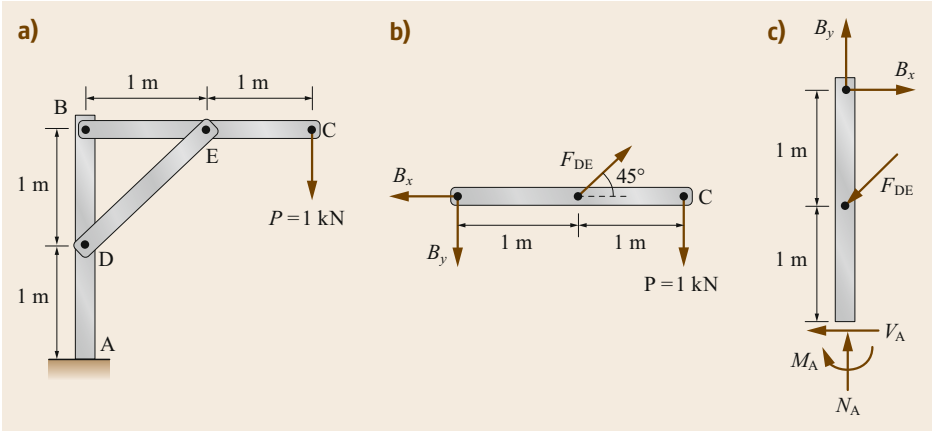

Fig. 2.14a–c Analysis of a simple frame structure. **(a)** Complete frame. **(b)** Free body diagram of member BD. **(c)** Free body diagram of member AB

free-body diagram in Fig. 2.14b as follows

$$\sum F_x = -B_x + F_{DE}\cos 45^\circ = 0\,,$$

$$\sum F_y = -B_y + F_{DE}\sin 45^\circ - 1\,\text{kN} = 0\,,$$

$$\sum M_B = (F_{DE}\sin 45^\circ)\,(1\,\text{m}) - (1\,\text{kN})\,(2\,\text{m}) = 0\,,$$

$$F_{DE} = 2.83\,\text{kN}\,,\ B_x = 2.00\,\text{kN}\,,\ B_y = 1.00\,\text{kN}\,.$$

Next, the forces on member AB can be analyzed using the free-body diagram shown in Fig. 2.14c. Note that the reaction forces at B in this free-body diagram are equal and opposite to those in the free-body diagram of member AB because the forces on member AB at B and the forces on member BC at B form an equal and opposite pair according to Newton's third law. The free-body diagram of member AB can be used with the known values of F_{DE}, B_x and B_y to find the unknown support reactions at A.

2.1.7 Internal Resultants in Structural Members

Principles of static equilibrium can be used to help understand the forces carried internally by structural members. This is a necessary step toward being able to design structural members to carry required loads. Consider the beam shown in Fig. 2.15. Principles of rigid body equilibrium described in Sect. 2.1.4 can be used to determine the reactions at fixed support A. Now, consider analytically *cutting* the beam at location C. A free-body diagram of either of the two portions of the beam can be drawn using the internal resultants shown in Fig. 2.15b. These figures have been rotated to emphasize the internal surfaces exposed by the cut. On each of these internal surfaces there will be a complicated distribution of forces resulting from the attachment of material on that surface to adjoining material on the opposite surface. These forces make equal and opposite reaction pairs according to Newton's third law, and

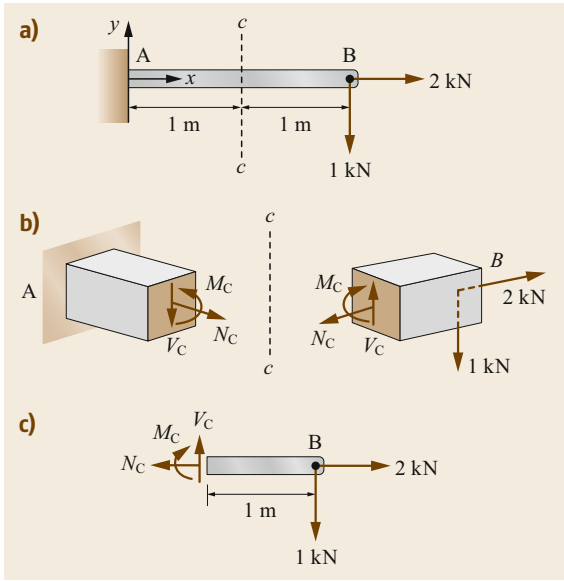

Fig. 2.15a–c Internal resultants in a beam. **(a)** Cantilevered beam AB. **(b)** Internal resultants on section *c–c*. **(c)** Free body diagram of a portion of the beam from section *c–c* to the beam tip

thus the direction of each resultant will be opposite on each of the two exposed surfaces. To simplify the analysis, we consider only the resultants of the forces on each cut surface. These are called the *internal resultants*. In a plane structure, such as in this example, we expect resultant force components in the x and y directions only as well as a resultant moment about the z axis. The force resultants are typically resolved into components perpendicular to the cut surface, called the normal force resultant N and a force component parallel to the surface, called the shear force resultant V. In a three-dimensional structure we expect internal force and moment resultants to have components in all three coordinate directions.

To solve for the internal resultants, one simply chooses one of the two free-body diagrams resulting from the cut and applies the equations of equilibrium. In the case of the example in Fig. 2.15, it is more convenient to choose free-body diagram CB because use of free-body diagram AC would require determination of the reaction forces at support A before finding the internal resultants. Using the free-body diagram for CB shown in Fig. 2.15c, the following equations of equilibrium and solution result.

$$\sum F_x = -N_C + 2\,\text{kN} = 0\,,$$
$$\sum F_y = V_C - 1\,\text{kN} = 0\,,$$
$$\sum M_C = M_C + (1\,\text{kN})(1\,\text{m}) = 0\,,$$
$$N_C = 2\,\text{kN}\,,\ V_C = 1\,\text{kN}\,,\ M_C = -1\,\text{kN m}\,.$$

In general, we expect that each cross-section of a beam will have unique values of internal resultants. These are often presented graphically in the form of shear-moment diagrams [2.6].

2.1.8 Distributed Forces

The mass elements of a body of mass m are affected by the forces of gravity $\mathrm{d}F = \mathrm{d}mg = \mathrm{d}W$, all of which are parallel to one another. The resultant of the gravitational forces acting on all elements is the weight of the body and is given by the integral $W = \int \mathrm{d}W$. To determine the location of the *center of gravity* of any body mathematically, we require that the moment of the resultant gravitational force W about any axis equal to the sum of the moments about the same axis of all the gravitational forces $\mathrm{d}W$ acting on all the particles in the body, be treated as infinitesimal elements. For example, as shown in Fig. 2.16, the moment about the y-axis of the elemental weight is $x\mathrm{d}W$, and the integral of these moments for all elements of the body is $\int x\mathrm{d}W$. This sum of moments must equal $W\overline{x}$, where $\overline{x}$ is the x coordinate of the center of gravity of the body. Therefore, $\overline{x}W = \int x\mathrm{d}W$. With similar expressions for the other two components, the coordinates of the center of gravity G are expressed as

$$\overline{x} = \frac{\int x\mathrm{d}W}{W}\,,\ \overline{y} = \frac{\int y\mathrm{d}W}{W}\,,\ \overline{z} = \frac{\int z\mathrm{d}W}{W}\,. \qquad (2.14)$$

With the substitutions $W = mg$ and $\mathrm{d}W = g\mathrm{d}m$, assuming g is constant within the body the expressions for the coordinates of the center of gravity become

$$\overline{x} = \frac{\int x\mathrm{d}m}{m}\,,\ \overline{y} = \frac{\int y\mathrm{d}m}{m}\,,\ \overline{z} = \frac{\int z\mathrm{d}m}{m}\,. \qquad (2.15)$$

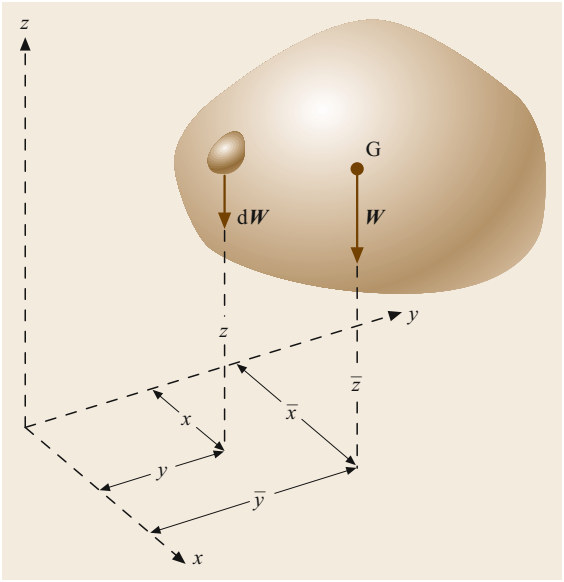

Fig. 2.16 Center of gravity

The density ρ of a body is its mass per unit volume. Therefore, the mass of a differential element of volume $\mathrm{d}V$ becomes $\mathrm{d}m = \rho\mathrm{d}V$, thus, (2.15) can be written as

$$\overline{x} = \frac{\int x\rho\mathrm{d}V}{\int \rho\mathrm{d}V}\,,\ \overline{y} = \frac{\int y\rho\mathrm{d}V}{\int \rho\mathrm{d}V}\,,\ \overline{z} = \frac{\int z\rho\mathrm{d}V}{\int \rho\mathrm{d}V}\,. \qquad (2.16)$$

Since g no longer appears in (2.15) and (2.16), a unique point that is only a function of the distribution of mass is defined in the body. This point is called the *center of mass* and coincides with the center of gravity as long as the gravity field is treated as uniform and parallel.

The *centroid* is defined as the mean position of all the points in a geometric shape. The location of the centroid is the same as the location of the center of mass of an object of the same shape that has uniform density. The concept of the centroid is used in many engineering computations. For example, internal resultant forces on the cross-section of a beam are typically defined with respect to the centroid of the cross-section because a force perpendicular to the cross-section at the centroid produces no bending effect on the beam, simplifying analysis of its behavior. The calculation of centroids is made with consideration of the nature of the geometric shape being considered:

1. Lines: for a slender rod or wire of length L, cross-sectional area A, and density ρ, the coordinates of the centroid C of the line segment may be written

$$\overline{x} = \frac{\int x\mathrm{d}L}{L}\,,\ \overline{y} = \frac{\int y\mathrm{d}L}{L}\,,\ \overline{z} = \frac{\int z\mathrm{d}L}{L}\,. \qquad (2.17)$$

Table 2.1 Properties of plane figures (after [2.2] for full definition of terms)

Figure	Centroid
Arc segment	$\bar{r} = \frac{r \sin \alpha}{\alpha}$
Quarter and semicircular arcs	$\bar{y} = \frac{2r}{\pi}$
Circular area	–
Semicircular area	$\bar{y} = \frac{4r}{3\pi}$
Quarter-circular area	$\bar{x} = \bar{y} = \frac{4r}{3\pi}$
Area of circular sector	$\bar{x} = \frac{2}{3} \frac{r \sin \alpha}{\alpha}$
Rectangular area	–
Triangular area	$\bar{x} = \frac{a+b}{3}, \bar{y} = \frac{h}{3}$
Area of elliptical quadrant	$\bar{x} = \frac{4a}{3\pi}, \bar{y} = \frac{4b}{3\pi}$
Subparabolic area	$\bar{x} = \frac{3a}{4}, \bar{y} = \frac{3b}{10}$
Parabolic area	$\bar{x} = \frac{3a}{8}, \bar{y} = \frac{3b}{5}$

Similarly, for area and volumes, the expressions of centroids are:

2. Areas

$$\bar{x} = \frac{\int x \mathrm{d}A}{A} , \quad \bar{y} = \frac{\int y \mathrm{d}A}{A} , \quad \bar{z} = \frac{\int z \mathrm{d}A}{A} . \qquad (2.18)$$

3. Volumes

$$\bar{x} = \frac{\int x \mathrm{d}V}{V} , \quad \bar{y} = \frac{\int y \mathrm{d}V}{V} , \quad \bar{z} = \frac{\int z \mathrm{d}V}{V} , \qquad (2.19)$$

where A and V represent the area and volume of the body, respectively. Some useful expressions for the centroid of various geometric figures are listed in Table 2.1.

2.1.9 Friction

Consider a solid block resting on an unlubricated horizontal surface, with the application of a horizontal force $\boldsymbol{P}$ that continuously increases from zero to a value sufficient to move the block and give it an appreciable velocity (Fig. 2.17a). Note that the block does not move at first, which shows that a friction force $\boldsymbol{F}$ must have developed to balance $\boldsymbol{P}$. As the magnitude of $\boldsymbol{P}$ increases, the magnitude of $\boldsymbol{F}$ also increases until it reaches a maximum value $F_{\max}$. If $\boldsymbol{P}$ is further increased, the block starts sliding and the magnitude of $\boldsymbol{F}$ drops from $\boldsymbol{F}_{\max}$ to a lower value $\boldsymbol{F}_{\mathrm{k}}$ (Fig. 2.17b). Experimental evidence shows that $\boldsymbol{F}_{\max}$ and $\boldsymbol{F}_{\mathrm{k}}$ are proportional to the normal component $\boldsymbol{N}$ of the reaction of the surface. Thus

$$F_{\max} = \mu_{\mathrm{s}} N , \quad F_{\mathrm{k}} = \mu_{\mathrm{k}} N , \qquad (2.20)$$

where μ_{s} and μ_{k} are called, respectively, the coefficients of static and kinetic friction.

It is sometimes convenient to replace the normal force $\boldsymbol{N}$ and the friction force $\boldsymbol{F}$ by their resultant $\boldsymbol{R}$, as shown in Fig. 2.18. As the friction force increases and reaches its maximum value $F_{\max} = \mu_{\mathrm{s}} N$, the angle ϕ that $\boldsymbol{R}$ forms with the normal to the surface increases and reaches a maximum value ϕ_{s}, called the angle of static friction. If motion actually takes place, the magnitude of $\boldsymbol{F}$ drops to $\boldsymbol{F}_{\mathrm{k}}$, similarly the angle ϕ drops to a lower value ϕ_{k}, called the angle of kinetic friction. Thus

$$\tan \phi_{\mathrm{s}} = \mu_{\mathrm{s}} , \quad \tan \phi_{\mathrm{k}} = \mu_{\mathrm{k}} . \qquad (2.21)$$

It is important to note that a coefficient of friction applies to a given pair of mating surfaces. It is meaningless to speak of a coefficient of friction for a single surface. Also friction coefficients vary considerably, depending on the exact condition of the mating surfaces.

Dry friction plays an important role in a number of engineering applications such as wedges, square-threaded screws, journal bearings, thrust bearings, and

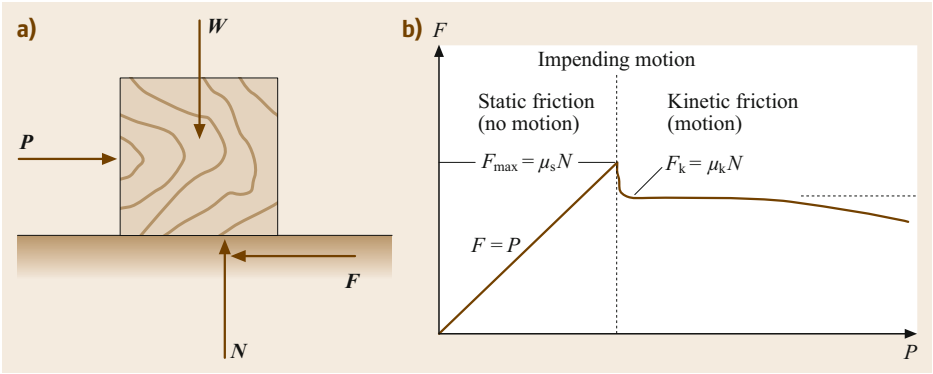

Fig. 2.17a,b Friction on a solid block. **(a)** Dry friction, **(b)** relation of friction

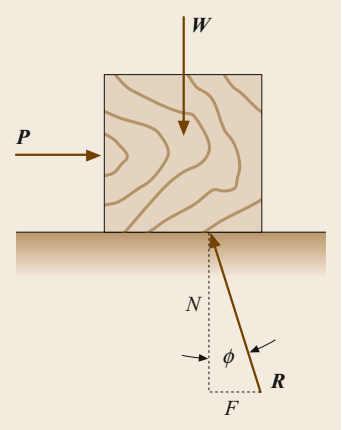

Fig. 2.18 Free-body diagram of a solid block

disk friction. In constructing a free-body diagram when friction is included it is important to draw the direction of the friction force to oppose the direction of motion (or the direction of the tendency toward motion in a purely static case).

2.1.10 Principle of Virtual Work

While static problems are often solved using direct application of Newton's laws, resulting in the equations of static equilibrium (2.13), they may also be approached using work and energy principles. Of these, the most commonly applied to equilibrium problems is the *principle of virtual work*. The principle of virtual work is an analytical technique based on consideration of what would happen to an object if it were somehow to be subject to a hypothetical or *virtual* displacement, $\delta \boldsymbol{r}$. For a rigid body, work would be done by all of the forces as they move in space. As applied to a particle, the principle of virtual work states that *if a particle is in equilibrium, the total virtual work done by the n applied forces during any arbitrary virtual displacement of the particle is zero*. This can easily be verified as follows.

Let the virtual displacement be $\delta \boldsymbol{r}$, then the virtual work done by any force $\boldsymbol{F}_i$ $(i = 1, 2, \ldots, n)$ is the product of the virtual displacement and the component of the force in the direction of the virtual displacement, thus

$$\begin{aligned} \delta U &= \boldsymbol{F}_1 \cdot \delta \boldsymbol{r} + \boldsymbol{F}_2 \cdot \delta \boldsymbol{r} + \cdots + \boldsymbol{F}_n \cdot \delta \boldsymbol{r} \\ &= \left(\sum \boldsymbol{F} \right) \cdot \delta \boldsymbol{r} \,. \end{aligned} \tag{2.22}$$

However, the equilibrium of these static forces requires that the sum of these forces in any direction be zero, hence

$$\delta U = 0 \,.$$

That is, the total virtual work done during any virtual displacement is zero.

In the case of a rigid body, the principle of virtual work states that: *if a rigid body is in equilibrium, the total virtual work of the external forces acting on the rigid body is zero for any virtual displacement of the body*.

The principle of virtual work can be extended to the case of a system of connected rigid bodies. If the system remains connected during a virtual displacement, only the work of the forces external to the system need be considered, since the total work of the internal forces at the various connections is zero. The benefit of the principle of virtual work is that for complex systems, such as mechanisms and machines, a solution may be easier to obtain than when using direct application of equations of equilibrium.

2.2 Dynamics

The study of the motion of a body without regard to the forces and moments causing the motion is known as kinematics. One may think of kinematics as the geometry of motion. Dynamics is the study of the relation between the forces and moments acting on a body, and the mass and motion of the body; it is used to predict the motion caused by given forces and moments or to determine the forces and moments required to produce a given motion. Material presented here is fundamental to the dynamics of systems of particles and rigid bodies.

Dynamic is one of the oldest branches of physics, with its development as a science beginning with Galileo about four centuries ago. His experiments on uniformly accelerated bodies led Newton to formulate his fundamental laws of motion. The study of dynamics of particles and rigid bodies as an engineering subject is not so old, perhaps going back to after World War II as a standard course in engineering curricula. An even later addition to engineering curricula is the study of vibrations, which can be regarded as the part of the dynamics concerned with the motion of elastic systems [2.6–9].

2.2.1 Motion of a Particle

Motion Relative to a Fixed Frame

The position of a particle P in space is defined at any time t by the three Cartesian coordinates $x(t)$, $y(t)$, and $z(t)$. To describe the motion of a particle P along curve C in a three-dimensional space, as depicted in Fig. 2.19, the position vector is expressed as

$$\boldsymbol{r}(t) = x(t)\boldsymbol{i} + y(t)\boldsymbol{j} + z(t)\boldsymbol{k} \,. \tag{2.23}$$

Velocity

The velocity of the particle P in space is defined as the time rate of change of the position. The velocity vector of P is written as

$$\begin{aligned}\boldsymbol{v}(t) = \frac{\mathrm{d}\boldsymbol{r}(t)}{\mathrm{d}t} &= \dot{x}(t)\boldsymbol{i} + \dot{y}(t)\boldsymbol{j} + \dot{z}(t)\boldsymbol{k} \\ &= v_x(t)\boldsymbol{i} + v_y(t)\boldsymbol{j} + v_z(t)\boldsymbol{k} \,,\end{aligned} \tag{2.24}$$

where

$$v_x(t) = \dot{x}(t) \,, \quad v_y(t) = \dot{y}(t) \,, \quad v_z(t) = \dot{z}(t) \tag{2.25}$$

are the Cartesian components of the velocity vector. From Fig. 2.19, the velocity vector is tangent to the curve trajectory C at all time.

Acceleration

The acceleration of the particle P in space is defined as the time rate of change of the velocity. The acceleration vector of P is written as

$$\begin{aligned}\boldsymbol{a}(t) = \frac{\mathrm{d}\boldsymbol{v}(t)}{\mathrm{d}t} &= \dot{v}_x(t)\boldsymbol{i} + \dot{v}_y(t)\boldsymbol{j} + \dot{v}_z(t)\boldsymbol{k} \\ &= a_x(t)\boldsymbol{i} + a_y(t)\boldsymbol{j} + a_z(t)\boldsymbol{k} \,,\end{aligned} \tag{2.26}$$

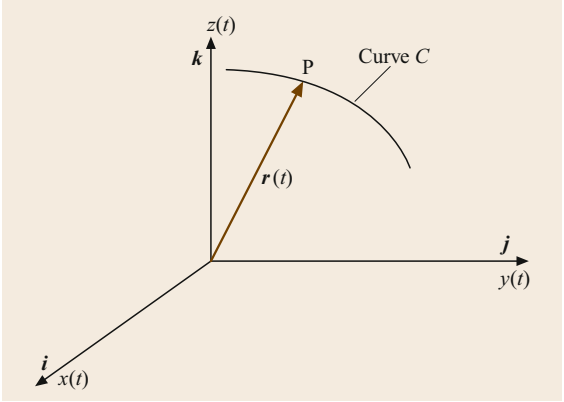

Fig. 2.19 The motion of a particle

where

$$\begin{aligned}&a_x(t) = \dot{v}_x(t) = \ddot{x}(t) \,, \quad a_y(t) = \dot{v}_y(t) = \ddot{y}(t) \,, \\ &a_z(t) = \dot{v}_z(t) = \ddot{z}(t)\end{aligned} \tag{2.27}$$

are the Cartesian components of the acceleration vector.

Rectilinear Motion

Rectilinear motion implies motion along a straight line. Since there is only one component of motion, we may dispense with the vector notation and describe the motion in terms of scalar quantities. Denoting the line along which the motion takes place by s and the distance of the particle P from the fixed origin O by $s(t)$ as depicted in Fig. 2.20, the velocity of P is written as

$$v(t) = \frac{\mathrm{d}s(t)}{\mathrm{d}t} = \dot{s}(t) \,. \tag{2.28}$$

The acceleration of P is written as

$$a(t) = \frac{\mathrm{d}v(t)}{\mathrm{d}t} = \frac{\mathrm{d}^2 s(t)}{\mathrm{d}t^2} = \ddot{s}(t) \,. \tag{2.29}$$

The distance $s(t)$, the velocity $v(t)$, the acceleration $a(t)$ are explicit functions of t. However, one can derive a relation among s, v, and a in which the time t is only implicit. Using the chain rule for differentiation

$$a = \frac{\mathrm{d}v}{\mathrm{d}t} = \frac{\mathrm{d}v}{\mathrm{d}s}\frac{\mathrm{d}s}{\mathrm{d}t} = \frac{\mathrm{d}v}{\mathrm{d}s}v \tag{2.30}$$

or

$$a\mathrm{d}s = v\mathrm{d}v \,. \tag{2.31}$$

Integrating (2.31) between the points $s = s_1$, $v = v_1$ and $s = s_2$, $v = v_2$, we obtain

$$\int_{s_1}^{s_2} a\mathrm{d}s = \int_{v_1}^{v_2} v\mathrm{d}v = \frac{1}{2}\left(v_2^2 - v_1^2\right) . \tag{2.32}$$

Uniform Motion

In this case, $v(t) = v_0 = \text{constant}$. By integration, it follows that

$$s(t) = \int v\mathrm{d}t = v_0 t + C_1 \,. \tag{2.33}$$

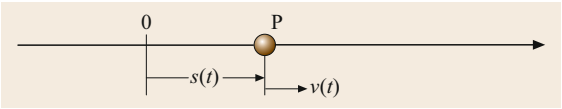

Fig. 2.20 Rectilinear motion

With the initial condition, $s(t=t_1)=s_1$, from this $C_1=s_1-v_0t_1$, therefore,

$$s(t)=v_0\,(t-t_1)+s_1\,. \tag{2.34}$$

Uniform Accelerated Motion

In this case, $a(t)=a_0=$ constant. By integration, it follows that

$$v(t)=\int a\mathrm{d}t=a_0t+C_1 \tag{2.35}$$

or

$$s(t)=\int v\mathrm{d}t=a_0\frac{t^2}{2}+C_1t+C_2\,. \tag{2.36}$$

With the initial condition, $v(t=t_1)=v_1$, and $s(t=t_1)=s_1$, the constants follow: $C_1=v_1-a_0t_1$ and $C_2=s_1-v_1t_1+a_0t_1^2/2$ and therefore

$$s(t)=a_0\frac{(t-t_1)^2}{2}+v_1\,(t-t_1)+s_1\,. \tag{2.37}$$

Example 2.1

A car starting from rest travels with constant acceleration a_0 for 10 s. Determine the value a_0 given that the car has reached a velocity of 108 km/h at the end of the 5 s. What is the distance traveled by the car?

$$v(t)=a_0t$$
$$a_0=\frac{v(t)}{5}|_{t=5}=\frac{108(1000)/3600}{5}=6\,\mathrm{m/s^2}$$
$$s=\frac{1}{2}a_0t^2=\frac{1}{2}6(5)^2=75\,\mathrm{m}$$

Nonuniform Accelerated Motion

In this case, $a(t)=f_0(t)$. By integration, it follows that

$$v(t)=\int a(t)\mathrm{d}t=\int f_0(t)\mathrm{d}t=f_1(t)+C_1 \tag{2.38}$$

or

$$s(t)=\int v(t)\mathrm{d}t=\int[f_1(t)+C_1]\,\mathrm{d}t$$
$$=f_2(t)+C_1t+C_2. \tag{2.39}$$

$f_2(t)=\int f_1(t)\mathrm{d}t$ and the constants C_1 and C_2 are determined from the initial conditions or equivalent conditions.

2.2.2 Planar Motion, Trajectories

Consider a particle with initial velocity v_0 traveling in the xz plane with constant acceleration (gravity) $\ddot{z}=-g$ as shown in Fig. 2.21. Let α be the angle between v_0 and the x-axis. The velocity of the particle at time t in Cartesian components is

$$\boldsymbol{v}=v_0\cos\alpha\boldsymbol{i}+(v_0\sin\alpha-gt)\,\boldsymbol{k}\,. \tag{2.40}$$

The trajectory of the particle at time t in Cartesian components is

$$x=v_0t\cos\alpha\,,\quad z=v_0t\sin\alpha-\frac{1}{2}gt^2\,, \tag{2.41}$$

from which the travel time and trajectory can then be computed as

$$t=\frac{x}{v_0\cos\alpha}\,,\quad z=x\tan\alpha-\frac{1}{2}\frac{gx^2}{v_0^2\cos^2\alpha}\,. \tag{2.42}$$

This trajectory represents a parabola. Its maximum altitude is calculated by locating the point with zero slope

$$\frac{\mathrm{d}z}{\mathrm{d}x}=\tan\alpha-\frac{gx}{v_0^2\cos^2\alpha}=0\,. \tag{2.43}$$

Let x_m be the distance along the x-axis corresponding to the maximum altitude z_m; one obtains

$$x_\mathrm{m}=\frac{v_0^2\sin\alpha\cos\alpha}{g}\,. \tag{2.44}$$

The maximum altitude z_m is

$$z_\mathrm{m}=\frac{v_0^2}{2g}\sin^2\alpha\,. \tag{2.45}$$

The trajectory is symmetrical with respect to the vertical through x_m, as shown in Fig. 2.21. One concludes that the particle hits the ground at $x_\mathrm{f}=2x_\mathrm{m}$. The final velocity $\boldsymbol{v}_\mathrm{f}$ in Cartesian component is

$$v_x=v_0\cos\alpha\,,\quad v_z=-v_0\sin\alpha\,. \tag{2.46}$$

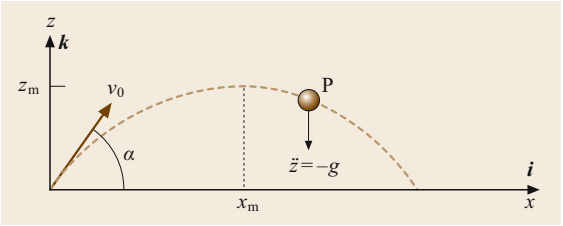

Fig. 2.21 Planar motion

2.2.3 Polar Coordinates

Sometimes it is more convenient to describe the motion of particles using a polar coordinate system. Consider a particle traveling along curve C as shown in Fig. 2.22. In polar coordinates, one defines the radial axis r as the axis coinciding at all times with the direction of the radius vector $\boldsymbol{r}(t)$ from the origin O to the point P. The transverse axis θ is normal to the radial axis as shown in Fig. 2.22. The unit vectors $\boldsymbol{u}_r(t)$ and $\boldsymbol{u}_\theta(t)$, representing the radial and transverse directions, are functions of time. This can be explained by observing that the radius vector $\boldsymbol{r}(t)$ changes directions continuously as the particle moves along the curve C. Because the unit vector $\boldsymbol{u}_r(t)$ is aligned with $\boldsymbol{r}(t)$, $\boldsymbol{u}_r(t)$ also changes direction continuously. Because $\boldsymbol{u}_\theta(t)$ is normal to $\boldsymbol{u}_r(t)$, $\boldsymbol{u}_\theta(t)$ is also a time-dependent unit vector.

The location of the particle P is expressed as

$$\boldsymbol{r}(t) = r(t)\boldsymbol{u}_r(t) \tag{2.47}$$

and the velocity of P is

$$\boldsymbol{v}(t) = \dot{\boldsymbol{r}}(t) = \dot{r}(t)\boldsymbol{u}_r(t) + r(t)\dot{\boldsymbol{u}}_r(t)\,. \tag{2.48}$$

From Fig. 2.23, it follows that

$$\begin{aligned}\dot{\boldsymbol{u}}_r(t) &= \lim_{\Delta t\to 0}\frac{\Delta \boldsymbol{u}_r(t)}{\Delta t} = \lim_{\Delta t\to 0}\frac{\Delta\theta(t)}{\Delta t}\boldsymbol{u}_\theta(t)\\ &= \dot{\theta}(t)\boldsymbol{u}_\theta(t) \qquad (2.49)\\ \dot{\boldsymbol{u}}_\theta(t) &= \lim_{\Delta t\to 0}\frac{\Delta \boldsymbol{u}_\theta(t)}{\Delta t} = \lim_{\Delta t\to 0}\frac{\Delta\theta(t)}{\Delta t}\left[-\boldsymbol{u}_r(t)\right]\\ &= -\dot{\theta}(t)\boldsymbol{u}_r(t)\,. \qquad (2.50)\end{aligned}$$

The velocity of P is rewritten as

$$\begin{aligned}\boldsymbol{v}(t) &= \dot{\boldsymbol{r}}(t) = \dot{r}(t)\boldsymbol{u}_r(t) + r(t)\dot{\boldsymbol{u}}_r(t)\\ &= v_r\boldsymbol{u}_r(t) + v_\theta\boldsymbol{u}_\theta(t)\,,\end{aligned} \tag{2.51}$$

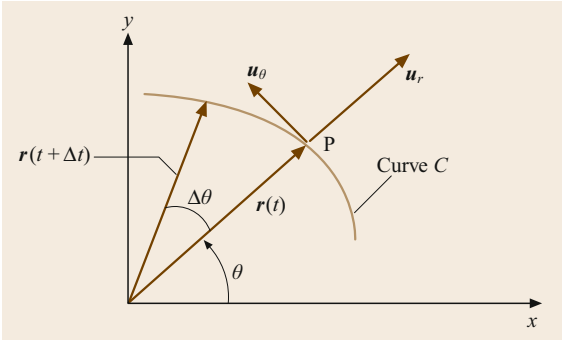

Fig. 2.22 Polar coordinates

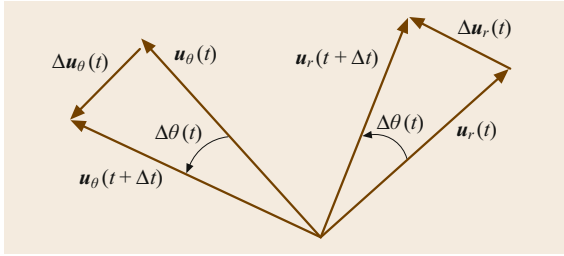

Fig. 2.23 Motion in polar coordinates

where $v_r = \dot{r}$ and $v_\theta = r\dot{\theta}$ are the radial and transverse components of the velocity vector, respectively.

Similarly, the acceleration of point P is

$$\begin{aligned}\boldsymbol{a}(t) &= \dot{\boldsymbol{v}}(t) = \ddot{\boldsymbol{r}}(t)\\ &= \ddot{r}\boldsymbol{u}_r(t) + \dot{r}(t)\dot{\boldsymbol{u}}_r(t) + \dot{r}\dot{\theta}\boldsymbol{u}_\theta + r\ddot{\theta}\boldsymbol{u}_\theta + r\dot{\theta}\dot{\boldsymbol{u}}_\theta\\ &= (\ddot{r} - r\dot{\theta}^2)\boldsymbol{u}_r + (r\ddot{\theta} + 2\dot{r}\dot{\theta})\boldsymbol{u}_\theta\\ &= a_r\boldsymbol{u}_r + a_\theta\boldsymbol{u}_\theta\,,\end{aligned} \tag{2.52a}$$

where

$$a_r = \ddot{r} - r\dot{\theta}^2 \quad \text{and} \quad a_\theta = r\ddot{\theta} + 2\dot{r}\dot{\theta} \tag{2.52b}$$

are the radial and transverse components of the acceleration vector, respectively.

By adding the coordinate z to the polar coordinates r and θ, one obtains the cylindrical coordinates, r, θ, z. The velocity and acceleration vectors can be expressed in terms of cylindrical coordinates as

$$\boldsymbol{v}(t) = v_r\boldsymbol{u}_r + v_\theta\boldsymbol{u}_\theta + v_z\boldsymbol{k}\,, \tag{2.53}$$

where $v_z = \dot{z}$,

$$\boldsymbol{a}(t) = a_r\boldsymbol{u}_r + a_\theta\boldsymbol{u}_\theta + a_z\boldsymbol{k}\,, \tag{2.54}$$

and $a_z = \ddot{z}$.

Example 2.2

A bicycler enters a semicircular track of radius $r = 60\,\mathrm{m}$, as shown in Fig. 2.24, with velocity $v_\mathrm{A} = 18\,\mathrm{m/s}$, and decelerates at a uniform rate, and exits with velocity $v_\mathrm{C} = 12\,\mathrm{m/s}$. Find the circumferential deceleration, the time it takes to complete the semicircle, and the velocity at point B.

Denote the magnitude of the circumferential deceleration as follows

$$a_\theta = r\ddot{\theta}\,. \tag{2.55a}$$

Integrating (2.55a) with respect to time yields

$$v_\theta = r\dot{\theta} = v_\mathrm{A} + a_\theta t\,. \tag{2.55b}$$

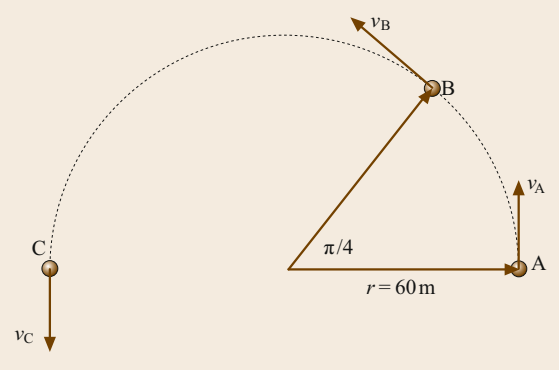

Fig. 2.24 A bicyclist on a semicircular track

Letting $t = t_f$ and $v_\theta = v_C$ in (2.55b), one can write

$$a_\theta t_f = v_C - v_A = 12 - 18 = -6\,\mathrm{m/s}\,. \tag{2.55c}$$

Integrating (2.55b) with respect to time, one obtains

$$r\theta = v_A t + \frac{1}{2} a_\theta t^2\,. \tag{2.55d}$$

Inserting $t = t_f$, $a_\theta t_f = -6$, and $\theta_f = \pi$ in (2.55d) yields

$$t_f = \frac{r\theta_f}{v_A + \frac{1}{2}a_\theta t_f} = \frac{60\pi}{18 + \frac{1}{2}(-6)} = 4\pi\,\mathrm{s} \tag{2.55e}$$

and

$$a_\theta = \frac{-6}{4\pi}\,\mathrm{m/s^2}\,. \tag{2.55f}$$

To obtain v_B, we use

$$a_\theta s_{AB} = \frac{1}{2}\left(v_B^2 - v_A^2\right) \tag{2.55g}$$

so that

$$v_B = \sqrt{v_A^2 + 2a_\theta s_{AB}} = \sqrt{18^2 + 2\left(\frac{-6}{4\pi}\right)\left(\frac{60\pi}{4}\right)}$$
$$= 16.7\,\mathrm{m/s}\,. \tag{2.55h}$$

2.2.4 Motion of Rigid Bodies (Moving Reference Frames)

Consider a reference frame xyz moving relative to the fixed reference frame XYZ as shown in Fig. 2.25. A point P relative to the system XYZ is expressed as

$$\boldsymbol{R} = \boldsymbol{r}_A + \boldsymbol{r}_{AP}\,. \tag{2.56}$$

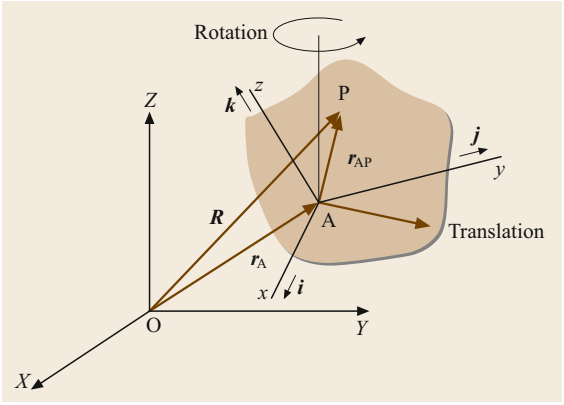

Fig. 2.25 Moving reference frame

The velocity of P relative to an inertial space is

$$\boldsymbol{v} = \dot{\boldsymbol{R}} = \boldsymbol{v}_A + \boldsymbol{v}_{AP}\,, \tag{2.57}$$

where

$$\boldsymbol{v}_A = \dot{\boldsymbol{r}}_A \quad \text{and} \quad \boldsymbol{v}_{AP} = \dot{\boldsymbol{r}}_{AP}\,. \tag{2.58}$$

Similarly, the acceleration of P relative to an inertial space is

$$\boldsymbol{a} = \dot{\boldsymbol{v}} = \ddot{\boldsymbol{R}} = \boldsymbol{a}_A + \boldsymbol{a}_{AP}\,, \tag{2.59}$$

where

$$\boldsymbol{a}_A = \dot{\boldsymbol{v}}_A = \ddot{\boldsymbol{r}}_A \quad \text{and} \quad \boldsymbol{a}_{AP} = \dot{\boldsymbol{v}}_{AP} = \ddot{\boldsymbol{r}}_{AP}\,. \tag{2.60}$$

Rotating Reference Frames

Consider the rigid body shown in Fig. 2.26. Assume that the rigid body is rotating about the axis AB, and consider a point P at a distance $d = |\boldsymbol{d}|$ from point C on axis AB, where C is the intersection between the axis AB and a plane normal to AB that contains the point P. In the time increment Δt the vector $\boldsymbol{d}$ from C to P sweeps an angle $\Delta\theta$ in the plane normal to AB. The vector $\boldsymbol{d}$ rotates in a plane normal to the axis AB with the angular rate $\dot{\theta}$. Because the vector $\boldsymbol{d}$ is embedded in the rigid body, the rigid body and the triad xyz rotate about the axis AB at the same rate $\dot{\theta}$. This angular rate is represented as a vector $\boldsymbol{\omega}$ directed along the axis AB. Note that $\boldsymbol{\omega}$ can be used to represent either the angular velocity of the rigid body, or of the frame xyz

$$\lim_{\Delta t \to 0} \frac{\Delta\theta}{\Delta t} = \dot{\theta} = |\boldsymbol{\omega}|\,. \tag{2.61}$$

Consider the rate of change $\dot{\boldsymbol{d}}$ of the vector $\boldsymbol{d}$ due to the rotation of the body. From Fig. 2.26, we observe that the

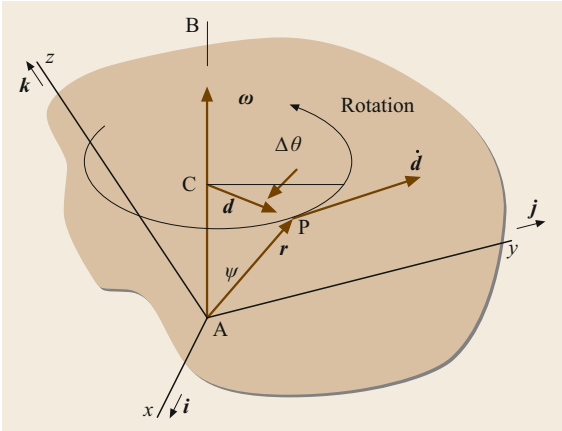

Fig. 2.26 Rotating rigid body

tip P of the vector $\boldsymbol{d}$ describes a circle of radius d, so that $\dot{\boldsymbol{d}}$ is tangent to the circle at P and is normal to the plane defined by the vectors $\boldsymbol{\omega}$ and $\boldsymbol{d}$. In the time increment Δt, the vector $\boldsymbol{d}$ makes the change in magnitude

$$\Delta d = d\Delta\theta \tag{2.62}$$

and

$$\dot{d} = \lim_{\Delta t\to 0}\frac{\Delta d}{\Delta t} = d\dot{\theta}\,. \tag{2.63}$$

In vector notation

$$\dot{\boldsymbol{d}} = \boldsymbol{\omega}\times\boldsymbol{d}\,. \tag{2.64}$$

One can generalize the above equation by observing that

$$d = r\sin\psi\,, \tag{2.65}$$

where r is the magnitude of the vector $\boldsymbol{r}$ and ψ is the angle between AB and $\boldsymbol{r}$. Hence the rate of change of the vector $\boldsymbol{r}$ is

$$\dot{\boldsymbol{r}} = \boldsymbol{\omega}\times\boldsymbol{r}\,. \tag{2.66}$$

The velocity of point P relative to point A is due entirely to the rotation of the frame xyz. Replacing the vector $\boldsymbol{r}$ by the radius vector $\boldsymbol{r}_{\mathrm{AP}}$, yields

$$\boldsymbol{v}_{\mathrm{AP}} = \dot{\boldsymbol{r}}_{\mathrm{AP}} = \boldsymbol{\omega}\times\boldsymbol{r}_{\mathrm{AP}}\,. \tag{2.67}$$

Because point A is at rest, $\boldsymbol{v}_{\mathrm{AP}}$ is also the absolute velocity of P, $\boldsymbol{v} = \boldsymbol{v}_{\mathrm{AP}}$.

The time rate of change of $\boldsymbol{\omega}$ is referred to as the angular acceleration

$$\boldsymbol{\alpha} = \dot{\boldsymbol{\omega}}\,. \tag{2.68}$$

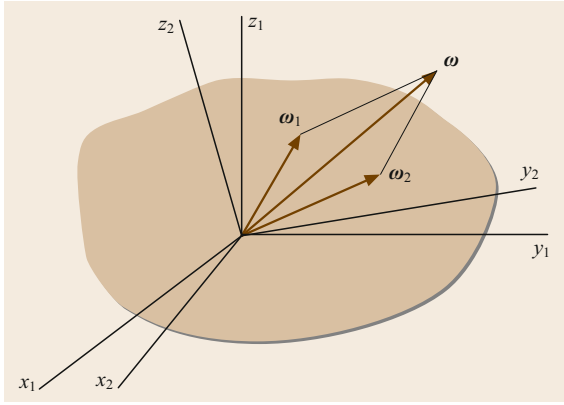

Fig. 2.27 Rotating frame

The acceleration of point P relative to point A is

$$\begin{aligned}\boldsymbol{a}_{\mathrm{AP}} &= \dot{\boldsymbol{v}}_{\mathrm{AP}} = \dot{\boldsymbol{\omega}}\times\boldsymbol{r}_{\mathrm{AP}} + \boldsymbol{\omega}\times\dot{\boldsymbol{r}}_{\mathrm{AP}}\\ &= \boldsymbol{\alpha}\times\boldsymbol{r}_{\mathrm{AP}} + \boldsymbol{\omega}\times(\boldsymbol{\omega}\times\boldsymbol{r}_{\mathrm{AP}})\,.\end{aligned} \tag{2.69}$$

Because point A is at rest, $\boldsymbol{a}_{\mathrm{AP}}$ is also the absolute acceleration of P, $\boldsymbol{a} = \boldsymbol{a}_{\mathrm{AP}}$.

When the origin A of the rotating frame xyz is not fixed, but moves relative to the inertial frame XYZ with the velocity $\boldsymbol{v}_{\mathrm{A}}$ and acceleration $\boldsymbol{a}_{\mathrm{A}}$, then the absolute velocity and acceleration of P are

$$\boldsymbol{v} = \boldsymbol{v}_{\mathrm{A}} + \boldsymbol{v}_{\mathrm{AP}} = \boldsymbol{v}_{\mathrm{A}} + \boldsymbol{\omega}\times\boldsymbol{r}_{\mathrm{AP}}\,, \tag{2.70}$$

$$\boldsymbol{a} = \boldsymbol{a}_{\mathrm{A}} + \boldsymbol{a}_{\mathrm{AP}} = \boldsymbol{a}_{\mathrm{A}} + \boldsymbol{\alpha}\times\boldsymbol{r}_{\mathrm{AP}} + \boldsymbol{\omega}\times(\boldsymbol{\omega}\times\boldsymbol{r}_{\mathrm{AP}})\,. \tag{2.71}$$

Consider the case in which the reference frame $x_1y_1z_1$ rotates with angular velocity $\boldsymbol{\omega}_1$ and the reference frame $x_2y_2z_2$ rotates relative to the frame $x_1y_1z_1$ with angular velocity $\boldsymbol{\omega}_2$, as shown in Fig. 2.27. The angular velocity of the frame $x_2y_2z_2$ is simply

$$\boldsymbol{\omega} = \boldsymbol{\omega}_1 + \boldsymbol{\omega}_2\,. \tag{2.72}$$

Assume that the vector $\boldsymbol{\omega}$ is expressed in terms of components along the frame $x_1y_1z_1$; the angular acceleration then consists of two parts: the first is due to the change in the components of $\boldsymbol{\omega}$ relative to the frame $x_1y_1z_1$ and the second is due to the fact that $\boldsymbol{\omega}$ is expressed in terms of components in a rotating frame. Denoting the first part by $\boldsymbol{\alpha}'$ and noting that the second part can be obtained from (2.66), by replacing $\boldsymbol{r}$ by $\boldsymbol{\omega}$ and $\boldsymbol{\omega}$ by $\boldsymbol{\omega}_1$, yields

$$\boldsymbol{\alpha} = \dot{\boldsymbol{\omega}} = \boldsymbol{\alpha}' + \boldsymbol{\omega}_1\times\boldsymbol{\omega} = \boldsymbol{\alpha}' + \boldsymbol{\omega}_1\times\boldsymbol{\omega}_2\,. \tag{2.73}$$

Example 2.3

A bicycle travels on a circular track of radius R with the circumferential velocity $\boldsymbol{v}_{\mathrm{A}}$ and acceleration $\boldsymbol{a}_{\mathrm{A}}$. Figure 2.28 shows one of the bicycle wheels rotating on

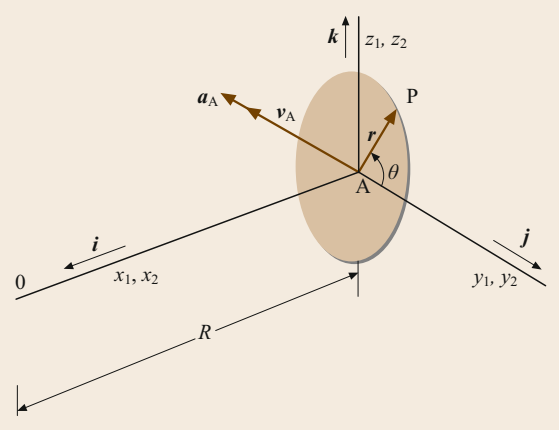

Fig. 2.28 Bicycle wheel

the vertical jk plane. The radius of the wheel is r. Determine the velocity $\boldsymbol{v}$ and acceleration $\boldsymbol{a}$ of a point P on the tire when the radius from the center of the wheel at the point P makes an angle θ with respect to the horizontal plane.

Two reference frames are employed. The frame $x_1y_1z_1$ is attached to the bicycle, and the frame $x_2y_2z_2$ is attached to the wheel. The two frames coincide instantaneously, although the frame $x_2y_2z_2$ rotates relative to the frame $x_1y_1z_1$.

The velocity of the wheel center is

$$\boldsymbol{v}_\mathrm{A} = -v_\mathrm{A}\boldsymbol{j} \tag{2.74a}$$

and the angular velocity of the frame $x_1y_1z_1$ is

$$\boldsymbol{\omega}_1 = \frac{v_\mathrm{A}}{R}\boldsymbol{k}\,. \tag{2.74b}$$

The angular velocity of the frame $x_2y_2z_2$ relative to $x_1y_1z_1$ is

$$\boldsymbol{\omega}_2 = \frac{v_\mathrm{A}}{r}\boldsymbol{i}\,. \tag{2.74c}$$

So, the absolute angular velocity of the frame $x_2y_2z_2$ is

$$\boldsymbol{\omega} = \boldsymbol{\omega}_1 + \boldsymbol{\omega}_2 = \frac{v_\mathrm{A}}{R}\boldsymbol{k} + \frac{v_\mathrm{A}}{r}\boldsymbol{i}\,. \tag{2.74d}$$

The radius vector from A to P is

$$\boldsymbol{r}_\mathrm{AP} = r\,(\cos\theta\boldsymbol{j} + \sin\theta\boldsymbol{k})\,. \tag{2.74e}$$

The velocity of P becomes

$$\begin{aligned}\boldsymbol{v} &= \boldsymbol{v}_\mathrm{A} + \boldsymbol{\omega}\times\boldsymbol{r}_\mathrm{AP}\\ &= -v_\mathrm{A}\boldsymbol{j} + \left(\frac{v_\mathrm{A}}{r}\boldsymbol{i} + \frac{v_\mathrm{A}}{R}\boldsymbol{k}\right)\times r\,(\cos\theta\boldsymbol{j} + \sin\theta\boldsymbol{k})\\ &= -\frac{v_\mathrm{A}r}{R}\cos\theta\boldsymbol{i} - v_\mathrm{A}\,(1+\sin\theta)\boldsymbol{j} + v_\mathrm{A}\cos\theta\boldsymbol{k}\,.\end{aligned} \tag{2.74f}$$

The acceleration of A has two components: a tangential component due to the acceleration of the bicycle along the track and a normal component due to motion along a curvilinear track. Therefore,

$$\begin{aligned}\boldsymbol{a}_\mathrm{A} &= -a_\mathrm{A}\boldsymbol{j} + \boldsymbol{\omega}_1\times(\boldsymbol{\omega}_1\times\boldsymbol{r}_{0\mathrm{A}})\\ &= -a_\mathrm{A}\boldsymbol{j} + \frac{v_\mathrm{A}}{R}\boldsymbol{k}\times\left[\frac{v_\mathrm{A}}{R}\boldsymbol{k}\times(-R)\,\boldsymbol{i}\right]\\ &= \frac{v_\mathrm{A}^2}{R}\boldsymbol{i} - a_\mathrm{A}\boldsymbol{j}\,.\end{aligned} \tag{2.74g}$$

Using (2.73), the angular acceleration of the frame $x_2y_2z_2$ is

$$\begin{aligned}\boldsymbol{\alpha} &= \dot{\boldsymbol{\omega}}_1 + \dot{\boldsymbol{\omega}}_2 + \boldsymbol{\omega}_1\times\boldsymbol{\omega}_2\\ &= \frac{a_\mathrm{A}}{R}\boldsymbol{k} + \frac{a_\mathrm{A}}{r}\boldsymbol{i} + \frac{v_\mathrm{A}}{R}\boldsymbol{k}\times\frac{v_\mathrm{A}}{r}\boldsymbol{i}\\ &= \frac{a_\mathrm{A}}{r}\boldsymbol{i} + \frac{v_\mathrm{A}^2}{rR}\boldsymbol{j} + \frac{a_\mathrm{A}}{R}\boldsymbol{k}\,.\end{aligned} \tag{2.74h}$$

Finally, the acceleration of P is

$$\begin{aligned}\boldsymbol{\alpha} &= \boldsymbol{a}_\mathrm{A} + \alpha\times\boldsymbol{r}_\mathrm{AP} + \boldsymbol{\omega}\times(\boldsymbol{\omega}\times\boldsymbol{r}_\mathrm{AP})\\ &= \frac{v_\mathrm{A}^2}{R}\boldsymbol{i} - a_\mathrm{A}\boldsymbol{j} + \left(\frac{a_\mathrm{A}}{r}\boldsymbol{i} + \frac{v_\mathrm{A}^2}{rR}\boldsymbol{j} + \frac{a_\mathrm{A}}{R}\boldsymbol{k}\right)\\ &\quad\times r\,(\cos\theta j + \sin\theta k) + \left(\frac{v_\mathrm{A}}{r}\boldsymbol{i} + \frac{v_\mathrm{A}}{R}\boldsymbol{k}\right)\\ &\quad\times\left[\left(\frac{v_\mathrm{A}}{r}\boldsymbol{i} + \frac{v_\mathrm{A}}{R}\boldsymbol{k}\right)\times r\,(\cos\theta j + \sin\theta k)\right]\\ &= \left[\frac{v_\mathrm{A}^2}{R}\,(1+2\sin\theta) - \frac{ra_\mathrm{A}}{R}\cos\theta\right]\boldsymbol{i}\\ &\quad - \left[\left(\frac{1}{r} + \frac{r}{R^2}\right)v_\mathrm{A}^2\cos\theta + a_\mathrm{A} + a_\mathrm{A}\sin\theta\right]\boldsymbol{j}\\ &\quad - \left(\frac{v_\mathrm{A}^2}{r}\sin\theta - a_\mathrm{A}\cos\theta\right)\boldsymbol{k}\,.\end{aligned} \tag{2.74i}$$

2.2.5 Planar Motion of a Rigid Body

A body has three degrees of motion in planar motion: two of translation (displacement in the x- and y-directions) and one of rotation (rotation about the z-axis) as shown in Fig. 2.29. The radius vector $\boldsymbol{r}_\mathrm{AP}$ is written as

$$\boldsymbol{r}_\mathrm{AP} = x_\mathrm{AP}\boldsymbol{i} + y_\mathrm{AP}\boldsymbol{j}\,. \tag{2.75}$$

The angular velocity and acceleration of point P are

$$\boldsymbol{\omega} = \omega\boldsymbol{k}\,,\quad \boldsymbol{\alpha} = \alpha\boldsymbol{k}\,, \tag{2.76}$$

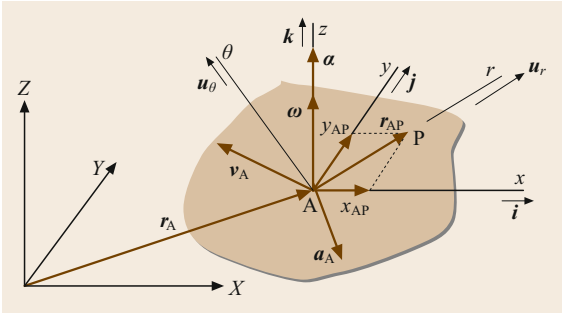

Fig. 2.29 Rigid body motion in a plane

respectively. The velocity of point P is

$$\begin{aligned} \boldsymbol{v} &= \boldsymbol{v}_\mathrm{A} + \boldsymbol{\omega} \times \boldsymbol{r}_\mathrm{AP} = \boldsymbol{v}_\mathrm{A} + \omega \boldsymbol{k} \times (x_\mathrm{AP}\boldsymbol{i} + y_\mathrm{AP}\boldsymbol{j}) \\ &= \boldsymbol{v}_\mathrm{A} - \boldsymbol{\omega} y_\mathrm{AP}\boldsymbol{i} + \boldsymbol{\omega} x_\mathrm{AP}\boldsymbol{j} \,. \end{aligned} \tag{2.77}$$

and the acceleration of point P is

$$\begin{aligned} \boldsymbol{a} &= \boldsymbol{a}_\mathrm{A} + \alpha \times \boldsymbol{r}_\mathrm{AP} + \boldsymbol{\omega} \times (\boldsymbol{\omega} \times \boldsymbol{r}_\mathrm{AP}) \\ &= \boldsymbol{a}_\mathrm{A} + \alpha \boldsymbol{k} \times (x_\mathrm{AP}\boldsymbol{i} + y_\mathrm{AP}\boldsymbol{j}) \\ &\quad + \omega \boldsymbol{k} \times [\omega \boldsymbol{k} \times (x_\mathrm{AP}\boldsymbol{i} + y_\mathrm{AP}\boldsymbol{j})] \\ &= \boldsymbol{a}_\mathrm{A} - \alpha\,(y_\mathrm{AP}\boldsymbol{i} - x_\mathrm{AP}\boldsymbol{j}) - \omega^2 \boldsymbol{r}_\mathrm{AP} \,. \end{aligned} \tag{2.78}$$

The motion can also be expressed in terms of radial and transverse components. The radius vector is

$$\boldsymbol{r}_\mathrm{AP} = r_\mathrm{AP}\boldsymbol{u}_r \,, \tag{2.79}$$

where $\boldsymbol{u}_r$ is the unit vector in the radial direction. The velocity of point P is

$$\boldsymbol{v} = \boldsymbol{v}_\mathrm{A} + \omega r_\mathrm{AP}\boldsymbol{u}_\theta \,, \tag{2.80}$$

where $\boldsymbol{u}_\theta$ is the unit vector in the transverse direction. The acceleration of point P is

$$\begin{aligned} \boldsymbol{a} &= \boldsymbol{a}_\mathrm{A} + \alpha r_\mathrm{AP}\boldsymbol{u}_\theta - \omega^2 \boldsymbol{r}_\mathrm{AP} \\ &= \boldsymbol{a}_\mathrm{A} + \alpha r_\mathrm{AP}\boldsymbol{u}_\theta - \omega^2 r_\mathrm{AP}\boldsymbol{u}_\mathrm{r} \,. \end{aligned} \tag{2.81}$$

Equation (2.77) consists of two parts. The first term represents the velocity of translation of a reference point A. The second part represents the velocity due to rotation about A. If the location of A is specially chosen, the velocity of P can be found to be instantaneously due entirely to rotation. Define this special point as C. It follows that the point C is instantaneously at rest. The point C is called the *instantaneous center of rotation*. Point C may lie inside or outside the body. If both the magnitude and direction of the velocity vector are known, and the angular velocity is also given, then the instantaneous center can be determined by a graphical

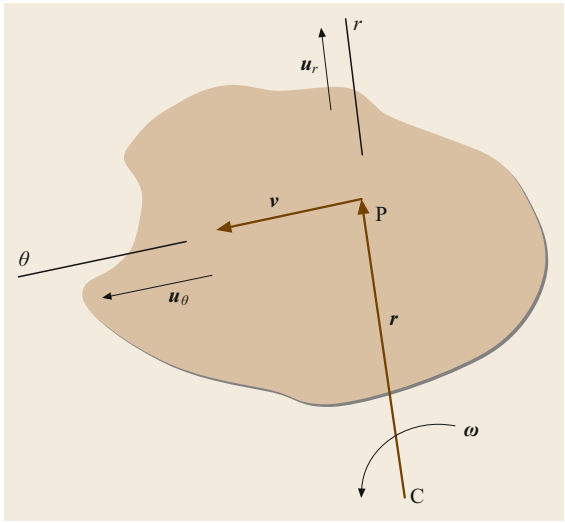

Fig. 2.30 Rigid body and the velocity vector

approach. Figure 2.30 depicts the rigid body and the velocity at point P. The velocity vector can be written

$$\boldsymbol{v} = \boldsymbol{\omega} \times \boldsymbol{r} = \omega \boldsymbol{k} \times r\boldsymbol{u}_r = \omega r \boldsymbol{u}_\theta = v\boldsymbol{u}_\theta \,. \tag{2.82}$$

The radius vector $\boldsymbol{r}$ is normal to the velocity vector $\boldsymbol{v}$, and the angular velocity ω is in the counterclockwise direction as shown in Fig. 2.30. The magnitude of the radius vector is

$$r = \frac{v}{\omega} \,. \tag{2.83}$$

The path taken by the instantaneous center of rotation in relation to a coordinate system fixed in space is called the *space centrode*. The path of the instantaneous center of rotation in relation to a fixed-body coordinate system is called the *body centrode*. During motion, the body centrode rolls on the space centrode.

Example 2.4

A slipping bar of length $L = 20\,\mathrm{m}$ is depicted in Fig. 2.31. The velocity of the point A has magnitude $v_\mathrm{A} = 40\,\mathrm{m/s}$ when the angle between the bar and the wall is $\theta = 30°$; determine the angular velocity of the bar and the velocity of the point B and plot the body and space centrodes.

The instantaneous center of rotation lies at the intersection of the normal to the wall at A and the normal to the floor at the point B. From Fig. 2.31, one has

$$\begin{aligned} r_\mathrm{A} &= L\sin\theta = 10\,\mathrm{m} \,, \\ r_\mathrm{B} &= L\cos\theta = 17.32\,\mathrm{m} \,. \end{aligned} \tag{2.84}$$

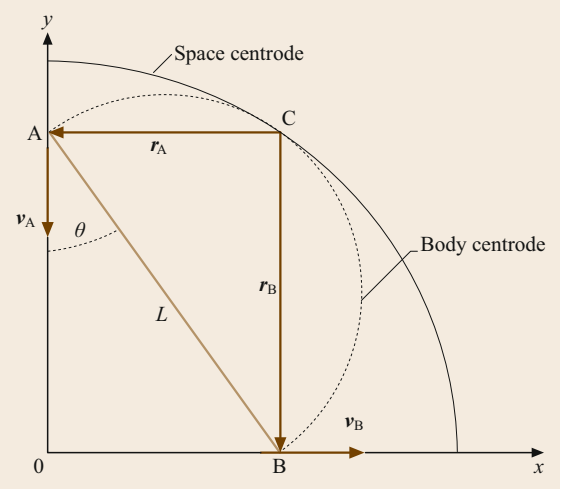

Fig. 2.31 A sliding rod

The velocity vector $\boldsymbol{v}_A$ is in the negative y-direction and the angular velocity in the counterclockwise direction is

$$\omega = \frac{v_A}{r_A} = 4\,\mathrm{rad/s}\,. \tag{2.85}$$

The velocity vector $\boldsymbol{v}_B$ is in the x-direction and its magnitude is

$$v_B = \omega r_B = 69.28\,\mathrm{m/s}\,. \tag{2.86}$$

The points A, O, B, and C are the corners of a rectangular with diagonals equal to L, as shown in Fig. 2.31. Point C is always at a distance L from O. Therefore, the space centrode is one quarter of a circle with radius L and the center at 0, as depicted by the solid line in Fig. 2.31. At the same time, the velocity vectors $\boldsymbol{v}_A$ and $\boldsymbol{v}_B$ make a 90° angle at C. The body centrode is the locus of the point C that is a semicircle as depicted by the dashed line in Fig. 2.31. As the bar slides, the body centrode rolls on the space centrode.

2.2.6 General Case of Motion

Consider the case that the particle P is no longer at rest relative to the moving frame xyz, but can move relative to that frame as depicted in Fig. 2.32. Given an arbitrary vector $\boldsymbol{r}$

$$\boldsymbol{r} = x\boldsymbol{i} + y\boldsymbol{j} + z\boldsymbol{k}\,, \tag{2.87}$$

where x, y, and z are the Cartesian components of the vector and $\boldsymbol{i}$, $\boldsymbol{j}$, and $\boldsymbol{k}$ are the unit vectors along these axes. The unit vectors $\boldsymbol{i}$, $\boldsymbol{j}$, and $\boldsymbol{k}$ rotate with the same

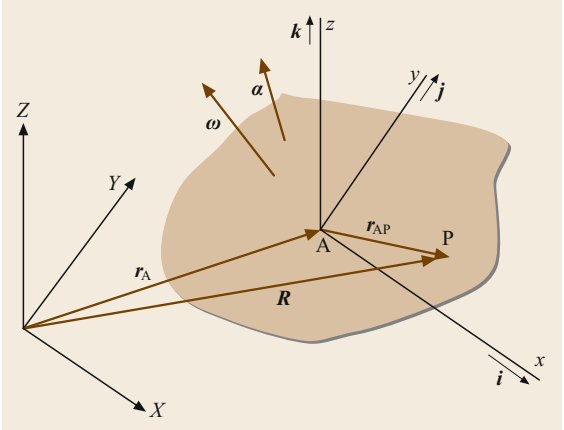

Fig. 2.32 General motion

angular velocity ω as the moving frame. Hence, from (2.66), we have

$$\begin{aligned}\dot{\boldsymbol{r}} &= \dot{x}\boldsymbol{i} + \dot{y}\boldsymbol{j} + \dot{z}\boldsymbol{k} + x\dot{\boldsymbol{i}} + y\dot{\boldsymbol{j}} + z\dot{\boldsymbol{k}} \\ &= \dot{x}\boldsymbol{i} + \dot{y}\boldsymbol{j} + \dot{z}\boldsymbol{k} + \boldsymbol{\omega}\times(x\boldsymbol{i} + y\boldsymbol{j} + z\boldsymbol{k}) \\ &= \dot{\boldsymbol{r}}' + \boldsymbol{\omega}\times\boldsymbol{r}\,,\end{aligned} \tag{2.88}$$

where

$$\dot{\boldsymbol{r}}' = \dot{x}\boldsymbol{i} + \dot{y}\boldsymbol{j} + \dot{z}\boldsymbol{k} \tag{2.89}$$

is the time rate of change of $\boldsymbol{r}$ regarding the reference frame xyz as inertial.

The position vector of point P as depicted in Fig. 2.32 is

$$\boldsymbol{R} = \boldsymbol{r}_A + \boldsymbol{r}_{AP}\,. \tag{2.90}$$

The absolute velocity of P is

$$\boldsymbol{v} = \dot{\boldsymbol{R}} = \dot{\boldsymbol{r}}_A + \dot{\boldsymbol{r}}_{AP} = \boldsymbol{v}_A + \boldsymbol{v}'_{AP} + \boldsymbol{\omega}\times\boldsymbol{r}_{AP}\,, \tag{2.91}$$

where $\boldsymbol{v}_A$ is the velocity of point A relative to the inertial space, and

$$\boldsymbol{v}'_{AP} = \dot{x}_{AP}\boldsymbol{i} + \dot{y}_{AP}\boldsymbol{j} + \dot{z}_{AP}\boldsymbol{k} \tag{2.92}$$

is the velocity of P relative to the moving frame xyz, where x_{AP}, y_{AP}, and z_{AP} are the Cartesian components of $\boldsymbol{r}_{AP}$, and $\boldsymbol{\omega}\times\boldsymbol{r}_{AP}$ is the velocity of P entirely due to the rotation of the frame xyz. Similarly, the absolute acceleration of P is

$$\begin{aligned}\boldsymbol{a} = \dot{\boldsymbol{v}} &= \dot{\boldsymbol{v}}_A + \frac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{v}'_{AP} + \dot{\boldsymbol{\omega}}\times\boldsymbol{r}_{AP} + \boldsymbol{\omega}\times\dot{\boldsymbol{r}}_{AP} \\ &= \boldsymbol{a}_A + \boldsymbol{a}'_{AP} + \boldsymbol{\omega}\times\boldsymbol{v}'_{AP} + \boldsymbol{\alpha}\times\boldsymbol{r}_{AP} + \boldsymbol{\omega}\times\boldsymbol{v}'_{AP} \\ &\quad + \boldsymbol{\omega}\times(\boldsymbol{\omega}\times\boldsymbol{r}_{AP}) \\ &= \boldsymbol{a}_A + \boldsymbol{a}'_{AP} + 2\boldsymbol{\omega}\times\boldsymbol{v}'_{AP} + \boldsymbol{\alpha}\times\boldsymbol{r}_{AP} \\ &\quad + \boldsymbol{\omega}\times(\boldsymbol{\omega}\times\boldsymbol{r}_{AP})\,,\end{aligned} \tag{2.93}$$

where

$$\boldsymbol{a}'_{\mathrm{AP}} = \ddot{x}_{\mathrm{AP}}\boldsymbol{i} + \ddot{y}_{\mathrm{AP}}\boldsymbol{j} + \ddot{z}_{\mathrm{AP}}\boldsymbol{k} \tag{2.94}$$

is the acceleration of P relative to the moving frame xyz, $2\boldsymbol{\omega} \times \boldsymbol{v}'_{\mathrm{AP}}$ is the Coriolis acceleration, and $\boldsymbol{\alpha} \times \boldsymbol{r}_{\mathrm{AP}} + \boldsymbol{\omega} \times (\boldsymbol{\omega} \times \boldsymbol{r}_{\mathrm{AP}})$ is the acceleration of P entirely due to the rotation of the frame xyz, where $\boldsymbol{\alpha} = \dot{\boldsymbol{\omega}}$ is the angular acceleration of the frame xyz.

2.2.7 Dynamics

Particle Dynamics

Dynamics describes the motion of mass particles, mass particle systems, bodies and body systems, in terms of the forces and moments, under the laws of kinematics [2.6–10].

Newton's Laws of Motion

Newton's laws of motion can be applied to systems of particles and rigid bodies. Newton suggested the concept of inertial systems of reference, i.e., systems of reference that are either at rest or moving with uniform velocity relative to a fixed reference frame. The motion of any particle measured relative to such an inertial system is said to be *absolute*. The linear momentum vector $\boldsymbol{p}$ of a particle is defined as the product of the mass m of the particle and its absolute velocity $\boldsymbol{v}$, or $\boldsymbol{p} = m\boldsymbol{v}$. Newton's second law can be expressed as the relationship between a resultant force vector and the time rate of change of momentum as

$$\boldsymbol{F} = \frac{\mathrm{d}\boldsymbol{p}}{\mathrm{d}t} = \frac{\mathrm{d}}{\mathrm{d}t} m\boldsymbol{v} \,. \tag{2.95}$$

In SI units, the unit of mass is the kilogram (kg) and the unit of force is newton (N). If the mass m is constant, then Newton's second law reduces to

$$\boldsymbol{F} = m\frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t} = m\boldsymbol{a} \,, \tag{2.96}$$

where $\boldsymbol{a} = \mathrm{d}\boldsymbol{v}/\mathrm{d}t$ is the absolute acceleration of m. Equation (2.96) is the equation of motion of a particle.

Example 2.5

The mass $m = 5\,\mathrm{kg}$ is moved from the position of rest (1) by the force $F_1 = 100\,\mathrm{N}$ with $\beta = 15°$ onto the inclined plane with $\gamma = 25°$ as depicted in Fig. 2.33. The friction coefficient is $\mu = 0.3$. Determine the acceleration, velocity, and time upon arrival at position 2 after traveling $s = 8\,\mathrm{m}$.

$$\begin{aligned} \boldsymbol{F}_{\mathrm{n}} &= mg\cos\gamma + \boldsymbol{F}_1 \sin(\beta+\gamma) = 108.7\,\mathrm{N} \\ ma &= \sum F = \boldsymbol{F}_1 \cos(\beta+\gamma) - \boldsymbol{F}_{\mathrm{g}} \sin\gamma - \mu \boldsymbol{F}_{\mathrm{n}} \\ &= 23.3\,\mathrm{N} \end{aligned} \tag{2.97a}$$

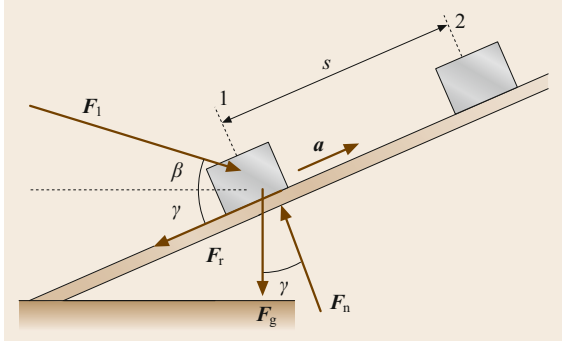

Fig. 2.33 Point mass on an inclined plane

In scalar notation, we have

$$\begin{aligned} a &= \frac{ma}{m} = 4.66\,\mathrm{m/s^2} \,, \quad t = \sqrt{\frac{2s}{a}} = 1.85\,\mathrm{s} \,, \\ v &= \sqrt{2as} = 8.63\,\mathrm{m/s} \,. \end{aligned} \tag{2.97b}$$

Basic Concepts of Energy, Work, and Power

Work. Work is a term used to describe the action of a force moving through a distance. For the simple case of a constant force F moving through a distance d along the line of action of the force, work is simply the product Fd. If the force is not constant, then an integral definition of work must be developed. From Fig. 2.34, the increment of work $\mathrm{d}W$, a scalar, occurring over an infinitesimal vector displacement $\mathrm{d}\boldsymbol{r}$ is defined as the dot product (scalar product) of the force vector and the increment of distance vector

$$\mathrm{d}W = \boldsymbol{F} \cdot \mathrm{d}\boldsymbol{r} = F\cos\beta\,\mathrm{d}r = F_1\,\mathrm{d}r \,. \tag{2.98}$$

The total work is the integral of $\mathrm{d}W$ over the total path length.

From Newton's second law, $\boldsymbol{F} = m\ddot{\boldsymbol{r}}$, and $\mathrm{d}\boldsymbol{r} = \dot{\boldsymbol{r}}\mathrm{d}t$, we obtain

$$\begin{aligned} \mathrm{d}W &= m\ddot{\boldsymbol{r}} \cdot \dot{\boldsymbol{r}}\mathrm{d}t = m\frac{\mathrm{d}\dot{\boldsymbol{r}}}{\mathrm{d}t} \cdot \dot{\boldsymbol{r}}\mathrm{d}t \\ &= m\dot{\boldsymbol{r}} \cdot d\dot{\boldsymbol{r}} = d\left(\frac{1}{2} m\boldsymbol{r} \cdot \boldsymbol{r}\right) . \end{aligned} \tag{2.99}$$

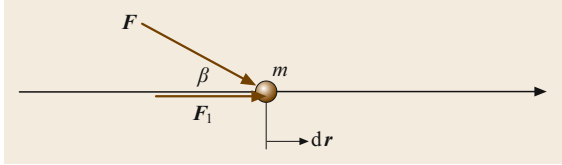

Fig. 2.34 Basic concept of work

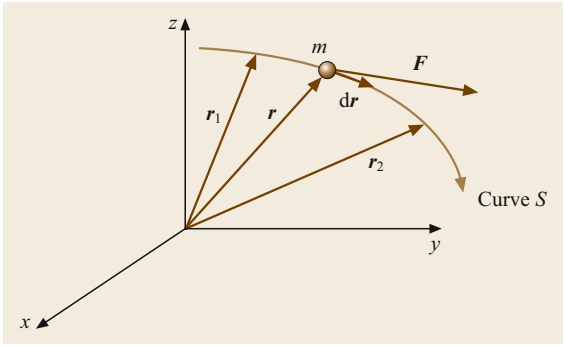

Fig. 2.35 Work of a force

The kinetic energy T, a scalar, is defined as

$$T = \frac{1}{2} m \dot{\boldsymbol{r}} \cdot \dot{\boldsymbol{r}} \,. \tag{2.100}$$

Consider the work performed by force $\boldsymbol{F}$ in moving the particle m from position $\boldsymbol{r}_1$ to position $\boldsymbol{r}_2$ along curve S as depicted in Fig. 2.35, one has

$$W_{1-2} = \int_{r_1}^{r_2} \boldsymbol{F} \cdot d\boldsymbol{r} = \int_{T_1}^{T_2} \mathrm{d}T = T_2 - T_1 \,. \tag{2.101}$$

If forces have a potential as below

$$\boldsymbol{F} = -\mathrm{grad}\, U = -\frac{\partial U}{\partial x}\boldsymbol{i} - \frac{\partial U}{\partial y}\boldsymbol{j} - \frac{\partial U}{\partial z}\boldsymbol{k} \,, \tag{2.102}$$

then it follows that

$$W = -\int_{\mathrm{P}_1}^{\mathrm{P}_2} \left(\frac{\partial U}{\partial x}\mathrm{d}x + \frac{\partial U}{\partial y}\mathrm{d}y + \frac{\partial U}{\partial z}\mathrm{d}z \right)$$

$$= -\int_{\mathrm{P}_1}^{\mathrm{P}_2} \mathrm{d}U = U_1 - U_2 \,. \tag{2.103}$$

In this case, work is independent of the integration distance and is equal to the difference in potential between the initial point P_1 and the final point P_2, as depicted in Fig. 2.36a. Such forces are called conservative forces, and we see from (2.103) that the work done by a conservative force moving from P_1 to P_2 is independent of the path taken between the two points. Examples of conservative forces are the force of gravity and elastic spring forces.

Special Work Examples.

1. Force of gravity. The potential energy $U = F_{\mathrm{g}} z$ and the work is

$$W_{\mathrm{g}} = -\int_{U_1}^{U_2} \mathrm{d}U = U_1 - U_2 = F_{\mathrm{g}}\,(z_1 - z_2) \,. \tag{2.104}$$

2. Spring force (Fig. 2.36b). Potential spring energy $U = cs^2/2$ with spring constant c. The spring force

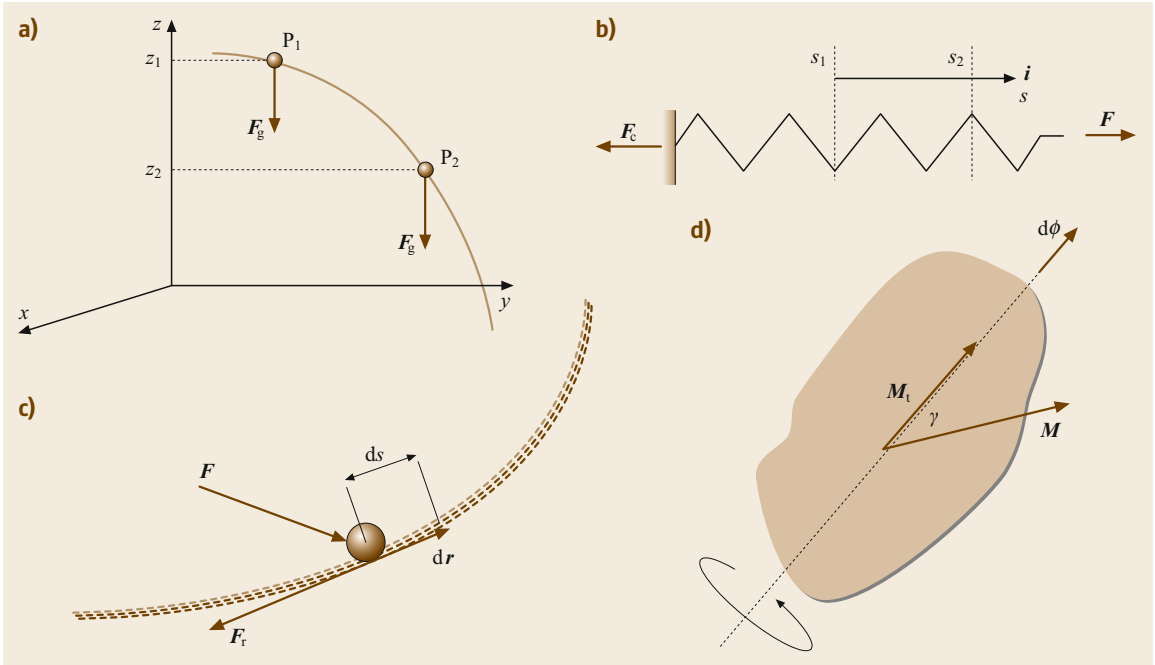

Fig. 2.36a–d Examples of work: **(a)** gravity, **(b)** spring force, **(c)** friction, **(d)** torque

is $\boldsymbol{F}_c = -\nabla U = -\partial U/\partial s\boldsymbol{i} = -cs\boldsymbol{i}$ and the work is

$$W_c = \int_{s_1}^{s_2} cs\mathrm{d}s = \frac{c\left(s_2^2 - s_1^2\right)}{2} . \tag{2.105}$$

3. Frictional force (Fig. 2.36c). This is not a conservative force because work is lost in the form of heat; there is no potential function for this force. For this case we see

$$W_r = \int_{s_1}^{s_2} \boldsymbol{F}_r \cdot \mathrm{d}r = \int_{s_1}^{s_2} F_r \cos\theta \mathrm{d}s$$
$$= -\int_{s_1}^{s_2} F_r \mathrm{d}s . \tag{2.106}$$

4. Torque (Fig. 2.36d). Work is also done by a moment rotating through an angular displacement. Only the moment component parallel to the axis of rotation, M_t, performs work

$$W_M = \int_{\phi_1}^{\phi_2} \boldsymbol{M}(\phi) \cdot d\boldsymbol{\phi} = \int_{\phi_1}^{\phi_2} M(\phi) \cos\gamma \mathrm{d}\phi$$
$$= \int_{\phi_1}^{\phi_2} M_t(\phi)\mathrm{d}\phi . \tag{2.107}$$

Total Work. If several forces and moments are at work on a body simultaneously, then

$$W = \int_{s_1}^{s_2} \sum \boldsymbol{F}_i \cdot \mathrm{d}\boldsymbol{r}_i + \int_{\phi_1}^{\phi_2} \sum \boldsymbol{M}_i \cdot \mathrm{d}\boldsymbol{\phi}_i , \tag{2.108}$$

where the subscript i is an index denoting a specific force or moment.

Power. Power is defined as the rate at which work is done

$$P(t) = \frac{\mathrm{d}W}{\mathrm{d}t} = \sum \boldsymbol{F}_i \cdot \boldsymbol{v}_i + \sum \boldsymbol{M}_i \cdot \boldsymbol{\omega}_i . \tag{2.109}$$

Mean Power. The mean power done over an interval of time relates to the total work done

$$P_m = \frac{\int_{t_1}^{t_2} P(t)\mathrm{d}t}{t_2 - t_1} = \frac{W}{t_2 - t_1} . \tag{2.110}$$

2.2.8 Straight-Line Motion of Particles and Rigid Bodies

Momentum Equation

The time integral of the force is known as the *linear impulse vector* $\boldsymbol{P}$. From (2.95), for constant mass, we have

$$\boldsymbol{P}_{1,2} = \int_{t_1}^{t_2} \boldsymbol{F}\mathrm{d}t = \int_{v_1}^{v_2} m\mathrm{d}\boldsymbol{v} = m\boldsymbol{v}_2 - m\boldsymbol{v}_1 = \boldsymbol{p}_2 - \boldsymbol{p}_1 . \tag{2.111}$$

The linear impulse vector is therefore equal to the change in momentum.

Angular Momentum Equation

Consider a particle of mass m moving under the action of a force $\boldsymbol{F}$. Fig. 2.37 defines the position of m relative to the origin O of the inertial frame xyz as $\boldsymbol{r}$ and the absolute velocity of m is given by $\boldsymbol{v}$. The moment of momentum or angular momentum of m with respect to point O is defined as the moment of the linear momentum $\boldsymbol{p}$ about O and is represented by the cross product of the vectors $\boldsymbol{r}$ and $\boldsymbol{p}$. The angular momentum of m about point O, $\boldsymbol{H}_O$, is

$$\boldsymbol{H}_O = \boldsymbol{r} \times \boldsymbol{p} = \boldsymbol{r} \times m\boldsymbol{v} = \boldsymbol{r} \times m\dot{\boldsymbol{r}} . \tag{2.112}$$

Assuming that m is a constant, the rate of change of angular momentum is

$$\dot{\boldsymbol{H}}_O = \dot{\boldsymbol{r}} \times m\dot{\boldsymbol{r}} + \boldsymbol{r} \times m\ddot{\boldsymbol{r}} = \boldsymbol{r} \times m\ddot{\boldsymbol{r}} = \boldsymbol{r} \times \boldsymbol{F} = \boldsymbol{M}_O . \tag{2.113}$$

Note that $\dot{\boldsymbol{r}} \times m\dot{\boldsymbol{r}} = m(\dot{\boldsymbol{r}} \times \dot{\boldsymbol{r}}) = 0$ and $\boldsymbol{r} \times \boldsymbol{F} = \boldsymbol{M}_O$ is the moment of the force about O. Therefore, the moment of a force about O is equal to the time rate of change of the moment of momentum about O.

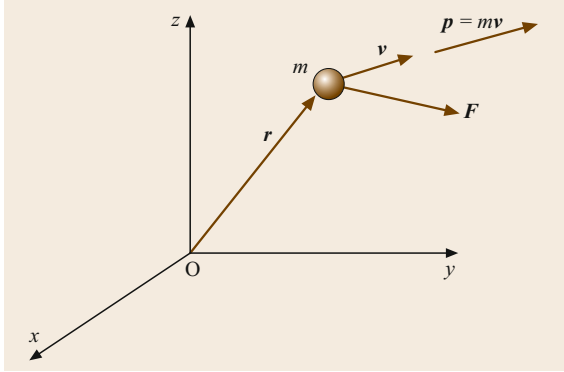

Fig. 2.37 Angular momentum of a particle

The angular impulse vector about O between the times t_1 and t_2 is

$$\hat{\boldsymbol{M}}_{\mathrm{O}} = \int_{t_1}^{t_2} \boldsymbol{M}_{\mathrm{O}} \mathrm{d}t = \int_{t_1}^{t_2} \frac{\mathrm{d}\boldsymbol{H}_{\mathrm{O}}}{\mathrm{d}t} \mathrm{d}t = \boldsymbol{H}_{\mathrm{O}}(t_2) - \boldsymbol{H}_{\mathrm{O}}(t_1)$$
$$= \Delta \boldsymbol{H}_{\mathrm{O}} . \qquad (2.114)$$

Therefore, the angular impulse vector about O between the times t_1 and t_2 is equal to the change in the angular momentum vector about O between the same two instants.

2.2.9 Dynamics of Systems of Particles

A system of particles is a group of n particles as shown in Fig. 2.38. The external and internal forces are denoted by $\boldsymbol{F}_i$ and $\boldsymbol{f}_i$, respectively. The internal force is the resultant of the interaction forces $\boldsymbol{f}_{ij}$ exerted by the particles m_j $(j = 1, 2, \ldots, n, j \neq i)$ on particle m_i $(i = 1, 2, \ldots, n)$. The equation of motion of the system of particles is

$$\sum_{i=1}^{n} \boldsymbol{F}_i + \sum_{j=1}^{n} \sum_{i=1}^{n} \boldsymbol{f}_{ij} = \sum_{i=1}^{n} m_i \ddot{\boldsymbol{r}}_i = \sum_{i=1}^{n} m_i \boldsymbol{a}_i . \qquad (2.115)$$

By Newton's third law, $\boldsymbol{f}_{ij} = -\boldsymbol{f}_{ji}$. Hence

$$\sum_{j=1}^{n} \sum_{i=1}^{n} \boldsymbol{f}_{ij} = 0 .$$

The center of mass C of the system is a point in space representing a weighted average position of the system. The weighting factor is the mass of the particle. We have

$$\boldsymbol{F} = m\boldsymbol{a}_{\mathrm{C}} , \qquad (2.116)$$

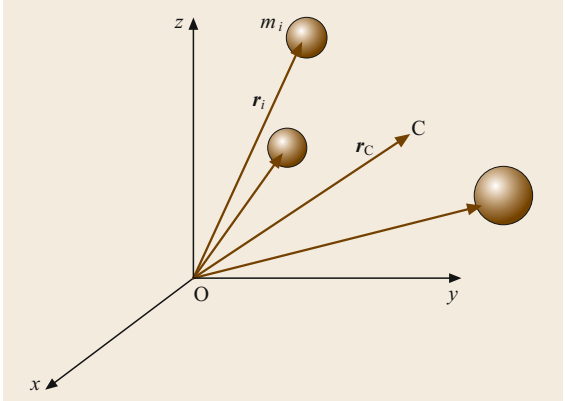

Fig. 2.38 A group of particles

where

$$\boldsymbol{F} = \sum_{i=1}^{n} \boldsymbol{F}_i = \sum_{i=1}^{n} m_i \ddot{\boldsymbol{r}}_i = m\boldsymbol{a}_{\mathrm{C}} . \qquad (2.117)$$

2.2.10 Momentum Equations

From Fig. 2.38, the linear momentum of m_i is

$$\boldsymbol{p}_i = m_i \boldsymbol{v}_i . \qquad (2.118)$$

The linear momentum of the system is

$$\boldsymbol{p} = \sum_{i=1}^{n} \boldsymbol{p}_i = \sum_{i=1}^{n} m_i \boldsymbol{v}_i = m\boldsymbol{v}_{\mathrm{C}} . \qquad (2.119)$$

The resultant of the external forces acting on the system is

$$\boldsymbol{F} = \dot{\boldsymbol{p}} = m\dot{\boldsymbol{v}}_{\mathrm{C}} = m\boldsymbol{a}_{\mathrm{C}} . \qquad (2.120)$$

If $\boldsymbol{F} = 0$, then $\boldsymbol{p} =$ constant. This is the conservation of linear momentum of a system of particles.

The angular momentum of the particle m_i about O is

$$\boldsymbol{H}_{\mathrm{O}i} = \boldsymbol{r}_i \times \boldsymbol{p}_i = \boldsymbol{r}_i \times m_i \boldsymbol{v}_i . \qquad (2.121)$$

The angular momentum of the system about O is

$$\boldsymbol{H}_{\mathrm{O}} = \sum_{i=1}^{n} \boldsymbol{H}_{\mathrm{O}i} = \sum_{i=1}^{n} \boldsymbol{r}_i \times m_i \boldsymbol{v}_i . \qquad (2.122)$$

Hence

$$\dot{\boldsymbol{H}}_{\mathrm{O}} = \sum_{i=1}^{n} \dot{\boldsymbol{r}}_i \times m_i \boldsymbol{v}_i + \sum_{i=1}^{n} \boldsymbol{r}_i \times m_i \dot{\boldsymbol{v}}_i$$
$$= \sum_{i=1}^{n} \boldsymbol{r}_i \times m_i \boldsymbol{a}_i = \sum_{i=1}^{n} \boldsymbol{r}_i \times \boldsymbol{F}_i . \qquad (2.123)$$

Since $\boldsymbol{M}_{\mathrm{O}} = \sum_{i=1}^{n} \boldsymbol{r}_i \times \ddot{\boldsymbol{F}}_i$, we have

$$\boldsymbol{M}_{\mathrm{O}} = \dot{\boldsymbol{H}}_{\mathrm{O}} . \qquad (2.124)$$

If $\boldsymbol{M}_{\mathrm{O}} = 0$, then $\boldsymbol{H}_{\mathrm{O}} =$ constant. This states that, in the absence of external torques about O, the angular momentum of the system about O is a constant. This is the conservation of angular momentum of the system about a fixed point. It can be extended to the conservation of angular momentum about the mass center.

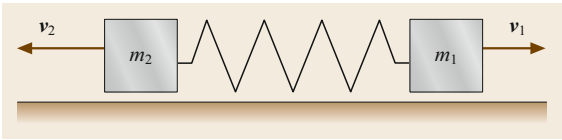

Fig. 2.39 Spring–mass system

Energy Equation

The kinetic energy of particle m_i is

$$T_i = \frac{1}{2} m_i \dot{\boldsymbol{r}}_i \cdot \dot{\boldsymbol{r}}_i \,. \tag{2.125}$$

and the kinetic energy of the system is

$$T = \sum_{i=1}^{n} T_i = \frac{1}{2} \sum_{i=1}^{n} m_i \dot{\boldsymbol{r}}_i \cdot \dot{\boldsymbol{r}}_i \,. \tag{2.126}$$

Example 2.6

A spring with spring constant c, which is compressed by the value s, thrusts the masses m_1 and m_2 apart from rest as depicted in Fig. 2.39. Disregarding the friction forces during the relaxation process of the spring, there is no external force. Determine the maximum velocities of m_1 and m_2.

From the conservation of momentum of a system of particles, we have $m_1 v_1 - m_2 v_2 = 0$.

The energy conservation equation is

$$\frac{1}{2} c s^2 = \frac{1}{2} \left(m_1 v_1^2 + m_2 v_2^2 \right) . \tag{2.127a}$$

It follows that

$$v_1 = \sqrt{\frac{c s^2}{m_1 + m_1^2/m_2}} \,, \quad v_2 = \sqrt{\frac{c s^2}{m_2 + m_2^2/m_1}} \,. \tag{2.127b}$$

Example 2.7

Two masses, connected by an inextensible chain, are drawn out of the position of rest by the constant force $\boldsymbol{F}$ as depicted in Fig. 2.40. Each mass moves along inclined surfaces as shown. Determine the velocity after traveling a distance s_1.

The friction force on masses m_1 and m_2 are $F_{r1} = \mu_1 (F_{g1} \cos\gamma_1 - F \sin\gamma_1)$ and $F_{r2} = \mu_2 F_{g2} \cos\gamma_2$, respectively. As a precondition for the mass m_1 not being lifted, we must have $F \le F_{g1} \cot\gamma_1$.

The energy equation is

$$F \cos\gamma_1 s_1 + F_{g1} h_1 - F_{r1} s_1 - F_{g2} h_2 - F_{r2} s_2 = \frac{1}{2} \left(m_1 v_1^2 + m_2 v_2^2 \right) . \tag{2.128a}$$

Because $s_1 = s_2$, $v_1 = v_2$, $h_1 = s_1 \sin\gamma_1$, and $h_2 = s_2 \sin\gamma_2$, it follows that

$$v_1 = \sqrt{\frac{2 s_1 \left(F \cos\gamma_1 + F_{g1} \sin\gamma_1 - F_{r1} - F_{g2} \sin\gamma_2 - F_{r2} \right)}{m_1 + m_2}} \,. \tag{2.128b}$$

2.2.11 D'Alembert's Principle, Constrained Motion

From Newton's law we know that $\boldsymbol{F} - m\boldsymbol{a} = \boldsymbol{0}$, i.e., the external forces and forces of inertia of a particle form a *state of equilibrium*. In the event of a system of particles m_i $(i = 1, 2, \ldots, n)$, Newton's equations of motion are

$$\boldsymbol{F}_i + \boldsymbol{f}_i - m_i \ddot{\boldsymbol{r}}_i = 0 \,, \quad i = 1, 2, \ldots, n \,, \tag{2.129}$$

where $\boldsymbol{F}_i$ are the applied forces, $\boldsymbol{f}_i$ are the constraint forces, and $-m_i \ddot{\boldsymbol{r}}_i$ are the inertial forces. Equation (2.129) is the dynamic equilibrium of the system of particles. The sum of virtual work for the entire sys-

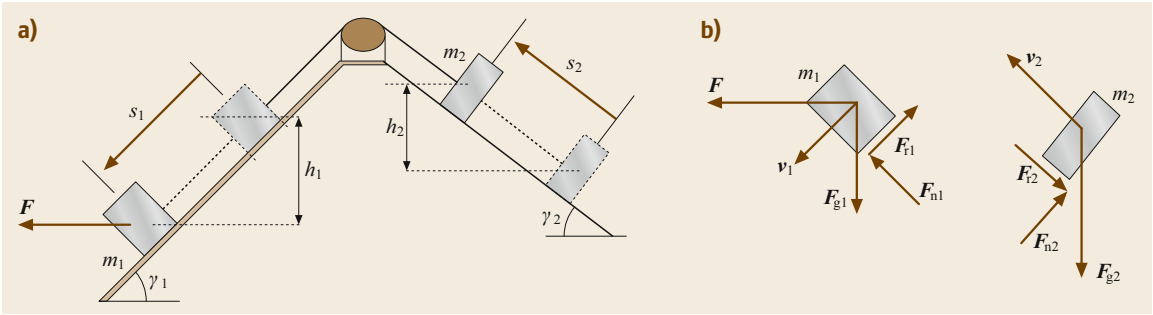

Fig. 2.40 **(a)** Two-mass system, **(b)** forces on each mass

tem is

$$\sum_{i=1}^{n} (\boldsymbol{F}_i + \boldsymbol{f}_i - m_i \ddot{\boldsymbol{r}}_i) \cdot \delta \boldsymbol{r}_i = 0 \,. \tag{2.130}$$

However, the virtual work performed by the constraint forces over virtual displacements is zero. Hence, it follows that

$$\sum_{i=1}^{n} (\boldsymbol{F}_i - m_i \ddot{\boldsymbol{r}}_i) \cdot \delta \boldsymbol{r}_i = 0 \,. \tag{2.131a}$$

Equation (2.131a) is D'Alembert's principle for a system of particles. It can also be applied to a system of rigid bodies. If the motion is planar, D'Alembert's principle for a system of rigid bodies gives

$$\sum_{i=1}^{n} (\boldsymbol{F}_i - m_i \ddot{\boldsymbol{r}}_{Ci}) \cdot \delta \boldsymbol{r}_{Ci} + \left(\boldsymbol{M}_{Ci} - I_{Ci} \ddot{\boldsymbol{\theta}}_i\right) \cdot \delta \boldsymbol{\theta}_i = 0 \,, \tag{2.131b}$$

where r_{Ci} is the position of the mass center of the i-th rigid body, M_{Ci} is the moment of the mass center of the i-th rigid body, and I_{Ci} is the mass moment of inertia about an axis normal to the plane of motion that passes through C.

Example 2.8

Derive the equation of motion of the system shown in Fig. 2.41 by using D'Alembert's principle. Use θ and x as independent coordinates.

There are two rigid bodies in Fig. 2.41. m_1 can be considered as a particle that is subjected to no moments and has no moment of inertia. m_2 is a rigid body with a moment of inertia about C of I_{C2}. Equation (2.130) becomes

$$(\boldsymbol{F}_1 - m_1 \ddot{\boldsymbol{r}}_{C1}) \, \delta \boldsymbol{r}_{C1} + (\boldsymbol{F}_2 - m_2 \ddot{\boldsymbol{r}}_{C2}) \, \delta \boldsymbol{r}_{C2} + \left(\boldsymbol{M}_{C2} - I_{C2} \ddot{\boldsymbol{\theta}}_2\right) \delta \boldsymbol{\theta}_2 = 0 \,. \tag{2.132a}$$

From Fig. 2.41, we have

$$\boldsymbol{F}_1 = -kx\boldsymbol{i} - m_1 g \boldsymbol{j} \,, \quad \boldsymbol{F}_2 = F\boldsymbol{i} - m_2 g \boldsymbol{j} \,,$$
$$\boldsymbol{M}_{C2} = Fa \cos\theta \boldsymbol{k} \,, \quad I_{C2} = \frac{1}{3} m_2 a^2 \,, \tag{2.132b}$$

and

$$\begin{aligned} \boldsymbol{r}_{C1} &= (L + x)\boldsymbol{i} \,, \\ \boldsymbol{r}_{C2} &= (L + x + a \sin\theta)\boldsymbol{i} - a \cos\theta \boldsymbol{j} \,, \\ \delta \boldsymbol{r}_{C1} &= \delta x \boldsymbol{i} \,, \\ \delta \boldsymbol{r}_{C2} &= (\delta x + a \cos\theta \delta\theta)\boldsymbol{i} + a \sin\theta \delta\theta \boldsymbol{j} \,, \end{aligned} \tag{2.132c}$$

where $\theta = \theta_2$, $\delta\theta = \delta\theta_2$, and L is the fixed length of the spring before moving. The accelerations are

$$\begin{aligned} \ddot{\boldsymbol{r}}_{C1} &= \ddot{x}\boldsymbol{i} \,, \\ \ddot{\boldsymbol{r}}_{C2} &= (\ddot{x} + a\ddot{\theta} \cos\theta - a\dot{\theta}^2 \sin\theta)\boldsymbol{i} \\ &\quad + a(\ddot{\theta} \sin\theta + \dot{\theta}^2 \cos\theta)\boldsymbol{j} \,. \end{aligned} \tag{2.132d}$$

Substituting (2.132b)–(2.132d) into (2.132a) and setting each of the coefficients of $\delta\theta$ and δx equal to zero, the equations of motion are

$$\begin{aligned} &(m_1 + m_2)\ddot{x} + m_2 a(\ddot{\theta} \cos\theta - \dot{\theta}^2 \sin\theta) + kx = F \,, \\ &m_2 \cos\theta \ddot{x} + \frac{4}{3} m_2 a \ddot{\theta} + m_2 g \sin\theta = 2F \cos\theta \,. \end{aligned} \tag{2.132e}$$

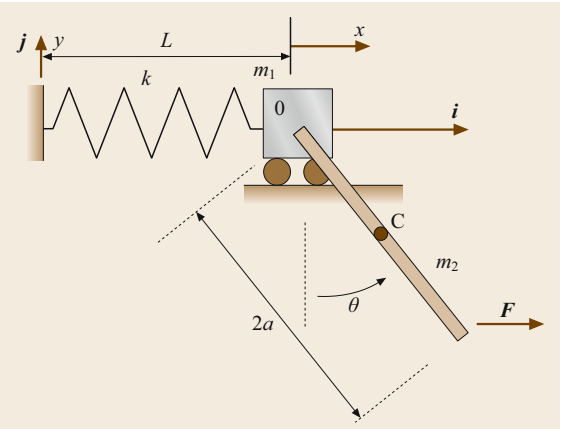

Fig. 2.41 Spring–mass and rod system

2.2.12 Lagrange's Equations

Lagrange provided the equations of motion for a system by a differentiation process related to the dynamic (kinetic and potential) energy. Considering an n-degree-of-freedom system, Lagrange's equations read

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial L}{\partial \dot{q}_i}\right) - \frac{\partial L}{\partial q_i} = Q_i \quad i = 1, 2, \ldots, n \,, \tag{2.133}$$

where the Lagrangian $L = T - V$, in which T is the kinetic energy, V is the potential energy, q_i are the generalized coordinates of the system, and Q_i are the generalized forces. The Lagrangian approach is very efficient for deriving the equations of motion for both linear and nonlinear systems.

Example 2.9

Derive the equation of motion of the system of Fig. 2.41 using Lagrange's equations.

Suppose $q_1 = x$ and $q_2 = \theta$. First, we need to calculate the virtual work with the nonconservative force $\boldsymbol{F}$. Denoting the point of application of the force by B, the position vector of B is

$$\boldsymbol{r}_\mathrm{B} = (L + x + 2a\sin\theta)\,\boldsymbol{i} - 2a\cos\theta\boldsymbol{j}\,. \tag{2.134a}$$

The virtual displacement of B is

$$\delta\boldsymbol{r}_\mathrm{B} = (\delta x + 2a\cos\theta\delta\theta)\,\boldsymbol{i} + 2a\sin\theta\delta\theta\boldsymbol{j}\,. \tag{2.134b}$$

The force $\boldsymbol{F}$ is

$$\boldsymbol{F} = F\boldsymbol{i}\,. \tag{2.134c}$$

The nonconservative virtual work is

$$\boldsymbol{F}\cdot\delta\boldsymbol{r}_\mathrm{B} = F\,(\delta x + 2a\cos\theta\delta\theta)\,. \tag{2.134d}$$

The coefficients of $\delta\theta$ and δx in (2.134d) are the nonconservative generalized forces

$$X = F\,,\quad \Theta = 2Fa\cos\theta\,. \tag{2.134e}$$

The kinetic energy is

$$\begin{aligned} T &= \frac{1}{2}m_1\boldsymbol{v}_1\cdot\boldsymbol{v}_1 + \frac{1}{2}m_2\boldsymbol{v}_2\cdot\boldsymbol{v}_2 + \frac{1}{2}I_\mathrm{C}\dot\theta^2 \\ &= \frac{1}{2}m_1\dot x^2 + \frac{1}{2}m_2\left[(\dot x + a\dot\theta\cos\theta)^2 + (a\dot\theta\sin\theta)^2\right] \\ &\quad + \frac{1}{2}\frac{1}{12}m_2(2a)^2\dot\theta^2 \\ &= \frac{1}{2}(m_1+m_2)\,\dot x^2 + m_2a\dot x\dot\theta\cos\theta + \frac{2}{3}m_2a^2\dot\theta^2\,. \end{aligned} \tag{2.134f}$$

The potential energy is

$$V = \frac{1}{2}kx^2 + m_2ga\,(1-\cos\theta)\,. \tag{2.134g}$$

Hence,

$$\begin{aligned} L &= T - V \\ \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial L}{\partial\dot x}\right) &= (m_1+m_2)\,\ddot x + m_2a(\ddot\theta\cos\theta - \dot\theta^2\sin\theta) \\ \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial L}{\partial\dot\theta}\right) &= m_2a(\ddot x\cos\theta - \dot x\dot\theta\sin\theta) + \frac{4}{3}m_2a^2\ddot\theta \\ \frac{\partial L}{\partial x} &= -kx\,,\ \frac{\partial L}{\partial\theta} = -m_2a\sin\theta(\dot x\dot\theta + g)\,. \end{aligned} \tag{2.134h}$$

From (2.133), the equations of motion are

$$\begin{aligned} &(m_1+m_2)\ddot x + m_2a(\ddot\theta\cos\theta - \dot\theta^2\sin\theta) + kx = F\,, \\ &m_2\ddot x\cos\theta + \frac{4}{3}m_2a\ddot\theta + m_2g\sin\theta = 2F\cos\theta\,. \end{aligned} \tag{2.134i}$$

Note that (2.134i) which were derived using Lagrange's equations agree exactly with (2.132e), derived using D'Alembert's principle.

2.2.13 Dynamics of Rigid Bodies

Rigid bodies can be viewed as a special type of systems of particles, where the distance between any two particles is rigidly constrained to be constant. The relative velocity of between points in a rigid body is due only to the angular velocity of the rigid body.

Linear and Angular Momentum

The angular momentum of a rigid body rotating with angular velocity ω about a fixed point O is defined as

$$H_\mathrm{O} = \int_m \boldsymbol{r}\times\boldsymbol{v}\,\mathrm{d}m\,. \tag{2.135}$$

From Fig. 2.42, because the velocity $\boldsymbol{v}$ of any point in the body is due entirely to the rotation about O, (2.135) becomes

$$\begin{aligned} \boldsymbol{H}_\mathrm{O} &= \int_m \boldsymbol{r}\times(\boldsymbol{\omega}\times\boldsymbol{r})\,\mathrm{d}m \\ &= \int_m ((\boldsymbol{r}\cdot\boldsymbol{r})\,\boldsymbol{\omega} - (\boldsymbol{r}\cdot\boldsymbol{\omega})\,\boldsymbol{r})\,\mathrm{d}m\,, \end{aligned} \tag{2.136}$$

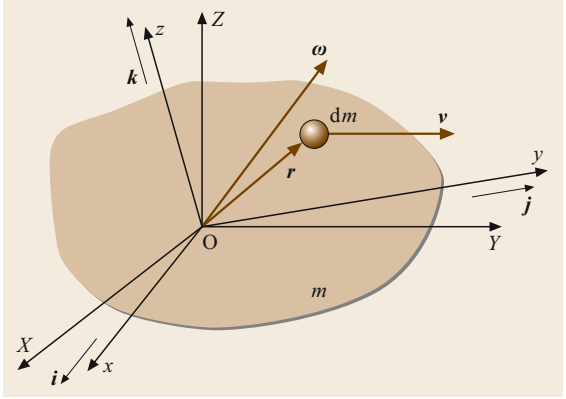

Fig. 2.42 A rotating rigid body

because $\boldsymbol{A}\times(\boldsymbol{B}\times\boldsymbol{C}) = (\boldsymbol{A}\cdot\boldsymbol{C})\boldsymbol{B} - (\boldsymbol{A}\cdot\boldsymbol{B})\boldsymbol{C}$ in vector analysis.

Let

$$\boldsymbol{r} = x\boldsymbol{i} + y\boldsymbol{j} + z\boldsymbol{k} \quad \text{and} \quad \boldsymbol{\omega} = \omega_x\boldsymbol{i} + \omega_y\boldsymbol{j} + \omega_z\boldsymbol{k}\,. \tag{2.137}$$

Substituting (2.137) into (2.135), we have

$$\begin{aligned}\boldsymbol{H}_\mathrm{O} = {} & \left(I_{xx}\omega_x - I_{xy}\omega_y - I_{xz}\omega_z\right)\boldsymbol{i} \\ & + \left(-I_{xy}\omega_x + I_{yy}\omega_y - I_{yz}\omega_z\right)\boldsymbol{j} \\ & + \left(-I_{xz}\omega_x - I_{yz}\omega_y + I_{zz}\omega_z\right)\boldsymbol{k}\,,\end{aligned} \tag{2.138}$$

where

$$I_{xx} = \int_m \left(y^2 + z^2\right)\mathrm{d}m\,, \quad I_{yy} = \int_m \left(x^2 + z^2\right)\mathrm{d}m\,,$$
$$I_{zz} = \int_m \left(x^2 + y^2\right)\mathrm{d}m \tag{2.139}$$

are mass moments of inertia about the body axes xyz, and

$$I_{xy} = I_{yx} = \int_m xy\mathrm{d}m\,, \quad I_{xz} = I_{zx} = \int_m xz\mathrm{d}m\,,$$
$$I_{yz} = I_{zy} = \int_m yz\mathrm{d}m \tag{2.140}$$

are mass products of inertia about the same axes.

Note that the moment of inertia can be represented as the moment of inertia tensor shown below

$$\boldsymbol{I} = \begin{pmatrix} I_{xx} & -I_{xy} & -I_{xz} \\ -I_{yx} & I_{yy} & -I_{yz} \\ -I_{zx} & -I_{zy} & I_{zz} \end{pmatrix}. \tag{2.141}$$

For a pure rotation about a fixed point O, the moment equation of motion is

$$\boldsymbol{M}_\mathrm{O} = \dot{\boldsymbol{H}}_\mathrm{O}\,. \tag{2.142}$$

For any body there are a special set of axes called principal axes which results in each of the products of inertia being zero. If we choose the axes x, y, and z to be the principal axes, $I_{xy} = I_{yz} = I_{zx} = 0$. Then the moment equation of motion becomes

$$\begin{aligned}\boldsymbol{M}_\mathrm{O} &= M_x\boldsymbol{i} + M_y\boldsymbol{j} + M_z\boldsymbol{k}\,, \\ M_x &= I_{xx}\dot{\omega}_x + \left(I_{zz} - I_{yy}\right)\omega_y\omega_z\,, \\ M_y &= I_{yy}\dot{\omega}_y + \left(I_{xx} - I_{zz}\right)\omega_x\omega_z\,, \\ M_z &= I_{zz}\dot{\omega}_z + \left(I_{yy} - I_{xx}\right)\omega_x\omega_y\,,\end{aligned} \tag{2.143}$$

which are called Euler's moment equations.

2.2.14 Planar Motion of a Rigid Body

Assuming that motion takes place in the xy plane, we have $v_z = a_z = 0$, $\omega_x = \dot{\omega}_x = \omega_y = \dot{\omega}_y = 0$, $\omega_z = \omega$. $I_{xz} = I_{yz}$ are approximately 0 if we assume a small dimension of the body in the z-direction compared to the dimensions in the xy plane.

For pure translation, i.e., $\omega = \dot{\omega} = 0$, we have

$$F_x = ma_{\mathrm{C}_x} \quad \text{and} \quad F_y = ma_{\mathrm{C}_y}\,. \tag{2.144}$$

The only moment equation is about the z-axis. The moment equation about the mass center C for pure translation is $M_{\mathrm{C}_z} = 0$.

The kinetic energy is

$$T = \frac{1}{2}m\boldsymbol{v}_\mathrm{C}\cdot\boldsymbol{v}_\mathrm{C} = \frac{1}{2}m\left(v_{\mathrm{C}_x}^2 + v_{\mathrm{C}_y}^2\right), \tag{2.145}$$

where v_{C_x} and v_{C_y} are the Cartesian components of the velocity vector of the mass center.

For pure rotation about a fixed point O, we have the scalar angular momentum and scalar equation of motion as follows

$$H_\mathrm{O} = I_{zz}\omega \quad \text{and} \quad M_\mathrm{O} = I_{zz}\dot{\omega}\,, \tag{2.146}$$

and the kinetic energy is

$$T = \frac{1}{2}I_{zz}\omega^2\,. \tag{2.147}$$

Example 2.10

A uniform horizontal bar with a total mass m is hinged at point O, as depicted in Fig. 2.43. The bar is released from rest. Determine the angular acceleration immediately after release, the reaction force at point O at the same time, and the angular velocity of the bar when it passes through the vertical position.

Consider the counterclockwise moments and angular motion as positive. From (2.113) and (2.146), we have

$$M_\mathrm{O} = I_{zz}\dot{\omega} = -\frac{1}{6}Lmg\,. \tag{2.148a}$$

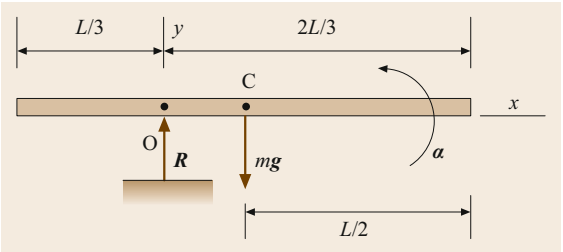

Fig. 2.43 A uniform bar hinged at point O

The mass moment of inertia of the bar about point O is obtained as

$$I_{zz} = \int_m x^2 \mathrm{d}m = \frac{m}{L} \int_{-L/3}^{2L/3} x^2 \mathrm{d}x = \frac{1}{9} L^2 m \,. \tag{2.148b}$$

Hence, the angular acceleration immediately after release is

$$\alpha = \dot{\omega} = -\frac{3g}{2L} \,. \tag{2.148c}$$

From (2.52b) and (2.144), we have the resultant force in the y-axis direction only as follows

$$F_y = R - mg = ma_{C_y} = m\frac{1}{6} L\alpha = \frac{-1}{4} mg \,. \tag{2.148d}$$

The reaction force R at point O is then obtained as

$$R = \frac{3}{4} mg \,. \tag{2.148e}$$

Both the potential and kinetic energy of the bar at horizontal position are zero. At vertical position, the potential energy becomes $V = (-1/6)Lmg$. The kinetic energy becomes $T = (1/2)I_{zz}\omega^2 = (1/18)mL^2\omega^2$. By applying the law of conservation of energy, we have

$$T + V = 0 \quad \text{and} \quad \omega = -\sqrt{\frac{3g}{L}} \,, \tag{2.148f}$$

where the negative sign indicates an angular velocity in the clockwise direction.

2.2.15 General Case of Planar Motion

By using the mass center C, the moment equation has the scalar form $M_C = I_C\alpha$, where I_C is the mass moment of inertia about an axis normal to the plane of motion that passing through C. The kinetic energy consists of the translation of C and rotation about C as follows

$$T = \frac{1}{2} m\left(v_{C_x}^2 + v_{C_y}^2\right) + \frac{1}{2} I_C \omega^2 \,. \tag{2.149}$$

Let us consider the system shown in Fig. 2.44 and write a moment equation about the arbitrary point A as

$$\begin{aligned} \boldsymbol{M}_A &= \int \boldsymbol{\rho}_A \times \mathrm{d}\boldsymbol{F} = \int (\boldsymbol{\rho}_{AC} + \boldsymbol{\rho}) \times \mathrm{d}\boldsymbol{F} \\ &= \boldsymbol{\rho}_{AC} \times \boldsymbol{F} + \boldsymbol{M}_C \,, \end{aligned} \tag{2.150}$$

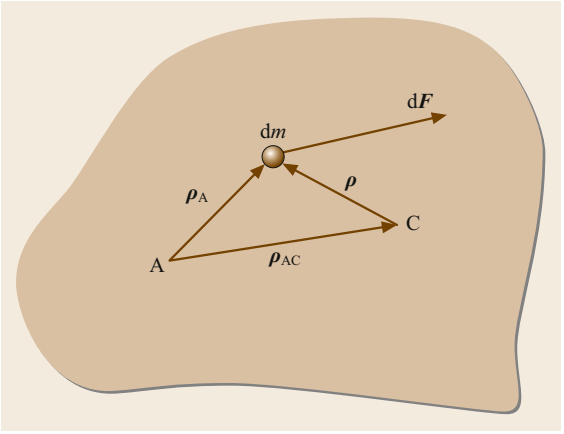

Fig. 2.44 Rigid-body planar motion

or

$$\boldsymbol{M}_A = \boldsymbol{\rho}_{AC} \times m\boldsymbol{a}_C + \boldsymbol{M}_C \quad \text{and} \quad \boldsymbol{M}_C = I_C\boldsymbol{\alpha} \,. \tag{2.151}$$

The acceleration at the mass center C can be written as

$$\boldsymbol{a}_C = \boldsymbol{a}_A + \boldsymbol{a}_{C/A} \,. \tag{2.152}$$

From (2.81), the acceleration reduces to

$$\boldsymbol{a}_C = \boldsymbol{a}_A - \omega^2 \boldsymbol{\rho}_{AC} + \alpha \times \boldsymbol{\rho}_{AC} \,. \tag{2.153}$$

Substituting (2.153) into (2.151) we have

$$\boldsymbol{M}_A = \boldsymbol{\rho}_{AC} \times m\boldsymbol{a}_A + I_A\boldsymbol{\alpha} \,, \tag{2.154}$$

where $I_A = (I_C + m\rho_{AC}^2)$ is the mass moment of inertia of the body about point A.

Example 2.11

A uniform disk of radius R is originally at rest at point 1. It rolls without slipping down to point 2 as depicted in Fig. 2.45. Calculate the velocity at point 2.

The kinetic energy at point 2 is

$$T_2 = \frac{1}{2} m v_2^2 + \frac{1}{2} I_C \omega_2^2 \,. \tag{2.155a}$$

Since $v_2 = -R\omega_2$ and $I_C = mR^2/2$, we have

$$T_2 = \frac{3}{4} m v_2^2 \,. \tag{2.155b}$$

Conservation of energy then yields

$$V_2 + T_2 = -mgh + \frac{3}{4} m v_2^2 = 0 \quad \text{and}$$

$$v_2 = \sqrt{\frac{4gh}{3}} \,. \tag{2.155c}$$

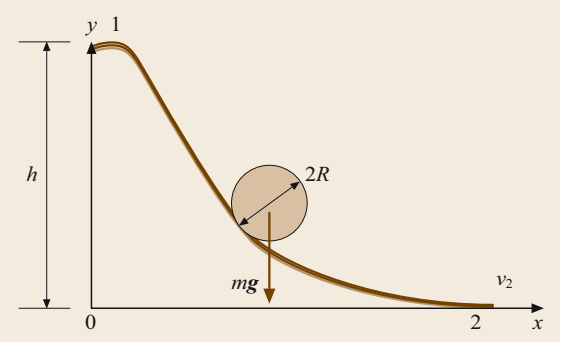

Fig. 2.45 A rolling ball

2.2.16 Rotation About a Fixed Axis

Let us consider the rigid body of Fig. 2.42 and assume that the only motion takes place about the fixed z-axis, i.e., $\omega_x = \dot{\omega}_x = \omega_y = \dot{\omega}_y = 0$, $\omega_z = \omega$. The fixed origin O is also on the fixed axis. The moment equations become

$$M_x = -I_{xz}\dot{\omega} + I_{yz}\omega^2 ,$$
$$M_y = -I_{yz}\dot{\omega} - I_{xz}\omega^2 ,$$
$$M_z = I_{zz}\dot{\omega} . \qquad (2.156)$$

Example 2.12

A thin, uniform disk with radius R and mass m is shown in Fig. 2.46. The normal to the disk makes an angle β with respect to the shaft. The disk rotates with $\omega_z = \omega =$ const. Determine the bearing forces at points A and B.

From Fig. 2.46a, axes XYZ are inertial and axes xyz are body axes, where z is along the shaft and x is embedded in the disk. Fig. 2.46b depicts the body axes xyz, and the principal axes $x'y'z'$. The relationship between these two sets of axes are

$$x = x' , \quad y = y'\cos\beta + z'\sin\beta ,$$
$$z = -y'\sin\beta + z'\cos\beta . \qquad (2.157a)$$

The inertia products I_{xz} and I_{yz} about the axes xyz are

$$I_{xz} = \int_m xz\,dm = \int_m x'\left(-y'\sin\beta + z'\cos\beta\right)dm$$
$$= -\sin\beta I_{x'y'} + \cos\beta I_{x'z'} = 0 \qquad (2.157b)$$

and

$$I_{yz} = \int_m yz\,dm$$
$$= \int_m (y'\cos\beta + z'\sin\beta)$$
$$\times(-y'\sin\beta + z'\cos\beta)dm$$
$$= \sin\beta\cos\beta(I_{y'y'} - I_{z'z'})$$
$$+ (\cos^2\beta - \sin^2\beta)I_{y'z'} . \qquad (2.157c)$$

Note that because $x'y'z'$ are the principal axes, the products of inertia are zero. The moments of inertia of the disk are

$$I_{x'x'} = I_{y'y'} = \frac{1}{4}mR^2 , \quad I_{z'z'} = \frac{1}{2}mR^2 . \qquad (2.157d)$$

Hence,

$$I_{yz} = -\frac{1}{4}mR^2\sin\beta\cos\beta . \qquad (2.157e)$$

Substituting (2.157b) and (2.157e) into (2.156), we obtain

$$M_x = -\frac{1}{4}mR^2\omega^2\sin\beta\cos\beta ,$$
$$M_y = 0 , \quad M_z = 0 . \qquad (2.157f)$$

The moment components along the X- and Y-axes are

$$M_X = M_x\cos\gamma \quad \text{and} \quad M_Y = M_x\sin\gamma . \qquad (2.157g)$$

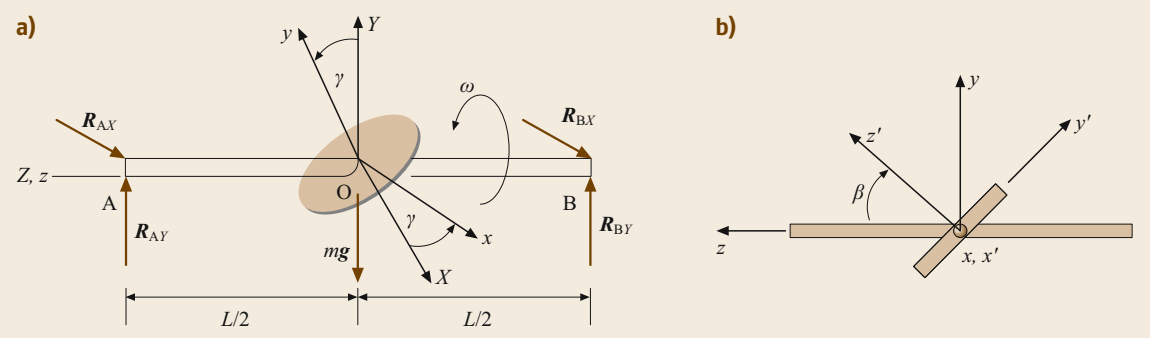

Fig. 2.46a,b A rotating disk: **(a)** the axes XYZ are inertial, **(b)** the axes xyz are body axes

Because the acceleration of the mass center is zero, the force equations along the X- and Y-axes are

$$F_X = R_{A_X} + R_{B_X} = 0 \quad \text{and}$$
$$F_Y = R_{A_Y} + R_{B_Y} - mg = 0 \,. \tag{2.157h}$$

From the reaction forces, the moment equations about 0 yield

$$\begin{aligned} M_X &= \frac{L}{2}\left(R_{B_Y} - R_{A_Y}\right) \\ &= -\frac{1}{4} mR^2\omega^2 \sin\beta \cos\beta \cos\gamma \,, \\ M_Y &= \frac{L}{2}\left(R_{A_X} - R_{B_X}\right) \\ &= -\frac{1}{4} mR^2\omega^2 \sin\beta \cos\beta \sin\gamma \,. \end{aligned} \tag{2.157i}$$

Because $\gamma = \omega t$, (2.157h) and (2.157i) yield

$$\begin{aligned} R_{B_X} &= -R_{A_X} = \frac{1}{4L} mR^2\omega^2 \sin\beta \cos\beta \sin\omega t \,, \\ R_{A_Y} &= \frac{mg}{2} + \frac{1}{4L} mR^2\omega^2 \sin\beta \cos\beta \cos\omega t \,, \\ R_{B_Y} &= \frac{mg}{2} - \frac{1}{4L} mR^2\omega^2 \sin\beta \cos\beta \cos\omega t \,. \end{aligned} \tag{2.157j}$$

Therefore, in addition to the static bearing forces equal to half the weight, there are dynamic bearing forces that vary harmonically with a frequency equal to the spin frequency ω. These dynamic bearing forces will cause the bearings to wear out faster than if the disk were oriented perpendicular to the Z axis.

2.2.17 Lagrange's Equations of Motion for Linear Systems

Lagrange's equations can be applied to the derivation of the equations of motion for a linear n-degree-of-freedom dynamic system. By extending the concept of Sect. 2.2.12, (2.133) can be rewritten as follows

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial T}{\partial \dot{q}_i}\right) - \frac{\partial T}{\partial q_i} + \frac{\partial D}{\partial \dot{q}_i} + \frac{\partial V}{\partial q_i} = Q_i \,,$$
$$i = 1, 2, \ldots, n \,, \tag{2.158}$$

where D, *the* dissipation function due to the damping force of viscous type, is defined as

$$D = \frac{1}{2}\sum_{i=1}^{n}\sum_{j=1}^{n} c_{ij}\dot{q}_i\dot{q}_j \quad \text{and}$$
$$\frac{\partial D}{\partial \dot{q}_i} = \sum_{j=1}^{n} c_{ij}\dot{q}_j \,, \tag{2.159}$$

where the c_{ij} are known as the damping coefficients.

Equation (2.158) can be rewritten in a compact matrix form as

$$M\ddot{\boldsymbol{q}}(t) + C\dot{\boldsymbol{q}}(t) + K\boldsymbol{q}(t) = \boldsymbol{Q}(t) \,, \tag{2.160}$$

where M is the mass matrix, C is the damping matrix, and K is the stiffness matrix. All three are $n \times n$ symmetric matrices.

$$\boldsymbol{q}(t) = [q_1(t)q_2(t), \ldots, q_n(t)]^\top \quad \text{and}$$
$$\boldsymbol{Q}(t) = [Q_1(t), Q_2(t), \ldots, Q_n(t)]^\top \tag{2.161}$$

Equation (2.161) defines the n-dimensional generalized displacement vector and generalized force vector.

The kinetic energy T, dissipation function D, and the potential energy V can be expressed as

$$\begin{aligned} T &= \frac{1}{2}\dot{\boldsymbol{q}}^\top(t) M \dot{\boldsymbol{q}}(t) \,, \\ D &= \frac{1}{2}\dot{\boldsymbol{q}}^\top(t) C \dot{\boldsymbol{q}}(t) \,, \\ V &= \frac{1}{2}\boldsymbol{q}^\top(t) K \boldsymbol{q}(t) \,. \end{aligned} \tag{2.162}$$

Example 2.13

Derive the equation of motion of the system shown in Fig. 2.47. Use q_1 and q_2 as independent coordinates.

The kinetic energy T, dissipation function D, and the potential energy V are

$$\begin{aligned} T &= \frac{1}{2}\left(m_1\dot{q}_1^2 + m_2\dot{q}_2^2\right) \\ &= \frac{1}{2}\begin{pmatrix}\dot{q}_1 \\ \dot{q}_2\end{pmatrix}^\top \begin{pmatrix} m_1 & 0 \\ 0 & m_2 \end{pmatrix}\begin{pmatrix}\dot{q}_1 \\ \dot{q}_2\end{pmatrix}, \\ D &= \frac{1}{2}\left[c_1\dot{q}_1^2 + c_2\left(\dot{q}_2 - \dot{q}_1\right)^2\right] \\ &= \frac{1}{2}\begin{pmatrix}\dot{q}_1 \\ \dot{q}_2\end{pmatrix}^\top \begin{pmatrix} c_1 + c_2 & -c_2 \\ -c_2 & c_2 \end{pmatrix}\begin{pmatrix}\dot{q}_1 \\ \dot{q}_2\end{pmatrix}, \\ V &= \frac{1}{2}\left[k_1 q_1^2 + k_2\left(q_2 - q_1\right)^2\right] \\ &= \frac{1}{2}\begin{pmatrix}q_1 \\ q_2\end{pmatrix}^\top \begin{pmatrix} k_1 + k_2 & -k_2 \\ -k_2 & k_2 \end{pmatrix}\begin{pmatrix}q_1 \\ q_2\end{pmatrix}. \end{aligned} \tag{2.163}$$

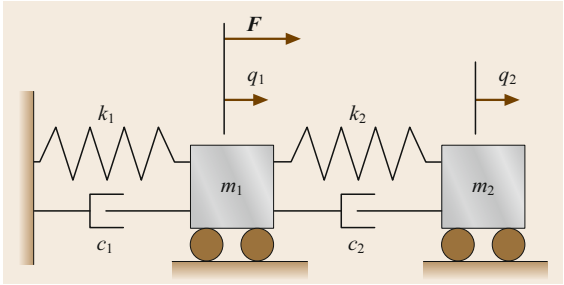

Fig. 2.47 Spring–mass–damping system

The equation of motion of the two-degree-of-freedom dynamic system is obtained as follows

$$\begin{pmatrix} m_1 & 0 \\ 0 & m_2 \end{pmatrix} \begin{pmatrix} \ddot{q}_1 \\ \ddot{q}_2 \end{pmatrix} + \begin{pmatrix} c_1 + c_2 & -c_2 \\ -c_2 & c_2 \end{pmatrix} \begin{pmatrix} \dot{q}_1 \\ \dot{q}_2 \end{pmatrix} + \begin{pmatrix} k_1 + k_2 & -k_2 \\ -k_2 & k_2 \end{pmatrix} \begin{pmatrix} q_1 \\ q_2 \end{pmatrix} = \begin{pmatrix} F \\ 0 \end{pmatrix}. \quad (2.164)$$

This second-order differential equation can be solved and time- and frequency-domain responses can be obtained. Furthermore, this type of problem can be treated as a spring–mass-damping vibration system. Additionally, modern control theory can be introduced to this type of dynamic systems with feedback loops to obtain the desired time- or frequency-domain response.

3.1 Scope of Thermodynamics and Definitions

Thermodynamics is a subfield of physics that deals with energy and its relationship with the properties of matter. It is concerned with the different forms of energy and their transformation between one another. It provides the general laws that are the basis for energy conversion, transfer, and storage.

3.1.1 Systems, System Boundaries, and Surroundings

A thermodynamic system, or briefly a system, is a quantity of matter or a region in space chosen for a thermodynamic investigation. Some examples of systems are

K.-H. Grote, H. Hefazi (Eds.), *Springer Handbook of Mechanical Engineering*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-47035-7_3

an amount of gas, a liquid and its vapor, a mixture of several liquids, a crystal, or a power plant. The system is separated from its surroundings, the so-called environment, by a boundary (real or imaginary). The boundary is allowed to move during the process under investigation, e.g., during the expansion of a gas, and matter and energy may cross the boundary. Energy can cross a boundary with matter or in the form of heat transfer or work (Sect. 3.3.2). The system with its boundary serves as a region with a barrier in which computations of energy conversion processes take place. The energies that cross the system boundary (in or out), the changes in the stored energy, and the properties of the system are linked by the application of an energy balance relationship (the first law of thermodynamics) to the system. A system is called closed when mass is not allowed to cross the boundary, and open when mass can cross the system boundary. While the mass of a closed system always remains constant, the mass inside an open system may also remain constant when the total mass flows in and out are equal. Changes of the mass stored in an open system will occur when the mass flow into the system over a certain time span is different from the mass flow out. Examples of closed systems are solid bodies, mass elements in mechanics, and a sealed container. Examples of open systems are turbines, turbojet engines, or a fluid (gas or liquid) flowing in a channel. A system is called adiabatic when it is completely thermally isolated from its surrounding and no heat transfer can occur across the boundary. A system that is secluded from all influences from its environment is called isolated. For an isolated system, neither energy in the form of heat transfer or work nor matter are exchanged with the environment.

The distinction between a closed and open system corresponds to the distinction between a Lagrangian and Eulerian reference system in fluid mechanics. In the Lagrangian reference system, which corresponds to a closed system, the fluid motion is examined by dividing the flow into small elements of constant mass and deriving the corresponding equations of motion. In the Eulerian reference system, which corresponds to an open system, a fixed volume element in space is selected and the fluid flow through it examined. Both descriptions are equivalent, and it is often only a question of convenience whether one chooses a closed or open system.

3.1.2 Description of States, Properties, and Thermodynamic Processes

A system is characterized by physical properties, which can be given at any instant, for example, pressure, temperature, density, electrical conductivity, and refractive index. The state of a system is determined by the values of these properties. The transition of a system from one equilibrium state to another is called a change of state.

Example 3.1
A balloon is filled with gas. The gas may then be the thermodynamic system. Measurements show that the mass of the gas is determined by its volume, pressure, and temperature. The properties of the system are thus volume, pressure, and temperature, and the state of the system (the gas) is characterized through a fixed set of values of volume, pressure, and temperature. The transition to another fixed set, e.g., when a certain amount of gas escapes, is called a change of state.

The mathematical relationship between such properties is called an equation of state.

Example 3.2
The volume of gas in the balloon proves to be a function of pressure and temperature. The mathematical relationship between these properties is an equation of state.

Properties can be subdivided into three classes: *intensive properties* are independent of the size of the system and thus keep their values after a division of the system into subsystems.

Example 3.3
If a space filled with a gas at uniform temperature is subdivided into smaller spaces, the temperature remains the same in each subdivided space. Thus, temperature is an intensive property. Pressure would be another example of an intensive property.

Properties that are proportional to the mass of the system (i.e., where the total is equal to the sum of the parts) are called *extensive properties*.

Example 3.4
The volume, the energy, or the mass.

An extensive property X divided by the mass m of the system yields the *specific property* $x = X/m$.

Example 3.5
Take volume as an extensive property of a given gas. The associated specific property is the specific volume $v = V/m$, where m is the mass of the gas. The SI unit for specific volume is m^3/kg. Specific properties all fall into the category of intensive properties.

Changes of state are caused by interactions of the system with the environment, for example, when energy is transferred to or from the system across the system boundary. To describe a change of state, it is sufficient to specify the time history of the properties. The description of a process requires additional specifications of the extent and type of the interactions with the environment. Consequently, a process is a change of state caused by certain external influences. The term *process* is more comprehensive than the term *change of state*; for example, the same change between two states can be induced by different processes.

3.2 Temperatures and Equilibria

3.2.1 Thermal Equilibrium

We often talk about *hot* or *cold* bodies without quantifying such states exactly by a property. When a closed hot system A is exposed to a closed cold system B, energy is transported as heat transfer through the contact area. Thereby, the properties of both systems change until, after a sufficient period of time, new fixed values are reached and the energy transport stops. The two systems are in *thermal equilibrium* in this final state. The speed with which this equilibrium state is approached depends on the type of contact between the two systems and on the thermal properties. If, for example, the two systems are separated by only a thin metal wall, the equilibrium is reached faster than in the case of a thick polystyrene wall. A separating wall that inhibits mass transfer and also mechanical, magnetic, or electric interactions but permits the transport of heat is called diathermal. A diathermal wall is *thermally* conductive. A completely thermally insulating wall such that no thermal interactions occur with the surroundings is called adiabatic.

3.2.2 Zeroth Law and Empirical Temperature

In the case of thermal equilibrium between systems A and C and thermal equilibrium between systems B and C, experience shows that systems A and B must also be in thermal equilibrium. This empirical statement is called the *zeroth law of thermodynamics*. It reads: if two systems are both in thermal equilibrium with a third system, they are also in thermal equilibrium with each other. To determine whether two systems A and B are in thermal equilibrium, they can thus be exposed successively to a system C. The mass of system C may be small compared with those of systems A and B. If so, the changes in state of systems A and B are negligible during equilibrium adjustment. When system C is exposed to system A, certain properties of system C will change, for example, its electrical resistance. These properties then remain unchanged during the subsequent exposure of system C to B, if system A and B were originally in thermal equilibrium. Using C in this way, it is possible to verify whether systems A and B are in thermal equilibrium. It is possible to assign any fixed values to the properties of system C after equilibrium adjustment. These values are called *empirical temperatures*, and the measurement instrument is known as a thermometer.

3.2.3 Temperature Scales

A gas thermometer (Fig. 3.1), which measures the pressure p of a constant volume V of gas, is used for the construction and definition of empirical temperature scales. The gas thermometer is brought into contact with systems of a constant state, e.g., a mixture of ice and water at fixed pressure. After a sufficient period of time, the gas thermometer will reach thermal equilibrium with the system with which it is in contact. The volume of gas is kept constant by changing the height Δz of the mercury column. The pressure exerted by the mercury column and environment is measured, and the

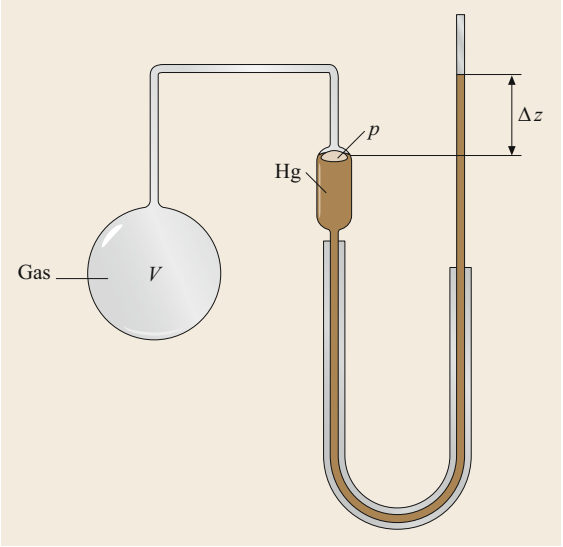

Fig. 3.1 Gas thermometer with gas volume in piston and mercury column

product pV is computed. The extrapolation of measurements at different, sufficiently low pressures leads to a threshold value A for the product pV as pressure approaches zero. This value A, which is determined from the measurements, is assigned to an empirical temperature via the linear relationship

$$T = \text{const}\, A\,. \tag{3.1}$$

After fixing the value *const*, it is only necessary to determine the value of A from the measurements in order to compute the empirical temperature using (3.1). The specification of the empirical temperature scale requires a fixed point. The 10th General Conference of Weights and Measures, held in Paris in 1954, assigned the triple point of water to a temperature $T_{\text{tr}} = 273.16\,\text{kelvin}$ (designated by K). At the triple point of water, vapor, liquid water, and ice coexist in equilibrium at a pressure of $611.657 \pm 0.010\,\text{Pa}$. The temperature scale introduced in this way is named the *Kelvin scale*, and it is identical to the thermodynamic temperature scale. It holds that

$$T = \frac{T_{\text{tr}} A}{A_{\text{tr}}}\,, \tag{3.2}$$

if A_{tr} is the value of A measured using a gas thermometer at the triple point of water.

On the *Celsius scale*, where the unit of temperature t is denoted °C, the ice and steam points are assigned the values of $t_0 = 0\,°\text{C}$ and $t_1 = 100\,°\text{C}$, respectively, at a pressure of 0.101325 MPa. This corresponds quite accurately to absolute temperatures of $T_0 = 273.15\,\text{K}$ and $T_1 = 373.15\,\text{K}$. The temperature $T_{\text{tr}} = 273.16\,\text{K}$ at the triple point of water is roughly 0.01 K higher than the temperature at the ice point. The conversion of temperatures is carried out according to the equation

$$T = t + 273.15\,, \tag{3.3}$$

where t is in °C and T is in K.

Additionally, the Fahrenheit scale is common in some countries, particularly the USA. The corresponding values on this scale are 32°F at the ice point and 212°F at the steam point of water (the pressure in each case being 0.101325 MPa). The conversion of a temperature t_{F} given in °F to a Celsius temperature t in °C is given by

$$t = \frac{5}{9}(t_{\text{F}} - 32)\,. \tag{3.4}$$

The degree increments of the Rankine scale (°R) are the same as Fahrenheit degrees, but the reference 0 is set at absolute zero. It thus holds that

$$T_{\text{R}} = \frac{9}{5} T\,, \tag{3.5}$$

where T_{R} is in °R and T is in K. The ice point of water is thus given as 491.67 °R.

The International Practical Temperature Scale

Since it is difficult and time consuming to measure temperatures precisely using a gas thermometer, the international practical temperature scale was introduced by law. It is arranged by the International Committee for Weights and Measures so that its temperature approaches as close as possible the thermodynamic temperature of certain substances. The international practical temperature scale is fixed by the freezing and boiling points of these substances, which were determined as precisely as possible using a gas thermometer by the scientific national institutes of different countries. Resistance thermometers, thermocouples, and radiation measuring devices are used to interpolate between the fixed points, whereas certain instructions are given for the relationships between the actually measured quantities and temperature. The basic regulations of the international temperature scale are the same in all countries. They read:

1. In the international temperature scale of 1948, the symbol for temperature is t and its unit is "°C" or "°C (Int. 1948)".
2. On the one hand the scale is based on a number of always reproducible equilibrium temperatures (fixed points), which are assigned to certain numerical values, and on the other hand on accurately defined formulas, which establish relationships between the temperature and the indications of the measuring instruments calibrated at the fixed points.
3. The fixed points and the assigned numerical values are summarized in tables (Table 3.1). With the exception of the triple points, the assigned temperatures correspond to equilibrium states at the pressure 0.101325 MPa, which is the standard atmospheric pressure at sea level.
4. Formulas, which also are established by international agreements, are used for interpolation between fixed points. Thus, the indications of the standard instruments with which the temperatures have to be measured are assigned to the numerical values of the international practical temperature.

To simplify temperature measurements,, other additional thermometric fixed points for substances, which can be easily produced in sufficiently pure form, were associated as accurately as possible with this le-

Table 3.1 Fixed points of the international temperature scale of 1990 (ITS-90)

Equilibrium state	Assigned values of the international practical temperature scale	
	T_{90} (K)	t_{90} (°C)
Vapor pressure of helium	3 to 5	−270.15 to −268.15
Triple point of equilibrium hydrogen	13.8033	−259.3467
Vapor pressure of equilibrium hydrogen	≈ 17	≈ −256.15
	≈ 20.3	≈ −252.85
Triple point of neon	24.5561	−248.5939
Triple point of oxygen	54.3584	−218.7916
Triple point of argon	83.8058	−189.3442
Triple point of mercury	234.3156	−38.8344
Triple point of water	273.16	0.01
Melting point of gallium	302.9146	29.7646
Solidification point of indium	429.7485	156.5985
Solidification point of tin	505.078	231.928
Solidification point of zinc	692.677	419.527
Solidification point of aluminum	933.473	660.323
Solidification point of silver	1234.93	961.78
Solidification point of gold	1337.33	1064.18
Solidification point of copper	1357.77	1084.62

All substances except helium may have their natural isotope composition. Hydrogen consists of ortho- and parahydrogen at equilibrium composition

gal temperature scale. The most important ones are summarized in Table 3.2. The platinum resistance thermometer is used as the normal instrument between the triple point of equilibrium hydrogen at 13.8033 K (−259.3467 °C) and the melting point of silver at 1234.93 K (961.78 °C). Between the melting point of silver and the melting point of gold at 1337.33 K (1064.18 °C) a platinum-rhodium (10% rhodium)/platinum thermocouple is used as the normal instrument. Above the melting point of gold, Planck's radiation law defines the international practical temperature

$$\frac{J_t}{J_{\mathrm{Au}}} = \frac{\exp\left(\frac{c_2}{\lambda(t_{\mathrm{Au}}+T_0)}\right)-1}{\exp\left(\frac{c_2}{\lambda(t+T_0)}\right)-1}, \qquad (3.6)$$

where J_t and J_{Au} are the radiation energies emitted by a black body at temperature t and at the gold point t_{Au}, respectively, at a wavelength of λ per unit area, time, and wavelength interval. The value of the constant c_2 is specified as 0.014388 K m (kelvin meters), $T_0 = 273.15$ K is the numerical value of the melting temperature of ice, and λ is the numerical value in m of a wavelength in the visible spectrum. For practical temperature measurements, see [3.1].

Table 3.2 Some thermometric fixed points: E solidification point, Sd boiling point at pressure 101.325 kPa, Tr triple point (after [3.2])

		°C
Normal hydrogen	Tr	−259.198
Normal hydrogen	Sd	−252.762

Iridium	E	2446
Tungsten	E	3418

3.3 First Law of Thermodynamics

3.3.1 General Formulation

The first law is an empirical statement, which is valid because all conclusions drawn from it are consistent with experience. Generally, it states that energy can be neither destroyed nor created, thus energy is a conserved property. This means that the energy E of a system can be changed only by energy exchange into or out of the system. It is generally agreed that energy transferred into a system is positive while energy transferred out of a system is negative. A fundamental formulation of the first law reads: every system possesses an extensive property called energy, which is constant in an isolated system.

3.3.2 Different Forms of Energy and Energy Transfer

To set up the first law mathematically, it is necessary to distinguish and define the different forms of energy transfer.

Work

In thermodynamics, the basic definition of the term *work* is adopted from mechanics: the work done on a system is equal to the product of the force acting on the system and the displacement from the point of application. The work done by a force F along the distance z between points 1 and 2 is given by

$$W_{12} = \int_1^2 \boldsymbol{F}\,\mathrm{d}z\,. \tag{3.7}$$

The mechanical work $W_{\mathrm{m}12}$ is the result of forces which accelerate a closed system of mass m from velocity w_1 to w_2 and raise it from level z_1 to level z_2 against gravity g. The changes in kinetic energy $mw^2/2$ and potential energy mgz of the system are thus related as

$$W_{\mathrm{m}12} = m\left(\frac{w_2^2}{2} - \frac{w_1^2}{2}\right) + mg(z_2 - z_1)\,. \tag{3.8}$$

Equation (3.8) is known as the energy theorem of mechanics.

Moving boundary work, or simply boundary work, is the work that has to be done to change the volume of a system. In a system of volume V, which possesses the variable pressure p, a differential element $\mathrm{d}A$ of the boundary surface thereby moves the distance $\mathrm{d}z$. The work done is

$$\mathrm{d}W_{\mathrm{v}} = -p\int_A \mathrm{d}\boldsymbol{A}\,\mathrm{d}z = -p\,\mathrm{d}V\,, \tag{3.9}$$

and thus

$$W_{\mathrm{v}12} = -\int_1^2 p\,\mathrm{d}V\,. \tag{3.10}$$

The minus sign is due to the formal sign convention which states that work transferred to the system, which is connected to a volume reduction, is positive. Equation (3.10) is only valid if the pressure p of the system is in each instance of the change of state a continuous function of volume and equal to the pressure exerted by the environment. Then a small excess or negative pressure of the environment causes either a decrease or increase of the system volume. Such changes between states, where even the slightest imbalance is sufficient to drive them in either direction, are called reversible. Accordingly, (3.10) is the moving boundary work for reversible changes of state. In real processes, a finite excess pressure of the environment is necessary to overcome the internal friction of the system. Such changes in state are irreversible, where the added work is increased by the dissipated part $W_{\mathrm{diss}12}$. The moving boundary work for an irreversible change of state is

$$W_{\mathrm{v}12,\mathrm{irr.}} = -\int_1^2 p\mathrm{d}V + W_{\mathrm{diss}12}\,. \tag{3.11}$$

The dissipation work is always positive, increases the system energy, and causes a different path $p(V)$ between the states than in the reversible case. The determination of the integral in (3.11) requires that p be a unique function of V. Equation (3.11) is, for example, not valid for a system area through which a sound wave travels.

Work can be derived as the product of a generalized force F_{k} and a generalized displacement $\mathrm{d}X_{\mathrm{k}}$. In real processes, the dissipated work has to be added

$$\mathrm{d}W = \sum F_{\mathrm{k}}\mathrm{d}X_{\mathrm{k}} + \mathrm{d}W_{\mathrm{diss}}\,. \tag{3.12}$$

This equation shows that, in irreversible processes ($W_{\mathrm{diss}} > 0$), more work has to be done or less work is received than in reversible processes ($W_{\mathrm{diss}} = 0$). Table 3.3 includes different forms of work.

Shaft work is work derived from a mass flow through machines such as compressors, turbines, and jet engines. When a machine increases the pressure of a mass m along the path $\mathrm{d}z$ by $\mathrm{d}p$, the shaft work is

$$\mathrm{d}W_{\mathrm{t}} = mv\mathrm{d}p + \mathrm{d}W_{\mathrm{diss}}\,. \tag{3.13}$$

When the kinetic energy and potential energy of the mass flow are also changed, mechanical work is done

Table 3.3 Different forms of work. SI units are given in parenthesis

Form of work	Generalized force	Generalized displacement	Work done
Linear elastic displacement	Force F (N)	Displacement $\mathrm{d}z$ (m)	$\mathrm{d}W = F\,\mathrm{d}z = \sigma\,\mathrm{d}\varepsilon V$ (N m)
Rotation of a rigid body	Torque M_d (N m)	Torsion angle $\mathrm{d}\alpha$ (–)	$\mathrm{d}W = M_\mathrm{d}\,\mathrm{d}\alpha$ (N m)
Moving boundary work	Pressure p (N/m^2)	Volume $\mathrm{d}V$ (m^3)	$\mathrm{d}W_\mathrm{v} = -p\,\mathrm{d}V$ (N m)
Surface enlargement	Surface tension σ' (N/m)	Area $\mathrm{d}A$ (m^2)	$\mathrm{d}W = \sigma'\,\mathrm{d}A$ (N m)
Electric work	Voltage U_e (V)	Charge Q_e (C)	$\mathrm{d}W = U_\mathrm{e}\,\mathrm{d}Q_\mathrm{e}$ (W s) in a linear conductor with resistance R $\mathrm{d}W = U_\mathrm{e} I\,\mathrm{d}t$ $= RI^2\,\mathrm{d}t$ $= (U^2/R)\,\mathrm{d}t$ (W s)
Magnetic work, in vacuum	Magnetic field strength H_0 (A/m)	Magnetic induction $\mathrm{d}B_0 = \mu_0 H_0$ (Vs/m^2)	$\mathrm{d}W_\mathrm{V} = \mu_0 H_0\,\mathrm{d}H_0$ (W s/m^3)
Magnetization	Magnetic field strength H (A/m)	Magnetic induction $\mathrm{d}B = \mathrm{d}(\mu_0 H + M)$ (Vs/m^2)	$\mathrm{d}W_\mathrm{V} = H\,\mathrm{d}B$ (W s/m^3)
Electrical polarization	Electric field strength E (V/m)	Dielectric displacement $\mathrm{d}D = \mathrm{d}(\varepsilon_0 E + P)$ (As/m^2)	$\mathrm{d}W_\mathrm{V} = E\,\mathrm{d}D$ (W s/m^3)

additionally. The shaft work done along path 1–2 is

$$W_{\mathrm{t}12} = \int_1^2 V\mathrm{d}p + W_{\mathrm{diss}12} + W_{\mathrm{m}12}\,, \tag{3.14}$$

with $W_{\mathrm{m}12}$ given according to (3.8).

Internal Energy

In addition to any kinetic and potential energy, every system possesses energy stored internally as translational, rotational, and vibrational kinetic energy of the elementary particles. This is called the internal energy U of the system and is an extensive property. The total energy E a system of mass m consists of internal energy, kinetic energy E_kin, and potential energy E_pot

$$E = U + E_\mathrm{kin} + E_\mathrm{pot}\,. \tag{3.15}$$

Heat Transfer

The internal energy of a system can be changed by doing work on it or by adding or removing matter. However, it can also be changed by exposing the system to an environment that has a different temperature. As a consequence, energy is transferred across the system boundary as the system tries to reach thermal equilibrium with the environment. This energy transfer is called heat transfer. Thus, heat transfer can generally be defined as the energy that a system exchanges with its environment which does not cross the system boundary as work or by an accompanying mass transfer. The heat transfer from state 1 to 2 is denoted Q_{12}.

3.3.3 Application to Closed Systems

The heat transfer Q_{12} to and work W_{12} done on a closed system during the change of state from 1 to 2 cause a change of the system energy E

$$E_2 - E_1 = Q_{12} + W_{12}\,, \tag{3.16}$$

where W_{12} includes all forms of work done on the system. If no mechanical work is done, only the internal energy changes, and according to (3.15), $E = U$ holds. If it is additionally assumed that only moving boundary work is done on the system, (3.16) reads

$$U_2 - U_1 = Q_{12} - \int_1^2 p\mathrm{d}V + W_{\mathrm{diss}12}\,. \tag{3.17}$$

3.3.4 Application to Open Systems

Steady-State Processes

Very often, work is done by a fluid flowing steadily through a device. If the work per unit time remains constant, such a process is called a *steady flow process*. Figure 3.2 shows a typical example: a flowing fluid (gas or liquid) of pressure p_1 and temperature T_1 may flow with velocity w_1 into system σ. If machine work is done as shaft work, $W_{\mathrm{t}12}$ is supplied at the shaft.

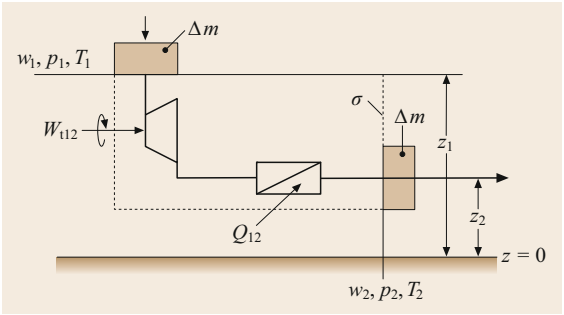

Fig. 3.2 Work for an open system

Then, the fluid flows through a heat exchanger, in which heat transfer Q_{12} occurs with the environment, and the fluid eventually leaves the system σ with pressure p_2, temperature T_2, and velocity w_2. Tracking the path of a constant mass element Δm through the system σ means that a moving observer would consider the mass element Δm as a closed system, thus this corresponds to the Lagrangian description in fluid mechanics. Therefore, the first law for closed systems (3.16) is valid in this case. The work done on Δm consists of $\Delta m p_1 v_1$ to push Δm out of the environment across the system boundary, of the technical work W_{t12}, and of $-\Delta m p_2 v_2$ to bring Δm back into the environment. Thus, the work done on the closed system is

$$W_{12} = W_{t12} + \Delta m(p_1 v_1 - p_2 v_2) \,. \tag{3.18}$$

The term $\Delta m\,(p_1 v_1 - p_2 v_2)$ is referred to as the *flow work*. This flow work is the difference between the shaft work W_{t12} and the work done on the closed system. With this relationship, the first law for closed systems, (3.16), becomes

$$E_2 - E_1 = Q_{12} + W_{t12} + \Delta m(p_1 v_1 - p_2 v_2) \tag{3.19}$$

with E according to (3.15). The property enthalpy is defined as

$$H = U + pV \quad \text{or} \quad h = u + pv \,, \tag{3.20}$$

then (3.19) can be written as

$$0 = Q_{12} + W_{t12} + \Delta m \left(h_1 + \frac{w_1^2}{2} + g z_1 \right) - \Delta m \left(h_2 + \frac{w_2^2}{2} + g z_2 \right) \,. \tag{3.21}$$

The first law is used in this form for steady flow processes in open systems. Equation (3.21) shows that the sum of all the energies entering or leaving the system across the system boundary σ (Fig. 3.2) is zero, because a steady flow process is considered. These energies are in the form of the heat transfer Q_{12}, the shaft work W_{t12}, and the energies $\Delta m(h_1 + w_1^2/2 + g z_1)$ transferred to the system and $\Delta m(h_2 + w_2^2/2 + g z_2)$ transferred from the system with the mass Δm. The differential form of (3.21) reads

$$0 = \mathrm{d}Q + \mathrm{d}W_t + \mathrm{d}m \left(h_1 + \frac{w_1^2}{2} + g z_1 \right) - \mathrm{d}m \left(h_2 + \frac{w_2^2}{2} + g z_2 \right) \,.$$

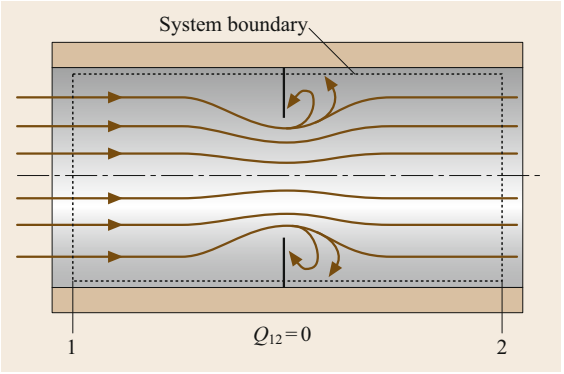

Fig. 3.3 Adiabatic throttling

When a continuous process is considered, it is better to use the following form of the balance equation instead of (3.21),

$$0 = \dot{Q} + P + \dot{m} \left(h_1 + \frac{w_1^2}{2} + g z_1 \right) - \dot{m} \left(h_2 + \frac{w_2^2}{2} + g z_2 \right) \,.$$

In the above equation, $\dot{Q} = \mathrm{d}Q/\mathrm{d}\tau$ is the heat transfer rate, $P = \mathrm{d}W_t/\mathrm{d}\tau$ is the shaft power, and $\dot{m}$ is the mass flow rate. Changes of kinetic and potential energy in these cases are often negligible, such that (3.21) can be simplified to

$$0 = Q_{12} + W_{t12} + H_1 - H_2 \,. \tag{3.22}$$

Special cases of this equation are:

a) Adiabatic changes of state, which typically appear in devices such as compressors, turbines, and jet engines

$$0 = W_{t12} + H_1 - H_2 \,. \tag{3.23}$$

b) Throttling of a flow in an adiabatic tube through a restriction (Fig. 3.3), which causes a pressure reduction. It holds that

$$H_1 = H_2 \tag{3.24}$$

before and after the throttling valve. Thus, the enthalpy remains constant during the throttling, assuming that the changes of kinetic and potential energies are negligible.

Transient Processes

Referring to Fig. 3.2, when the mass Δm_1 transferred to the system over a period of time differs from the

mass Δm_2 transferred from the system during the same period, the result is mass storage (or loss) in the system. This results in a time-variable internal energy of the system and possibly also time-variable kinetic and potential energies. The energy change of a system during a change of state 1–2 is $E_2 - E_1$. Therefore, (3.21) has to be replaced by the following form of the first law,

$$E_2 - E_1 = Q_{12} + W_{t12} + \Delta m_1 \left(h_1 + \frac{w_1^2}{2} + g z_1 \right) - \Delta m_2 \left(h_2 + \frac{w_2^2}{2} + g z_2 \right) . \quad (3.25)$$

If the fluid states 1 at the inlet and 2 at the outlet vary in time, it is appropriate to use the differential notation

$$\mathrm{d}E = \mathrm{d}Q + \mathrm{d}W_t + \mathrm{d}m_1 \left(h_1 + \frac{w_1^2}{2} + g z_1 \right) - \mathrm{d}m_2 \left(h_2 + \frac{w_2^2}{2} + g z_2 \right) . \quad (3.26)$$

When investigating the filling and emptying of containers, it is usually possible to neglect changes in kinetic and potential energies. Furthermore, often no shaft work is done, thus (3.26) reduces to

$$\mathrm{d}U = \mathrm{d}Q + h_1 \mathrm{d}m_1 - h_2 \mathrm{d}m_2 , \quad (3.27)$$

with $U = um$ being the (time-variable) internal energy of the mass stored in the container. It is agreed that $\mathrm{d}m_1$ is mass transferred to and $\mathrm{d}m_2$ mass transferred from the system. If mass is only supplied, $\mathrm{d}m_2$ is equal to zero; if mass is only discharged, $\mathrm{d}m_1$ is equal to zero. For a continuously running process, the following form of the balance equation is more suitable than (3.25),

$$\frac{\mathrm{d}E}{\mathrm{d}\tau} = \dot{Q} + P + \dot{m}_1 \left(h_1 + \frac{w_1^2}{2} + g z_1 \right) - \dot{m}_2 \left(h_2 + \frac{w_2^2}{2} + g z_2 \right) . \quad (3.28)$$

3.4 Second Law of Thermodynamics

3.4.1 The Principle of Irreversibility

When two systems A and B are exposed to each other, energy exchange processes take place and a new equilibrium state is reached after a sufficient period of time. As an example, a system A may be in contact with a system B that has a different temperature. In the final state, both systems will have the same temperature and equilibrium will have been reached. Until equilibrium has been reached, a continuous series of nonequilibrium states will be passed. Common experience shows that this process has a natural direction (e.g., heat transfer from hot to cold) but does not proceed in the reverse direction independently, i.e., without exchange with the environment. Such processes are referred to as being irreversible. Exchange processes, which pass through nonequilibrium states, are in principle irreversible. On the other hand, a process that consists of a continuous series of equilibrium states is reversible. This may be exemplified by the frictionless, adiabatic compression of a gas. It is possible to transfer moving boundary work to the system *gas* by exerting a force, for example, an excess pressure of the environment, on the system boundary. If this force is increased very slowly, the volume of the gas decreases while the temperature increases, whereas the gas is at all times in an equilibrium state. If the force is slowly reduced to zero, the gas returns to its initial state; thus, this process is reversible. Reversible processes are idealized borderline cases of real processes and do not occur in Nature. All natural processes are irreversible, because a finite force is necessary to initiate a process, e.g., a finite force to move a body against friction or a finite temperature difference for heat transfer. These facts known from experience lead to the following formulations of the second law:

- All natural processes are irreversible.
- All processes including friction are irreversible.
- Heat transfer does not independently occur from a body of lower to a body of higher temperature.

Independently in this regard means that it is not possible to carry out the mentioned process without causing effects on Nature. Beside these examples, further formulations valid for other special processes exist.

3.4.2 General Formulation

The mathematical formulation of the second law is realized by introducing the term *entropy* as another property of a system. The practicality of this property can be shown by using the example of heat transfer between a system and its environment. According to the first law, a system can exchange energy by work

and by heat transfer with its environment. The supply of work causes a change of the internal energy such that, for example, the system's volume is changed at the expense of the environment's volume. Consequently, $U = U(V, \ldots)$. The volume is an exchange variable. It is an extensive property, which is *exchanged* between the system and environment. It is also possible to look upon the heat transfer between a system and its environment as an exchange of an extensive property. In this way, only the existence of such a property is postulated. Its introduction is solely justified by the fact that all statements derived from it correspond with experience. This new extensive property is called entropy, and it is denoted S. Consequently, $U = U(V, S, \ldots)$. If only moving boundary work occurs and heat transfer occurs, $U = U(V, S)$. Differentiation leads to the *Gibbs equation*

$$\mathrm{d}U = T\mathrm{d}S - p\mathrm{d}V \tag{3.29}$$

with the thermodynamic temperature

$$T = \left(\frac{\partial U}{\partial S}\right)_V \tag{3.30}$$

and the pressure

$$p = -\left(\frac{\partial U}{\partial V}\right)_S . \tag{3.31}$$

A relationship equivalent to (3.29) can be derived by eliminating U and replacing it by the enthalpy $H = U + pV$, such that

$$\mathrm{d}H = T\mathrm{d}S + V\mathrm{d}p . \tag{3.32}$$

It can be shown that the thermodynamic temperature is identical to the temperature measured by a gas thermometer (Sect. 3.2.3). From examination of the characteristics of entropy, it follows, that in an isolated system which is initially in nonequilibrium (for example, because of a nonuniform temperature distribution) and then approaches equilibrium, the entropy always increases. In the borderline case of equilibrium, a maximum of entropy is reached. The internal entropy increase is denoted by $\mathrm{d}S_{\mathrm{gen}}$. For the considered case of an isolated system, it holds that

$$\mathrm{d}S = \mathrm{d}S_{\mathrm{gen}}$$

with $\mathrm{d}S_{\mathrm{gen}} > 0$. If a system is not isolated, the entropy is also changed by $\mathrm{d}S_{\mathrm{Q}}$ due to heat transfer (with the environment) and by $\mathrm{d}S_{\mathrm{m}}$ because of mass transfer with the environment. However, energy transfer by work with the environment does not change the system entropy. Thus, it holds generally that

$$\mathrm{d}S = \mathrm{d}S_{\mathrm{Q}} + \mathrm{d}S_{\mathrm{m}} + \mathrm{d}S_{\mathrm{gen}} . \tag{3.33}$$

The formulation for the time-variable system entropy $\dot{S} = \mathrm{d}S/\mathrm{d}\tau$ reads

$$\dot{S} = \dot{S}_{\mathrm{Q}} + \dot{S}_m + \dot{S}_{\mathrm{gen}} \tag{3.34}$$

with $\dot{S}_{\mathrm{gen}}$ being the entropy generation rate caused by internal irreversibilities; $\dot{S}_{\mathrm{Q}} + \dot{S}_{\mathrm{m}}$ is called the entropy flow. These values, which are exchanged across the system boundary, are combined thus

$$\dot{S}_{\mathrm{fl}} = \dot{S}_{\mathrm{Q}} + \dot{S}_{\mathrm{m}} . \tag{3.35}$$

The rate of change of the system entropy S therefore consists of the entropy flow $\dot{S}_{\mathrm{fl}}$ and the entropy generation $\dot{S}_{\mathrm{gen}}$:

$$\dot{S} = \dot{S}_{\mathrm{fl}} + \dot{S}_{\mathrm{gen}} . \tag{3.36}$$

For the entropy generation, it holds that

$$\begin{aligned} \dot{S}_{\mathrm{gen}} &= 0 \quad \text{for reversible processes,} \\ \dot{S}_{\mathrm{gen}} &> 0 \quad \text{for irreversible processes,} \\ \dot{S}_{\mathrm{gen}} &< 0 \quad \text{for impossible processes.} \end{aligned} \tag{3.37}$$

3.4.3 Special Formulations

Adiabatic Closed Systems

Since $\dot{S}_{\mathrm{Q}} = 0$ for adiabatic systems and $\dot{S}_{\mathrm{m}} = 0$ for closed systems, it follows that $\dot{S} = \dot{S}_{\mathrm{gen}}$. Thus, the entropy of an adiabatic closed system can never decrease. It can only increase during an irreversible process or remain constant during a reversible process. If an adiabatic closed system consists of α subsystems, then it holds for the sum of entropy changes ΔS^{α} of the subsystems that

$$\sum_{\alpha} \Delta S^{\alpha} \geq 0 . \tag{3.38}$$

With $\mathrm{d}S = \mathrm{d}S_{\mathrm{gen}}$, (3.29) reads for an adiabatic closed system

$$\mathrm{d}U = T\mathrm{d}S_{\mathrm{gen}} - p\mathrm{d}V .$$

On the other hand, it follows from the first law according to (3.17) that

$$\mathrm{d}W_{\mathrm{diss}} = T\mathrm{d}S_{\mathrm{gen}} = \mathrm{d}\Psi \tag{3.39}$$

or

$$W_{\mathrm{diss12}} = TS_{\mathrm{gen12}} = \Psi_{12} , \tag{3.40}$$

where Ψ_{12} is called the dissipated energy during the change in state 1–2. The dissipated energy is always

positive. This statement is true not only for adiabatic systems but also for all general cases, because, by definition, the entropy generation is the fraction of the entropy change that arises when the system is adiabatic and closed, and thus $\dot{S}_{\mathrm{fl}} = 0$ holds.

Systems with Heat Transfer

For closed systems with heat transfer, (3.29) becomes

$$\begin{aligned} \mathrm{d}U &= T\mathrm{d}S_{\mathrm{Q}} + T\mathrm{d}S_{\mathrm{gen}} - p\mathrm{d}V \\ &= T\mathrm{d}S_{\mathrm{Q}} + \mathrm{d}W_{\mathrm{diss}} - p\mathrm{d}V \,. \end{aligned} \tag{3.41}$$

A comparison with the first law, (3.17), results in

$$\mathrm{d}Q = T\mathrm{d}S_{\mathrm{Q}} \,. \tag{3.42}$$

Thus, heat transfer is energy transfer, which together with entropy crosses the system boundary, whereas work is exchanged without entropy exchange. Adding the always positive term $T\mathrm{d}S_{\mathrm{gen}}$ to the right-hand side of (3.42) leads to the *Clausius inequality*

$$\mathrm{d}Q \le T\mathrm{d}S \quad \text{or} \quad \Delta S \ge \int_1^2 \frac{\mathrm{d}Q}{T} \,. \tag{3.43}$$

In irreversible processes, the entropy change is larger than the integral over all $\mathrm{d}Q/T$; the equals sign is only valid for the reversible case. For open systems with heat addition, $\mathrm{d}S_{\mathrm{Q}}$ in (3.41) must be replaced by

$$\mathrm{d}S_{\mathrm{fl}} = \mathrm{d}S_{\mathrm{Q}} + \mathrm{d}S_{\mathrm{m}} \,.$$

3.5 Exergy and Anergy

According to the first law, the energy of an isolated system is constant. As it is possible to transform every nonisolated system into an isolated one by adding the environment, it is always possible to define a system in which the energy remains constant during a thermodynamic process. Thus, a loss of energy is not possible, and energy is only converted in a thermodynamic process. How much of the energy stored in a system is converted depends on the state of the environment. If it is in equilibrium with the system, no energy is converted. The larger the difference from equilibrium, the more energy of the system can be converted and thus the greater the potential to perform work.

Many thermodynamic processes take place in the Earth's atmosphere, which is the environment of most thermodynamic systems. In comparison with much smaller thermodynamic systems, the Earth's atmosphere can be considered as an infinitely large system, in which the intensive properties pressure, temperature, and composition do not change during a process (as long as daily and seasonal variations of the intensive properties are neglected). In many engineering processes, work is obtained by bringing a system with a given initial state into equilibrium with the environment. The maximum work is obtained when all changes of state are reversible.

The maximum work that could be obtained by establishing equilibrium with the environment is called the exergy W_{ex}.

3.5.1 Exergy of a Closed System

To calculate the exergy of a system at state 1, consider a process that brings the system reversibly into thermal and mechanical equilibrium with its environment. Equilibrium exists if the temperature of the system at the final state 2 is equal to the temperature of the environment, i.e., $T_2 = T_{\mathrm{env}}$, and if the pressure of the system in state 2 is equal to the pressure of the environment, i.e., $p_2 = p_{\mathrm{env}}$. Neglecting the kinetic and potential energy of the system, the first law according to (3.16) reads

$$U_2 - U_1 = Q_{12} + W_{12} \,. \tag{3.44}$$

To execute the entire process reversibly, it is necessary to bring the system to the environmental temperature through a reversible, adiabatic change of state. Then, heat transfer has to occur reversibly at the constant temperature T_{env}.

From the second law, (3.42), it follows for the heat transfer that

$$Q_{12} = T_{\mathrm{env}}(S_2 - S_1) \,. \tag{3.45}$$

The work W_{12} done on the system consists of the maximum useful work and the moving boundary work $-p_{\mathrm{env}}(V_2 - V_1)$, which is necessary to overcome the pressure of the environment. The maximum useful work is the exergy W_{ex}, thus it follows that

$$W_{12} = W_{\mathrm{ex}} - p_{\mathrm{env}}(V_2 - V_1) \,. \tag{3.46}$$

Inserting (3.45) and (3.46) into (3.44) gives

$$U_2 - U_1 = T_{\mathrm{env}}(S_2 - S_1) + W_{\mathrm{ex}} - p_{\mathrm{env}}(V_2 - V_1) \,. \tag{3.47}$$

In state 2, the system is in equilibrium with the environment, denoted by the index *env*. Thus, the exergy of

the closed system is

$$-W_{ex} = U_1 - U_{env} - T_{env}(S_1 - S_{env}) + p_{env}(V_1 - V_{env}) \,. \quad (3.48)$$

For a constant-volume system, it holds that $V_1 = V_{env}$ and the last term cancels. If the initial state of the system is already in equilibrium with the environment (state 1 = state env), according to (3.48), no work can be obtained.

Thus, it holds that the internal energy of the environment cannot be transformed into exergy. Consequently, the enormous energies stored in the atmosphere surrounding us cannot be used to power vehicles.

3.5.2 Exergy of an Open System

The maximum shaft work, or the exergy from a mass flow, is obtained when the mass flow is brought reversibly into equilibrium with the environment by performing work and heat transfer with the environment. Neglecting changes of kinetic and potential energies, the first law for steady flow processes in open systems, (3.22), reads

$$-W_{ex} = H_1 - H_{env} - T_{env}(S_1 - S_{env}) \,. \quad (3.49)$$

This means that only a part of the enthalpy, H_1 reduced by $H_{env} + T_{env}(S_1 - S_{env})$, is transformed into shaft work. If the heat transfer from the environment to the mass flow, $T_{env}(S_1 - S_{env})$, is negative, then the exergy exceeds the change in enthalpy by the fraction of this added heat.

3.5.3 Exergy and Heat Transfer

Figure 3.4 shows a device which is used to transform the heat transfer Q_{12} from an energy storage of temperature T into work W_{12}. The heat transfer Q_{env12}, which cannot be transformed into work, is rejected to the environment. The maximum shaft work is obtained if all changes in state are reversible. This maximum shaft work is equal to the exergy of the heat transfer. All changes in state are reversible if

$$\int_1^2 \frac{dQ}{T} + \int_1^2 \frac{dQ_{env}}{T_{env}} = 0$$

with $dQ + dQ_{env} + dW_{ex} = 0$ according to the first law. The resulting exergy of the heat transfer to machines and apparatuses is

$$-W_{ex} = \int_1^2 \left(1 - \frac{T_{env}}{T}\right) dQ \quad (3.50)$$

or in differential notation

$$-dW_{ex} = \left(1 - \frac{T_{env}}{T}\right) dQ \,. \quad (3.51)$$

In a reversible process, only the fraction of the supplied heat transfer multiplied by the so-called Carnot factor $1 - (T_{env}/T)$ can be transformed into work. The fraction $dQ_{env} = -T_{env}(dQ/T)$ has to be transferred to the environment, and it is impossible to obtain it as work. This shows additionally that the heat transfer, which is available at ambient temperature, cannot be transformed into exergy.

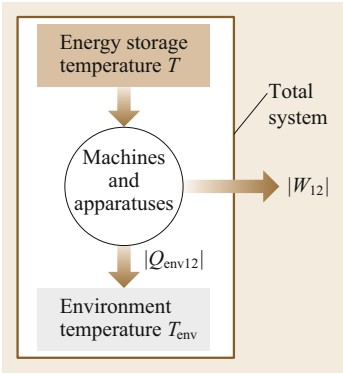

Fig. 3.4 Conversion of heat into work

3.5.4 Anergy

The energy that cannot be converted into exergy W_{ex} is denoted B. Each amount of energy consists of exergy W_{ex} and anergy B, i.e.,

$$E = W_{ex} + B \,. \quad (3.52)$$

Thus, it holds that:

- For a closed system according to (3.48) with $E = U_1$

$$B = U_{env} + T_{env}(S_1 - S_{env}) - p_{env}(V_1 - V_{env}) \quad (3.53)$$

- For an open system according to (3.49) with $E = H_1$

$$B = H_{env} + T_{env}(S_1 - S_{env}) \quad (3.54)$$

- For heat transfer according to (3.51) with $dE = dQ$

$$B = \int_1^2 \frac{T_{env}}{T} dQ \,. \quad (3.55)$$

3.5.5 Exergy Losses

The energy dissipated in a process is not lost completely. It increases the entropy, and because of $U(S, V)$, also the internal energy of a system. It is possible to think of the dissipated energy as heat transfer in a substitutional process, which is transferred from the outside ($\mathrm{d}\Psi = \mathrm{d}Q$) and causes the same entropy increase as in the irreversible process. Since the heat transfer $\mathrm{d}Q$, (3.51), is partly transformable into work, the fraction

$$-\mathrm{d}W_{\mathrm{ex}} = \left(1 - \frac{T_{\mathrm{env}}}{T}\right)\mathrm{d}\Psi \tag{3.56}$$

of the dissipated energy $\mathrm{d}\Psi$ can also be obtained as work (exergy). The remaining fraction $T_{\mathrm{env}}\mathrm{d}\Psi/T$ of the dissipated energy has to be transferred to the environment as heat transfer and is not transformable into work. This exergy loss is equal to the anergy of the dissipated energy and is, according to (3.55), given by

$$W_{\mathrm{loss}12} = \int_1^2 \frac{T_{\mathrm{env}}}{T}\mathrm{d}\Psi = \int_1^2 T_{\mathrm{env}}\mathrm{d}S_i\,. \tag{3.57}$$

For a process in a closed adiabatic system, it holds that $\mathrm{d}S_i = \mathrm{d}S$ and thus

$$W_{\mathrm{loss}12} = \int_1^2 T_{\mathrm{env}}\mathrm{d}S = T_{\mathrm{env}}(S_2 - S_1)\,. \tag{3.58}$$

In contrast to energy, exergy does not follow a conservation equation. The exergy transferred to a system at steady state is equal to the sum of the exergy transferred from the system plus exergy losses. The thermodynamic effect of losses caused by irreversibilities is more unfavorable when the process takes place at lower temperature T; see (3.57).

3.6 Thermodynamics of Substances

In order to utilize the primary laws of thermodynamics, which are generally set up for any arbitrary substance, and to calculate exergies and anergies, it is necessary to determine actual numerical values for the properties U, H, S, p, V, and T. Among these, U, H, and S are typically called caloric, whereas p, V, and T are known as thermal properties. The relationships between these properties depend on the corresponding substance. Equations that specify the relationships between the properties p, V, and T are called *equations of state*.

3.6.1 Thermal Properties of Gases and Vapors

An equation of state for pure substances is of the form

$$F(p, v, T) = 0 \tag{3.59}$$

or $p = p(v, T)$, $v = v(p, T)$, or $T = T(p, v)$. For calculations, equations of state of the form $v = v(p, T)$ are preferred, as the pressure and temperature are typically the independent variables used to describe a system.

Ideal Gases

A particularly simple equation of state is that for ideal gases

$$pV = mRT \quad \text{or} \quad pv = RT, \tag{3.60}$$

which relates the absolute pressure p, the volume V, the specific volume v, the individual gas constant R, and the thermodynamic temperature T. A gas is assumed to behave as an ideal gas only when the pressure is sufficiently low compared with the critical pressure p_{cr} of the substance, i.e., $p/p_{\mathrm{cr}} \to 0$.

Gas Constant and Avogadro's Law

As a measure of the amount of a given system, the *mole* is defined with the unit symbol mol. The amount of a substance is 1 mol when it contains as many identical elementary entities (i.e., molecules, atoms, or elementary particles) as there are atoms in exactly 12 g of pure carbon-12.

The number of particles of the same type contained in a mole is called Avogadro's number (in German literature the number is sometimes referred to as Loschmidt's number). It has the numerical value

$$N_{\mathrm{A}} = 6.02214076 \times 10^{23}\,/\mathrm{kmol}\,. \tag{3.61}$$

The mass of a mole (N_{A} particles of the same type) is a specific quantity for each substance and is referred to as the molar mass (see Table 3.4 for values), which is given by

$$M = \frac{m}{n} \tag{3.62}$$

(SI unit kg/kmol, m mass in kg, n molar amount in kmol). According to Avogadro (1811), ideal gases con-

Table 3.4 Critical data for some substances, ordered according to critical temperature (after [3.3–5])

tain an equal number of molecules at the same pressure and at the same temperature, occupying equal spaces.

After introducing the molar mass into the equation of state for ideal gases, (3.60), it follows that $pV/(nT) = MR$ has a fixed value for all gases

$$MR = R_u \,, \tag{3.63}$$

where R_u is called the universal gas constant, being a fundamental constant with the numerical value

$$R_u = 8.314472 \pm 1.5 \times 10^{-5}\,(\mathrm{kJ/(kmol\,K)}) \,. \tag{3.64}$$

Incorporating R_u, the equation of state for ideal gases reads

$$pV = nR_uT \,. \tag{3.65}$$

Example 3.6

A gas bottle of volume $V_1 = 200\,\mathrm{L}$ contains hydrogen at $p_1 = 120\,\mathrm{bar}$ and $t_1 = 10\,^\circ\mathrm{C}$. What space is occupied by the hydrogen at $p_2 = 1\,\mathrm{bar}$ and $t_2 = 0\,^\circ\mathrm{C}$, if the hydrogen is assumed to behave as an ideal gas? According to (3.65), $p_1V_1 = nRT_1$ and $p_2V_2 = nRT_2$; thus

$$V_2 = \frac{p_1T_2}{p_2T_1}V_1 = \frac{120\,\mathrm{bar} \times 273.15\,\mathrm{K}}{1\,\mathrm{bar} \times 283.15\,\mathrm{K}}0.2\,\mathrm{m}^3 = 23.15\,\mathrm{m}^3 \,. \tag{3.66}$$

Real Gases

The ideal gas equation of state is valid for real gases and vapors only as a limiting law at sufficiently low pressures. The deviation of the behavior of gaseous water from the ideal gas equation of state is shown in Fig. 3.5, in which $pv/(RT)$ is displayed against t for different pressures. The real gas factor Z, where $Z = pv/(RT)$, is equal to 1 for ideal gases, but deviates from this value for real gases. For air between 0 and 200 °C, and for hydrogen between −15 and 200 °C, the deviations of Z from ideal gas behavior are approximately 1% at a pressure of 20 bar. At atmospheric pressure, the deviations from the ideal gas law are negligible for nearly all gases. For cases where significant deviation is found from ideal gas behavior, different equations of state are established to describe the behavior of real gases. In one of the simplest forms, a series of additive correc-

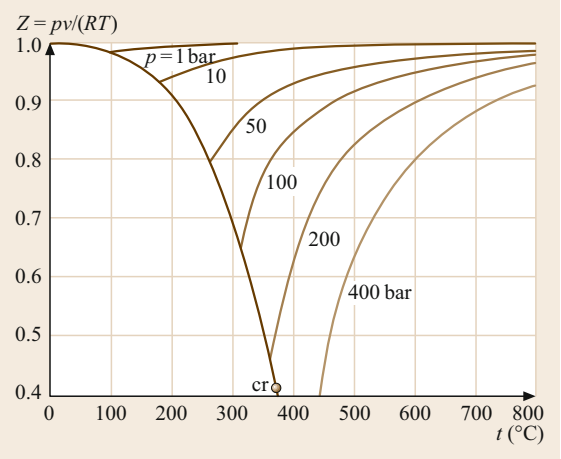

Fig. 3.5 The real gas factor of water vapor

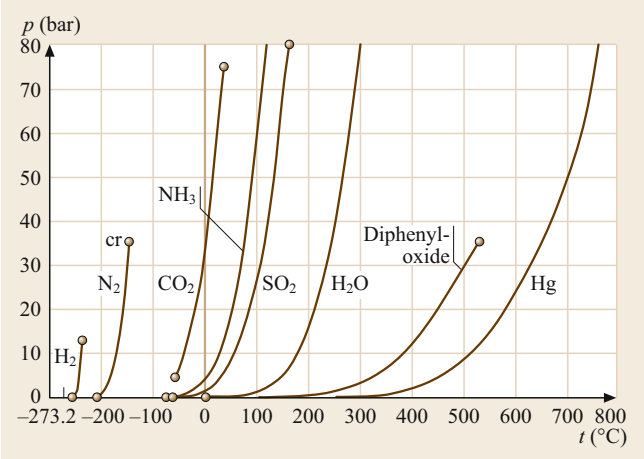

Fig. 3.6 Liquid–vapor saturation curves of some substances

tion terms are used to modify the real gas factor Z from the value of unity for the ideal gas case:

$$Z = \frac{pv}{RT} = 1 + \frac{B(T)}{v} + \frac{C(T)}{v^2} + \frac{D(T)}{v^3} , \qquad (3.67)$$

where B is called the second, C the third, and D the fourth virial coefficients. A compilation of second virial coefficients for many gases is provided by reference charts [3.6, 7]. The virial equation with two or three virial coefficients is only valid at moderate pressures. A balanced compromise between computational effort and achievable accuracy is given by the equation of state of Benedict–Webb–Rubin [3.8] for denser gases, which reads

$$Z = 1 + \frac{B(T)}{v} + \frac{C(T)}{v^2} + \frac{a\alpha}{v^5 RT} + \frac{c}{v^3 RT^2}\left(1 + \frac{\gamma}{v^2}\right)\exp\left(-\frac{\gamma}{v^2}\right) , \qquad (3.68)$$

with

$$B(T) = B_0 - \frac{A_0}{RT} - \frac{C_0}{RT^3} \quad \text{and} \quad C(T) = b - \frac{a}{RT} .$$

The equation contains eight constants A_0, B_0, C_0, a, b, c, α, and γ, which are available for many substances [3.8]. Highly exact equations of state are needed for the working substances water [3.9], air [3.10], and refrigerants [3.11] used in heat engines and refrigerators. The equations for these substances are more elaborate and contain more constants, and computer software is typically needed to utilize them.

Vapors

Vapors are gases which are close to saturation conditions and to condensation. A vapor is called *saturated* if the slightest temperature reduction leads to condensation, and *superheated* if a finite temperature reduction is necessary to obtain condensation. If heat is transferred to a liquid at constant pressure, the temperature of the liquid rises. When a certain temperature is reached, vapor at the same temperature begins to be generated, where the vapor and liquid are in equilibrium. This state is called the saturation state. It is characterized by corresponding values for *saturation temperature* and *saturation pressure*. Their interdependence is described by the *liquid–vapor saturation curve* in Fig. 3.6. It starts at the triple point and ends at the critical point (cr) of a substance. Above the critical state p_{cr}, T_{cr}, vapor and liquid are no longer separated by a clear boundary but merge continuously (Table 3.4). As with the triple point, at which the vapor, liquid, and solid phases of a substance are in equilibrium, every substance also has a characteristic critical point.

The vapor pressure of many substances is well approximated between the triple point and the boiling point at atmospheric pressure by the Antoine equation

$$\ln p = A - \frac{B}{C + T} , \qquad (3.69)$$

in which A, B, and C are the *Antoine coefficients* that vary from substance to substance (Table 3.5). If superheated vapor is compressed at constant temperature by reducing the volume, the pressure increases similar to an ideal gas almost like a hyperbola; e.g., see the 300 °C isotherm in Fig. 3.7. Condensation starts as soon as the saturation pressure is reached, and the volume is reduced without a pressure increase until all vapor is condensed. Any further volume reduction causes a considerable pressure increase. The band of curves in Fig. 3.7 is, as a graphical description of an

equation of state, characteristic for many substances. Connecting the specific volumes of the liquid at saturation temperature before evaporation and of the saturated vapor, v' and v'', results in two curves a and b, called the *saturated liquid line* and the *saturated vapor line*, which meet at the critical point. With the steam quality x, defined as the mass of the saturated vapor m'' related to the total mass of saturated vapor m'' and saturated liquid m', and the specific volumes v' of the saturated liquid and v'' of the saturated vapor, it holds for wet steam that

$$v = xv'' + (1-x)v' \,. \tag{3.70}$$

Lines of constant x are shown in Fig. 3.7.

Example 3.7

Consider 1000 kg of saturated wet steam at 121 bar in a vessel of 2 m^3 volume. How is the total mass distributed between liquid and vapor? An interpolation of the values in the saturated water table (Table 3.6) leads to the specific volumes $v' = 0.001530\,\mathrm{m^3/kg}$ of saturated liquid and $v'' = 0.01410\,\mathrm{m^3/kg}$ of saturated vapor at 121 bar. The average specific volume $v = V/m$ is $v = 2\,\mathrm{m^3}/1000\,\mathrm{kg} = 0.002\,\mathrm{m^3/kg}$. Equation (3.70) gives

$$\begin{aligned} x &= \frac{v - v'}{v'' - v'} \\ &= \frac{0.002 - 0.001530}{0.01410 - 0.001530} \\ &= 0.03739 \\ &= \frac{m''}{m} \,, \end{aligned}$$

and thus

$$\begin{aligned} m'' &= 1000 \times 0.03739\,\mathrm{kg} = 37.39\,\mathrm{kg} \,, \\ m' &= (1000 - 37.39)\,\mathrm{kg} = 962.61\,\mathrm{kg} \,. \end{aligned}$$

It is also possible to display the equation of state as a surface in space with coordinates p, v, and t (Fig. 3.8).

The two-dimensional diagrams in Figs. 3.6 and 3.7 are projections of this three-dimensional surface onto the respective planes.

3.6.2 Caloric Properties of Gases and Vapors

Ideal Gases

The internal energy of ideal gases depends only on temperature, $u = u(T)$, and thus also the enthalpy $h = u + pv = u + RT$ is solely a function of temperature, $h = h(T)$. The derivatives of u and h with respect to

Table 3.6 Saturated water temperature table (after [3.9])

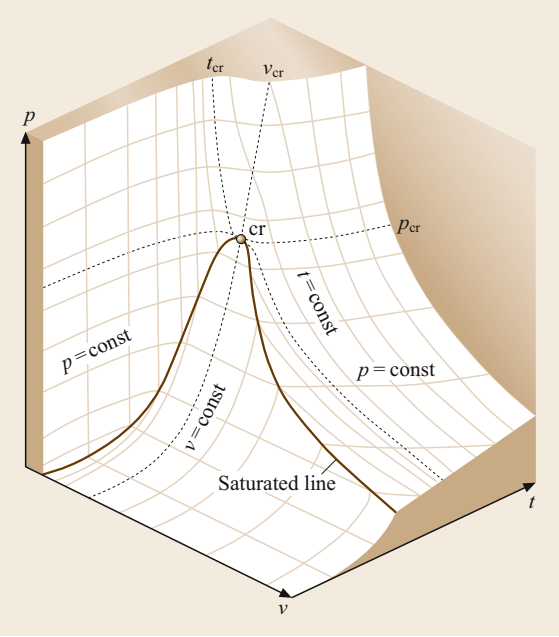

Fig. 3.8 Area of states for water

temperature are called *specific heats*. The specific heats are also functions of temperature (Table 3.7 for values of air).

$$\frac{\mathrm{d}u}{\mathrm{d}T} = c_v \tag{3.71}$$

is the specific heat at constant volume and

$$\frac{\mathrm{d}h}{\mathrm{d}T} = c_p \tag{3.72}$$

is the specific heat at constant pressure. The derivative of $h - u = RT$ is

$$c_p - c_v = R\,. \tag{3.73}$$

The difference between the molar specific heats $\overline{C}_p = Mc_p$ and $\overline{C}_v = Mc_v$ is equal to the universal gas constant

$$\overline{C}_p - \overline{C}_v = R_\mathrm{u}\,.$$

The specific heat ratio $\varkappa = c_p/c_v$ plays an important role in reversible adiabatic changes of state and is hence also called an *adiabatic exponent*.

Fairly accurately, the specific heat ratio is $\varkappa = 1.66$ for monatomic gases, $\varkappa = 1.40$ for diatomic gases, and $\varkappa = 1.30$ for triatomic gases. The average specific heat is the integral mean value defined by

$$\left[c_p\right]_{t_1}^{t_2} = \frac{1}{t_2 - t_1}\int_{t_1}^{t_2} c_p \mathrm{d}t\,,$$

$$\left[c_v\right]_{t_1}^{t_2} = \frac{1}{t_2 - t_1}\int_{t_1}^{t_2} c_v \mathrm{d}t\,. \tag{3.74}$$

From (3.71) and (3.72), it follows for the change of internal energy and enthalpy that

$$u_2 - u_1 = \left[c_v\right]_{t_1}^{t_2}(t_2 - t_1) = \left[c_v\right]_0^{t_2} t_2 - \left[c_v\right]_0^{t_1} t_1 \tag{3.75}$$

and

$$h_2 - h_1 = \left[c_p\right]_{t_1}^{t_2}(t_2 - t_1) = \left[c_p\right]_0^{t_2} t_2 - \left[c_p\right]_0^{t_1} t_1\,. \tag{3.76}$$

Numerical values for $\left[c_p\right]_0^t$ and $\left[c_v\right]_0^t$ can be determined from the average molar specific heats given in Table 3.8.

Taking into account (3.71) and (3.60), the specific entropy arises from (3.29) as

$$\mathrm{d}s = \frac{\mathrm{d}u + p\mathrm{d}v}{T} = c_v\frac{\mathrm{d}T}{T} + R\frac{\mathrm{d}v}{v}\,, \tag{3.77}$$

or after integration with $c_v = \text{const}$ as

$$s_2 - s_1 = c_v \ln\frac{T_2}{T_1} + R\ln\frac{v_2}{v_1}\,. \tag{3.78}$$

The integration of (3.32) with constant c_p leads to the equivalent equation

$$s_2 - s_1 = c_p \ln\frac{T_2}{T_1} + R\ln\frac{p_2}{p_1}\,. \tag{3.79}$$

Real Gases and Vapors

The caloric properties of real gases and vapors are usually determined by measurements, but it is also possible to derive them, apart from an initial value, from equations of state. They are displayed in tables and diagrams

Table 3.7 Specific heats of air at different pressures calculated with the equation of state (after [3.10])

p (bar)		1	25	50	100	150	200	300	
$t = 0\,°C$	$c_p =$	1.0065	1.0579	1.1116	1.2156	1.3022	1.3612	1.4087	kJ/(kg K)
$t = 50\,°C$	$c_p =$	1.0080	1.0395	1.0720	1.1335	1.1866	1.2288	1.2816	kJ/(kg K)
$t = 100\,°C$	$c_p =$	1.0117	1.0330	1.0549	1.0959	1.1316	1.1614	1.2045	kJ/(kg K)

Table 3.8 Mean molar specific heats $[\bar{C}_p]_0^t$ of ideal gases in kJ/(kmol K) between 0 and t °C. The mean molar specific heat $[\bar{C}_v]_0^t$ is determined by subtracting the value of the universal gas constant 8.3143 kJ/(kmol K) from the numerical values given in the table. For the conversion to 1 kg, the numerical values have to be divided by the molar weights given in the last line

t (°C)	$[\bar{C}_p]_0^t$ (kJ/(kmol K))

M (kg/kmol)	2.01588	28.01340	31.999	28.01040	18.01528	44.00980	28.953	17.03052

as $u = u(v,T)$, $h = h(p,T)$, $s = s(p,T)$, $c_v = c_v(v,T)$, and $c_p = c_p(p,T)$. Often, computer software is necessary to analyze equations of state.

For vapors, it holds that the enthalpy h'' of the saturated vapor differs from the enthalpy h' of the saturated boiling liquid at p, T = const by the enthalpy of vaporization

$$\Delta h_v = h'' - h' \,, \tag{3.80}$$

which decreases with increasing temperature and reaches zero at the critical point, where $h'' = h'$. The enthalpy of wet vapor is

$$h = (1-x)h' + xh'' = h' + x\Delta h_v \,. \tag{3.81}$$

Accordingly, the internal energy is

$$u = (1-x)u' + xu'' = u' + x(u'' - u') \tag{3.82}$$

and the entropy

$$s = (1-x)s' + xs'' = \frac{s' + x\Delta h_v}{T} \,, \tag{3.83}$$

because the enthalpy of vaporization and the entropy of vaporization $s'' - s'$ are related through

$$\Delta h_v = T(s'' - s') \,. \tag{3.84}$$

According to the Clausius–Clapeyron relation, the enthalpy of vaporization with gradient $\mathrm{d}p/\mathrm{d}T$ is connected to the liquid–vapor saturation curve $p(T)$ via

$$\Delta h_v = T(v'' - v')\frac{\mathrm{d}p}{\mathrm{d}T} \,, \tag{3.85}$$

with T being the saturation temperature at pressure p. This relationship can be used to calculate the remaining quantity when two out of the three quantities Δh_v, $v'' - v'$, and $\mathrm{d}p/\mathrm{d}T$ are known.

If properties do not have to be calculated continuously or if powerful computers are not available, saturated water tables, in which the results of theoretical and experimental investigations are collected, are used for practical calculations. Such tables are collected in Tables 3.6–3.12 for working fluids important in engineering. Diagrams are advantageous to determine reference values and to display changes of state, e.g., a t–s diagram as shown in Fig. 3.9. Most com-

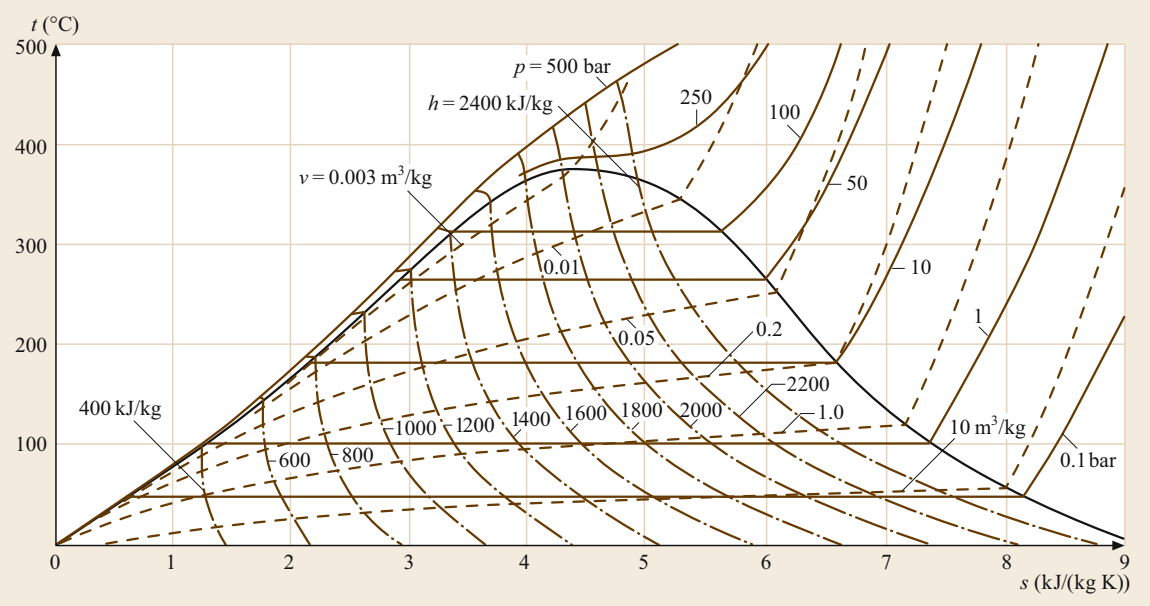

Fig. 3.9 *t–s* diagram of water with curves $p = \text{const}$ (*solid lines*), $v = \text{const}$ (*dashed lines*), and $h = \text{const}$ (*dash-dotted lines*)

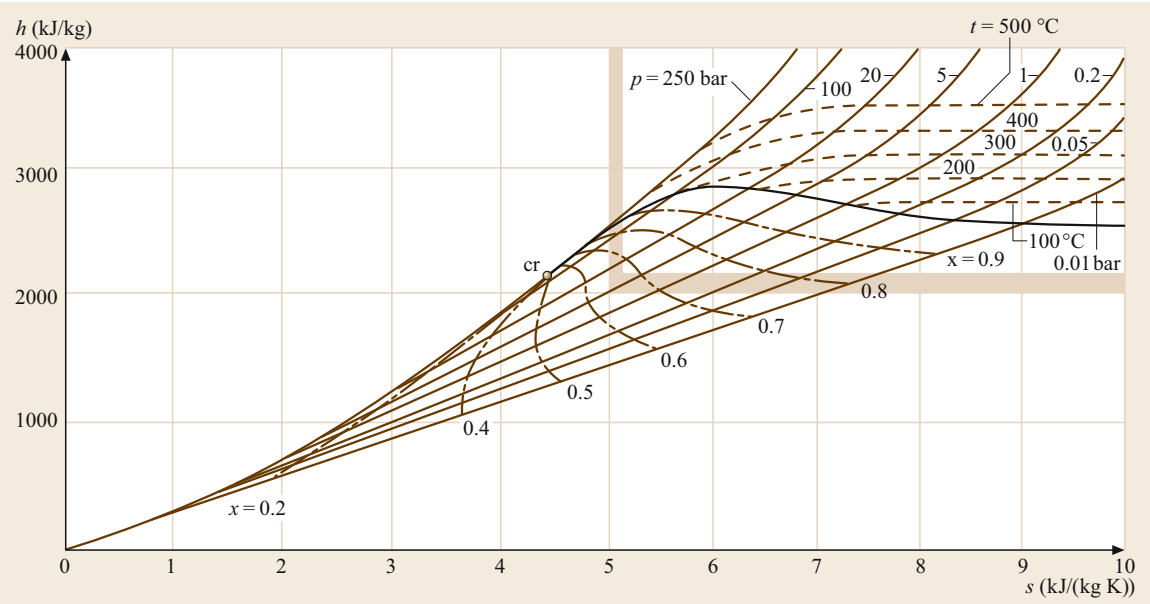

Fig. 3.10 *h–s* diagram of water with curves $p = \text{const}$ (*solid lines*), $t = \text{const}$ (*dashed lines*), and $x = \text{const}$ (*dot* and *dash lines*). The area of interest for the purpose of vapor technology is marked by the *hatched boundary*

monly used in practice are Mollier diagrams, which include the enthalpy as one of the coordinates, see Fig. 3.10.

The specific heat $c_p = (\partial h/\partial T)_p$ of vapor depends, as well as on temperature, also considerably on pressure. In the same way, $c_v = (\partial u/\partial T)_v$ depends, besides on temperature, also on the specific volume. Approaching the saturated vapor line, the c_p of the superheated vapor increases considerably with decreasing temperature and tends toward infinity at the critical point. While $c_p - c_v$ is a constant for ideal gases, this is not true for vapors.

Table 3.9 Properties of water and superheated water vapor (after [3.9])

3.6.3 Incompressible Fluids

An incompressible fluid is a fluid whose specific volume depends on neither temperature nor pressure, such that the equation of state is given by $v = \text{const}$. As a good approximation, liquids and solids can generally be considered as incompressible. The specific heats c_p and c_v do not differ for incompressible fluids, $c_p = c_v = c$. Thus, the caloric equations of state are

$$\mathrm{d}u = c\mathrm{d}T \tag{3.86}$$

and

$$\mathrm{d}h = c\mathrm{d}T + v\mathrm{d}p\,, \tag{3.87}$$

as well as

$$\mathrm{d}s = c\frac{\mathrm{d}T}{T}\,. \tag{3.88}$$

3.6.4 Solid Materials

Thermal Expansion

Similar to liquids, the influence of pressure on volume in equations of state $V = V(p, T)$ for solids is mostly negligibly small. Nearly all solids expand like liquids with increasing temperature and shrink with decreasing temperature. An exception is water, which has its highest density at 4 °C and expands at temperatures both higher and lower than 4 °C. A Taylor-series expansion with respect to temperature of the equation of state, truncated after the linear term, leads to the volumetric expansion with the cubic volumetric expansion coefficient γ_V (SI unit 1/K)

$$V = V_0\left[1 + \gamma_\mathrm{V}(t - t_0)\right]\,.$$

Accordingly, the area expansion is

$$A = A_0\left[1 + \gamma_\mathrm{A}(t - t_0)\right]$$

and the length expansion

$$l = l_0\left[1 + \gamma_\mathrm{L}(t - t_0)\right],$$

where $\gamma_\mathrm{A} = (2/3)\gamma_\mathrm{V}$ and $\gamma_\mathrm{L} = (1/3)\gamma_\mathrm{V}$. Average values for γ_L in the temperature interval between 0 °C and t °C can be derived for some solids from the values in Table 3.13 by dividing the given length change $(l - l_0)/l_0$ by the temperature interval $t - 0\,°C$.

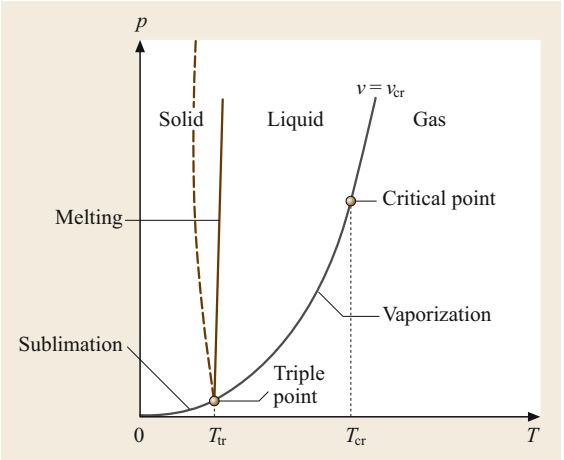

Fig. 3.11 p–T diagram with the three boundary lines of the phases. (The gradient of the melting line of water is negative, *dashed line*)

Melting and Sublimation Curves

Within certain limits, each pressure of a liquid corresponds to a temperature at which the liquid is in equilibrium with its solid. This relationship $p(T)$ is determined by the melting curve (Fig. 3.11), whereas the sublimation curve displays the equilibrium between gas and solid. Figure 3.11 includes additionally the liquid–vapor saturation curve. All three curves meet at the triple point, at which the solid, the liquid, and the gaseous phase of a substance are in equilibrium with each other. The triple point of water is 273.16 K by definition, which corresponds to a pressure at the triple point of 611.657 Pa.

Caloric Properties

During the freezing of a liquid, the latent heat of fusion Δh_f is released (Table 3.14). At the same time, the liquid entropy is reduced by $\Delta s_\mathrm{f} = \Delta h_\mathrm{f}/T_\mathrm{f}$, with T_f being the melting or freezing temperature. According to the Dulong–Petit law, the molar specific heat divided by the number of atoms in the molecule is, above ambient temperature, about 25.9 kJ/(kmol K). If absolute zero is approached, this approximate rule is no longer valid. Therefore, for all solids, the molar specific heat at constant volume is

$$\overline{C} = a\left(\frac{T}{\Theta}\right)^3\,, \quad \text{for} \quad \frac{T}{\Theta} < 0.1$$

with $a = 4782.5\,\mathrm{J/(mol\,K)}$ and where Θ is the Debye temperature (Table 3.15).

3.6.5 Mixing Temperature and Measurement of Specific Heats

If several substances with different masses m_i, temperatures t_i, and specific heats c_{pi} ($i = 1, 2, \ldots$) are mixed at constant pressure without external heat supply, a mixing temperature t_m arises after a sufficient period of time. It is

$$t_\mathrm{m} = \frac{\sum m_i c_{pi} t_i}{\sum m_i c_{pi}}$$

with c_{pi} being the mean specific heats between 0 °C and t °C. It is possible to calculate an unknown specific heat from the measured temperature t_m, if all the other specific heats are known.

Example 3.8

A mass of $m_\mathrm{a} = 0.2\,\mathrm{kg}$ of aluminum at $t_\mathrm{a} = 100\,^\circ\mathrm{C}$ is inserted into a thermally perfectly isolated calorimeter, which is filled with 0.8 kg water ($c_p = 4.186\,\mathrm{kJ/(kg\,K)}$) at 15 °C and which consists of 0.25 kg of silver ($c_{ps} = 0.234\,\mathrm{kJ/(kg\,K)}$). After reaching equilibrium, a mixing temperature of 19.24 °C is measured. What is the specific heat of aluminum? We proceed thus:

$$t_\mathrm{m} = \frac{(mc_p + m_\mathrm{s}c_{ps})t + m_\mathrm{a}c_{pa}t_\mathrm{a}}{mc_p + m_\mathrm{s}c_{ps} + m_\mathrm{a}c_{pa}} ,$$

which resolves to

$$c_{pa} = \frac{(mc_p + m_\mathrm{s}c_{ps})(t - t_\mathrm{m})}{m_\mathrm{a}(t_\mathrm{m} - t_\mathrm{a})} ,$$

$$c_{pa} = \left(0.8\,\mathrm{kg} \times 4.186 \frac{\mathrm{kJ}}{\mathrm{kg\,K}} + 0.25\,\mathrm{kg} \times 0.234 \frac{\mathrm{kJ}}{\mathrm{kg\,K}}\right) \times \frac{15\,^\circ\mathrm{C} - 19.24\,^\circ\mathrm{C}}{0.2\,\mathrm{kg}(19.24\,^\circ\mathrm{C} - 100\,^\circ\mathrm{C})} ,$$

$$c_{pa} = 0.894\,\mathrm{kJ/(kg\,K)} .$$

3.7 Changes of State of Gases and Vapors

3.7.1 Changes of State of Gases and Vapors in Closed Systems

A closed thermodynamic system has a fixed mass Δm. The following changes of state (constant volume, constant pressure, and constant temperature) are idealized limiting cases of real changes of state. The gas volume remains unchanged during changes of state at *constant volume* or *isochoric* changes of state, e.g., when a gas volume is in a container with solid, rigid walls. No work is done, and the supplied heat transfer causes only a change of internal energy. During a change of state at *constant pressure* or an *isobaric* change of state, the gas volume has to increase if heat transfer is supplied. The supplied heat transfer increases the enthalpy during reversible changes of state. Changes of state at constant temperature are also called isothermal changes of state. Apart from a very few exceptions, heat has to be transferred to the gas during expansion and transferred from the gas during compression in order for the temperature to remain constant. For an ideal gas at constant temperature, the internal energy does not change, as $U(T) = \mathrm{const}$, thus the supplied heat transfer is equal to the work done by the system. The isotherm of an ideal gas ($pV = mRT = \mathrm{const}$) is a hyperbola in the p–V diagram.

During adiabatic changes of state, there is no heat exchange between the system and its environment. This case is approximately realized in compressors and expansion machines, because there the compression or expansion takes place in a very short period of time such that little heat transfer is exchanged with the environment during the change of state. According to the second law (see Sect. 3.4.3) the entire entropy change is caused by internal irreversibilities of the system, $\dot{S} = \dot{S}_\mathrm{gen}$. A reversible adiabatic process proceeds at constant entropy $\dot{S} = 0$, where such a change of state is called isentropic. Thus, a reversible adiabatic process is at the same time also an isentropic process. However, an isentropic process is not necessarily also an adiabatic

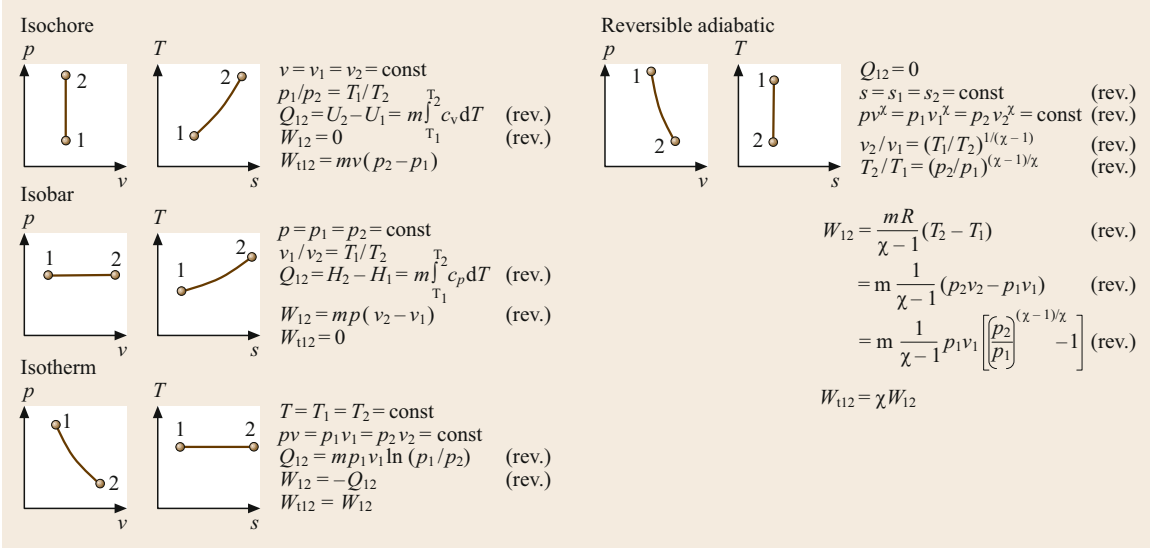

Fig. 3.12 Changes of state of ideal gases. The (rev.) denotes that the change of state is reversible

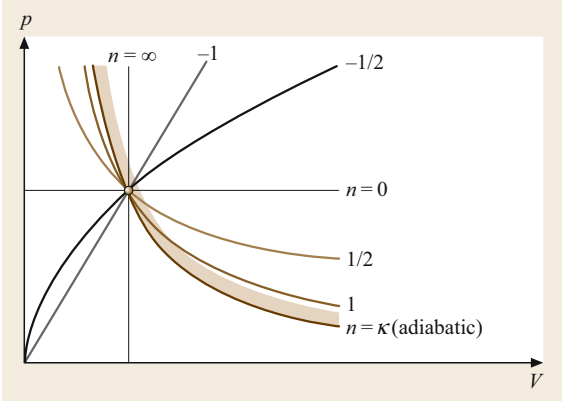

Fig. 3.13 Polytropic processes with different exponents

process, because from $\dot{S} = \dot{S}_Q + \dot{S}_{gen} = 0$ it does not always follow that $\dot{S}_Q = 0$.

Figure 3.12 shows the different changes of state in p–V and T–S diagrams. Additionally, the most important relationships for the properties of ideal gases are given.

An isothermal change of state requires perfect heat exchange, whereas no heat exchange at all with the environment must take place during an adiabatic change of state. Both cannot be achieved completely in reality. Therefore, a *polytropic* change of state is introduced via

$$pV^n = \text{const}\,, \tag{3.89}$$

where in practice n is usually between 1 and $\varkappa$. Isochore, isobar, isotherm, and reversible adiabate are special cases of a polytrope with the following exponents (Fig. 3.13): isochore ($n = \infty$), isotherm ($n = 1$), and reversible adiabate ($n = \varkappa$). It holds further that

$$\frac{v_2}{v_1} = \left(\frac{p_1}{p_2}\right)^{1/n} = \left(\frac{T_1}{T_2}\right)^{1/(n-1)}\,,$$

$$\begin{aligned} W_{12} &= \frac{mR(T_2 - T_1)}{n-1} \\ &= \frac{p_2V_2 - p_1V_1}{n-1} \\ &= \frac{p_1V_1\left[\left(\frac{p_2}{p_1}\right)^{(n-1)/n} - 1\right]}{n-1} \end{aligned} \tag{3.90}$$

and

$$W_{t12} = nW_{12}\,. \tag{3.91}$$

The heat exchanged is

$$Q_{12} = mc_v(n - \varkappa)\frac{T_2 - T_1}{n-1}\,. \tag{3.92}$$

Example 3.9

A compressed air system should deliver 1000 m_n^3 compressed air of 15 bar/h (note: 1 m_n^3 = 1 standard cubic meter for a gas volume at 0 °C and 1.01325 bar). The air inlet is at a pressure of $p_1 = 1$ bar and a temperature of $t_1 = 20$ °C. The adiabatic exponent of air is $\varkappa = 1.4$. How much power is required, if the compression is polytropic with $n = 1.3$? What heat transfer rate has to be exchanged for this process?

The inlet air volume flow is, as given in the requirements, 1000 m³ at 0 °C and 1.01325 bar,

$$\begin{aligned}\dot{V}_1 &= \frac{p_0 T_1}{p_1 T_0}\dot{V}_0 \\ &= \frac{1.01325 \times 293.15}{1 \times 273.15} 1000 \frac{\mathrm{m}^3}{\mathrm{h}} \\ &= 1087.44 \frac{\mathrm{m}^3}{\mathrm{h}} .\end{aligned}$$

For polytropic changes of state, (3.91) and (3.90) yield

$$\begin{aligned}P = \dot{W}_\mathrm{t} &= \frac{n p_1 \dot{V}_1}{n-1}\left[\left(\frac{p_2}{p_1}\right)^{\frac{n-1}{n}} - 1\right] \\ &= \frac{1.3 \times 10^5 \frac{\mathrm{N}}{\mathrm{m}^2} 1087.44 \frac{\mathrm{m}^3}{\mathrm{h}}}{1.3-1}\left(15^{\frac{1.3-1}{1.3}} - 1\right) \\ &= 113.6\,\mathrm{kW} .\end{aligned}$$

According to (3.91) and (3.92),

$$\frac{Q_{12}}{W_{\mathrm{t}12}} = \frac{\dot{Q}}{P} = c_v \frac{n-\varkappa}{nR}$$

or, since $R = c_p - c_v$ and $\varkappa = c_p/c_v$,

$$\frac{\dot{Q}}{P} = \frac{1}{n}\frac{n-\varkappa}{\varkappa-1} .$$

Thus,

$$\dot{Q} = \frac{1}{1.3}\frac{1.3-1.4}{1.4-1} 113.6\,\mathrm{kW} = -21.85\,\mathrm{kW} .$$

3.7.2 Changes of State of Flowing Gases and Vapors

To describe the flow of a fluid mass Δm, in addition to the thermodynamic properties, the size and direction of the velocity everywhere in the field are also required. The following discussion is limited to steady flows in channels with constant, diverging, or converging cross sections.

In addition to the first and second laws, the conservation of mass law holds

$$\dot{m} = A w \varrho = \text{const} . \tag{3.93}$$

For a flow that does no work on the environment, the first law, (3.21), reduces to

$$\begin{aligned}&\Delta m(h_2 - h_1) + \Delta m\left(\frac{w_2^2}{2} - \frac{w_1^2}{2}\right) + \Delta m g(z_2 - z_1) \\ &= Q_{12} ,\end{aligned} \tag{3.94}$$

regardless of whether the flow is reversible or irreversible. Neglecting changes in potential energy, it holds that, for an adiabatic flow,

$$h_2 - h_1 + \frac{w_2^2}{2} - \frac{w_1^2}{2} = 0 . \tag{3.95}$$

Thus, the increase in kinetic energy is equal to the decrease in enthalpy of the fluid. For an adiabatic throttle process, it follows from (3.93), provided A and $\varrho = \text{const}$, that $w = \text{const}$ and thus from (3.95) that $h_1 = h_2 = \text{const}$. The pressure reduction in an adiabatic throttle process is accompanied by an entropy increase, since the process is irreversible. According to (3.32), the enthalpy change in a reversible adiabatic flow is caused by a change in pressure, $\mathrm{d}h = v\,\mathrm{d}p$.

Flow of Ideal Gases

Applying (3.95) to an ideal gas exiting a vessel (Fig. 3.14), in which the gas in the vessel possesses the constant state p_0, v_0, T_0 with $w_0 = 0$, and where $h_\mathrm{e} - h_0 = c_p(T_\mathrm{e} - T_0)$, $w_0 = 0$, leads to

$$\begin{aligned}\frac{w_\mathrm{e}^2}{2} &= c_p(T_0 - T_\mathrm{e}) \\ &= c_p T_0\left(1 - \frac{T_\mathrm{e}}{T_0}\right) .\end{aligned}$$

For a reversible adiabatic change of state, according to (3.90), $T_\mathrm{e}/T_0 = (p_\mathrm{e}/p_0)^{(\varkappa-1)/\varkappa}$. Additionally, it holds that $T_0 = p_0 v_0/R$ according to (3.60) and $c_p/R = \varkappa/(\varkappa-1)$ according to (3.73). Thus, the exit velocity is given by

$$w_\mathrm{e} = \sqrt{2\frac{\varkappa}{\varkappa-1} p_0 v_0\left[1 - \left(\frac{p_\mathrm{e}}{p_0}\right)^{\frac{\varkappa-1}{\varkappa}}\right]} . \tag{3.96}$$

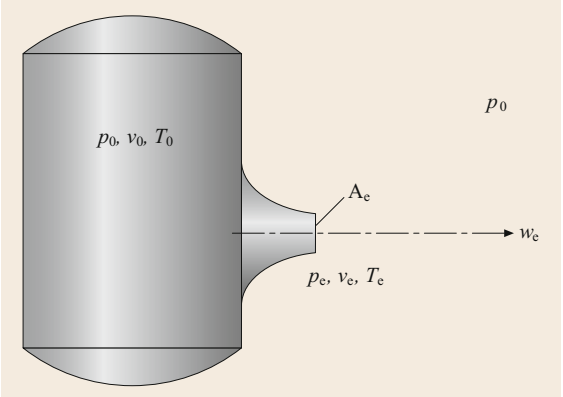

Fig. 3.14 Flow out of a pressure vessel

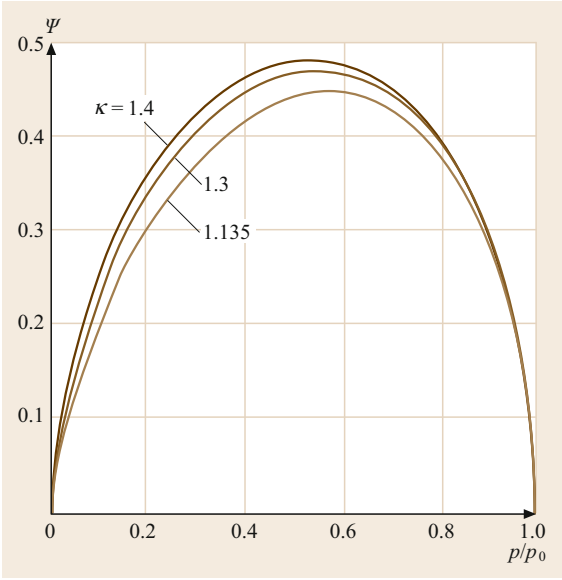

Fig. 3.15 Outlet function Ψ

Taking into account $p_0 v_0^{\varkappa} = p_e v_e^{\varkappa}$, the out-flowing mass $\dot{m} = A_e w_e / v_e$ is

$$\dot{m} = A\Psi \sqrt{\frac{2p_0}{v_0}} \tag{3.97}$$

with the outlet function

$$\Psi = \sqrt{\frac{\varkappa}{\varkappa - 1}} \sqrt{\left(\frac{p}{p_0}\right)^{\frac{2}{\varkappa}} - \left(\frac{p}{p_0}\right)^{\frac{\varkappa+1}{\varkappa}}} \,. \tag{3.98}$$

The result is a function of the adiabatic exponent $\varkappa$ and of the pressure ratio p/p_0 (Fig. 3.15) and has a maximum Ψ_{max}, which can be determined from evaluating $d\Psi/d(p/p_0) = 0$. This maximum corresponds to a specific pressure ratio that is called the *Laval pressure ratio*

$$\frac{p_s}{p_0} = \left(\frac{2}{\varkappa + 1}\right)^{\frac{\varkappa}{\varkappa - 1}} \,. \tag{3.99}$$

At this pressure ratio

$$\Psi_{max} = \left(\frac{2}{\varkappa + 1}\right)^{\frac{1}{\varkappa - 1}} \sqrt{\frac{\varkappa}{\varkappa + 1}} \,. \tag{3.100}$$

Corresponding to this pressure ratio, according to (3.96) with $p_e/p_0 = p_s/p_0$ and a velocity $w_e = w_s$, is the relation

$$w_s = \sqrt{2\frac{\varkappa}{\varkappa + 1} p_0 v_0} = \sqrt{\varkappa p_s v_s} = \sqrt{\varkappa R T_s} \,. \tag{3.101}$$

This is equal to the sonic velocity in the state p_s, v_s. Generally, the sonic velocity is the velocity at which pressure and density fluctuations are transmitted. For reversible adiabatic changes of state, it is given by

$$w_s = \sqrt{\left(\frac{\partial p}{\partial \varrho}\right)_s} \,.$$

Thus, for ideal gases, it takes on the value $w_s = \sqrt{\varkappa R T}$, where the sonic velocity is a property.

Example 3.10

A steam boiler produces 10 t of saturated vapor at $p_0 = 15$ bar. The vapor may be treated as an ideal gas ($\varkappa = 1.3$). How large must the cross section of the safety relief valve be in order to be able to discharge the entire vapor mass flow?

Since the out-flowing mass $\dot{m}$ is constant in every cross section, it follows from (3.97) that $A\Psi =$ const as well. As the discharge flow area is decreased, A decreases, and Ψ increases, reaching at most the value Ψ_{max}. Then the back pressure is less than or equal to the Laval pressure. In the present case the back pressure of the atmosphere, $p = 1$ bar, is less than the Laval pressure, which is calculated with (3.99) to be 8.186 bar. With this result, the required cross section follows from (3.97), if $\Psi = \Psi_{max} = 0.472$ according to (3.100) is inserted. With $\dot{m} = 10 \times 10^3 \times (1/3600)\,\mathrm{kg/s} = 2.7778\,\mathrm{kg/s}$ and $v_0 = v'' = 0.1317\,\mathrm{m^3/kg}$ (according to Table 3.9 at $p_0 = 15$ bar), it follows from (3.97) that $A = 12.33\,\mathrm{cm^2}$. Because of the jet's contraction, where the size depends on the design of the valve, an increase should be added.

Jet and Diffusion Flow

As shown in Fig. 3.16, for a given adiabatic exponent $\varkappa$, a certain pressure ratio p/p_0 corresponds to a spe-

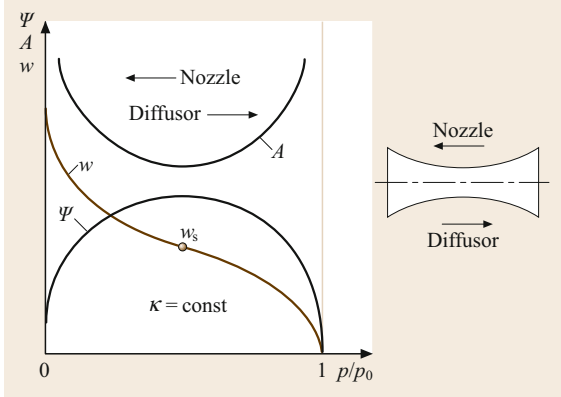

Fig. 3.16 Nozzle and diffusor flow

cific value of the outlet function Ψ. Since the mass flow $\dot{m}$ is constant in each cross section, it follows from (3.97) that also $A\Psi = \text{const}$. Thus, it is possible to assign to each pressure ratio a certain cross section A; see Fig. 3.16. Two cases have to be distinguished:

a) The pressure decreases in the flow direction. The curves Ψ, A, and w in Fig. 3.16 are passed through from right to left. At first the cross section A decreases, then it increases again. The velocity increases and goes from subsonic to supersonic. The kinetic energy of the flow increases. Such an apparatus is called a nozzle. In a nozzle that operates only in the subsonic regime the cross section decreases continuously, whereas it increases in the supersonic regime. In a nozzle narrowing in the flow direction the pressure at the outlet cross section cannot decrease below the Laval pressure, even if the outside pressure is arbitrarily small. This follows from $A\Psi = \text{const}$. Since A decreases in the flow direction, Ψ can only increase, reaching at most the value $\Psi_{\max}$ to which the Laval pressure ratio corresponds.
If the pressure at the outlet cross section of a nozzle is reduced below the pressure value corresponding to the outlet cross section, the jet expands after leaving the nozzle. If the back pressure is increased above the correct value, the pressure increase moves upstream, where in this case the gas exits with subsonic velocity. If the gas exits with sonic, or in a diverging nozzle with supersonic velocity, a shock occurs at the nozzle outlet and the pressure increases to the pressure of the environment.
b) The pressure increases in the flow direction. The curves Ψ, A, and w in Fig. 3.16 are passed through from left to right. At first the cross section decreases, then increases again. The velocity decreases from supersonic to subsonic, and the kinetic energy decreases while the pressure increases. Such an apparatus is called a diffuser. In a diffuser that works only in the subsonic regime the cross section increases continuously, whereas it decreases in the supersonic regime.

3.8 Thermodynamic Processes

3.8.1 Combustion Processes

Heat transfer for technical processes is still mostly obtained through combustion. Combustion is a chemical reaction during which a substance, e.g., carbon, hydrogen, or hydrocarbons, is oxidized, which is strongly exothermic; i.e., a large quantity of heat is released. Fuels can be solid, liquid, or gaseous (Tab. 3.16). The required oxygen is mostly provided by atmospheric air. To start a combustion process, the fuel must be brought above its ignition temperature, which, in turn, varies according to the type of fuel being used. The main components of all important technical fuels are carbon (C) and hydrogen (H). In addition, oxygen (O), and with the exception of natural gas a certain amount of sulfur, are also present. Sulfur reacts during a combustion process to produce the unwanted compound sulfur dioxide SO_2.

Reaction Equations

The elements H, C, and S, which are contained in fuels as mentioned above, are burned to CO_2, H_2O, and SO_2, if complete combustion takes place. The reaction equations determine the amount of oxygen required and the resulting amount of each product in the exhaust gas. For combustion of carbon C, it holds that

$$\begin{aligned} \mathrm{C} + \mathrm{O_2} &= \mathrm{CO_2}\,, \\ 1\,\mathrm{kmol\,C} + 1\,\mathrm{kmol\,O_2} &= 1\,\mathrm{kmol\,CO_2}\,, \\ 12\,\mathrm{kg\,C} + 32\,\mathrm{kg\,O_2} &= 44\,\mathrm{kg\,CO_2}\,. \end{aligned}$$

From this, it follows that the minimum oxygen demand for complete combustion is

$$o_{\min} = \frac{1}{12}\,\frac{\mathrm{kmol\,O_2}}{\mathrm{kg\,C}}$$

Table 3.16 Composition and calorific values of solid fuels

Fuel	Ash (mass%)	Water (mass%)	Composition of ash-free dry substance (mass%)					Gross calorific value (MJ/kg)	Net calorific value (MJ/kg)
			C	H	S	O	N		
Wood, air-dried	< 0.5	10–20	50	6	0.0	43.9	0.1	15.91–18.0	14.65–16.75
Peat, air-dried	< 15	15–35	50–60	4.5–6	0.3–2.5	30–40	1–4	13.82–16.33	11.72–15.07
Raw soft coal	2–8	50–60	65–75	5–8	0.5–4	15–26	0.5–2	10.47–12.98	8.37–11.30
Soft coal briquette	3–10	12–18	65–75	5–8	0.5–4	15–26	0.5–2	20.93–21.35	19.68–20.10
Hard coal	3–12	0–10	80–90	4–9	0.7–1.4	4–12	0.6–2	29.31–35.17	27.31–34.12
Anthracite	2–6	0–5	90–94	3–4	0.7–1	0.5–4	1–1.5	33.49–34.75	32.66–33.91

or

$$O_{\min} = 1\,\frac{\text{kmol O}_2}{\text{kmol C}}\,.$$

The minimum air demand for complete combustion is called the *theoretical air* and results from the oxygen fraction of 21 mol% in air

$$l_{\min} = \left(\frac{o_{\min}}{0.21}\right)\,\text{kmol air/kg C}$$

or

$$L_{\min} = \left(\frac{O_{\min}}{0.21}\right)\,\text{kmol air/kmol C}\,.$$

The amount of CO_2 in the exhaust gas is $(1/12)$ kmol/kg C. Similarly, the reaction equations for the combustion of hydrogen H_2 and sulfur S are

$$\begin{aligned}
\text{H}_2 + \tfrac{1}{2}\,\text{O}_2 &= \text{H}_2\text{O}\,,\\
1\,\text{kmol H}_2 + \tfrac{1}{2}\,\text{kmol O}_2 &= 1\,\text{kmol H}_2\text{O}\,,\\
2\,\text{kg H}_2 + 16\,\text{kg O}_2 &= 18\,\text{kg H}_2\text{O}\,,
\end{aligned}$$

$$\begin{aligned}
\text{S} + \text{O}_2 &= \text{SO}_2\,,\\
1\,\text{kmol S} + 1\,\text{kmol O}_2 &= 1\,\text{kmol SO}_2\,,\\
32\,\text{kg S} + 32\,\text{kg O}_2 &= 64\,\text{kg SO}_2\,.
\end{aligned}$$

Denoting the carbon, hydrogen, sulfur, and oxygen fractions by c, h, s, and o in kg per kg fuel, according to the above calculations, the minimum oxygen demand becomes

$$o_{\min} = \left(\frac{c}{12} + \frac{h}{4} + \frac{s}{32} - \frac{o}{32}\right)\,\text{kmol/kg}\,, \qquad (3.102)$$

or for short

$$o_{\min}\,\frac{1}{12}c\sigma\,\text{kmol/kg}\,, \qquad (3.103)$$

where σ is a characteristic of the fuel (O_2 demand in kmol related to the kmol C in the fuel). The actual air demand (related to 1 kg fuel) is

$$l = \lambda l_{\min} = \left(\frac{\lambda o_{\min}}{0.21}\right)\,\text{kmol air/kg}\,, \qquad (3.104)$$

where λ is the excess air number. In addition to the combustion products CO_2, H_2O, and SO_2, the exhaust gases also ordinarily contain water with a content of $w/18$ (SI units of kmol per kg fuel), and the supplied combustion air l less the spent oxygen $o_{\min}$. The supplied combustion air is therefore assumed to be dry, or it is assumed that the water vapor content is negligibly small. The corresponding exhaust amounts, related to 1 kg of fuel, are given by

$$\begin{aligned}
n_{\text{CO}_2} &= \frac{c}{12}\,,\\
n_{\text{H}_2\text{O}} &= \frac{h}{2} + \frac{w}{18}\,,\\
n_{\text{SO}_2} &= \frac{s}{32}\,,\\
n_{\text{O}_2} &= (\lambda - 1)o_{\min}\,,\\
n_{\text{N}_2} &= 0.791\,.
\end{aligned}$$

The sum is the total exhaust amount

$$n_{\text{exh}} = \left[\frac{c}{12} + \frac{h}{2} + \frac{w}{18} + \frac{s}{32} + (\lambda - 1)o_{\min} + 0.791\right]\,\text{kmol/kg}.$$

This can be simplified by using (3.102) and (3.104) to yield

$$n_{\text{exh}} = \left[l + \frac{1}{12}\left(3h + \frac{3}{8}o + \frac{2}{3}w\right)\right]\,\text{kmol/kg}\,. \qquad (3.105)$$

Example 3.11

Consider 500 kg coal with composition $c = 0.78$, $h = 0.05$, $o = 0.08$, $s = 0.01$, and $w = 0.02$ and ash content $a = 0.06$ which is completely burned per hour in a furnace with excess air number $\lambda = 1.4$. How much air is necessary, how much exhaust arises, and what is its composition?

The minimum oxygen demand is determined according to (3.102)

$$\begin{aligned}
o_{\min} &= \left(\frac{0.78}{12} + \frac{0.05}{4} + \frac{0.01}{32} - \frac{0.08}{32}\right)\,\text{kmol/kg}\\
&= 0.0753\,\text{kmol/kg}\,.
\end{aligned}$$

The minimum air demand is

$$l_{\min} = \frac{o_{\min}}{0.21} = 0.3586\,\text{kmol/kg}\,.$$

The amount of air that has to be supplied is

$$l = \lambda l_{\min} = 1.4 \times 0.3586 = 0.502\,\text{kmol/kg}\,.$$

Thus $0.502\,\text{kmol/kg} \times 500\,\text{kg/h} = 251\,\text{kmol/h}$. With the molar mass of air $M = 28.953\,\text{kg/kmol}$, the air demand becomes $0.502 \times 28.953\,\text{kg/kg} = 14.54\,\text{kg/kg}$.

Thus, $14.54\,\mathrm{kg/kg} \times 500\,\mathrm{kg/h} = 7270\,\mathrm{kg/h}$. The exhaust amount is determined according to (3.105)

$$n_{\mathrm{exh}} = \left(0.502 + \frac{1}{12}\left(3 \times 0.05 + \frac{3}{8} \times 0.08 + \frac{2}{3} \times 0.02\right)\right) \mathrm{kmol/kg} = 0.518\,\mathrm{kmol/kg}\,.$$

Thus, $0.581\,\mathrm{kmol/kg} \times 500\,\mathrm{kg/h} = 259\,\mathrm{kmol/h}$ with $0.065\,\mathrm{kmol\,CO_2/kg}$, $0.0261\,\mathrm{kmol\,H_2O/kg}$, $0.0003\,\mathrm{kmol\,SO_2/kg}$, $0.3966\,\mathrm{kmol\,N_2/kg}$ and $0.0301\,\mathrm{kmol\,O_2/kg}$.

Net Calorific Value and Gross Calorific Value

The net calorific value is the energy released during combustion, if the exhaust gases are cooled down to the temperature at which the fuel and air are supplied. Water is included in the exhaust gases as vapor. If the water vapor is condensed, the released heat is called the gross calorific value. Net and gross calorific values are specified, according to DIN 51900, for combustion at atmospheric pressure, if all involved substances are at a temperature of 25 °C before and after combustion. Net and gross calorific values (Tables 3.17–3.19) are independent of the amount of excess air and are only a characteristic of the fuel. The gross calorific value Δh_{gcv} exceeds the net calorific value Δh_{ncv} by the enthalpy of vaporization Δh_{v} of the water included in the exhaust gas

$$\Delta h_{\mathrm{gcv}} = \Delta h_{\mathrm{ncv}} + (8.937h + w)\,\Delta h_{\mathrm{v}}\,.$$

Because the water leaves technical furnaces mostly as vapor, often only the net calorific value can be utilized. The net calorific value of heating oil can be expressed quite well, as experience shows [3.17], by the equation

$$\Delta h_{\mathrm{ncv}} = (54.04 - 13.29\varrho - 29.31s)\,\mathrm{MJ/kg}\,, \tag{3.106}$$

where the density ϱ of the heating oil in $\mathrm{kg/dm^3}$ is at 15 °C and the sulfur content s is in kg/kg.

Table 3.17 Net calorific values of the simplest fuels at 25 °C and 1.01325 bar

	C	CO	H_2 (gross calorific value)	H_2 (net calorific value)	S

[a] According to DIN 51850: gross and net calorific values of gaseous fuels, April 1980

Example 3.12

What is the net calorific value of a light heating oil with a density of $\varrho = 0.86\,\mathrm{kg/dm^3}$ and a sulfur content of $s = 0.8$ mass%? According to (3.106)

$$\begin{aligned}\Delta h_{\mathrm{ncv}} &= (54.04 - 13.29 \times 0.86 \\ &\quad - 29.31 \times 0.8 \times 10^{-2})\,\mathrm{MJ/kg} \\ &= 42.38\,\mathrm{MJ/kg}\,.\end{aligned}$$

Combustion Temperature

The theoretical combustion temperature is the temperature of the exhaust gas at complete isobar–adiabatic combustion if no dissociation takes place. The heat released during combustion increases the internal energy and thus the temperature of the gas, which provides the basis for doing flow work. The theoretical combustion temperature is calculated under the condition that the enthalpy of all substances transferred to the combustion chamber must be equal to the enthalpy of the discharged exhaust gas.

$$\begin{aligned}&\Delta h_{\mathrm{ncv}}\,[c_{\mathrm{fuel}}]_{25\,^\circ\mathrm{C}}^{t_{\mathrm{fuel}}}\,(t_{\mathrm{fuel}} - 25\,^\circ\mathrm{C}) \\ &\quad + l\,\left[\overline{C}_{p\,\mathrm{air}}\right]_{25\,^\circ\mathrm{C}}^{t_{\mathrm{air}}}\,(t_{\mathrm{air}} - 25\,^\circ\mathrm{C}) \\ &= n_{\mathrm{exh}}\,\left[\overline{C}_{p\,\mathrm{exh}}\right]_{25\,^\circ\mathrm{C}}^{t}\,(t - 25\,^\circ\mathrm{C})\,. \qquad (3.107)\end{aligned}$$

This equation includes the temperatures t_{fuel} of the fuel and t_{air} of the air, the theoretical combustion temperature t, the mean specific heat $[c]_{25\,^\circ\mathrm{C}}^{t_{\mathrm{fuel}}}$ of the fuel, and the mean specific heats $\left[\overline{C}_{p\,\mathrm{air}}\right]_{25\,^\circ\mathrm{C}}^{t_{\mathrm{air}}}$ of the air and $\left[\overline{C}_{p\,\mathrm{exh}}\right]_{25\,^\circ\mathrm{C}}^{t}$ of the exhaust gas. The latter consists of the mean molar specific heats of the single components

$$\begin{aligned}&n_{\mathrm{exh}}\,\left[\overline{C}_{p\,\mathrm{exh}}\right]_{25\,^\circ\mathrm{C}}^{t} \\ &= \frac{c}{12}\,\left[\overline{C}_{p\mathrm{CO_2}}\right]_{25\,^\circ\mathrm{C}}^{t} + \left(\frac{h}{2} + \frac{w}{18}\right)\,\left[\overline{C}_{p\mathrm{H_2O}}\right]_{25\,^\circ\mathrm{C}}^{t} \\ &\quad + \frac{s}{32}\,\left[\overline{C}_{p\mathrm{SO_2}}\right]_{25\,^\circ\mathrm{C}}^{t} + (\lambda - 1)\,o_{\mathrm{min}}\,\left[\overline{C}_{p\mathrm{O_2}}\right]_{25\,^\circ\mathrm{C}}^{t} \\ &\quad + 0.79 l\,\left[\overline{C}_{p\mathrm{N_2}}\right]_{25\,^\circ\mathrm{C}}^{t}\,. \qquad (3.108)\end{aligned}$$

The theoretical combustion temperature must be determined iteratively from (3.107) and (3.108). The actual combustion temperature is, even with complete combustion of the fuel, lower than the theoretical combustion temperature due to heat transfer to the environment, mainly by radiation. Another effect that lowers the combustion temperature is the break-up of molecules (dissociation) starting above 1500 °C and the considerable dissociation above 2000 °C. The dissociation heat is released again when the temperature decreases below the dissociation temperature.

3.8.2 Internal Combustion Cycles

In internal combustion cycles, the combustion gas serves as a working fluid. It does not operate through a closed process but is discharged as exhaust gas to the environment after performing work in a turbine or a piston engine. Open, gas turbine cycles and internal combustion engines (Otto and Diesel), as well as fuel cells, are internal combustion cycles. The quality of the energy transformation is assessed by the total energy efficiency

$$\eta = -\frac{P}{\dot{m}_{\mathrm{fuel}}\,\Delta h_{\mathrm{ncv}}}\,,$$

where P is the power output of the cycle, $\dot{m}$ is the mass flow rate of the supplied fuel, and Δh_{ncv} is its net calorific value. The total exergetic efficiency $\xi = -P/(\dot{m}_{\mathrm{fuel}}\,w_{\mathrm{ex,fuel}})$ specifies the fraction of the exergy flow coming with the fuel that is transformed into power output. Generally, w_{ex} is only slightly larger than the net calorific value, and η and ξ thus hardly differ in their numerical values. The typical total efficiency is approximately 45% for large engines (Diesel), 30% for automotive engines, and 30% for open gas turbine cycles.

Open Gas Turbine Cycle

In an open gas turbine plant, the inlet air is brought to a high pressure through a compressor, then preheated

and heated in a combustion chamber via the combustion of the injected fuel. The combustion gases pass through a turbine, in which they do work (against the blades). The gas exiting the turbine is used to preheat the combustion air in a heat exchanger, and is then discharged into the environment. The compressor and turbine are placed on the same shaft. The power output is transformed into electric energy by a generator, which is connected to the shaft.

Otto Engine

Figure 3.17 shows the cycle of an Otto engine on p–V and T–S diagrams. At the end of the intake stroke, the cylinder is filled with a combustible fresh air–fuel mixture of state 1 at the environmental temperature and atmospheric pressure. The mixture is compressed along the adiabate 1–2 from the initial volume $V_c + V_d$ to the compression volume V_c, where V_d is the displacement volume. At the top dead center 2, combustion is initiated by electric spark ignition, whereby the pressure rises from state 2 to state 3. This change of state takes place so quickly that it can be assumed to be isochoric. In Fig. 3.17 (simplifying), it is assumed that the gas is not changed and that the heat released during combustion $Q_{23} = Q$ is supplied from the outside. The gas expands along the adiabatic 3–4–4″–4′ and forces the piston to return. The exhaust beginning in state 4 is substituted by the removal of energy by heat transfer $|Q_0|$ at constant volume, whereas the pressure decreases from state 4 to state 1. In state 1, the combustion gases have to be replaced by a new mixture. In order to do so, twin-stroke operation (not shown) is necessary in a four-stroke Otto engine.

The heat transfer to the gas is

$$Q = Q_{23} = mc_v(T_3 - T_2)\,, \tag{3.109}$$

while that from the gas is

$$|Q_0| = |Q_{41}| = mc_v(T_4 - T_1)\,. \tag{3.110}$$

The work is

$$|W_t| = Q - |Q_0|\,, \tag{3.111}$$

and the thermal efficiency is given by

$$\eta = \frac{|W_t|}{Q} = 1 - \frac{T_4 - T_1}{T_3 - T_2} = 1 - \frac{T_1}{T_2}$$
$$= 1 - \left(\frac{p_1}{p_2}\right)^{\frac{\varkappa-1}{\varkappa}} = 1 - \frac{1}{\varepsilon^{\varkappa-1}}\,. \tag{3.112}$$

The compression ratio $\varepsilon = V_1/V_2 = (V_c + V_d)/V_c$ specifies the degree of adiabatic compression of the mixture.

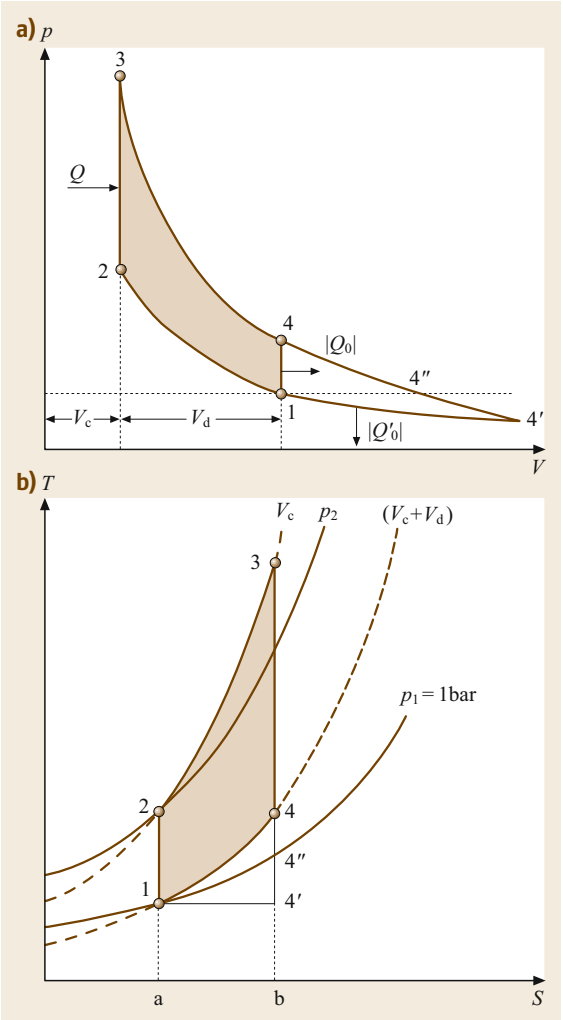

Fig. 3.17a,b Theoretical process of the Otto engine on **(a)** p–V and **(b)** T–S diagrams

Thus, the thermal efficiency depends, except for the adiabatic exponent, only on the pressure ratio p_2/p_1 or the compression ratio ε but not on the amount of energy supplied by heat transfer. The compression ratio is limited by the self-ignition temperature of the fuel–air mixture.

Diesel Engine

The limitation to moderate compression ratios and pressures does not apply for the Diesel engine, in which the high compression heats the combustion air above the self-ignition temperature of the fuel that is injected into the hot air. Figure 3.18 shows the simplified process of the Diesel engine. It consists of the adiabatic compression 1–2 of the combustion air, isobaric combustion 2–3′ after the injection of the fuel into the hot,

compressed combustion air, adiabatic relaxation 3′–4, and ejection 4–1 of the exhaust gases, which is replaced in Fig. 3.18 by an isochore with heat removal. The supplied heat transfer is

$$Q_{23'} = Q = mc_p(T_{3'} - T_2)\,, \tag{3.113}$$

and the removed heat transfer is

$$|Q_{41}| = |Q_0| = mc_v(T_4 - T_1) \tag{3.114}$$

during the imaginary isochore 4–1. The work is given by

$$|W_t| = Q - |Q_0|\,,$$

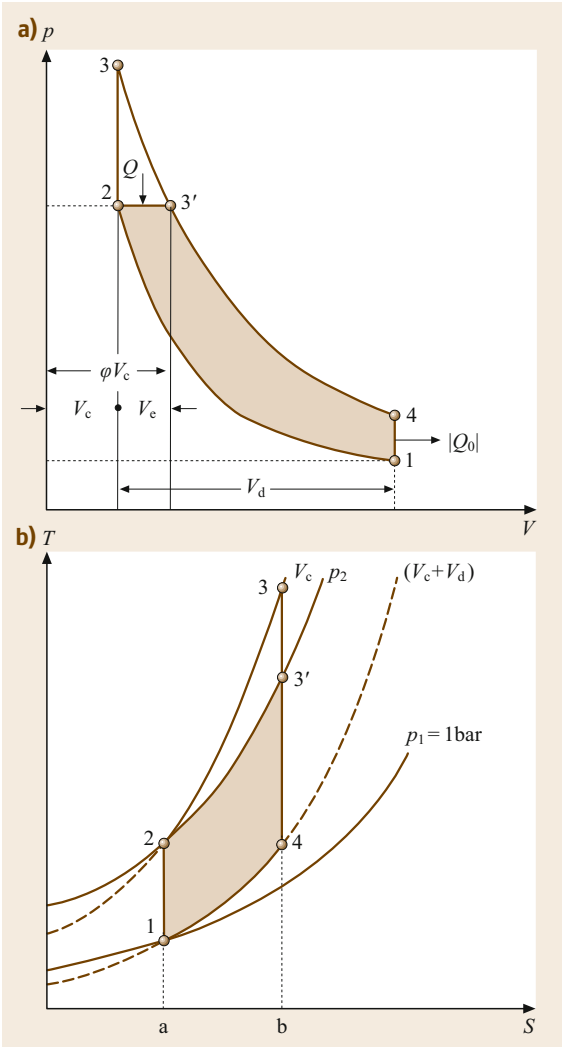

Fig. 3.18a,b Theoretical process of the Diesel engine on **(a)** p–V and **(b)** T–S diagrams

and the thermal efficiency by

$$\eta = \frac{|W_t|}{Q} = 1 - \frac{1}{\varkappa}\frac{T_4 - T_1}{T_{3'} - T_2} = 1 - \frac{1}{\varkappa}\frac{\frac{T_4}{T_3}\frac{T_3}{T_2} - \frac{T_1}{T_2}}{\frac{T_{3'}}{T_2} - 1}\,. \tag{3.115}$$

With the compression ratio $\varepsilon = V_1/V_2 = (V_c + V_d)/V_c$ and the cutoff ratio $\varphi = (V_c + V_e)/V_c$, the following equation for the thermal efficiency results:

$$\eta = 1 - \frac{1}{\varkappa\,\varepsilon^{\varkappa-1}}\frac{\varphi^{\varkappa} - 1}{\varphi - 1}\,. \tag{3.116}$$

The thermal efficiency of the Diesel cycle depends, except for the adiabatic exponent, only on the compression ratio ε and on the cutoff ratio φ, which increases with increasing load.

Fuel Cells

In a fuel cell, hydrogen reacts electrochemically with oxygen to produce water

$$H_2 + \frac{1}{2}O_2 \rightarrow H_2O\,.$$

In this so-called cold combustion, the chemical bond energy is transformed directly into electrical energy. Figure 3.19 shows, as an example, a fuel cell with a proton-conductive electrolyte, where hydrogen is supplied at the anode side. With the help of a catalyst, it is decomposed into two protons (H^+) and two electrons (e^-). The electrons move through a load, e.g., a motor, to the cathode. The protons move through the electrolyte to the cathode, where they, supported by a catalyst, react with the supplied oxygen, O_2, and the electrons to produce water, H_2O. There is a voltage U

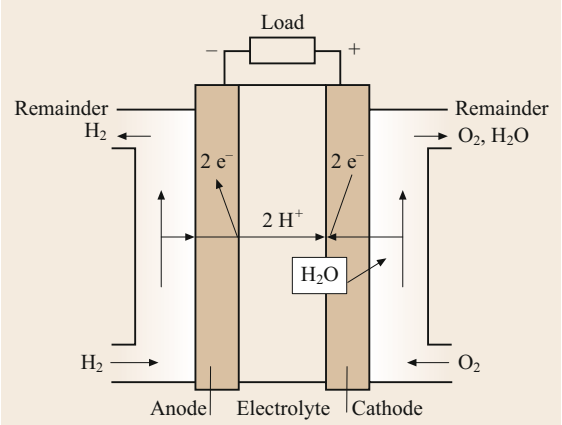

Fig. 3.19 Scheme of a fuel cell with a proton-conductive electrolyte

between the anode and cathode, and an electric current $I = F\dot{n}_{el}$ with $\dot{n}_{el} = 2\dot{n}_{H_2}$ flows. F is the Faraday constant $F = 96\,485.3\,\mathrm{As/mol}$, and $\dot{n}_{el}$ is the flow rate of electrons (SI units mol/s). The actual terminal voltage is smaller than the reversible one because of losses due to energy dissipation in the cell. The electric power of the cell is calculated from

$$\dot{Q} + P = \dot{n}_{H_2} \Delta H^{R}_{H_2}$$

with the flow rate $\dot{n}_{H_2}$ of the supplied hydrogen and its molar reaction enthalpy $\Delta H^{R}_{H_2}$ (SI unit J/mol), which is equal to the negative molar net calorific value $\Delta H_{m\,ncv} = M_{H_2} \Delta h_{ncv}$ (Sect. 3.8.1). Analogous to the efficiency of other combustion plants, the efficiency of a fuel cell is defined as

$$\eta_{fc} = \frac{-P}{\dot{n}_{H_2}\, \Delta H_{m\,ncv}} ,$$

with fuel cells generally being about 50% efficient.

3.8.3 Cyclic Processes: Principles

A process that brings a system back to its initial state is called a cyclic process. After the system has passed through such a cycle, all the properties of the system such as pressure, temperature, volume, internal energy, and enthalpy return to their initial values and thus produce

$$\sum Q_{ik} + \sum W_{ik} = 0 . \qquad (3.117)$$

The total work done is $-W = -\sum W_{ik} = \sum Q_{ik}$.

Machines in which a fluid is undergoing a cyclic process serve to transform heat transfer into work or to transfer thermal energy from a low to a high-temperature level while work is supplied. According to the second law of thermodynamics, it is not possible to transform all the supplied heat transfer into work. If the amount of heat supplied is larger than the amount of heat discharged, the process works as a power cycle or a thermal power plant whose purpose is to deliver work. If the amount of heat discharged is smaller than the amount of heat supplied, work must be supplied. Such a process can be used for heat transfer from a medium at a lower temperature to a medium at a higher temperature, e.g., ambient temperature. The required work is also discharged as heat at the higher temperature. Such a process works as a refrigeration cycle. In a heat pump process, heat is absorbed from the environment and is discharged together with the supplied work at a higher temperature.

Carnot Cycle

The cyclic process introduced in 1824 by Carnot is shown in Figs. 3.20 and 3.21. Even though not very important in practice, the Carnot cycle played a decisive roll in the historical development of heat transfer theory. It consists of the following changes of state (here, the clockwise process of a power cycle):

1–2 Isothermal expansion at temperature T with heat addition Q
2–3 Reversible adiabatic expansion from pressure p_2 to pressure p_3
3–4 Isothermal compression at temperature T_0 with heat removal $|Q_0|$
4–1 Reversible adiabatic compression from pressure p_4 to pressure p_1.

The heat supplied is

$$Q = mRT \ln \frac{V_2}{V_1} = T(S_2 - S_1) , \qquad (3.118)$$

and the heat removed is

$$|Q_0| = mRT_0 \ln \frac{V_3}{V_4} = T_0(S_3 - S_4) = T_0(S_2 - S_1) . \qquad (3.119)$$

The technical work done is $-W_t = Q - |Q_0|$, and the thermal efficiency is

$$\eta = \frac{|W_t|}{Q} = 1 - \left(\frac{T_0}{T}\right) . \qquad (3.120)$$

With the inverse sequence 4–3–2–1 of changes of state, the heat absorbed Q_0 is from a body at a lower temperature and, with the supply of the technical work W_t, the heat discharged Q is at the higher temperature T. Such a counterclockwise Carnot cycle results in heat removal Q_0 from a chilled system at the low temperature T_0, thus working as a refrigerator, and can discharge the

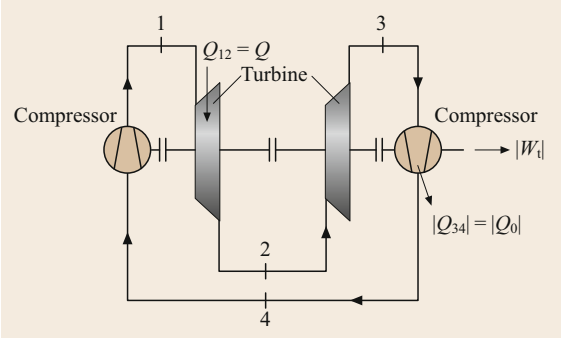

Fig. 3.20 Scheme of a Carnot power cycle

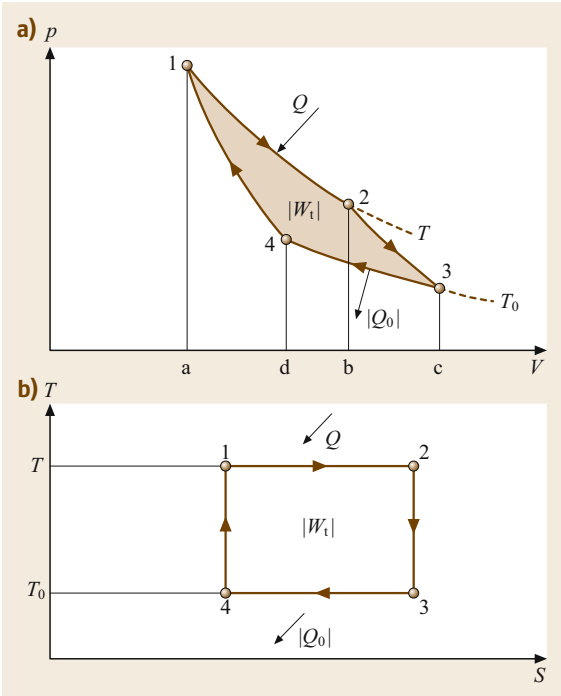

Fig. 3.21a,b The Carnot cycle on **(a)** p–V and **(b)** T–S diagrams

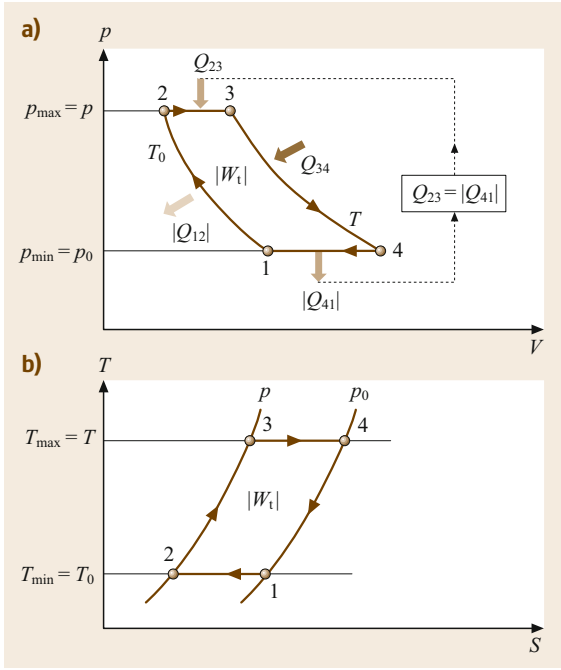

Fig. 3.22a,b The Ackeret–Keller process on **(a)** p–V and **(b)** T–S diagrams

heat $|Q| = W_t + Q_0$ at the higher temperature T to the environment. If the purpose of the process is the heat release $|Q|$ at the higher temperature T for heating, the process works as a heat pump. The heat transfer Q_0 is then removed from the environment at the lower temperature T_0. Carnot cycles have not achieved practical importance, however, because their power relative to the volume of the corresponding machine is very small. However, as an ideal, i.e., reversible, process the Carnot cycle is often used for comparison in order to assess other cyclic processes.

3.8.4 Thermal Power Cycles

In thermal power plants, energy in the form of heat transfer is transformed from the combustion gases in the working fluid, which undergoes a cyclic process. The Ackeret–Keller process consists of the following changes of state as shown in Fig. 3.22 in a p–V and T–S diagram:

1–2 Isothermal compression from pressure p_0 to pressure p at temperature T_0
2–3 Isobaric heat supply at pressure p
3–4 Isothermal expansion from pressure p to pressure p_0 at temperature T
4–1 Isobaric heat removal at pressure p_0.

Because this process can be traced back to a proposal by the Swedish engineer J. Ericsson (1803–1899), it is also called the Ericsson cycle. It was first used in 1941, however, by Ackeret and Keller as a comparison process for gas turbine plants. The heat transfer required for the isobaric heating 2–3 of the compressed working fluid is provided by the isobaric cooling 4–1 of the expanded working fluid, $Q_{23} = |Q_{41}|$.

The thermal efficiency is equal to the efficiency of the Carnot cycle, because

$$-W_t = Q_{34} - |Q_{21}| \tag{3.121}$$

and

$$\eta = 1 - \frac{|Q_{21}|}{Q_{34}} = 1 - \frac{T_0}{T} \,. \tag{3.122}$$

However, the technical realization of this process is difficult because isothermal compression and relaxation are hardly achievable due to the fact that they can only be approximated by multistage adiabatic compression with intermediate cooling. The Ackeret–Keller process serves mainly as a comparison process for the gas turbine process with multistage compression and relaxation. In a closed gas turbine plant (Fig. 3.23), a gas is compressed in the compressor, heated to a high temperature in the heat exchanger and the gas heater, then

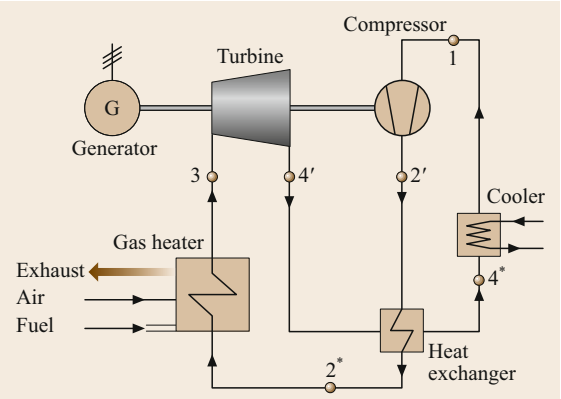

Fig. 3.23 Gas turbine process with a closed cycle

expanded in a turbine, where work is done, and cooled again to the initial temperature in the heat exchanger and the adjacent cooler. Then, the gas is drawn in by the compressor once again. Often air is used as the working fluid, but other gases such as helium or nitrogen are also sometimes used. The closed gas turbine plant is easily adjustable, and fouling of the turbine blades can be prevented by using suitable gases. A drawback in comparison with open plants is the higher energy costs, because a cooler is required and high-quality steels are needed for the heater. Figure 3.24 shows the process on p–V and T–S diagrams.

The reversible cyclic process consisting of two isobars and two isentropes is called the Joule process (states 1, 2, 3, 4). The supplied heat transfer is

$$\dot{Q} = \dot{m} c_p \, (T_3 - T_2) \ , \tag{3.123}$$

and the discharged heat transfer is

$$\left|\dot{Q}_0\right| = \dot{m} \, c_p \, (T_4 - T_1) \ . \tag{3.124}$$

The power is

$$\begin{aligned} -P &= -\dot{m} w_t = \dot{Q} - \left|\dot{Q}_0\right| \\ &= \dot{m} \, c_p (T_3 - T_2) \left(1 - \frac{T_4 - T_1}{T_3 - T_2}\right) \ , \end{aligned} \tag{3.125}$$

and the thermal efficiency is

$$\eta = \frac{|P|}{\dot{Q}} = \left(1 - \frac{T_4 - T_1}{T_3 - T_2}\right) \ . \tag{3.126}$$

Because of the isentropic equation,

$$\left(\frac{p_0}{p}\right)^{\frac{\varkappa-1}{\varkappa}} = \frac{T_1}{T_2} = \frac{T_4}{T_3} \tag{3.127}$$

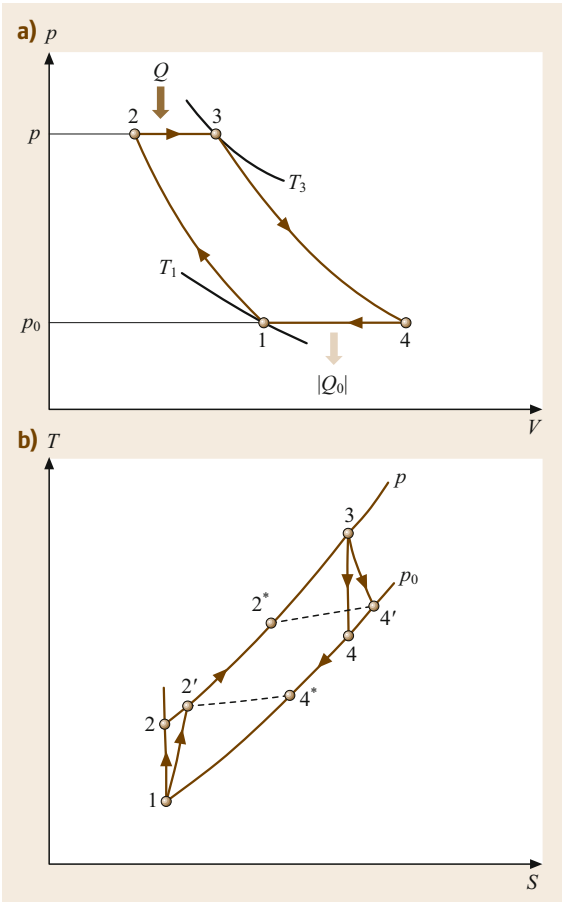

Fig. 3.24a,b The gas turbine process on **(a)** p–V and **(b)** T–S diagram. The p–V diagram shows only the reversible process (Joule process) 1, 2, 3, 4

so

$$\frac{T_4 - T_1}{T_3 - T_2} = \frac{T_1}{T_2} = \left(\frac{p_0}{p}\right)^{\frac{\varkappa-1}{\varkappa}} \ , \tag{3.128}$$

and the thermal efficiency is

$$\eta = \frac{|P|}{\dot{Q}} = 1 - \left(\frac{p_0}{p}\right)^{\frac{\varkappa-1}{\varkappa}} \ , \tag{3.129}$$

which depends only on the pressure ratio p/p_0 or on the temperature ratio T_2/T_1 of the compression. The compressor power increases faster with the pressure ratio than does the turbine power, so the received power output according to (3.125), taking into account (3.128), becomes

$$-P = \dot{m} c_p T_1 \left[\frac{T_3}{T_1} - \left(\frac{p}{p_0}\right)^{\frac{\varkappa-1}{\varkappa}}\right]\left[1 - \left(\frac{p_0}{p}\right)^{\frac{\varkappa-1}{\varkappa}}\right] \ , \tag{3.130}$$

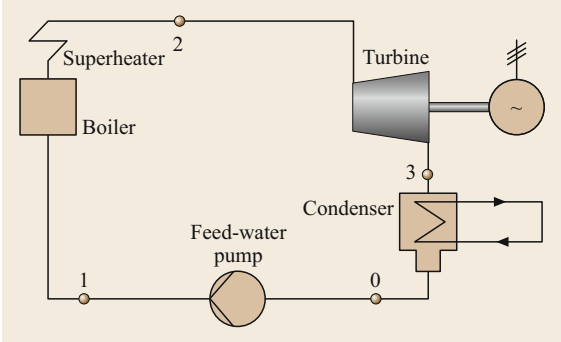

Fig. 3.25 Vapor power plant

which reaches a maximum at a certain pressure ratio for given values of the highest temperature T_3 and the lowest temperature T_1. This optimal pressure ratio follows from (3.130) through differentiation as

$$\left(\frac{p}{p_0}\right)^{\frac{\varkappa-1}{\varkappa}}_{\text{opt}} = \sqrt{\frac{T_3}{T_1}}\,, \tag{3.131}$$

which is, because of (3.128), equivalent to $T_4 = T_2$. Considering the efficiencies η_T of the turbine and η_C of the compressor, and the mechanical efficiency η_m for the energy transformation between the turbine and compressor, the optimal pressure ratio results as

$$\left(\frac{p}{p_0}\right)^{\frac{\varkappa-1}{\varkappa}}_{\text{opt}} = \sqrt{\eta_\text{m}\eta_\text{T}\eta_\text{C}\left(\frac{T_3}{T_1}\right)}\,. \tag{3.132}$$

More than half of the turbine power of a gas turbine plant is required to drive the compressor. The completely installed power is thus four to six times the power output.

The working fluid of vapor power plants, usually water, evaporates and condenses during the process. Most electric energy is generated with such plants. The simplest form of the cyclic process (Fig. 3.25) is as follows:

In the boiler, the working fluid is heated isobarically at a high pressure to the boiling point, evaporated, then superheated in the superheater. The vapor is then expanded adiabatically in the turbine, where work is done, and condensed with heat removal in the condenser. The liquid is pressurized in the feed-water pump to the pressure of the boiler and again discharged into the boiler. The reversible cyclic process 0–1′–2–3′–0 (Fig. 3.26), consisting of two isobars and two isentropes, is called the Clausius–Rankine process. The real cycle consists of the changes of state 0–1–2–3–0 in Fig. 3.26. The heat absorption in the steam generator is

$$\dot{Q}_\text{in} = \dot{m}(h_2 - h_1)\,, \tag{3.133}$$

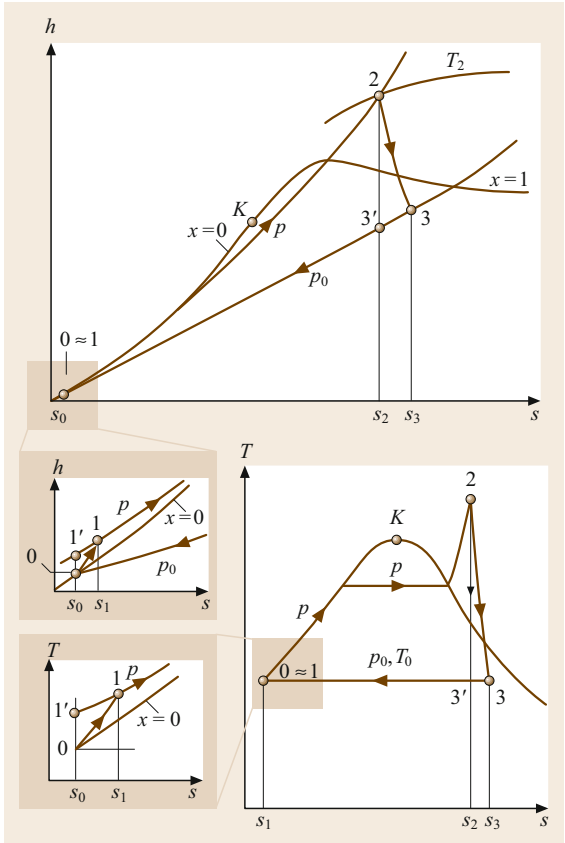

Fig. 3.26 Changes of state of the water in the cycle of a basic vapor power plant on T–S and h–s diagrams

and the power of the adiabatic turbine is

$$|P_\text{T}| = |\dot{m}w_{\text{t}23}| = \dot{m}(h_2 - h_3) = \dot{m}\eta_\text{T}(h_2 - h_3')\,, \tag{3.134}$$

with the isentropic turbine efficiency η_T. The heat transfer discharged in the condenser is

$$-\dot{Q}_\text{out} = \dot{m}(h_3 - h_0)\,. \tag{3.135}$$

The power output of the cyclic process is

$$-P = -\dot{m}w_\text{t} = -P_\text{T} - P_\text{P}\,, \tag{3.136}$$

with the pump power

$$P_\text{P} = \dot{m}(h_1 - h_0) = \dot{m}\frac{1}{\eta_\text{C}}(h_{1'} - h_0)\,, \tag{3.137}$$

where η_C is the efficiency of the feed-water pump. The power output differs only slightly from the power output of the turbine. The thermal efficiency is

$$\eta = -\frac{\dot{m}w_\text{t}}{\dot{Q}_\text{in}} = \frac{(h_2 - h_3) - (h_1 - h_0)}{h_2 - h_1}\,. \tag{3.138}$$

At a counterpressure of $p_0 = 0.05$ bar, a main steam pressure of 150 bar, and a vapor temperature of 500 °C, the thermal efficiency achieves values of $\eta \approx 0.42$. Considerably higher thermal efficiencies of (presently) up to $\eta \approx 0.58$ can be achieved in combined gas–vapor power plants, in which the combustion gas at first does work in a gas turbine, where it is expanded, then is supplied to a vapor power plant in order to generate steam.

3.8.5 Refrigeration Cycles and Heat Pumps

Compression Refrigeration Cycle

In refrigerating machines, as well as in power plants, gases or vapors are used as working fluids. These gases/vapors are called refrigerants. A refrigeration machine is used to remove heat from a chilled system. For this purpose, it is necessary to do work, which is then transferred as heat together with the heat removed from the chilled system to the environment. For cooling with temperatures to about −100 °C, compression refrigeration machines are primarily used.

Figure 3.27 shows a schematic diagram of a compression refrigeration machine. The compressor, which is usually a piston compressor for small powers and a turbo compressor for large powers, draws in vapor from the evaporator at the pressure p_0 and the corresponding saturation temperature T_0 and compresses it along adiabate 1–2 (Fig. 3.28) to pressure p. The vapor is then liquefied at pressure p in the condenser. The liquid refrigerant is expanded in the throttle valve and returns to the evaporator, where it is supplied with heat. The refrigeration machine removes from the chilled system the heat transfer q_0, which is transferred to the evaporator. In the condenser, the heat transfer $|q| = q_0 + w_t$ is transferred to the environment.

Since water freezes at 0 °C, and water vapor has an inconveniently large specific volume, other fluids such as ammonia NH_3, carbon dioxide CO_2, propane C_3H_8, butane C_4H_{10}, and tetrafluoroethane $C_2H_2F_4$ are used as refrigerants. Saturated refrigerant properties are given in Tables 3.10–3.12. For mass flow $\dot{m}$ of the circulating refrigerant, the refrigeration capacity is

$$\dot{Q}_0 = \dot{m} q_0 = \dot{m}(h_1 - h_4) = \dot{m}\left[h''(p_0) - h'(p)\right] , \tag{3.139}$$

since $h_4 = h_3 = h'(p)$. The required power for the compressor is

$$P_C = \dot{m} w_{t12} = \dot{m}(h_2 - h_1) = \dot{m}\frac{1}{\eta_C}\left[h_{2'} - h''(p_0)\right] , \tag{3.140}$$

where η_C is the isentropic efficiency of the compressor. The heat transfer from the condenser is given by

$$|\dot{q}| = \dot{m}\,|q| = \dot{m}(h_2 - h_3) = \dot{m}\left[h_2 - h'(p)\right] . \tag{3.141}$$

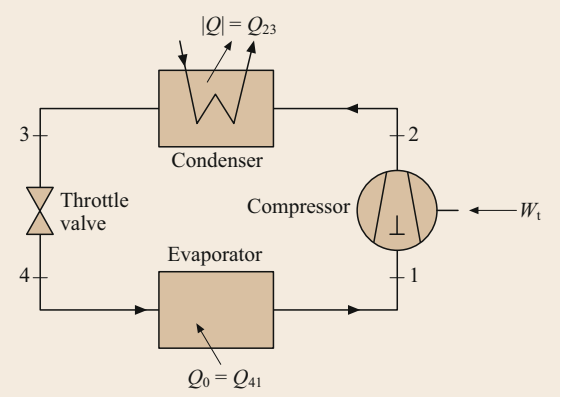

Fig. 3.27 Scheme of a vapor refrigeration plant (see text for explanation)

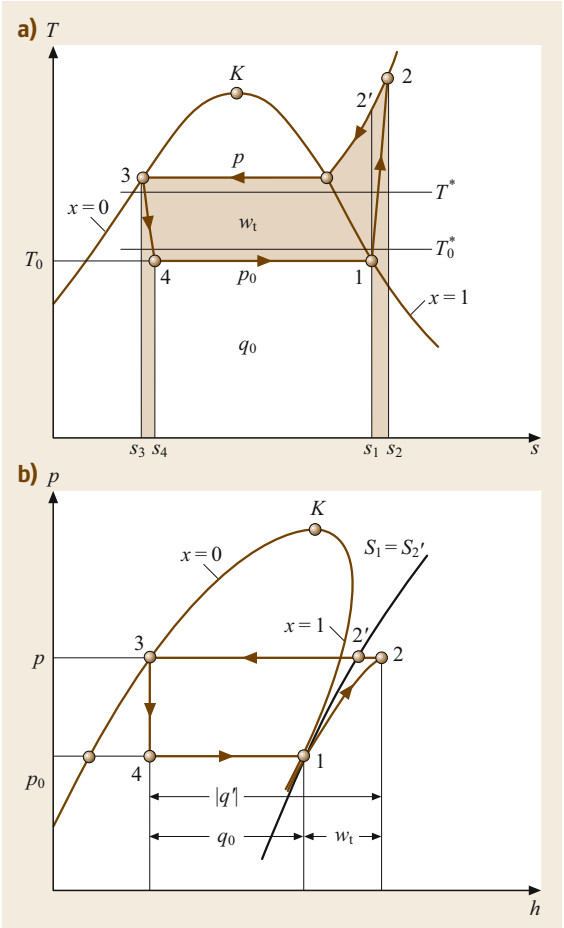

Fig. 3.28a,b Cycle of the refrigerant in a vapor refrigeration plant on **(a)** the T–S and **(b)** the p–h (Mollier) diagrams

The coefficient of performance of a refrigeration machine is defined as the ratio of the refrigeration capacity $\dot{q}_0$ to the required power P of the compressor

$$\varepsilon_R = \frac{\dot{q}_0}{P_C} = \frac{q_0}{w_{t12}} = \eta_C \frac{h''(p_0) - h'(p)}{h_{2'} - h''(p_0)} , \qquad (3.142)$$

which depends, besides on the isentropic compressor efficiency, only on the two pressures p and p_0.

Compression Heat Pump

A compression heat pump works according to the same process as the compression refrigeration system shown in Figs. 3.27 and 3.28, but its purpose, however, is for heating. To provide heating, then, the heat transfer q_0 (anergy) is from the environment and is, together with the done work, w_t (the exergy), supplied as a heat transfer $|q| = q_0 + w_t$ to the heated system. The coefficient of performance of a heat pump is defined as the ratio of the heating output $|\dot{q}|$ to the required power P of the compressor

$$\varepsilon_{hp} = \frac{|\dot{q}|}{P} = \frac{|q|}{w_t} = \eta_V \frac{h_2 - h'(p)}{h_{2'} - h''(p_0)} . \qquad (3.143)$$

As shown in the T–S diagram in Fig. 3.28, the area representing w_t becomes smaller at a high ambient temperature T_0^* and at a low heating temperature T^* because less power is required for the compressor and the coefficient of performance increases. To run heat pumps economically for the heating of housing spaces, the heating temperature must be kept low, e.g., by using floor heating at $t^* \lessapprox 29\,^\circ\mathrm{C}$. Additionally, heat pumps become uneconomic when the environment temperature is too low. If the coefficient of performance decreases below about 2.3, no primary energy is saved when compared with conventional heating, because the mean efficiencies for the transformation of primary energy P_{Pr} into electrical energy P in a power plant in order to run the heat pump $\eta_{el} = P/P_{Pr}$ are typically about 0.4. In that case, the heating coefficient $\xi = |\dot{q}|/P_{Pr}$ of 0.92 corresponds to the efficiency of conventional heating. Today's electrically driven heat pumps rarely achieve heating coefficients of 2.3 in the annual mean, unless the heat pump is switched off at ambient temperatures lower than approximately 3 °C and the housing space is heated conventionally. Motor-driven heat pumps with waste heat recovery and sorption heat pumps exploit the primary energy better than electrically driven heat pumps.

3.8.6 Combined Heat and Power (CHP)

The generation of thermal energy and electrical energy in heating power plants is called combined heat and power generation. A large amount of a power plant's waste heat, which arises in the process, is used for heating. Since the heat required for heating consists mainly—more than 90%—of anergy, less primary energy, which consists mainly of exergy, is transformed into thermal energy than in conventional heating. Low-pressure vapor is discharged from the vapor turbine; it contains, in addition to the anergy, so much exergy that the heating energy and the exergy losses in the heat distribution—normally in a long-distance heating network—are covered. Even though, compared with a simple power plant, operation work is lost due to the vapor withdrawal, the primary energy consumption for the simultaneous generation of work and thermal energy is smaller than the separate generation of work in a power plant and of thermal energy in a conventional heating system. A simplified circuit is shown in Fig. 3.29. Depending on the kind of circuit used, heating coefficients, $\xi = |\dot{q}|/P_{Pr}$, up to about 2.2 are accessible [3.18], whereas P_{Pr} is only the fraction of the primary energy that accounts for the heating. The heating coefficients are considerably above those of most heating pump systems.

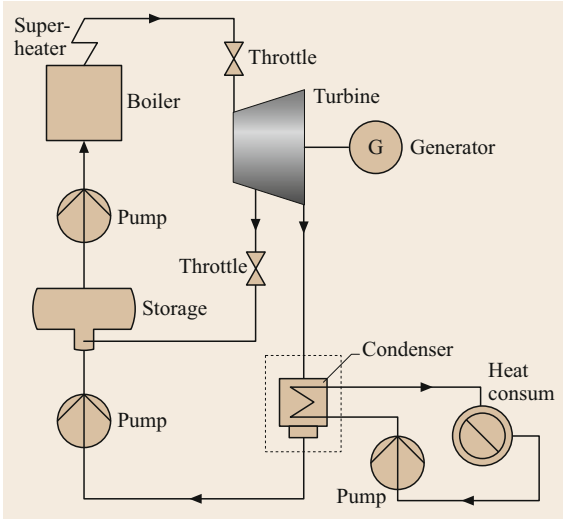

Fig. 3.29 Scheme of combined heat and power generation in extraction back-pressure operation

3.9 Ideal Gas Mixtures

A mixture of ideal gases that do not react chemically with each other also behaves as an ideal gas. The following equation of state holds:

$$pV = nR_u T \,. \tag{3.144}$$

Each single gas, called a component, spreads over the entire space V as though the other gases were not present. Thus, the following equation holds for each component:

$$p_i V = n_i R_u T \,, \tag{3.145}$$

where p_i is the pressure exerted by each gas individually, which is referred to as the partial pressure. The sum of all the *partial pressures* leads to $\sum p_i V = \sum n_i R_u T$ or $V \sum p_i = R_u T \sum n_i$. Comparison with (3.144) shows that

$$p = \sum p_i \tag{3.146}$$

holds. In other words, the total pressure p of the gas mixture is equal to the sum of the partial pressures of the single gases, if each gas occupies the volume V of the mixture at temperature T (Dalton's law). The thermal equation of state of an ideal gas mixture can also be written as

$$pV = mRT \,, \tag{3.147}$$

with the gas constant R of the mixture

$$R = \sum R_i \frac{m_i}{m} \,. \tag{3.148}$$

Specific (related to the mass in kg) caloric properties of a mixture at pressure p and temperature T result from adding the caloric properties at the same values p and T of the single gases according to their mass fractions, or

$$\begin{aligned} c_v &= \frac{1}{m} \sum m_i c_{vi} \,, & c_p &= \frac{1}{m} \sum m_i c_{pi} \,, \\ u &= \frac{1}{m} \sum m_i u_i \,, & h &= \frac{1}{m} \sum m_i h_i \,. \end{aligned} \tag{3.149}$$

An exception to this general rule is entropy. During the mixing of single gases in state p, T to a mixture of the same state, an entropy increase takes place. This process is described by the following relation:

$$s = \frac{1}{m} \left(\sum m_i s_i - \sum m_i R_i \ln \frac{n_i}{n} \right) \,, \tag{3.150}$$

where n_i is the number of moles of the single gases and n is the number of moles of the mixture. Consequently, $n_i = m_i / M_i$ and $n = \sum n_i$, with the mass m_i and the molar mass M_i of the single gases. Mixtures of real gases and liquids deviate from the above relations, in particular at higher pressures.

3.9.1 Mixtures of Gas and Vapor: Humid Air

Mixtures of gases and easily condensable vapors occur often in physics and in technology. Atmospheric air consists mostly of dry air and water vapor. Drying and climatization processes are governed by the laws of vapor–air mixtures. This holds true in the same way for the formation of fuel and vapor–air mixtures in a combustion engine. The following discussion is limited to the examination of atmospheric air. Dry air consists of 78.04 mol% nitrogen, 21.00 mol% oxygen, 0.93 mol% argon, and 0.03 mol% carbon dioxide. Atmospheric air can be considered as a binary mixture of dry air and water, which can be present as vapor, liquid, or solid. This mixture is also called humid air. Dry air is considered a uniform substance. Since the total pressure during changes of state is almost always close to atmospheric pressure, it is possible to consider humid air, consisting of dry air and water vapor, as a mixture of ideal gases. The following relation then holds for dry air and water vapor:

$$p_{air} V = m_{air} R_{air} T \quad \text{and} \quad p_v V = m_v R_v T \,. \tag{3.151}$$

These equations, together with $p = p_{air} + p_v$, allow the determination of the mass of water vapor which is added to 1 kg dry air.

$$x_v = \frac{m_v}{m_{air}} = \frac{R_{air} p_v}{R_v (p - p_v)} \,. \tag{3.152}$$

The quantity $x_v = m_v / m_{air}$ is called the absolute or specific humidity. This quantity must not be confused with the quality x for mixtures of vapors and liquid. If water in the air is not only present as vapor, but also as liquid or solid, the water content x must be distinguished from the specific humidity x_v. The water content is defined as

$$x = \frac{m_w}{m_{air}} = \frac{m_v + m_\ell + m_{ice}}{m_{air}} = x_v + x_\ell + x_{ice} \,, \tag{3.153}$$

where m_v denotes the vapor mass, m_ℓ denotes the liquid mass, and m_{ice} denotes the ice mass in the dry air of mass m_{air}. The value x_v is the specific humidity (vapor content), x_ℓ is the liquid content, and x_{ice}

is the ice content. The water content can lie between 0 (dry air) and ∞ (pure water). If humid air at temperature T is saturated with water vapor, the partial pressure of the water vapor is equal to the saturation pressure $p = p_{vs}$ at temperature T, and the specific humidity becomes

$$x_s = \frac{R_{air} p_{vs}}{R_v (p - p_{vs})} \,. \tag{3.154}$$

Example 3.13

What is the specific humidity of saturated humid air at a temperature of 20 °C and a total pressure of 1000 mbar?

The gas constants are $R_{air} = 0.2872\,\mathrm{kJ/(kg\,K)}$ and $R_v = 0.4615\,\mathrm{kJ/(kg\,K)}$. The saturated water temperature (Table 3.6) includes the vapor pressure, which is $p_{vs}(20\,°C) = 23.39\,\mathrm{mbar}$. It follows then that

$$x_s = \frac{0.2872 \times 23.39}{0.4615\,(1000 - 23.39)} \times 10^3 \,\frac{\mathrm{g}}{\mathrm{kg}} = 14.905 \,\frac{\mathrm{g}}{\mathrm{kg}} \,.$$

Other values of x_s are given in Table 3.20.

Degree of Saturation and Relative Humidity

The degree of saturation is defined as $\Psi = x_v/x_s$, which is a relative measure of the vapor content. In meteorology, however, the relative humidity $\varphi = p_v(t)/p_{vs}(t)$ is often used. Close to saturation, the two values differ only slightly because

$$\frac{x_v}{x_s} = \frac{p_v(p-p_{vs})}{p_{vs}(p-p_v)} \quad \text{or} \quad \Psi = \varphi\frac{(p-p_{vs})}{(p-p_v)} .$$

At saturation, $\Psi = \varphi = 1$. If the pressure of saturated humid air is increased or if the temperature is decreased, the excess water vapor condenses. The condensed vapor drops out as fog or precipitation (rain); at temperatures below 0 °C, ice crystals (snow) arise. In this case, the water content is larger than the vapor content: $x > x_v = x_s$. The relative humidity can be determined with directly displaying instruments (e.g., a hair hygrometer) or with the help of an aspiration psychrometer.

Enthalpy of Humid Air

Since the amount of dry air remains constant during changes of state of humid air, and only the added amount of water varies as a result of thawing or evaporation, all properties are related to 1 kg dry air. The dry air contains $x = m_w/m_{air}$ kg water per kg dry air, of which $x_v = m_v/m_{air}$ is vaporous. For the enthalpy h_{1+x} of the unsaturated ($x = x_v < x_s$) mixture of 1 kg dry air and x vapor, it holds that

$$h_{1+x} = c_{p\,air}t + x_v(c_{p\,v}t + \Delta h_v) , \qquad (3.155)$$

with the constant-pressure specific heats $c_{p\,air} = 1.005\,\text{kJ/(kg K)}$ of air and $c_{p\,v} = 1.86\,\text{kJ/(kg K)}$ of water vapor, and the enthalpy of vaporization $\Delta h_v = 2500.5\,\text{kJ/kg}$ of water at 0 °C. In the temperature range of interest between −60 and 100 °C, constant values of c_p can be assumed. At saturation, $x_v = x_s$ and $h_{1+x} = (h_{1+x})_s$. If the water content x is larger than the saturation content x_s at temperatures $t > 0\,°\text{C}$, the water fraction $x - x_s = x_\ell$ drops out of the mixture as fog or as precipitate, and it holds that

$$h_{1+x} = (h_{1+x})_s + (x-x_s)c_w t . \qquad (3.156)$$

At temperatures $t < 0\,°\text{C}$, the water fraction $x - x_s = x_{ice}$ drops out as snow or ice, then

$$h_{1+x} = (h_{1+x})_s - (x-x_s)(\Delta h_f - c_{ice}t) . \qquad (3.157)$$

The specific heat of water is $c_w = 4.19\,\text{kJ/(kg K)}$, the specific heat of ice is $c_{ice} = 2.04\,\text{kJ/(kg K)}$, and the latent heat of fusion of ice is $\Delta h_f = 333.5\,\text{kJ/kg}$. Saturation pressures, specific humidities, and enthalpies of saturated humid air at temperatures between −20 and +100 °C for a total pressure of 1000 mbar are given in Table 3.20. At $t = 0\,°\text{C}$, water can be present simultaneously in all three states of aggregation. The following relation then holds for the enthalpy h_{1+x} of the mixture:

$$h_{1+x} = x_s\Delta h_v - x_{ice}\Delta h_f . \qquad (3.158)$$

Mollier Diagram of Humid Air

Figure 3.30a shows the h_{1+x}–x diagram introduced by Mollier for the graphical depiction of changes of state of humid air. The enthalpy h_{1+x} of $(1+x)$ kg humid air is plotted in an oblique coordinate system against the water content. The axis $h = 0$ corresponding to humid air at 0 °C is inclined right downward in such a way that the 0 °C isotherm of unsaturated humid air is horizontal. Figure 3.30b shows the construction of isotherms according to (3.155) and (3.156). Lines of constant x are vertical, while lines of constant h are straight lines parallel to the axis $h_{1+x} = 0$. Figure 3.30a includes the saturation curve $\varphi = 1$ for a total pressure of 1000 mbar. It divides the region of unsaturated mixtures (top) from the fog region (bottom), in which the humidity is contained in the mixture partly as vapor, partly as liquid (fog, precipitate) or solid (ice, fog, snow). Isotherms in the unsaturated region are, according to (3.155), towards the right, slightly ascending straight lines, which deviate at the saturation curve downward and in the fog region are nearly parallel to the straight lines of constant enthalpy, according to (3.156). The vapor content of a state in the fog region with temperature t and water content x is determined by following isotherm t until it intersects with the saturation curve $\varphi = 1$. The fraction x_s read off at the intersection point is as vapor, thus the fraction $x - x_s$ is as liquid and/or ice contained in the mixture. The inclined, beam-like pieces of straight lines $\Delta h_{1+x}/\Delta x$ determine, together with the zero point, the direction of a change of state starting from an arbitrary state in the diagram, when water or vapor with an enthalpy in kJ/kg corresponding to the values at the boundary beams is added to the mixture. In order to find the direction of the change of state, a straight line parallel to the line determined by the origin ($h = 0$, $x = 0$) and the boundary beam must be drawn through the point of the initial state.

Changes of State of Humid Air

Heating or Cooling. If a given mixture is heated, the change of state is vertically upwards (1–2 in Fig. 3.31a). If a given mixture is cooled, the change of state is vertically downwards (2–1). As long as states 1 and 2 are in the unsaturated region, the exchanged heat related to 1 kg dry air corresponds to the vertical distance of two state points measured on the enthalpy scale.

$$Q_{12} = m_{\text{air}}(c_{\text{p air}} + c_{\text{p v}}x)(t_2 - t_1)\ , \tag{3.159}$$

where $c_{\text{p air}} = 1.005\,\text{kJ/(kg K)}$ and $c_{\text{p v}} = 1.852\,\text{kJ/(kg K)}$. When humid air is cooled below the dew point of water (1–2 in Fig. 3.31b), precipitation drops out. The discharged heat is

$$Q_{12} = m_{\text{air}}\left[(h_{1+x})_2 - (h_{1+x})_1\right]\ , \tag{3.160}$$

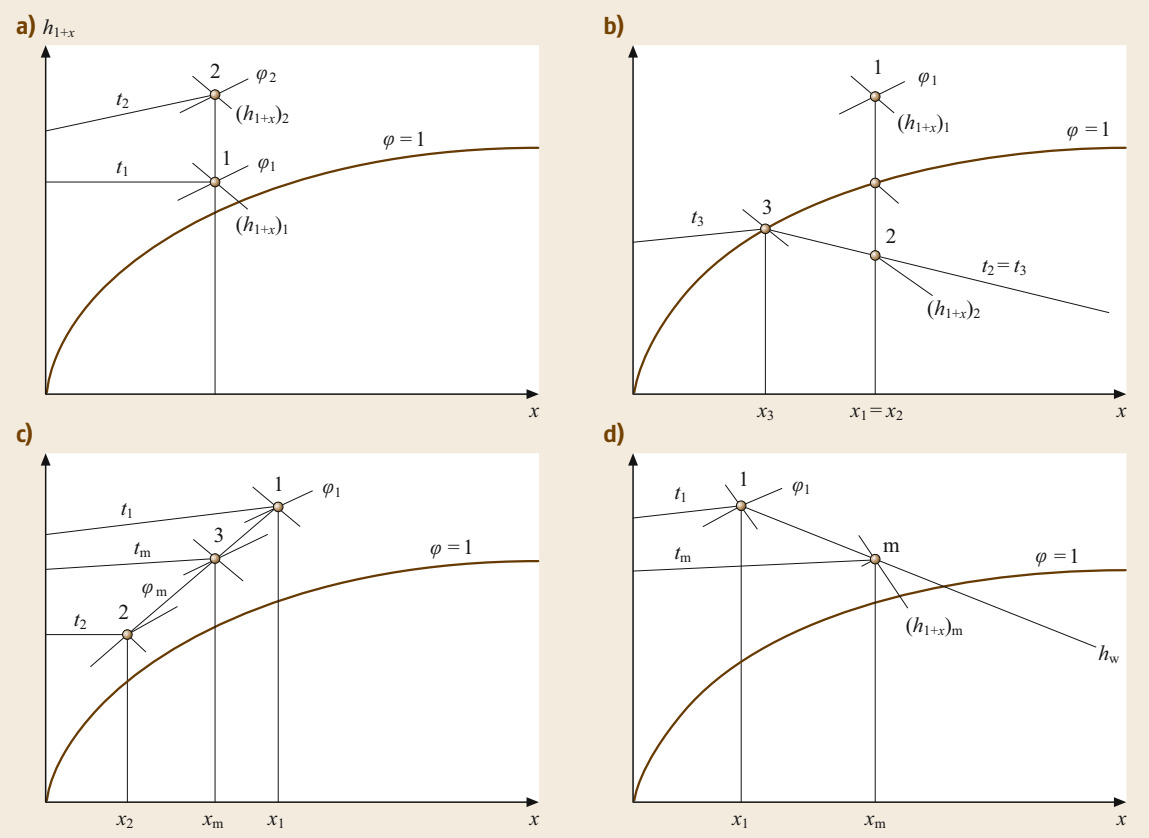

Fig. 3.31a–d Changes of state of humid air: **(a)** heating and cooling **(b)** cooling below dew point **(c)** mixture **(d)** addition of water or vapor

where $(h_{1+x})_1$ is given by (3.155) and $(h_{1+x})_2$ by (3.156). An amount of water specified by

$$m_w = m_{air}(x_1 - x_3) \tag{3.161}$$

is removed.

Example 3.14

Consider 1000 kg of humid air at $t_1 = 30\,°C$, $\varphi_1 = 0.6$, and $p = 1000$ mbar that is cooled to 15 °C. How much precipitation falls out?

The specific humidity results from (3.152) with $p_v = \varphi_1 p_{vs}$. According to Table 3.20, $p_{vs}\,(30\,°C) = 42.46$ mbar, thus

$$x_1 = \frac{R_{air}\,(\varphi_1\,p_{vs})}{R_v\,(p - \varphi_1\,p_{vs})} = \frac{0.2872 \times 0.6 \times 42.46}{0.4615\,(1000 - 0.6 \times 42.46)} = 16.25 \times 10^{-3}\,\text{kg/kg} = 16.25\,\text{g/kg}\,.$$

The 1000 kg of humid air consists of $1000/(1+x_1) = 1000/1.01625\,\text{kg} = 984.01\,\text{kg}$ dry air and $(1000 - 984.01)\,\text{kg} = 15.99\,\text{kg}$ water vapor. The water content at point 3, $x_3 = x_s$, follows from Table 3.20 at $t_3 = 15\,°C$ to $x_3 = 10.79\,\text{g/kg}$, thus

$$m_\ell = 984.01 \times (16.25 - 10.80) \times 10^{-3}\,\text{kg} = 5.36\,\text{kg}\,.$$

Mixture of Two Amounts of Air. If two amounts of humid air at states 1 and 2 are mixed adiabatically (i.e., without heat exchange with the environment), state m after the mixture (point 3 in Fig. 3.31c) is located on the straight line connecting states 1 and 2. Point m is determined by subdividing the straight connecting line 1–2 equivalent to the ratio of the dry air masses m_{air2}/m_{air1}. It is then

$$x_m = \frac{m_{air1}x_1 + m_{air2}x_2}{m_{air1} + m_{air2}}\,. \tag{3.162}$$

Mixing two amounts of saturated air at different temperatures always leads to the formation of fog, as the water amount $x_m - x_s$ drops out, where x_s is the specific humidity at saturation on the isotherm passing through the mixture point in the fog region.

Example 3.15

Consider 1000 kg of humid air at $t_1 = 30\,^\circ\text{C}$ and $\varphi_1 = 0.6$ mixed at 1000 mbar with 1500 kg of saturated humid air at $t_2 = 10\,^\circ\text{C}$. What is the temperature of the mixture?

As calculated in the previous example, $x_1 = 16.25\,\text{g/kg}$. The specific humidity at saturation for $t_2 = 10\,^\circ\text{C}$ given in Table 3.20 is $x_{2s} = 7.7377\,\text{g/kg}$. The dry air masses are

$$m_{air1} = \frac{1000}{1+x_1}\,\text{kg} = \frac{1000}{1+16.25\times10^{-3}}\,\text{kg} = 984.01\,\text{kg}\,,$$

and

$$m_{air2} = \frac{1500}{1+x_{2s}}\,\text{kg} = \frac{1500}{1+7.7377\times10^{-3}}\,\text{kg} = 1488.5\,\text{kg}\,.$$

The water content after mixing therefore becomes

$$x_m = \frac{984.01\times16.25 + 1488.5\times7.7377}{984.01+1488.5}\,\text{g/kg} = 11.12\,\text{g/kg}\,.$$

The enthalpies, calculated according to (3.155), are

$$(h_{1+x})_1 = \left[1.005\times30 + 16.25\times10^{-3}\times(1.86\times30+2500.5)\right]\text{kJ/kg} = 71.69\,\text{kJ/kg}\,,$$

$$(h_{1+x})_2 = \left[1.005\times10 + 7.7377\times10^{-3}\times(1.86\times10+2500.5)\right]\text{kJ/kg} = 29.54\,\text{kJ/kg}\,.$$

The enthalpy of the mixture is

$$(h_{1+x})_m = \frac{m_{air1}(h_{1+x})_1 + m_{air2}(h_{1+x})_2}{m_{air1}+m_{air2}} = \frac{984.01\times71.69 + 1488.5\times29.54}{984.01+1488.5}\,\text{kJ/kg} = 46.31\,\text{kJ/kg}\,.$$

On the other hand, according to (3.155), the following also holds:

$$(h_{1+x})_m = \left[1.005\,t_m + 11.12\times10^{-3}\times(1.86\,t_m + 2500.5)\right]\text{kJ/kg}\,.$$

From this, it follows that $t_m = 18\,^\circ\text{C}$.

Addition of Water or Vapor. If humid air is mixed with m_w kg of water or water vapor, the water content after mixing is $x_m = (m_{air1}x_1 + m_w)/m_{air1}$. The enthalpy is

$$(h_{1+x})_m = \frac{m_{air\,1}(h_{1+x})_1 + m_w h_w}{m_{air1}}\,. \qquad (3.163)$$

The final state after mixing is located in the Mollier diagram for humid air (Fig. 3.31d) on a straight line passing through the origin with the gradient h_w, where $h_w = \Delta h_{1+x}/\Delta x$ is given by the pieces of straight lines on the boundary scale.

Wet-Bulb Temperature. When unsaturated humid air of state t_1, x_1 passes over a water or ice surface, water evaporates or ice sublimates, causing the specific humidity of the humid air to increase. During this increase in specific humidity, the temperature of the water or of the ice decreases and adopts, after a sufficiently long time, a final value, which is called the wet-bulb temperature. The wet-bulb temperature t_{wb} can be determined in the Mollier diagram by looking for the isotherm t_{wb} in the fog region whose extension passes through state 1.

3.10 Heat Transfer

If temperature differences exist between bodies that are not isolated from each other or within different areas of the same body, energy flows from the region of higher temperature to the region of lower temperature. This process is called heat transfer and will continue until the temperatures are balanced. Three modes of heat transfer are distinguished:

- Heat transfer by conduction in solids, motionless liquids, or motionless gases. Kinetic energy is hereby transferred from a molecule or an elementary particle to its neighbor.
- Heat transfer by convection in liquids or gases with bulk fluid motion.
- Heat transfer by radiation takes place in the form of electromagnetic waves and without the presence of an intervening medium.

In engineering, all three modes of heat transfer are often present at the same time.

3.10.1 Steady-State Heat Conduction

Steady-State Heat Conduction Through a Plane Wall

If different temperatures are prescribed on two surfaces of a plane wall with thickness δ, according to Fourier's law, the heat transfer

$$Q = \lambda A \frac{T_1 - T_2}{\delta} \tau$$

flows through the area A over time τ. Here, λ is a material property (SI unit W/(K m)) that is called the thermal conductivity (Table 3.21). The rate of heat transfer is given by $Q/\tau = \dot{Q}$ (SI unit W), and $Q/(\tau A) = \dot{q}$ is referred to as the heat flux (SI unit W/m^2). It holds, then

$$\dot{Q} = \lambda A \frac{T_1 - T_2}{\delta} \quad \text{and} \quad \dot{q} = \lambda \frac{T_1 - T_2}{\delta} . \qquad (3.164)$$

Table 3.21 Thermal conductivities λ (W/(K m))

Similar to electric conduction, where a current I flows only when a voltage U exists to overcome the resistance R ($I = U/R$), heat transfer occurs only when a temperature difference $\Delta T = T_2 - T_1$ exists

$$\dot{Q} = \frac{\lambda A}{s} \Delta T .$$

Analogous to Ohm's law, $R_{th} = \delta/(\lambda A)$ is called the thermal resistance (SI unit K/W).

Fourier's Law

Considering a layer perpendicular to the heat transfer of thickness dx instead of the wall with the finite thickness δ leads to Fourier's law in the differential form

$$\dot{Q} = -\lambda A \frac{\mathrm{d}T}{\mathrm{d}x} \quad \text{and} \quad \dot{q} = -\lambda \frac{\mathrm{d}T}{\mathrm{d}x} , \qquad (3.165)$$

where the minus sign results from the fact that heat transfer occurs in the direction of decreasing temperature. Here, $\dot{Q}$ is the heat transfer in the direction of the x-axis, as is the same for $\dot{q}$. The heat flux in the direction of the three coordinates x, y, and z is given in vector

form by

$$\dot{q} = -\lambda \left(\frac{\partial T}{\partial x} \boldsymbol{e}_x + \frac{\partial T}{\partial y} \boldsymbol{e}_y + \frac{\partial T}{\partial z} \boldsymbol{e}_z \right) \tag{3.166}$$

with the unit vectors $\boldsymbol{e}_x$, $\boldsymbol{e}_y$, and $\boldsymbol{e}_z$. At the same time, (3.166) is the general form of Fourier's law. In this form, Fourier's law holds for isotropic materials, i.e., materials with equal thermal conductivities in the direction of the three coordinate axes.

Steady-State Heat Conduction Through a Tube Wall

According to Fourier's law, the heat transfer rate through a cylindrical area of radius r and length l is $\dot{Q} = -\lambda\, 2\pi r l (\mathrm{d}T/\mathrm{d}r)$. Under steady-state conditions, the heat transfer rate is the same for all radii and thus $\dot{Q} = \text{const}$. It is therefore possible to separate the variables T and r and to integrate from the inner surface of the cylinder, $r = r_\mathrm{i}$ with $T = T_\mathrm{i}$, to an arbitrary location r with temperature T. The temperature profile in a tube wall of thickness $r - r_\mathrm{i}$ becomes

$$T_\mathrm{i} - T = \frac{\dot{Q}}{\lambda\, 2\pi l} \ln \frac{r}{r_\mathrm{i}} \,.$$

With temperature T_o at the outer surface at radius r_o, the heat transfer rate through a tube of thickness $r_\mathrm{o} - r_\mathrm{i}$ and length l becomes

$$\dot{Q} = \lambda\, 2\pi l \frac{T_\mathrm{i} - T_\mathrm{o}}{\ln \frac{r_\mathrm{o}}{r_\mathrm{i}}} \,. \tag{3.167}$$

In order to obtain formal agreement with (3.164), it is also possible to write

$$\dot{Q} = \lambda A_\mathrm{m} \frac{T_\mathrm{i} - T_\mathrm{o}}{\delta} \,, \tag{3.168}$$

where $\delta = r_\mathrm{o} - r_\mathrm{i}$ and $A_\mathrm{m} = (A_\mathrm{o} - A_\mathrm{i})/\ln(A_\mathrm{o}/A_\mathrm{i})$, if $A_\mathrm{o} = 2\pi r_\mathrm{o} l$ is the outer and $A_\mathrm{i} = 2\pi r_\mathrm{i} l$ is the inner surface of the tube. A_m is the logarithmic mean of the outer and inner tube surfaces. The thermal resistance of the tube $R_\mathrm{th} = \delta/(\lambda A_\mathrm{m})$ (SI unit K/W) must be overcome by the temperature difference so that heat transfer occurs.

3.10.2 Heat Transfer and Heat Transmission

If heat is transferred from a fluid to a wall, conducted through the wall and, on the other side, transferred to a second fluid, this process is called heat transmission. In this case, two heat transfer processes and a heat conduction process are connected in series. There exists a steep temperature drop in a layer directly at the wall (Fig. 3.32), while the temperature changes only slightly farther away from the wall. Due to the no-slip condition

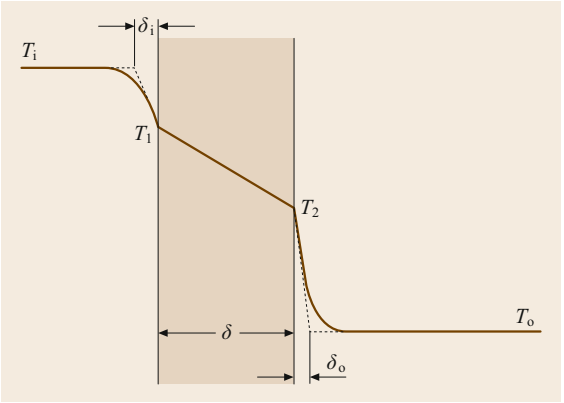

Fig. 3.32 Heat transmission through a flat wall

for the fluid at the wall surface, it can simplistically be assumed that a thin fluid boundary layer at rest, of thickness δ_i and δ_o, respectively, adheres to the wall while the fluid outside balances the temperature differences. In the thin fluid layer, heat transfer is by conduction and, according to Fourier's law, the heat flow transfer rate at the left wall side is given by

$$\dot{Q} = \lambda A \frac{T_\mathrm{i} - T_1}{\delta_\mathrm{i}} \,,$$

where λ is the thermal conductivity of the fluid. The film thickness depends on many parameters such as the velocity of the fluid along the wall and the form and surface conditions of the wall. It has been proven suitable to use the quotient $\lambda/\delta_\mathrm{i} = \alpha$ instead of the film thickness δ_i. This leads to the Newtonian formulation for the heat transfer rate from a fluid to a solid surface

$$\dot{Q} = \alpha A (T_\mathrm{f} - T_0) \,, \tag{3.169}$$

where T_f is the fluid temperature and T_0 is the surface temperature. The quantity α is defined as the heat transfer coefficient (SI unit $\mathrm{W/(m^2K)}$). Orders of magnitude for heat transfer coefficients are given in Table 3.22.

Table 3.22 Heat transfer coefficients α

Natural convection in	α ($\mathrm{W/(m^2K)}$)
Gases	3–20
Water	100–600
Boiling water	1000–20 000
Forced convection in	**α ($\mathrm{W/(m^2K)}$)**
Gases	10–100
Liquids	50–500
Water	500–10 000
Condensing vapor	1000–100 000

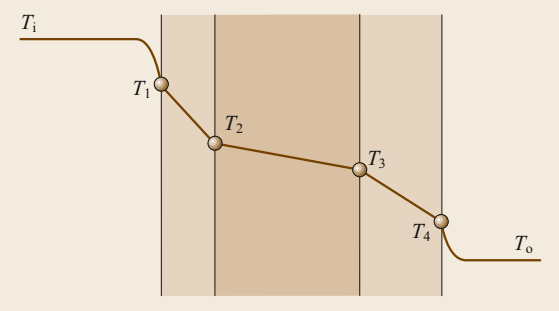

Fig. 3.33 Heat transmission through a plane, multilayered wall

The basics needed for the calculation of α are contained in Sect. 3.10.4. Following Ohm's law $I = (1/R) \times U$, the quantity $1/(\alpha A) = R_{th}$ is also called the convective heat transfer resistance (SI units K/W). It must be overcome by the temperature difference $\Delta T = T_f - T_0$ to enable the heat transfer $\dot{Q}$. In Fig. 3.32, the heat transfer must overcome three single resistances in series, which sum to the total resistance.

Heat Transmission Through a Plane Wall

The heat transfer passing through a plane wall (Fig. 3.32) is given by

$$\dot{Q} = kA(T_i - T_o) \,, \tag{3.170}$$

where $1/(kA)$ is the total heat resistance, which is, again, the sum of the individual resistances

$$\frac{1}{kA} = \frac{1}{\alpha_i A} + \frac{\delta}{\lambda A} + \frac{1}{\alpha_o A} \,. \tag{3.171}$$

The quantity k, defined by (3.170), is called the heat transmission coefficient (SI units $W/(m^2K)$). If the wall consists of several homogeneous layers (Fig. 3.33) with thicknesses $\delta_1, \delta_2, \ldots$ and thermal conductivities $\lambda_1, \lambda_2, \ldots$, (3.170) holds likewise with the total resistance

$$\frac{1}{kA} = \frac{1}{\alpha_i A} + \sum \frac{\delta_j}{\lambda_j A} + \frac{1}{\alpha_o A} \,. \tag{3.172}$$

Example 3.16

The wall of a cold store consists of a 5-cm-thick, internal concrete layer ($\lambda = 1\,W/(K\,m)$), a 10-cm-thick cork stone insulation ($\lambda = 0.04\,W/(K\,m)$), and a 50-cm-thick external brick wall. The inner heat transfer coefficient is $\alpha_i = 7\,W/(m^2\,K)$, and the outer coefficient is $\alpha_o = 20\,W/(m^2\,K)$. What is the heat transfer rate through $1\,m^2$ of the wall if the temperatures inside and outside are -5 and $25\,^\circ C$, respectively?

According to (3.172) the heat transmission resistance is

$$\frac{1}{kA} = \left(\frac{1}{7 \times 1} + \frac{0.05}{1 \times 1} + \frac{0.1}{0.04 \times 1} + \frac{0.5}{0.75 \times 1} + \frac{1}{20 \times 1} \right) \frac{K}{W} = 3.41 \frac{K}{W} \,.$$

The heat transfer rate is $\dot{Q} = (1/3.41)\,(-5 - 25)\,W$, $|\dot{Q}| = 8.8\,W$.

Heat Transmission Through Tubes

For heat transmission through tubes, (3.170) again holds, where the thermal resistance is the sum of the single resistances

$$\frac{1}{kA} = \frac{1}{\alpha_i A_i} + \frac{\delta}{\lambda A_m} + \frac{1}{\alpha_o A_o} \,.$$

The heat transmission coefficient k is usually related to the outer tube surface $A = A_o$, which is often easier to determine. The following equation therefore holds:

$$\frac{1}{kA_o} = \frac{1}{\alpha_i A_i} + \frac{\delta}{\lambda A_m} + \frac{1}{\alpha_o A_o} \,, \tag{3.173}$$

where $A_m = (A_o - A_i)/\ln(A_o/A_i)$. If the tube consists of several homogeneous layers with thicknesses $\delta_1, \delta_2, \ldots$ and thermal conductivities $\lambda_1, \lambda_2, \ldots$, (3.170) likewise holds for the total resistance

$$\frac{1}{kA_o} = \frac{1}{\alpha_i A_i} + \sum \frac{\delta_j}{\lambda_j A_{mj}} + \frac{1}{\alpha_o A_o} \,, \tag{3.174}$$

where the total resistance must be summed from the single layers j with their respective mean logarithmic areas

$$A_{mj} = (A_{oj} - A_{ij}) \ln\left(\frac{A_{oj}}{A_{ij}}\right) .$$

3.10.3 Transient Heat Conduction

During transient heat conduction, the temperatures vary with respect to time. In a plane wall with prescribed surface temperatures, the temperature profile is no longer linear as the heat transfer into the wall differs from the heat transfer out. The difference between the transfer in and the heat transfer out increases (or decreases) the internal energy of the wall, thus its temperature is a function of time. For plane walls with heat transfer

in the direction of the x-axis, Fourier's heat conduction equation holds

$$\frac{\partial T}{\partial \tau} = a\frac{\partial^2 T}{\partial x^2} \,. \tag{3.175}$$

Multidimensional heat conduction is represented by the following relation:

$$\frac{\partial T}{\partial \tau} = a\left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2}\right) \,. \tag{3.176}$$

In this form, both equations assume constant thermal conductivity λ (isotropic). The quantity $a = \lambda/(\varrho\, c)$ is defined as the thermal diffusivity (SI units m^2/s), numerical values for which are given in Table 3.23.

For the solution of Fourier's equation, it is suitable to introduce—as in other heat transfer problems—dimensionless quantities, which reduce the number of variables. Equation (3.175) is considered to demonstrate the basic procedure. The dimensionless temperature is set to $\Theta = (T - T_c)/(T_0 - T_c)$, where T_c is a characteristic constant temperature and T_0 is the initial temperature. If the cooling of a plate with an initial temperature T_0 in a cold environment is considered, T_c could be, for example, the ambient temperature T_{env}. All lengths are related to a characteristic length X, e.g., half of the plate thickness. Furthermore, it is suitable to introduce the dimensionless time, which is called the *Fourier number*, as $\mathrm{Fo} = a\tau/X^2$. The solution of the heat conduction equation then has the form

$$\Theta = f\frac{x}{X, \mathrm{Fo}} \,.$$

In many problems, the heat transfer from the surface of a body occurs by convection to the surrounding fluid at temperature T_{env}. The energy balance then holds at the surface (index w = wall)

$$-\lambda\left(\frac{\partial T}{\partial x}\right)_w = \alpha(T_w - T_{env})$$

or

$$\frac{1}{\Theta_w}\left(\frac{\partial \Theta}{\partial \xi}\right)_w = -\frac{\alpha X}{\lambda} \,,$$

where $\xi = x/X$, $\Theta = (T - T_{env})/(T_0 - T_{env})$, and $\Theta_w = (T_w - T_{env})/(T_0 - T_{env})$. The solution is also a function of the dimensionless quantity $\alpha X/\lambda$, which is defined as the Biot number Bi, where the thermal conductivity λ of the body is assumed to be constant, and α is the heat transfer coefficient between the body and the surrounding fluid. Solutions of (3.175) have the form

$$\Theta = f\frac{x}{X}, \mathrm{Fo}, \mathrm{Bi} \,. \tag{3.177}$$

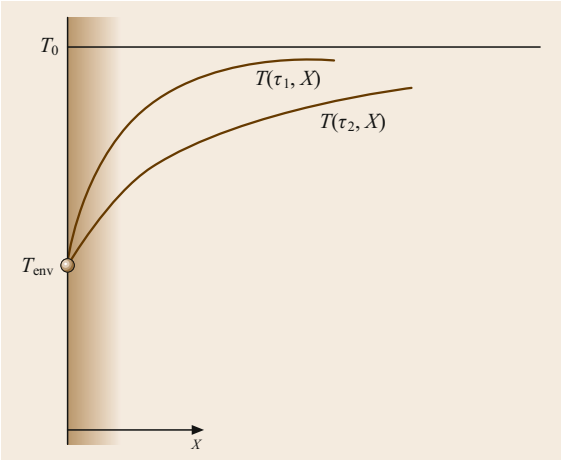

Fig. 3.34 Semiinfinite body

Semiinfinite Body

Temperature changes may also take place in a region that is thin in comparison with the overall dimensions of the body. Such a body is called semiinfinite. In this case, a semiinfinite plane wall (Fig. 3.34) with a constant initial temperature T_0 is considered. At time $\tau = 0$, the surface temperature of the wall is reduced to $T(x = 0) = T_{env}$ and then remains constant. The temperature profiles at different times $\tau_1, \tau_2 \ldots$ are given by

$$\frac{T - T_{env}}{T_0 - T_{env}} = f\left(\frac{x}{2\sqrt{a\tau}}\right) \tag{3.178}$$

with the Gaussian error function $f(x/(2\sqrt{a\tau}))$; see Fig. 3.35. The heat flux at the surface results from the differentiation $\dot{q} = -\lambda(\partial T/\partial x)_{x=0}$, which yields

$$\dot{q} = \frac{b}{\sqrt{\pi\tau}}(T_{env} - T_0) \,. \tag{3.179}$$

The heat penetration coefficient $b = \sqrt{\lambda \varrho c}$ (SI units W s$^{1/2}$/(m^2 K)) (Table 3.24) is a measure for the heat transfer that would penetrate into the body at a given time, if the surface temperature were suddenly increased by the amount $T_{\text{env}} - T_0$ as compared with the initial temperature T_0.

Example 3.17

A sudden change in weather causes the temperature at the Earth's surface to drop from +5 to −5 °C. How much does the temperature decrease at a depth of 1 m after 20 days? The thermal diffusivity of the soil is $a = 6.94 \times 10^{-7}$ m^2/s. According to (3.178), the decrease

Table 3.24 Heat penetration coefficients $b = \sqrt{\lambda \varrho c}$

	b ($\mathrm{W\,s^{1/2}/(m^2\,K)}$)

Gases	6

is

$$\frac{T-(-5)}{5-(-5)} = f\left(\frac{1}{2(6.94\times10^{-7}\times20\times24\times3600)^{1/2}}\right) = f(0.456)\,.$$

Figure 3.35 gives $f(0.456) = 0.48$, thus $T = -0.2\,^{\circ}\mathrm{C}$.

Finite Heat Transfer at the Surface. According to Fig. 3.34, heat transfer is by convection from the surface of a body to the environment. At the surface, the relation $\dot{q} = -\lambda(\partial T/\partial x) = \alpha(T_\mathrm{w} - T_\mathrm{env})$ holds, with the ambient temperature T_env and the time-variable wall temperature $T_\mathrm{w} = T(x=0)$. In this case, (3.178) no longer holds. Instead, the heat transfer rate is given by

$$\dot{q} = \frac{b}{\sqrt{\pi\tau}}(T_\mathrm{env} - T_0)\Phi(z)\,, \qquad (3.180)$$

where

$$\Phi(z) = 1 - \frac{1}{2z^2} + \frac{1\times3}{2^2z^4} - \ldots + (-1)^{n-1}\left(\frac{1\times3\times\ldots\times(2n-3)}{2^{n-1}z^{2n-2}}\right) \quad \text{and}$$

$$z = \alpha\frac{\sqrt{a\tau}}{\lambda}\,.$$

Two Semiinfinite Bodies in Thermal Contact

Two semiinfinite bodies at different, but initially constant, temperatures T_1 and T_2 with the thermal properties λ_1, a_1 and λ_2, a_2 are suddenly brought into contact at time $t = 0$ (Fig. 3.36). After a very short time at both sides of the contact area, a temperature T_m is present and remains constant. This temperature is given by

$$\frac{T_\mathrm{m} - T_1}{T_2 - T_1} = \frac{b_2}{b_1 + b_2}\,.$$

The contact temperature T_m is closer to the temperature of the body with the higher heat penetration coefficient b. One of the values b can be determined by measuring T_m, if the other value is known.

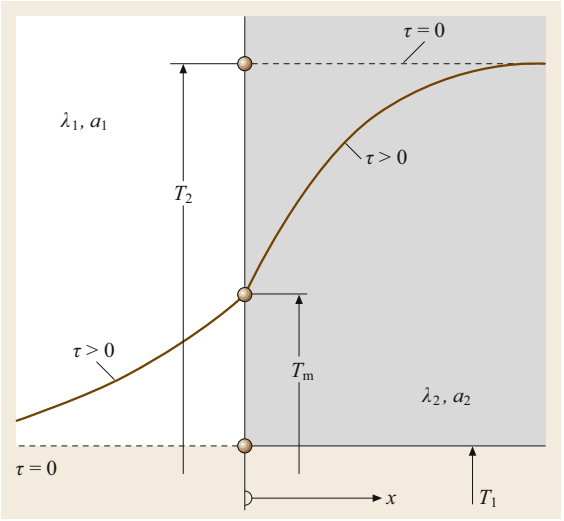

Fig. 3.36 Contact temperature T_m between two semiinfinite bodies

Temperature Equalization in Simple Bodies

A simple body such as a plate, a cylinder, or a sphere may have a uniform temperature T_0 at time $\tau = 0$. Afterwards, however, it is cooled or heated due to heat transfer between the body and a surrounding fluid of temperature T_env given by the boundary condition $-\lambda(\partial T/\partial n)_\mathrm{w} = \alpha(T_\mathrm{w} - T_\mathrm{env})$, where n is the coordinate perpendicular to the body surface.

Plane Plate. The temperature profile shown in Fig. 3.37 is described by an infinite series. However, for $a\tau/X^2 \geq 0.24$ (where $a = \lambda/(\varrho c)$ is the thermal diffusivity), the following relation provides a good approximation:

$$\frac{T - T_\mathrm{env}}{T_0 - T_\mathrm{env}} = C\exp\left(-\delta^2\frac{a\tau}{X^2}\right)\cos\left(\delta\frac{x}{X}\right) \qquad (3.181)$$

with less than a 1% error in temperature. The constants C and δ depend, according to Table 3.25, on the Biot number $\mathrm{Bi} = \alpha X/\lambda$. When $x = X$, (3.181) leads to the surface temperature T_w at the wall. The heat transfer rate follows from $\dot{Q} = -\lambda A(\partial T/\partial x)_{x=X}$.

Cylinder. The radial coordinate r replaces the coordinate x in Fig. 3.37, and the radius of the cylinder is R. Again, the temperature profile is described by an infinite series, which can be approximated for $a\tau/R^2 \geq 0.21$ by

$$\frac{T - T_\mathrm{env}}{T_0 - T_\mathrm{env}} = C\exp\left(-\delta^2\frac{a\tau}{R^2}\right)I_0\left(\delta\frac{r}{R}\right) \qquad (3.182)$$

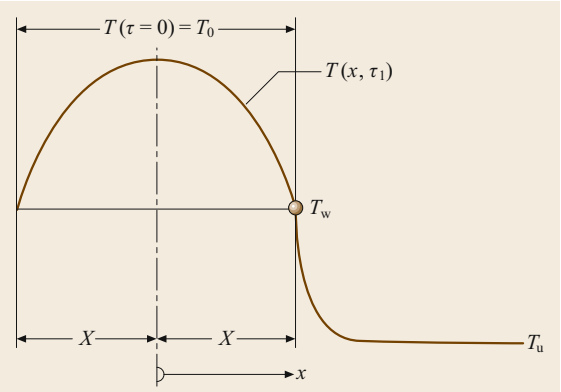

Fig. 3.37 Cooling of a flat plate

with less than 1% error. The term I_0 is a Bessel function of zeroth order. Its values are presented in tables [3.20]. The constants C and δ depend, according to Table 3.26, on the Biot number. When $r = R$, the surface temperature at the wall results from (3.182) and the heat transfer rate from $\dot{Q} = -\lambda A(\partial T/\partial r)_{r=R}$, where the first derivative of the Bessel function $I_0' = I_1$ appears. The Bessel function of first order I_1 is also given in [3.21].

Sphere. The cooling or heating of a sphere of radius R is also described by an infinite series. For $a\tau/R^2 \geq 0.18$, the temperature profile can be approximated by

$$\frac{T - T_{\text{env}}}{T_0 - T_{\text{env}}} = C \exp\left(-\delta^2 \frac{a\tau}{R^2}\right) \frac{\sin\left(\delta \frac{\mathrm{r}}{R}\right)}{\delta \frac{\mathrm{r}}{R}} \qquad (3.183)$$

with less than 2% error. The constants C and δ depend, according to Table 3.27, on the Biot number.

3.10.4 Heat Transfer by Convection

If heat transfer in fluids with bulk fluid motion is considered, in addition to (molecular) heat conduction, energy transport by convection must be taken into account. Each volume element of the fluid possesses internal energy, which is transported by the flow and, in the case considered here, is transferred by convection to a solid body.

Dimensionless Characteristic Numbers

The basis for the description of processes of convective transport is the use of similarity mechanics. These descriptions allow for a considerable reduction of the number of influencing parameters and for the expression of the general heat transfer laws for geometrically similar bodies and different substances. The following dimensionless characteristic numbers are of importance:

- Nusselt number

$$\mathrm{Nu} = \frac{\alpha l}{\lambda} ,$$

- Reynolds number

$$\mathrm{Re} = \frac{wl}{\nu} ,$$

- Prandtl number

$$\mathrm{Pr} = \frac{\nu}{a} ,$$

- Péclet number

$$\mathrm{Pe} = \frac{wl}{a} = \mathrm{Re}\,\mathrm{Pr} ,$$

- Grashof number

$$\mathrm{Gr} = l^3 g \beta \Delta \frac{T}{\nu^2} ,$$

- Stanton number

$$\mathrm{St} = \frac{\alpha}{\varrho\, w c_\mathrm{p}} = \frac{\mathrm{Nu}}{\mathrm{Re\,Pr}} ,$$

- Geometric characteristic numbers

$$\frac{l_n}{l} , \quad n = 1, 2, \ldots$$

The variables signify the following:

λ thermal conductivity of the fluid
l a characteristic length of the flow domain $l_1, l_2, \ldots$
ν the kinematic viscosity of the fluid
ϱ density
a $= \lambda/(\varrho\, c_p)$ thermal diffusivity
c_p constant-pressure specific heat of the fluid
g gravitational acceleration
ΔT $= T_\mathrm{w} - T_\mathrm{f}$ difference between the wall temperature T_w of a cooled or heated body and the mean temperature T_f of the fluid along the body
β thermal volume expansivity at the wall temperature with $\beta = 1/T_\mathrm{w}$ for ideal gases.

The Prandtl number is a fluid property (Table 3.23).

Forced and natural convection are distinguished as follows: In forced convection, the fluid motion is caused by external forces, e.g., by the pressure increase in a pump. In natural convection, the fluid motion is caused by density differences in the fluid and the corresponding buoyancy effects in a gravitational field. These density differences usually arise due to temperature differences, rarely due to pressure differences. In mixtures, density differences are also caused by concentration differences. The heat transfer in forced convection is described by equations of the form

$$\mathrm{Nu} = f_1 \left(\mathrm{Re}, \mathrm{Pr}, \frac{l_n}{l} \right) , \tag{3.184}$$

and in natural convection by

$$\mathrm{Nu} = f_2 \left(\mathrm{Gr}, \mathrm{Pr}, \frac{l_n}{l} \right) . \tag{3.185}$$

The desired heat transfer coefficient is obtained from the Nusselt number by $\alpha = \mathrm{Nu}\lambda/l$. The functions f_1 and f_2 can be determined theoretically only for special cases. In general, they must be determined through experimentation and depend on the shape of the cooling or heating areas (even, vaulted, smooth, rough, or finned), the flow structure and, usually to a minor extent, on the direction of the heat transfer (heating or cooling).

Heat Transfer Without Change of Phase

Forced Convection.

Laminar Flow Along a Flat Plate. According to *Pohlhausen* [3.22], for the mean Nusselt number of a plate of length l, the following relation holds:

$$\mathrm{Nu} = 0.664\, \mathrm{Re}^{1/2} \mathrm{Pr}^{1/3} , \tag{3.186}$$

where $\mathrm{Nu} = \alpha l/\lambda$, $\mathrm{Re} = wl/\nu < 10^5$, and $0.6 \le \mathrm{Pr} \le 2000$. The material properties must be evaluated at the mean fluid temperature $T_\mathrm{m} = (T_\mathrm{w} - T_\infty)/2$, where T_w is the wall temperature and T_∞ is the free-stream temperature far beyond the wall surface.

Turbulent Flow Along a Flat Plate. From about $\mathrm{Re} = 5 \times 10^5$, the boundary layer becomes turbulent. The mean Nusselt number of a plate of length l in this case is

$$\mathrm{Nu} = \frac{0.037\, \mathrm{Re}^{0.8} \mathrm{Pr}}{1 + 2.443\, \mathrm{Re}^{-0.1} (\mathrm{Pr}^{2/3} - 1)} , \tag{3.187}$$

where $\mathrm{Nu} = \alpha l/\lambda$, $\mathrm{Re} = wl/\nu$, $5 \times 10^5 < \mathrm{Re} < 10^7$, and $0.6 \le \mathrm{Pr} \le 2000$. The material properties must be evaluated at the mean fluid temperature $T_\mathrm{m} = (T_\mathrm{w} - T_\infty)/2$. T_w is the wall temperature and, T_∞ is the free-stream temperature far beyond the wall surface.

Flow Through Pipes in General. Below a Reynolds number of $\mathrm{Re} = 2300$ ($\mathrm{Re} = wd/\nu$, where w is the mean cross-sectional velocity and d is the pipe diameter), the flow is laminar, while above $\mathrm{Re} = 10^4$, the flow is turbulent. In the range $2300 < \mathrm{Re} < 10^4$, whether the flow is laminar or turbulent depends on the roughness of the pipe, the means of inflow, and the shape of the pipe in the inflow section. The mean heat transfer coefficient α over the pipe length l is defined by $\dot{q} = \alpha \Delta\vartheta$, with the mean logarithmic temperature difference described by

$$\Delta\vartheta = \frac{(T_\mathrm{w} - T_\mathrm{in}) - (T_\mathrm{w} - T_\mathrm{out})}{\ln \frac{T_\mathrm{w} - T_\mathrm{in}}{T_\mathrm{w} - T_\mathrm{out}}} , \tag{3.188}$$

where T_w is the wall temperature, T_in is the temperature at the inlet, and T_out is the temperature at the outlet cross-section.

Laminar Flow Through Pipes. A flow is termed hydrodynamically developed if the velocity profile no longer changes in the flow direction. In a laminar flow of a highly viscous fluid, the velocity profile adopts the shape of a Poiseuillean parabola after only a short distance from the inlet. The mean Nusselt number at constant wall temperature can be calculated exactly via an infinite series (the Graetz solution), which, however,

converges poorly. According to *Stephan* [3.23], as an approximate solution for the hydrodynamically developed laminar flow, the following equation holds:

$$\mathrm{Nu}_0 = \frac{3.657}{\tanh(2.264X^{1/3} + 1.7X^{2/3})} + \frac{0.0499}{X}\tanh X\,, \qquad (3.189)$$

where $\mathrm{Nu}_0 = \alpha d/\lambda$, $X = l/(d\mathrm{Re}\,\mathrm{Pr})$, $\mathrm{Re} = wd/\nu$, and $\mathrm{Pr} = \nu/a$. This equation is valid for laminar flow ($\mathrm{Re} \leq 2300$) in the entire range $0 \leq X \leq \infty$ and the maximum deviation from the exact values of the Nusselt number is 1%. The fluid properties must be evaluated at the mean fluid temperature $T_\mathrm{m} = (T_\mathrm{w} + T_\mathrm{B})/2$, where $T_\mathrm{B} = (T_\mathrm{in} + T_\mathrm{out})/2$.

If a fluid enters a pipe at an approximately constant velocity, the velocity profile changes along the flow path until it reaches the Poiseuillean parabola after a distance described by the equation $l/(d\mathrm{Re}) = 5.75 \times 10^{-2}$. According to *Stephan* [3.23], for this case, that of a hydrodynamically developed laminar flow, the following equation holds for the range $0.1 \leq \mathrm{Pr} \leq \infty$:

$$\frac{\mathrm{Nu}}{\mathrm{Nu}_0} = \frac{1}{\tanh(2.43\,\mathrm{Pr}^{1/6}X^{1/6})}\,, \qquad (3.190)$$

where $\mathrm{Nu} = \alpha d/\lambda$ and the quantities are defined as above. The error is less than 5% for $1 \leq \mathrm{Pr} \leq \infty$ but is up to 10% for $0.1 \leq \mathrm{Pr} < 1$. The fluid properties must be evaluated at the mean fluid temperature $T_\mathrm{m} = (T_\mathrm{w} + T_\mathrm{B})/2$, where $T_\mathrm{B} = (T_\mathrm{in} + T_\mathrm{out})/2$.

Heat Transfer for Turbulent Flow Through Pipes. For a hydrodynamically developed flow ($l/d \geq 60$), the McAdam equation holds in the range $10^4 \leq \mathrm{Re} \leq 10^5$ and $0.5 < \mathrm{Pr} < 100$:

$$\mathrm{Nu} = 0.024\,\mathrm{Re}^{0.8}\mathrm{Pr}^{1/3}\,. \qquad (3.191)$$

The fluid properties have to be evaluated at the mean temperature $T_\mathrm{m} = (T_\mathrm{w} + T_\mathrm{B})/2$ with $T_\mathrm{B} = (T_\mathrm{in} + T_\mathrm{out})/2$.

For hydrodynamically undeveloped flow and for developed flow, Petukhov's equation (modified by Gnielinski) holds in the range $10^4 \leq \mathrm{Re} \leq 10^6$ and $0.6 \leq \mathrm{Pr} \leq 1000$:

$$\mathrm{Nu} = \frac{\mathrm{Re}\,\mathrm{Pr}\zeta/8}{1 + 12.7\sqrt{\zeta/8}(\mathrm{Pr}^{2/3} - 1)}\left[1 + \left(\frac{d}{l}\right)^{2/3}\right], \qquad (3.192)$$

where the friction factor $\zeta = (0.78\ln\mathrm{Re} - 1.5)^{-2}$, $\mathrm{Nu} = \alpha d/\lambda$, and $\mathrm{Re} = wd/\nu$. The fluid properties must be evaluated at the mean temperature $T_\mathrm{m} = (T_\mathrm{w} + T_\mathrm{B})/2$. Under otherwise similar conditions, the heat transfer coefficients are larger in pipe bends than in straight pipes with the same cross section. For a pipe bend with a bend diameter D, the following equation holds, according to Hausen, for turbulent flow:

$$\alpha = \alpha_\mathrm{straight}\left[1 + (21\,\mathrm{Re}^{0.14})\left(\frac{d}{D}\right)\right]. \qquad (3.193)$$

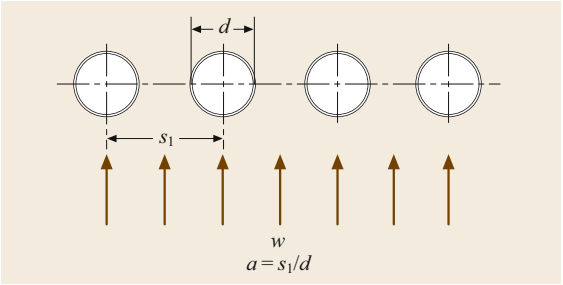

Fig. 3.38 A row of pipes placed transversely in a flow

A Single Pipe Placed Transversely in a Flow. The heat transfer coefficient for a pipe placed transversely in a flow can be determined from Gnielinski's equation:

$$\mathrm{Nu} = 0.3 + \left(\mathrm{Nu}_\ell^2 + \mathrm{Nu}_\mathrm{t}^2\right)^{1/2}\,, \qquad (3.194)$$

where the Nusselt number Nu_ℓ of the laminar plate flow is described according to (3.186), Nu_t of the turbulent plate flow is described according to (3.187), and $\mathrm{Nu} = \alpha l/\lambda$, $1 < \mathrm{Re} = wl/\nu < 10^7$, and $0.6 < \mathrm{Pr} < 1000$. For length l, the overflowed length $l = d\pi/2$ must be inserted. The fluid properties must be evaluated at the mean temperature $T_\mathrm{m} = (T_\mathrm{in} + T_\mathrm{out})/2$. This equation holds for mean turbulence intensities of 6–10%, which can be expected in technical applications.

A Row of Pipes Placed Transversely in a Flow. Mean heat transfer coefficients for a single row of pipes placed transversely in a flow (Fig. 3.38) can also be determined using (3.194). Now, however, the Reynolds number must be calculated with the mean velocity w_m in the pipe row placed transversely in the flow. The Reynolds number is described by the equation: $\mathrm{Re} = w_\mathrm{m}l/\nu$, where $w_\mathrm{m} = w/\psi$, w is the far-field velocity and $\psi = 1 - \pi/(4a)$ is the void space fraction, where $a = s_1/d$ (Fig. 3.38).

A Pipe Bundle. If the pipes are placed in straight lines (Fig. 3.39a), the axes of all the pipes are consecutively in the flow direction. If the arrangement is staggered (Fig. 3.39b), the axes of a pipe row are shifted in comparison with the axes of the row in front. The

heat transfer depends additionally on the crosswise and longwise division of the pipes, $a = s_1/d$ and $b = s_2/d$. The determination of the heat transfer coefficient starts with the calculation of the Nusselt number for a single pipe placed transversely in the flow, according to (3.194), in which the Reynolds number contains the mean velocity w_m in the pipe bundle: $\mathrm{Re} = w_m l/\nu$, where $w_m = w/\psi$, w is the far-field velocity of the pipe row, and ψ is the void space fraction $\psi = 1 - \pi/(4a)$ for $b > 1$ and $\psi = 1 - \pi/(4ab)$ for $b < 1$. The Nusselt number determined in this way must be multiplied by an arrangement factor f_A. This leads to the Nusselt number $\mathrm{Nu_B} = \alpha_B l/\lambda$ (where $l = d\pi/2$) of the bundle

$$\mathrm{Nu_B} = f_A \mathrm{Nu} \,. \tag{3.195}$$

For a straight arrangement, the following holds:

$$f_A = 1 + 0.7 \frac{\frac{b}{a} - 0.3}{\psi^{3/2}\left(\frac{b}{a} + 0.7\right)^2} \,, \tag{3.196}$$

and for a staggered arrangement

$$f_A = 1 + \frac{2}{3b} \,. \tag{3.197}$$

The heat flux is $\dot{q} = \alpha \Delta\vartheta$ with $\Delta\vartheta$ according to (3.188). Equations (3.196) and (3.197) hold for pipe bundles consisting of ten or more pipe rows. For heat exchangers with fewer pipe rows, the heat transfer coefficient (3.195) must be multiplied by a factor $(1 + (n - 1) f_A/n)$, where n is the number of pipe rows.

Natural Convection. The heat transfer coefficient for a vertical wall can be calculated by using the equation of Churchill and Chu:

$$\mathrm{Nu} = \left(0.825 + \frac{0.387\,\mathrm{Ra}^{1/6}}{[1 + (0.492/\mathrm{Pr})^{9/16}]^{8/27}}\right)^2 \,, \tag{3.198}$$

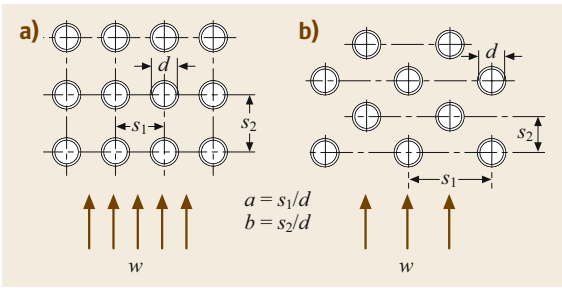

Fig. 3.39a,b Arrangement of pipes in pipe bundles: **(a)** in straight lines and **(b)** staggered

in which the mean Nusselt number $\mathrm{Nu} = \alpha l/\lambda$ is formed with the wall height l, and the Rayleigh number is defined as $\mathrm{Ra} = \mathrm{GrPr}$, where the Grashof number is described as

$$\mathrm{Gr} = \frac{g l^3}{\nu^2} \frac{\varrho_\infty - \varrho_w}{\varrho_w}$$

and the Prandtl number as $\mathrm{Pr} = \nu/a$.

If natural convection is caused solely by temperature differences, the Grashof number can be written as

$$\mathrm{Gr} = \frac{g l^3}{\nu^2} \beta (T_w - T_\infty) \,,$$

where the volume expansivity is denoted by β, where $\beta = 1/T_w$ for ideal gases. Equation (3.198) holds in the range $0 < \mathrm{Pr} < \infty$ and $0 < \mathrm{Ra} < 10^{12}$. The fluid properties must be evaluated at the mean temperature $T_m = (T_w - T_\infty)$. A similar equation holds according to Churchill and Chu also for natural convection in a horizontal cylinder:

$$\mathrm{Nu} = \left(0.60 + \frac{0.387\,\mathrm{Ra}^{1/6}}{[1 + (0.559/\mathrm{Pr})^{9/16}]^{8/27}}\right)^2 \,. \tag{3.199}$$

The same definitions used in (3.198) hold over the range of validity $0 < \mathrm{Pr} < \infty$ and $10^{-5} \le \mathrm{Ra} \le 10^{12}$, and the characteristic length is the diameter d. For *horizontal rectangular plates*, the following holds for $0 < \mathrm{Pr} < \infty$:

$$\mathrm{Nu} = 0.766(\mathrm{Ra} f_2)^{1/5} \quad \text{if} \quad \mathrm{Ra} f_2 < 7 \times 10^4 \tag{3.200}$$

and

$$\mathrm{Nu} = 0.15(\mathrm{Ra} f_2)^{1/3} \quad \text{if} \quad \mathrm{Ra} f_2 > 7 \times 10^4 \,, \tag{3.201}$$

where

$$f_2 = \left[1 + \left(\frac{0.322}{\mathrm{Pr}}\right)^{11/20}\right]^{-20/11} \,,$$

where $\mathrm{Nu} = \alpha l/\lambda$, if l is the shorter side of the rectangle.

Heat Transfer in Condensation and in Boiling

Condensation. If the temperature of a wall surface is lower than the saturation temperature of adjacent vapor, the vapor condenses at the wall surface. Depending on the wetting characteristics, the condensate forms drops or a continuous liquid film. The heat transfer coefficients are usually larger for dropwise condensation than for film condensation. However, in order to maintain dropwise condensation for a certain amount of time, particular measures such as the application of dewetting agents are necessary. Dropwise condensation therefore appears rather seldom.

Film Condensation. If the condensate flows as a laminar film on a vertical wall of height l, the mean heat transfer coefficient α is

$$\alpha = 0.943 \left(\frac{\varrho g r \lambda^3}{\nu (T_s - T_w)} \frac{1}{l} \right)^{1/4} . \tag{3.202}$$

For condensation on horizontal single pipes with an outer diameter d, the following relation holds:

$$\alpha = 0.728 \left(\frac{\varrho g r \lambda^3}{\nu (T_s - T_w)} \frac{1}{l} \right)^{1/4} . \tag{3.203}$$

These equations require that no noticeable shear stress be exerted by the vapor on the condensate film. At Reynolds number $\mathrm{Re}_\delta = w_m \delta / \nu$ (where w_m is the velocity of the condensate, δ the film thickness, and ν the kinematic viscosity) between 75 and 1200 the transition to turbulent flow in the condensate film gradually takes place. In the transition range, the following relation holds:

$$\alpha = 0.22 \frac{\lambda}{\left(\frac{\nu^2}{g} \right)^{1/3}} , \tag{3.204}$$

whereas for turbulent film flow ($\mathrm{Re}_\delta > 1200$), the following relation according to Grigull holds:

$$\alpha = 0.003 \left(\frac{\lambda^3 g \, (T_s - T_w)}{\varrho \nu^3 r} l \right)^{1/2} . \tag{3.205}$$

Equations (3.204) and (3.205) are valid also for vertical pipes and plates but not for horizontal pipes.

Evaporation. If a liquid in a container is heated, evaporation starts after the boiling temperature T_s is exceeded. For small excess wall temperatures $T_w - T_s$, the liquid evaporates only on its free surface (silent boiling). Heat is transported by the buoyancy flow from the heating surface to the free surface of the liquid. For higher excess wall temperatures, vapor bubbles are formed at the heating surface (nucleate boiling) and rise. They increase the movement of the liquid and thus the heat transfer. With increasing excess wall temperature, the bubbles merge more and more into a continuous vapor film, whereby the heat transfer is decreased (transition boiling). Figure 3.40 shows the different heat transfer ranges. The heat transfer coefficient α is defined as

$$\alpha = \frac{\dot{q}}{T_w - T_s} ,$$

where the heat flux is $\dot{q}$ in $\mathrm{W/m^2}$.

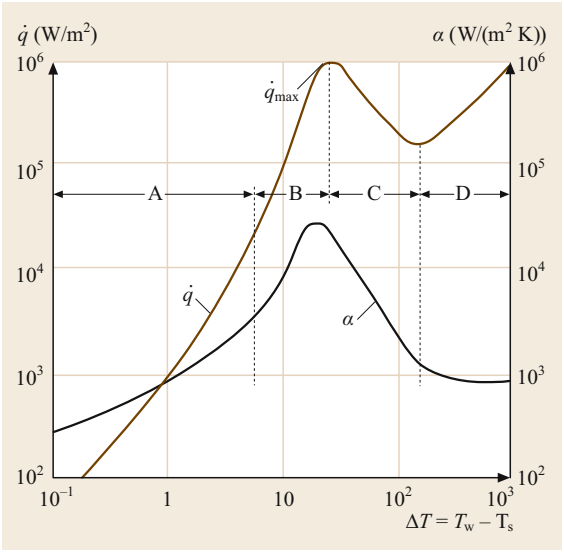

Fig. 3.40 Boiling ranges for water of 1 bar. A: natural convection (silent boiling), B nucleate boiling, C transition boiling, D film boiling

Industrial evaporators work in the range of silent boiling or, more often, in the nucleate boiling range. In the silent boiling range, the laws for heat transfer in natural convection hold, (i.e., (3.198) and (3.199)). In the nucleate boiling region,

$$\alpha = c \dot{q}^n F(p) \quad \text{with } 0.5 < n < 0.8 .$$

For water at boiling pressures between 0.5 and 20 bar, according to *Fritz* [3.24], the following relation holds:

$$\alpha = 1.95 \dot{q}^{0.72} p^{0.24} \tag{3.206}$$

with α in $\mathrm{W/(m^2\,K)}$, $\dot{q}$ in $\mathrm{W/m^2}$, and p in bar. According to Stephan and Preußer, for arbitrary liquids the following relation is valid for nucleate boiling close to ambient pressure:

$$\mathrm{Nu} = 0.0871 \left(\frac{\dot{q} d}{\lambda' T_s} \right)^{0.674} \left(\frac{\varrho''}{\varrho'} \right)^{0.156} \times \left(\frac{r d^2}{a'^2} \right)^{0.371} \left(\frac{a'^2 \varrho'}{\sigma d} \right)^{0.350} (\mathrm{Pr}')^{-0.162} . \tag{3.207}$$

$\mathrm{Nu} = \alpha d / \lambda'$ is formed with the detachment diameter of the vapor bubbles $d = 0.851 \beta_0 [2\sigma / g(\varrho' - \varrho'')]^{1/2}$, where the contact angle is $\beta_0 = 45°$ for water, 1° for low-boiling and 35° for other liquids. Quantities denoted with a single prime relate to the boiling liquid, while those with a double prime relate to the saturated vapor. The equations above are not valid for boiling in forced flow.

Table 3.28 Emissivity ε at temperature t

Substance	Surface	t (°C)	ε
Roofing paper		21	0.91

Steel	Matt oxidized	26–356	0.96

3.10.5 Radiative Heat Transfer

In addition to direct contact modes, heat can also be transferred by radiation. Thermal radiation (heat radiation) consists of a spectrum of electromagnetic waves in the wavelength range between 0.1 and 1000 µm. Visible light, as a reference, has a wavelength range between 0.4 and 0.76 µm. If a body is supplied with a heat transfer $\dot{Q}$ by radiation, the fraction $r\dot{Q}$ is reflected, the fraction $a\dot{Q}$ is absorbed, and the fraction $d\dot{Q}$ passes through (where $r + d + a = 1$). A body that reflects radiation completely ($r = 1$, $d = a = 0$) is called an ideal mirror, while a body that absorbs radiation completely ($a = 1$, $r = d = 0$) is called a black body. A body is called diathermal ($d = 1$, $r = a = 0$) if radiation passes completely through, where examples for this are gases such as O_2, N_2, etc.

Stefan–Boltzmann Law

Every body emits radiation corresponding to its surface temperature. The maximum radiation possible is emitted by a black body. It can be experimentally ap-

proximated by a blackened surface (e.g., with soot) or by a hollow space, whose walls have the same temperature everywhere and that has a small opening to let radiation out. The total radiation emitted by a black body per unit area is

$$\dot{e}_\mathrm{s} = \sigma T^4 \,, \tag{3.208}$$

where $\dot{e}_\mathrm{s}$ is called the emission ($\mathrm{W/m^2}$) of the black radiator, and $\sigma = 5.67 \times 10^{-8}\,\mathrm{W/(m^2\,K^4)}$ is the *radiation coefficient*, also called the Stefan–Boltzmann constant. The emission $\dot{e}_\mathrm{s}$ is an energy flux and thus equal to the heat flux $\dot{q}_\mathrm{s} = \mathrm{d}\dot{Q}/\mathrm{d}A$ a black radiator emits. With the emission $\dot{e}_\mathrm{n}$ in a normal direction and $\dot{e}_\varphi$ in the direction of angle φ to the normal, *Lambert's cosine law* $\dot{e}_\varphi = \dot{e}_\mathrm{n} \cos\varphi$ for black radiators holds true. Often the radiation of real bodies differs from this general law, however.

Kirchhoff's Law

Real bodies emit less than black radiators, where the energy emitted from real surfaces is

$$\dot{e} = \varepsilon \dot{e}_\mathrm{s} = \varepsilon \sigma T^4 \tag{3.209}$$

with the emissivity being in the range $0 < \varepsilon < 1$ and in general depending on temperature (Table 3.28). In limited temperature ranges, many engineering surfaces (with the exception of shiny metal) can be interpreted as grey radiators. The energy radiated by them is distributed over wavelength in the same way as it is for black radiators, but reduced by a factor $\varepsilon < 1$. Strictly speaking, $\varepsilon = \varepsilon(T)$ holds true for grey radiators. For small temperature ranges, however, it is admissible to assume ε as constant. Assuming a body emits energy per unit area $\dot{e}$, and this energy flux strikes another body, this second body absorbs the energy or rather the heat transfer

$$\mathrm{d}\dot{Q} = a\dot{e}\,\mathrm{d}A \,. \tag{3.210}$$

The absorptivity defined by this equation depends on the temperature T of the origin of the incident radiation and on the temperature T' of the receiving surface. For black bodies, this value is $a = 1$, as all radiation striking the surface is absorbed. For surfaces which are not black, this value is $a < 1$. For grey radiators, the absorptivity is $a = \varepsilon$. According to Kirchhoff's law, the emissivity is equal to the absorptivity, $\varepsilon = a$, for each surface which is in thermal equilibrium with its environment so that the temperature of the surface does not change in time.

Heat Exchange by Radiation

Between two parallel black surfaces with temperatures T_1 and T_2 and area A, which is very large in comparison with their separation, the heat transfer

$$\dot{Q}_{12} = \sigma A \left(T_1^4 - T_2^4\right) \tag{3.211}$$

is exchanged by radiation. Between grey radiators with emissivities ε_1 and ε_2, the heat transfer is

$$\dot{Q}_{12} = C_{12} A \left(T_1^4 - T_2^4\right) \tag{3.212}$$

with the *radiation exchange number*

$$C_{12} = \frac{\sigma}{\frac{1}{\varepsilon_1} + \frac{1}{\varepsilon_2} - 1} \,. \tag{3.213}$$

Between an internal pipe with outer surface A_1 and an external pipe with inner surface A_2, which are both grey radiators with emissivities ε_1 and ε_2, respectively, the heat transfer rate is given according to (3.212), but with

$$C_{12} = \frac{\sigma}{\frac{1}{\varepsilon_1} + \frac{A_1}{A_2}\left(\frac{1}{\varepsilon_2} - 1\right)} \,. \tag{3.214}$$

If $A_1 \ll A_2$, e.g., for a pipe in a large room, it holds that $C_{12} = \sigma\varepsilon_1$.

Gas Radiation

Most gases are transparent to thermal radiation and neither emit nor absorb radiation. Exceptions are carbon dioxide, carbon monoxide, hydrocarbons, water vapor, sulfur dioxide, ammonia, hydrochloric acid, and alcohols. They emit and absorb radiation only in certain wavelength regions. The emissivity and absorptivity of these gases depend not only on temperature, but also on the geometric shape of the gas body.

4. Atomic Structure and Microstructure Characterization

Jens Freudenberger, Martin Heilmaier, Ulrich Wendt

This chapter is structured into two main parts. Part 1 describes the fundamentals of the atomic (ideal) structure and (real) microstructure arrangement of solid matter. The way in which (metallic) materials are generated from the melt and the resulting phase diagrams for common binary systems are elucidated in the first part of this chapter (Sect. 4.1). In order to understand materials properties, microstructural characterization has to be carried out on various length scales. Therefore, in the second part (Sect. 4.2), the most common preparation steps for microscopy methods used in materialography are given. Next, basic micromethods for the investigation of the local chemical composition and local crystalline structure are outlined. This includes methodologies for the quantification of the complex microstructures in engineering materials.

4.2.1 Basics 152
4.2.2 Crystal Structure Analysis by X-ray Diffraction 152
4.2.3 Materialography 154
References 162

This chapter covers the structure of *engineering materials*, ranging from the atomistic level to the microstructural scale on which their properties are based. As the chemical composition determines the formation of phases and the arrangement of matter (atoms, ions, and molecules) in the solid state, the creation of (metallic) solid-state materials from the melt is discussed, including nucleation theory, and the thermodynamics and kinetics of phase transformation. The nature of phase equilibria is discussed upon principle binary phase diagrams, which also include the non-variant reactions.

The real crystal structure (i.e., microstructure), which includes all the lattice defects within crystalline solids, has a strong influence on their structural and functional properties, which is why *engineering materials* can be tuned to create a wide property portfolio to fulfill the demands of various application ranges. The fundamental underlying principle with respect to mechanical properties is exemplified by the mechanism of the movement of dislocations within the crystal lattice. The paramount influence of two- and three-dimensional lattice defects such as grain boundaries, precipitates, and dispersoids on those movements is discussed.

To gain an understanding of the performance of materials, thorough characterization of their microstructure on various length scales must be carried out. Therefore, an overview of the preparation steps used in materialography is given first. Second, the basic micromethods used to investigate the local chemical composition and local crystalline structure are outlined in this chapter too. Third, common methodologies for the quantification of the microstructure with respect to the volume fraction as well as geometrical arrangements (size, size distribution, shape, grain and crystal orientation, etc.) of grains, phases, precipitates, dispersoids, other reinforcements, filler, etc. are discussed.

https://doi.org/10.1007/978-3-030-47035-7_4

4.1 Order in Solid State

While many physical and/or chemical problems should be considered at the atomic level, it may be satisfactory for mechanical engineers to remain on the microstructural level. Therefore, we discuss in this section the different possibilities for the (ideal) arrangement of matter (atoms, ions, and molecules) in the solid state, then introduce the so-called *lattice defects* in the subsequent section. Then, three main categories of atomic arrangement can be distinguished (Fig. 4.1):

- No order (or disordered state), which is the case for gases (Fig. 4.1a), where the interaction between the single atoms is essentially limited to random collisions. Since we focus on materials in the solid state, gases will be disregarded in the following.
- Short-range order (SRO), where only a few atoms or building blocks are regularly arranged e.g., in polymers and glasses; e.g., silica is built of chains of tetrahedrons with a (central) Si atom surrounded by four oxygen atoms (Fig. 4.1c). These materials are thus called *amorphous solids* or, in view of their similarity to liquids, *undercooled liquids*.
- Long-range order (LRO), which requires the atoms to be arranged on a periodic *crystal lattice* (*crystallos* is Greek for *ice*) with—in principle—infinite extension in three-dimensional space, where the atoms sit at certain lattice points in such a way that the next-neighbor situation is the same for each atom under consideration. An example of a *primitive cubic lattice* is shown in Fig. 4.1d. Such an ideal atomic arrangement is also called a *single crystal*. Then, the smallest possible three-dimensional geometrical unit representing the lattice structure is called the *unit cell* of the corresponding crystal structure, with the three unit vectors defining the *lattice constants* of the crystal structure. This equilibrium distance of adjacent atoms can then be considered to result from a superposition of the attractive and repulsive forces between them.

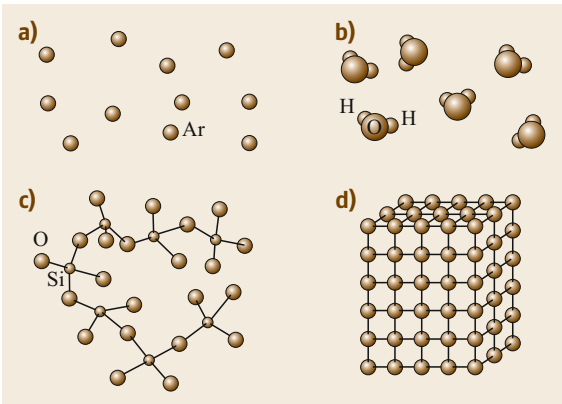

Fig. 4.1a–d Categories of atomic arrangement in materials: **(a)** inert gases with no order, **(b)** and **(c)** polar liquids and amorphous solids with short-range order, and **(d)** crystalline materials with long-range order (of infinite extension)

4.1.1 Principal Arrangements in Solids

Amorphous Structures

As pointed out before, two important classes of materials, namely glasses and many polymers, exist in the solid state but without possessing a long-range periodic crystallographic lattice structure: these are amorphous solids. Figure 4.2 elucidates how these structures may form upon cooling from the melt: usually, a liquid starts to form a crystalline solid when it is cooled below the melting point T_m of the material due to crystal nucleation and growth (see Sect. 4.2.3 for details). The crystallization event is accompanied by an abrupt jump in density. If, however, the kinetics for this transition to solid state is too sluggish or the cooling rate is too high,

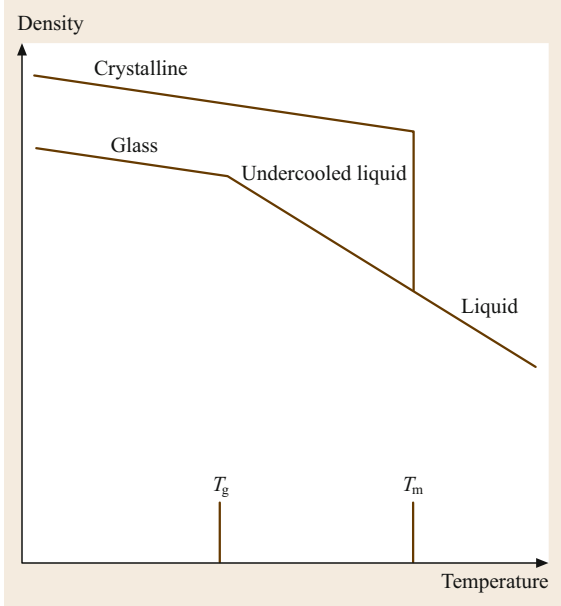

Fig. 4.2 Cooling of a silica melt: crystallization at T_m leads to an abrupt increase in density; if crystallization is suppressed, however, the undercooled melt transforms into a glassy state at T_g and the density–temperature curve shows a bend

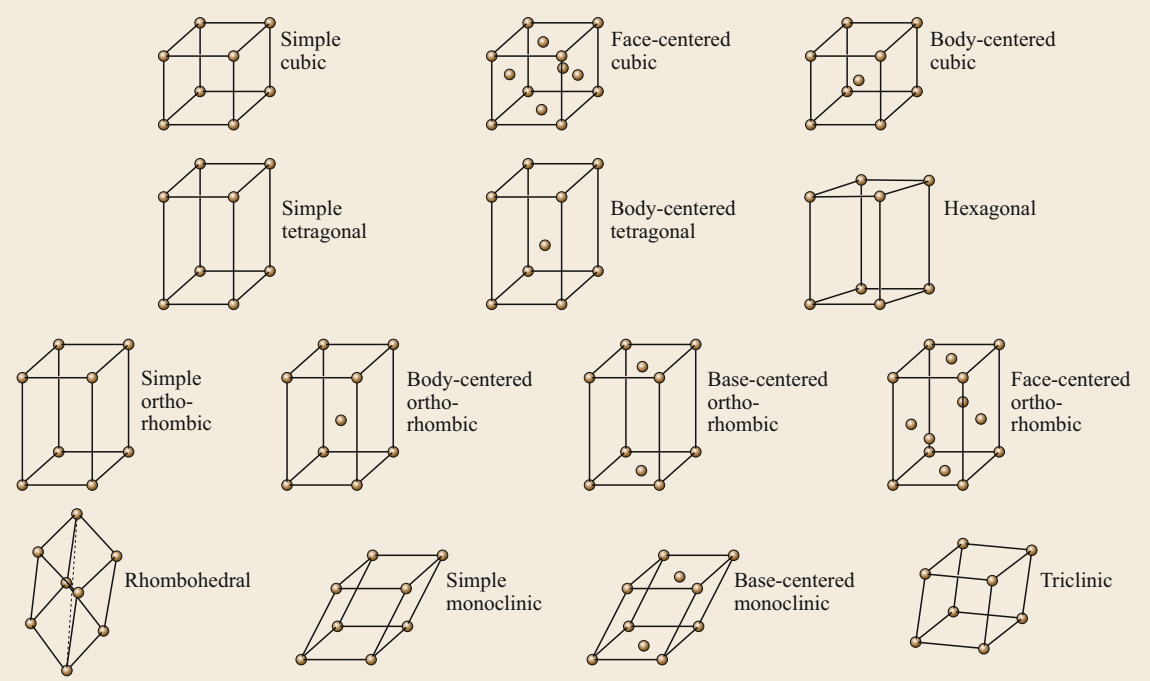

Fig. 4.3 The 7 crystal systems and 14 types of unit cell (Bravais lattices)

crystallization may be completely suppressed and an undercooled liquid be formed, which eventually transforms below the glass-transition temperature T_g into a glassy state. Note that the transition from the undercooled liquid into a glassy state (with both structures being *amorphous*) is a second-order thermodynamic reaction. This is manifested in Fig. 4.2 as a bend of the curve such that both the crystalline and glassy states show an identical temperature dependence of density below the glass transition.

An important conclusion can be drawn from Fig. 4.2. Since the glassy state exhibits the lower density, it is in a thermodynamically metastable state (with higher free energy G, Sect. 4.2.3) and will eventually transform into the crystalline structure, i.e., into the thermodynamically stable state (with minimal free energy G_{min}).

Like glasses and polymers, some metals can also be solidified into an amorphous structure. However, while simple binary and ternary systems can be produced only in the form of thin metallic ribbons via rapid solidification (requiring cooling rates of up to $10^6\,K\,s^{-1}$; see [4.1] for a review), multicomponent metallic glassy alloys in bulk form produced by slow cooling from the melt have attracted widespread interest, ranging from scientific curiosity about their structure and resulting properties to technological aspects of their preparation and potential applications. Readers interested in the outstanding properties of this new emerging class of advanced metallic materials may refer to relevant literature [4.2–5].

Crystal Structures

As early as the 19th century, the French scientist *Bravais* demonstrated that, in three-dimensional space, the seven major crystallographic unit cells can be better classified into 14 *Bravais lattices* (Fig. 4.3). The resulting geometric relations between the crystal axes are presented in Table 4.1. However, of those listed, most metallic materials used in mechanical engineering crystallize in hexagonal or cubic form, i.e., in crystal lattice structures with high symmetry and close packed crystal structures.

The most important characteristics of these crystal structures are summarized in Table 4.2. In essence, they can be distinguished by the number of atoms per unit cell (NA), the coordination number (i.e., the number of nearest neighbors, CN), and the packing density (PD). The latter is defined as $PD = NA/V_{uc}$ (with V_{uc} being the volume of the unit cell) and ranges between 0 and 1.

The comparison of the different crystal structures in Table 4.2 yields that:

1. For the cubic systems, both the coordination number and packing density increase with increasing number of atoms in the unit cell.

Table 4.1 Characteristic relations between crystallographic axes (lattice constants) and angles in the seven crystal systems

Structure	Lattice constants	Angles between axes
Cubic	$a = b = c$	All angles equal 90°
Tetragonal	$a = b \neq c$	All angles equal 90°
Orthorhombic	$a \neq b \neq c$	All angles equal 90°
Hexagonal	$a = b \neq c$	Two angles equal 90°, one angle equals 120°
Rhombohedral	$a = b = c$	All angles are equal and none equals 90°
Monoclinic	$a \neq b \neq c$	Two angles equal 90°, one angle (β) is not equal to 90°
Triclinic	$a \neq b \neq c$	All angles are different and none equals 90°

Table 4.2 Characteristics of cubic and hexagonal unit cells unit cells (bcc: body-centered cubic, fcc: face-centered cubic)

Structure	NA	CN	PD
Simple cubic	1	6	0.52
bcc	2	8	0.68
fcc	4	12	0.74
Hexagonal	6	12	0.74 (if $c/a = 1.633$)

2. CN and PD are identical for fcc and hexagonal crystals if the ratio of the *c*- and *a*-axis in the hexagonal system is 1.633 (which is nearly the case for the metallic elements Ti, Mg, and Co).

These systems are then called *hexagonally close-packed* (hcp) and can be distinguished from fcc structures only by the different stacking sequence, which is *ABAB*... along the *c*-axis for hcp and *ABCABC*... along the space diagonal ⟨111⟩ for fcc (in crystallography it is convenient to use Miller indices to describe lattice vectors and planes; in cubic systems, the space diagonal is the ⟨111⟩ direction [4.6]).

It is obvious from the comparison in Table 4.2 that even the close-packed crystal structures with space filling of 74% are still far from being fully dense. The open spaces left between the regular lattice sites are called *interstitial sites*. They may be filled by atomic species that are significantly smaller than the matrix atoms which build the regular crystal lattice. For cubic systems, three different interstitial sites can be distinguished depending on the crystal structure and the ratio of the radii of the (foreign) interstitial atom r_{ia} and matrix atom r_m, respectively (Fig. 4.4). For relatively large interstitial atoms and $r_{ia}/r_m = 0.732$–1, these interstitials will likely occupy *cubic interstitial lattice sites* with CN = 8. *Octahedral interstitial sites* with CN = 6 may be filled when $r_{ia}/r_m = 0.414$–0.732. *Tetrahedral interstitial sites* with CN = 4 provide the least free space, hence $r_{ia}/r_m = 0.225$–0.414. This is technically most relevant since the interstitial carbon atom in the Fe–C alloy system (i.e., *steel*) obeys these empirical rules and favors octahedral sites (largest holes) in the fcc structure, whereas it occupies tetrahedral sites in the bcc structure. The incorporation of carbon atoms at interstitial sites leads to significant elastic lattice distortion and, thus, readily explains the increased strength of steels as compared with pure iron.

Polymorphism

If materials of identical chemical composition exist in more than one crystal structure depending on temperature and/or pressure, they are called *polymorphic*. A more specific term applicable for pure elements is *allotropy*. Two prominent representative metallic materials show polymorphism:

1. Iron and low carbon steels transform from the low-*T ferritic* bcc structure into a higher-temperature *austenitic* fcc structure and back to a bcc structure called δ-*ferrite* close to the melting point.
2. Titanium undergoes a transformation from α-hcp structure at low *T* to a β-bcc structure at high *T*.

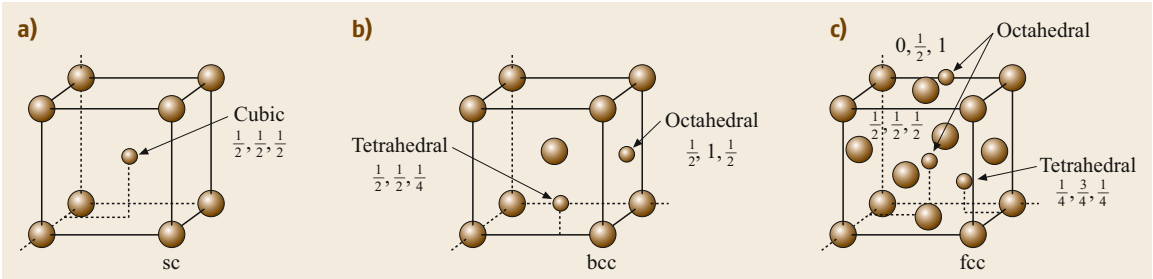

Fig. 4.4a–c Location of interstitial sites within cubic unit cells: (**a**) simple cubic, (**b**) body-centered cubic (bcc), (**c**) face-centered cubic. The numbers denote the lattice positions of the interstitial sites

Both transformation reactions form the basis for the heat treatment of steels and titanium alloys and, thus, the potential for widely adjusting the properties of these alloy systems; see Part B, Chaps. 5 and 8, respectively. A further example of polymorphism is the covalently bonded element carbon, which exists in a hexagonal structure of two-dimensional layers called *graphite*, or *diamond* with the open diamond cubic crystal structure (with a PD of only 0.34).

Crystal Structures with More than One Chemical Element/Component

In most cases, technically relevant materials consist of more than one chemical element. Depending on how the different elements are mixed with each other, one can classify them into:

1. *Solid solutions*, where the different atomic elements are randomly mixed and placed at the lattice points of the crystal structure. Two subcases can be distinguished:
   - Substitutional solid solutions, where the atomic species occupy regular lattice points in a random manner (see also Fig. 4.6c,d). According to Hume-Rothery [4.6, 7] this occurs when the elements (e.g., A and B) have comparable atomic radii ($\delta = (r_B - r_A)/r_A < 15\%$) and crystallize in the same structure. A prominent example is the binary alloy system Ag-Au, which exhibits unlimited mutual solubility.
   - Interstitial solid solution, where the smaller atomic species occupies interstitial sites because of too large a difference in atomic radius between them and the matrix atoms ($\delta > 15\%$) (Fig. 4.6b). The most prominent example is again C in Fe, but this can be generalized to impurities such as H, O, and N in metals. In contrast to the former case, the maximum solubility is much smaller, typically < 1 at.%, which means that, in the case of a bcc lattice, only about every 50th unit cell hosts one interstitially solved atom:
2. Stoichiometric compositions, where the ratio between the atomic species is fixed to small integer numbers. This is called *stoichiometry*. Two categories can be distinguished here, depending on how these structures are formed:
   - An ordered *superlattice structure* with the same basic crystal structure type may form upon cooling a disordered solid solution. The following example elucidates this scenario: a Cu alloy containing 25 at.% Au has a simple fcc crystal structure in the solid state at elevated temperatures. Upon further cooling, it transforms into an ordered fcc $L1_2$ crystal structure of type Cu_3Au, where the gold atoms occupy the corner lattice points of the unit cell while the copper atoms sit on the faces of the cube.
   - An intermetallic compound made up of two or more elements, producing a new phase with its own composition, crystal structure, and properties substantially different from those of its constituents, namely higher hardness, strength, and melting point but almost always at the expense of a lack of ductility. A recent, technically relevant example are the titanium aluminides (Fig. 4.5), which are being considered for a variety of high-temperature applications, such as automotive valves and turbocharger wheels, and turbine blades and vanes in aerospace engines, as structural materials, mainly because of their attractive combination of high melting point and strength together with low density.

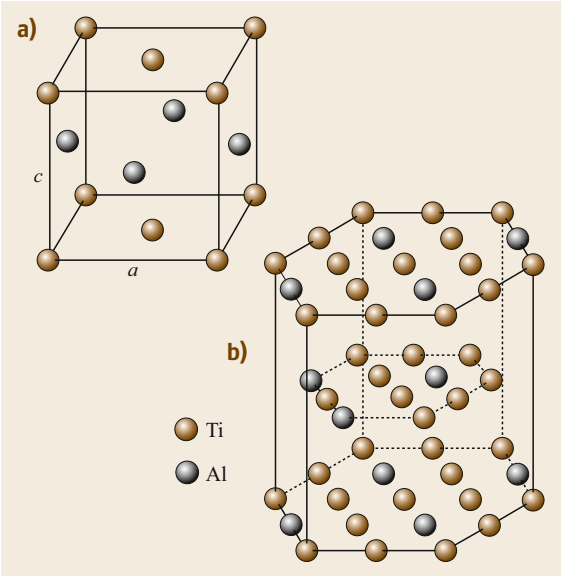

Fig. 4.5a,b Some unit cells of technically relevant intermetallic phases within the binary Ti-Al system: **(a)** γ-TiAl with (tetragonally distorted) $L1_0$ crystal structure, **(b)** α_2-Ti_3Al with hexagonal $D0_{19}$ crystal structure (Pearson symbols [4.8])

A final point should be noted here: many superlattice structures and intermetallic compounds have a range of compositions (*stoichiometry range*) in which they appear with the same crystal structure as compared with the fixed stoichiometric composition. This is, e.g., the case for both of the TiAl-based inter-

metallic compounds shown in Fig. 4.5, making alloy property improvement and fine-tuning through addition of further alloying elements more feasible. This *nonstoichiometry* can lead to partial disordering of the atomic arrangement within the unit cell.

4.1.2 Microstructure

The crystal structure introduced in the previous section describes the ideal arrangement of atoms within a crystalline material and, hence, determines several *intrinsic* material properties (e.g., elastic stiffness and compliance constants). However, lattice imperfections, which destroy the infinite extension of the periodic atomic structure, are decisive for many *extrinsic* properties (e.g., the mechanical properties discussed in Sect. 4.2.1). As a result, a real structure containing crystalline areas and a variety of lattice imperfections is called a *microstructure*. Lattice imperfections are created and can be controlled during the processing and manufacturing of materials. They can be classified based on their dimensionality as follows.

Point Defects

Figure 4.6 provides an overview of the various types of point defects (of zero dimensionality) in materials. Foreign atoms, solved either substitutionally at regular lattice sites (Fig. 4.6c,d) or interstitially (Fig. 4.6b), have already been treated in the previous section. If a lattice site lacks an atom, a *vacancy* is formed in the lattice (Fig. 4.6a). From thermodynamics calculations, it is known that a certain (small) number of vacancies will exist in thermal equilibrium. A more detailed treatment [4.9] yields

$$c_{\mathrm{V}}^{\mathrm{e}} = \exp\frac{-\Delta G_{\mathrm{V}}}{RT} = \exp\frac{-(\Delta H_{\mathrm{V}} - T\Delta S_{\mathrm{V}})}{RT}\,, \qquad (4.1)$$

where $c_{\mathrm{V}}^{\mathrm{e}}$ is the equilibrium concentration of vacancies, which follows an Arrhenius-type increase with increasing temperature. At the melting point of the material, $c_{\mathrm{V}}^{\mathrm{e}} = 10^{-4}{-}10^{-3}$; meanwhile, at absolute zero, i.e., 0 K, then $c_{\mathrm{V}}^{\mathrm{e}} \equiv 0$. From the above, it becomes obvious that vacancies will very likely be introduced into materials upon solidification from the melt. Figure 4.6b–d represents the various types of alloying elements in solid solution, which were already treated in the previous section. Two special types of point defect are displayed in Fig. 4.6e,f: *Frenkel defects*, consisting of a vacancy-interstitial atom pair, can be created upon neutron irradiation (Fig. 4.6e), while *Schottky defects* exist only in ionic crystals as pairs of vacancies formed in the cationic and anionic partial lattice, respectively (Fig. 4.6f).

Solid-Solution Strengthening. It has long been well known that the introduction of alloying elements into a pure metal increases its hardness. When the difference in size and electronegativity of the alloying element is less than a critical value, the alloying element forms a solution with the matrix. The alloy atoms occupy either lattice sites, leading to a *substitutional solid solution*, or interstitial voids in the lattice, i.e., *interstitial solid solutions*. Carbon, nitrogen, oxygen, hydrogen, and boron are elements that commonly occupy interstitial sites. Solute atoms interact with dislocations (see next paragraph) in a number of ways.

- *Parelastic interaction* due to the overlapping strain energy of the solute atom and dislocation core. The interaction energy is directly proportional to the size difference between the solute and matrix atoms.
- *Modulus interaction* due to a local change of modulus, thereby affecting the elastic energy of the dislocation. This is also called the *dielastic interac-*

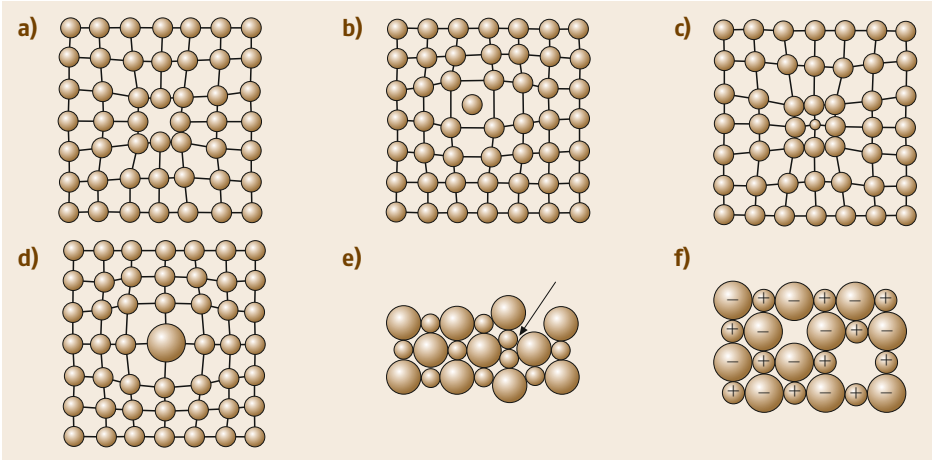

Fig. 4.6a–f Overview of the various types of point defect: **(a)** vacancy, **(b)** interstitial atom, **(c)** smaller and **(d)** larger substitutional atom, **(e)** Frenkel defect, and **(f)** Schottky defect

tion in the literature [4.7]. The interaction energy is directly proportional to the difference in shear modulus between the solute and matrix atoms.

- *Stacking-fault interaction* or *Suzuki hardening* due to preferential segregation of solutes to the stacking fault of extended dislocations.
- *Electrical interactions* due to localization of the electron cloud, leading to interaction with dislocations with electrical dipoles. This effect is smaller than the above mechanisms.

All these interactions require extra energy to be expended to overcome the solute atom, requiring higher stresses for dislocation motion and, hence, giving rise to *solid-solution hardening*. It may be pointed out that the presence of vacancies, introduced due to rapid quenching or high-energy radiation, also leads to considerable strengthening via some of the above mechanisms. For further details see [4.7].

Dislocations

Independently from each other, Orowan, Polanyi, and Taylor introduced the term "dislocations" in 1934 to explain the observed strength values and plastic deformability of materials on a theoretical basis. It should be emphasized here that the existence of these one-dimensional lattice imperfections was proven experimentally more than a decade later with the advent of the first transmission electron microscopes in materials science. To motivate why dislocations are essential in explaining the deformation behavior of materials, first consider the theoretical (shear) strength of materials shown in Fig. 4.7, in which A and B represent sites of stable equilibrium for the atoms within the hexagonal plane. Then, a is the displacement required to shift any atom to another stable position, thus the potential connected with a displacement z of any atom is

$$U(z) = U_0 \left(1 - \cos \frac{2\pi z}{a}\right) . \tag{4.2}$$

From (4.2), one can obtain the necessary force by differentiating with respect to z

$$F(z) = \frac{\partial U(z)}{\partial z} = U_0 \frac{2\pi}{a} \sin \frac{2\pi z}{a} . \tag{4.3}$$

The shear stress is simply $\tau = F(z)/A$. For $z \ll a$ and since the sin function is point-symmetric about the origin, one gets from (4.3) that

$$\tau \approx \tau_{\max} \frac{2\pi z}{a} . \tag{4.4}$$

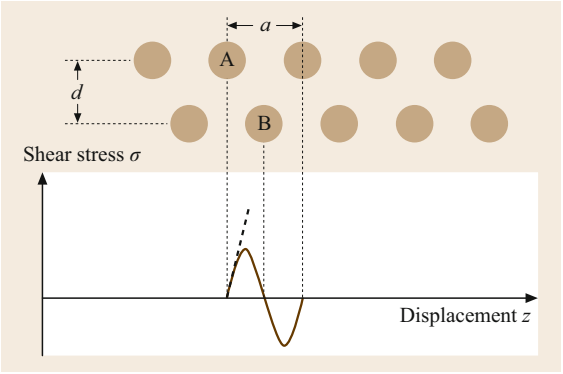

Fig. 4.7 The theoretical strength of crystalline materials: the shear displacement z between two neighboring lattice planes of interplanar spacing d causes a sinusoidal shear stress fluctuation σ. A and B are regular lattice sites, respectively, and a is the lattice constant within the hexagonal plane

On the other hand, Hooke's law for simple shear is

$$\tau = G\gamma = G\frac{z}{d} . \tag{4.5}$$

Setting (4.4) and (4.5) equal, one obtains for the maximum shear stress

$$\tau_{\max} = \frac{Ga}{2\pi d} \approx \frac{G}{6} . \tag{4.6}$$

Thus, the theoretical shear strength $\tau_{\max}$ is only dependent on the elastic properties of a material, i.e., the shear modulus G. As an example, for pure copper with $G \approx 45\,\text{GPa}$, one gets $\tau_{\max} = 7500\,\text{MPa}$. However, in experiments one observes for pure copper single crystals that plastic shearing occurs already at shear stresses below 10 MPa [4.7] (Fig. 4.11). This obvious discrepancy by about three orders of magnitude can be rationalized only by assuming the existence of dislocations that enable plastic shearing by moving in a direction $\boldsymbol{r}$ perpendicular to its line (the dislocation line represented by the vector $\boldsymbol{s}$) through the lattice.

We can identify two basic types of dislocations:

1. *Screw dislocations*, which can be illustrated by cutting halfway through a perfect crystal (Fig. 4.8a) and subsequently skewing the crystal by one atomic spacing (Fig. 4.8b,c). If one follows a crystallographic plane one revolution around the axis on which the crystal was skewed, starting at point x and moving an equal number of atomic spacings in each of the four planar directions, one ends up one lattice site below the starting point (point y). The vector required to close the loop is called the *Burgers vector* $\boldsymbol{b}$ and represents the unit of plastic shearing of the crystal through the movement of the dislocation line

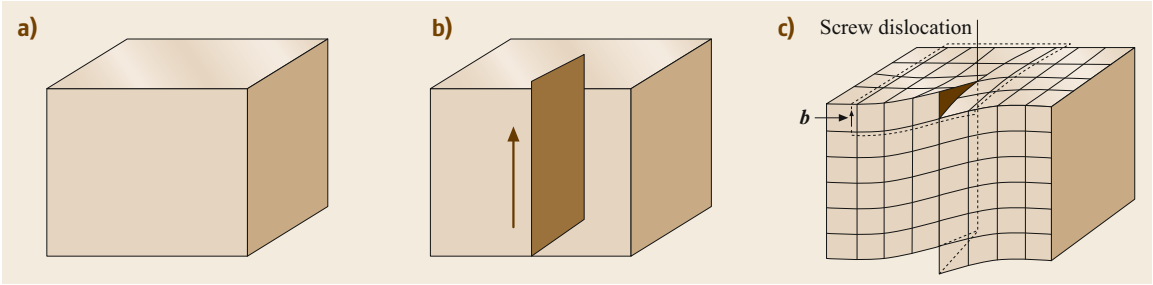

Fig. 4.8a–c A perfect crystal (a) is cut and (b) and (c) sheared by one atomic spacing. The line along which shearing is carried out is a screw dislocation with its Burgers vector $\boldsymbol{b}$ closing a loop of equal atomic spacings around itself

(from the front to the back in Fig. 4.8c). Hence, in screw dislocations, $\boldsymbol{b} \parallel \boldsymbol{s} \perp \boldsymbol{r}$.

2. *Edge dislocations*, which can be illustrated by slicing halfway through a perfect crystal (Fig. 4.9a), tearing the crystal apart, and inserting an extra (half) plane of atoms into the cut (Fig. 4.9b). The bottom edge of this inserted plane represents the edge dislocation (Fig. 4.9c). A clockwise loop, starting at point x and going an equal number of lattice sites into each direction within the plane, finishes at point y, hence leaving the required Burgers vector $\boldsymbol{b}$ to close the loop in Fig. 4.9c. For edge dislocations, $\boldsymbol{r} \parallel \boldsymbol{b} \perp \boldsymbol{s}$.

The more general case of a dislocation with *mixed* character when $\boldsymbol{b}$ is neither parallel nor perpendicular to $\boldsymbol{s}$ is plotted in Fig. 4.10. Likewise, note from Fig. 4.10 that pure screw or edge configurations can be considered as the extremal cases of the general mixed configuration for either $\boldsymbol{b} \parallel \boldsymbol{s}$ or $\boldsymbol{b} \perp \boldsymbol{s}$.

From the above, the following important conclusions can be drawn:

- The dislocation line is the border between the undeformed and slipped area of the crystal plane.
- Dislocations cannot end within a crystal: they have to either form a loop or penetrate an internal (e.g., grain or phase boundaries, see below) or external surface.
- Dislocations exhibit a long-range three-dimensional stress field within the crystal lattice, allowing them to interact with all kinds of other lattice imperfections. This feature is the basis for the various approaches for strengthening materials in metallurgy.
- Dislocations are the carriers of plastic (i.e., irreversible) deformation in crystalline materials.
- The slip system of a dislocation in crystalline materials is composed of: 1. A close-packed slip plane and 2. A short slip direction which is identical to $\boldsymbol{b}$.
- The Burgers vector must be contained within the slip plane. Both the slip plane and slip direction depend on the lattice structure of the material.

Similarly as for the grain boundaries explained below, dislocations are created in crystals during solidification due to thermal stresses arising from the density mismatch between the liquid and solid phases. Hence, the creation of a dislocation within a crystal increases the (total) free energy of the system. A satisfactory approximation for the dislocation line energy E is

$$E = \frac{1}{2} G b^2 \,. \tag{4.7}$$

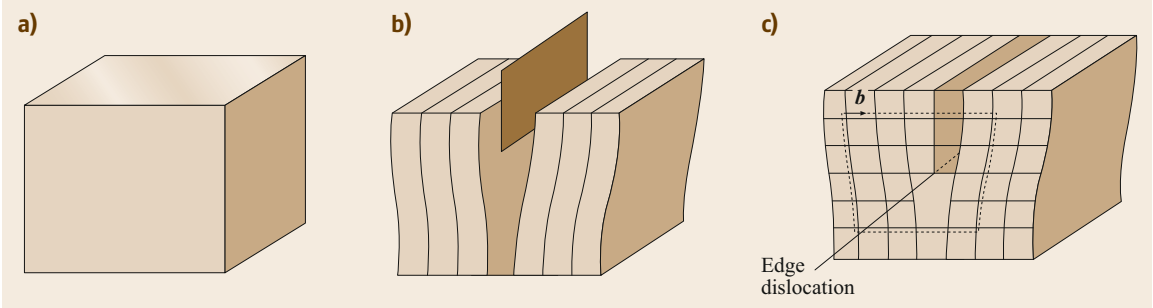

Fig. 4.9a–c A perfect crystal (a) is cut and an extra half-plane of atoms is inserted (b). The bottom edge of the extra plane is an edge dislocation with its Burgers vector $\boldsymbol{b}$ closing a loop of equal atomic spacings around itself

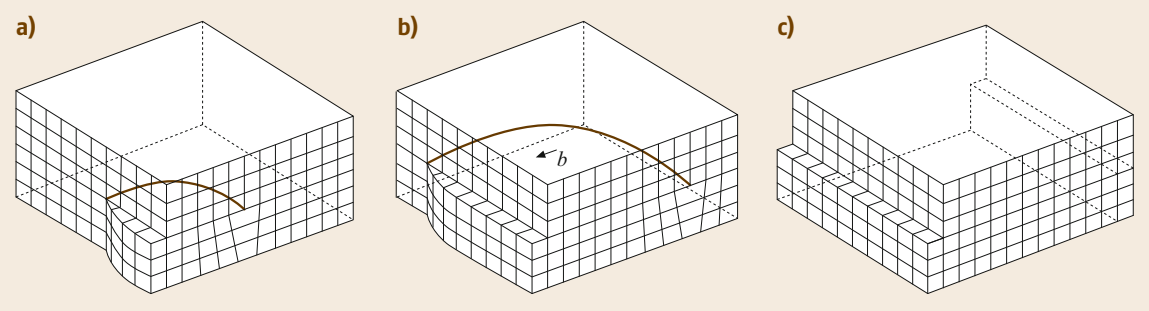

Fig. 4.10a–c Movement of a mixed dislocation through a simple cubic lattice: **(a)** and **(b)** the dislocation character is purely screw type *on the left-hand side* and purely edge type *on the right-hand side* of the crystal; **(c)** after completion of the movement, the dislocation has disappeared, leaving a slip step of height b

Equation (4.7) reveals that the dislocation line energy is an *intrinsic* materials property, depending only on crystal lattice parameters. Experimentally, dislocations can be detected either via optical microscopy as *etch pits* stemming from the penetration points of the dislocation lines through the crystal surface or via transmission electron microscopy (TEM), where the slight lattice distortions caused by the dislocations gives rise to a visible contrast; see [4.10] for details. To explain the strength and deformability of materials, it is useful to introduce the dislocation density as the number of dislocations per unit volume

$$\rho = \frac{\text{dislocation line length}}{\text{unit volume}} = \frac{\text{number of dislocations}}{\text{unit area}} \,. \tag{4.8}$$

As an example, for well-annealed metals, $\rho = 10^9 - 10^{11}\,\mathrm{m}^{-2}$; meanwhile, for ceramics and semiconductors, $\rho = 10^4 - 10^{10}\,\mathrm{m}^{-2}$.

Strain Hardening. Strain hardening is caused by the interaction of dislocations with each other. During plastic deformation, e.g., cold working, the number of dislocations increases with increasing strain to values of $\rho = 10^{14} - 10^{16}\,\mathrm{m}^{-2}$. Similarly, an increase of the dislocation density is connected with tensile straining. An example for the stress–strain behavior of Cu single crystals with different crystallographic orientations with respect to the loading axis is depicted in Fig. 4.11. The *flow curve* comprises three stages:

1. Stage I or *easy glide*
2. Stage II or *dislocation pile-ups*
3. Stage III or *dynamic recovery*.

Stage I is observed only in well-annealed crystals oriented such that only one slip system is operative (cf.

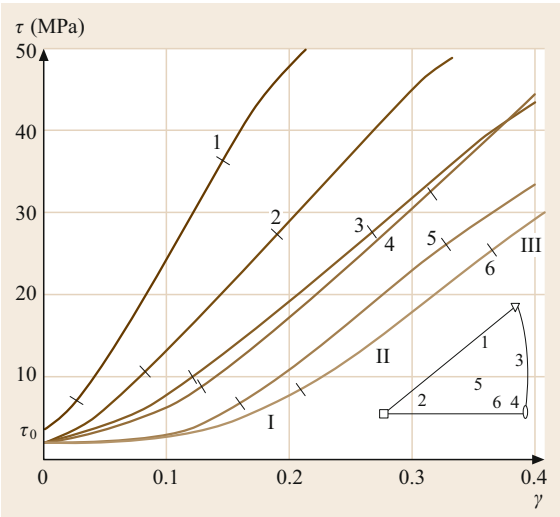

Fig. 4.11 Shear stress τ versus shear strain γ curves for differently oriented copper single crystals at room temperature. Samples 1–6 are oriented within the standard orientation triangle as depicted

curves 5 and 6 in Fig. 4.11). Stage II dominates the flow curve of most engineering polycrystalline alloys, and measurements over a wide range show that

$$\sigma_\rho = \sigma_\mathrm{i} + \alpha \mathrm{G} \mathrm{b} \sqrt{\rho} \,, \tag{4.9}$$

where α is a numeric constant (typically ≈ 0.3). Equation (4.9) is also referred to as Taylor's relation and originates from the interaction of the stress fields of dislocations (long-range interaction) or from dislocations cutting due to intersecting slip systems. The strain hardening rate during stage II is fairly insensitive to temperature and/or impurities. On the other hand, the region of dominance of stage III, *dynamic recovery*, is strongly temperature dependent. For further details see, e.g., [4.11].

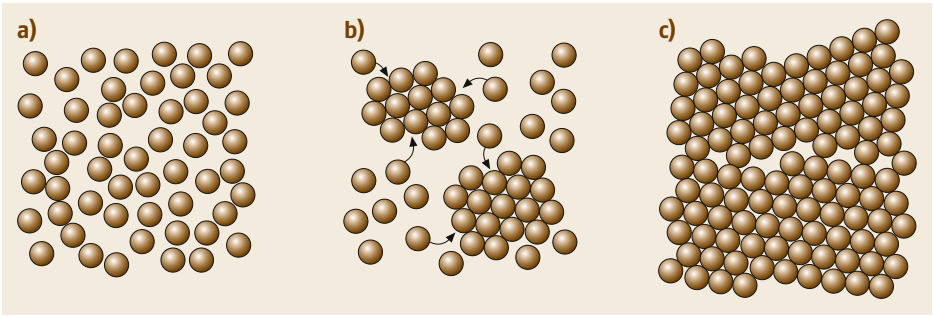

Fig. 4.12a–c The development of grains and grain boundaries upon solidification from the melt: **(a)** amorphous melt, **(b)** two crystals begin to nucleate within the liquid melt, **(c)** a grain boundary has been created between two crystallites of different crystallographic orientation

Grain Boundaries

Grain boundaries are two-dimensional lattice faults. Like vacancies and dislocations, they are created during the manufacture of materials, as can be exemplified by metallic materials upon solidification from the amorphous (or disordered) melt (Fig. 4.12a). When decreasing the temperature of the melt below the liquidus temperature (Sect. 4.1.2), nuclei that have the crystal structure of the solid are formed within the liquid and grow with continuing time and cooling (Fig. 4.12b). When T falls below the solidus temperature, the material has solidified completely and adjacent grains with the same crystal lattice but different crystallographic orientation (Fig. 4.12c) do not fit perfectly to each other. The narrow zone where the atoms are not properly spaced, but lie in a more or less disordered state, is called a *grain boundary*. Typically, $d_{gb} = 0.5$ nm is a good estimate for the grain boundary thickness.

Fine-Grain Strengthening. One important method for controlling the properties of a material is to adjust the grain size. By reducing the grain size, the number of grains and hence the fraction of grain boundaries is increased. As far as the mechanical properties are concerned, any dislocation that moves within a grain is stopped when it encounters a grain boundary. The mean free path of dislocations is, thus, limited by the grain size or the grain boundary density (Sect. 4.2.3, *Quantification of Microstructure/Quantitative Stereology*), and the strength of the metal is increased. The famous Hall–Petch relation relates the grain size to the yield strength at room temperature [4.12, 13],

$$\sigma_y = \sigma_0 + K_y d_{gb}^{-1/2} , \qquad (4.10)$$

where σ_y is the yield strength (Sect. 4.2.1), $d_{gb}^{-1/2}$ is the inverse square root of the grain size, preferentially measured as the mean intercept length (4.44) in Sect. 4.2.3, and σ_0 and K_y are material constants (σ_0 is often related to the *Peierls stress* in crystallographic slip [4.7]). Figure 4.13 shows the relationship according to (4.10) for some steels.

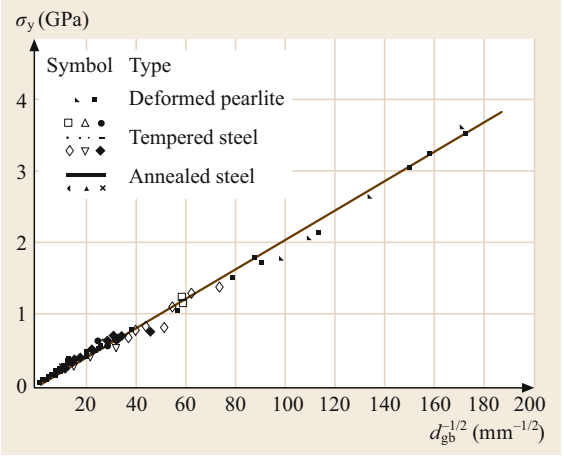

Fig. 4.13 Dependence of yield strength σ_y on inverse root of grain size, $d_{gb}^{-1/2}$, for steel (after [4.14])

Optical or scanning electron microscopy (SEM) can be used to reveal microstructural features such as grain boundaries (Sect. 4.2.3) and to assess the grain size of materials quantitatively.

Dispersoids and Precipitates

When the solubility of a material is exceeded for any alloying element, a second phase forms in the volume and a two-phase alloy is produced. Hence, second-phase particles such as *dispersoids* or *precipitates* are classified as three-dimensional lattice imperfections. The continuous phase that surrounds the particles and is usually present in a larger fraction is called the *matrix*. The boundary between the two phases is an internal surface or *interface*, at which, as for the grain boundaries in the previous section, the atomic arrangement is not perfect. Again, this boundary impedes the slip of dislocations and, thus, strengthens the material.

Dispersion and Precipitation Strengthening. Two types of second-phase particles can be distinguished. In *dispersion strengthening*, particles are introduced into the matrix using powder metallurgical techniques or

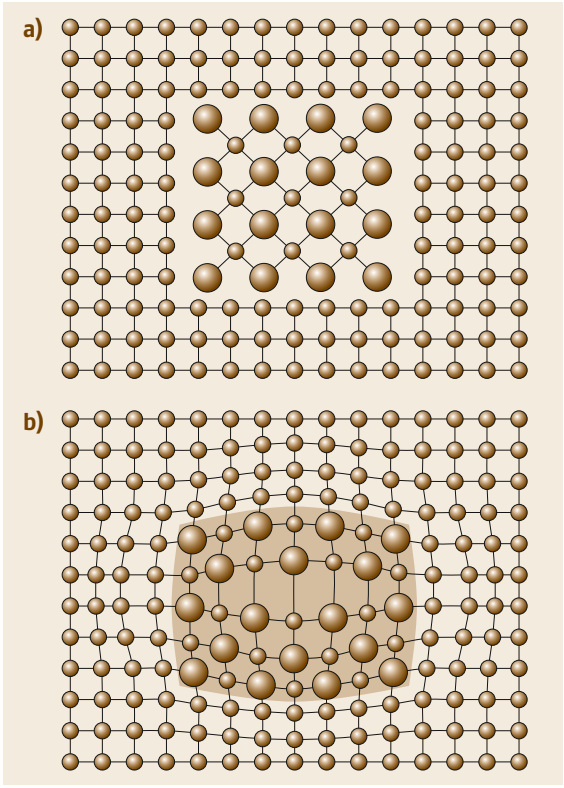

Fig. 4.14 **(a)** An incoherent second-phase particle has no crystallographic relationship with the structure of the surrounding matrix; **(b)** coherent precipitates show a definite crystallographic relationship with the matrix

through solid reactions. These particles are in essence insoluble in and *incoherent* (Fig. 4.14a) with the matrix. *Precipitation strengthening* or *age hardening* is produced through a series of heat treatments that exploit the decrease in solubility of a given solute with decreasing temperature. This requirement for elevated-temperature solubility places a limitation on the number of useful precipitate-strengthened alloy systems. Due to their insolubility within the metallic matrix, dispersion-hardened alloys are stable up to temperatures relatively close to the melting point of the matrix, in contrast to precipitate-strengthened alloys, which are degraded upon prolonged exposure to high temperature due to *precipitate coarsening*, i.e., *Ostwald ripening*. Nevertheless, precipitation hardening due to very small *coherent* particles (2–10 nm, Fig. 4.14b) is a very efficient strengthening mechanism. Fine particles can act as barriers to dislocation motion, either by requiring the dislocations to shear them or by acting as strong impenetrable particles, forcing dislocations to bypass them. When the particles are small and/or soft, they get sheared and the following mechanisms contribute to the strength increment:

- *Coherency strain*, arising from the strain field resulting from the mismatch between the particle and matrix.
- *Stacking fault energy* variation between the matrix and particles, which leads to local variation in the stacking fault width.
- If the precipitates have an *ordered structure*, as in many Ni-based superalloys (Sect. 8.5.2), motion of dislocation through them introduces antiphase boundaries (APB).
- A difference in the *local modulus* between the particle and matrix alters the energy of a dislocation passing through the particle. Likewise, counterintuitively, voids can contribute significantly to the strength via this mechanism.
- As dislocations pass through a precipitate, a step that is one Burgers vector high is produced. This raises the particle–matrix *interfacial energy*, contributing to strengthening.
- Finally, there is a strengthening contribution due to the difference in lattice friction stress or Peierls stress between the particle and matrix.

For larger precipitates or dispersoids, Orowan proposed a mechanism for particle overcoming, as illustrated in Fig. 4.15. In essence, the strength increase is related to the increase of the dislocation line length when the dislocation deposits a loop around the particle after bypassing it (Fig. 4.15d). The critical situation for bypassing is reached when the dislocation line possesses its maximum curvature around the particle, i.e., the half-circle. According to Fig. 4.16, one obtains for the critical configuration for dislocation bypassing

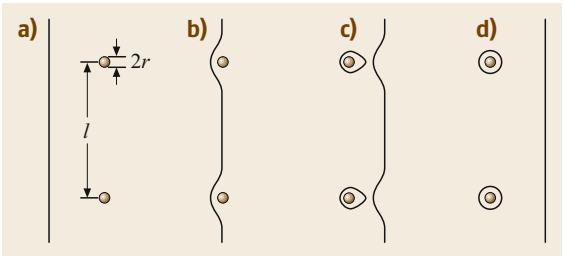

Fig. 4.15a–d Schematic of dislocation bypassing fine nonshearable particles by Orowan bowing: driven by shear stress τ, a dislocation approaches an array of (two) particles with radius r separated by a distance l **(a)**. It bows out between the particles **(b)**, until it deposits loops around them **(c)**. After bypassing, the dislocation line remains unchanged **(d)**

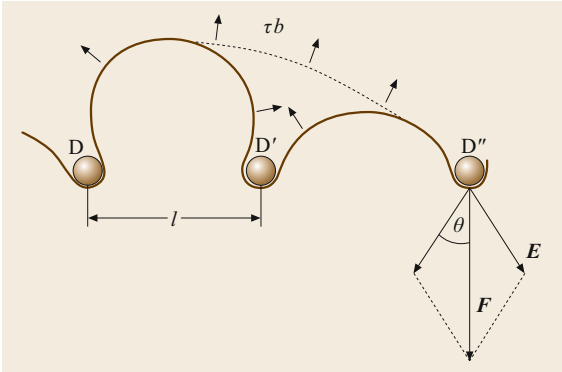

Fig. 4.16 Bowing out of a dislocation line between an array of impenetrable incoherent particles (designated D, D′, D″) with spacing l due to a shear force (per unit length of dislocation) τb. The obstacle force acting against bypassing is F

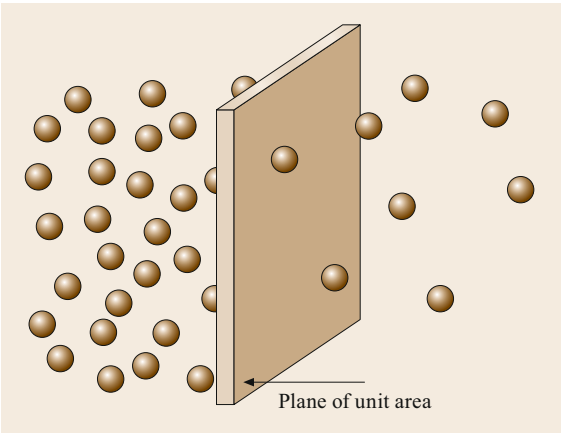

Fig. 4.17 The flux j_D during diffusion is defined as the number of atoms passing through a plane of unit area per unit time

$(\theta \to 0°)$

$$F = \tau b l = 2E \cos \Theta = Gb^2 \,. \tag{4.11}$$

Solving (4.11) for τ and assuming maximum force for $\theta = 0$, one obtains the strength increase due to Orowan bypassing as

$$\tau_{Or} = \frac{Gb}{l} \,. \tag{4.12}$$

Since the particle spacing l is not directly extractable from microstructure analysis (Sect. 4.2), the following more useful expression has been established for the strength increment from Orowan bypassing which also takes into account the conversion of the shear stress τ into a normal stress σ via the Taylor factor $M = \sigma/\tau$

$$\sigma_{Or} = 0.8MGb\frac{\sqrt{f}}{r} \,, \tag{4.13}$$

where f is the volume fraction of particles present in the material and r is the (directly measurable) particle radius within the slip plane. For a detailed review on the various types of particle strengthening sketched above, see [4.15].

4.1.3 Atomic Movement in Materials

The movement of atoms (or molecules) within materials (or liquids) is called *diffusion*. It is emphasized here that diffusion can take place without a superimposed mechanical stress just by random movement of atoms, provided that sufficient thermal energy is introduced into the system. Vice versa, as for the concentration of vacancies, (4.1) in Sect. 4.1.2, atoms in crystalline solids are at rest only at absolute zero. The driving force behind this movement is usually a gradient in concentration of atoms according to

$$j_D = -D \,\mathrm{grad}\, c = -D\frac{\partial c}{\partial y} \,, \tag{4.14}$$

where the latter fraction is the *concentration gradient* in the simplified case for one-dimensional atom movement. Equation (4.14) is called *Fick's first law* and is visualized in Fig. 4.17. j_D is the flux of atoms through a plane of unit area per unit time, and D is the *diffusion coefficient* ($m^2\,s^{-1}$).

Consider now a sheet of nickel and copper bonded to each other (Fig. 4.18a). The steep concentration gradient at the contact surface will cause continuous mutual diffusion of both atomic species to either side (Fig. 4.18b) until eventually an equilibrium concentration is attained (Fig. 4.18c). The kinetics, i.e., the velocity of this interdiffusion process, is triggered by the absolute temperature T according to an Arrhenius law

$$D = D_0 \exp\left(-\frac{Q}{RT}\right) . \tag{4.15}$$

D_0 is a constant prefactor and—in essence—an intrinsic material parameter, $R = 8.314\,J\,mol^{-1}\,K^{-1}$ is the gas constant, and Q is the activation energy required for an atom to carry out a single jump event. In crystalline solids, as pointed out in Sect. 4.1.2, two mechanisms of atom movement are conceivable depending on the size ratio δ of the solute and matrix atom (Sect. 4.1.1):

- $\delta < 0.15$: This is the case for self-diffusion and diffusion of substitutionally solved atoms and requires the presence of a vacancy next to the lattice site of the moving atom (see the upper part of Fig. 4.19).

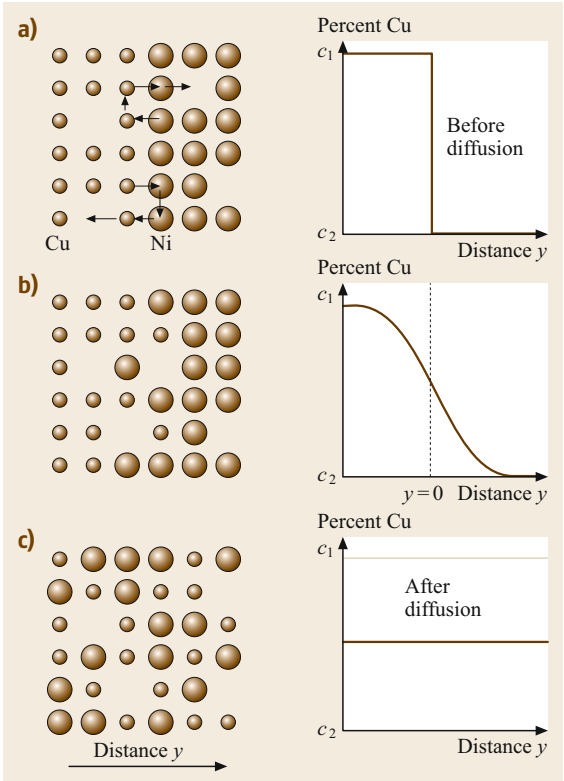

Fig. 4.18a–c Mutual diffusion of Cu and Ni atoms into each other through a vacancy mechanism: **(a)** $t = 0$, **(b)** $t > 0$, intermediate time, **(c)** $t \to \infty$

After the jump, the atom has created a new vacancy at the original lattice site, hence one observes counterflows of atoms and vacancies. Consequently, this mechanism is also called *vacancy diffusion*. Since this diffusion mechanism requires the presence of vacancies, its activation energy Q_v is composed of two terms, namely one for the formation of vacancies, Q_f, and one for their migration, Q_m, hence $Q_v = Q_f + Q_m$ replaces Q in (4.15) for self-diffusion or vacancy diffusion.

- $\delta > 0.15$: This is the case for (small) interstitial atoms moving from one interstitial site to another. No vacancies are required for this mechanism, and the activation energy for *interstitial diffusion*, Q_i, accounts for the migration of interstitials and is therefore smaller than its counterpart for vacancy diffusion Q_v (Fig. 4.19). For interstitial diffusion, Q_i substitutes for Q in (4.15).

Examples of the temperature dependence of the diffusion coefficient according to (4.15) are given in Fig. 4.20 in the form of an Arrhenius-type plot of $\ln D$ versus reciprocal temperature $1/T$. One notes the following characteristic features:

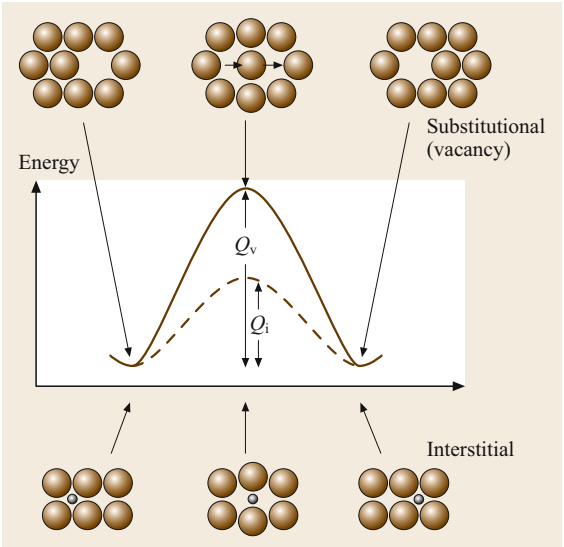

Fig. 4.19 Visualization of diffusion mechanisms in crystalline solids. *Top*: vacancy diffusion with activation energy Q_v, *bottom*: interstitial diffusion with activation energy Q_i

1. The slope of the curves is a measure of the activation energy Q, with a steeper slope indicating a higher value of Q.
2. As anticipated from Fig. 4.19, interstitial diffusion is considerably faster than vacancy diffusion (cf. the curves for Fe self-diffusion with those of carbon and hydrogen diffusion in iron).
3. The lower PD of the bcc crystal structure as compared with the fcc or hcp structure (Table 4.2) gives rise to a higher diffusivity D.

This holds for Fe as well as for Ti, which undergoes an allotropic transformation from hcp α-Ti to bcc β-Ti at 882 °C.

The scenario depicted in Fig. 4.18 is typical for many engineering applications of diffusional processes such as the heat treatment of materials for equilibrating concentration inhomogeneities stemming from alloy solidification or joining operations. Figure 4.18 can be considered as an exemplification of diffusional bonding or the consolidation of metallic and/or ceramic powder particles by solid-state sintering (*powder metallurgy*). Fick's first law (4.14) is unable to describe the local and temporal distribution of atoms during different time stages of diffusion, e.g., the concentration profile shown in Fig. 4.18b. However, as the number of atomic species

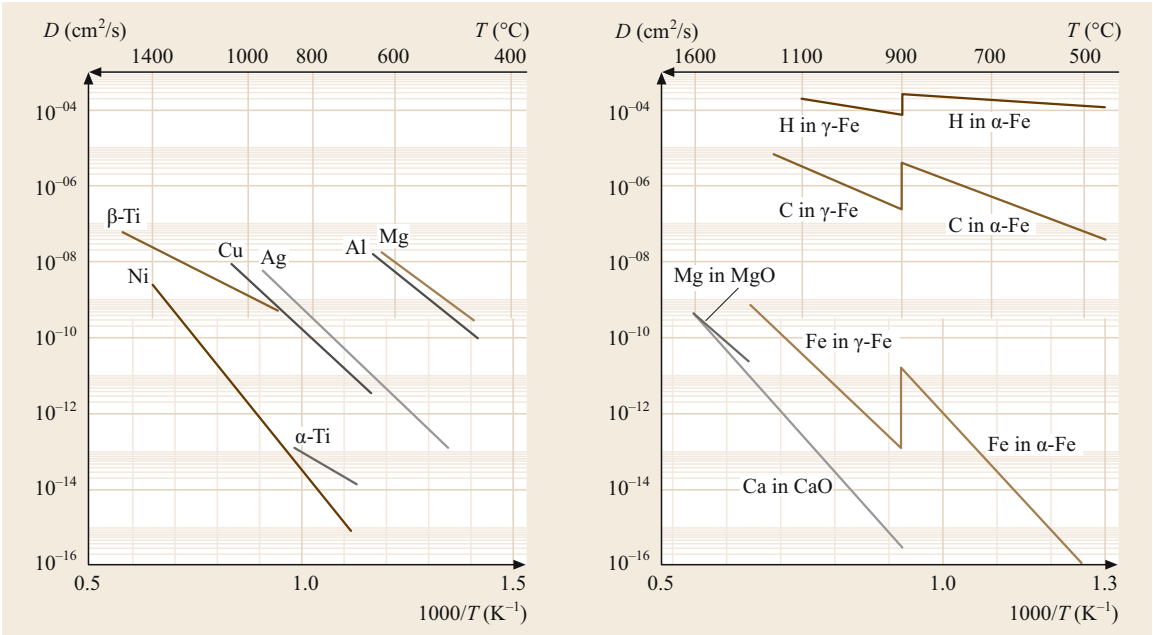

Fig. 4.20 Temperature dependence of diffusion coefficient D in various metals and oxide ceramics. The slope of the ln D versus $1/T$ plot represents the activation energy for diffusion Q

in the system remains constant

$$\frac{\partial c}{\partial t} + \nabla j_{\mathrm{D}} = 0 \qquad (4.16)$$

and with (4.14) one obtains finally after some manipulations (see [4.9] for a detailed derivation) Fick's second law (in its one-dimensional form)

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial y^2}\,, \qquad (4.17)$$

whose solution depends on the specific boundary conditions of the diffusion problem. For the scenario depicted in Fig. 4.18 (*diffusion bonding* of two semiinfinite rods of different metals), one obtains

$$\frac{c(y,t) - c_1}{c_2 - c_1} = \frac{1}{2}\left[1 + \mathrm{erf}\left(\frac{y}{2\sqrt{Dt}}\right)\right], \qquad (4.18)$$

with erf(ξ) being the *error function* (also called the *Gaussian probability integral*), which can only be solved numerically. Note that the error function is point-symmetric with respect to the origin and $-1 \le \mathrm{erf}(\xi) \le 1$ for $-\infty \le \xi \le \infty$. Equation (4.18) reveals that, to obtain a certain given concentration c_0 at depth y_0, both the temperature (via D) and time t can be varied independently to design an optimum heat treatment in view of the availability of appropriate furnaces as well as the cost of the operation. The most prominent application of diffusional problems is carburization of steels, for which solutions similar to (4.18) are available in literature [4.9].

4.1.4 Transformation into Solid State

In Sect. 4.1.2, we already noted that the solidification process of materials critically influences their microstructure in general, and the amount of dislocations and grain boundaries in particular. While physical vapor deposition (PVD) and chemical vapor deposition (CVD) techniques on (cold) surfaces have become increasingly important for thin-film technologies, the main and most important phase transformation in metallic materials, semiconductors, and glasses in terms of both mass production and annual turnover is still by far solidification from the melt (*cast metallurgy*). This phase transformation can be quantitatively treated by applying the principles of thermodynamics. Hence, in this section, we introduce the basic thermodynamic concepts, focusing on the behavior of pure materials, in other words a single-component *system*, a material that can exist as a mixture of one or more phases. A *phase* can then be defined as a portion of the system with the same structure. The *components* are the different (chemical) elements which make up a system, and the composition of a phase or the system can be described by giving the relative amounts of each component.

Consequently, the subsequent sections show how solidification occurs in alloys and multiple-*phase* systems, and the main species of binary phase diagrams are derived.

The reason why a transformation occurs at all is because the initial state of the material is unstable relative to the final state. This scenario can be expressed by thermodynamics principles (at constant temperature T and pressure p) through the Gibbs free energy G of the system

$$G = U + pV - TS = H - TS\,, \tag{4.19}$$

where U is the intrinsic energy, H is the enthalpy, i.e., the heat content arising (to a good approximation for condensed matter) from the total kinetic and potential energies of the atoms, and S is the entropy, i.e., a measure of the randomness of the system.

A system is in *equilibrium* when it is in its most stable state. This translates (4.19) for a closed system (with fixed mass and composition) at constant T and p into

$$\mathrm{d}G = 0\,. \tag{4.20}$$

From (4.19) and (4.20), one can intuitively conclude that the state with the highest stability will be the one with the best compromise between a low value of H and a high entropy. Thus, at low temperatures, solid phases are most stable, since they have the strongest atomic binding and hence lowest enthalpy. At higher temperatures, however, the $-TS$ term in (4.19) will dominate over H, and phases with increasingly greater degrees of atom movement become stable: first liquids, then gases. This is elucidated in Fig. 4.21, where the intersection of the curves with the ordinate is a measure of the enthalpy of the respective phases and the slope of the curves represents the entropy.

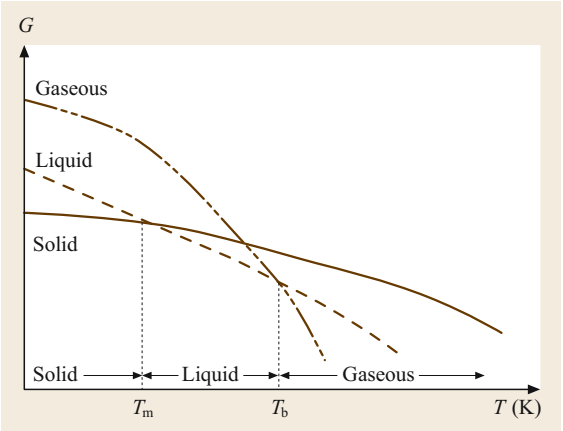

Fig. 4.21 Differences in molar free energy ΔG between solids, liquids, and gases in a single-component system (pure material). T_m and T_b denote the melting and boiling point, respectively

Homogeneous Nucleation

Undercooling a liquid below its equilibrium temperature T_m yields a driving force for solidification $\Delta G = (G_{Solid} - G_{Liquid}) < 0$, so one might expect the melt to solidify spontaneously. However, this is not the case, and liquids can be supercooled by more than a hundred kelvin below T_m without crystallization [4.2–5], as a nucleus of solid matter has to be formed within the homogeneous liquid. The change in free energy of the system ΔG_{cryst} when producing a solid sphere of radius r within the liquid for a given undercooling ΔT consists of two terms

$$\Delta G_{cryst} = -\frac{4}{3} r^3 \pi \Delta G_V + 4 r^2 \pi \gamma_{SL}\,, \tag{4.21}$$

of which the first, ΔG_V, is the gain in energy due to the formation of a spherical volume of crystalline solid, while the second, ΔG_S, is the expenditure energy due to the formation of the interface with specific interfacial energy γ_{SL} between the liquid and solid phases. The individual terms ΔG_V and ΔG_S are plotted together with the sum curve ΔG_{cryst} as a function of the crystal radius r in Fig. 4.22.

The critical radius r^* of a stable nucleus of crystalline solid is reached when further growth of the nucleus leads to a gain in ΔG_{cryst}. Mathematically, this is obtained from the first derivative of ΔG_{cryst} in (4.21)

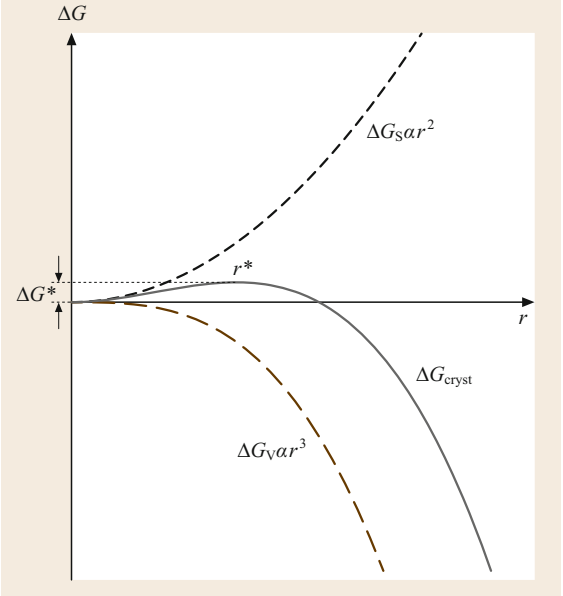

Fig. 4.22 Free energy change associated with homogeneous nucleation of a sphere of radius r

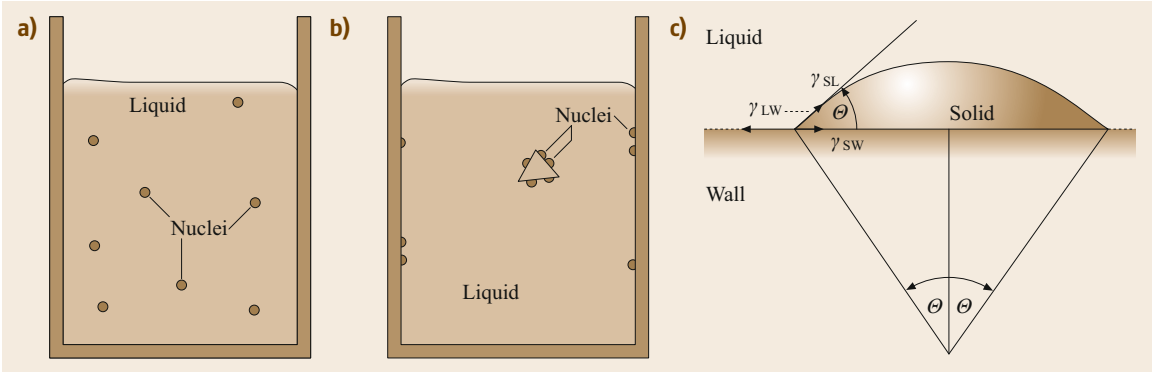

Fig. 4.23a–c Homogeneous (a) versus heterogeneous nucleation (b,c): a spherical cap of a solid needs fewer atoms to become a stable nucleus than a sphere, see text

with respect to r

$$\frac{\partial \Delta G_{\text{cryst}}}{\partial r} = 0 = -4r^{*2}\pi\Delta G_{\text{V}} + 8r^{*}\pi\gamma_{\text{SL}} \,. \qquad (4.22)$$

Solving (4.22) yields the critical radius as

$$r^{*} = \frac{2\gamma_{\text{SL}}}{\Delta G_{\text{V}}} \,, \qquad (4.23)$$

and for the excess free energy

$$\Delta G^{*} = \frac{16\pi\gamma_{\text{SL}}^{3}}{3(\Delta G_{\text{V}})^{2}} \,. \qquad (4.24)$$

Since ΔG is proportional to the undercooling ΔT, (4.23) and (4.24) straightforwardly demonstrate that small undercoolings require a large amount of ΔG^{*} and the formation of a large cluster of atoms to create a stable nucleus. Vice versa, for large undercoolings, nuclei with a small critical radius are already stable within the melt and can grow.

Heterogeneous Nucleation

From (4.24) for ΔG^{*}, it is obvious that nucleation can become easier if the interfacial energy term is reduced. This is effectively achieved if the nuclei form in contact with the mold wall (or likewise, impurities within the melt). Consider a solid embryo in contact with a perfectly flat mold wall (Fig. 4.25b,c). For a given volume of solid, the total interfacial energy of the system can be minimized if the condition

$$\gamma_{\text{LW}} = \gamma_{\text{SW}} + \gamma_{\text{SL}}\cos\Theta \qquad (4.25)$$

is fulfilled in the plane of the mold wall. The embryo has the shape of a spherical cap with radius r and wetting angle Θ. *Porter* and *Easterling* [4.9] compared this situation with that of a sphere with the same radius r which undergoes homogeneous nucleation (Fig. 4.23a) and derived the following relation for the energy barrier for heterogeneous nucleation

$$\Delta G^{*}_{\text{het}} = \frac{16\pi\gamma_{\text{SL}}^{3}}{3(\Delta G_{\text{V}})^{2}} S(\Theta) \,, \qquad (4.26)$$

where

$$S(\Theta) = \frac{(2+\cos\Theta)(1-\cos\Theta)^{2}}{4} \,. \qquad (4.27)$$

Except for the shape factor $S(\Theta)$, (4.26) is the same as the relation obtained for homogeneous nucleation in (4.24). Since $S(\Theta) \leq 1$ and the critical radius r^{*} is unaffected, heterogeneous nucleation is always energetically favored over homogeneous nucleation, thus also the rate of heterogeneous nucleation becomes faster [4.9]. If, for example, $\Theta = 10°$, then $S(\Theta) \approx 10^{-4}$ and the energy barrier for heterogeneous nucleation becomes dramatically smaller than that for homogeneous nucleation. Even for the upper limit $\Theta = 90°$ (half sphere), $S(\Theta) = 0.5$.

Heat Flow and Interface Stability

Neglecting the effect of alloying, solidification is controlled by the rate at which the heat of crystallization is conducted away from the solid–liquid interface. Two options are conceivable:

1. If the solid grows with a planar interface into a superheated liquid (Fig. 4.24a), the heat flow away from the interface through the solid must balance that from the liquid plus the heat of crystallization generated at the interface. Then, a small branch of solid protruding into the liquid will arrive in a region of increased temperature. Consequently, more heat will be conducted into the protruding solid and less heat will be transported away, such that

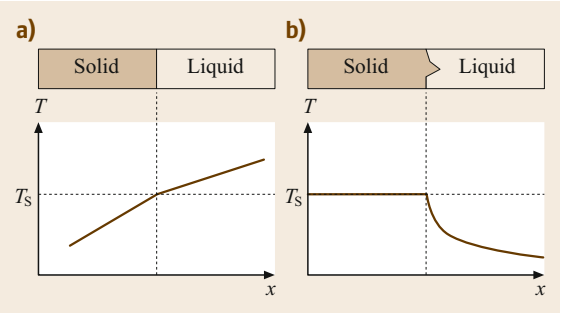

Fig. 4.24a,b Temperature distribution for solidification and the form of the solid–liquid interface when the heat is conducted through **(a)** the solid and **(b)** the liquid

the growth rate will slow down below that of the surrounding planar region and the protrusion will eventually disappear and the solid–liquid interface remains planar. Heat conduction through the solid, as depicted in Fig. 4.24a, can be promoted when solidification takes place from the cooler walls of the mold. This effect is applied technically by using a cold plate or a zone melter to apply a temperature gradient for producing microstructures consisting of coarse and elongated grains or even single crystals. An example for the Ni-20Cr alloy is shown in Fig. 4.25: starting from the left side with coarse but equiaxed grains, the temperature gradient causes a single dominant grain to grow preferentially towards the right of the sample.

2. If the solid grows into a supercooled liquid (Fig. 4.24b), an eventual protrusion of the solid into the liquid is forced to grow more rapidly by the negative temperature gradient in the liquid because the heat is removed more efficiently from the tip of the protrusion than from the surrounding regions. Thus, a solid–liquid interface advancing into a supercooled liquid is inherently unstable.

In alloys, the formation of dendrites is connected with compositional changes (or constitutional effects) between the solid and liquid phase, so dendrite formation is known to be caused by *constitutional supercooling*. An example of a dendritic microstructure in a cast Al alloy is shown in Fig. 4.26. For further details and a more quantitative treatment of these issues see [4.9].

4.1.5 Binary Phase Diagrams

In single-component systems, all phases have the same composition, and equilibrium involves temperature T and pressure p as variables. Obviously, in alloys, the composition is also variable and understanding phase transformations requires an appreciation of how the Gibbs free energy of the respective phases involved depends on all these parameters. However, pressure p can be ruled out and treated as being constant in what follows, since we consider only the liquid–solid transformation with both phases being essentially incompressible. Besides, to keep the physical model simple, we restrict ourselves in the following to binary alloys, i.e., two-component systems.

Gibbs Free Energy of Binary Solutions

Assume that two components A and B can be mixed in any proportions (because they have the same crystal structure; an example of this scenario would be the alloy system Ag-Au). Then the Gibbs free energy of a homogeneous solid solution can be calculated in two steps: first, we bring together x_A moles of pure A and

Fig. 4.25 Microstructure of Ni-20Cr alloy produced by zone melting, a single (*light grey*) grain evolves on the right half of the micrograph due to the horizontal temperature gradient

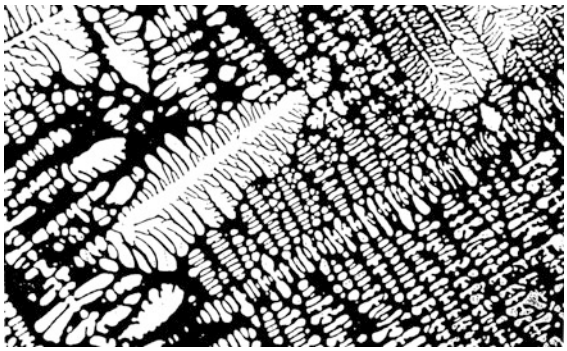

Fig. 4.26 Dendritic microstructure in die-cast Al-Zn10-Si8-Mg alloy

x_B moles of pure B, so the free energy of the system is simply the arithmetic mean

$$\overline{G}(x) = G_A x_A + G_B x_B \,, \tag{4.28}$$

with $x_A + x_B = 1$ for binary systems. Please note that in this section (Sect. 4.1.5) x is used as parameter for the molar concentration (in contrast to the concentration c used in Sect. 4.1.3). For all alloy compositions, $\overline{G}(x)$ lies on a straight line between G_A and G_B. The second step is now to let A and B mix in a random fashion. The free energy of the system will not remain constant during mixing, and

$$G(x) = \overline{G} + \Delta G_M \,, \tag{4.29}$$

where $\Delta G_M = \Delta H_M - T\Delta S_M$ is the change in the Gibbs free energy due to mixing. The simplest case of mixing is the *ideal solution*, in which one assumes that no preferences can be found for the different types of interatomic bonds between neighboring atoms. If preferred bondings are found, however, this situation is called a *regular solution* and describes more realistic scenarios of alloying; this case will not be treated here for simplicity. For ideal solutions, $\Delta H_M = 0$ and $\Delta G_M = -T\Delta S_M$. From statistical thermodynamics [4.6, 16] we know that entropy is quantitatively related to randomness by Boltzmann's equation and one obtains

$$\Delta G_M = -T\Delta S_M = RT\,(x_A \ln x_A + x_B \ln x_B)\,. \tag{4.30}$$

Since $\Delta S_M > 0$, i.e., there is an increase in entropy on mixing, ΔG_M is negative and the course of $G(x)$ according to (4.29) is shown schematically in Fig. 4.27. Note that, as the temperature increases, G_A and G_B decrease and the free energy curve $G(x)$ assumes a greater curvature due to the increasing degree of randomness.

For any given mole fraction x_B, the extrapolation of the tangent to G to both sides of the molar free energy

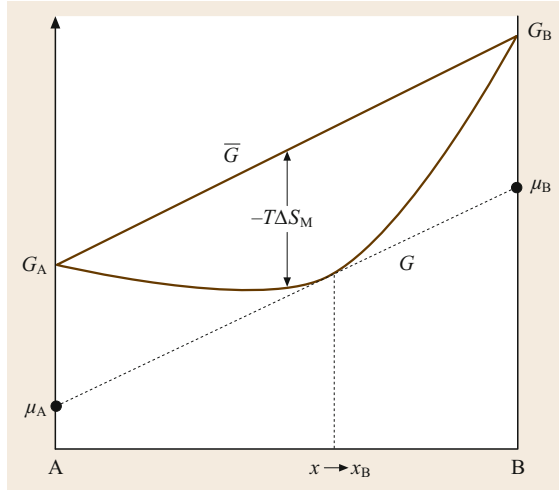

Fig. 4.27 Molar free energy of a system consisting of two components A and B before mixing ($\overline{G}$) and for an ideal solution (G)

diagram (Fig. 4.27) yields the chemical potentials μ_A and μ_B of the components A and B, respectively, which describe how the free energy changes when an infinitesimally small quantity of the atomic species i is added to the system (at constant T and p). Consequently,

$$\mu_i = \left(\frac{\partial G}{\partial x_i}\right). \tag{4.31}$$

Equilibrium in Heterogeneous Systems

Assume now that the components A and B do not form a homogeneous solid solution in the whole concentration range, but form two different phases appearing next to the two components with a limited extension towards the other component. In this case, two free energy curves G_α and G_β have to be sketched, as shown in Fig. 4.28, and the stable forms of both structures are those with the lower free energy; thus, in thermodynamic equilibrium, a homogeneous α solid solution is found for A-rich compositions while β is the stable phase for B-rich compositions. For alloy compositions near the crossover in the $G(x)$ curves (see, e.g., the composition x_0 in Fig. 4.28), a minimal total free energy can be achieved by forming a mixture of two phases α and β with equilibrium compositions x_α and x_β, respectively. From Fig. 4.28, it can be concluded that heterogeneous equilibrium between the two phases requires that the tangents to each G curve at x_α and x_β lie on a common line (the *common tangent rule*). In other words, each component must have the same chemical potential in the two phases and

$$\mu_A^\alpha = \mu_A^\beta \,, \quad \mu_B^\alpha = \mu_B^\beta \,. \tag{4.32}$$

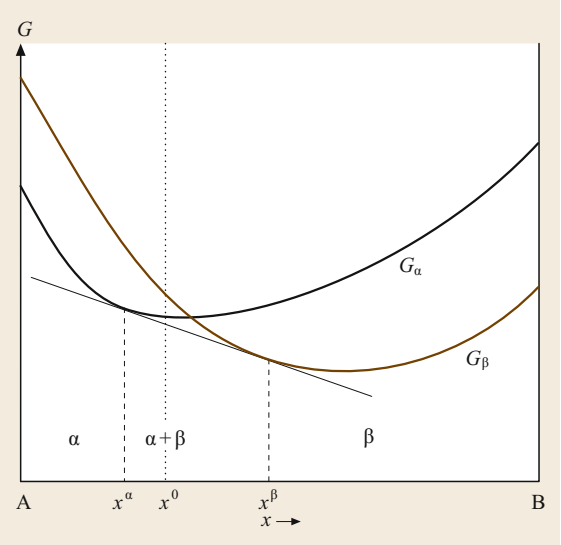

Fig. 4.28 Molar free energy curves for two phases α and β. At equilibrium, alloy x_0 has a minimum free energy when it is composed of a mixture of x_α and x_β

Binary Phase Diagram with Complete Miscibility

The simplest case conceivable is when the two components A and B are completely miscible in both the liquid and solid states and both are ideal solutions. Then, the free energy curves for the liquid and solid phases vary with temperature according to Fig. 4.29. At T_1, the liquid phase is thermodynamically stable over the whole composition range (Fig. 4.29a), thus $G_\alpha > G_L$. With decreasing temperature, one approaches the melting points T_2 and T_4 of pure A and B (see Fig. 4.29b,d, respectively), where the $G(x)$ curves meet in a single point on either side of the diagram. These points are plotted on the temperature axes for pure A and B, respectively, in the *equilibrium phase diagram* (Fig. 4.29f). With a further decrease in temperature (T_5), the solid phase is stable for all compositions (Fig. 4.29e), and $G_\alpha < G_L$. In the temperature interval between T_2 and T_4, the common tangent rule indicates a two-phase region with coexisting solid and liquid phase (see the two vertical dashed lines at T_3 in Fig. 4.29c). These points are transferred into the equilibrium phase diagram at T_3.

Lever Arm Rule

Figure 4.30 shows an enlarged view of the binary phase diagram with complete miscibility derived in Fig. 4.29. The region where the two phases coexist is limited by the two curved lines, the upper of which separates this region from the liquid phase. Consequently, this line is called the *liquidus line*. The lower line separates the two-phase region from the solid phase and is thus called the *solidus line*. For any given temperature T_3 and overall composition x_0 within the two-phase region, it may now be interesting to know the amount of liquid and

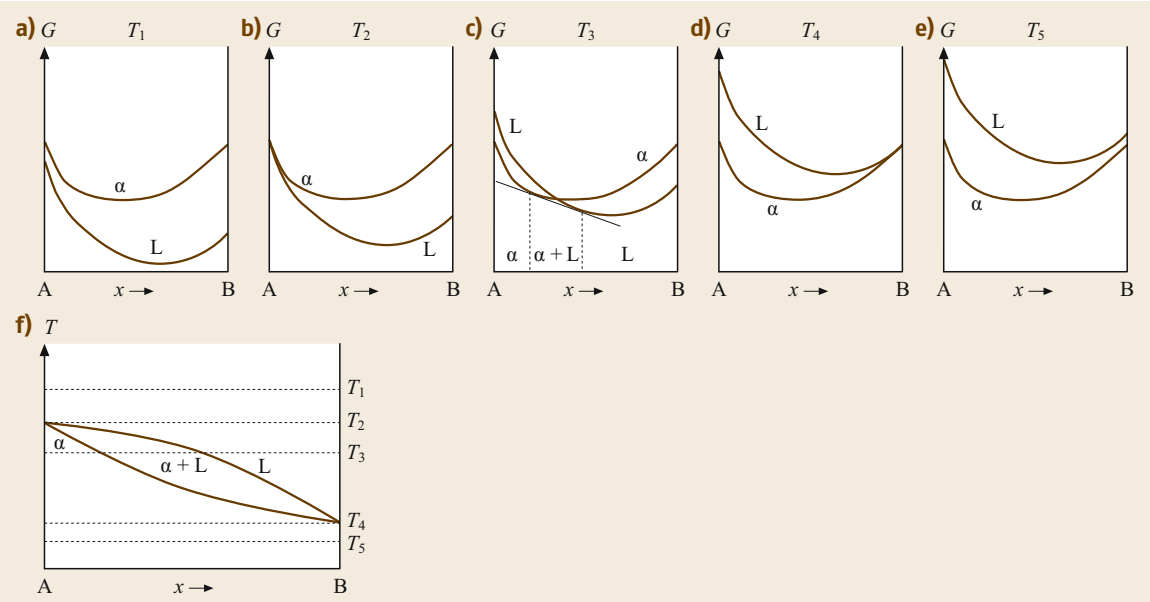

Fig. 4.29a–f Derivation of a phase diagram with complete miscibility in the liquid (L) and solid (α) state **(f)**: **(a)** at T_1, all compositions are liquid, **(b)** T_2 represents the melting point of element A, **(c)** at T_3, a two-phase region of α and L exists, **(d)** T_4 is the melting point of element B, **(e)** all compositions are solid at T_5

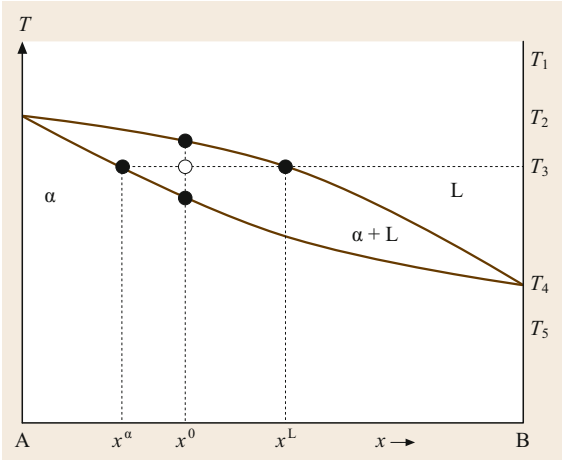

Fig. 4.30 Lever arm rule for estimating the molar fraction of solid and liquid phase in a two-phase region

solid phase, respectively, as well as their concentration (or, more precisely, their molar fractions). Drawing a horizontal straight line at T_3, the intersection with the liquidus and solidus line yields the concentration x_L and x_α of the liquid and the solid phase, respectively, within the two-phase region. The amount of α-phase f_α can be determined graphically utilizing the lever arm rule

$$f_\alpha = \frac{x_L - x_0}{x_L - x_\alpha} \,. \tag{4.33}$$

Analogously, one obtains for the amount of liquid phase f_L

$$f_L = \frac{x_0 - x_\alpha}{x_L - x_\alpha} \,, \tag{4.34}$$

and finally for the ratio between the solid and liquid phase

$$\frac{f_\alpha}{f_L} = \frac{x_L - x_0}{x_0 - x_\alpha} \,. \tag{4.35}$$

Equations (4.33)–(4.35) hold in general for all two-phase regions in binary phase. The application of this law to the eutectoid pearlite grains (0.8% carbon) (Sect. 8.1.1) shows that they contain 88% ferrite and 12% cementite, what can be confirmed by quantitative stereology (Sect. 4.2.3, *Quantification of Microstructure/Quantitative Stereology*).

Eutectic Systems

Figure 4.31 exemplifies the situation where the liquid phase is approximately ideal but the solid phase α is composed of two solid solutions α_1 and α_2; i.e., the atoms A and B *dislike* each other. Rather, preferred A–A- and B–B-type bondings can be found and ΔH_M in (4.31) becomes positive (regular solution). Therefore, at low temperatures T_5, the (combined) free energy

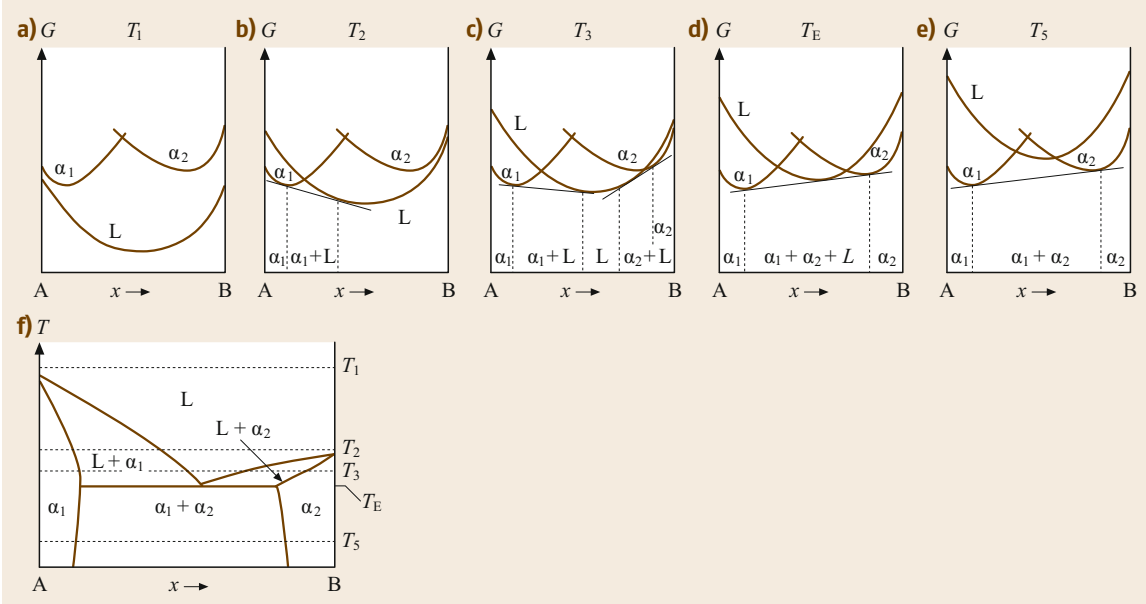

Fig. 4.31a–f Derivation of a eutectic phase diagram with a limited solubility for the A-rich solid solution α_1 and the B-rich solid solution α_2 **(f)**: **(a–e)** G–x curves of the solid phases α_1 and α_2, respectively, and the liquid phase L at temperatures T_1–T_3, T_E, and T_5. For further details see text

For further details see text

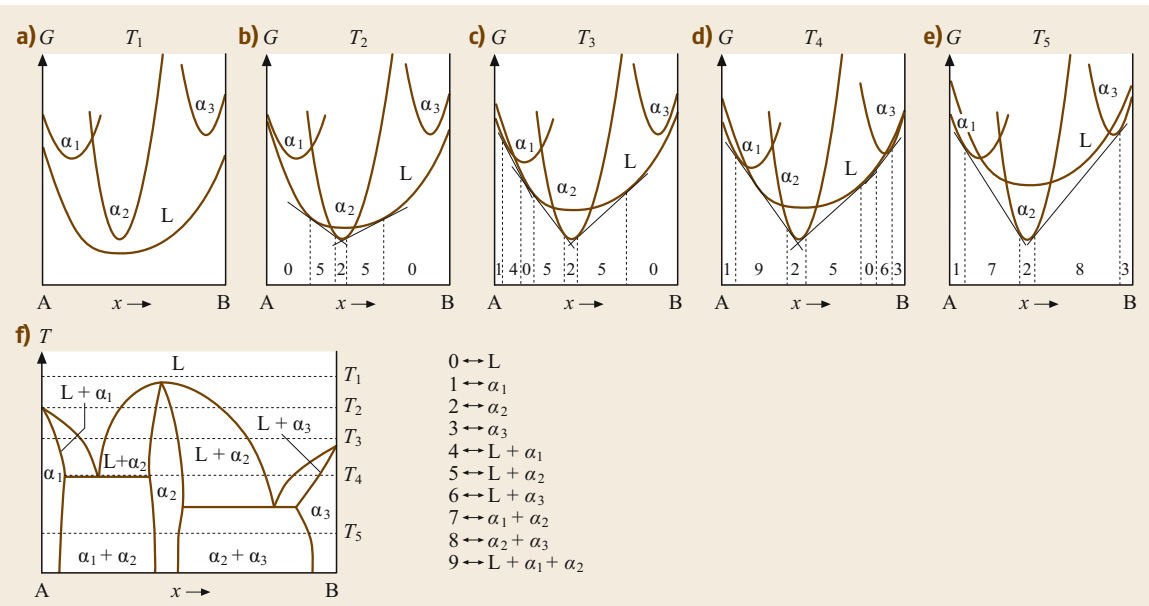

Fig. 4.33a–f Derivation of a complex system with an intermetallic phase α_2 **(f)**: **(a–e)** G–x curves of the solid phases α_1 to α_3 and the liquid phase L at temperatures T_1–T_5

curves of α_1 and α_2 in Fig. 4.31 assume a negative curvature in the middle and the solid solution is most stable as a mixture of the two phases α_1 and α_2. In this region eutectic decomposition occurs, and the lever arm rules (4.33)–(4.35) apply. The second effect of $\Delta H_M > 0$ becomes obvious at the *eutectic temperature* T_E, where one common tangent line can be applied to the $G(x)$ curves of all three phases: as a consequence, the *eutectic* composition has the lowest melting point within the system. For a *eutectic*

reaction,

$$L \rightarrow \alpha_1 + \alpha_2 \,. \tag{4.36}$$

Peritectic Systems

Figure 4.32 illustrates how a *peritectic* phase transformation is related to the free energy curves. Again, $\Delta H_M > 0$, but in contrast to the eutectic system, the $G(x)$ curves for the two solid solutions α_1 and α_2 are shifted to one side of the composition relative to the liquid phase L. As for the eutectic system, one common tangent line can be applied to the $G(x)$ curves of all three phases at T_P and the *peritectic reaction* is

$$\alpha_1 \rightarrow L + \alpha_2 \,, \tag{4.37}$$

which quite naturally explains why peritectic systems likely emerge when two components with substantially different melting points are alloyed.

Systems with Intermetallic Phases

The opposite type of effect arises when $\Delta H_M < 0$ and the atoms *like* each other within a certain composition range. In such systems (Fig. 4.33), melting will be more difficult in the α_2 phase because of its very deep $G(x)$ curve and a maximum melting point may appear. If the attraction between the unlike atoms is very strong and the α_2 phase extends as far as the liquid, it may be called an *intermetallic* phase.

4.2 Microstructure Characterization

4.2.1 Basics

The primary characteristic of a material is its integral and percentual chemical composition, that is, e.g., for metals the chemical elements, for polymer materials the types of polymers and possible reinforcements, and for ceramics the oxides, nitrides, or carbides. For the analysis of the chemical composition, for example, to monitor metallurgical processes or identify materials in warehouses, mostly *atomic emission spectroscopy (AES/OES)*, based on light emission, and *x-ray fluorescence spectroscopy (XRF)*, based on x-ray emission, are used. For chemical depth profiling of coatings, for example, methods based on step-by-step ablation of the material are necessary during the analysis process, e.g., *glow-discharge optical emission spectroscopy (GDOES)*. Starting with the chemical composition, a specific microstructure [4.17] will be generated during the solidification of a melt, the mixing of polymeric components, heat treatment, the manufacturing process (rolling, milling, deep drawing, and welding), or during usage (aging and corrosion).

The (usually three-dimensional) microstructure of materials can consist of several constituents, for example, grains (or crystallites) with different chemical compositions or crystallographic orientations (separated from each other by grain boundaries, Fig. 4.25) or precipitates, dispersoids, impurities (slags, oxides, and sulfides), pores, reinforcement particles, fibers, and others.

The constituents of a microstructure can be visualized using material-specific preparation and imaging methods. However, for complete characterization of a microstructure (materialography, or more specifically metallography, plastography, and ceramography), more methods than microscopic imaging are often necessary. For the interpretation and understanding of a microstructure, knowledge on the presence and nature of the crystallinity of the constituent phases is essential. This information can be obtained by x-ray diffraction analysis, which is a nonmicroscopic integral method. Meanwhile, information on the local chemical composition, local crystal structure, and characteristic geometric parameters of the constituents can be obtained using microscopic methods, which differ in their generated signals, optical resolution, and contrast mechanism.

4.2.2 Crystal Structure Analysis by X-ray Diffraction

The first goal of microstructure characterization is to learn which crystalline phases are present in a material. This is achieved mainly by x-ray diffraction (XRD) analysis [4.18, 19], which provides information on the crystal structure of the constituents of a microstructure. This is possible based on their crystallographic parameters such as type of crystal lattice, crystal symmetry, and unit cell dimension (Sect. 4.1). Moreover, information on the perfection of the crystal lattice (or number of dislocations), and thereby the degree of plastic deformation, and on the external and residual stresses acting on the lattice is also obtainable.

The theory of x-ray diffraction is based on Bragg's law, which describes how electromagnetic waves of a certain wavelength λ interfere with a regular lattice. At certain angles of incidence (θ) with regard to a set of parallel crystal planes, which are therefore called reflectors, constructive interaction takes place according to

$$n\lambda = 2d_{hkl} \sin\theta \,, \tag{4.38}$$

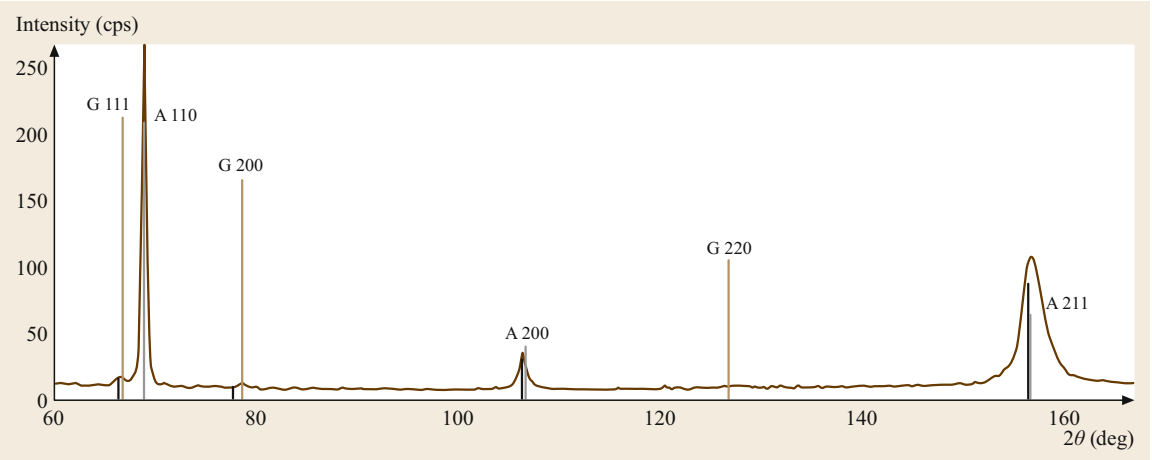

Fig. 4.34 X-ray diffraction pattern of a quenched and tempered hot-working steel 56NiCrMoV7, with metastable austenite (8%); the small peaks marked with a G represent the austenite phase, whereas the large peaks marked with an A show the ferrite matrix. G and A can be attributed to γ-Fe and α-Fe, respectively

where n is a positive integer and d_{hkl} is the interplanar spacing between the crystal planes that cause constructive interaction; λ is the known wavelength of the incident x-ray beam.

In XRD analysis, the specimen is irradiated using a monochromatic x-ray beam, e.g., Cu-K_α or Cr-K_α, which is generated by an x-ray tube with a metallic film for monochromatization. The diffracted x-ray beam is detected by, e.g., a scintillation counter at an angle of 2θ from the incident beam, and the signal is stored in a computer. Both the x-ray source and detector rotate on a circle around the sample in the center. The measuring spot typically has an area of several mm^2—in special cases of a few μm^2. Measurements are possible on bulk specimens, powders, and films. In materials science, XRD analysis applied to polycrystalline bulk materials is also called the *powder* diffraction method. Sample preparation is relatively easily accomplished by grinding or polishing, although destruction of the crystal structure by severe plastic deformation must be avoided. X-ray diffraction can be treated as an integral method for measuring the crystal structure, because the exposed area is usually composed of a number of crystallites. However, single-crystal measurements are also possible. The information depth of a few tens of μm depends on the angle of incidence, atomic number of the sample, and x-ray energy used.

From the x-ray diffraction profile, which is commonly plotted as the x-ray intensity versus 2θ (Fig. 4.34), the following information can be obtained [4.19, 20]: From the angle θ of the Bragg peaks, the lattice constants of the unit cell of the crystal can be calculated by applying (4.38). From the combination of these values, the type of crystal and its symmetry can also be deduced. Because a set of d values and the relative intensities of their corresponding x-ray peaks are characteristic of a certain crystalline material, they can be used for phase identification by comparing the measured diffraction pattern with those contained in databases. The most commonly used database is the powder diffraction file (PDF), maintained and distributed by the International Centre for Diffraction Data (ICDD).

In the case of a material consisting of multiple phases, the weight ratio of the crystalline phases can be calculated from the relative peak intensities. Quantification without a standard sample is based on such comparison of the peak intensities. However, a better way to obtain such ratios is to use a standard substance.

The width of the peaks provides information on the perfection of the arrangement of the atoms within the crystal lattice and on the number of dislocations resulting from plastic deformation. External and residual stresses applied to a crystal lead to dilatation or compression of the atomic distances and therefore to a shift of the diffraction peaks to greater or smaller angle. Practically, the strain in a sample is measured by recording the angular shift of a given reflector as a function of the angle of incidence. The measured strain is then used to calculate the stress with the help of the elastic modulus [4.21].

A preferred orientation of the crystallites in polycrystalline materials with respect to the sample coordinate system is called (crystallographic) texture. The orientation distribution can be determined by x-ray diffraction (XRD)-based texture analysis [4.22]. In this technique, pole figures are measured by recording the intensity distribution of a single reflection by tilting and rotating the sample while radiating it with an x-ray beam. In this way, the orientation distribution of a single

reflection, and thus for a single lattice plane, is determined [4.23].

4.2.3 Materialography

Materialography is the investigation of the microstructure of materials [4.24]. It includes specimen preparation and imaging of the microstructure, the quantification of the constituents (volume fraction, arrangement, size, shape, and grain orientation), as well as the local chemical and crystallographic characterization of the constituents, if necessary.

Specimen Preparation

The three-dimensional microstructure of a material is usually deduced from two-dimensional images, which are obtained by sectioning the sample. The resulting specimen is either in bulk form or thin and transparent, depending on the type of material and the goal of the investigation. The whole process of specimen preparation, starting with cutting small parts from larger pieces, has to be performed without disturbing the microstructure by mechanical or thermal effects. Small specimens (wire, or cross sections of sheet metal) are mounted in resin using pans which can be easily handled and have the right size for grinding machines. Bulk samples are prepared by grinding and polishing using metallographic machines with rotating disks fit with grinding paper or diamond pads, for example. A large number of material-specific abrasives and lubricants are available [4.25]. The selection of the most suitable ones is based on the material's composition and the mechanical properties of its constituents. Mechanical polishing is performed using a rotating wheel covered with cloth and small particle abrasives (for final polishing steps with grain size $< 1\,\mu m$), such as powders of diamond or aluminum oxide, or colloidal silicon dioxide. For further smoothing of the surface, electrolytic polishing can be applied, especially for homogeneous, i.e., single-phase, materials.

A prerequisite for microscopic imaging is a sufficient optical contrast, meaning that neighboring regions must show a certain difference of brightness or color. The contrast (C) is defined as the ratio of intensities I, which can be the intensity of white light (gray values) or colors (red, green, and blue)

$$C = \frac{I_1 - I_2}{I_1}\,, \tag{4.39}$$

where $I_2 < I_1$. Contrast can already be present after polishing the samples, e.g., if black graphite is present in a bright matrix of gray cast iron, colored grains in copper alloys and mineralic materials, and contours due to different abrasion of constituents. In most cases, however, the contrast has to be developed by means of chemical or physical etching [4.26]. Chemical etchants are water-based acidic or basic solutions or complex solutions of salts, sometimes containing organic substances. Grain boundary etching is usually applied to microstructures consisting of only one constituent (Fig. 4.35), where the etching agent reacts preferentially with the more reactive grain boundaries. Large differences in the etching rate of the constituents of a microstructure generate slopes at the grain boundaries between different constituents, which also gives a grain boundary contrast. For some etching agents, the ablation depends on the crystallographic orientation of the grains, so topographies with different light-scattering capability are developed. If a grain consists of two phases, such as pearlite (consisting of ferrite and cementite), one of them can be selectively etched, leaving a light-scattering topography of pearlite grains, which are dark under the microscope as compared with the brighter ferrite grains in a carbon steel (Fig. 4.36, compare also Fig. 4.38).

Fig. 4.35 Grain-boundary etching of an austenitic CrNi steel; the large number of twins is due to severe plastic deformation; light optical micrograph

Physical etching methods are based on selective ablation of constituents by a plasma generated in a glow-discharge apparatus or by ion-beam bombardment, for example, in a focused ion beam (FIB) instrument (see below).

For light and electron microscopy [4.27] of polymer materials, transparent specimens are prepared by cutting lamellae using a microtome with a glass or dia-

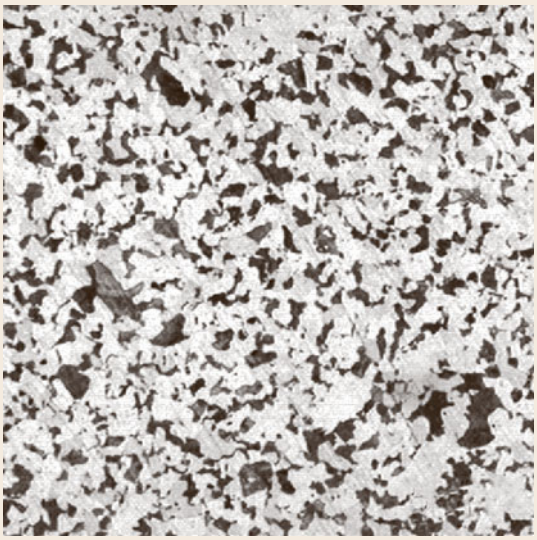

Fig. 4.36 Microstructure of a carbon steel (0.35% C), etched with 3% HNO_3; light microscopy of a polished and etched metallographic cross-section

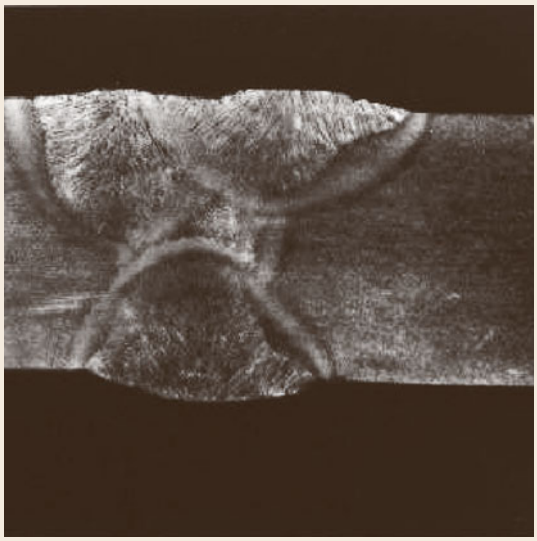

Fig. 4.37 Microstructure of a weld; macroscopy of an etched specimen

mond knife from the sample. The specimens are some micrometers thick and are positioned between a glass microscope slide and a cover glass by adding a drop of immersion oil to exclude air bubbles and increase the refractive index of the interspace. Easily plastically deformable polymers, such as polyethylene, are cut at low temperature (at −70 °C or lower) using a cryomicrotome or a ultra-cryomicrotome (at −175 °C). From polymer matrix composites, thin transparent specimens are obtained by grinding and polishing small pieces which are glued to a glass strip.

Microscopy of Microstructure

For some metallographic samples, it is sufficient to image the specimen with no or little magnification. This *macrometallography* is used, e.g., for the inspection of the microstructure of welds (Fig. 4.37).

In most cases, however, microscopy is necessary to visualize the microstructure, with magnification ranging from 20- to about 1000-fold. The most commonly used method is reflection light microscopy of bulk specimens. The contrast, as mentioned above, is based on the different reflection capability or color intensities of the constituents. If sufficient contrast cannot be obtained by specimen preparation, other imaging modes can be used, such as light microscopy with polarized light for aluminum and magnesium alloys, or differential interference contrast microscopy (DIC) for refractory metals (Mo, W, and V).

Inverted microscopes are used for bulk metallographic samples, because they allow easy positioning of the specimen on the microscope stage with the viewed surface exactly perpendicular to the optical axis. This is a basic requirement to have all parts of the viewed area in focus. Images are captured using a digital microscope camera with a charge-coupled device (CCD) or complementary metal–oxide–semiconductor (CMOS) sensor and a computer; easy-to-handle software is useful, which should allow calibration, the setting of scale markers (micrometer bar), and some interactive distance measurements. Microscope calibration standard patterns are imaged to calibrate the magnification of a selected microscope configuration. As a calibration value, the pixel size, viz. the micrometers per edge length of the square pixels, is stored with the image. A micrometer bar can then be burned permanently into the image if necessary, although one then has to be careful if the micrograph is to be used for automatic image analysis afterwards.

In some cases, dark-field microscopy, in which the diffuse reflected light is detected instead of the directly reflected light, gives better visibility of small objects. The lateral resolution of light microscopy is 0.25 µm at best (due to the wavelength of visible light). The best values are obtained when a substance with a high refractive index (immersion oil) is placed between the specimen and the objective.

For higher resolutions (and magnifications) than are possible with optical methods, *electron microscopy* is

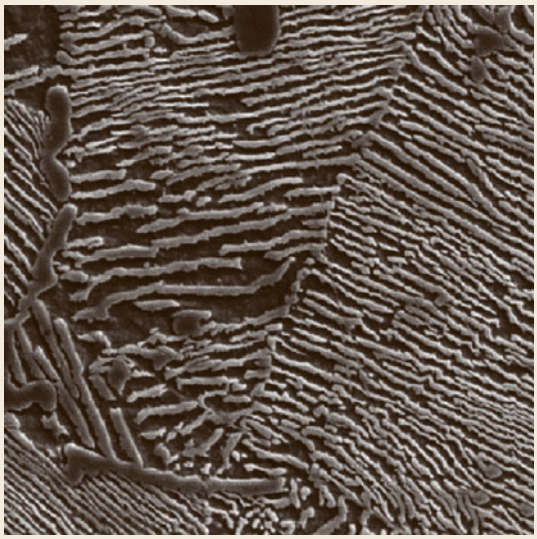

Fig. 4.38 Scanning electron microscopy (SEM) image of pearlite in plain carbon steel; secondary-electron (SE) image

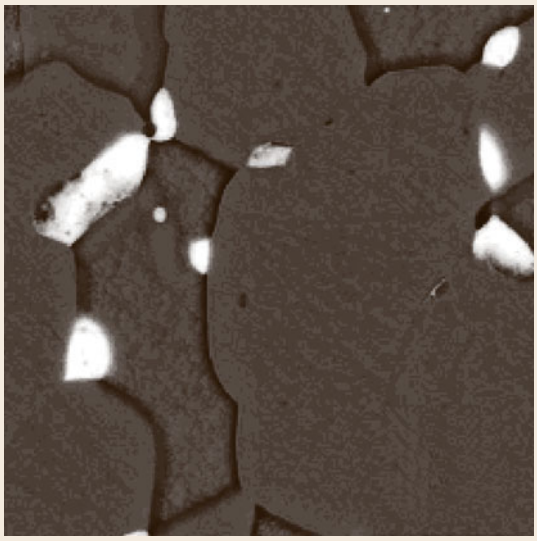

Fig. 4.39 Atomic number contrast in a SEM BSE image of brass; Pb particles are *bright* due to their higher atomic number as compared with Cu and Zn

a method that is widely applied in metallography. In addition, it can provide complementary information on the local chemical composition and the crystal structure. *Scanning electron microscopy* (SEM) is used for imaging metallographically prepared surfaces of bulk samples, and *transmission electron microscopy* (TEM) is used for imaging thin foils which are transparent to electrons. With both techniques, electrons are emitted from an electron gun, accelerated in an electric field (0.5–25 kV in SEM, and 80–400 kV—in some cases over 1 MV—in TEM) towards the anode, and then formed into a narrow beam (with a diameter of a few nanometer) by means of an electron optical system. High vacuum is necessary all along the electron path to prevent collisions of the electrons with gas molecules.

In an SEM [4.28, 29], the specimen, mounted on a multiaxis stage in the specimen chamber, is scanned with a focused electron beam. The emitted secondary electrons (SE) and backscattered electrons (BSE) are registered by detectors mounted above the specimen, and the signal intensities are stored as digital grayscale images. The SE detector is a scintillator–photomultiplier system, while for BSE a scintillator or semiconductor detector can be used.

The best resolution is achievable with the SE signal, and can be as good as 1 nm for suitable instrument parameters and specimen constitution. The information depth is a few tens of nanometers in the SE mode. For imaging of very small particles or thin layers, especially if they consist of low-atomic-number elements, the emission depth can be decreased by applying a lower accelerating voltage, down to some hundred volts. With SE, a topography contrast is generated, which is based on the dependence of the SE intensity on the angle of incidence between the electron beam and the imaged surface area (Fig. 4.38).

With BSE, a composition contrast image can be obtained, because the intensity of the BSE emission is related to the atomic number of the material. Regions containing higher-atomic-number elements are brighter than those composed of lower-atomic-number elements (Fig. 4.39). Even atomic number differences smaller then unity can result in a contrast which is in many cases good enough for imaging the microstructure of polished, but unetched, specimens.

SEM samples must be stable under high-vacuum conditions. This is not the case if they contain water or other liquids which can evaporate. Therefore, in some SEMs, fit with special vacuum devices and detectors, imaging at a pressure of up to about 25 mbar is possible by the injection of water vapor into the specimen chamber; this is known as variable-pressure SEM (VPSEM) or environmental SEM (ESEM). The resulting water partial pressure prevents the evaporation of water from the specimen and the resulting alteration of its structure. Cooling the specimen with the aid of a cooling stage to a temperature just above the freezing point supports this effect. Imaging electrically nonconductive materi-

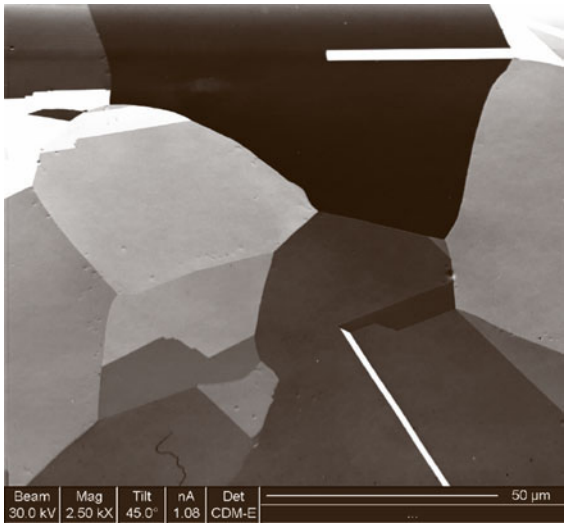

Fig. 4.41 Crystal orientation contrast due to ion channeling effect in Cu; FIB IISE image

als, such as polymers, ceramics, oxides, and mounting resins, is possible in different ways. Either they are coated with a conductive layer (Au, C, Pt, or Cr) by sputtering or evaporation, or a low accelerating voltage is applied (< 2 kV), or imaging is performed under low-vacuum conditions (at least 1 mbar), whereby ions generated by the collisions of electrons with gas atoms prevent the specimen surface from becoming charged.

Cross sections are commonly prepared for microstructural investigation of subsurface regions and of thin surface layers. The edge of the specimen must be preserved to prevent its rounding and the ablation of thin layers during grinding and polishing. Often, resins filled with hard particles are used, or a metal is plated on the sample surface before mounting; chemical deposition of Ni is preferred. A good alternative for the inspection of subsurface regions is cross sectioning with ion beams. Larger areas (with edge length of up to some millimeters) are cut with broad beams of Ar [4.30]. Target cross sections can be prepared using focused ion beam (FIB) instruments [4.31], in which a Ga^+ ion beam (0.5–30 kV accelerating voltage, 7 nm diameter) is scanned over the specimen. The ion bombardment results in a milling effect. Preparation is possible in any region of interest on the specimen surface by milling a stair-shaped trench, typically 20 µm wide and deep. The cross section is imaged after the specimen is tilted (Fig. 4.40). The edge of the trench is protected by a Pt strip, which is deposited before milling by ion-induced decomposition of a metalorganic Pt compound that is fed into the specimen chamber through a small tube. Imaging is possible in a FIB by means of secondary ions (SI) or ion-induced secondary electrons (IISE). The latter give both topographical and compositional contrast. Some crystalline materials show good orientation contrast due to the channeling effect [4.32], and the microstructure is visible without etching (Fig. 4.41).

Modern instruments combine the SEM and FIB functions. The SEM mode is used for conventional imaging with electrons, even during ion-milling steps, and for charge neutralization. An *energy-dispersive* (EDX) and a *wavelength-dispersive* (WDX) x-ray spectrometer and a digital camera for electron backscatter diffraction (EBSD) imaging (see below) can additionally be fit into such an instrument. Thus, the real three-dimensional chemical composition, crystal structure, and microstructure of a sample can be obtained by slice-milling the wall of a cross section in small steps (50 nm to a few µm) and subsequent reconstruction of the microstructure from the resulting EDX and EBSD image series.

TEM [4.33] is used to investigate microstructural constituents smaller than about 50 nm in the conventional (CTEM) or scanning mode (STEM), whereby a resolution of 0.1 nm can be achieved with dedicated instruments. The specimen must be electron transparent, with a thickness of 20–1000 nm, depending on the electron energy and specimen composition. Areal ion beam milling, electrolytic thinning, and ultramicrotomy are common methods applied for specimen preparation. Usually, the specimen is mounted on a 3-mm-diameter Cu grit, which is fixed to the TEM specimen holder. Target preparation, starting with a bulk specimen, is possible by means of FIB milling. One approach is to mill a trench on either side of the region of interest,

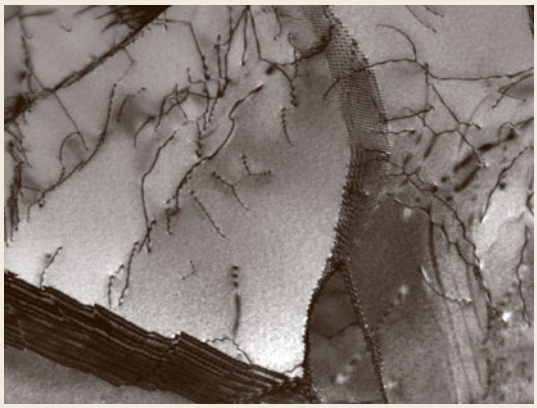

Fig. 4.42 Single dislocations within grains and dislocations forming subgrain boundaries; Mo alloy; multibeam TEM image of a 180-nm-thick specimen; 200 kV accelerating voltage

followed by cutting free the resulting lamella and its transfer to a TEM grid with the help of a nanomanipulator. In some cases, STEM can be carried out in a SEM equipped with a FIB and a STEM detector.

The contrast in TEM imaging depends on different materials properties and the imaging conditions. Mass–thickness contrast is based on differences in elemental composition and in the thickness of the corresponding transmitting region. Diffraction contrast appears if the crystal planes are oriented such that they give rise to Bragg diffraction as described by (4.38) (Fig. 4.42). Analysis of the local chemistry of a sample is possible in TEM by means of EDX and *electron energy-loss spectroscopy* (EELS) [4.34] with a resolution of a few nanometers.

Local Chemical Analysis

Local chemical analysis is a mandatory tool to identify microstructural features such as grains, precipitates, particles, and corrosion products, or to record concentration profiles. For this purpose, spectroscopy of x-rays emitted as a result of electron bombardment can be performed in a SEM or TEM (*electron probe microanalysis*, EPMA) [4.35]. In most cases, *energy-dispersive x-ray spectroscopy* (EDX) is used with a silicon drift detector (SDD) or semiconductor (Si-Li) detector connected to a multichannel analyzer. The resulting x-ray spectrum (Fig. 4.43) provides information on the presence of chemical elements represented by element-characteristic x-ray energies. The quantitative composition can be calculated from the intensities of the peaks by taking various correction parameters into account [4.36]. The x-ray spectrum can

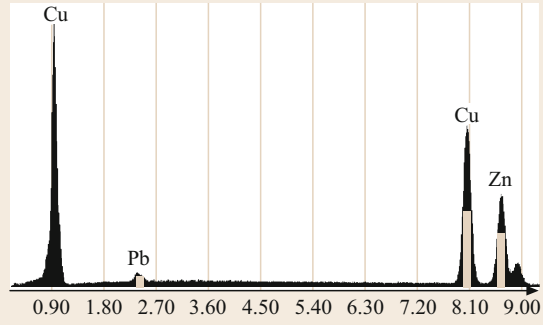

Fig. 4.43 Energy-dispersive x-ray spectrum (EDX) of brass: element-specific peaks and energy windows for element mapping

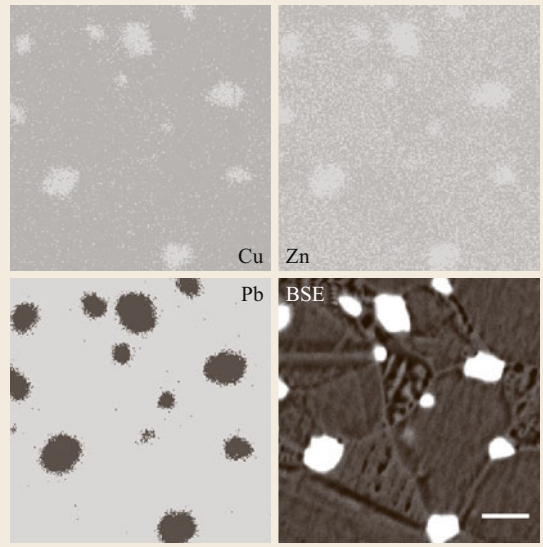

Fig. 4.44 EDX element map showing presence of Cu, Zn, and Pb as well as BSE image of the microstructure of brass

represent the average elemental composition of a larger scanned area (up to 1×1 mm) or of a spot as small as about 0.5 µm in diameter, which is the lateral resolution of EDX measurements. With a line scan, the intensity of an element-specific peak (energy window) is recorded and used to determine the concentration of this chemical element along a preselected line, across a grain border, for example. Extending this method to an area of interest enables so-called element mapping (Fig. 4.44).

Typically, EDX measurements in a SEM have a lateral and depth resolution of 0.5 µm for high-atomic-number elements, and up to 10 µm for low-atomic-number elements (graphite, polymers), and relative errors of 3–8%. Better resolution can be obtained if

the analysis is performed on thin specimens (≈ 100 nm thick) in a SEM or a TEM. Elements can be analyzed qualitatively starting with the atomic number of ^{5}B, whereas quantitative results can be obtained for elements starting from ^{11}Na. *Wavelength-dispersive x-ray spectroscopy* (WDX), using one or more crystal spectrometers attached to a SEM, allows the quantification of low-atomic-number elements (B, C, N, and O) and the analysis of trace elements. Because WDX cannot be used in a TEM, EELS is the alternative method of interest here.

Chemical Analysis of Thin Layers

Methods which are suitable for the chemical analysis of thin layers (in the nanometer thickness range), for measuring the concentration profile perpendicular to the surface within such layers, and for interface layers must possess a very small information depth. Layers of interest are, e.g., galvanic, sputtered or plasma-assisted coatings, corrosion layers, tribological reaction layers, and grain boundaries. The methods most widely used for the analysis of engineering materials are *scanning Auger electron spectroscopy* (SAM), *x-ray-exited photoelectron spectroscopy* (XPS)/electron spectroscopy for chemical analysis (ESCA), and *secondary-ion mass spectroscopy* (SIMS) [4.35]. Their lateral resolution ranges from a few nm (SAM, SIMS) to a few µm (XPS). Concentration–depth profiles with a resolution of a few nanometers can be obtained during spectroscopy by simultaneous sputtering of the specimen with accelerated ions (O^+, Ar^+, Ga^+, etc.). A method for depth profiling without local resolution is GDOES (Sect. 4.2.1).

Local Measurement of the Crystal Structure

Knowing the crystal structure locally in a microstructure, for example, of a single grain or a specific precipitate, is of interest for the following reasons:

1. In cases when EDX analysis cannot discriminate between chemically similar phases, determining the crystal structure may support phase identification.
2. Crystallographic orientation of single grains with respect to the specimen coordinates, for example, with respect to the rolling direction of sheet metal, can influence many properties significantly, such as the deformation behavior, corrosion, electrical conductivity, magnetic permeability, etc. of electrical steel.

The local crystal structure is obtained by electron diffraction with different resolutions in a TEM (< 1 nm) or SEM (> 20 nm) by applying Bragg's law (4.38). In a TEM, electron diffraction of a single grain gives rise to a point pattern (Fig. 4.45), from which the relevant crystal parameters (crystal structure, symmetry, and unit cell dimensions) can be deduced. It is noteworthy here that, when using TEM, only a few grains or particles can be investigated and the sample preparation may become a difficult and tedious task.

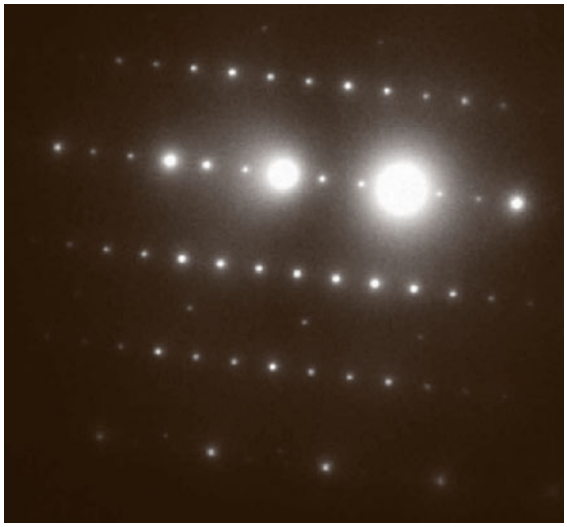

Fig. 4.45 Electron diffraction pattern of a Ni alloy obtained in a TEM at 200 kV; the *small spots* are superlattice peaks stemming from coherent and ordered precipitates embedded in a disordered fcc matrix

In an SEM, *electron backscatter diffraction* (EBSD) [4.37, 38] patterns can be recorded by using a combination of a phosphor screen and a digital camera fit to the specimen chamber. In the pattern (Fig. 4.46), each of the so-called Kikuchi bands represents a pair of lattice planes, with their width corresponding to the lattice plane spacing. The EBSD technique utilizes the knowledge of the crystal structure to visualize symmetry, and crystallographic orientation of a single grain by using commercial software. This method is also known as orientation imaging microscopy (OIM) [4.38]. Note, that the image quality (sharpness) deteriorates as the number of dislocations within a grain increases, in other words with the degree of plastic deformation. Since the information depth of EBSD is about 50 nm, the investigated surfaces have to be prepared very carefully by mechanical and occasionally electrochemical polishing, without disturbing the microstructure through the generation of dislocations due to plastic deformation [4.39, 40]. Milling the surface in a FIB or with a broad-beam ion miller is an elegant alternative preparation procedure.

For phase identification [4.41], the different crystal structures visualized by EBSD and the chemical composition simultaneously acquired by EDX analysis can

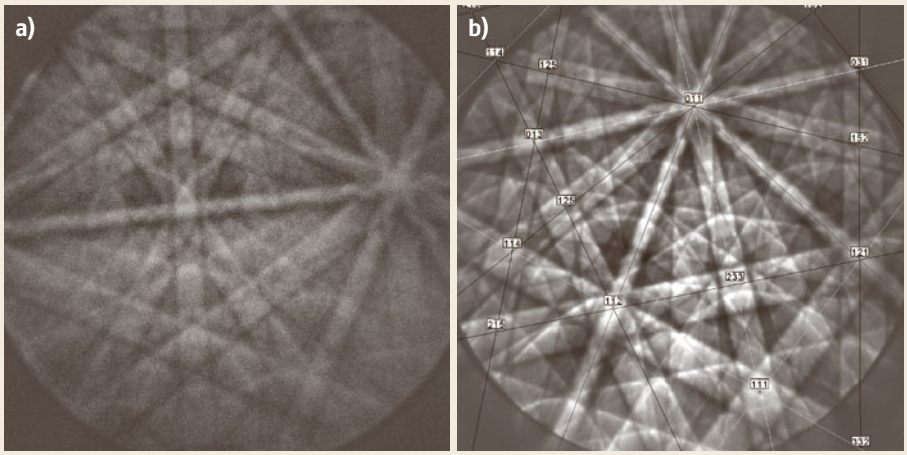

Fig. 4.46a,b Electron backscatter diffraction pattern (EBSD) of austenitic steel **(a)** and obtained from a grain in Ni with displayed zone axis directions **(b)**

be compared with data for known phases in a database such as the ICDD database (Sect. 4.2.2).

The crystallographic orientation, defined as the orientation of the coordinate system of a crystallite with respect to the coordinate system of the sample and represented by the Euler angles, can be calculated from the orientation of the diffraction pattern in an EBSD image. For engineering materials, the coordinate system of the sample is often defined by the rolling direction (RD), transversal direction (TD), and normal direction (ND). To obtain an orientation map, selected areas of the specimen (up to several hundred µm in edge length) are scanned with step sizes between 20 and 2000 nm, depending on the grain size, and the orientation at each measuring point is calculated [4.42]. The results are usually presented as an inverse pole figure, in which the orientation is color coded (Fig. 4.47). Specifically, in Fig. 4.47, the red-colored grains have an orientation in which the crystallographic direction [001] is parallel to the normal direction of the sample while the main axes of the cubic unit cell are parallel to RD, TD, and ND.

The different crystallographic orientations of neighboring grains can be used to generate an image of the microstructure. For this purpose, the difference in the crystallographic orientation between adjacent measuring points is used; for example, a difference of $> 15°$ can be chosen as a criterion for discriminating between high-angle grain boundaries. The result is a colored grain map (Fig. 4.48), from which a quantitative determination of grain sizes is possible.

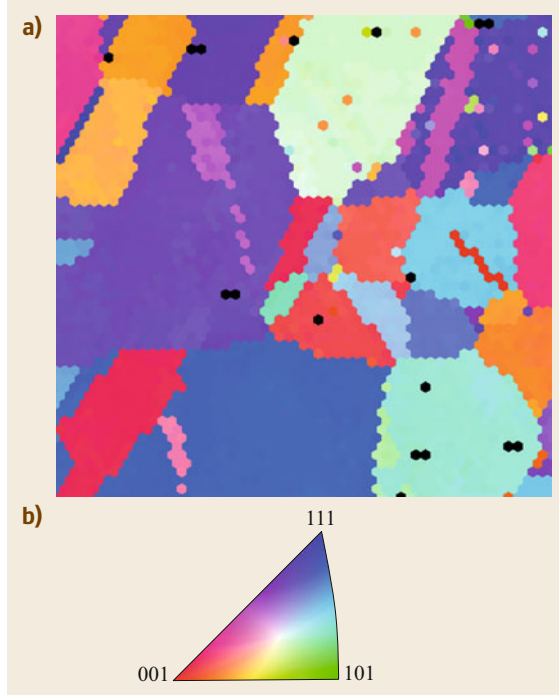

Fig. 4.47a,b Crystallographic orientation of grains in a polished section of pure Cu; inverse pole figure map **(a)** and corresponding legend **(b)**

Quantification of Microstructure/Quantitative Stereology

In many cases, a quantitative analysis of the microstructure is desired, e.g., to detect small differences between microstructures for quality control purposes, or to obtain numbers for modeling the material behavior. One example is the correlation of the grain size with the strength of a material, as described by the Hall–Petch equation (4.10) (Sect. 4.1.2).

Microstructure quantification can be performed by image comparison using standard charts, by manual measurement or counting, and with the help of digital image analysis software. Standards for microstructure

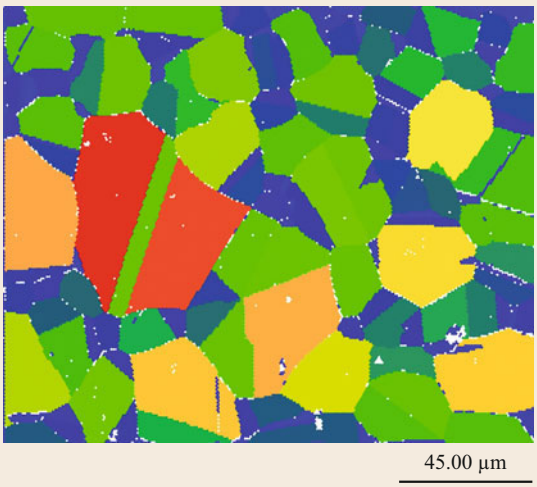

Fig. 4.48 Microstructure of an austenitic Cr-Ni steel based on EBSD measurements; different grains are defined as areas with misorientation > 15°

quantification describe the specimen preparation as well as the measuring procedure, the necessary equipment, and the form of the test report.

The study of the three-dimensional microstructure using images of two-dimensional sections through the structure is known as stereology [4.43, 44]. A basic stereological parameter [4.45, 46] is the volume fraction $V_V(\alpha)$ of a constituent (α), expressed as the ratio of the constituent volume $V(\alpha)$ and the testing volume V_t

$$V_V(\alpha) = \frac{V(\alpha)}{V_t} \,. \tag{4.40}$$

The volume fraction equals that fraction which can be obtained from the corresponding equilibrium phase diagram (Sect. 4.1.5, *Lever Arm Rule*), where the volume fraction has to be calculated from the weight fraction using the densities of the constituents. The volume fraction can be estimated using the fundamental stereological equation

$$V_V(\alpha) = A_A(\alpha) = L_L(\alpha) = P_P(\alpha) \tag{4.41}$$

from the areal fraction $A_A(\alpha)$ or line fraction $L_L(\alpha)$ determined by digital image analysis, by measuring the sum of the length of all the segments $L(\alpha)$ of the test lines L_t which lie within the grains of the constituent (α), or from the point fraction $P_P(\alpha)$. The latter is estimated by a manual point-counting procedure, in which a point grid is placed on the micrograph and the total number of points in the testing area P_t and the number of points hitting the constituent of interest $P(\alpha)$ are counted. This method has been standardized for steel [4.47] and duplex steel [4.48]. Rules for the use of automatic image analysis to determine the volume fraction of constituents are also described [4.49].

Another important stereological parameter is the surface density as an equivalent to the grain size (Sect. 4.1.2). It is calculated as the sum of the surfaces (boundaries) of all grains $S(\alpha)$ of a constituent (α) in a given test volume V_t

$$S_V(\alpha) = \frac{S(\alpha)}{V_t} \quad (\mathrm{m}^{-1}) \,. \tag{4.42}$$

$S_V(\alpha)$ is obtained by counting the number of intersections of test lines of total length L_t with grain boundaries P

$$S_V(\alpha) = \frac{2P}{L_t} = 2P_L \quad (\mathrm{m}^{-1}) \,. \tag{4.43}$$

Several parameters can be applied for the quantification of grains, for example, size, shape, orientation, and arrangement. A simple procedure for determining the average grain size is accomplished by comparing micrographs of the sample at a given magnification against a standard chart of grains, as standardized for graphite in gray cast iron [4.50] and for copper and its alloys [4.51], or by measuring the mean intercept length $\overline{L}_S$ (intercept method). The latter has been standardized for ferritic and austenitic steel [4.52, 53]. It is estimated by laying test lines of total length L_t over the micrograph and measuring the mean length of the segments $\overline{L}_S$ within the grains, or the number P of intersections of the test lines L_t with grain boundaries P_L in order to calculate $\overline{L}_S$ as

$$\overline{L}_S = \frac{L_t}{P} \,. \tag{4.44}$$

The surface density is then related to the mean intercept length by

$$S_V = \frac{2}{\overline{L}_S} = 2P_L \,. \tag{4.45}$$

A relatively simple and quick procedure to describe the grain size, particularly applied for ferritic and austenitic steel, is to use the grain size number G [4.53]. This is obtained by image comparison or by estimating the number of grains m in a unit area of 1 mm^2 of the specimen. In this procedure, a circle is drawn on the micrograph and the number of grains within the circle n_1 and those touching the perimeter n_2 are counted. With the microscopic magnification g and the circle radius r, the number of grains per mm^2 of the specimen surface can then be calculated as

$$m = \frac{\left(n_1 + \frac{n_2}{2}\right) g^2}{r^2 \pi} \,. \tag{4.46}$$

The grain size index G is calculated from [4.52]

$$m = 8 \times 2^G \,, \tag{4.47}$$

and is related to the mean intercept length $\overline{L}_S$ and the surface density S_V through

$$\begin{aligned} G &= 16.64 - 6.64 \log\left(\overline{L}_S\right) \\ &= 16.64 - 6.64 \log\left(2/S_V\right) \\ &= 16.64 - 6.64 \log\left(P_L\right) . \end{aligned} \tag{4.48}$$

The shape of single grains and particles can be estimated by image comparison or digital image analysis. With the latter method, geometric parameters for each particle such as the area A, perimeter P, and greatest and smallest extent d_{max} and d_{min} are measured. Shape factors are calculated by expressing the deviation from a circular shape (circular form factor $f_c = 4\pi A/P^2$) and the aspect ratio $f_a = d_{max}/d_{min}$. These form factors are needed to verify the results of heat treatment, where grains are rounded, or rolling and deep drawing processes, where grains may be elongated.

wendt@ovgu.de

Professor Ulrich Wendt studied chemistry and earned a diploma degree with a thesis on organic synthesis, a doctoral degree RNDr on heterogeneous catalysis, and a habil. degree on polymer melt crystallization. For more than 30 years he headed the Microscopy and Stereology Laboratory at the Department of Materials and Joining Technology, University Magdeburg. He lectured on microscopic and spectroscopic characterization, image analysis, topometry, and failure analysis of materials. He is now a freelance Materials Science consultant.

5. Mechanical Properties

Vivek Srivastava, Martin Heilmaier

This chapter is structured into two main parts. Section 5.1 provides an overview of the most common methods for mechanical testing of materials. In this section, the different available and standardized methods are further subdivided into quasistatic and dynamic testing methods. The former include, e.g., tensile and hardness testing, while the latter focus on impact and cyclic testing, including linear elastic fracture mechanics. Section 5.2 introduces the most common electrical (Sect. 5.2.1) and thermal (Sect. 5.2.2) physical properties for all material classes relevant for mechanical engineering applications.

5.1 Mechanical Properties

5.1.1 Framework

Measurements regarding elastic properties, fracture toughness, fatigue, plastic flow, creep, etc. all belong to the framework of *mechanical properties*. Engineers and scientists working in fields related to engineering materials require a fundamental understanding of mechanical properties. Engineers are primarily concerned with the *strength* of a material, which is a measure of the external force required to overcome the internal forces of attraction between its fundamental building blocks. In most engineering applications, only very small deformation of a component under a given loading condition is tolerable, and the strength often governs the choice of an acceptable material. Meanwhile, for a production engineer, the ease of inducing permanent deformation at the expense of as little energy as possible (i.e., *malleability* and *ductility*) is the critical mechanical property for a material under consideration. Given the importance of mechanical properties, it is essential to have a range of tests to *quantify* these mechanical properties. Additionally, standardized and inexpensive tests are needed for *quality assurance*. Scientists and alloy designers routinely use mechanical tests to assess the *performance* of a new material as compared with available materials.

5.1.2 Quasistatic Mechanical Properties

Tensile Testing

In this section, we address the response of a material to the application of an external applied static (or quasistatic) force. In its simplest form, the basic description of a material is obtained by a *tension* (or pull) test. Standard procedures for sample preparation and conducting such tests are described in ASTM (American Society for Testing of Materials) standard E8M-16ae1. Accordingly, the test specimen may be in plate, sheet, round, wire, or pipe form (Fig. 5.1) but must conform to certain guidelines in terms of its dimensions. Different gripping mechanisms, such as wedge grips, threads, pins, or shoulders, may be considered during specimen design. It is important to emphasize that, during specimen preparation, special care must be directed towards ensuring that the reduced section of the sample is free of defects, both microstructural and due to machining, and that the specimen is representative of the bulk material.

A typical tensile testing machine (Fig. 5.2) comprises a stiff frame, a specimen gripping device, a force measuring device (or load cells), an elongation measuring device (extensometer), and a data-recording device (X–Y plotter or computer). After careful measurement

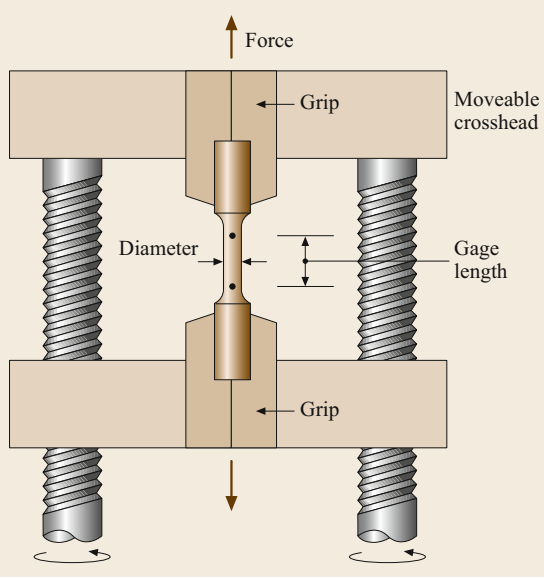

Fig. 5.2 Schematic representation of the components of a tensile testing machine (after [5.2])

of the relevant specimen dimensions, a tensile test may be run at a constant displacement, stress or strain rate. The load required to produce a given elongation is recorded as the specimen is pulled and is then plotted on a load–elongation chart. To obtain a more fundamental description of the material properties, it is essential to normalize the load–elongation data for the used specimen geometry. To achieve this, the load and elongation are converted to engineering stress and engineering strain, respectively.

The engineering stress (σ) is defined as

$$\sigma = \frac{P}{A_0}\,, \tag{5.1}$$

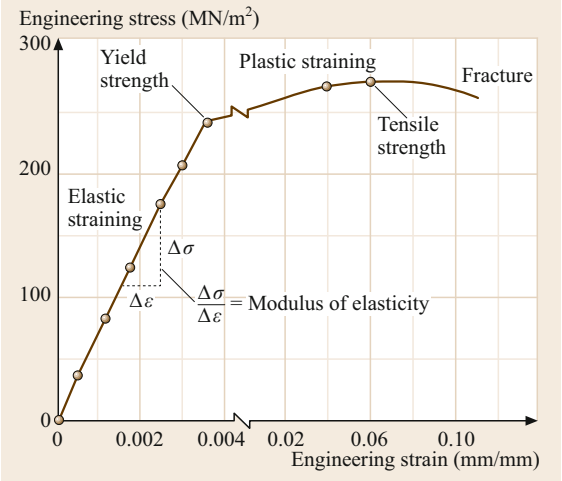

Fig. 5.3 A typical engineering stress–strain curve for a ductile material showing key mechanical properties (after [5.2])

where P is the applied load in MN and A_0 is the original cross-sectional area of the test specimen in square meter. The engineering strain (ε) is defined as

$$\varepsilon = \frac{l - l_0}{l_0} = \frac{\Delta l}{l_0}\,, \tag{5.2}$$

where l and l_0 are the gage length (see Fig. 5.1 for definition) under load and the original gage length, respectively.

Figure 5.3 shows a schematic engineering stress–strain diagram obtained from a tension test. The diagram is divided into two distinct regions:

1. Exclusively elastic deformation, i.e., linear and fully recoverable upon removal of load
2. (Elastic and) plastic deformation, where the latter is the nonlinear and nonrecoverable portion of the total deformation.

From this curve, certain key material properties can be evaluated, as described below:

- The *Young's modulus* E is the ratio of the axial stress to the corresponding strain in the elastic region. In some materials (typically polymers), the elastic region of the curve is not perfectly linear and a chord method is applied to estimate the elastic modulus (Fig. 5.4).
- The *yield strength* σ_y is the stress at which it is considered that plastic elongation of the material has commenced. This stress may be specified according to one of the following definitions:

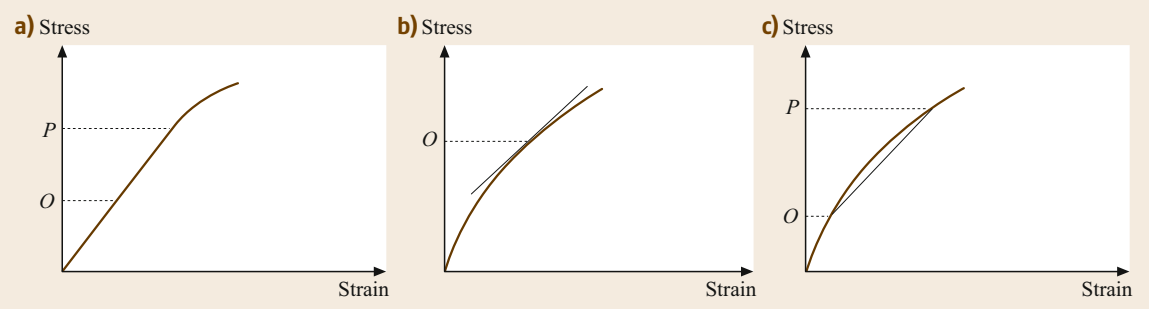

Fig. 5.4a–c Different methods to calculate the Young's modulus: **(a)** from the slope of the curve between *O* and *P* below the proportional limit, **(b)** from the tangent at a given stress *O*, and **(c)** from the slope of the chord between the stress *O* and *P* (after [5.3])

  - A specified deviation from a linear stress–strain relationship, i.e., the proof stress
  - A specified total extension attained
  - The maximum and minimum engineering stresses measured during discontinuous yielding, i.e., the upper and lower yield point, respectively (Fig. 5.5).
- The yield stress of a material may be engineered by several mechanisms including altering the grain size or adding alloying elements and/or second phases.
- The *ultimate tensile strength (UTS)*: is the maximum stress recorded during the tensile test. After this stress level has been reached, the specimen starts to show localized deformation called *necking*. Beyond this point, the engineering stress is seen to fall due to the fact that the engineering stress is defined according to the original specimen dimensions. However, the true stress ($\sigma = P/A$, where A is the actual cross-sectional area) continues to rise until fracture.
- The *ductility/elongation* is the ability of a material to deform before fracture under tensile load. Ductility, using this test method, is frequently quantified as the percentage elongation at failure, i.e., $\varepsilon_{\text{fracture}}$ ($\times 100$), where $\varepsilon_{\text{fracture}}$ is the plastic strain at the point of fracture.
- The *resilience and toughness* is the ability of a material to absorb energy when deformed elastically/plastically. It is defined as the area under the stress–strain curve in the elastic and plastic region, respectively.

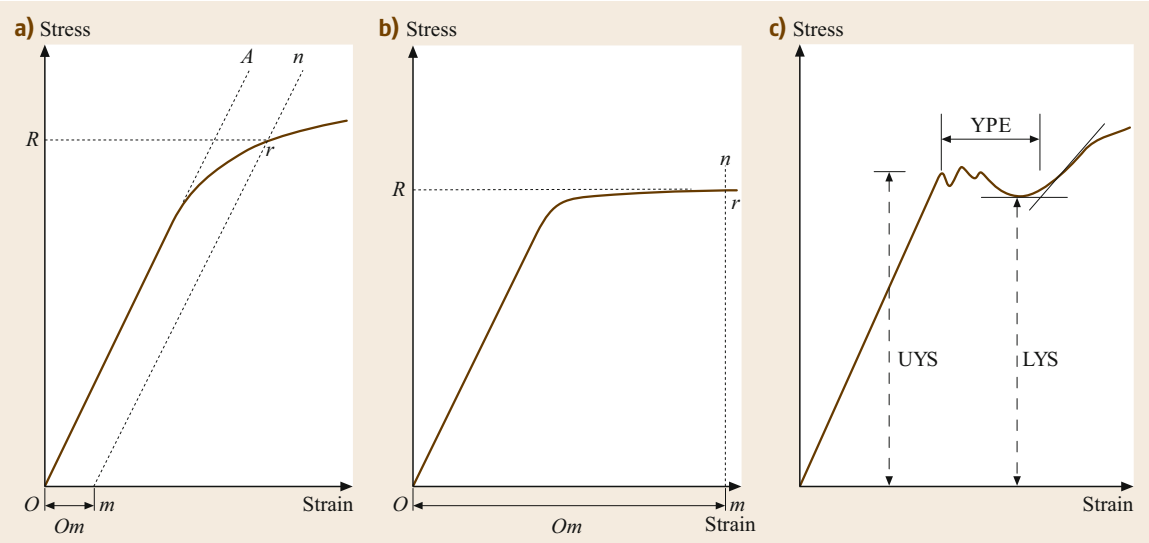

Fig. 5.5a–c Calculation of the yield stress according to **(a)** a prespecified plastic offset (*Om* = specified offset), **(b)** a prespecified total strain (*Om* = specified extension under load), **(c)** the upper and lower yield point (upper yield stress (UYS), lower yield stress (LYS), yield point elongation (YPE)) (after [5.3])

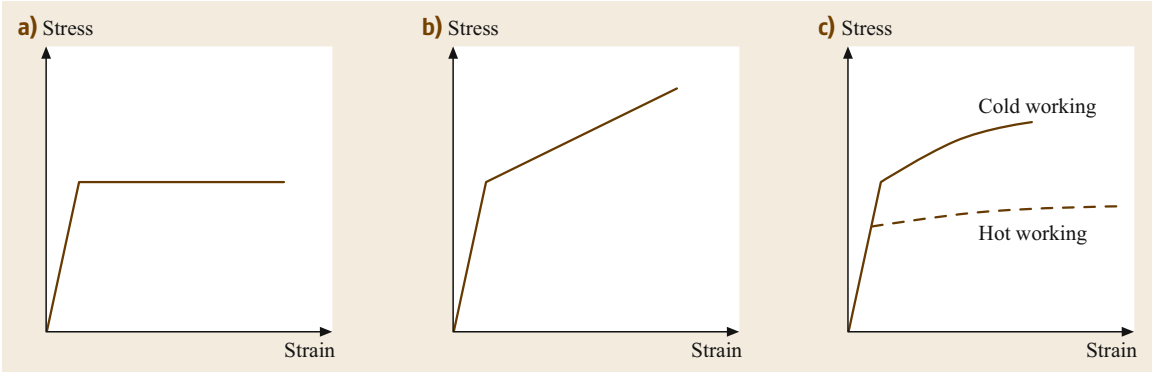

Fig. 5.6a–c Schematic representation of strain hardening in ductile metals: **(a)** elastic–ideal plastic, **(b)** elastic–plastic, and **(c)** flow curve during cold working showing strain hardening and hot working without significant strain hardening (after [5.4])

To differentiate between the elastic and plastic regions of the stress–strain curve, it is appropriate to look at the origin of strain. During elastic deformation, it is the stretching of interatomic bonds that leads to the observed macroscopic strain, which is (to a good approximation) linear due to the nature of the interatomic forces. On the other hand, the fundamental mechanism of plastic deformation is distortion and re-formation of atomic bonds. During this process, the total volume of the material is however conserved. During plastic deformation of crystalline solids (note that this does not apply for glassy materials and most polymers), *dislocations* within the material become operative and *slip* due to the shear stresses acting on them. For an ideal plastic material, the stress required for dislocations to continue slipping is a material constant and does not depend on the prior strain (Fig. 5.6a). However, in real materials, as the deformation proceeds, more dislocations are generated within the material and an additional driving force/stress is required for slip to proceed. This phenomenon is called *strain hardening* and is beneficially exploited during *cold working* to raise the yield strength of the resultant material. Strain hardening may be overcome by *hot working*, since dislocations start to become annihilated at higher temperatures ($T > 0.5T_{\mathrm{m}}$, where T is the hot working temperature and T_m is the absolute melting temperature in kelvin; Fig. 5.6). Furthermore, mechanical properties such as the elastic modulus and tensile strength are strongly temperature dependent and decrease with increasing temperature. Ductility though is generally found to increase with increasing temperature.

The plastic region of the true stress–true strain curve is also referred to as the *flow curve*, as it is the locus of stress required to cause the metal to *flow* plastically to any given strain. The expression most commonly used to describe the flow curve empirically takes the form

$$\sigma = K\varepsilon^n \,, \tag{5.3}$$

where K is the stress at $\varepsilon = 1$ and n is the strain hardening exponent, viz. the slope of a log–log plot of the flow curve. It can be shown mathematically that $n = \varepsilon_{\mathrm{fracture}}$, thus it is a measure of the ductility of the material.

The appearance of the surface of the specimen after fracture provides clues to the mode of fracture. Brittle fracture is accompanied by a flat (and *grainy, often shiny*) surface (Fig. 5.7a), while ductile fracture after considerable plastic deformation results in a *cup-and-cone* fracture surface (Fig. 5.7b).

Compression Testing

Mechanical properties such as the yield strength, yield point, elastic modulus, and stress–strain curve may also be determined from compressive tests. This test procedure offers the possibility to test brittle and nonductile metals that fracture at low strains and avoids the complications arising out of necking. On the other hand, for certain metallic materials, *buckling* and *barreling* complicate such testing (Fig. 5.8) but can be minimized by designing the samples as per specifications and using proper lubricants. Solid round/rectangular cylindrical samples (aspect ratio 0.8–10) may be used. Surface flatness and parallelism are important considerations during sample machining. After marking the gauge length and measuring the specimen dimensions, the specimen is placed in the test fixture and should be aligned carefully to ensure concentric loading. The specimen is then subjected to an increasing axial compressive load; both load and strain may be monitored either continuously or in finite increments. Relevant mechanical properties may be determined as

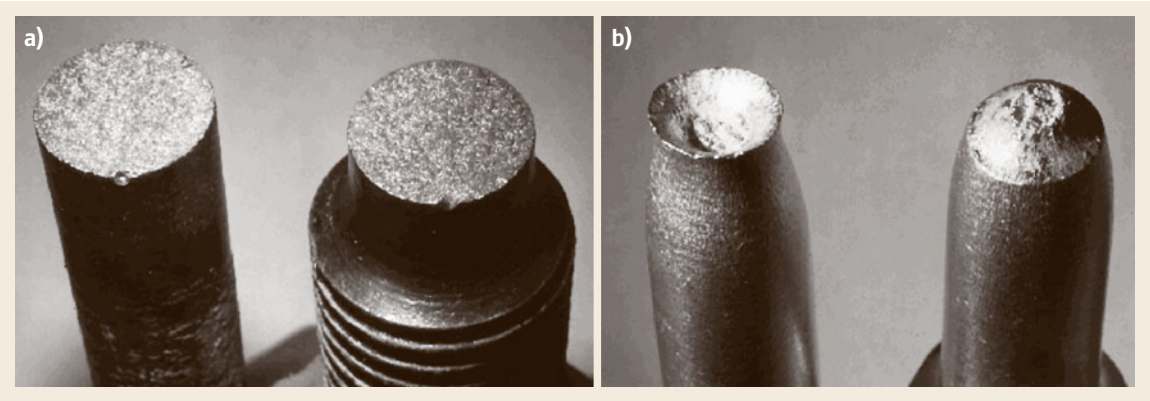

Fig. 5.7a,b Appearance of fracture surfaces after tensile testing. **(a)** Brittle fracture leads to a relatively flat surface, whereas **(b)** ductile fracture shows considerable deformation prior to fracture, leading to a classical cup-and-cone arrangement

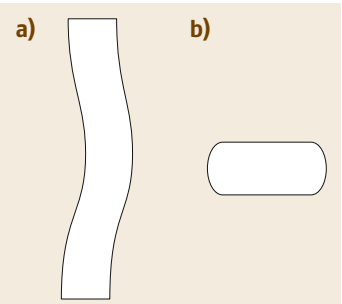

Fig. 5.8a,b Schematic representation of **(a)** buckling and **(b)** barreling during compressive testing (after [5.3])

described in Sect. 5.1.1. Compression testing is usually easier to conduct than tension testing and is used more commonly at elevated temperatures in plasticity or formability studies, since it simulates compressive stress as is expected under rolling, forging, or extrusion operations.

Hardness

In general, the hardness of a material refers to its resistance to plastic deformation, although it is a loosely defined term. However, it is an easily measurable quantity and frequently employed in quality assurance and inspection. Standard hardness test procedures involve slowly applying an indentation to the surface of the material and measuring the relevant dimensions of the depression. Depending on the shape of the indenter and method of calculation, the following hardness tests are commonly employed:

Brinell hardness: An indenter made of a hardened steel or tungsten carbide *ball* with diameter D (1−10 mm) is forced into the surface of a test piece, and the diameter of the indentation, d, left in the surface after removal of the test force F (100−3000 kgf) is measured. The Brinell hardness (BHS or BHW) is then obtained by dividing the test force by the curved surface area of the indentation as

$$\text{BHS} \quad \text{or} \quad \text{HBW} = \frac{2F}{\pi D\left(D - \sqrt{D^2 - d^2}\right)} \,. \tag{5.4}$$

Later, Meyer suggested a more rational definition of hardness based on the projected area, but it did not gain acceptance despite its more fundamental nature. The Meyer hardness is given as $4F/\pi d^2$ in kgf/mm^2.

The *Vickers hardness* test uses a *square-based diamond pyramid* as the indenter with the included angle between the opposite faces being 136°. Due to the shape of the indenter, the Vickers hardness number (VHN) or Vickers pyramid hardness (VPH) is also frequently referred to as the diamond-pyramid hardness number (DPH) and is defined as the load divided by the surface areas of the indentation according to the equation

$$\text{DPH} = \frac{2F\sin(\theta/2)}{L^2} = \frac{1.854F}{L^2} \,, \tag{5.5}$$

where L is the average length of the diameters in mm and θ is the angle between opposite faces of the diamond (= 136°). The advantage of the Vickers hardness is that it provides a continuous scale of hardness, from very soft to very hard materials. However, the VHN is fairly sensitive to surface finish and human error.

The *Rockwell hardness* test is the most widely used in industry due to its speed, freedom from human error, and ability to distinguish small hardness differences in hardened steels. This test utilizes the depth of indentation, under constant load, as a measure of hardness. A minor load of 10 kg is first applied to seat the specimen, followed by the major load for the required dwell time. The depth of indentation is automatically recorded

electronically or using a dial indicator in terms of an arbitrary scale without units. The Rockwell hardness indenter is either a 120° diamond *spheroconical* or steel *ball* $\frac{1}{16} - \frac{1}{2}$ inches in diameter. Major loads of 60, 100, and 150 kg are used. Different combinations of load and indenter are used for materials with different hardnesses, and it is necessary to specify the combination employed when reporting Rockwell hardness values. This is done by prefixing the hardness number with a letter that indicates the particular combination. Hardened stress is tested on the *C* scale using the diamond indenter and a major load of 150 kg.

Hardness testing is a very useful and reproducible method to measure and compare the mechanical strength of a material, provided that sufficient precautions are taken during testing. Hardness tests are carried out on the surface of the specimen, so it is very important that the surface be flat, free of defects, and representative of the bulk material. Additionally, there are empirical correlations available to estimate the tensile strength from the hardness value and to convert a result from one type of hardness test to that of a different type. However, it is important to verify these correlations for the specific class of material under consideration, although some standard conversion tables are available for commercial carbon and alloy steels and aluminum alloys. Micro- and nanohardness testing procedures are available for measuring hardness over smaller areas, while hot hardness testers are used to measure hardness at elevated temperatures.

Bend or Flexure Testing

Bend tests are used primarily to obtain values of proof stress and modulus of elasticity in bending (E_b) as well as the ductility of relatively flexible materials such as polymers and their composites. Bend testing also provides a convenient method for characterizing the strength of the miniature components and specimens that are typical of those found in microelectronics applications.

There are two test types (Fig. 5.9): three-point flex and four-point flex. In a three-point test, the area of uniform stress is quite small and concentrated under the central loading point. In a four-point test, the area of uniform stress extends between the inner span loading points (typically half the outer span length).

A flexure test produces tensile stress on the convex side of the specimen but compressive stress on the concave side, resulting in an area of shear stress along the midline. To ensure that the primary failure comes from tensile or compressive stress, the shear stress must be minimized; This is done by controlling the span (S) to depth (h) ratio, the length of the outer span divided by the height (depth) of the specimen. For most materials,

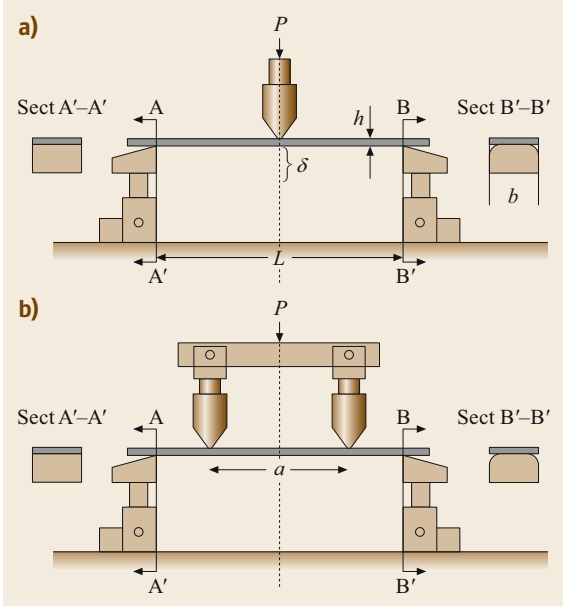

Fig. 5.9a,b Schematic representation of **(a)** three- and **(b)** four-point bend tests (after [5.3])

$S/h = 16$ is acceptable. However, some materials require $S/h = 32-64$ to keep the shear stress low enough. Usually, a specimen with a rectangular cross-section is used. E_b varies as the third power of the beam thickness, thus the uniformity of the thickness is of paramount importance.

The test apparatus consists of two adjustable supports and means for measuring the deflection and applying the load. The supports are generally knife-edge or convex. The load applicator is a rounded knife-edge with an included angle of 60°, applied either at the midspan (for three-point testing) or symmetrically spaced from the supports (for four-point testing). The elastic deflection δ is measured at the midspan, as shown in Fig. 5.9. The stress and E_b are related to the applied load and deflection as

$$\sigma_p = \frac{3PL}{2bh^2}\,; \qquad E_b = \frac{PL^3}{4bh^3\delta}$$

for three-point bend testing (5.6)

and

$$\sigma_p = \frac{3Pa}{bh^2}\,; \qquad E_b = \frac{Pa\left(3L^2 - 4a^2\right)}{4bh^3\delta}$$

for four-point bend testing. (5.7)

Torsion Testing

Torsion tests have not met with the same wide acceptance and use as tensile testing. However, in many

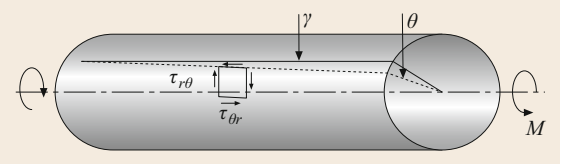

Fig. 5.10 Idealized schematic of a tubular pipe under torsion showing the shear stress and strain (after [5.4])

engineering applications and theoretical studies, they are of considerable importance. Torsion tests are used to determine properties such as the modulus of elasticity in shear (G), torsional yield strength, and modulus of rupture. During a torsion test, measurements are made of the twisting moment, M_T and the angle of twist θ. From linear elastic mechanics (Fig. 5.10), the shear stress τ and shear strain γ can then be calculated according to the relation

$$\tau_{max} = G\gamma = \frac{M_T r}{J}, \qquad \gamma = \frac{r\theta}{L}, \tag{5.8}$$

where r and L are the radius and length of the test specimen, respectively, and J is the polar moment of inertia of the area with respect to the axis of the specimen. For a solid cylindrical specimen, $J = \pi r^4/2$. Because of the stress gradient across the diameter of a solid bar, it is preferable to use a tubular specimen for the determination of the shearing yield strength and elastic modulus. However, care must to be taken to avoid buckling in this case.

Beyond the torsional yield strength, the shear stress is no longer a linear function of distance from the axis and the analysis becomes slightly more complicated; in this case, the maximum shear at the surface is given as

$$\tau_{max} = \frac{1}{2\pi r^3}\left(\theta\frac{dM_T}{d\theta} + 3M_T\right). \tag{5.9}$$

It is possible to convert the shear stress–strain curve into a tensile stress–strain curve using the following relations

$$\sigma = \sqrt{3}\tau_{max}, \qquad \varepsilon = \frac{\gamma}{\sqrt{3}}. \tag{5.10}$$

A major advantage of torsion tests over tensile tests is that the fracture is delayed and it is possible to extend the flow curve to larger strains. This is of significance for the study of the plastic flow behavior of ductile materials. Torsion tests are regarded as complicated due to the considerable labor involved in converting torque–twist data to stress–strain data. However, the computational resources available today considerably ease this restraint. Torsion testing provides a more fundamental description of the plasticity of metals and avoids complications such as the necking and barreling associated with tension and compression tests.

As mentioned above, the specimen design and fabrication are rather important for obtaining reliable mechanical properties from torsion tests. Specimens in the form of solid cylinders should be straight and of uniform diameter, with a length equal to the gauge length plus two to four diameters. In the case of tubes, the total specimen length should be the gauge length plus at least four outer diameters. The prescribed ratio of the gauge length to diameter is at least four to ten. For tubular samples, the ratio of the outer diameter to the wall thickness should lie between eight and ten. During testing, the twist angle is generally applied by mechanical, optical, or electrical means using rings fastened to the sample. A torsiometer, fastened to the sample and the base of the machine, is used to measure the angle of twist in radians in both the elastic and plastic regions.

Creep Testing

A metal subjected to a constant load at elevated temperature ($> 0.5T_m$, where T_m is the absolute melting temperature) undergoes time-dependent (anelastic) deformation called creep. At these temperatures, the mobility of vacancies increases significantly according to Fick's laws and diffusion-controlled processes have a significant effect on the mechanical properties (Chap. 4). The rate of dislocation climb, the concentration and mobility of vacancies, activation of new slip systems, and grain-boundary sliding are all temperature and diffusion controlled and affect the mechanical behavior of materials at high temperatures. In addition, corrosion or oxidation mechanisms, which also are diffusion rate dependent, will have an effect on the lifetime of materials at high temperatures.

Conceptually, a creep test is rather simple: a force is applied to a test specimen exposed to a relatively high temperature, and the dimensional change over time is measured. If a creep test is continued to its conclusion (that is, the fracture of the test specimen), often without precise measurement of the dimensional change, then it is called a stress rupture test. Although conceptually quite simple, creep tests are more complicated in practice. Temperature control is critical (the absolute temperature must be met within a few degrees and the fluctuation must be kept to $< 0.5\,^{\circ}C$). The resolution and stability of the extensometer are important concerns (for low-creep materials, the displacement resolution must be on the order of 0.5 μm). Environmental effects can complicate creep tests by causing premature failure unrelated to elongation and thus must either mimic the actual service conditions or be controlled to limit the failure to creep mechanisms. The uniformity of the applied stress is critical if creep tests are to be

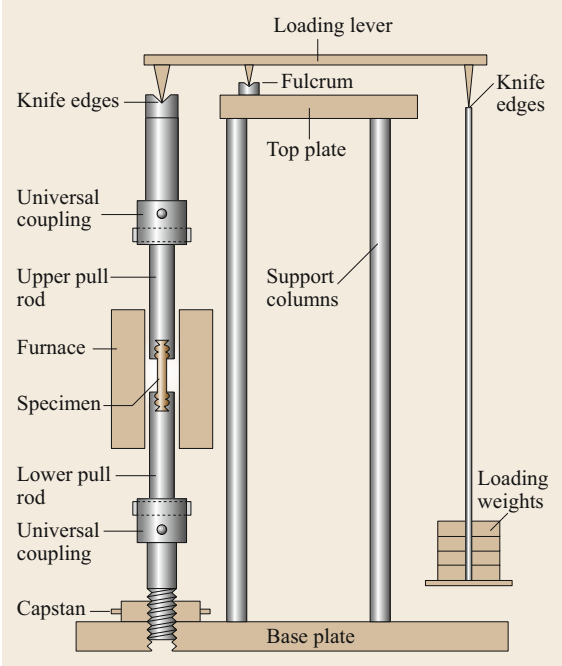

Fig. 5.11 Schematic of a constant-load creep testing setup

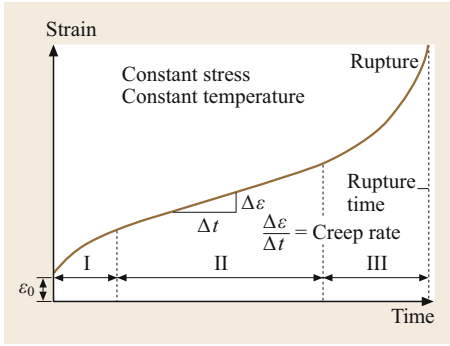

Fig. 5.12 An idealized creep curve showing the three stages during creep (ε_0 = elastic strain) (after [5.2])

interpreted properly. Figure 5.11 shows a typical creep testing setup.

The curve in Fig. 5.12 illustrates the idealized shape of a creep (strain–time) curve. The slope of this curve ($\Delta\varepsilon/\Delta t$ or $\dot{\varepsilon}$) is referred to as the creep rate. The initial strain $\varepsilon_i = \sigma_i/E$ is simply the elastic response to the applied load. The strain itself is usually calculated as the engineering strain, $\varepsilon = \Delta l/l_0$, see (5.2). The primary region (I) is characterized by transient creep, with a decreasing creep rate due to the increase in the creep resistance of the material by virtue of material deformation. The secondary region (II) is characterized by steady-state creep (where the creep strain rate $\dot{\varepsilon}_{min} = \dot{\varepsilon}_{ss}$ is constant), in which competing mechanisms of strain hardening and recovery may occur. The tertiary region (III) is characterized by an increasing creep strain rate, in which necking under constant load or consolidation of the failure mechanism occur prior to failure of the test piece. The relative significance of the three creep stages depends on the temperature, creep stress, and material.

Traditionally, a creep curve is described by the following empirical relation, due to *Andrade* [5.2]:

$$\varepsilon = \left(1 + \beta t^{1/3}\right) \exp(\kappa t) \,, \tag{5.11}$$

where β and κ are empirically determined constants related to the primary and steady stages of the creep curve, respectively. However, for engineering applications, it is the steady-state creep rate that is of major concern; for example, what is the permissible stress needed to produce a minimum strain rate of 10^{-6}/h (i.e., a strain of 0.01 in 10 000 h)? The *Mukherjee–Bird–Dorn* equation is often used as a scaling relation

$$\frac{\dot{\varepsilon} k T}{D_0 G \boldsymbol{b}} = A_0 \left(\frac{\sigma}{\mu}\right)^n \left(\frac{d}{\boldsymbol{b}}\right)^p \exp\left(-\frac{Q_c}{\mathrm{RT}}\right) \,, \tag{5.12}$$

where $\boldsymbol{b}$ is the Burgers vector, d is the grain size, D_0 is the self-diffusion coefficient, μ is the shear modulus, k is Boltzmann's constant, σ is the applied stress, Q_c is the activation energy for creep, R is the universal gas constant, T is the absolute temperature, and A, p, and n are dimensionless constants. Various creep mechanisms have been identified (both theoretically and experimentally) and can be classified as

1. Diffusion creep
2. Dislocation creep
3. Dower-law breakdown.

In diffusion creep processes, atomic vacancies generated close to grain boundaries normal to the applied stress migrate to grain boundaries parallel to the applied stress, where they are absorbed. This process leads to a shape change, but it does not involve dislocation flow (as the higher-stress processes do). This diffusive transport of vacancies at higher temperatures occurs through the bulk of the grain (Nabarro–Herring creep), whilst at lower temperatures it dominates along the grain boundaries (Coble creep). Creep rates are reported to be inversely proportional to the square of the grain size for Nabarro–Herring creep ($p = -2$ in (5.12)) but inversely proportional to the cube of the grain size for Coble creep ($p = -3$). When creep is controlled by diffusion alone, $n = 1$ in (5.12).

At higher stresses, steady-state creep occurs by dislocation glide plus climb and values of n are typically 3–5; this is called the power-law regime. The upper boundary of the power-law creep regime is defined by

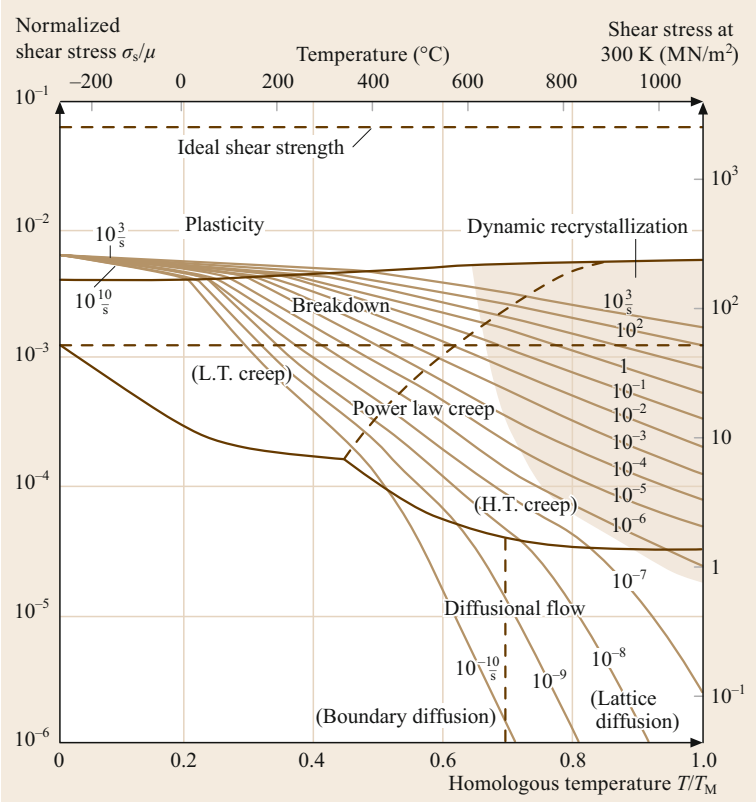

Fig. 5.13 Deformation mechanism map for pure copper with grain size of 100 μm showing different creep mechanisms operating in a given temperature–stress region (after [5.5])

the ratio of the applied shear stress to the elastic shear modulus that corresponds to the onset of general plasticity. For face-centered cubic (fcc) metals, this ratio is given as 1.26×10^{-3} and deformation at stresses exceeding this value is said to be in the power-law breakdown regime, where the Dorn equation is no longer valid. In the power-law and power-law breakdown regime, the steady-state creep rate is independent of grain size, i.e., $p = 0$. By solving the equations for diffusional flow, power-law creep, and general plasticity, it is possible to prepare deformation mechanism diagrams for a given material. The diagram for pure copper with a 100 μm grain size is reproduced in Fig. 5.13.

Two important phenomena related to creep are *superplasticity* and *stress relaxation*. Superplasticity is the ability of a material to undergo large elongation without failure; see [5.6] for an overview. Stress jump tests are carried out to assess the superplasticity of a material quickly at a given temperature by measuring the flow stress at different loading rates while keeping the temperature constant. The strain-rate exponent, m $(= 1/n)$, can then be evaluated and should be close to 0.5 for superplastic behavior to be observed. To determine the stress relaxation of a material, the specimen is deformed by a given amount, and the decrease in stress is recorded over a prolonged period of exposure at a constant, elevated temperature. The stress-relaxation rate is then the slope of the curve at any point.

The goal in engineering design for creep is to predict the performance over the long term. To this end, one of three approaches is applied:

- Stress-rupture tests. A large number of tests are run at various stresses and temperatures to develop plots of applied stress versus time to failure. While it is relatively easy to use these plots to provide estimates of stress rupture life, it is very expensive and time consuming to develop these plots. Additionally, extrapolation of the data can be problematic.
- Minimum strain rate versus time to failure. This type of relation is based on the observation that strain is the macroscopic manifestation of cumulative creep damage. A critical level of damage, independent of stress and/or temperature, is then defined as the failure criterion as follows

$$\dot{\varepsilon}_{\min} t_f = C \propto \varepsilon_f \,. \tag{5.13}$$

A log–log plot of $\dot{\varepsilon}_{\min}$ versus t_f or Monkman–Grant chart can then be constructed from relatively few

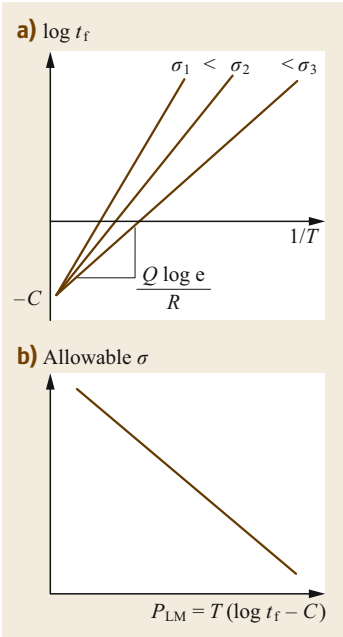

Fig. 5.14a,b Summary of the Larson–Miller method for creep life prediction. **(a)** Experimental results, **(b)** *universal* Larson–Miller relation

creep tests to determine the value of the empirical constant C and be used to predict the creep life.

- Temperature-compensated time. In these methods, a higher temperature is used at the same stress so as to cause a shorter time to failure, such that temperature is traded for time. In this form of accelerated testing, it is assumed that the failure mechanism does not change and hence is not a function of temperature or time. In the most commonly used method, the Larson–Miller parameter P_{LM} at a given stress is expressed as

$$P_{LM} = 2.303\frac{Q_c}{R} = T(C + \log t_f)\,, \qquad (5.14)$$

where C is the Larson–Miller constant, typically ranging between 25 and 60. Experimental data in terms of $\log t_f$ and $1/T$ at a given stress are plotted to estimate Q_c and C_1 as shown in Fig. 5.14.

5.1.3 Dynamic Mechanical Properties

In structural applications, members are often subjected to varying load/stress over time, in the form of either vibrations or high-energy impacts. It is important to have an understanding of the effect of such forces on their structural integrity to avoid catastrophic failure due to fractures.

Impact Testing

Toughness is a qualitative measure of a material's ability to absorb impact energy by undergoing plastic deformation. Notched-bar impact tests are generally used to detect the tendency of a material to fail in a brittle manner. Two classes of notched specimens are commonly used for this class of tests, namely the *Charpy* notched bar and the *Izod* specimen (Fig. 5.15). The specimen may have a square or circular cross-section, and a V notch is machined either at the center (Charpy) or towards one end (Izod) of the specimen. The impact load is then applied by a heavy swinging hammer as indicated in Fig. 5.15 by the arrows. The presence of the notch results in a triaxial stress state on the fracture plane. The response of the sample is usually measured by the energy absorbed in fracturing the specimen and can be estimated from the loss in kinetic energy before and after the impact.

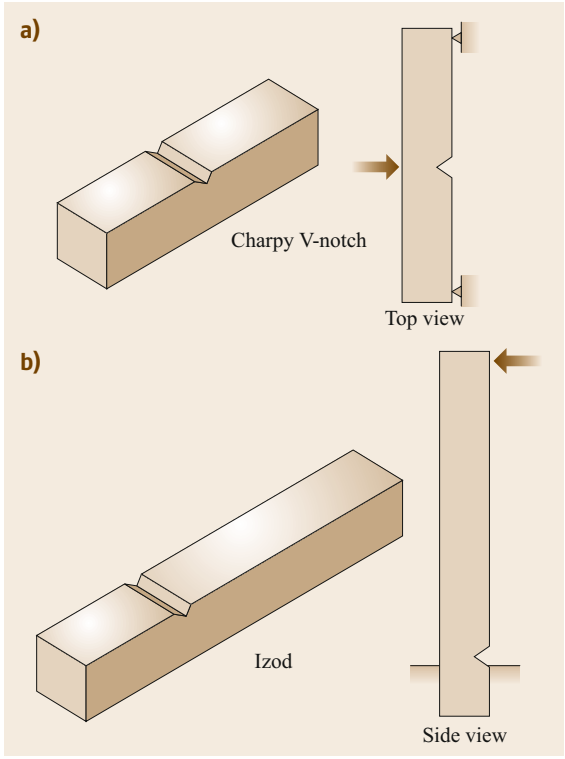

Fig. 5.15a,b Specimen geometry and test procedure for **(a)** Charpy V-notch test and **(b)** Izod impact test (after [5.4])

The notched-bar impact test is most meaningful when conducted over a range of temperatures. Most metallic materials undergo a transition from a ductile to brittle mode of fracture with decreasing temperature. This transition temperature is called the ductile to brittle transition temperature (DBTT) and is an important design parameter. Figure 5.16 shows the typical variation of the absorbed impact energy as a function of temperature for two steels, a ferritic one with body-centered

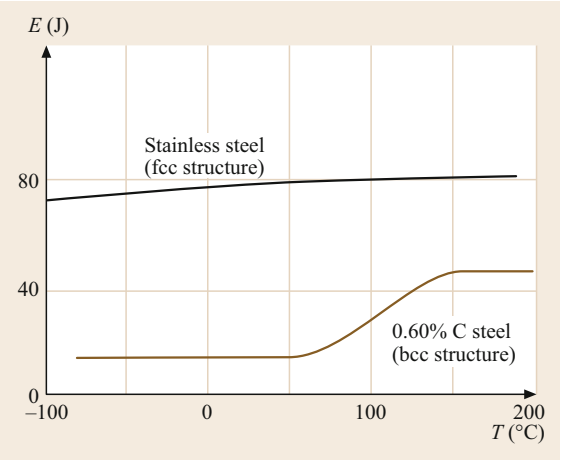

Fig. 5.16 Variation of absorbed energy as a function of temperature showing ductile to brittle transition (DBTT) in a plain carbon steel (after [5.4])

cubic (bcc) structure and an austenitic one with fcc structure. The material with the lowest DBTT should be preferred in structural applications at low temperatures to avoid catastrophic failure, hence austenitic stainless steels are recommended.

Cyclic Testing

It is well known that a component subjected to a load well below its yield stress can still fail due to fatigue, i.e., a fluctuating load over a period of time (Fig. 5.17). Fatigue failure usually occurs without any obvious warning and is usually accompanied by fracture. A periodic stress cycle of the kind shown in Fig. 5.18a,b comprises a mean stress, σ_m $(= (\sigma_{max} + \sigma_{min})/2)$, and an alternating stress amplitude σ_a $(= (\sigma_{max} - \sigma_{min})/2)$. The stress ratio R is then defined as

$$R = \frac{\sigma_{min}}{\sigma_{max}} , \qquad (5.15)$$

where σ_{max} and σ_{min} are the maximum and minimum stress, respectively. The basic method of presenting engineering fatigue data is by means of the S–N curve, which represents the dependence of the cycles to failure N on the maximum applied stress σ_{max}. Most investigations of fatigue properties are carried out by means of a rotating beam machine, where $\sigma_m = 0$ and $R = -1$. Figure 5.18 shows a schematic of the test apparatus and a typical S–N curve for this type of test. For most ferrous alloys, the S–N curve becomes horizontal at a certain limiting stress called the endurance or fatigue limit. Most nonferrous metals have S–N curves that do not show a true endurance limit, and in such cases, it is customary to define the endurance limit as the maximum stress that does not cause failure after 5×10^8 cycles. It must be noted that considerable scatter is observed during fatigue testing and it is standard to test three or four samples at a given stress level.

Application of a cyclic load, i.e., σ_a, leads to a cyclical strain response $\Delta\varepsilon_a$, which comprises elastic $\Delta\varepsilon_e$ and plastic $\Delta\varepsilon_p$ components. Figure 5.19 shows the variation of the elastic, plastic, and total strain amplitude as a function of the number of cycles to failure. Based on this figure, it is easy to visualize that, below a particular *transition life* ($N_{f,t}$), plastic deformation controls the cycles to failure, while above the transition life, elastic strain is the major source of fatigue damage. The two regions are termed low- or high-cycle fatigue, respectively, and the transition life is usually close to 10^4 cycles.

The fatigue process of a material can be divided into the following stages:

- *Crack initiation*, including the early state of fatigue damage due to localization of slip at persistent slip bands (PSB) or embryonic cracks.
- *Slip-band crack growth*, which involves the deepening of the initial crack on planes of high shear stress. This is frequently called stage I crack growth.
- *Crack growth on planes of high tensile stress*, which involves the growth of well-defined cracks in a direction normal to the maximum tensile stress. This is usually called stage II crack growth.

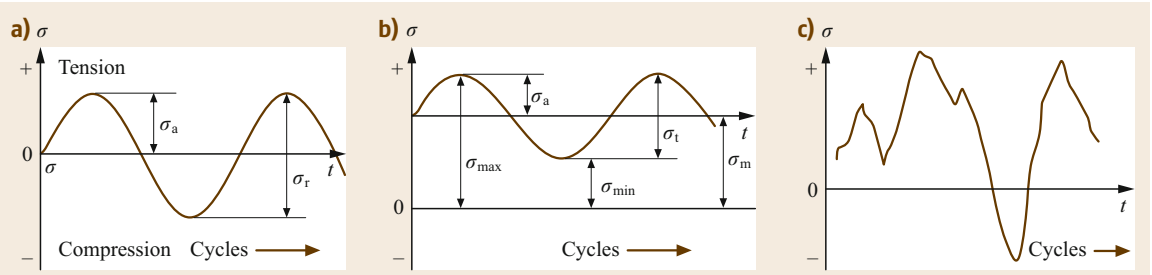

Fig. 5.17 (a,b) Definition of different stress parameters during cyclic stress testing of materials. (c) A typical stress variation curve for an airfoil in service (after [5.4])

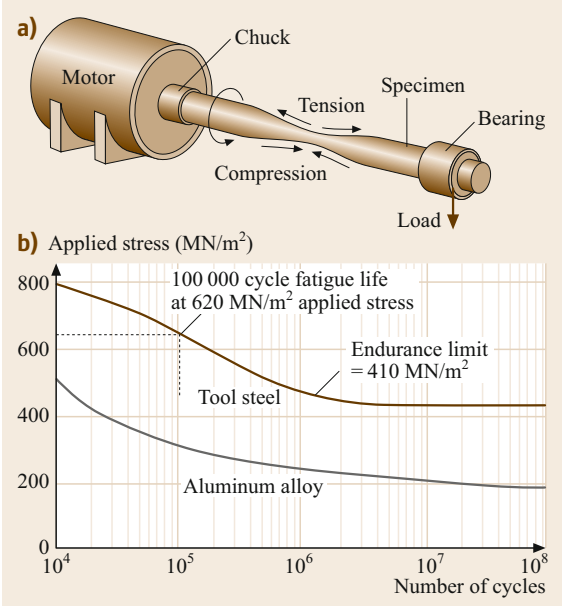

Fig. 5.18 (a) Schematic of rotation bending fatigue testing equipment and (b) typical stress–number of cycles (S–N) curve for a ferrous and nonferrous alloy (after [5.2])

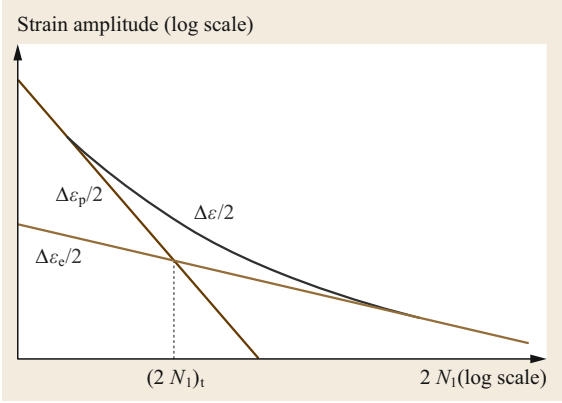

Fig. 5.19 Definition of a transition life between low- and high-cycle fatigue (after [5.7])

- *Ultimate ductile failure*, which occurs when the crack reaches a sufficient length that the remaining cross section cannot support the applied load.

In general, larger proportions of the total cycles to failure are involved with the propagation of stage II cracks in low-cycle fatigue than in high-cycle fatigue, while stage I crack growth accounts for the largest segment during low-stress high-cycle fatigue. If the tensile stress is high, as in the fatigue of specimens with preexisting surface flaws or notches, stage I crack growth may not be observed at all. Specialized crack growth-

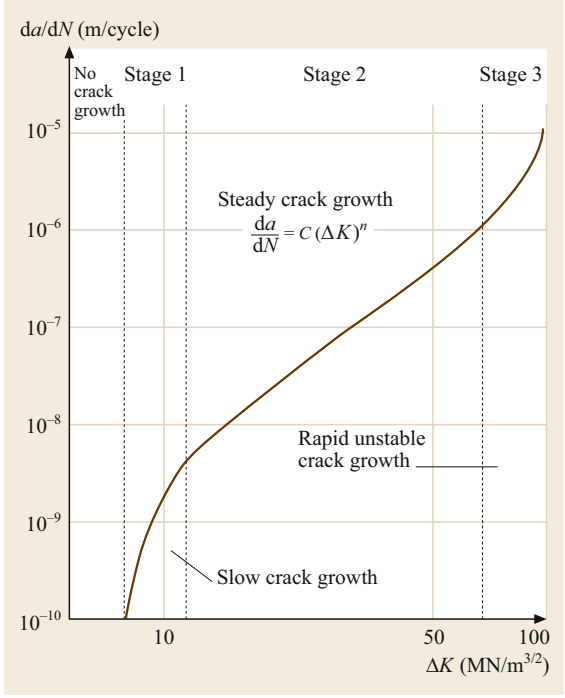

Fig. 5.20 A schematic fatigue crack-growth curve showing the three regimes of crack growth, in the steady state regime the so-called Paris law is observed (after [5.2])

rate tests using specimens which have been precracked in fatigue (see below) are employed to establish material selection criteria and establish the effect of the following factors that are known to have a significant influence on fatigue life:

1. Stress or strain range
2. Mean stress
3. Surface finish and quality
4. Surface treatments
5. Load sequence and overload.

Typical test results from these crack growth studies are shown in Fig. 5.20. Additional factors such as environmental conditions, elevated temperatures, and corrosive media also drastically affect the fatigue life and can accelerate failure.

Fracture Mechanics

New nondestructive testing techniques allow designers to adopt a more *damage-tolerant* approach to structural design. Accordingly, material with defects is no longer considered as failed but can be further used in service provided it is safe against *fast fracture*. The criterion for continued safe operation is that the strain energy release rate (called G for brittle materials and J for duc-

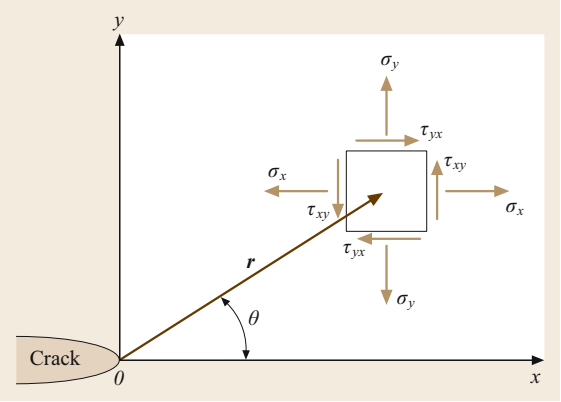

Fig. 5.21 Stress distribution at a point (r, θ) in the material stressed under a far-field tensile stress (mode 1) away from an elliptical crack (after [5.7])

tile materials) should be less than a critical value. The strain energy release rate is the amount of energy per unit length along the crack edge that is supplied by the elastic and plastic energy in the body and by the applied force in creating the new fracture surface area.

From linear elastic theory, the stress field around a crack (Fig. 5.21) can be expressed as

$$\lim_{r\to 0}\sigma_{ij}^{\mathrm{M}} = \frac{K_{\mathrm{M}}}{\sqrt{2\pi r}} f_{ij}^{\mathrm{M}}(\theta)\,, \tag{5.16}$$

where the superscript and subscript "M" denote the mode of load application (Fig. 5.22), f_{ij} is a function of location, and K is the stress intensity factor, expressed as

$$K = Y\sigma\sqrt{\pi a}\,, \tag{5.17}$$

where Y is a dimensionless factor dependent on the sample geometry and a is the crack half-length. K can be related to G according to the following relations:

$$G = \begin{cases} \frac{K^2}{E} & \text{(plane stress)} \\ \frac{K^2}{E}\left(1-\nu^2\right) & \text{(plane strain)} \end{cases}. \tag{5.18}$$

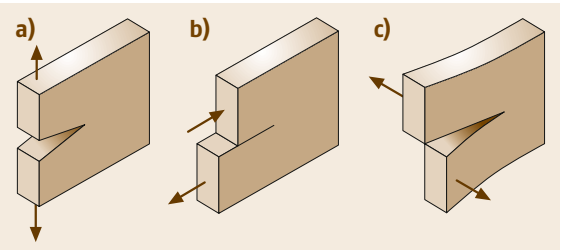

Fig. 5.22a–c Schematic representation of the three crack opening modes: **(a)** tensile (mode 1), **(b)** shear (mode 2), and **(c)** bending (mode 3) (after [5.3])

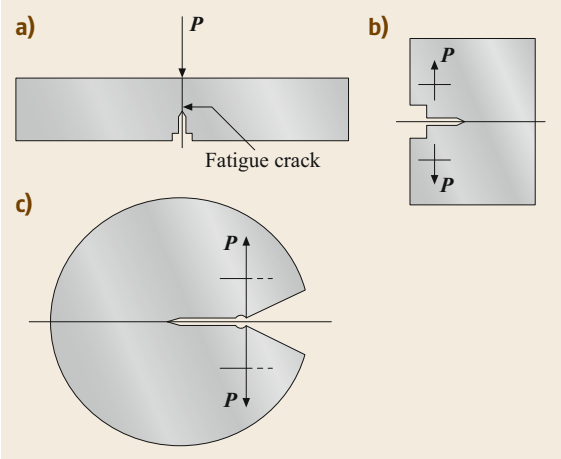

Fig. 5.23a–c Standard samples for fracture toughness (K or J) measurement: **(a)** single-edge bend, **(b)** compact tension (CT), and **(c)** cylindrical disc; ***P*** denotes the loading vector (after [5.3])

For ductile materials, the equivalent of the energy release rate G is the J-integral, which is defined as

$$J = \int_{\Gamma}\left(W\mathrm{d}y - \overline{T}\frac{\partial\overline{u}}{\partial x}\mathrm{d}s\right)\,, \tag{5.19}$$

where W is the load per unit volume, Γ is the path of the line integral that encloses the crack tip, ds is the increment of the contour path, and $\overline{\boldsymbol{T}}$ and $\overline{\boldsymbol{u}}$ are the outward traction and normal vectors, respectively, on ds. The first term corresponds to the elastic component, while the second term corresponds to the plastic energy due to the crack.

As mentioned above, the stress intensity factor K should be less than a critical value (K_{c}) as a design criterion. The critical stress intensity factor in the tension mode, K_{Ic}, is a material property and can be interpreted as the inherent resistance of a material to failure. Hence, it is frequently called the *fracture toughness* of a material. Like other mechanical properties, it is determined experimentally as described below. The same test procedure applies to the determination of the J-integral, although the test data are treated differently. The test specimen may be a single-edge notched beam, compact tension specimen, or cylindrical disc (Fig. 5.23). The load line displacement is recorded as a function of the applied load. A fatigue precracked test specimen is loaded in tension or bending to induce either:

1. Unstable crack extension (or *fracture instability*) or
2. Stable crack extension (or *stable tearing*).

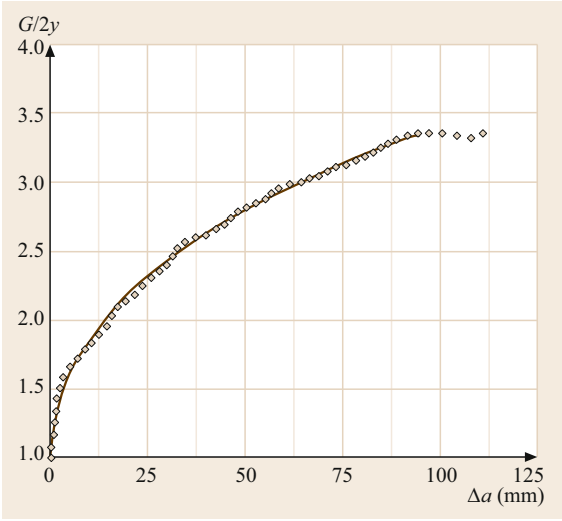

Fig. 5.24 A typical *R*-curve for a ferrous alloy showing the resistance to unstable crack extension (after [5.3])

The first method is used to determine the value of the fracture toughness at the point of instability, while the second method results in a continuous relationship for the fracture toughness versus the crack extension (called the *R*-curve, Fig. 5.24). For *R*-curve determination, the crack extension is also recorded simultaneously by optical or electrical means. The recorded data are then used to evaluate K_{Ic}, J_{Ic} or the *J*–*R* curve using standard relations. K_{Ic} is independent of the specimen geometry only under plane-strain conditions, and this criterion should be assessed carefully. Similar crack growth tests may also be used to evaluate the performance of a material under creep and/or fatigue.

Table 5.1 summarizes standards for mechanical testing of materials according to ASTM [5.8].

Table 5.1 Standards for mechanical testing of materials [5.8]

Test type	Standard
Methods of mechanical testing	ASTM E6-15e3
Tensile test of metallic materials	ASTM E8-15ae1
Elevated-temperature tension tests for metallic materials	ASTM E21-17e1
Young's modulus, tangent modulus, and chord modulus	ASTM E111-17
Brinell hardness of metallic materials	ASTM E10-18
Vickers hardness of metallic materials	ASTM E92-17
Rockwell hardness and Rockwell superficial hardness of metallic materials	ASTM E18-20
Hardness conversion tables for metals	ASTM E140-12b
Microhardness of materials	ASTM E384-17
Compression testing of metallic materials at room temperature	ASTM E9-19
Compression tests of metallic materials at elevated temperatures with conventional or rapid heating and strain rates	ASTM E209-18
Bend testing of mechanical flat materials for spring applications	ASTM E855-08
Shear modulus at room temperature	ASTM E143-13
Conducting creep, creep-rupture, and stress-rupture tests of metallic materials	ASTM E139-11
Stress relaxation for materials and structures	ASTM E328-13
Notched-bar impact testing of metallic materials	ASTM E23-18
Conducting force-controlled constant-amplitude axial fatigue tests of metallic materials	ASTM E466-15
Constant-amplitude low-cycle fatigue testing	ASTM E606-19e1
Measurement of fatigue crack growth rates	ASTM E647-15e1
Measurement of fracture toughness	ASTM E1820-20a

5.2 Physical Properties

While the prime design criteria in most applications in mechanical engineering relate to mechanical properties (Sect. 5.1), physical properties are instead decisive for most applications of functional materials. As some of these materials are of paramount importance in fields related to mechanical engineering, such as microelectronics, mechatronics, and the production, conversion, and distribution of electric power, we briefly discuss in this section selected properties such as electrical and thermal conductivity with respect to materials in mechanical engineering, i.e., metals, ceramics, glasses, and polymers, as described in more detail in Chap. 4. In particular, a discussion of the broad and still-emerging fields of *magnetism and superconductivity* and *semiconducting materials* must be omitted here. For in-depth information, the interested reader is referred to the recent version of [5.9] and to the *Springer Handbook of Materials Data* [5.10].

5.2.1 Electrical Properties

Ohm's Law and Electrical Conductivity

The relation between the voltage *U* (in V) and the current *I* (in A) in an electric conductor (often in the form

of a wire) is given by (the macroscopic) form of *Ohm's law* as

$$R = \frac{U}{I} , \tag{5.20}$$

where R is the resistance (in Ω) of the material to the current flow and depends critically on the geometry and (intrinsic) properties of the material, therefore

$$R = \rho\frac{l}{A} = \frac{l}{\sigma A} , \tag{5.21}$$

where l is the length and A is the cross-section of the conductor; ρ (Ω^{-1} m) and σ (Ω^{-1} m^{-1}) are the *electrical resistivity* and *electrical conductivity*, respectively, being specific to the material under consideration. Combining (5.20) and (5.21) yields

$$j = \frac{I}{A} = \sigma\frac{V}{l} = \sigma E , \tag{5.22}$$

with the current density j (A/m^2) and the electric field strength E (V/m). Alternatively, j is given by the product of the number of charge carriers n, the charge of each carrier q, and the average *drift velocity* v of the carriers, thus

$$j = nqv . \tag{5.23}$$

Setting (5.22) and (5.23) equal yields the microscopic form of Ohm's law, which is more relevant for materials engineers

$$\sigma = nq\frac{v}{E} = nq\mu . \tag{5.24}$$

The term v/E is called the *mobility* μ (m^2 V^{-1} s^{-1}) of the charge carriers. While the charge q of the carriers of the electric current is a constant, one may readily recall from (5.24) that the electrical conductivity of materials can be controlled essentially by two factors, namely:

1. The number of charge carriers n
2. Their mobility μ.

While electrons are the charge carriers in conductors (metals), semiconductors, and many insulators, ions carry the charge in ionic compounds. Therefore, in pure materials, the mobility μ depends critically on the bonding strength and—in addition in ionic compounds—on diffusion rates, which in turn gives rise to the tremendous variation of electrical conductivity over more than 20 decades (Table 5.2).

Table 5.2 Electrical conductivity σ at RT for selected (pure) materials [5.2, 10]

Material	Electric conductivity σ (Ω^{-1} m^{-1})
Al	3.77×10^7
Ag	6.80×10^7
Au	4.26×10^7
Cu	5.98×10^7
Fe	1.00×10^7
Mg	2.257×10^7
Ni	1.46×10^7
Pb	5.21×10^6
Ti	2.56×10^6
W	1.82×10^7
Zn	1.84×10^7
Si	5×10^{-4}
Polyethylene	10^{-13}
Polystyrene	10^{-15}–10^{-17}
Al_2O_3	10^{-12}
Diamond	$< 10^{-16}$
SiC	1–10
SiO_2 (silica)	10^{-15}

Effect of Temperature on the Electrical Conductivity of Metallic Materials

When heat is applied to metallic materials, the atoms gain thermal energy and vibrate at a particular amplitude and frequency. Thus, increasing the temperature increases the probability of scattering electrons within the crystal, which ultimately leads to a reduction of the mobility of electrons; the resistivity ρ_T (of a pure material) at a particular temperature changes according to

$$\rho_T = \rho_{RT}[1 + a(T - RT)] , \tag{5.25}$$

where a is the *temperature resistivity coefficient* and "RT" indicates room temperature. The relationship between resistivity and temperature is linear over a wide temperature range; values of a for metals are positive and are tabulated in [5.10].

Effect of Lattice Defects on the Electrical Conductivity of Metallic Materials

An additional contribution to electron scattering stems from all kinds of lattice imperfections, as described in Chap. 4. As a representative, the increase in resistivity due to atoms in solid solution can be described as

$$\rho_d = C(1 - x)x , \tag{5.26}$$

where ρ_d is the increase in resistivity due to the lattice defects present in the material and x is defined as the molar fraction of these defects (Sect. 4.1.2); C is the defect resistivity coefficient. Thus, the overall resistivity is

$$\rho = \rho_T + \rho_d . \tag{5.27}$$

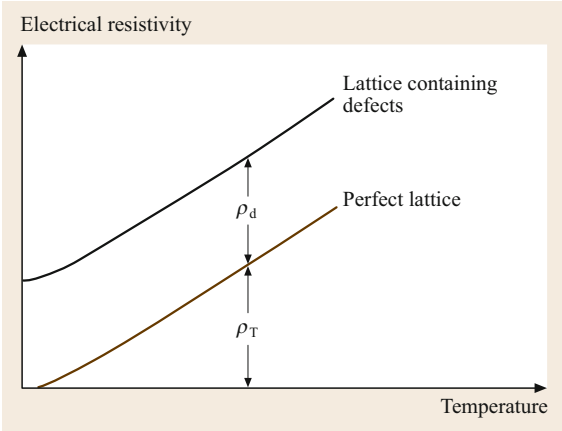

Fig. 5.25 Dependence of electrical resistivity of metallic materials on temperature; see text for further explanation

Note that the effect of defects is virtually independent of temperature (Fig. 5.25).

5.2.2 Thermal Properties

As outlined in Sect. 4.1.2, the atoms in a material have a minimum free energy at absolute zero. However, as mentioned in the previous subsection, the supply of thermal energy causes the atoms to vibrate at a particular amplitude and frequency. This gives rise to a number of physical effects and related quantities such as the *heat capacity* or *specific heat*, *thermal expansion*, and *thermal conductivity*, which will be discussed briefly in the following subsections.

Heat Capacity and Specific Heat

Since vibrations of atoms are transferred through the whole crystal as elastic waves, heating up or cooling down a material is realized by accepting or losing *phonons* of energy

$$E = \frac{hc}{\lambda} = h\nu \,. \tag{5.28}$$

Then, the *heat capacity* is the energy required to raise the temperature of *one mole* of a given material by 1 K. It can be determined by various methods either at constant pressure C_p or at constant volume C_V. As depicted in Fig. 5.26, the heat capacity approaches a nearly constant value of $C_p = 3R \approx 25\,\mathrm{J\,mol^{-1}\,K^{-1}}$ at sufficiently high temperatures for most metallic (above $\approx$ RT) and ceramic (> 800 K) materials. An exception to this rule is the (toxic) element Be, which has a mere $C_p \approx 16\,\mathrm{J\,mol^{-1}K^{-1}}$ [5.10].

By contrast, the *specific heat* c is the energy required to raise the temperature of a particular weight

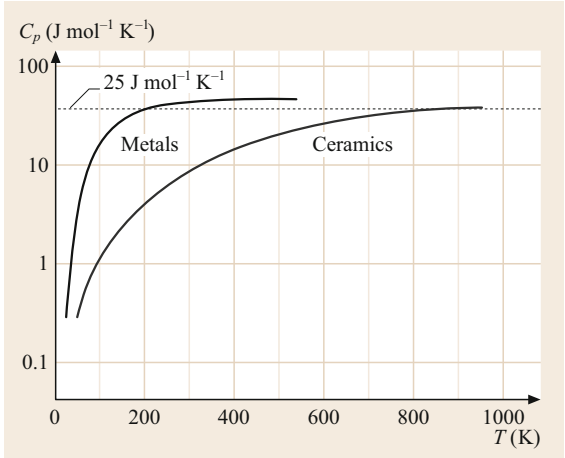

Fig. 5.26 Heat capacity as a function of temperature for metals and ceramics

Table 5.3 Specific heat c of selected materials at RT [5.2, 10]

Material (metals)	c ($\mathrm{J\,kg^{-1}\,K^{-1}}$)	Material (others)	c ($\mathrm{J\,kg^{-1}\,K^{-1}}$)
Al	900	Al_2O_3	837
Cu	385	Diamond	519
Fe	444	SiC	1047
Mg	1017	Si_3N_4	712
Ni	444	SiO_2 (silica)	1109
Pb	159	Polyamide	1674
Ti	523	Polystyrene	1172
W	134	Water	4186
Zn	389	Nitrogen	1042

or mass of a material by 1 K. The relationship between the heat capacity and specific heat is simply given by $c = C_p/M$, where M is the atomic mass (see Periodic Table). For engineering applications, the specific heat is more appropriate to use than the heat capacity. A compilation of specific heat values of typical materials is presented in Table 5.3. Data on water (liquid) and nitrogen (gas) are given also for comparison, with H_2O having the highest value of specific heat. Note that neither the specific heat nor the heat capacity depend significantly on microstructure.

Thermal Expansion

As pointed out in Sect. 5.1.1, the lattice constant of a material is a measure of the strength of atomic bonding, which is in turn the result of the force equilibrium between an attractive and repulsive potential. If a material gains thermal energy, however, this equilibrium separation increases, since the material is lifted from its energy minimum into a higher-energy state. The change in the dimensions of the material is usually measured by

Table 5.4 Linear coefficient of thermal expansion α at RT for selected materials [5.2, 10]

Material	α (10^{-6} K^{-1})
Al	23.03
Cu	16.5
Fe	12.3
Mg	26.1
Ni	13.3
Pb	29.1
Ti	8.35
W	4.31
Zn	25.0
0.2% C steel	12.0
304 stainless steel	17.3
Invar alloy (Fe-36%Ni)	1.54
Polyamide	80
Polystyrene	70
Al_2O_3	6.7
Diamond	1.06
SiC	4.3
Si_3N_4	3.3
SiO_2 (silica)	0.55

dilatometry as

$$\alpha = \frac{l_f - l_0}{l_0\,(T_f - T_0)} = \frac{\Delta l}{l_0 \Delta T}\,, \tag{5.29}$$

where the indices "f" and "0" denote the final and initial values of the length l and temperature T. Linear coefficients of thermal expansion α at RT for selected materials are listed in Table 5.4.

Two conclusions can be drawn from the compilation in Table 5.4, namely that materials possessing strong atomic bonds, in particular covalently bonded materials such as many ceramics, have:

1. Low α values and
2. High melting points T_m

The latter relationship is shown for metals in Fig. 5.27.

A particular behavior must be noted for the Invar alloy Fe-36%Ni, which reveals that the interaction with magnetic domains may suppress the thermal expansion nearly completely until the Curie temperature is reached. This makes Invar attractive for bimetallic applications.

Thermal Conductivity

In essence, *thermal energy* is transferred in solid materials by two mechanisms:

1. Transfer of free (valence) electrons
2. Lattice vibrations (phonons)

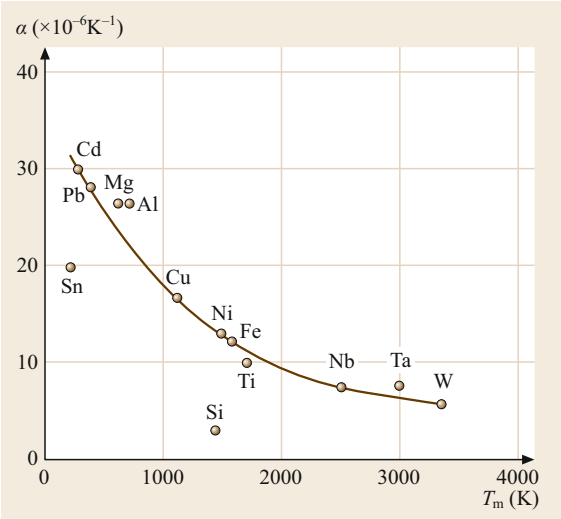

Fig. 5.27 Relationship between the linear coefficient of thermal expansion (at RT) and the melting point in metals

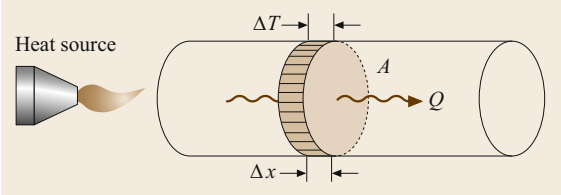

Fig. 5.28 Schematic of method for measuring the thermal conductivity k according to (5.27)

of which the latter is closely related to the phenomenon of storing thermal energy, i.e., the *heat capacity* (see above).

Hence, the *thermal conductivity* k is a measure of the rate at which heat is transferred through the material and follows the relationship

$$\frac{Q}{A} = k\frac{\Delta T}{\Delta x}\,, \tag{5.30}$$

where Q is the heat transferred through a cross-section A induced by a temperature gradient $\Delta T/\Delta x$. Note the striking similarity between k and the diffusion coefficient D in mass transfer, where the *heat flux* Q/A is analogous to the flux of atoms j_D. A schematic experimental setup for measuring k is shown in Fig. 5.28, where heat is introduced on one side of a bar- or disc-shaped sample through a heat source and the change of temperature on the other side is measured as a function of time. The commonly employed technique is called the *laser flash method*.

Values for the thermal conductivity k of selected materials are listed in Table 5.5. A comparison reveals that the k values of metals and alloys are usually much

larger than those of ceramics, glasses, and polymers. This is due to the fact that, in metals and alloys, thermal energy is transferred through the movement of (loosely bonded) valence electrons, which can be excited with little thermal energy into the conduction band. This leads to a relationship between the thermal and electrical conductivity of many metals of the form

$$\frac{k}{\sigma T} = L = 2.3 \times 10^{-8}\,\mathrm{W\,\Omega\,K^{-2}}\,, \tag{5.31}$$

where L is the Lorenz constant.

In contrast, the prime energy transfer mechanism in ceramics, glasses, and polymers is vibration of lattices and (silicate or molecular polymeric) chains, respectively. Since the electronic contribution is absent, the thermal conductivity in these material classes is usually much lower than that in metals and alloys. An exception to this rule is *carbon* in its covalently bonded form as *diamond*, which has the highest k value and therefore commonly serves as a *heat sink* material.

The situation is reversed when the temperature of the materials is increased: the greater lattice and chain vibrations usually lead to an increase of the thermal conductivity in ceramics, glasses, and polymers. In metals and alloys the same mechanism applies in principle, however, the electronic contribution will be lowered, even though the number of carriers is increased, as their mobility is more strongly reduced due to increasing scattering effects. Therefore, the thermal conductivity of metals and alloys usually decreases with increasing temperature. Like the electrical conductivity, the thermal conductivity of metals and alloys also decreases with increasing number of lattice defects of various dimensionality, introduced into the microstructure due to the increased electron scattering.

Table 5.5 Thermal conductivity k of selected materials at RT [5.2, 10]

Material (metals/alloys)	k ($\mathrm{W\,m^{-1}\,K^{-1}}$)	Material (others)	k ($\mathrm{W\,m^{-1}\,K^{-1}}$)
Al	238	Al_2O_3	16

Since November 2011 he holds the chair for Materials Science & Technology at Karlsruhe Institute ofTechnology. His research is dedicated to the synthesis and properties of structural materials such as refractory metal silicide alloys and intermetallic alloys for high-temperature applications.

6. Corrosion and Corrosion Resistance

Thomas Böllinghaus, Michael Rhode, Thora Falkenreck

The chapter starts with a brief introduction about corrosion, which is defined as the interdependency between a metal, a corrosive environment, and the respective component design. The second section introduces the most important forms of aqueous electrochemical corrosion (uniform corrosion, galvanic corrosion, selective and intergranular corrosion, and finally pitting and crevice corrosion in the case of passive layer forming metals). In addition, electrochemical corrosion under applied mechanical load is introduced (stress corrosion cracking, hydrogen-assisted cracking, corrosion fatigue), as well as special forms of corrosion (erosion, fretting, and microbiologically induced corrosion). The third section of this chapter introduces (mostly dry) chemical corrosion and high-temperature corrosion (oxidation, carburization, high-temperature hydrogen attack, sulfurization, nitriding, halogenation). As in the case of electrochemical corrosion, chemical corrosion can also be superimposed by mechanical loads. Finally, general facts on the testing of corrosion are introduced.

6.1 Fundamental Aspects

The corrosion of metals is the physicochemical interdependency between a metal and its environment, which may result in a change of material properties. This can cause serious impairments of the material performance, the environment, or of the entire technical system, of which both material and environment are part [6.1]. Thus, corrosion resistance is a property of a component member or of the entire component in a technical system. Corrosion resistance defines the ability of a material, considering the component design, to withstand a corrosive environment to keep the function of the technical system (Fig. 6.1). The corrosive load is a result of the environmental conditions from both corrosive environments and constructional design aspects. If the corrosive load exceeds the corrosion resistance of a material that is used in a component, then corrosion damage may occur. Hence, damage is not necessarily existent in the presence of corrosion itself. Only in the case of impaired functional capability of the technical system is this, then, called corrosion damage. Additionally, corrosion damage of a component does not necessarily mean that failure occurs, i.e., there is not necessarily a total loss of function of the entire system. The term corrosion is mostly related to metallic materials. Nonetheless, this term is also used for the corrosive effect in glasses, ceramics, and organic nonmetallic materials. However, these phenomena are not considered below.

Basically, the corrosion of metals is separated into the following:

1. Electrochemical corrosion (for example, atmospheric corrosion of steels, which is commonly expressed as "rusting")

K.-H. Grote, H. Hefazi (Eds.), *Springer Handbook of Mechanical Engineering*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-47035-7_6

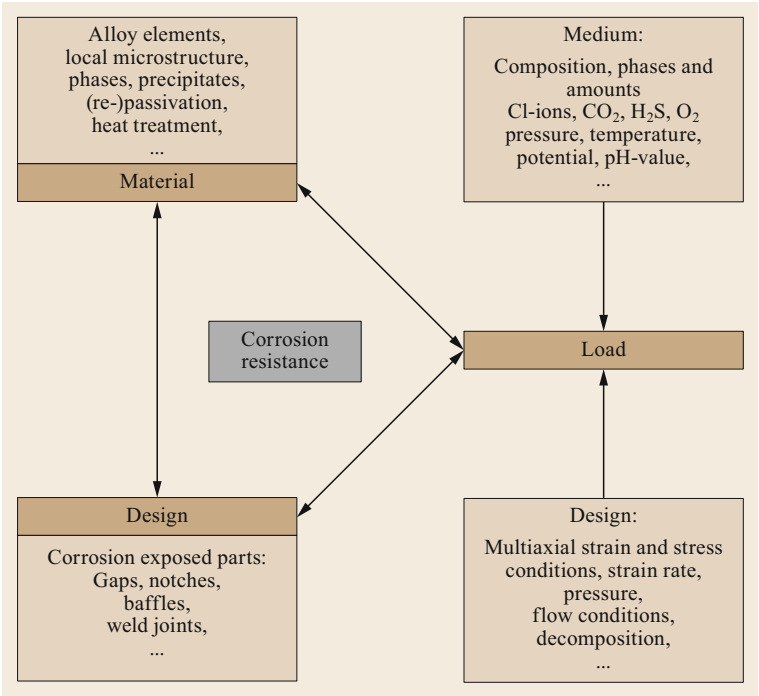

Fig. 6.1 Corrosion resistance as a part of component properties

2. Chemical corrosion (which encompasses mostly high-temperature corrosion processes).

In contrast to many other fields of technology, it is very often impossible to describe the behavior of components and facilities in equations, tables, or standards. The main reason is that corrosion is more complex than the interdependencies between the three mentioned facts: material, design, and load (Fig. 6.1). Furthermore, very different physical processes and chemical reactions take place in the three local areas of influence: the medium, the material, and the interface between both. To summarize, these processes and reactions are the actual corrosive load (Fig. 6.2).

Both process and reaction are time-dependent. Hence, the corrosive load always has a thermodynamic part and a kinetic part. The corrosive load may be superimposed by an additional load type in the three areas of influence at the same time. For example, corrosion cracking occurs if corrosive and mechanical loads are coupled. If friction and corrosive loads are coupled, it is called fretting. Respectively, erosion corrosion is the coupled effect of erosion and corrosion [6.2].

Due to the local and temporal variation of the manifold influences, the reasons for corrosion damage are often quite different, even in cases of frequently similar damage symptoms. To understand and assess the individual cases of corrosion as well as to recommend preemptive actions, it is necessary to be familiar with the different influencing factors (Fig. 6.1) and the local physical processes and chemical reactions (Fig. 6.2).

6.2 Electrochemical Corrosion

In most cases, the interaction between the metal and its environment consists of electrochemical reactions and their physical processes, e.g., diffusion processes. The thermodynamic driving force of electrochemical reactions is for the material to attain a lower energy state. Electrochemical corrosion is, therefore, the pursuit of a metallic material to reach a favorable energy state by electron donation (oxidation). In an electrically conductive environment (electrolyte), the electron donation commonly causes the dissolution of a metal.

If a metallic surface comes into contact with an electrolyte, the process of metal dissolution begins spontaneously. During this process, the metal dissolves as an ion (Me^{z+}) and, depending upon its valence (z), one or more electrons ($z\,e^-$) are released and remain within the metal. The location of this process is referred

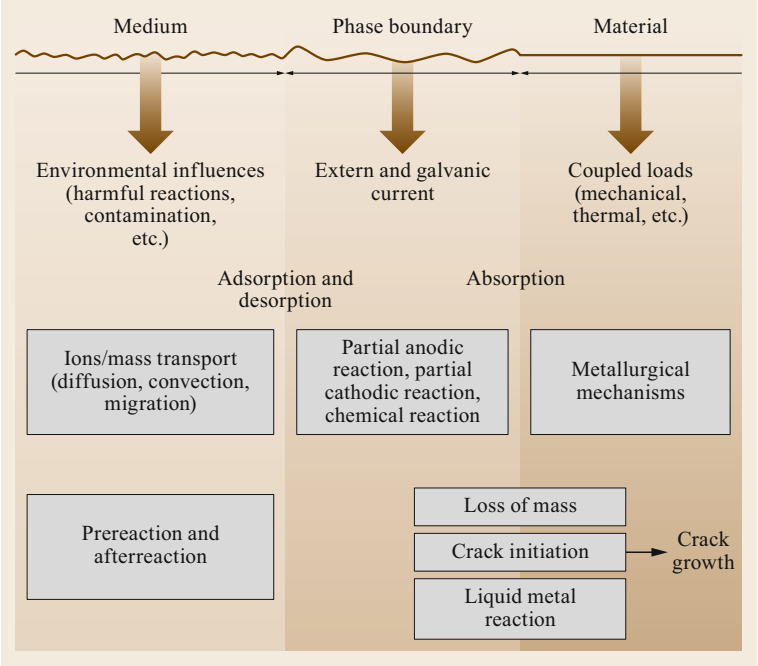

Fig. 6.2 Corrosion processes at the interface of material and medium

to as an anode. The metal ions undergo dissolution and are returned to the metallic state (6.1).

$$\mathrm{Me} \rightarrow \mathrm{Me}^{z+} + z\,\mathrm{e}^- \qquad (6.1)$$

The dissolution process can be described electrically by means of Faraday's law (6.2).

$$\Delta m = \frac{MIt}{zF} \quad (\mathrm{g}) \qquad (6.2)$$

In (6.2), Δm is the loss of mass, M is the molarity, I is the flow of electrons (current amplitude) as a result of metal dissolution, t is time, and $F = 96\,485\,\mathrm{C\,mol^{-1}}$ is Faraday's constant.

The originally neutral metal becomes negatively charged via the electrons left behind during this process. If the electrons are not consumed, charge separation rapidly leads to an increase in electrostatic forces, which then prevents further metal dissolution.

Thus, a so-called dynamic equilibrium is attained, in which the same number of metal ions undergo dissolution as are returned to the metallic state. This only applies to homogeneous, pure metals with contact to an electrolyte.

In practice, however, metals represent technical materials that are anything but homogeneous. The presence of impurities and/or alloying elements (either in solution or as precipitates), the existence of different heat treatment states, levels of deformation, different protective or adsorbed layers, crystallographic anisotropy, and various lattice defects all lead to the creation of locations with different (usually higher) energy states. The tendency of the metal to return to an energetically lower state is, thus, particularly high at such locations.

Furthermore, the equilibrium of the electrostatic forces between free electrons and metal ions on the material surface is often disturbed.

Since electron neutrality must prevail both for the electrolyte and for the metallic material, electrons are absorbed at another site on the inhomogeneous metal surface, i.e., they are absorbed by a reaction partner from the electrolyte. Due to this process of electron acceptance (referred to as reduction), which takes place at the cathode, dissolution at the anode is enabled. The following four different types of corrosion can take place as a cathodic reaction:

1. Reduction of hydrogen in oxygen-free/oxygen-reduced neutral or alkaline electrolytes

$$2\,\mathrm{H_2O} + 2\,\mathrm{e}^- \rightarrow \mathrm{H_2} + 2\,\mathrm{OH}^- \qquad (6.3a)$$

Moreover, in oxygen-free/oxygen-reduced sour electrolytes (e.g., local corrosion, corrosion in acid)

$$2\,\mathrm{H}^+ + 2\,\mathrm{e}^- \rightarrow \mathrm{H_2} \qquad (6.3b)$$

(more exactly: $2\,\mathrm{H_3O}^+ + 2\,\mathrm{e}^- \rightarrow 2\,\mathrm{H_2O} + \mathrm{H_2}$)

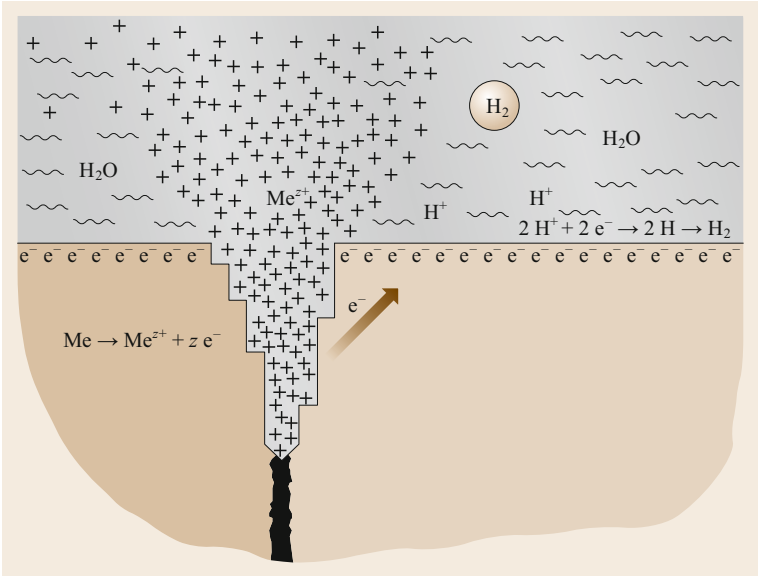

Fig. 6.3 Corrosion at a grain boundary

2. Reduction of oxygen dissolved in the water (atmospheric corrosion leading to formation of rust via subsequent reactions)

$$O_2 + 2\,H_2O + 4\,e^- \rightarrow 4\,OH^- \qquad (6.4a)$$

and in sour electrolytes with contact of the ambient atmosphere (corrosion in acid)

$$O_2 + 4\,H^+ + 4\,e^- \rightarrow 2\,H_2O \qquad (6.4b)$$

(more precisely: $O_2 + 4\,H_3O^+ + 4\,e^- \rightarrow 6\,H_2O$)

3. Deposition of more noble metallic ions (corrosion through use of mixed metals)

$$Cu^{2+} + 2\,e^- \rightarrow Cu \qquad (6.5)$$

4. Applied current (e.g., corrosion through stray currents in soil near tram lines).

Figure 6.3 shows a local inhomogeneity where dissolution of metal and electron acceptance can take place. The dissolution of a polycrystalline metallic material in acid at a grain boundary is shown schematically. When anodes and cathodes are of limited size and spread homogeneously on the metal surface, this is referred to as mixed electrodes. This applies to corroding low-alloyed steel surfaces in liquid electrolytes. Due to the high mobility of the electrons in the electron cloud of the metal, the electron acceptance can take place far away from the location of the dissolution of metal. So, the electron transfer—the reaction of the acid—takes place at the grain and not at the location of the dissolution of the metal. The distance between dissolution at the anode and electron acceptance at the cathode can be quite far. This can be seen in liquid electrolytes of materials with phases of different alloy content (e.g., austenitic-ferritic duplex steels) or components consisting of different materials which are in contact (e.g., galvanic corrosion or bimetallic corrosion of two metals with different alloy content in a weld).

Electrochemically, the cathode and the anode form a corrosion cell together with the electrolyte. Corrosion reactions occur spontaneously when metal atoms can attain a condition of lower energy. Much like in a battery, the corrosion cell is doing work ($W_{el} = EQ$). Therefore, the Gibbs free energy ΔG has to adopt a negative value. The excess heat available is released as work energy. For one mole of mass, the representative amount of charge is $Q = zF$. Therefore, the energy released is

$$\Delta G = -zF\Delta E\,. \qquad (6.6)$$

In this equation, E represents the electromotive force EMF. It can be regarded as voltage ΔU and measured like in a battery; ΔG results from the activities or approximations of the concentration C of the reactant at the cathode (reduction) and anode (oxidation) according to the law of mass action.

$$\Delta G = \Delta G^0 + RT\ln(K) = RT\ln\frac{C_{Red}}{C_{Ox}}$$
$$= RT\,2.303\lg\frac{C_{Red}}{C_{Ox}} \qquad (6.7)$$

Table 6.1 Standard potentials (electrochemical series) and closed-circuit potentials in simulated sea water (practical electrochemical series) in comparison to a standard hydrogen electrode (N/A: not available)

Element/material → partial reactions	Standard potential ΔE^0 (V)	Closed-circuit potentials in simulated sea water [6.3] (V)
$H_2 \rightarrow 2\,H^+ + 2\,e^-$	0.00 (Reference)	N/A
$Mg \rightarrow Mg^{2+} + 2\,e^-$	−2.36	−1.40
$Al \rightarrow Al^{3+} + 3\,e^-$	−1.66	−0.67 (Al99.5)
$Ti \rightarrow Ti^{2+} + 2\,e^-$	−1.77	−0.11
$Zn \rightarrow Zn^{2+} + 2\,e^-$	−0.76	−0.80 (Zinc coating on steel)
$Cr \rightarrow Cr^{3+} + 3\,e^-$	−0.71	−0.29
$Fe \rightarrow Fe^{2+} + 2\,e^-$	−0.44	−0.35 (Quenched and tempered steel), −0.05 (X5CrNi18.8)
$Sn \rightarrow Sn^{2+} + 2\,e^-$	−0.14	−0.19
$Cu \rightarrow Cu^{2+} + 2\,e^-$	+0.34	+0.01
$Ag \rightarrow Ag^{+} + e^-$	+0.80	+0.15
$Pt \rightarrow Pt^{2+} + 2\,e^-$	+1.20	N/A

The combination of (6.6) and (6.7) results in the important Nernst equation

$$\Delta G = \Delta G^0 + RT\ln(K) = RT\ln\frac{C_{\mathrm{Red}}}{C_{\mathrm{Ox}}} = RT\,2.303\,\lg\frac{C_{\mathrm{Red}}}{C_{\mathrm{Ox}}}\,. \tag{6.8}$$

In the electrochemical corrosion of metallic materials however, the anodic and cathodic partial reactions are not as strict as in a battery. In order to have a thermodynamic measure of the severity of an electrochemical corrosion reaction, the standard conditions are defined as room temperature 298 K, a normal pressure of 0.1 MPa, and the concentration of reactants 1 mol L^{-1}. Due to the neutrality of the complete corrosion cell, the anodic and cathodic partial reactions cannot be measured individually. As a substitute, the overall reaction ((6.1) and (6.3b)) is used to define the standard electromotive force ΔE^0, where the EMF as a standard potential of the individual reactions explains the metal dissolution.

$$z\,H_3O^+ + M \rightarrow M^{z+} + z\,H_2O + \tfrac{z}{2}\,H_2 \tag{6.9}$$

This also means that the standard potential of the hydrogen deposition is equal to zero, which also considers the high binding energy of the hydrogen molecule H_2 (approximately 436 kJ mol^{-1}) in corrosive reactions. Table 6.1 shows the single reactions and standard potentials of the most important alloying elements of technical materials in comparison to the standard hydrogen electrode, which allows estimating the dissolution in liquid electrolyte. Metals and materials that are lower in the galvanic series (electropotential series) compared to the standard hydrogen electrode are referred to as less noble, while elements with higher electrode potential are referred to as noble. However, the disadvantage is that these standard potentials usually do not reflect the technical application. Additionally, Table 6.1 contains a list of closed circuit potentials that depend on the medium (e.g., simulated sea water, pH7.5) [6.3]. These lists are referred to as practical electrochemical series.

The thermodynamics of the electrochemical corrosion reactions which are mentioned above are superimposed by kinetic influences. These are caused by the resistance and the inhomogeneity in the electrolyte and on the metal surface. Inhomogeneous electrolytes are formed by depletion processes (e.g., locally high consumption of oxygen), enrichment processes (e.g., alkalization by formation of OH^- ions) and diffusion processes (e.g., transport processes at the surface and in the electrolyte). In the electrolyte, the mobility of the reaction partners and ions is significantly lower than the electrons in the metal and those which are on the metal surface. If chlorides are present in aqueous electrolytes, the conductivity increases as compared to pure water and also, the solubility of metal ions in the water is increased which accelerates the metal dissolution. Especially at locations where positively charged ions in the electrolyte (cations) are neutralized by electrons, the charge exchange strongly depends on the diffusion velocity in the direction of the metal surface. In other words, this causes an electron congestion on the metal surface and causes a negative polarization. In the same way, locations where metal atoms are dissolving have a higher anodic potential. At the cathode, such diffusion boundary layers can significantly impede the charge exchange. These are the explanations for the decrease of ion mobility in an electrolyte because of the interference of cations at high salt concentrations. The corrosion at the metal surface proceeds slower than at lower salt concentrations. If hydrogen is neutralized at the cathode (6.3b) and the hydrogen solubility of the

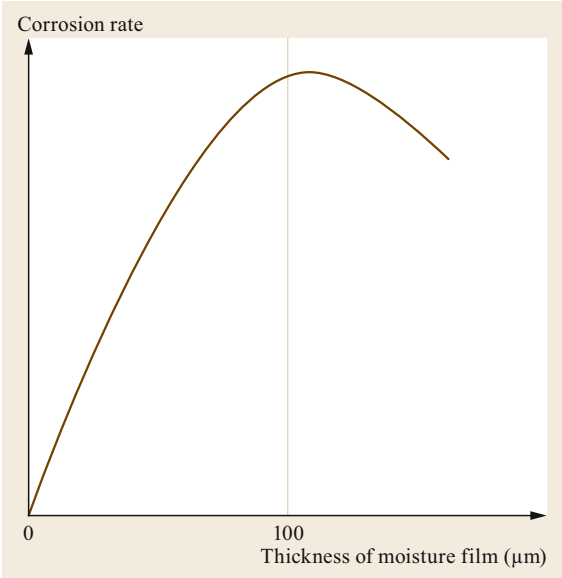

Fig. 6.4 Influence of the thickness of a moisture film on the rate of atmospheric corrosion [6.3, 4]

metal is comparatively low, a so-called hydrogen over voltage is produced. The resulting molecular gaseous hydrogen covers the cathode and impedes further cathodic reactions. Therefore, the anodic partial reaction of the metal solution can also be blocked. Figure 6.4 shows these effects using the example of the moisture film thickness on the corrosion under atmospheric conditions. It shows that as the water supply increases, the consumption of electrons is faster and the metal dissolves more easily. However, starting from a certain film thickness (100 μm), the corrosion rate decreases because of the larger diffusion path of the oxygen from the atmosphere. Consequently, no more electrons can be consumed. In practice, this means that thin films of Cl containing condensates or dew on metal surfaces are more corrosive than large quantities of liquid electrolyte or rain. Inhomogeneous metal surfaces are caused by hindered charge transitions through adsorption layers and secondary corrosion products (rust). Oxide layers on the surface of technical materials, so-called passive layers, have a particularly large kinetic influence. These are layers with very large electrical resistances, which are poorly soluble by an electrolyte. The kinetics of the anodic reaction of the metal dissolution is influenced primarily by how these passive layers are formed again after destruction (repassivation of metal surface). Due to a very low diffusivity of hydrogen atoms or protons compared to the subjacent metal, these layers also influence the kinetics of the cathodic hydrogen reaction. As a result, the hydrogen absorption at the cathode is extremely reduced, more molecular hydrogen is formed on the metal surface, and the adsorption of further hydrogen protons is hindered. Metals like chromium, aluminum, and titanium form these oxide/passive layers.

Seldom, a result of these kinetic processes is that the closed-circuit potentials at real metal surfaces correspond to the electromotive force of dissolution at a standard hydrogen electrode (Table 6.1). Based on practical electrochemical series in realistic electrolytes, the corrosion behavior of material pairings, especially for bimetallic corrosion, can be assessed much better.

While the scientific consideration of corrosion is based essentially on the investigation of electrochemical reactions and kinetics, a classification according to the type of corrosion is suitable for technical consideration. Out of 56 types of corrosion, listed in [6.1], the most important for mechanical engineering are shown in Fig. 6.5; they will be dealt with in more detail in the following sections.

6.2.1 Uniform Corrosion

Uniform corrosion (Fig. 6.5) is predominantly homogeneous on the entire metal surface and is referred to as uniform corrosion [6.1]. The best example is corrosion of low-alloyed steels in a humid atmosphere or neutral water. Oxygen and water are necessary for oxidation of the iron, and corrosion occurs as the sum of the partial reactions (6.1) and (6.4a).

$$2\,\mathrm{Fe} + \mathrm{O_2} + 2\,\mathrm{H_2O} \rightarrow 2\,\mathrm{Fe(OH)_2} \qquad (6.10)$$

A sufficient amount of oxygen is available from the atmosphere. Water mostly condenses from the ambient air as an electrolyte film on the steel surface, preferably on particles. No noteworthy corrosion occurs below a relative humidity of 70%. In very clean air no noticeable corrosion takes place even at 100% relative humidity.

During uniform corrosion, the entire material surface is removed by alternating anodic and cathodic partial regions. These local reactions can be simplified by the illustration of the corrosion of iron underneath a water drop (Fig. 6.6). At the edge of the droplet, the diffusion path of the oxygen is shortest. This is where the cathodic and electron-accepting process takes place with the formation of OH ions. The anodic partial reaction of the iron dissolution takes place in the center of the droplet. At first, iron(II) hydroxide is formed, which is not rust in the classical meaning. In the presence of dissolved oxygen, it transforms due to secondary reactions (shown in (6.11)–(6.15)) to different rust minerals. Cl ions are mainly responsible for iron dissolution due to the increased solubility in water and the formation of unstable hydroxyl complexes. These keep the anodic

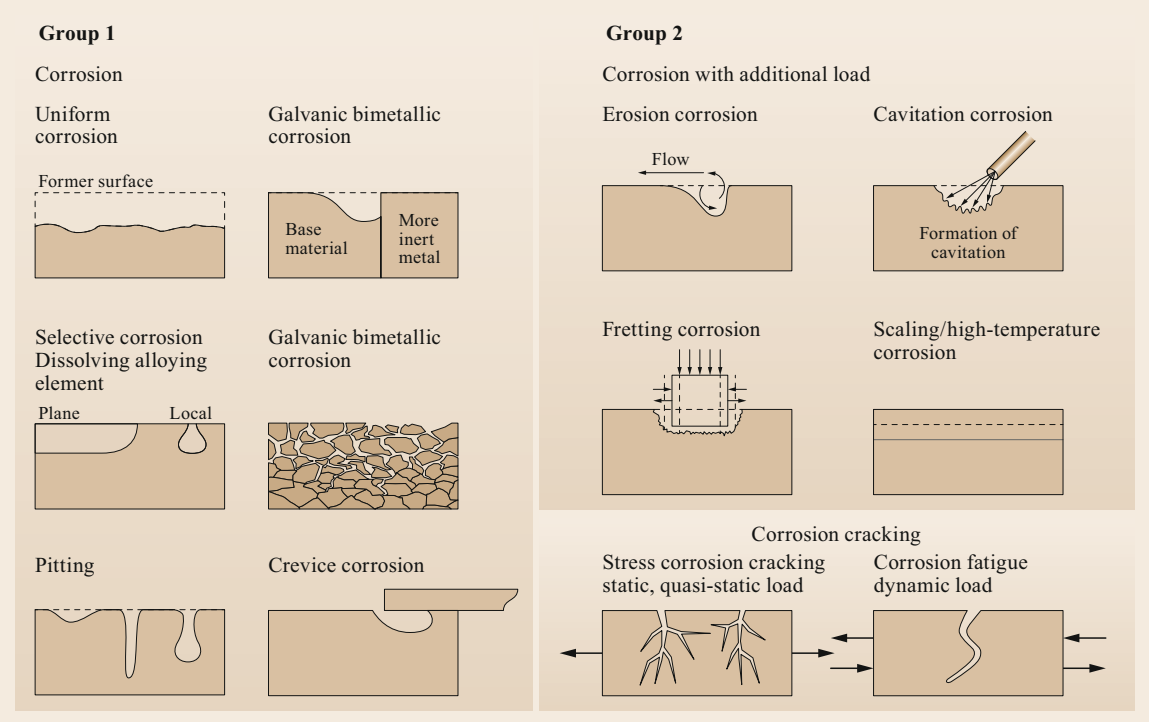

Fig. 6.5 Forms of corrosion at metal

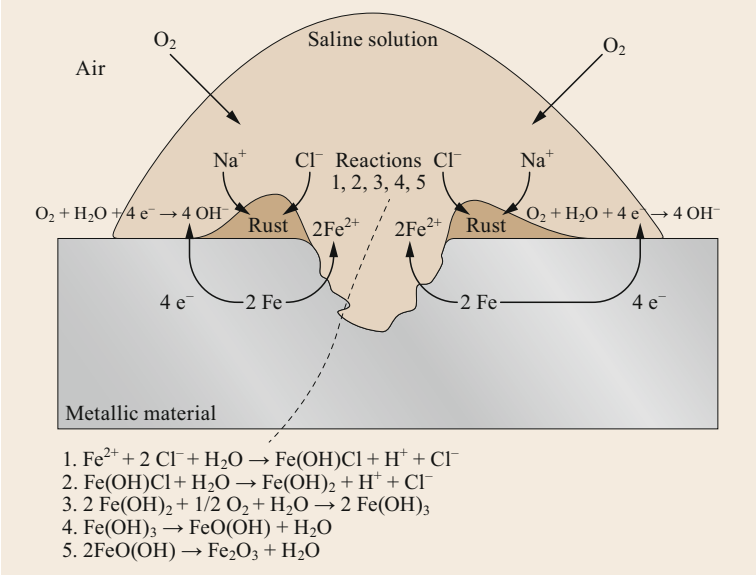

Fig. 6.6 Corrosion underneath a drop of water [6.5]

metal dissolution in motion (Fig. 6.6).

$$Fe^{2+} + 2\,Cl^- + H_2O \rightarrow Fe(OH)Cl + H^+ + Cl^- \quad (6.11)$$

$$Fe(OH)Cl + H_2O \rightarrow Fe(OH)_2 + H^+ + Cl^- \quad (6.12)$$

$$2\,Fe(OH)_2 + \tfrac{1}{2}\,O_2 + H_2O \rightarrow 2\,Fe(OH)_3 \quad (6.13)$$

$$Fe(OH)_3 \rightarrow FeO(OH) + H_2O \quad (6.14)$$

$$2\,FeO(OH) \rightarrow Fe_2O_3 + H_2O \quad (6.15)$$

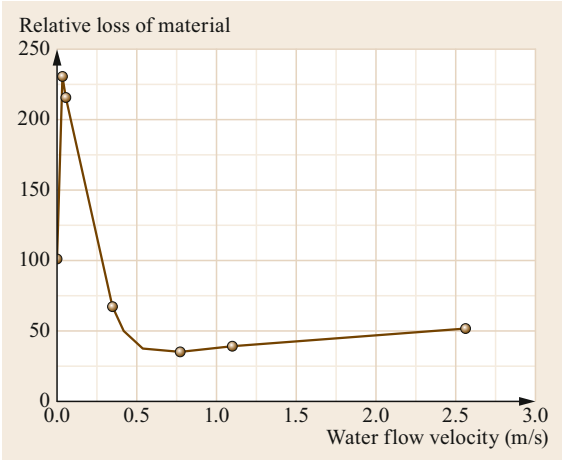

Fig. 6.7 Dependence of corrosion on flow velocity in drinking pipes [6.6]

The volume of the rust is, depending on the composition, six to eight times greater than the amount of absent (corroded) iron. The conversion of rust products depends very much on climate conditions and the resulting weather cycles. Rust products do not form a cohesive top layer but can significantly reduce the corrosion rate. Depending on the chemical composition of the steel and the surrounding medium, the corrosion rates can be reduced from 0.1 to 0.01 mm/a. The flow velocity of the ambient medium is also important, for example in fresh water pipes. Initially, corrosion increases with higher flow rates because more oxygen collects on the surface. At medium speed, corrosion products deposit on the surface that are removed at higher flow speeds (Fig. 6.7). Permissible flow velocities have been specified, for example, by *Mörbe* et al. [6.6] and are summarized in Table 6.2.

6.2.2 Galvanic Corrosion

When two materials or regions of materials that differ in their electrochemical behavior are connected to conduct electrons, they are referred to as galvanic elements.

Table 6.2 Permissible flow velocities according to *Mörbe* et al. [6.6]

Material	v_{min} (m/s)	v_{max} (m/s)
Unalloyed steel	0.5	2.0
Hot-dip galvanized steel	0.5	2.0
Polymer-coated steel	0.5	6.0
Chromium-nickel steel	0.5	5.0
Copper DR-Cu 99,7	0.7	1.2
Brass CuZn30	1.0	2.0
Special brass CuZn20Al2	1.0	2.5

Galvanic corrosion, sometimes also referred as to contact corrosion or bimetallic corrosion, describes that as a result of the conductive contact, the metal dissolution is accelerated at the less noble material (anode), and the electron acceptance process proceeds preferentially at the more noble region (cathode). If both materials are metals, this process is referred to as bimetallic corrosion. Depending on the contact geometry, bimetallic corrosion can be distinguished as uneven, often ditch-shaped dissolution of the less noble material at the immediate contact area. Simultaneously, the more noble material shows reduced corrosion. Bimetallic corrosion can cause decreased strength of the joined materials or their perforation. Furthermore, it can accelerate the formation of corrosion products and change the optical appearance.

However, it is difficult to evaluate the galvanic corrosion resistance of material pairings based on standard potential differences of both materials (Table 3.8). Out of practical experience, materials can be summarized as groups with a reduced risk of pronounced galvanic corrosion within one group:

Group 1. Highly electronegative, nonnoble metals: magnesium, and its alloys
Group 2. Nonnoble metals: aluminum, cadmium, zinc, and their alloys
Group 3. Moderate nonnoble metals: lead, tin, iron, and their alloys (except for high-alloyed chromium and chromium-nickel steels)
Group 4. Precious metals: copper, silver, gold, platinum, and their alloys
Group 5. Strongly passivating metals: titanium, chromium, nickel, cobalt, and their alloys, as well as highly alloyed chromium and chromium-nickel steels
Group 6. Nonmetallic cathodes: graphite, CFK, well-conductive carbides, oxides, and borides.

This simplified consideration cannot eliminate the possibility of galvanic corrosion. Especially if one or even several group boundaries are exceeded, the corrosive behavior of the material pairing needs to be evaluated.

The kinetics of the anodic and cathodic partial reaction on both materials and the characteristics of the partial flow density potential curves are essential for the overall corrosive behavior. The joint potential of the electrically short-circuited elements differs from the equilibrium state of a single material during corrosion (open corrosion potential). The less noble partner produces an increased anodic corrosion current in addition to self-corrosion. This enhances metal dissolution, and the cathodic partial reaction is shifted proportionally to

the more noble partner. In an acid solution, this is often accompanied by an increased amount of hydrogen gas at the more noble cathodic metal than would be the case if it would be sporadically dipped into the solution. If, in such a case, additional mechanical stresses are present, bimetallic corrosion could lead to hydrogen-assisted cracking of the more noble metal. This danger especially exists when the electrolyte contains promoters. These substances prevent recombination to molecular hydrogen (recombination poisons), such as, e.g., H_2S, cyanide, and arsenic compounds.

Attention should be paid to the area ratio between anode and cathode. According to the condition that the magnitude of the anodic and cathodic partial currents in the equilibrium state must be equal, the dissolution current density ($i = I/F$) at the anode increases proportionally to the area ratio F_A/F_K,

$$I_A = |I_K|^+ \quad (A)\,, \tag{6.16}$$

$$i_A = \left(\frac{F_K}{F_A}\right)|i_K|^+ \quad (A\,mm^{-2})\,. \tag{6.17}$$

To avoid highly localized corrosion of the anode ($i_A \gg i_K$), it is recommended that the noble anode be as large, and the cathode as small, as possible. An example of this is when aluminum sheets (large anode) are joined with rivets made of Monel (about 70% Ni and 30% Cu) to homogenize bimetallic corrosion as far as possible. In the case of high-alloyed chromium and chromium-nickel steel welds, a higher-alloy filler material is used for the smaller surface area, which then acts as a cathode.

In practice, the formation of contacting materials as a cathode or anode is less dependent on the galvanic series, but rather on the ability to repassivate. The ability to repassivate influences the kinetics of the anodic and cathodic partial reactions. The formation as a cathode or anode also relies on the electrical transitional resistances between the connected metals and the conductivity of the electrolyte solution.

The following list provides solutions to avoid galvanic corrosion, which has consequences on the design of components, especially in multimaterial applications under light-weight aspects:

- Materials that are corrosion resistant in a solution can be incompatible in a conductive connection, e.g., due to accelerated corrosion of the less noble material.
- The combination of approved standard assembly groups in complex systems needs to be questioned, e.g., the connection of copper pipes with Al-heat exchangers in cooling circuits. Also, traces of incompatible metals (such as the deposit of dissolved Cu-ions on aluminum) or conductive materials (graphite in lubricants) can also form galvanic elements.
- Passive and cover layers can make incompatible pairs possible by inhibiting rate-determining partial reactions, such as contact between aluminum and Cr-Ni steel parts at mild atmospheric conditions or dense carbonate-containing deposits on copper water pipes.
- An increase of transition resistances (up to isolation) between materials reduces or prevents bimetallic corrosion.
- The extent of the galvanic element is directly proportional to the conductivity of the solution. Reduced conductivity can limit damage at the immediate contact area, e.g., by formation of thin adsorbed films during atmospheric corrosion.

There are also applications in mechanical engineering where bimetallic corrosion is deliberately generated to extend the lifetime of components and systems. This is achieved by applying a less noble contact partner, e.g., by galvanizing of nonalloy steels in automobile construction or by so-called sacrificial anodes, made of aluminum or magnesium, in maritime technology. In principle, cathodic protection of high-strength, low-alloyed steels needs to be weighed against the risk of hydrogen absorption, especially in slightly acidic electrolytes. In the case of less noble coatings, a so-called long-distance protection effect is achieved by dissolving the less noble regions adjacent to defects, which allows a greater robustness when the coating is damaged. Coating of low-alloyed steels with more noble metals, e.g., during nickel-plating or chromium-plating, must be produced without errors to prevent galvanic corrosion of the base material.

6.2.3 Selective and Intergranular Corrosion

In contrast to galvanic corrosion, selective corrosion occurs at material pairings that are identical or at least similar. Only certain parts of the microstructure, such as areas near grain boundaries or alloying parts, corrode [6.3, 5, 7]. The preferred corrosion of certain parts of the microstructure requires a heterogeneous formation of the material structure. During selective corrosion, the less noble phase forms the anode, and the more noble phase becomes the cathode. During this process, microscopic contact elements are formed. Welded joints are the preferred areas of attack, since the weld metal and the heat-affected zone (HAZ) often differ in microstructure and alloy composition. Reasons for these differences are the

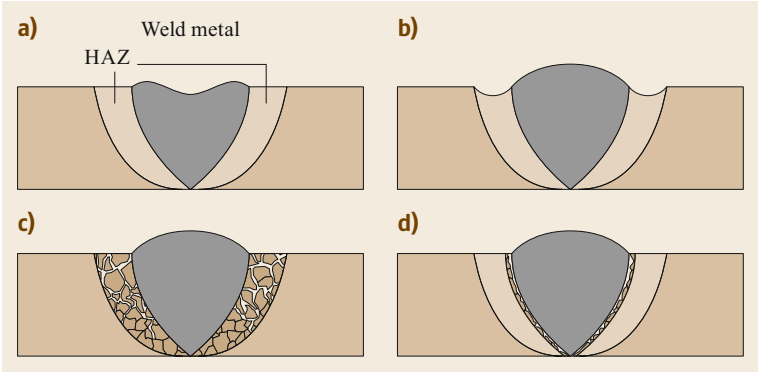

Fig. 6.8a–d Types of selective corrosion in welded joints [6.5]. **(a)** Selective corrosion of weld metal, **(b)** selective corrosion of HAZ, **(c)** intergranular corrosion, **(d)** knife-line corrosion

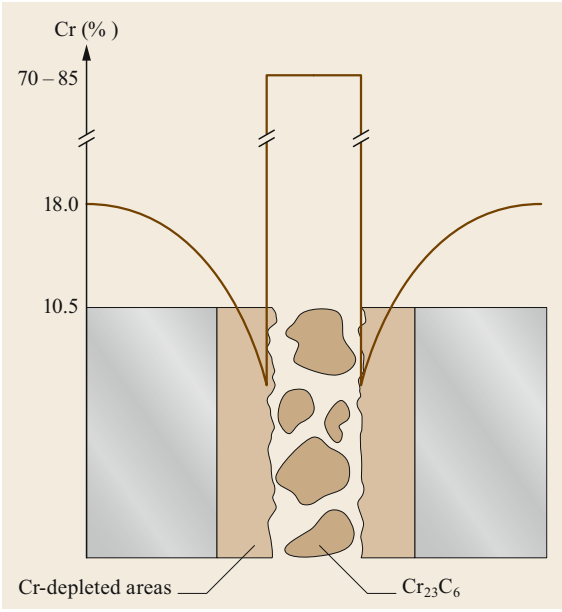

Fig. 6.9 Chromium distribution at a grain boundary of Cr-Ni steel with 18% chromium

combustion of alloying elements during welding, segregation, and precipitation. Depending on which welding region is less noble, it can be distinguished between selective corrosion of weld metal or HAZ. Intergranular corrosion and its special type, the so-called knife-line attack, frequently occur in welded joints.

Intergranular corrosion takes place when metallic materials are subject to less corrosion-resistant phases at grain boundaries, and these form a coherent network. This can cause localized dissolution along grain boundaries and complete decomposition of the material into individual crystallites (grain decay). This can occur in aluminum-magnesium alloys as a result of the Al_3Mg_2-phase and, in the case of brass, due to the β-phase. During welding and heat treatment of high-alloyed chromium and chromium-nickel steels, precipitation of chromium carbides ($Cr_{23}C_6$) at grain boundaries is a major cause of intergranular corrosion. The formation and growth of phases up to 85% chromium at temperatures between 425 and 815 °C (depending on alloying and microstructure) can result in chromium depletion in the immediate surroundings (Fig. 6.9). This process is called sensitization and is often caused by improper heat treatment, operating temperatures, or temperature control during welding. If the chromium content drops below a critical limit of 10.5% Cr and the conditions in the media are disadvantageous, a stable passive layer is no longer formed, and the dissolution speed increases. A 10^6 times higher corrosion rate can occur along such precipitate-rich grain boundaries compared to the grain surface (Fig. 6.10).

It is important that the sensitization and subsequent intergranular corrosion are caused by the growth of the chromium carbides and not by the segregation or their presence per se (Fig. 6.11). The microstructure of the material, in combination with the chromium and carbon contents, is relevant for the susceptibility to sensitization and intergranular corrosion. An example of this is that high-alloyed ferritic chromium steels are much more susceptible to intergranular corrosion than austenitic chromium-nickel steels with the same chromium and carbon contents, due to their lower solubility in carbon.

Both groups of materials are, however, prone to intergranular corrosion because they segregate chromium carbides solely at the grain boundaries and not in the grain interior. On the other hand, high-alloyed martensitic steels with about 13% chromium can be alloyed with more than four times higher carbon contents (> 0.2%) without an increased susceptibility to intergranular corrosion after welding or heat treatment. This is due to the fact that these steels precipitate chromium carbides predominantly within the former austenite grains along the martensite plate. Therefore,

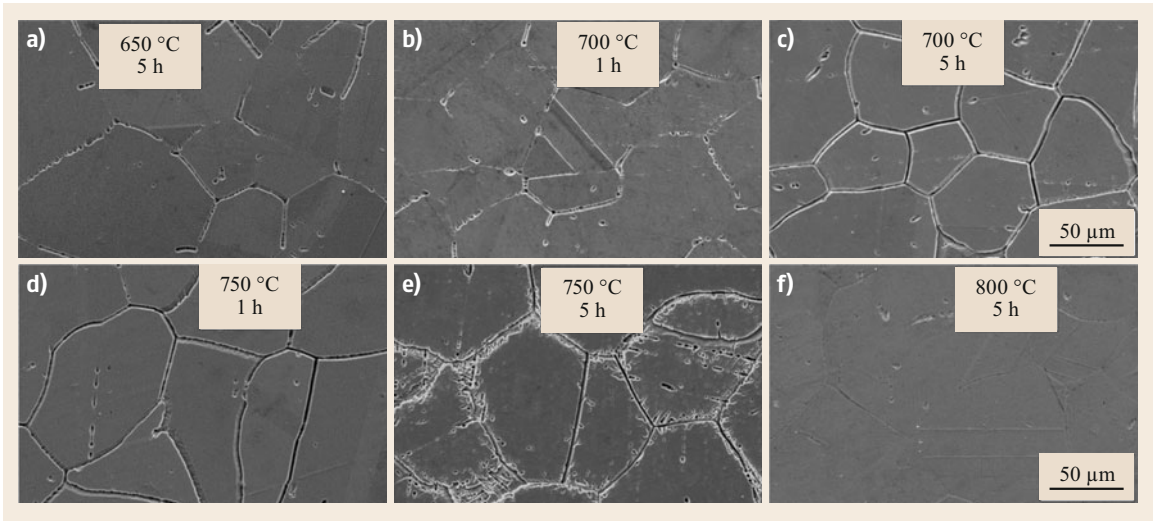

Fig. 6.10a–f Different states of sensitization for intergranular corrosion depending on the heat treatment condition (temperature and time) of 316L-based corrosion resistant steel tested with 10% oxalic acid solution [6.8]

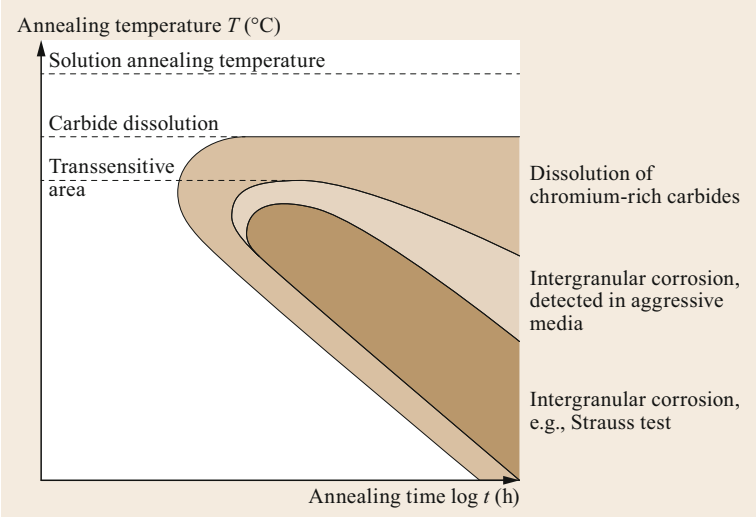

Fig. 6.11 Time–temperature–precipitation

chromium depletion takes place over the whole surface area and is not preferred only along the former austenite grain boundaries. To roughly estimate the susceptibility of a material for intergranular corrosion, time–temperature–precipitation (TTP) diagrams, which characterize the area of chromium carbide precipitation, can be used (Fig. 6.11). The real sensitization is illustrated in so-called grain decomposition diagrams, which are often determined by a Strauss test (Fig. 6.12). However, realistic quantitative evidence of sensitization due to chromium depletion along the grain boundaries can only be achieved by analytical methods such as energy dispersive x-ray spectroscopy (EDX).

Since the formation of a passive layer is strongly influenced by the corrosion potential, while the pH value has a great influence on the potential, a paradoxical behavior occurs at steels that can passivate. An example of this is when strong intergranular corrosion can occur on sensitized steel in a low-acid medium (e.g., beer, wine, shampoo), and no corrosion occurs in a substantially acidic medium by a shift of the potential in the positive direction. In oxidizing acids with even higher positive potential, the chromium carbides may dissolve and, therefore, lead to intergranular corrosion.

High-alloyed austenitic chromium-nickel steels can be stabilized against intergranular corrosion by alloy-

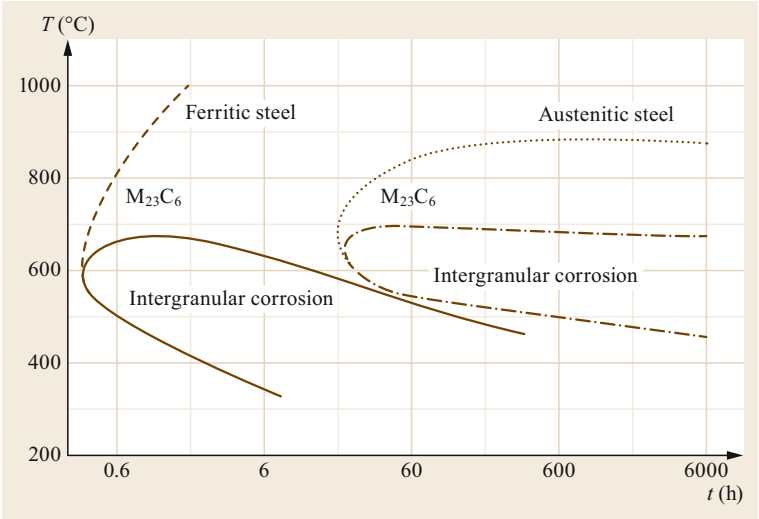

Fig. 6.12 Grain decomposition diagram for high-alloyed, ferritic Cr steels and austenitic Cr-Ni steels

ing with titanium. This causes the formation of titanium carbides instead of chromium carbides, which cause chromium depletion at the grain boundaries.

However, welding of these stabilized high-alloyed austenitic chromium-nickel steels can lead to knife-line corrosion as a particular form of intergranular corrosion. The stabilizing (titanium) carbides are being dissolved in a very narrow region of the HAZ, usually parallel to the fusion line. This area is characterized by the high temperature, which is only slightly below the melting temperature of the steel. The new formation of carbides is suppressed as a result of the rapid cooling. The welding of the following layers causes the precipitation of both titanium and chromium carbides in this narrow zone because of the heat input. This sensitization of the base material results in intergranular corrosion in a very narrow area next to the fusion line.

6.2.4 Passivation, Pitting, and Crevice Corrosion

Reactive metals, such as aluminum, titanium, zirconium, zinc, chromium, tantalum, cobalt, and nickel, form an oxide-like layer, the so-called passive layer, on the surface of the material. Passive layers are naturally grown, do not have a uniform chemical structure and, therefore, do not have the properties of a technical coating. It cannot be detected by conventional means because the layer is substantially smaller than the wavelength of visible light. High mechanical stresses and high potential gradients (about 1 MV/cm) are usually present in the layer. Iron and nickel alloys are usually alloyed with chromium to achieve a protective passive layer.

These materials form a stable passive layer of 10 nm (about 50 atomic layers, pure chromium only 5 atomic layers) at an alloy content of 10.5% chromium. The passive layer is more amorphous towards the metal and has a crystalline structure on the side of the medium. These layers, which are predominantly composed of chromium oxide, have a significantly lower ductility than the base material underneath. These are more likely to crack when subjected to mechanical loads.

The thermodynamics of electrochemical corrosion reactions are superimposed by kinetic influences due to the formation of such semiconducting, partially insulating passive layers. The kinetic property of the self-healing of passive layers after destruction or tearing, e.g., due to mechanical or tribological stress, is a great advantage. This property significantly differentiates passive coatings from technical coatings, which, after exposure of the base material, can no longer provide adequate barrier effects.

The passive layer is not a rigid cover layer but a dynamic system. Submicroscopic activation and repassivation processes take place on the surface, which can be measured as small potential and current impulses. These pulses are referred to as electrochemical noise. They depend on the type of metal and its state, temperature, and pH value, and also on the type and concentration of ions dissolved in the medium. These pulses provide valuable information about the condition of the passive layer and thus possible corrosive processes. Figure 6.13 shows a typical current pulse, which occurs as a result of metal dissolution in a locally destroyed passive layer.

At this small active location, a new passive layer is formed within a short time. This process is called repassivation.

Fresh metal surfaces have a large transient during the start of passive layer formation (dashed line

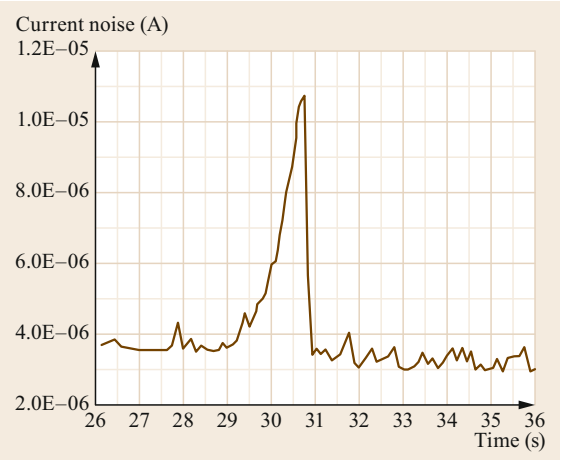

Fig. 6.13 Individual transient on a fresh surface of high-alloyed steel (X5CrNi18-10/SS304L) in a chloride-ion containing environment [6.9]. The amount of charge can be used to calculate the number of metall ions released to the electrolyte and corresponds further to a cubic metal defect

in Fig. 6.14). Over time, these events become less frequent, and the amplitudes decrease. A solution containing chloride ions has a significant noise behavior (solid line in Fig. 6.14). Multiple large current pulses are detectable, which only decay slightly after long periods. Chloride ions are not the initiator of local defects, but they interfere with the process of repassivation by increasing the solubility of metal ions in the local electrolyte significantly. In the case of larger amounts of chloride and material impurities, the repassivation can be severely affected. The electrochemically active sites grow and become a starting point for visible local corrosion.

This means that, for example, containers made of high-alloyed chromium-nickel steels should not be filled with chloride-containing media until the passive layer is built up and the activities of the passive layer are decayed. This can take hours or days, depending on the microstructure and alloy content of the material, as well as the ambient conditions. It must be considered that chloride ions are present as small concentrations in many neutral electrolytes. The low concentrations can accumulate, for example, due to evaporation processes on the material surface.

For the manufacture, processing, and operation of materials that form passive layers, it has to be considered that good corrosion properties are based on an extremely sensitive surface. The passive layer is only effective if the conditions for a constant, new formation are present. All deposits and impurities on the surface, whether visible or invisible (for example, in high-alloyed steels: sweat, dust, tool abrasion, rust particles, etc.) make the formation of the passive layer difficult and can result in local corrosion. However, a change in the metal itself due to high heat input, local work hardening, tensile stresses, etc., has an effect on the formation of the passive layer and, therefore, on local corrosion. Local corrosion can be divided into pitting and crevice corrosion.

Intentionally controlled corrosion is also used to form a homogeneous passive layer and to remove im-

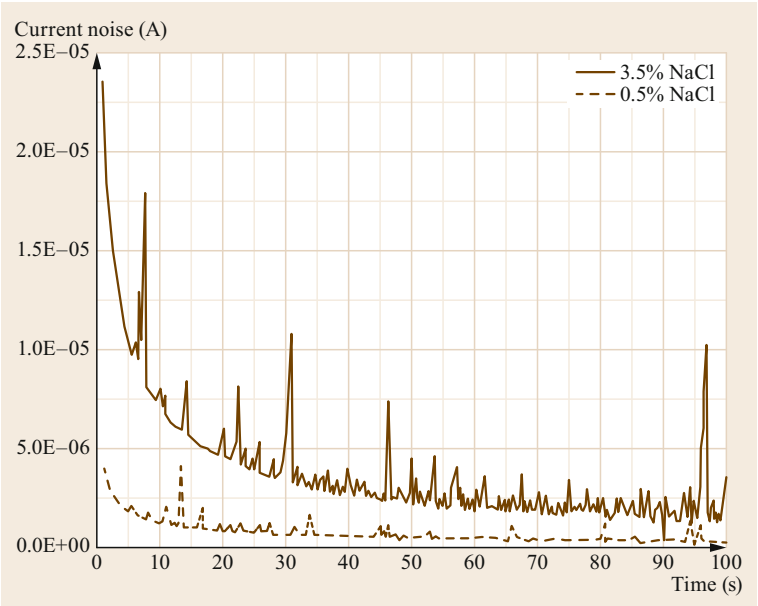

Fig. 6.14 Current noise of X5CrNi18-10/SS304L in different chloride-ion containing electrolytes: 0.5% NaCl (*dashed line*) and 3.5 NaCl (*solid line*) in accordance with [6.9]

purities. One example is the pickling of high-alloyed chromium-nickel steels in nitric acid to reduce the probability of types of local corrosion. The unavoidable priming colors after welding of high-alloyed corrosion resistant steels need to be removed mechanically or by chemical pickling. This region has locally different chemical compositions at the surface, and this causes a heterogeneous passive layer.

Pitting Corrosion

Pitting corrosion can occur in all technical systems that are made of materials that form passive layers. These are especially high-alloyed chromium-nickel steels, titanium and aluminum alloys, as well as nickel based-alloys. Pitting corrosion occurs mainly in the following steps:

1. Local destruction of the protective passive layer, for example, by mechanical, abrasive, erosive, or tribological stress.
2. Formation of a pit: the chemical composition of the surrounding medium reduces the rate of healing due to an increased solubility of metals in liquids with a higher halide ion concentration (especially chlorides and bromides) or sulfur concentration.
3. Metastable pit formation due to ongoing metal dissolution in the depth of the pit: simultaneous formation of a porous layer at the pit opening traps the electrolyte inside the pit with no connection to the ambient medium. This causes oxygen deficiency approximately 100 µm below the porous layer, and the electrolyte composition differs from the ambient medium outside the pit.
4. Stable growth of pit and hydrogen absorption due to local acidification: Chloride ions can enter the electrolyte of the pit through the porous layer. These cause increased solubility of metal ions in the pit electrolyte and disturb the repassivation in the case of an existing oxygen deficiency. The oxidation and formation of a passive layer is replaced by hydrolysis of the metals and the reactivity of the chromium acts as a reinforcing agent. As a result, the pit electrolyte is so strongly acidified (pH < 1) that the repassivation stops, and the pit corrosion can accelerate into the depth of the material. The hydrolysis causes the release of a great amount of hydrogen ions in the pit electrolyte. Only a small fraction of hydrogen recombines to molecular hydrogen, which, however, can hardly transfer through the porous layer. Larger quantities of gas would cover the metal surface in a way that the partial anodic reaction of the metal dissolution in the pit ground would also come to a stop. For this reason, it can be assumed that most of the hydrogen ions that are created in the base of the pit by hydrolysis are directly absorbed by the material (Fig. 6.15).

Two separate cathodic reactions are carried out during pitting corrosion, as well as during crevice corrosion. In addition to the partial cathodic hydrogen reaction, the anodic partial reaction in the pit electrolyte is additionally accelerated by the electron acceptance of the cathodic oxygen reaction (6.4a) even in a neutral ambient electrolyte. Pitting corrosion spreads rapidly into the material depth when only a few pit nuclei are formed.

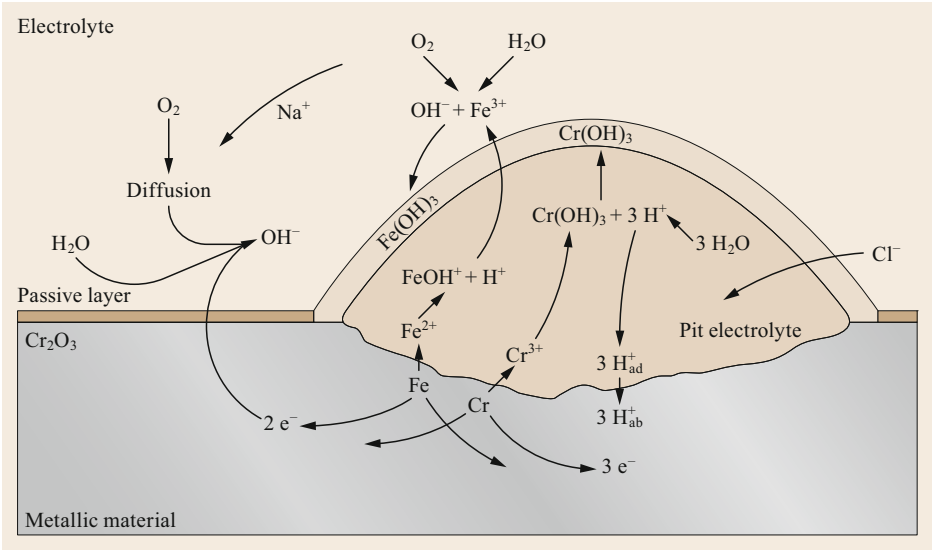

Fig. 6.15 Individual reactions and separation of the cathodic partial reaction during pitting corrosion of high-alloyed chromium-containing steels

The ability of a material to repassivate, and, therefore, the resistance to pitting corrosion, is predominantly determined by its alloying elements. Chromium and molybdenum are particularly important. To evaluate the influence of the alloying elements, the concentrations are provided with factors and summed up. For this purpose, various so-called pitting resistance equivalent numbers (PREN) were determined. However, there are several approaches that weigh the main alloying elements such as chromium, nickel, and molybdenum (and in many cases nitrogen) differently.

The critical pitting temperature (CPT) is a common, easily determinable parameter. It is determined in a 10% $FeCl_3$ solution, and the temperature is increased by 2.5 °C every 24 h until pitting corrosion becomes visible. A faster procedure is the determination of CPT by electrochemical noise. It is, however, more important to quantify the behavior of repassivation. This is evaluated by the so-called repassivation potential or repassivation temperature.

Crevice Corrosion

At first, crevice corrosion is similar to pitting corrosion. For components made of high-alloyed steels, the following four stages of crevice corrosion, which occur in a similar manner also in the electrolyte solution in the crack, can be distinguished (Fig. 6.16):

1. Oxygen consumption in the crevice.
   At first, uniform corrosion with the formation of metal hydroxide occurs in the crevice. The typical passive layer is formed on the surface of high-alloyed steels and nickel alloys. The anodic metal dissolution and cathodic oxygen reduction run parallel inside and outside the crevice. As a result of passive layer formation, the oxygen consumption increases inside the crevice. Depending on the crevice width, oxygen can no longer diffuse from the ambient electrolyte into deeper regions exceeding 100 µm. The time until total consumption of oxygen in the crevice can be calculated by Faraday's law. In combination with Fick's first law, the critical depth of the crevice can be determined. Within the critical depth, there is still a sufficient oxygen supply, and no crevice corrosion occurs.
2. Hydrolysis and drop of pH, as well as drop of electrochemical potential.
   As a result of oxygen deficiency, hydrolysis of chromium takes place, which precipitates as $Cr(OH)_3$. This often closes the crevice opening with a porous layer and prevents the further supply of relatively large oxygen molecules. Reasons for the preferential hydrolysis of chromium are its reactivity, the increased solubility of chromium due to diffusing chloride ions, and the higher solubility of other hydroxides. Hydrolysis causes the release of a large amount of hydrogen ions. This results in drops in pH and electrochemical potential with increasing hydrolysis. Cracks in metals cause similar corrosion mechanisms as crevices, and the pH at the tip of progressive cracks is significantly lower than in stationary cracks. The pH value in crevices and cracks of high-alloyed steels in a maritime environment is typically $0 \leq pH \leq 3$. The tendency of crevice corrosion increases with an increasing chromium content of above 15% due to the anodic current density and Cr concentration in the crevice increasing with decreasing pH.
3. Destruction of the passive layer and accelerated corrosion.
   As the hydrogen ions in the crevice increase, chloride ions diffuse from the ambient medium

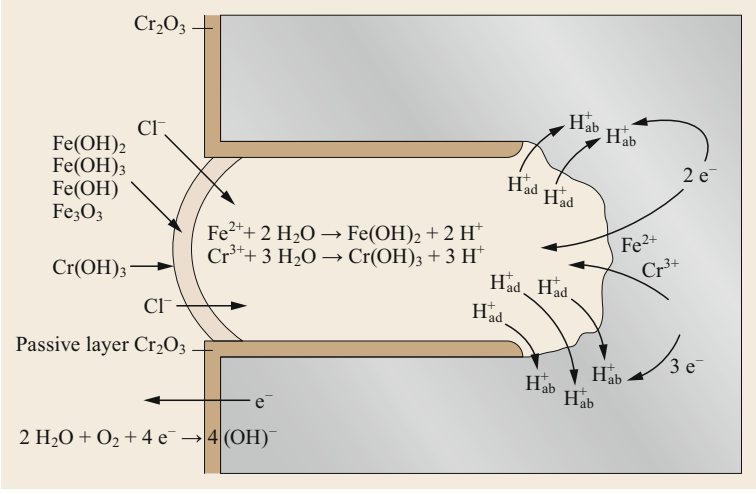

Fig. 6.16 Individual reactions and the separation of the cathodic partial reactions during crevice corrosion of high-alloyed chromium-containing steels

through the porous layer into the crevice to restore charge equalization. This increases the solubility of chromium in the gap and the formation of hydroxyl complexes [6.2, 4]. The hydrolysis of the chromium comes to a standstill and no passive layer can be formed. The crevice is activated, and the anodic current density in the crevice increases. The activation of the crevice can be registered as a drop in the open circuit potential.

4. Repassivation and hydrogen absorption.
In natural and artificial crevices or cracks, most of the hydrogen formed by metal hydrolysis is absorbed by the nonpassivated crevice ends or crack ends. Only a small amount recombines to form molecular hydrogen, which cannot effuse from deep crevices or cracks. If more gaseous hydrogen is produced in the gap, it would cover the metal surface in the crevice, and crevice corrosion would stop. The absorbed hydrogen causes material degradation, particularly at the end of the crevice or crack. Crevice and pitting corrosion can also cause hydrogen-induced cracking if an additional mechanical stress perpendicular to the crevice or crack is applied. If fresh metal surfaces are provided at the crack tip, further corrosion depends on the oxygen deficiency and crack length, as well as the repassivation behavior of the metal.

Crevice corrosion and its effects can be avoided by

- High purity and adaption of the alloying contents of material
- Low vertical mechanical stresses
- Avoiding crevices and the access of Cl-ions containing aqueous electrolytes into the crevice.

6.2.5 Stress Corrosion Cracking

Significant for all cracking phenomena coupled with corrosion is that the actual corrosive load due to an aggressive corrosive environment is superimposed by a mechanical load (stresses), mostly perpendicular to the crack propagation direction (Fig. 6.17). Hence, the mechanical load is regarded as the main cause for crack initiation, and the corrosion reactions, as a result of the surrounding medium, only assist the cracking process. This process is called environmentally assisted cracking (EAC). Frequently, the environmental conditions influence both mechanical and corrosive loads. Ambient temperature and pressure load the material mechanically but also have a particular influence on the simultaneous corrosion reactions. Crack initiation mostly occurs at already prematurely damaged surfaces. From the phenomenological point of view, it is necessary to distinguish between mere corrosion cracking and superimposed corrosion cracking with previous local corrosion (for example, pitting or crevice corrosion).

Basically, cracking in corrosive environments occurs with the interaction of three areas of influence: the material (mostly with a susceptible microstructure), coupled corrosion and mechanical loads (simultaneously), and design aspects (for example, gaps or unfavorable cross sections versus the load direction). In the case of a superimposed static mechanical load, this is commonly called stress corrosion cracking (SCC). Nonetheless, even straining of the material as the result of static tensile stresses can be the cause of SCC. In the case of mere cyclic mechanical load, it is called corrosion fatigue (CF).

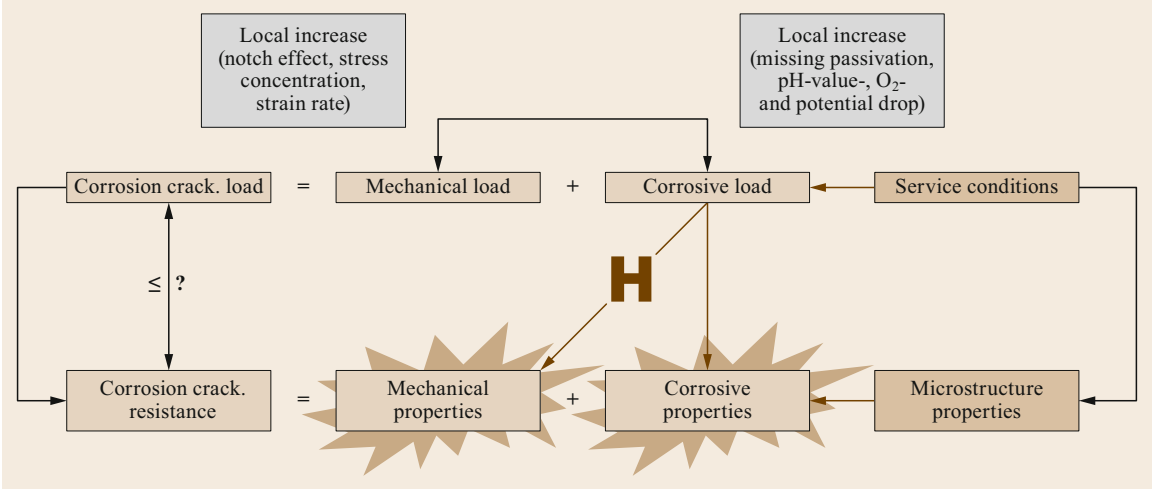

Fig. 6.17 Coupled loads for initiation of corrosion cracking

Stress Corrosion Cracking Under an Open-Circuit Potential

In the case of an open-circuit potential (OCP), in most cases, SCC starts from already existing corrosion types or from other respective defects at the material's surface. Especially in the case of pitting or crevice corrosion, an aggressive medium can be generated at the bottom of the pit or the gap within a depth of ca. 100 mm due to the decreased oxygen content and the potential drop. Under these circumstances, crack initiation is not only a consequence of the anodic dissolution of the metal. In fact, the separation of the cathodic partial reaction is responsible for the highly-increased hydrogen absorption in the material. This locally accumulated hydrogen may result in a distinct degradation of the mechanical properties (ductility) of the material and assists crack initiation because of the additional high strains and stresses at the bottom of the pit or gap. Components made from materials that form passive or cover layers and where pitting or crevice corrosion can take place, are generally susceptible to an SCC failure. Gaps, undercuts, a lack of penetration, and temper colors located at welded components (made from materials forming the passive layer) are quite often locations for initiation of SCC.

After crack initiation, the velocity of further crack propagation can increase rapidly under the coupled effect of the mechanical load and the corrosive environment. The corrosion reactions inside the crack are similar to those during crevice corrosion. Two different and separate cathodic reactions are involved, local and global reaction. Supported by the sharp decrease in oxygen content, the pH value and potential drop in the sharp and narrow crack, the generating electrolyte in the crack becomes more aggressive (compared to crevice corrosion). Hence, the crack propagation is a result of the accompanying hydrolysis due to the missing oxygen. Most of the generated hydrogen is absorbed at the fresh metal surface directly at the crack tip. However, partial pressure of the generated gaseous hydrogen can suppress further recombination. Nonetheless, even small amounts of promoters (like H_2S, arsenate, or cyanide compounds) in the electrolyte may suppress the hydrogen absorption totally at the freshly formed and not yet passivated metal surface at the crack tip. Hence, crack propagation depends on how fast the material is locally strained at the crack tip (Fig. 6.18). This is important for the necessary passivation to hinder further anodic dissolution of the metal and subsequent hydrogen absorption.

Hence, under the OCP condition, crack initiation with previous pitting or crevice corrosion and the corresponding crack propagation are not solely initiated by the anodic partial reaction at the bottom of the pit or the end of the crevice. In that connection, the former term anodic dissolution seems to be outdated.

SCC under the OCP condition takes place mostly in aqueous, especially Cl-ion-containing, electrolytes. This reaction is always accompanied by hydrogen absorption due to the local cathodic partial reaction. The partial cathodic reaction itself is mostly unaffected by the surrounding electrolyte (pH value, oxygen content, and composition of the electrolyte). The level of the locally absorbed and accumulated hydrogen concentration versus hydrogen-dependent material properties, decides if and how fast this type of SCC generates. Hence, this type

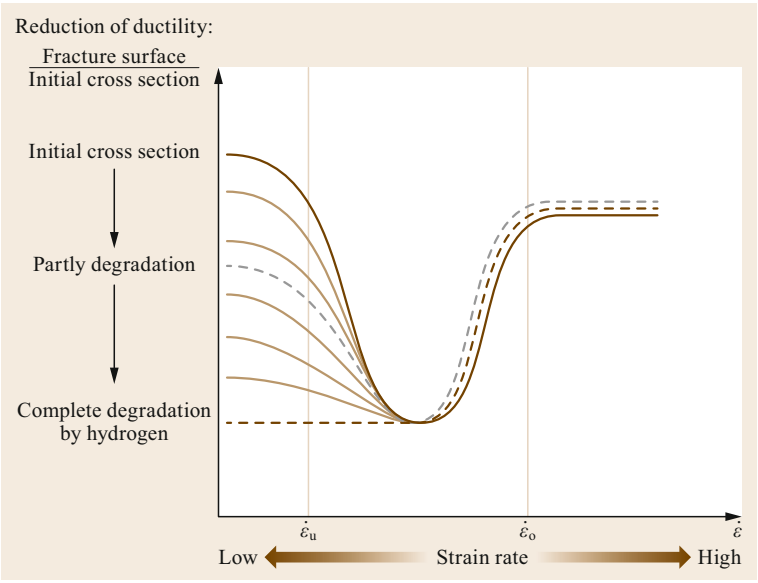

Fig. 6.18 HASCC susceptibility versus strain rate dependency

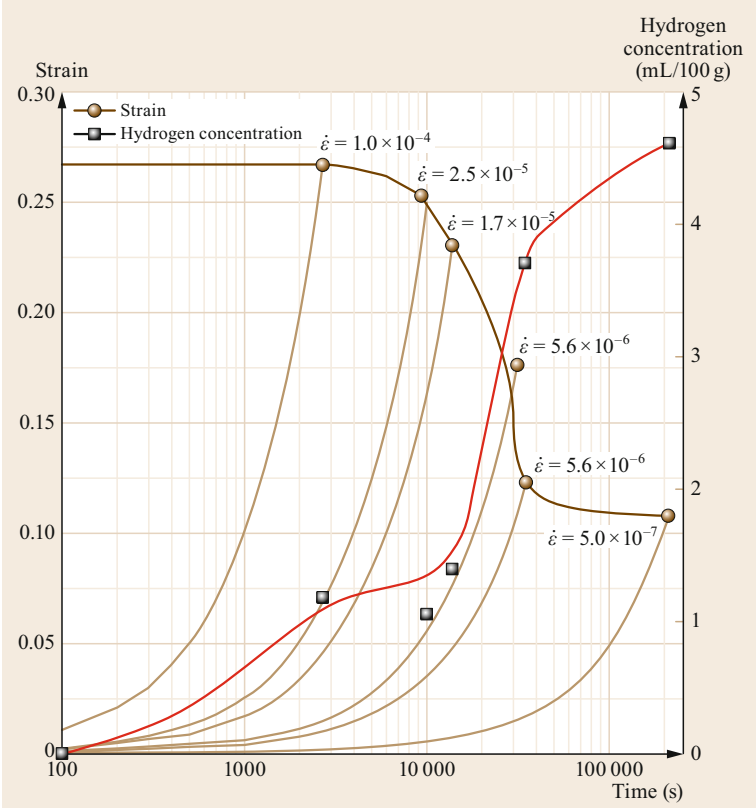

Fig. 6.19 Time-strain-to-fracture (TSF) diagram of Ni-Mo alloyed 13% Cr martensitic steel, tested in 10% NaCl H_2S-saturated solution

of corrosion is called hydrogen-assisted stress corrosion cracking (HASCC), as shown in Figs. 6.18 and 6.19.

In specific environments, SCC under the OCP condition can appear without previously visible pitting or crevice corrosion. This is the case if aqueous media contains high amounts of promoters (or recombination poison) so that crack initiation can occur directly at the metal surface. These substances suppress the cathodic oxygen reaction as well as the cathodic hydrogen recombination at the metal surface. The use of high-alloyed materials in neutral Cl-containing media, which contain pH value reducing H_2S, is called *sour service* internationally. During sour service, hydrogen protons can enter the material unaffectedly and are absorbed in very high concentrations at a large area. As a consequence of the significant reduction of ductility, the crack grows very fast and results in sudden component failure without any prior visible change of the metal surface. The avoidance of this SCC sequence is, therefore, of high importance. International standards for the construction of components in the oil and gas industry demand operators of such facilities to communicate with the respective manufacturers and to disclose possible sour service conditions.

In oxygen-free conditions, as well as at elevated temperatures and pressure, hydrogen can be generated from the so-called Schikkor reaction [6.3], for example, in high-temperature water or steam. Practically, this reaction is intentionally used in thermal power plants. At first, the Fe surface of the components undergoes electrochemical corrosion. Subsequently, the generated $Fe(OH)_2$ decomposes to magnetite (Fe_3O_4), water (H_2O), and molecular hydrogen (H_2).

$$3\,Fe(OH)_2 \rightarrow Fe_3O_4 + H_2O + H_2 \qquad (6.18)$$

The aim is to form a stable cover layer of magnetite in pipes made of heat and creep-resistant steels, for example in boiler components. This layer protects the metal surface from further electrochemical corrosion.

Stress Corrosion Cracking at a Defined Corrosion Potential

A whole component or specific area, e.g., in a welded joint, can be exposed to a solely cathodic partial reaction during galvanic or selective corrosion. The same applies to the intended cathodic protection by sacrificial anodes or artificial current supply. In the worst case, the

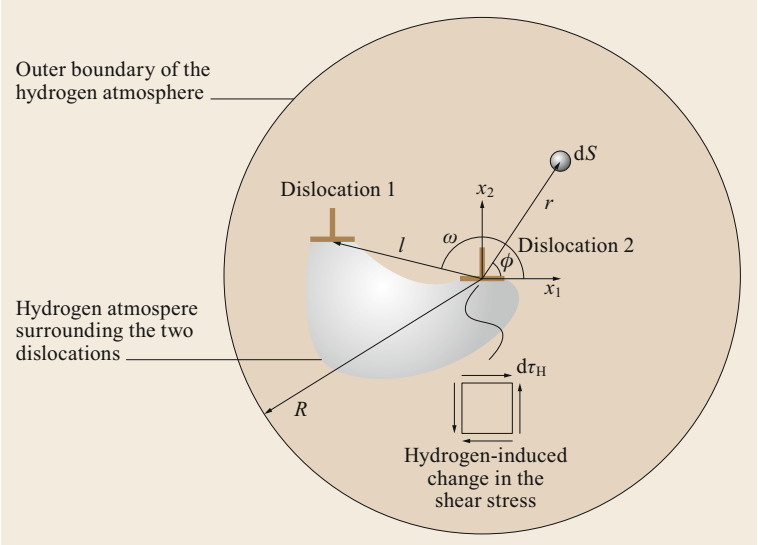

Fig. 6.20 The HELP mechanism by *Hirth* [6.10] and *Brinbaum* et al. [6.11] The effect of hydrogen on interacting dislocations is considered as a change in the shear stresses $d\tau_H$ (dS is the considered area in the material at the coordinates r and ϕ; the coordinates l, ω describe the position of two dislocations towards each other)

cathodic potential is in the range of the cathodic hydrogen reaction. This could cause hydrogen absorption and, therefore, rapidly progressing hydrogen-induced cracking, especially if additional promoters are present in the electrolyte. These cases are commonly referred to as cathodic stress corrosion cracking.

In the opposite case, a positive/anodic potential is applied to the component or specific area. It has to be distinguished whether or not the material is able to form a passive layer. Materials without this ability and simultaneously applied mechanical stress will not fail due to the combination of mechanical stresses and corrosion. The reduction of the cross section because of other highly abrasive corrosion forms, such as shallow pits or groove corrosion, will cause failure. If, in a rarer case, a material that can form passive layers is exposed to an anodic potential, the above-mentioned pitting or crevice corrosion takes place with a separate cathodic partial reaction. The speed of the crack start and crack propagation depends on the local strain rate, hydrogen absorption rate, diffusion capacity, and the rate of repassivation.

Crack Mechanisms

The mechanical properties of most metallic materials can be deteriorated by hydrogen. This affects, the deformability in particular and to a lesser extent, the strength. An outdated term for this is hydrogen embrittlement, which is replaced by the concept of degradation of material properties by hydrogen. In order to describe the metallurgical process of hydrogen-assisted cracking (HAC) microscopically, two metallurgical mechanisms are combined [6.10–13]. On the one hand, this is the interaction of hydrogen with dislocations. The absorbed hydrogen emits new dislocations locally, which then begin to migrate (hydrogen-enhanced localized plasticity, HELP) (Fig. 6.20) [6.11]. In this case, ductility-reducing effects due to hydrogen trapped at dislocations can also occur in the form of blockages, stacking errors, accumulation at grain boundaries, etc. On the other hand, the dissolved hydrogen at the interstitials decreases the cohesion of the metal lattice (hydrogen-enhanced decohesion, HEDE) (Fig. 6.21) [6.11].

It should be noted that in addition to the hydrogen, which is dissolved in the lattice, hydrogen that is bound to defects (dislocations, etc.) also has an effect. Furthermore, it must be noted that mechanical stress and strain are primarily the cause of crack formation (material separation). This results in the terminology of HAC and, instead of cathodic stress corrosion cracking, it is referred to as hydrogen-assisted stress corrosion cracking (HASCC). Cracking occurs if the mechanical stress exceeds the deformability of the material. This depends on the degradation of properties due to hydrogen concentration. The following aspects are important for the occurrence of HASCC: how much hydrogen is absorbed at the crack tip; how much is absorbed in the strain field; and the concentration of hydrogen that decreases the deformability. These criteria are increasingly used in numerical models to avoid HASCC in components [6.12].

Corrosion Fatigue

As in the case of corrosion cracking, conjoint corrosion and cyclic mechanical loading may also result in sudden component failure. In a similar manner, this type of corrosion cracking (corrosion fatigue) is separated

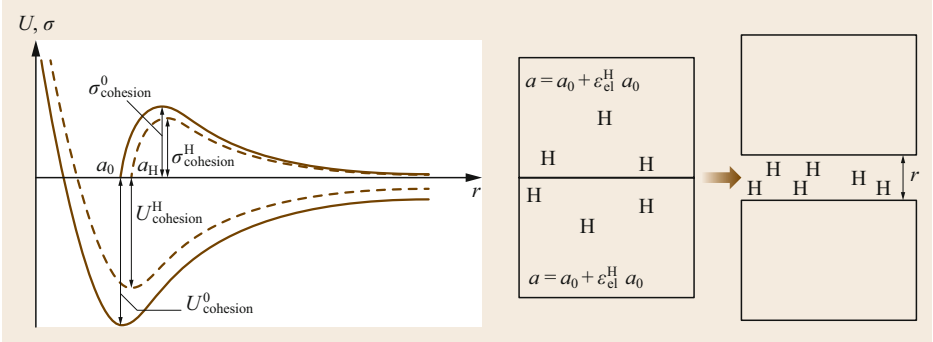

Fig. 6.21 The HEDE mechanism by *Schatt* et al. [6.14]. The effect of hydrogen is understood as a reduction of the cohesive energy U^0_{cohesion} (the cohesive stress $\sigma^0_{\text{cohesion}}$) on $U^{\text{H}}_{\text{cohesion}}$ ($\sigma^{\text{H}}_{\text{cohesion}}$); $\varepsilon^{\text{H}}_{\text{el}}$ is the elastic strain induced by H, and a_0 is the lattice constant

into incubation of crack, crack propagation, and overload fracture. The crack initiation is typically located at already damaged surface areas, as a consequence of pitting or crevice corrosion, or at a grain boundary.

Nonetheless, a crack can be initiated only by cyclic mechanical loads. For example moving edge dislocations can be transferred to the material surface by plastic straining and act as nuclei for corrosion. Under the OCP condition, the crack initiation and propagation are like those of SCC, i.e., it depends on oxygen content and the related decrease of pH value and the potential drop. In addition, the cathodic partial reactions are separated, and locally high amounts of hydrogen may be absorbed in the material. Then, the hydrogen can degrade the mechanical properties and influences crack propagation and the crack path. Hence, crack initiation and propagation of CF are not only influenced by the anodic partial reaction, neither for OCP nor for defined corrosion potentials in electrolytes.

Similarly to the strain rate influence during SCC, the frequency and amplitude of the load cycles during CF have great influence on crack initiation, the crack path, and its growth velocity. As a consequence of the alternating mechanical load, pump effects may occur in the electrolyte in an existing crack. These pump effects are responsible for the exchange of oxygen with the surrounding electrolyte and permanently change the passivation behavior. Thus, the independency of anodic and cathodic partial reaction is much more influenced in the case of CF compared to SCC.

CF occurs within a limited frequency range (i.e., the number of load cycles per time increment). This range is characterized by a very high crack growth rate. Hence, testing of CF should always be conducted with a varied frequency of the load cycles. The effect of the coupled cyclic mechanical and corrosive load (decreased cycle number) is demonstrated in Fig. 6.22 in the respective Wöhler diagrams (S/N curve).

Generally, it can be stated that the very high frequency of the load cycles mostly results in mechanical effects. During the single cycles, there is insufficient time to generate corresponding corrosion reactions at the freshly formed metal surfaces. In that case, crack propagation is merely mechanically based without any visible corrosion effect at the surface.

In the case of low frequency, the effect of corrosion is predominantly due to the extended corrosive load. Here, the crack path is characterized by a typical corrosion effect. Contrary to mechanical fatigue cracking, typical features like streaking cannot be seen immediately. This becomes more complicated due to very frequent intergranular and transgranular hydrogen-assisted cracks.

6.2.6 Erosion and Cavitation Corrosion

The combination of corrosive fluids with high flow velocity can result in erosion corrosion [6.2]. Often, a different kind or no corrosion occurs in the same media in the stationary or slow flowing state. The surface of passivated materials is especially susceptible to erosion corrosion at high flow velocities due to the small thickness of the protective oxide layer (or the passive layer). If this layer is removed by erosion, material is exposed to aggressive media and is activated. In many water or steam-bearing facilities, erosion corrosion can appear if the medium has a high flow velocity and contains solid-state particles, which additionally load the metal surface due to their mechanical impact. However, the relative share of the mechanical and electrochemical parts of corrosion can be different. Hence, erosion corrosion ranges from pure erosion loads to pure corrosive loads. The appearance of erosion corrosion is typically flow-oriented and dependent on the ability of the material to generate a protective coating layer. For example, copper alloys generally form light and loose

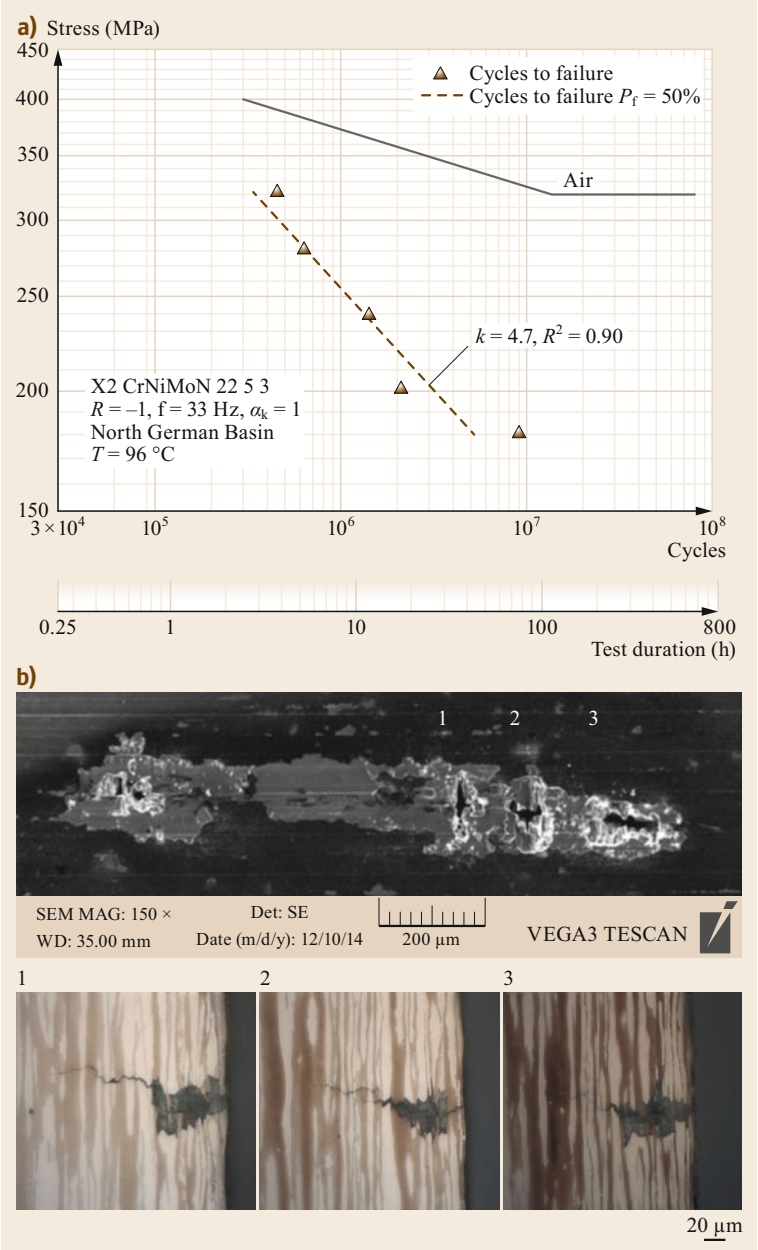

Fig. 6.22a,b CF exemplified by austenitic-ferritic duplex steel in 96 °C hot salt solution versus air. **(a)** Decrease of stress amplitudes in the case of CF, **(b)** pitting corrosion coupled with starting CF at the surface. (Reprinted from [6.15], with permission from Elsevier)

layers, which can be easily destroyed and removed. In practice, erosion corrosion is a well-known problem in heat exchangers [6.5].

Cavitation is the process of formation and collapse of steam and gas-filled bubbles in fluids, caused by a temporary decreased static pressure below the vapor pressure. This can be initiated by flow instabilities (flow cavitation) or waves of low pressure (oscillation cavitation). As a result of the implosion of the bubbles, the material surface can be locally destroyed. This prematurely damaged surface is indicated by increased reactivity. If corrosion superimposes the cavitation process, then it is called cavitation corrosion. Repeated bubble implosions in the same position prevent the material from renewing the protective covering layer, and the existent layer is destroyed followed by crater-like corrosion pits. In addition, the bubble implosions increase the local temperature, whereby the corrosion rate increases. Cavitation corrosion typically occurs in technical components, where the material surface has to

withstand a high relative movement within (corrosive) surrounding media, for example in centrifugal pumps, turbines, propellers, or stirring devices. To avoid cavitation corrosion, the geometry of the components should be optimized, media pressure increased, and the flow velocity decreased. From the material point of view, hardened materials or coatings can be used [6.5].

6.2.7 Fretting Corrosion

Fretting is a special type of erosion corrosion in gaseous media [6.2]. Basically, this process involves the coupled effect of an environmental (corrosive) medium and a tribological load in terms of friction. Vibrations are very often the main cause. Both corrosion and tribological loads result in wear. In this case, the material is in contact with another solid-state body via relative movement. These small movements, like vibrations or slipping, lead to the abrasion of oxide layers on the contact surfaces of frictional connections. Subsequently, the freshly formed metal surface can undergo accelerated anodic dissolution. The generation of metallic particles by wear is the primary cause for fretting. These particles react instantaneously with the surrounding medium. They are ground, sintered, chemically changed, or compacted further because of the simultaneous tribological load. During fretting, the formation of dimples can frequently be superimposed by additional oscillating mechanical loads so that subsequent corrosion fatigue occurs.

6.2.8 Microbiologically Induced Corrosion

Microbiologically induced corrosion (MIC) is a synonym for all types of corrosion that are initiated, intensified, or perpetuated by microbial activities [6.5, 16]. Microbiologically affected corrosion encompasses multiple partial reactions (Fig. 6.23) and is not fully understood still today. However, it can occur on almost all plant and building materials and estimates are that at least 20% of all corrosion damage is microbiologically influenced. Microorganisms that initiate this type of corrosion are a wide range of fungi, algae, and lichens. These can colonize on material surface in nearly all environments. So-called biofilms require liquid surrounding media, solid-state material, and microorganisms. Their formation can be divided into three stages:

1. Incubation: primary adhesion of the biofilm, which is mostly without effects for technical systems.
2. Irreversible absorption of macromolecules (polysaccharides, lipopolysaccharides, humic substances, proteins, and so on) and related growth of primary colonizers on the material surface.
3. Plateau-stage: the biofilm thickness depends on the growth rate of colonizers and is in biodynamic equilibrium.

Inside such biofilms, anaerobic conditions are generated with an increasing thickness of the biofilm due to the decreasing partial pressure of missing oxygen.

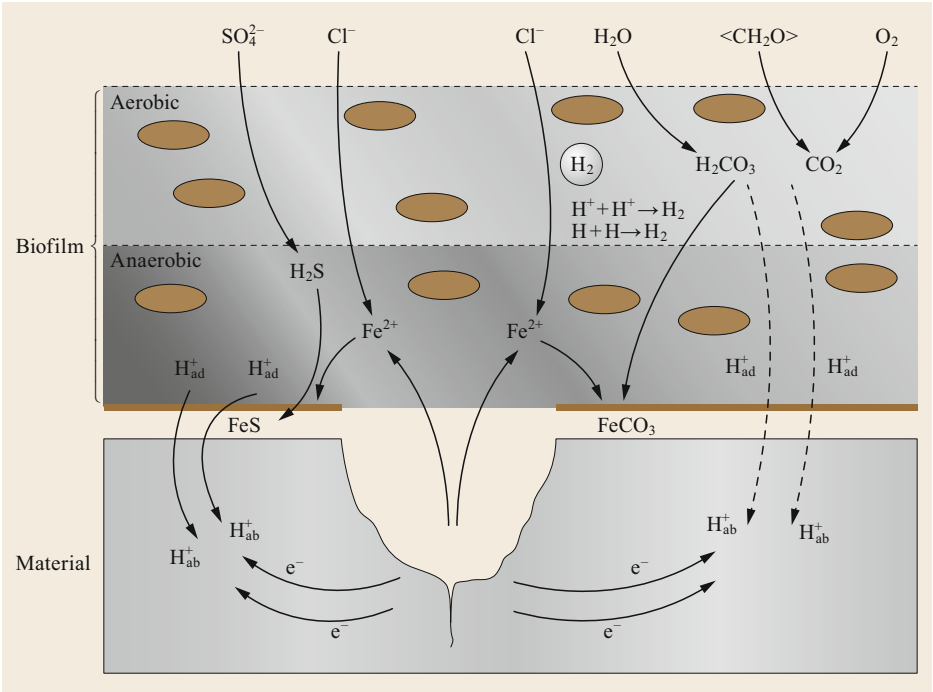

Fig. 6.23 Reactions of microbiologically affected corrosion, simplified in accordance with *Enning* and *Garrelfs* [6.16]

In the outer area, the organic substances are oxidized under aerobic conditions. They are then released into the surrounding media. In between, there is a layer of anaerobic bacteria that forms decomposition products in terms of water and organic acids via fermentation. Directly at the material surface (the inner area of the biofilm), anaerobic sulfate-reducing bacteria transform hydrogen, organic acids, and SO_4^{2-} ions to sulfides and water (Fig. 6.23).

Thus, amongst others, H_2S is produced, which acts as a promoter for hydrogen absorption in the material beneath the biofilm. In the case of a simultaneous mechanical load, hydrogen-assisted stress corrosion cracking can occur. Additional surface corrosion, as a result of firmly adhering biofilms, is pitting and crevice corrosion. Special attention is paid to microbiologically affected corrosion in the petrochemical branch of the offshore industry. In this industrial branch, H_2S is produced mostly as a result of subsoil oil or gas reservoirs being flushed with seawater to increase output. In that case, microorganisms are enriched in anaerobic conditions.

6.3 Chemical Corrosion and High-Temperature Corrosion

Chemical corrosion is characterized by the instantaneous reaction of the material and the corrosive environment. The resulting corrosion products determine any further reactions. As in the case of conventional corrosion, the generation of protective layers that impede the diffusion of elements and, hence, disable or delay further corrosion reactions is desired. In contrast to electrochemical corrosion, chemical corrosion implies that partial reactions occur at the same local position. The result of the corrosion can be determined by gravimetric or metallographic analysis.

If the instantaneous chemical reaction of a material occurs in the corrosive environment at elevated temperatures (mostly accompanied by elevated pressure) and in the absence of aqueous electrolytes, this process is called high-temperature corrosion. High-temperature levels create a reactive layer at the atmosphere–solid boundary layer. The adsorption and absorption of molecules from the gas phase at the material surface and the diffusion of absorbed molecules (or ions) through the reactive layer determine the chemical reaction kinetics, as well as the diffusion of elements from the bulk material to the surface. If the material is permanently dissolving or decomposing, catastrophic corrosion is existent.

6.3.1 High-Temperature Corrosion Without Mechanical Load

Different types of high-temperature corrosion exist (Fig. 6.24) and occur mostly in different combinations in technical utilization [6.18]. The reaction product formed at the material surface in a gaseous atmosphere is called scale. In general, this term is used for corrosion processes in oxidizing (oxygen-containing) or reducing (sulfur-containing) atmospheres. A special type

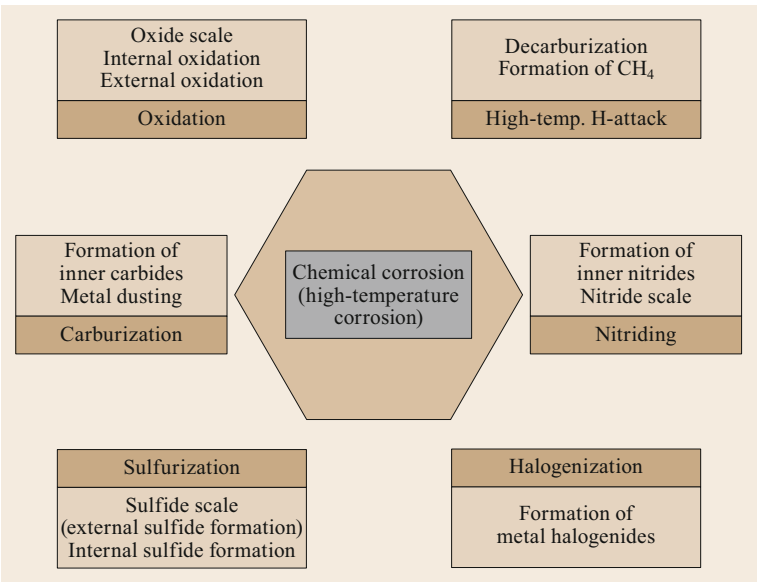

Fig. 6.24 Types of high-temperature corrosion

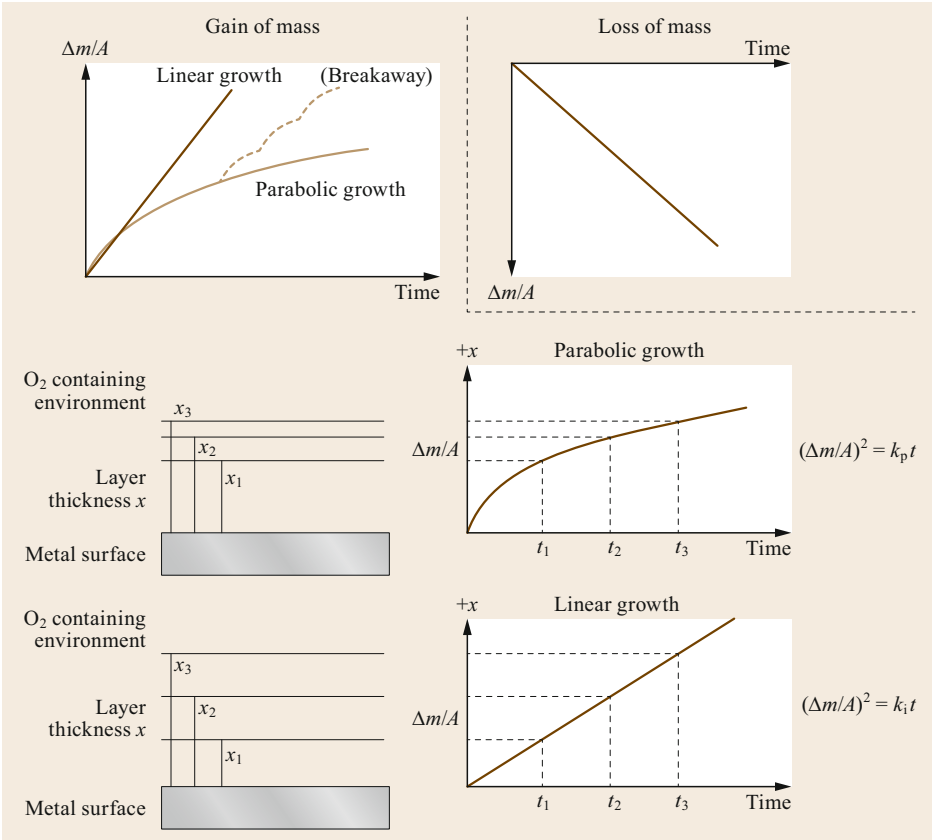

Fig. 6.25 Evolution of mass change during high-temperature corrosion: assumption of linear or parabolic scale growth and linear loss of mass (catastrophic oxidation, in accordance with *Schütze* [6.17])

of high-temperature corrosion is hot corrosion, which occurs with the participation of molten salts. Thus, sulfurization, nitriding, and oxidation (Fig. 6.24) are significantly accelerated. In a few technical processes, e.g., glass-making, molten salts can be directly present. However, in most technical processes, the corrosion promoting molten salts condense from the surrounding atmosphere on the hot component surface, e.g., in the case of combustion of fossil fuels (coal, petroleum, or natural gas). Hot corrosion is mostly more complicated to handle due to the nonprotective and porous nature of the scales generated. These scales cannot protect the material from decomposition in corrosive environments. Susceptible materials are, for instance, Ni- or Co-based alloys and high-alloyed ferritic steels.

A simplified assessment of the corrosion resistance of metals in gaseous atmospheres is the use of the Ellingham–Richardson diagrams. These diagrams show the stability of the scale formers versus the partial pressure of the corrosive gas. Thus, the corrosive reaction of the base material can be observed [6.19]. The reaction kinetics can be determined by the scale growth by gravimetric analysis due to the loss of mass, Δm. An increase in mass (scale growth) or loss in mass (flaking or evaporating of the corrosive scale) depends on the material, temperature, partial pressure, and dissociation kinetics of the gas at the corrosion scale and many more. The scale growth (e.g., in the case of oxidation) can be described by parabolic, linear or logarithmic law and is in all cases related to a certain material surface area A (Fig. 6.25). The proportionality constant k_p describes the corrosion resistance of different materials in the case of parabolic scale growth. This law represents the common case for most technical materials. The typical range of k_p for steels with 12–14% Cr content is about 10^{-8}–10^{-9} kg^2 m^{-4} s^{-1} (corrosion in air). However, the opposing effect by loss of mass is existent in the case of flaking of the oxide scales at very high temperatures or increased mass loss by evaporating reaction products (breakaway corrosion). This is also called catastrophic oxidation and is indicated by a linear loss of mass.

To avoid or reduce high-temperature corrosion protective scales must be generated (as in the case of electrochemical corrosion), for example, stable oxides like Cr_2O_3 or Al_2O_3. Alloys that form one or both mentioned

covering scales are called chromium or aluminum oxide formers. Al-oxide forming materials can be used up to 1300 °C. The temperature limit of the technical usage of a material is also dependent on a simultaneous mechanical load. Dense oxide scales also protect against carburization, nitriding, and sulfurization.

Oxidation

Pure high-temperature corrosion in terms of oxidation is the formation of scales (for example, during milling) on steel surfaces. The surface of Fe-rich alloys reacts with scale formation at 570 °C in oxygen-rich gases. The sequence of the scales is Fe-FeO-Fe_3O_4-Fe_2O_3-O_2. The wüstite (FeO) formed covers nearly 90%, magnetite (Fe_3O_4) has a share of 7–10%, and hematite (Fe_2O_3) only has a share of 1–3%. In the case of slow cooling (below 570 °C), wüstite decomposes to pure Fe and magnetite. Due to the different density and decreased ductility of magnetite, the scales generated are brittle and contain microcracks. By rapid cooling, for example, in the case of hot rolling of sheet metal, this transformation can be suppressed, and the scale remains on the material surface. In that connection, the oxidation rate of steels can be reduced by alloying of Cr, Al, or Si. Typically, low-alloyed heat-resistant steels are sufficiently resistant to scale formation.

Furthermore, special scale-resistant high-alloyed steels are used as commercial alloys. These steels can be pure ferritic or martensitic, or may have a ferritic-martensitic microstructure. They are typically used in steam boilers and tubes or in industrial furnaces. Austenitic scale-resistant steels are mostly used in flue-gas treatment facilities or in components of the chemical or petrochemical industries [6.14]. Depending on the Al, Si and Cr content, the scale resistance is sufficient up to 800 °C (for example, X10CrAl7) or 1200 °C (X10CrAl24 and X15CrNiSi25-20). Alternatively, low-alloyed steels can be protected by coatings during steel-making. This is exemplified by the Al-Si or Al-Zn coatings used in the automotive industry. These are used to protect 22MnB5 steel during press-hardening (austenitization and quenching during drop forging) against scale (or oxide scale) formation. Otherwise, these scales would later complicate painting of the car body parts [6.20].

Carburization (Metal Dusting)

A representative example of carburization of materials is the carbide formation in corrosion-resistant Cr-Ni alloys in a carbon-dispensing gas atmosphere. Subsequently, carbides are also formed in the bulk material. The inner carbide formation occurs from 800 to 1200 °C (formation of Cr, Ni, or Fe-rich carbides of type $M_{23}C_6$, which decompose to type M_7C_3). This kind of corrosion reaction causes deterioration of the mechanical properties (ductility and toughness at low temperatures), the thermal properties (conductivity), as well as the oxidation resistance. Especially the weldability of a material can be influenced (an increase of carbon equivalent).

A catastrophic carburization can occur in an intermediate temperature range (400 to 800 °C) and is called metal dusting [6.21]. Nonetheless, this temperature range can vary (350 to 900 °C) depending on the material and its service conditions. Metal dusting is characterized by the decomposition of the material into a dust of pure metal and carbon. In contrast to conventional carburization, metal dusting demands a carbon-supersaturated gaseous atmosphere. The process of metal dusting starts with fast supersaturation of the material with carbon of both surface areas and grain boundaries. This is followed by the formation of unstable carbides like Me_3C (Me = Fe, Ni) and the final decomposition into the metal and pure carbon.

$$Me_3C \rightarrow 3\,Me + C \tag{6.19}$$

The fine metal particles generated additionally accelerate the carbon absorption due to the catalytic effect of the enlarged surface of particles compared to the solid-state material. The result is voluminous segregation of carbon at the metal surface. In the case of insufficient adherence of the particles (for example, by removal due to flowing gases), indentations that are similar to electrochemical pits occur.

High-Temperature Hydrogen Attacks

In contrast to carburization, steel components in the chemical or petrochemical industries (for example, synthesis gas production, ammonia, and so on) can suffer from decarburization. This loss of carbon is mostly a result of pressurized hydrogen. This phenomenon is called a high-temperature hydrogen attack (HTHA). Typically, service conditions of 200 °C and 200 bar pressure are necessary for atomic hydrogen to be generated by thermal dissociation from the surrounding corrosive environment (pressurized pure molecular hydrogen or synthesis gases). The degradation of the component itself occurs due to the adsorption of atomic hydrogen into the material. Subsequently, the hydrogen reduces the cementite (Fe_3C) of the steel by removing the carbon and further forms methane (CH_4) and pure iron.

$$4\,H_{(Fe)} + Fe_3C \rightarrow CH_4 + 3\,Fe \tag{6.20}$$

Due to its size, the methane molecule cannot diffuse and is trapped in the microstructure. The result is an ag-

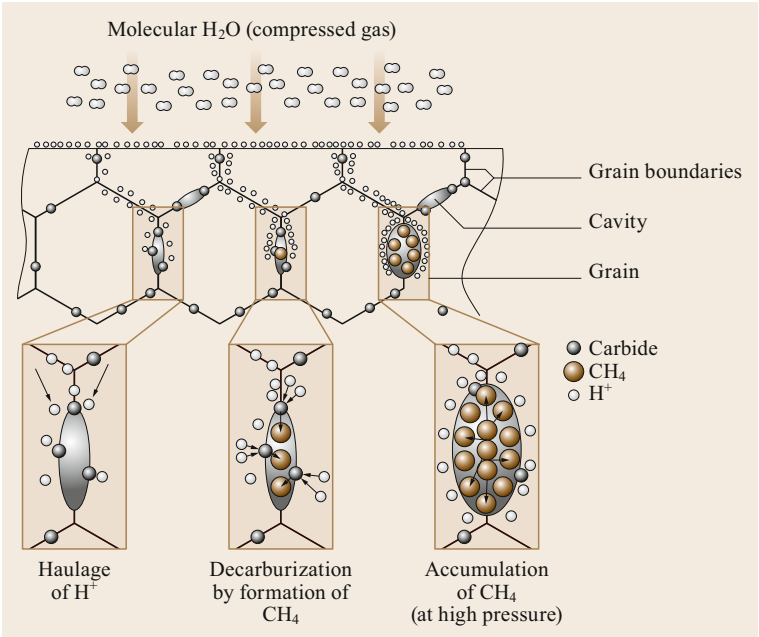

Fig. 6.26 HTHA in low-alloyed steels

glomeration of methane molecules under high pressure in the material. In addition to the detrimental formation of gas bubbles in the material there is the degradation of the mechanical properties of the steel by dissolution of the carbides (reduction of precipitation strengthening effect). In the case of already present microcracks at inclusions (preferably at grain boundaries), HTHA results in brittle fractures, which perhaps result in unexpected component failure. The mechanism of degradation by HTHA is exemplified in Fig. 6.26. The most susceptible steels are unalloyed carbon steels, Cr-Mo alloy steels show a much higher HTHA resistance. However, this resistance is also strongly related to the service conditions of the material (pressure, temperature, corrosive environment).

To avoid decarburization service the pressure and temperature of the components should be strictly monitored. The maximum boundaries for service conditions (pressurized hydrogen) can be found in the latest version of the Nelson diagram, for example, in API RP (American Petroleum Institute Recommended Practice) 941 (2016). The chemical and petrochemical industries operate components under high pressure and elevated temperatures for the processing of pure hydrogen or ammonia. Nowadays, 2.25% Cr-1% Mo-0.25% V-alloy steels are state-of-the-art and have replaced the conventional Cr-Mo steels. The alloying of V results in very small and very finely dispersed carbides (VC, V_4C, V_4C_3) in the microstructure. These precipitates have two positive effects: (1) they improve the necessary creep resistance of the material at higher temperatures, and (2) stabilize the carbides due to the higher affinity of V to carbon compared to hydrogen. Metallurgically optimized steels may also contain carbide stabilizers like Nb or Ti. The result is a higher strength of the material accompanied by an increased possible operational temperature and pressure.

Sulfurization

The ingress of sulfur into the microstructure leads to soft or brittle metal sulfides (Me_xS_2, Me_xS_3, Me_xS_4), or metal sulfates (Me_xSO_4) on the steel surface. These can also be molten at elevated temperatures. Typically, they are formed in combustion chambers as a part of the flue gas as a result of combustion of S-rich fuels (such as lignite coal or crude oil). Nonetheless, sulfurization occurs in waste incineration plants or biogas plants due to the complex composition of the flue-gas mixture.

Corrosion by sulfurization is called catastrophic in the case of the formation of eutectic phases with a low melting point, such as NiS ($T_m = 995\,°C$) or Ni/Ni_3S_2 ($T_m = 637\,°C$). For example, sulfur forms together with alkaline metals (Na, K), chloride, and oxygen aggressive molten salts. Additional reactions with Ni, Co, or Fe result in complex molten salts with a very low melting point compared to the surrounding atmosphere, e.g., $Na_3Fe(SO_4)_3$ ($T_m = 620\,°C$), $Na_3Fe(SO_4)_3/K_3Fe(SO_4)_3$ ($T_m = 555\,°C$), $CoSO_4$ ($T_m = 565\,°C$), and $NiSO_4$ ($T_m = 671\,°C$). These molten salts can result in very fast corrosion that perhaps finally leads to component failure. In contrast

to carburization, sulfurization is more dangerous. The reason is the increased rate of material degradation. In oxygen-rich atmospheres, a high content of SO_2 is the reason for sulfurization of the material and its further accelerated corrosion. As mentioned, the chemical corrosion of a material is mostly the result of a complex interaction of several corrosion mechanisms like oxidation and sulfurization.

Nitriding

Nitriding is a side effect of the service of components in N_2-containing atmospheres at high temperatures. Examples are materials operated in the flue-gas environment or for ammonia synthesis (Haber–Bosch process). Nitrogen is adsorbed on the material surface and forms corrosion scales. For example, at 300 °C high-alloyed Cr steels already show the formation of covering scales that consist of chromium nitrides. The scales are very brittle and have low thermal expansion coefficients. These are not stable and flake off each time in the case of mechanical or thermal loads. Hence, they are permanently formed and cause a high amount of removed parent material.

Compared to the formation of nitride covering scales, inner nitriding is more common. In this case, nitrogen diffuses into the bulk material and causes microstructural changes. In general, phases are formed that are hard and brittle (Me_2N or Me_3N) but increase the hardness of the material. This effect is intentionally used in the case of surface hardening to increase the wear resistance of a component. However, this technique is limited, e.g., in the case of high-Cr steels. In this case, Cr could diffuse from the bulk material to the surface in the nitrided scale. The hardened surface would be accompanied by decreased corrosion resistance.

Halogenation

Besides oxygen, carbon, sulfur, and nitrogen a few more dry corrosive environments like halogens can result in high-temperature corrosion. The most important halides are Cl, F, or Br. A halogen-containing atmosphere is the basis for very aggressive hydrogen halides (HF, HCl, HBr), and their acids are responsible for very high corrosion rates. For example, HCl can react with oxygen to form pure chlorine accompanied by water generation. This purified Cl can react with Cr-oxides (for example from the passive layer of corrosion-resistant Cr-Ni steels). This finally results in the formation of metal chlorides, for example (in accordance to [6.21]).

$$2\,Cr_2O_3 + 6\,Cl_2 \rightarrow 4\,CrCl_3 + 3\,O_2 \qquad (6.21)$$

These chlorides influence the protective oxide scale of the stainless steel. In addition, the metal chlorides show high vapor pressure at higher temperatures. This results in instantaneous evaporation of the unprotected material surface accompanied by highly increased corrosion rates. This effect should be considered in waste incineration plants or biogas plants due to the complex composition of the flue gas. Waste products may contain halogens. Sources for chlorine can be polymers like PVC and fluorine maybe from halogenated hydrocarbons like PTFE (in general known as *teflon*). Nonetheless, halogenation is intentionally used in coating processes like CVD (chemical vapor deposition) to deposit Cr, Al, or Si.

6.3.2 High-Temperature Corrosion with Superimposed Mechanical Loads

High-temperature corrosion as well as an additional superimposed mechanical load have a synergistic effect: a reduced lifetime of the component. On the one hand, it should be considered that a cross section can already be damaged due to an oxidation-related decrease of the material thickness. In addition, high-temperature corrosion can change the chemical composition and microstructure of the material, even in deeper sections. Thus, the tensile and ductile properties may vary significantly from the as-delivered condition. On the other hand, the protective oxide scales mostly have a decreased ductility compared to the parent material. Hence, these scales can crack and flake off very easily because of mechanical tensile loads. For example, due to unwanted nitriding, scales of chromium nitrides are very brittle. In addition, thermally induced stresses and distortions or temperature gradients between material and the covering scale (accompanied by internal growth stresses in the scale) can lead to early failure of the covering scale. All these facts increase the corrosion rates and accelerate the material degradation.

A practical example for high-temperature corrosion with a superimposed mechanical load is the increased number of shutdowns in fossil-fired power plants (due to the increasing peak power of renewable green energy—wind, water, solar—that has to be compensated in the power grid). The power-on and shutdown cycles causes high-temperature gradients and mechanical stresses in the steam tubes accompanied by a weakening of the inner magnetite layer. Additional creep load and alternating mechanical loads (short-term tensile/compression) always result in accelerated crack initiation and propagation [6.18]. Based on these facts, the monitoring of high-temperature loaded components is necessary.

6.4 Corrosion Testing

For corrosion resistance testing of a component, it is necessary to investigate the material behavior in a way that considers the design aspects of the component as well as realistic mechanical (mostly multiaxle) loads. Hence, no uniform corrosion test is available. To have realistic conditions, a corrosion test must be close to the loads that occur. To keep the time and cost frame within the necessities, the aims of the corrosion test must be defined in advance. These can be, for example:

- Determination of the best material (fitness for purpose)
- Determination of the service duration/lifetime of the technical product
- Investigation of new alloys or technical processes
- Development of new materials with increased corrosion resistance
- Investigation of the effect of different corrosive environments
- Determination of the most economic corrosion protection system
- Research studies to reveal corrosion mechanisms.

To achieve these aims, and in terms of product-oriented testing, several combinations of corrosion tests exist. These can be categorized with respect to their rate of abstraction compared to the real system (Fig. 6.27):

- Online monitoring and in-field experiments at real sites
- Full-scale tests with realistic modeling of the entire corrosion system for identification of type, location, and time of corrosion damage
- Product-oriented testing of component-like specimens with prior identification of relevant loads considering their value, location, and direction
- Small-scale tests with standardized mechanical loads
- Basic experiments to identify and examine corrosion mechanisms and time-dependent appearance of corrosion under laboratory conditions.

Nowadays, modern corrosion tests are accompanied by modeling and simulation techniques within the entire range from laboratory specimens to full-scale specimens. The choice of corrosion tests is very important and tailored for a defined aim and corrosion system. Corrosion testing demands highly skilled and trained staff and should be conducted by designated corrosion experts.

Thora E. Falkenreck studied industrial engineering at Kassel University (Germany) within the scope of a dual study scholarship. Afterwards, she was at the Bundesanstalt für Materialforschung und -prüfung (BAM) in Berlin to accomplish her doctoral degree in mechanical engineering. The main topic of her research is arc welding of high-strength steels at high strain rates. Since 2018, she has been applying her knowledge at Rheinmetall Landsysteme GmbH (Kassel).

7. Nondestructive Inspection (NDI)

Gerhard Mook, Islam Shyha

This chapter discusses various nondestructive inspection (NDI) methods. Nondestructive inspection includes all methods to characterize a material without indenting, extracting samples, reducing its service capabilities or destroying it. The following chapter describes principles of NDI. Subsequently, NDI methods will be classified into seven categories namely, acoustic, potential drop, magnetic, electromagnetic, thermography, optical, and radiation methods. Each category may involve several methods where all will be discussed. For each method presented in this chapter, principles, setup and probes, nondestructive testing (NDT), nondestructive evaluation (NDE) and current scope are discussed. Last but not least, the chapter presents NDI methods that rely on integrated sensors in the inspected structure itself, known as structural health monitoring (SHM).

NDI includes defect detection and quantification, called nondestructive testing (NDT), and the assessment of material properties, called nondestructive evaluation (NDE). NDI is an integral part of the design, manufacturing, maintenance, and recycling of components.

More components are now designed following the rule of fitness-for-service. This concept assumes the presence of a maximum undetectable-by-NDI defect. The designer has to make sure that this defect does not become critical during a well-defined service period. To maintain the safety coefficient at a predefined level, the component will be larger or heavier than it should be without the defect. With the increasing capabilities of NDI, the scale of this maximum undetectable defect is reduced, allowing the designer to reduce component weight without lowering the safety coefficient.

In manufacturing, NDI enables the inspection of the whole output, while destructive methods rely on a more or less satisfactory number of samples, which are more or less representative for the current production. Besides questions of its suitability, the speed of inspection is the deciding criterion for NDI application.

In maintenance, there is no alternative to NDI. According to considerations of fracture mechanics, the concept of damage tolerance requires the detection and characterization of all defects starting from

K.-H. Grote, H. Hefazi (Eds.), *Springer Handbook of Mechanical Engineering*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-47035-7_7

an individually defined level. Depending on the findings of NDI, the next service period may be shorter or longer. The typical requirement for inspection is a high probability of defect detection accompanied by a tolerable rate of false indications. Modern maintenance concepts include the online monitoring of components or the structural health of the entire component.

All industrial sectors use NDI, the best known of which is the manufacturing of flying structures. However, pipelines, heat exchangers, vessels, bridges, and car components are also inspected nondestructively. This chapter focuses on the most important and widely used methods in mechanical engineering but also touches on the promising field of structural health monitoring (SHM).

7.1 Principles of Nondestructive Inspection

The basic principles of NDI are shown in Fig. 7.1. The goal is either to detect relevant defects or to estimate quality parameters such as hardness or the thickness of the heat treatment or coating layers. This goal cannot easily be achieved using nondestructive methods. The only possible way is to measure physical properties such as thermal or electric conductivity, sound propagation or magnetic behavior. Both quality parameters and physical properties are defined by the material's structure. The challenge is to find a correlation between them. Research is needed to fully understand the relationship between the quality parameters to be inspected and the physical properties which can be recorded nondestructively.

A wide variety of NDI sensors and transducers are able to record physical properties locally or integrally. The relevant signals are processed in an instrument and displayed in different forms. Some physical properties may be recorded by matrix sensors, immediately providing an image, while other properties have to be measured by point-like sensors that are hand-guided by an operator or mechanically guided by a scanner.

The result will be either an image, a vector or a scalar value. In most applications a threshold is used to separate acceptable from nonacceptable quality. For this purpose, differential measurements are most suitable. The current measurement is compared with the measurement of a master piece or of a neighboring area of the same object. If the difference is below the threshold, the object passes; otherwise it fails. If quantitative assessment is required, calibration curves are typically considered based on well-known samples with a gradual variation of the parameter to be evaluated. Here, the increasing effectiveness of numerical modeling provides valuable help. In some cases of NDI, absolute values of a physical property are expected, which can be provided using dedicated instruments.

How reliable is NDI? To date no method is known to detect defects with a probability of 100%. On the other hand, all methods may produce false indications, such as indicating a defect in a material/component when none is actually present. All NDI applications have to be optimized regarding both probabilities.

The following sections present a selection of approved methods and show directions for future development. Comprehensive fundamentals of NDI are presented elsewhere [7.1–5]. Further references on individual methods will provide detailed information, but it is recommended that users should seek advice from experienced specialists. International standards and rules of application are also described for all methods.

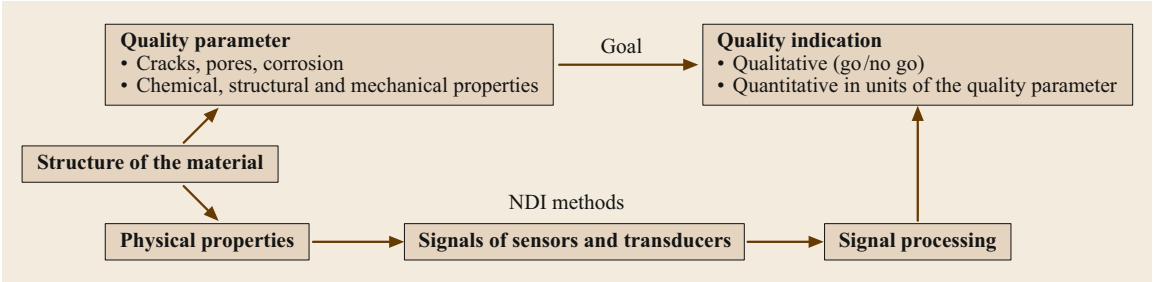

Fig. 7.1 Principles of nondestructive inspection

7.2 Acoustic Methods

Acoustic methods rely on the propagation of sound waves though the material. These waves may be excited by external or internal sources. In solids, longitudinal (compressional) and transverse (shear) waves may spread and are partially reflected and their modes converted at boundaries. Additional wave modes may exist at the material's surface and in thin plates (Rayleigh and Lamb waves). While propagating through the material, the waves are attenuated depending on the material's properties and the wave's frequency.

7.2.1 Ultrasonic Methods

Principles

The basic idea is to transmit a short elastomechanical wave packet into the material. If its wavelength is short enough, it will interact with defects starting from ≈ 0.5 mm in diameter. Therefore, exiting frequencies from 0.5 to 15 MHz (ultrasonic frequencies) are required. Depending on the material's attenuation, the wave packet can travel over long distances through the material. In the transmission technique, the pulse is received at the opposite side of the object whereas in the pulse-echo technique the reflected waves are recorded at the same side as where they are fed. Nearly all metals, ceramics, concrete, low-damping plastics and composites may be inspected using ultrasonic methods [7.6, 7].

Probes (Transducers)

For perpendicular wave propagation, perpendicular-incidence probes are attached to the surface. For non-perpendicular wave propagation angle-beam probes are required which commonly generate longitudinal waves diffracted into a longitudinal and a transverse wave at different angles at the material's surface. The acoustic waves must be coupled to the material using a couplant such as water or grease. Figure 7.2 shows a perpendicular-incidence probe consisting of a piezoelectric ceramic disc emitting and receiving the ultrasonic waves. A resin damping block absorbs the waves emitted in the reverse direction. The ultrasonic waves are passed through a protecting layer and the couplant into the material. After entering the material, the sound field is characterized by local maxima and minima due to the interference of waves emitted from different parts of the piezoelectric disc. This initial area of the sound field is called the near field, where no inspection is possible. The near field becomes taller and ends in a final maximum sound pressure. From this point onwards, the sound field diverges and the sound pressure gradually decreases. This area is best suited for NDI.

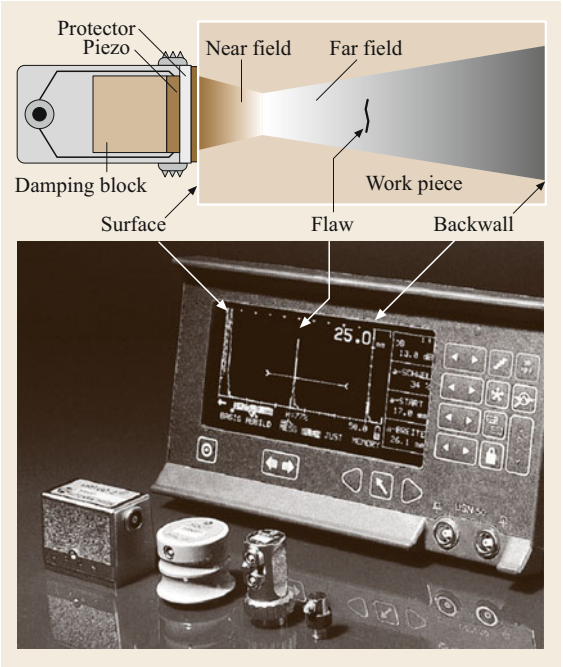

Fig. 7.2 Principles of ultrasonic inspection, instrument, transducers, and signal representation

NDT

Defects may be detected if they interact with the ultrasonic waves. The best detection performance is available for defects oriented perpendicularly to the sound field axis. Both transmission and pulse-echo techniques are suitable. With decreasing wavelength (increasing frequency) smaller defects may be detected, but reflections from grain boundaries are also superimposed onto the signal. In Fig. 7.2, the screen of an ultrasonic instrument displays the A-scan formed by the rectified and amplified echo sequence. At the entrance, a significant part of the sound energy is directly reflected back to the probe, producing the large entrance echo. At the back wall nearly all the sound energy is reflected. A properly oriented planar or volumetric defect produces an intermediate echo between the entrance and back wall echo. This echo may be analyzed to evaluate the defect's position and dimensions. In weld inspection, angle beam probes are generally used due to the nonsmooth surface of the weld and the orientation of possible defects.

NDE

Sound velocity and attenuation carry information about the structural and geometrical parameters of the material. The time-of-flight method is used in measuring the

dynamic Young's modulus and to evaluate the structure of cast iron with spherical graphite, stress and strain assessment in steel, and the thickness of metal or nonmetal walls. Grain boundary reflections are used to estimate grain size or surface hardening depth. Sound attenuation measurement is also applied for structural characterization such as grain sizing and deformation-induced alterations.

Current Scope

Instead of single transducers, one- or two-dimensional arrays are used to incline and shape the ultrasonic beam. Electronic movement enables fast imaging techniques. To avoid liquid couplants, current research focuses on air-coupled techniques and thermally induced sound waves and interferometric readout.

7.2.2 Resonance Methods

Principles

The object is excited by a mechanical pulse or a continuous wave in a defined audible or ultrasonic range. It starts vibrating on its eigenmodes and the eigenfrequencies are recorded. The signal is analyzed in the time and frequency domains, comparing the signals to those of one or more master pieces with well-known properties. Nearly all metals, ceramics, plastics, and composites, and often the adhesive bonding between them, may be inspected according to the *go/no go* principle.

Setup and Probes

The object is positioned on a low-damping fixture and is excited by defined mechanical pulses using impact hammers, piezoactuators or electromechanical shakers. In the low-frequency range the acoustic response

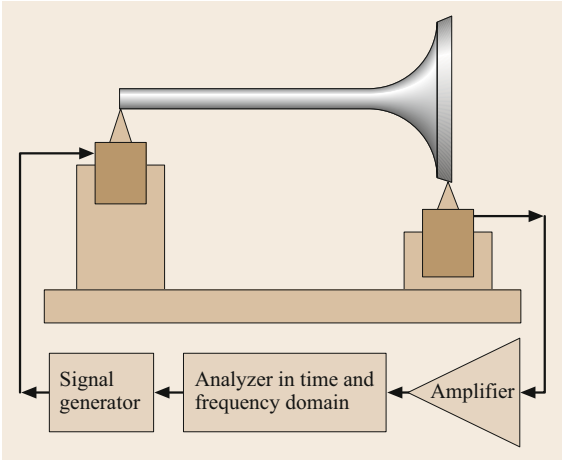

Fig. 7.3 Schematic view of valve inspection using resonance method (after [7.8])

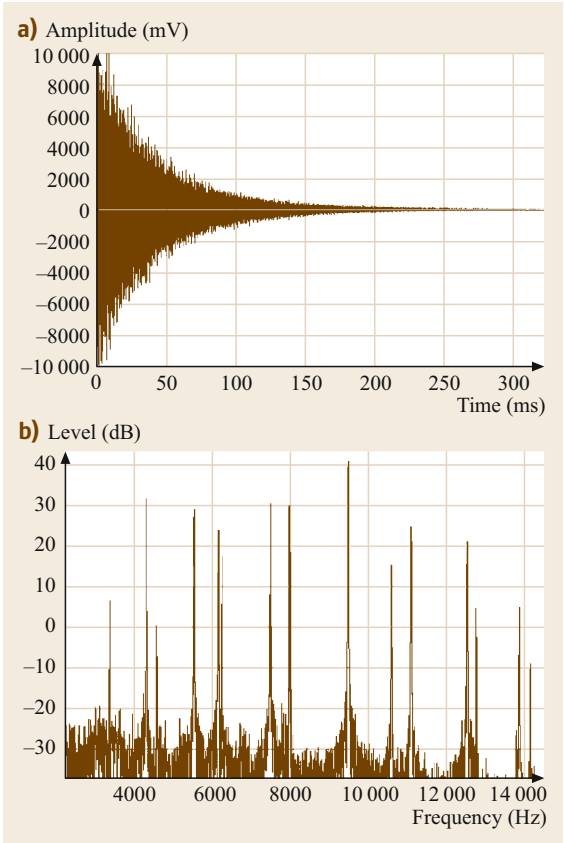

Fig. 7.4a,b Resonance analysis of valve: **(a)** signal in the time domain, **(b)** signal in the frequency domain (after [7.9])

can be heard or is picked up by microphones via air coupling. At higher frequencies and lower amplitudes piezoelectric sensors are attached to the object or optical interferometers record the oscillation at one or more positions. Figure 7.3 shows the setup for valve inspection. Figure 7.4 presents the signals in the time and frequency domains.

NDT

Complex-shaped objects such as gears and cast housings are inspected for missing components, imperfect shape, cracks, and cavities. The frequency content of the response signal is usually analyzed. In a first step, a representative amount of sound and flawed objects are analyzed in a broad frequency band. Comparing the response spectra, the most sensitive narrow bands are selected for defect detection.

NDE

The resonance method allows the estimation of structural damping, the comparison of elastic properties

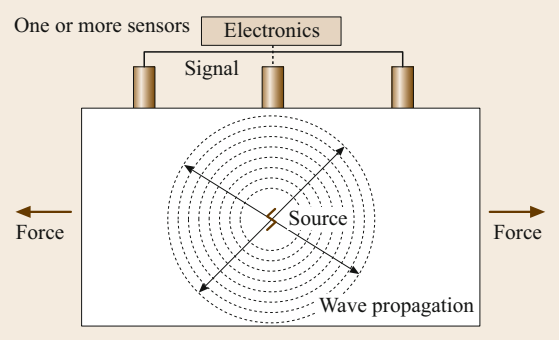

Fig. 7.5 Acoustic emission generated by a discontinuously growing crack

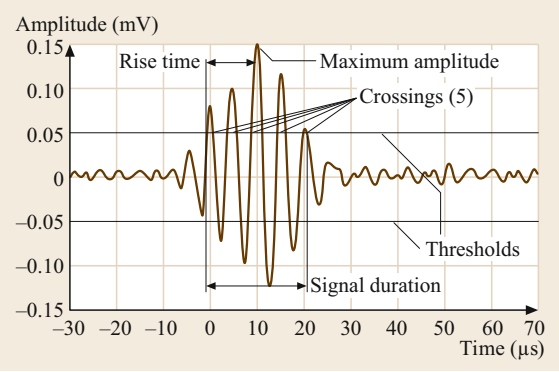

Fig. 7.6 Burst signal recorded by attached sensors

between identically shaped samples, and even the measurement of the dynamic Young's modulus with simply shaped specimens.

Current Scope

With increasing sensitivity, smaller defects become detectable. Extensive signal processing allows the suppression of disturbing signals from the environment.

7.2.3 Acoustic Emission Analysis

Principles

When an object is loaded, defects grow and discontinuously radiate elastic wave bursts (Figs. 7.5 and 7.6). These bursts are picked up and analyzed according to their spectral content, signal energy, and other specific parameters. Defect location becomes possible using time-of-flight differences to different sensors [7.10]. For leakage detection, the continuous acoustic radiation arising at the leak point is recorded. For leakage location, signals from two or more separated sensors are correlated to determine the time-of-flight difference.

Setup and Probes

For loading, the object may be heated or stressed by different means. Piezoelectric probes with internal or closely attached external preamplifiers pick up the emission. More than one sensor is usually required to cover the whole object or to locate defects.

NDT

Growing cracks, hydrogen embrittlement, stress corrosion, and creep can generate acoustic emissions. The advantage of analyzing these is that they enable information about the whole object to be gathered at the same time. Inspection is commonly performed before running the object and during inspection breaks. Generally, acoustic emissions may be recorded online, thus enabling structural health monitoring (see Sect. 7.9). No information about defect dimensions is available.

Current Scope

With increasing knowledge of signal generation, signal conversion, and nonresonant sensors, more detailed information can be obtained by characterizing the source of radiation, thus making acoustic emission analysis more reliable.

7.3 Potential Drop Method

7.3.1 Principles

Once found, a surface crack's depth should often be estimated. For this, an electric current is passed perpendicularly across the crack. The current will be deflected by the crack depending on its depth and length [7.11]. Two electrodes are placed in contact on both sides of the crack to measure the potential drop. Assuming that the crack is much longer than its depth, the voltage primarily depends on the crack depth. Figure 7.7 shows the reason for increasing potential drop with crack depth.

7.3.2 Probes

Modern probes combine current supply and potential drop electrodes in one probe. Figure 7.8 presents such a four-point probe. The outer electrodes feed the current and the inner ones measure the voltage. For the online

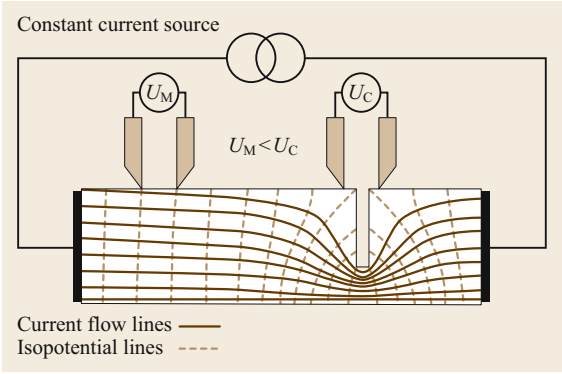

Fig. 7.7 Potential drop measurement of crack depth

observation of crack growth, electrodes may be permanently fixed to the object.

7.3.3 NDT

For crack depth assessment in ferrous steels, alternating current is advantageous due to the skin effect. This effect causes a current concentration at the near-surface regions while direct current spreads out at much deeper levels. That is why the crack's influence on lengthening the current path is more pronounced with alternating than with direct current. After careful calibration, the crack depth can be estimated with an accuracy of some tenths of a millimeter, taking into account the fact that the first electric bridge between the crack faces defines the measured crack depth. To estimate crack inclination, an additional electrode fixed at a greater distance from the crack is necessary.

Fig. 7.8 Potential probes able to measure crack depth and inclination

7.3.4 NDE

Potential drop measurement can be used to measure the conductivity of metals. The advantage over the eddy-current method (Sect. 7.5) is its suitability for ferrous steels, while eddy-current conductivity measurement may only be applied with nonferromagnetic materials. The disadvantage is the unavoidable direct contact with the metal, requiring at least local stripping of paint and corrosion products.

7.3.5 Current Scope

Calibration curves of most common materials are stored in the instrument. Combined inductive feed and contact gauging is a subject of current research.

7.4 Magnetic Methods

Magnetic methods use the ferromagnetism of ferritic steels. A magnetic flux passing through the material orients the magnetic domains of the material, thus increasing the flux density. This orientation process is nonlinear and follows a hysteresis loop. When all domains are oriented according to the exciting field, the material is magnetically saturated. For NDI, a number of physical properties may be used such as saturation induction, remanence, coercive force, and magnetic permeability [7.12].

7.4.1 Stray Flux and Magnetic Particle Inspection

Principles

If the magnetic flux passing through the ferromagnetic material faces a boundary to a less permeable area such as air in a crack, it is refracted into this area nearly perpendicularly to the boundary. Figure 7.9 details this situation where a part of the flux spreads over the boundaries of the workpiece. This stray or leakage flux is much wider than the crack. The remaining flux lines pass below the crack or across it. They are not accessible for NDI. The estimation of crack depth is not possible.

Setup and Probes

The magnetic flux must be oriented perpendicularly to the crack. This flux may be excited, whether by permanent magnets, electric current or electromagnetic coils. For stationary equipment, combined electric and electromagnetic excitation is preferred to produce a circular magnetic field. The objects are placed in the gap of a yoke that carries the magnetic flux as well as the electric current. Mobile excitation is possible us-

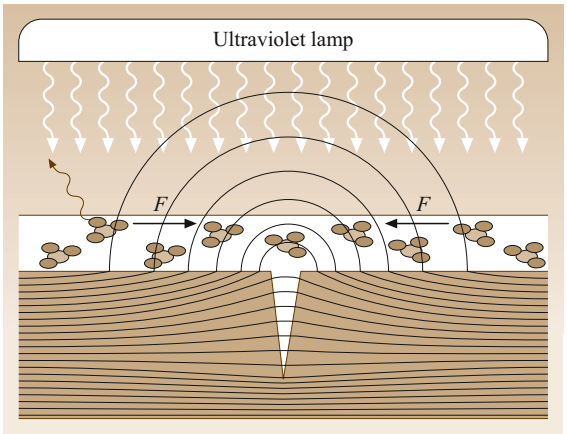

Fig. 7.9 Magnetic stray flux generates the force F attracting the magnetic particles

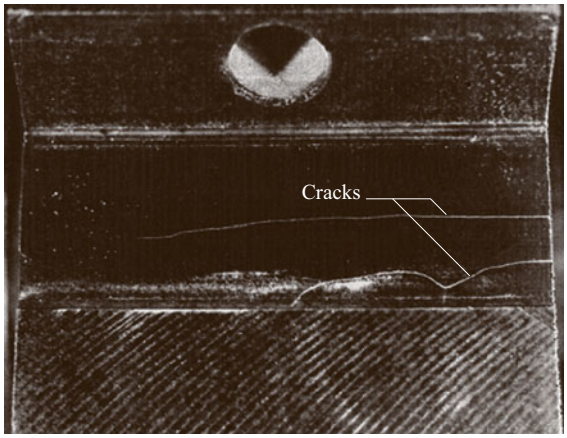

Fig. 7.10 Magnetic particle indication of cracks in a switch shaft

ing electromagnetic hand yokes and current electrodes. The stray flux can be detected by magnetic sensors such as flux gates, magnetoresistors, Hall sensors or moving coils, or even visualized according to magnetic particles (magnetic particle inspection, MPI). After inspection, the object has to be demagnetized.

NDT by Flux Sensors

In automatic inspection lines, objects such as pipes, rods or sheets are moved through a magnetizing yoke. Between the poles, sensors or sensor arrays are guided over the surface to detect and quantify the stray flux.

NDT by MPI

A suspension of high-permeability fluorescent powder in a low-viscosity carrier liquid is flushed over the surface. The magnetic particles are attracted by the stray flux, dragging the fluorescent particles with them. In a darkroom under ultraviolet illumination, these particles become visible, indicating the crack (Fig. 7.10) [7.13]. For documentation, photographs can be taken. In difficult conditions such as underwater inspection, the suspension is contained in a double-wall package. After exposing the package to the stray flux, the suspension can be cured by a second component to fix the particles at their positions and to analyze the image later.

Current Scope

To increase the reliability of MPI, attempts are being made to record MPI images using video cameras and to process the image automatically. Instead of magnetic particles, magneto-optical flux sensors are being investigated in order to enable the direct visualization of stray flux.

7.4.2 Flux Method

Principles

The object becomes a part of a magnetic circuit. The flux in this circuit is generated by a permanent magnet or an electromagnet. The measured flux magnitude depends on the object's cross-section and its magnetic permeability.

Probes

The flux in the circuit is measured directly by flux gates, magnetoresistors, Hall sensors or mechanical forces caused by the flux.

NDT

To detect and quantify corrosion damage that reduces the cross-section of ferritic steel components, magnetic yokes are guided over the surface. Assuming that the permeability of the material is constant, the flux only depends on the cross-section of the object. To locate corrosion, the flux magnitude should be mapped.

NDE

Under the assumption of constant permeability, the wall thickness or cross-section of ferritic steel components such as sheets, pipes or cables may be assessed. The measurement of magnetic permeability becomes possible with components of sufficient thickness and lateral dimensions starting from a few square centimeters. The sensors pick up the degree of flux deflection caused by the ferromagnetic object. The same principles may be used to measure the thickness of nonferromagnetic walls. An additional ferromagnetic body (usually a steel ball) placed on the back side deflects the magnetic field [7.14].

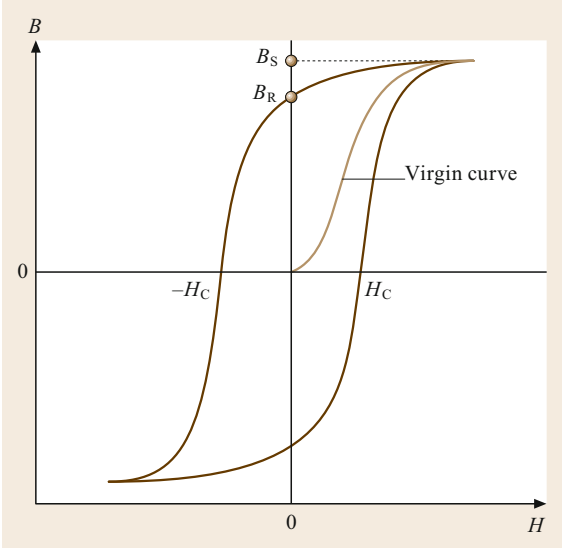

Fig. 7.11 Ferromagnetic hysteresis loop. B_S – saturation induction, B_R – remanent induction remaining on the part after removing the exciting magnetic field H, H_C – coercivity

Current Scope

For the assessment of more distant ferromagnetic objects, high-sensitivity superconducting quantum interference devices (SQUIDs) are used.

7.4.3 Residual-Field Method

Principles

The ferromagnetic object or a part of it is firstly magnetized by a strong direct field as close as possible to its saturation. In the second step, the residual field (Fig. 7.11, remanent induction, remanence) is measured, carrying information about the presence of the object, its microstructure, dimensions, and orientation.

Setup and Probes

The object can be magnetized by a yoke, a permanent magnet or an electromagnet. The magnetization can include the whole object or can be limited to a small area of a few square millimeters. The residual field is measured by flux gates, magnetoresistors, Hall sensors, or SQUIDs.

NDT

This method is suitable for the detection and characterization of ferromagnetic particles in nonferromagnetic surroundings, such as splinters of cutting tools in nonferromagnetic pieces [7.15].

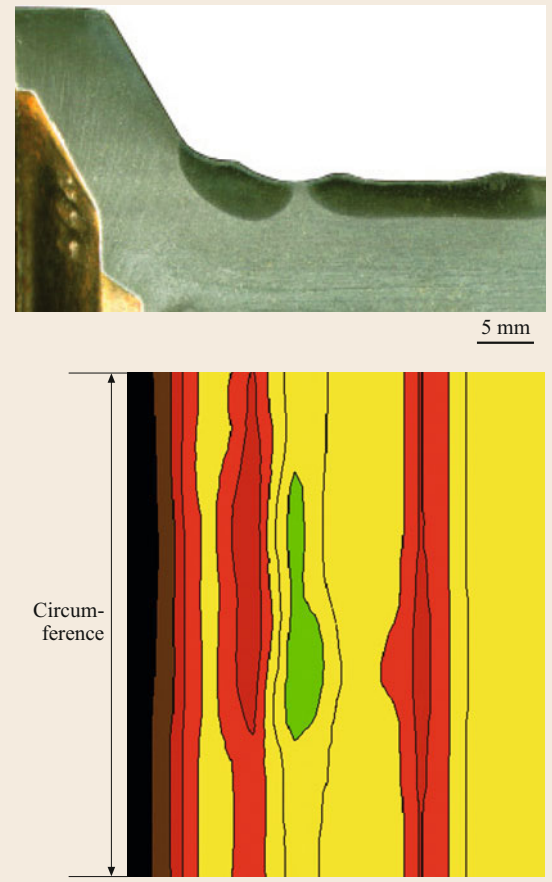

Fig. 7.12 Imperfectly hardened surface layer and residual field distribution along the circumference (after [7.16])

NDE

The residual induction strongly depends on the microstructure of ferromagnetic steels or cast iron due to its correlation with the mobility of magnetic domain walls. The evaluation of residual induction allows the assessment of heat treatment, toughness, hardness, surface hardening (Fig. 7.12, [7.16]) or even carbon content. Calibration is the most important feature for the success of this method and should be accomplished according to appropriate guidelines. The method allows fast automatic inspection using the conveyer movement of the objects through a magnetization tunnel and along a sensor station. Usually the object must be demagnetized afterwards.

Current Scope

In order to mitigate the influence of the dimensions of the object, on the results of NDE, the coercive force

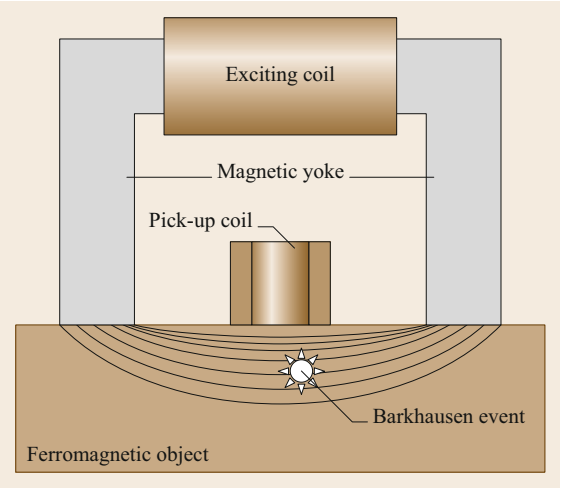

Fig. 7.13 Barkhausen noise excitation and measurement

may be evaluated. For this, after magnetization, the object is demagnetized by a contrary field, and the strength of the demagnetizing field when the residual field vanishes is recorded.

7.4.4 Barkhausen Noise Analysis

Principles

The excitation of ferromagnetic material by a magnetic field that varies with time changes the spatial dimensions of the magnetic domains. The Bloch walls separating the domains from each other move discontinuously through the grain, emitting electromagnetic pulses. The superposition of these pulses produces a noise-like signal called magnetic Barkhausen noise [7.17]. The amplitude and rate of these pulses are discontinuously distributed over a complete magnetization cycle. They reach their maximum when close to coercivity.

Setup and Probes

Excitation is accomplished by a magnetic yoke placed on the object. The driving coil is fed by an alternating current of a frequency ranging from a few tenths of a hertz to a few hundred hertz. Figure 7.13 displays a yoke and a sensing coil between the yoke limbs to receive the emitted pulses.

NDE

The amplitude and pulse rate of Barkhausen noise depend on the Bloch wall mobility at different field

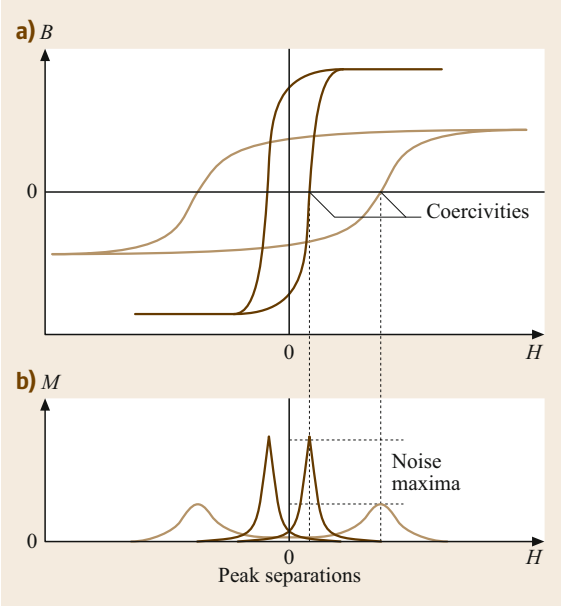

Fig. 7.14a,b Assessment of surface hardening depth of ferromagnetic steel. **(a)** Hysteresis loops, **(b)** Barkhausen noise (after [7.18])

strengths. This mobility is influenced by load and residual stress, grain and phase boundaries, grain orientation, and microstructural defects such as vacancies, dislocations, precipitates, segregations, and inclusions. The method is used to estimate hardness obtained by lattice defects, laser- and case-hardening depth, and stress state.

Figure 7.14 shows the principle of the thickness assessment of surface-hardened layers in ferromagnetic steel. The wide hysteresis loop describes the magnetic properties of the surface layer, while the narrow loop results from the bulk material. During cyclic magnetization, different maxima of the amplitude of Barkhausen noise may be observed [7.18]. At lower field strength, the bulk material provides the first maximum followed by the maximum of the surface layer. The ratio of these maxima correlates with the depth of the hardened layer [7.19].

Current Scope

A frequency analysis of the noise signal yields the source depth of the pulses. In combination with other micromagnetic parameters such as incremental permeability, local remanence or tangential field strength, the method will find a wide field of applications.

7.5 Electromagnetic Methods

Electromagnetic methods rely not only on magnetic properties but also on the behavior of the material in an alternating electric field. For conductive materials such as metals, even low-frequency electromagnetic fields induce an electric current. For nonconductive materials such as most ceramics and plastics, higher frequencies (> 10 MHz) are necessary to generate a so-called dislocation current caused by various polarization mechanisms in the atoms or molecules.

7.5.1 Eddy-Current Method

Principles

An alternating magnetic field between 10 Hz and 10 MHz is applied to a conductive material. This field induces a circular voltage that drives a circular current with alternating direction almost parallel to the surface. As Fig. 7.15 shows, this so-called eddy current builds up its own magnetic field that counteracts the source. The sensor evaluates the resulting field, which contains information about magnetic permeability, conductivity, and geometric parameters [7.14].

Probes

The probe consists of a transmitter generating the alternating magnetic field and a receiver to pick up the resultant magnetic field. The transmitter is commonly a coil; the receiver may be a coil or another magnetic field sensor such as a magnetoresistor, a flux gate, or even a SQUID for very low frequencies. Most simple sensors combine the transmitter and receiver in a single coil. For the direct visualization of eddy currents in flat surfaces, their magnetic fields can be picked up by magneto-optic sensors such as garnet films.

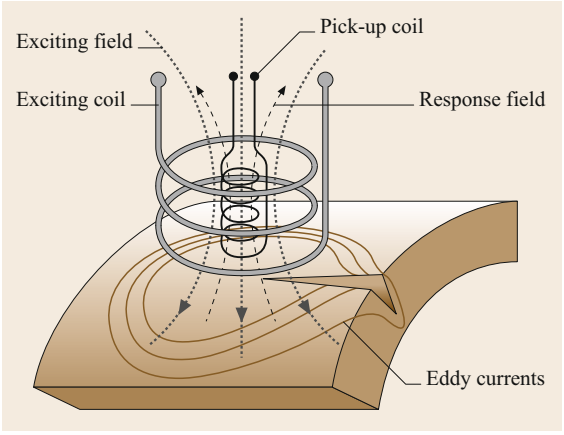

Fig. 7.15 An eddy-current surface probe detects cracks due to the deflection of eddy-current lines

NDT

Surface crack detection in all metals, even below nonconducting coatings, is the most common field of application [7.20]. The detection and quantification of hidden defects such as pores, corrosion, and cracks is also possible in nonferromagnetic materials up to a few millimeters below the surface. Figure 7.16 shows an example of eddy-current turbine blade inspection.

NDE

The eddy-current method is best suited for the measurement of conductivity in nonferromagnetic materials and heat treatment characterization of pure metals and alloys. Material sorting can be accomplished as well as the thickness assessment of nonconducting layers or conducting bulk or wall thickness assessment of nonferromagnetic sheets or pipes. In conducting composites such as carbon fiber reinforced plastic (CFRP), fiber orientation can be evaluated using the anisotropy of conductivity.

Current Scope

Array sensors provide a fast and convenient opportunity to visualize eddy-current behavior. Highly sensitive and resolving sensors make smaller defects visible at greater material depth.

7.5.2 Microwave Method

Principles

Electromagnetic fields excited at frequencies from a few to a few hundred gigahertz provide wavelengths in

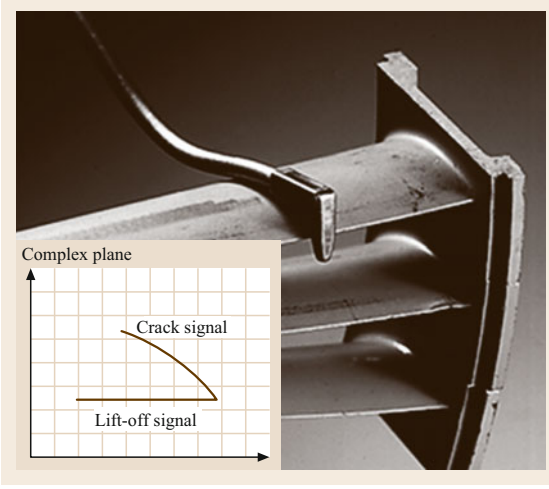

Fig. 7.16 Eddy-current inspection of the trailing edge of a turbine blade

the centimeter and subcentimeter range; so-called microwaves. These waves are reflected at the surface of metals but can penetrate many nonmetals, such as plastics, ceramics, and composites. Various polarization mechanisms of the material components change the amplitude, phase, and polarization of the microwaves.

Setup and Probes

Horn aerials are generally used to transmit and receive microwaves. Single- or double-sided aerials allow reflection and transmission measurements. For near-field applications, an aperture may shape the field transmitted from the antenna. Directional couplers, phase shifters, and modulators complete the equipment [7.21].

NDT

Flaws in metals may be detected and characterized if they break through the surface. At very high frequencies, wave propagation in open cracks may be used for crack depth estimation. In dielectric material, internal flaws such as pores and delaminations may be detected due to the scattering of energy.

NDE

Nonconductive materials can be inspected for material composition, structure, density, porosity, homogeneity, the orientation of reinforcing fibers, state of cure, and moisture content. The reinforcing components in concrete in buildings may be visualized. For metals, only the thickness measurement of plates becomes possible using a double-sided reflection technique [7.22].

Current Scope

Smaller electronic devices enable the integration of increasing numbers of components into one instrument, so that handling problems are decreasing. With the use of higher frequencies, smaller defects will become detectable.

7.6 Thermography

7.6.1 Principles

Heat storage and transport capabilities depend on the heat capacity and thermal conductivity of the material as well as the local geometry of the object. Stimulated heat transport is used to evaluate the material for homogeneity, isotropy, and defects. For noncontact assessment, the temperature distribution in the object is recorded using the thermally induced electromagnetic radiation of the object, which starts from wavelengths of about 10 μm at room temperature and can be visualized using infrared sensors.

7.6.2 Setup and Probes

Figure 7.17 shows that a dynamic heat flow can be generated by periodically activated external (or internal) sources. External sources such as lamps, electric heaters, fans, and liquids heat the object from the front or back side. Internal sources may be stimulated by vibration or electric current. The temperature of the surface is recorded by infrared cameras based on scanning point, line or matrix sensors [7.23, 24].

7.6.3 NDT

Lock-in thermography is based on the harmonic excitation of the heat source. The surface temperature of the object is analyzed according to its amplitude and phase. The phase signal is free of disturbances resulting from the emissivity of the surface. Another approach is the pulsed heating of the object and the time-dependent analysis of surface temperature. Both methods are able to detect and characterize inner flaws like delaminations in composites, impact damage and the debonding of joints. Figure 7.18 presents an application for turbine blades.

Defect selection may be achieved by activating cracks as heat sources. To do this, powerful acoustic waves are fed into the object. A local temperature in-

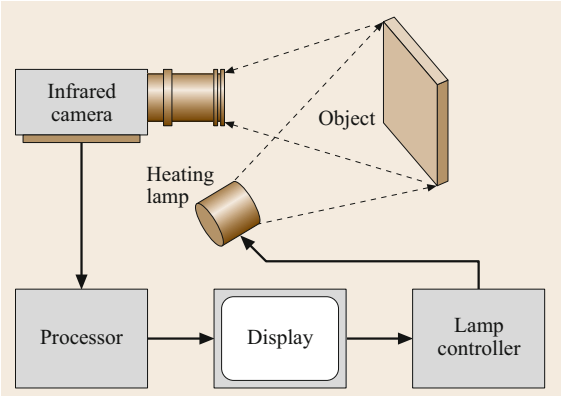

Fig. 7.17 An infrared camera picks up the temperature profile of the surface. The object can be heated by lamps (after [7.23])

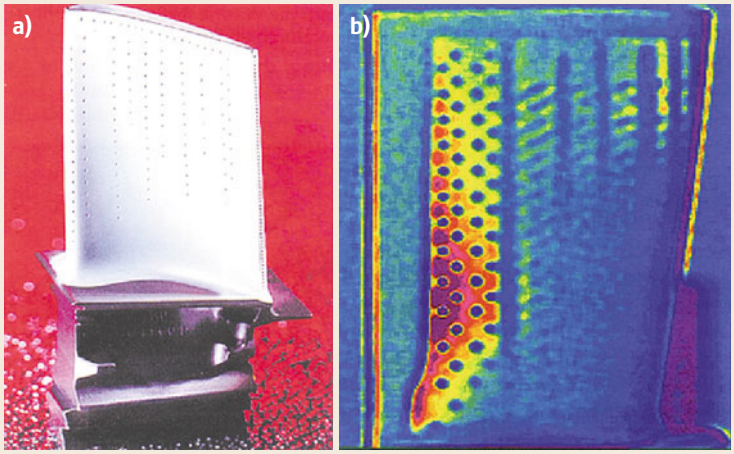

Fig. 7.18 (a) Turbine blades with heat protection layer and cooling channels. (b) Thermography highlights clogged channels

crease due to face friction indicates the presence of a crack.

7.6.4 NDE

The thickness of surface layers in conducting and nonconducting bulk material can be measured as well as the orientation of carbon fibers in CFRP.

7.6.5 Current Scope

Current investigations focus on defect-selective thermography, the assessment of the quality of adhesive joints, and composite materials. The increasing efficiency of infrared sensors means that infrared cameras are increasingly affordable and convenient.

7.7 Optical Methods

This section summarizes methods based on visible light that is reflected from the object's surface. Most attention has been paid to the illumination and the visual abilities of operators. Clear instructions and master pieces of what to look for are required.

7.7.1 Visual Methods

Principles

The object surface is cleaned and systematically searched for defined patterns corresponding to cracks, corrosion, microstructure change or other features.

Probes

Many tasks are solved using the naked human eye. If necessary, lenses, microscopes, endoscopes, and appropriate recording instruments are used. The incidence, intensity, and color of the illumination have to be optimized for a specific inspection task.

NDT

Without optical enlargement, only large surface-breaking defects may be detected. For the maintenance of engines, gearboxes, and other nearly closed hollow objects, endoscopes combining illumination, sensors, and sensor controllers are used [7.25]. Despite the distorted aspect ratio of the recorded picture, it is possible to measure the dimensions of the visual pattern.

NDE

For the analysis of structural features, the object has to be carefully prepared, including mechanical surface treatment such as grinding, polishing and, if necessary, etching. Patterns can be interpreted under defined illumination, but this requires long experience.

Current Scope

Tube-based endoscopes are being replaced by fiber and video endoscopes. Additionally, endoscopes may carry sensors for other NDI methods such as eddy-current probes. Some endoscopes allow the use of mechanical tools to treat any defects found.

7.7.2 Penetration Methods

Principles

Figure 7.19 illustrates the operation of this method. The cleaned surface of the object is coated with a penetrant

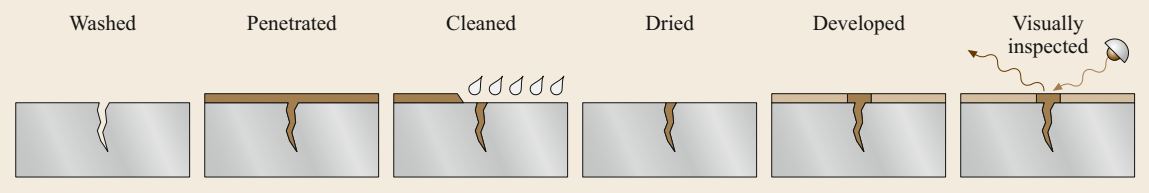

Fig. 7.19 For penetration inspection the object is first washed, then penetrated, cleaned, dried, developed, and visually inspected

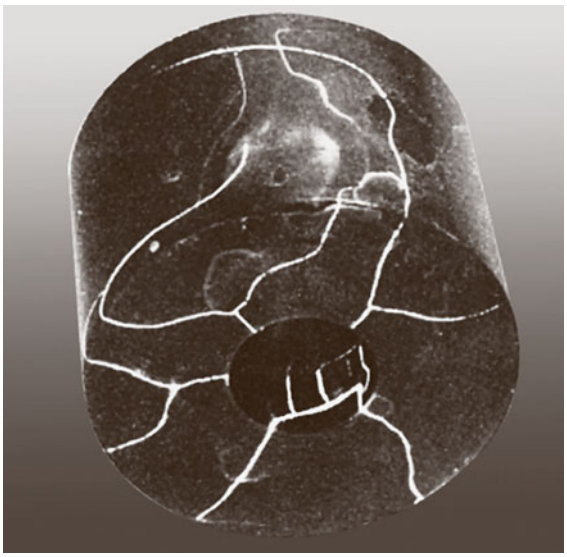

Fig. 7.20 Result of penetrant inspection for cracks in a roller

in which a visible or fluorescent dye is dissolved or suspended. The penetrant is pulled into surface cracks by capillary action. After cleaning the surface of excess penetrant, a developer is sprayed or dusted over the object, partially lifting the penetrant out of the crack. Under defined illumination, the penetrant provides an enlarged crack pattern with high contrast [7.26]. A roller with surface cracks is shown in Fig. 7.20.

Equipment and Inspection Agents

For manual inspection, spray cans with the penetrant and the developer are used. In modern inspection lines, all objects are washed, penetrated, cleaned, and developed automatically at defined agent temperatures and action times in immersion tanks. Visual inspection for defect indication is performed by human operators under either visible or ultraviolet illumination.

NDT

Crack indication varies with developing time. Reference master pieces with known defects and exact instructions enhance the reliability of this method. No information about defect depth can be obtained. Post-emulsifiable penetrants keep viscosity at low levels over time.

Current Scope

To date the interaction of an operator is needed to distinguish between real defects and pseudo-indications. Much effort is focused on replacing inspectors with an automatic vision system.

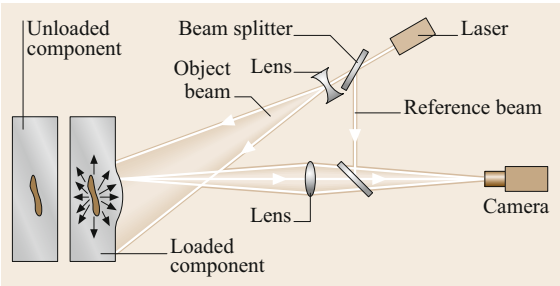

Fig. 7.21 Electronic speckle interferometer (after [7.23])

7.7.3 Speckle Interferometry

Principles

Speckle interferometry uses the interference phenomena of laser light. Figure 7.21 shows that the object is entirely illuminated with laser light, producing a speckle pattern on the object surface. This pattern is superimposed by reference light and the resulting image is recorded using a video camera. For NDI, this method is used to detect and quantify surface dislocation at loading.

Setup and Probes

Laser illumination is performed by a defocused laser so that the entire surface is illuminated at once. No scanning is necessary. To smooth the illumination, the laser light may reach the surface via several paths. A beam splitter directs a small portion of the light as a reference to the camera for interference with the reflected light from the object. The camera records the images and passes them to data storage.

NDT

The speckle pattern of the object is recorded twice. The correlation of the images of the unloaded and loaded object highlights discontinuities or displacements penetrating the surface and allows local debonding, delaminations, and cavities to be recognized as fringes. An example is shown in Fig. 7.22.

Current Scope

The differential speckle interferometry method, known as shearography, highlights differences in the surface dislocation at points at a certain distance from each other. The method is less sensitive to disturbances and is best suited for in-field inspection [7.27].

Fig. 7.22 Speckle fringes caused by discontinuities of off-plane surface displacements

7.8 Radiation Methods

High-energy radiation is able to penetrate solid bodies and to interact with their atoms. The transmitted intensity depends on the atomic number of the material and its density and thickness. The object is illuminated entirely and imaging can be performed by filming or electronic matrix imagers [7.28, 29].

7.8.1 X-ray Method

Principles

An x-ray tube generates radiation with energy up to a few hundred keV. The radiation is directed to the object positioned a certain distance from the tube. A radiographic film or conversion screen close behind the object records the transmitted radiation intensity as a grey scale image.

Equipment

An x-ray source is shown in Fig. 7.23. It consists of an evacuated tube in which a cathode emits electrons that are accelerated towards the anode. The electrons strike the anode and emit bremsstrahlung, which is x-ray radiation with a continuous range of energies. This energy can by controlled by the voltage between the cathode and anode. The radiation leaves the tube via a beryllium window and radiates the object. Increasingly, conversion screens and storage foils are used for imaging.

NDT

Defect detection is based on the alteration of the attenuation of x-rays by the defect. Depending on the defect material, this attenuation may be smaller or greater than in its absence, so that either increased or decreased x-ray intensity can be detected. While the detection of volume defects such as pores starting from a defined extension is very reliable, crack detection requires their correct orientation in the x-ray beam. Figure 7.24 shows the equipment involved and an x-ray image of a weld. For defect detection in steel, x-ray energy of up to 500 keV is required to penetrate walls of 100 mm thickness.

NDE

X-rays are used to gauge the wall thickness of pipes and sheets. With a multi-energy technique it is possible to detect the atomic order of the material, which is used for material identification.

Current Scope

To reduce blurring in x-ray images, microfocus tubes are used. For cross-sectional imaging computer tomo-

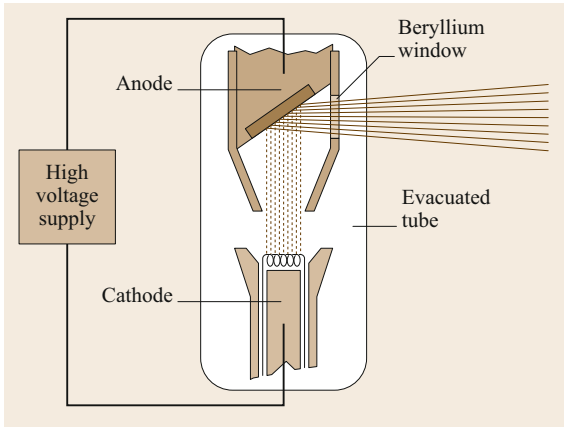

Fig. 7.23 Scheme of an x-ray tube (for explanation see text)

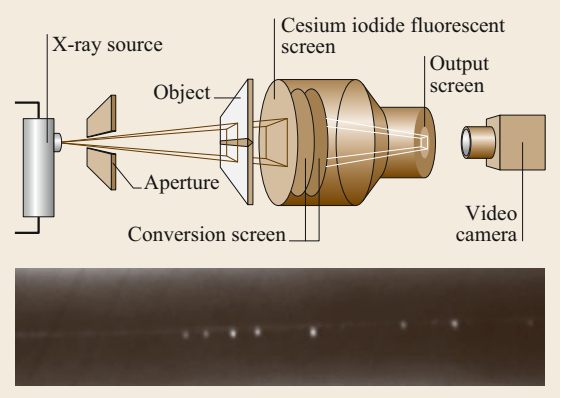

Fig. 7.24 Radioscopic equipment and x-ray image of a weld with pores

graphs are used, turning the object in the x-ray beam. Tubes with turning anodes are needed to increase x-ray intensity with increased electron current in the tube.

7.8.2 Gamma-Ray Method

Principles

The radioactive decay of some elements produces high-energy gamma rays that are able to penetrate metals to a thickness of a few centimeters. Small pellets measuring a few millimeters are activated in a nuclear reactor and then stored in highly damping containers. These continuously radiating pieces are called sources. The decrease in their activity with time is described by the half-life constant, which depends strongly on the source material.

Equipment

The source is loaded into a mobile source holder made from a dense material such as tungsten, uranium or lead. Via remote control, this holder is opened and the source is moved out to radiate the object through a beam collimator. The transmitted radiation is recorded using a radiographic film.

NDT

For very thick steel components, cobalt-60, which radiates with an energy of more than 1 MeV, is used. For steel less than 50 mm thick, softer sources such as iridium-192 are sufficient. The safety requirements for X- and gamma-ray exploitation are very restrictive due to their harmful interaction with biological tissues.

Current Scope

Selenium-75 is best suited for steel walls up to 30 mm and has a significantly longer half-life. This source is able to replace x-ray equipment.

7.9 Health Monitoring

Structural health monitoring (SHM) refers to nondestructive inspection methods that rely on integrated sensors in the inspected structure itself. The sensor signals may be monitored online at the loaded structure or recorded for offline analysis. Various NDI techniques are being investigated for SHM applications in aircraft [7.30, 31], buildings [7.32], and power stations. Active sensors can transmit and receive signals while passive sensors receive signals generated by the damage process or damage growth.

Acoustic emissions (see Sect. 7.2.3) can be recorded by embedded or attached piezoelectric sensors. As shown in Fig. 7.25, the source of an emission can be an impact, the growth of cracks, fiber or matrix breakage, delamination, and other damage processes. To localize these sources, signals from different sensors are correlated, yielding differences in time-of-flight for use in triangulation algorithms.

Acousto-ultrasonic interrogation is a single-sided nondestructive inspection technique employing separate sending and receiving transducers (Fig. 7.26). The method is used in assessing microstructural conditions and distributed damage states in the material between the transducers [7.11].

Impedance spectroscopy uses either a single piezoelectric element or a transmitter–receiver combination (Fig. 7.27). The excitation oscillates in a predefined frequency band and either the impedance or the complex voltage at the receiver is measured. The frequency-dependent behavior of the measurement indicates defects on or close to the piezoelectric element [7.34]. Both acousto-ultrasonic and impedance spectroscopy can be used to inspect polymer, metal, ceramic matrix composites, and even monolithic metallic materials.

Eddy-current foil sensors are an alternative technology to the classical eddy-current technique (see Sect. 7.5) for the detection of surface or hidden cracks. In this method, a copper winding is printed onto a plastic substrate, just like an electronic track. Due to their thin geometry, these sensors can be mounted onto the interfaces between structural parts, around bolts, in corners, and in other hardly accessible regions. Periodic

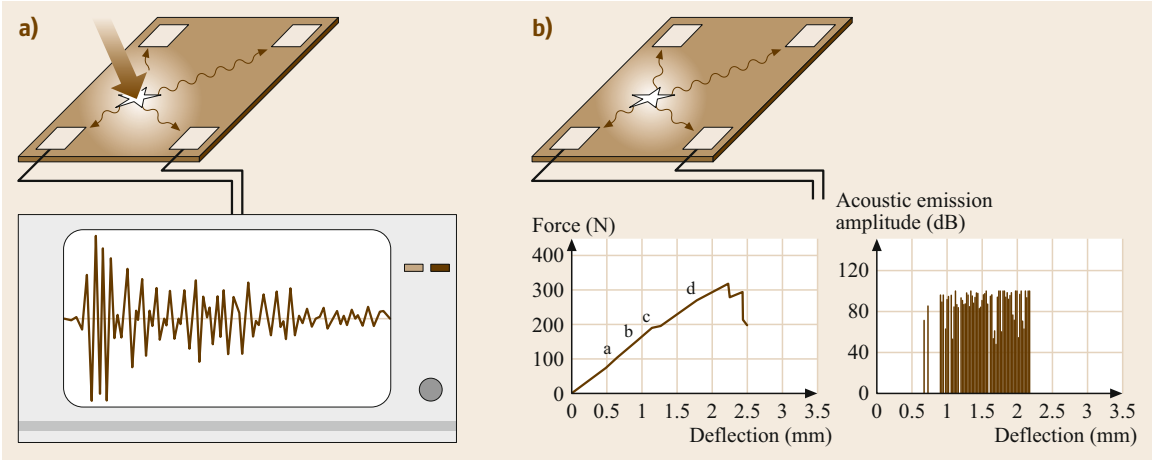

Fig. 7.25a,b Damage processes can be detected by their acoustic emission. Impact damage **(a)** or crack growth **(b)** can be detected and localized (after [7.33])

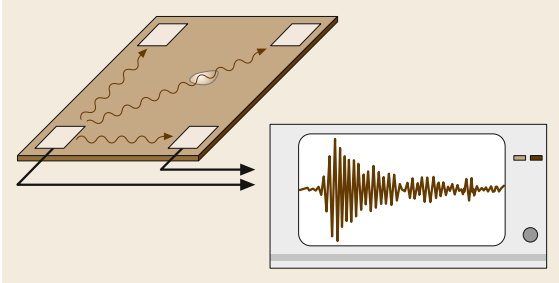

Fig. 7.26 Acousto-ultrasonic measurements (*left*) reveal defects between transmitter and receiver

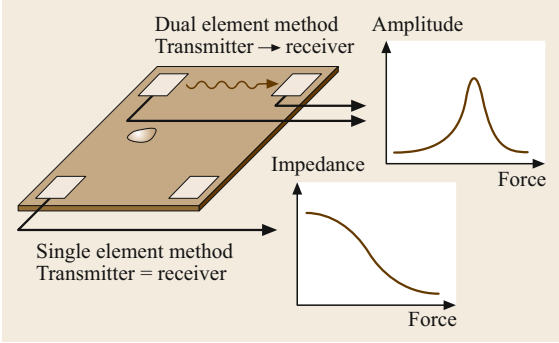

Fig. 7.27 Impedance spectroscopy allows the detection of defects on or close to the piezoelectric element (after [7.34])

reading of the coils can provide information on structural health.

Comparative vacuum monitoring offers an effective method for the in situ real-time monitoring of crack initiation and/or propagation. This method measures the

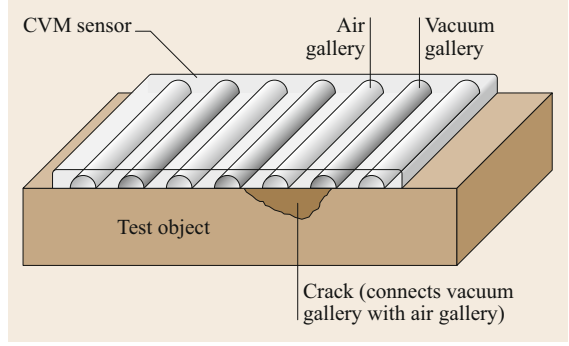

Fig. 7.28 Comparative vacuum monitoring (CVM) detects defects due to varying differential pressure (after [7.35])

differential pressure between fine galleries containing a low vacuum alternating with galleries at atmosphere in a simple manifold (Fig. 7.28). Comparative vacuum monitoring enables the monitoring of the external surfaces of materials for crack initiation, propagation, and corrosion. The galleries can also be embedded between components or within compound materials such as composite fiber.

Fiber Bragg gratings measure either the tensile or compressive strain applied along the grating length of an optical fiber (Fig. 7.29). The grating consists of a periodic variation of the index of refraction and provides a linear relationship between the change in wavelength of the reflected light and the strain in the fiber caused by externally applied loads or thermal expansion. To operate multiple sensors along a single optical fiber, the various Bragg gratings should have different Bragg wavelengths in order to differentiate between them.

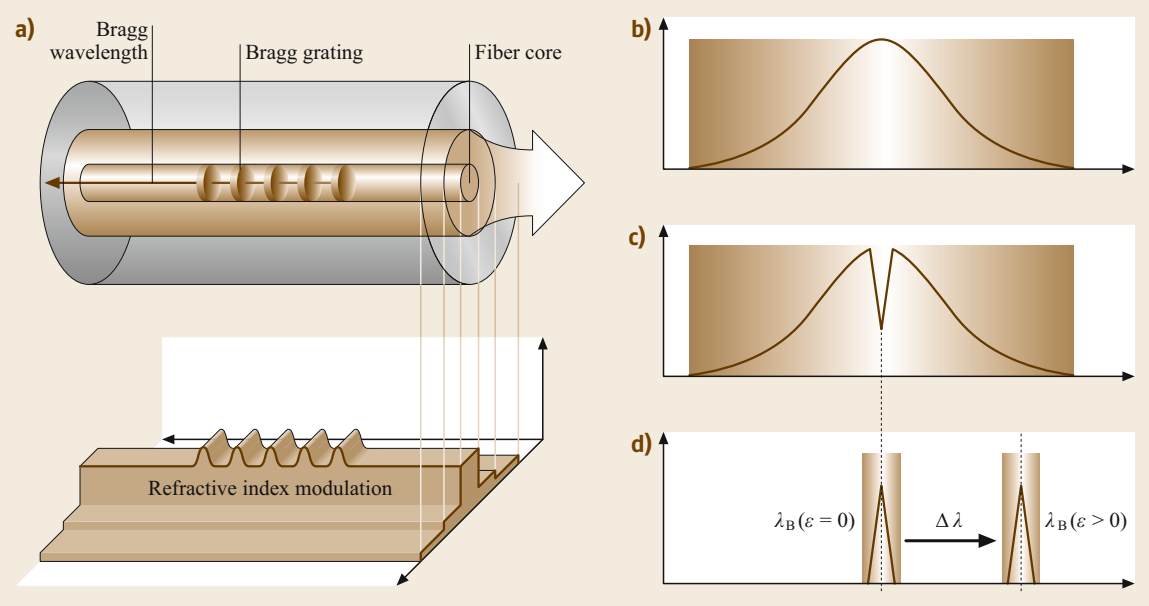

Fig. 7.29a–d Fiber Bragg grating. **(a)** Sensor principle; **(b)** emitted, **(c)** transmitted, **(d)** reflected spectrum (after [7.35])

Dr Shyha received his PhD from The University of Birmingham in 2010. He is now an Associate Professor in Mechanical Engineering and Director of Postgraduate Research in the Faculty of Engineering and Environment at Northumbria University, UK. He teaches mechanical and manufacturing courses and supervises PhD projects in the field of advanced manufacturing and materials.

8. Engineering Materials and Their Properties

Ulrich Wendt

Because engineering materials must cover a wide range of very different properties, a great number of such materials are necessary to address all technical applications. The main classes of engineering materials are dealt with in this chapter: metals and their alloys, polymeric materials, ceramics, glasses, and composites. The specific composition, the manufacturing processes leading to specific constituents/phases and structures, and the resulting properties are outlined for iron and its alloys, for some light metals, and for alloys based on nickel, cobalt, and copper. Great space is dedicated to iron alloys, because they offer the widest range of properties and thus applications in mechanical engineering based on one metal, such as construction steel, automobile sheet steel, cutting tools, and silverware, to name but a few examples. The fine-tuning of properties using heat and mechanical treatments is outlined. A special field of modification is the chemical alteration of surfaces to increase the carbon concentration, leading to different properties of the core and surface of parts.

Polymeric materials with carbon as the main component can be distinguished into thermoplastics, elastomers, and duromers, depending on their mechanical and thermal properties. The most widely used polymers are described. Special attention is paid to the interaction of polymeric materials with solvents and mineral oils. Glasses and ceramics are included as examples of nonmetallic inorganic materials. Composites combine the properties of two or more materials, opening important applications based on their mechanical properties and density.

Engineering materials, in principle, can be divided into four main classes:

1. Metals
2. Carbon-based polymeric materials
3. Ceramics and glasses
4. Composites.

Materials in each classes exhibit comparable properties, processing routes, and most often applications as well. The criteria for material selection are rather complex and depend on the intended application purpose. The main design criteria are based on strength, stiffness, fracture toughness, formability, joinability, corrosion resistance, thermal expansion, cost, density, and last but not least recyclability. For structural applications in mechanical engineering, metallic materials [8.4, 5] are still the most widely used group of materials; their order of importance is Fe, Al, Cu, Ni, then Ti. While the physical properties of materials belonging to different classes are described in Chap. 5, Table 8.1 presents a comparison of the mechanical properties of some important metals and alloys, carbon fiber, and a polymer.

8.1 Iron-Based Materials

Iron-based materials are the most widely used metallic materials in terms of number of applications and tonnage, mainly because of their relatively inexpensive manufacturing and enormous flexibility. Accordingly, the properties of Fe-based materials can be varied to a great extent, allowing precise adaptation to specific application requirements ranging from high-strength, high-temperature, and wear-resistant alloys for tools to soft or hard ferromagnetic alloys for applications in electrical industries.

Pure iron, however, is only of minor importance in structural applications, since its mechanical properties are simply inadequate. Alloying with carbon leads to the most important groups of constructional alloys, namely:

1. Steels with carbon content of up to about 2.06% carbon (unless otherwise stated, all compositions are giving in wt%)
2. Cast iron, which practically contains 2.5–5% carbon.

These Fe-C alloys exhibit outstanding properties, including widely variable mechanical properties: yield strengths ranging from 200 MPa to values exceeding 2000 MPa, hot and cold rolling ability, weldability, chip-removing workability, high toughness, high wear resistance, high corrosion resistance, heat resistance, high-temperature resistance, high Young's modulus, nearly 100% recyclability, and many more.

In the following sections, the characteristic phases, microstructures, compositions, and applications of iron-carbon alloys are treated, with an emphasis on the fundamental background. For further reading, references such as [8.6–11] and the online database [8.12] are recommended.

8.1.1 The Iron-Carbon Phase Diagram and Relevant Microstructures

Fe-C-based materials, in general, can be classified into two main categories:

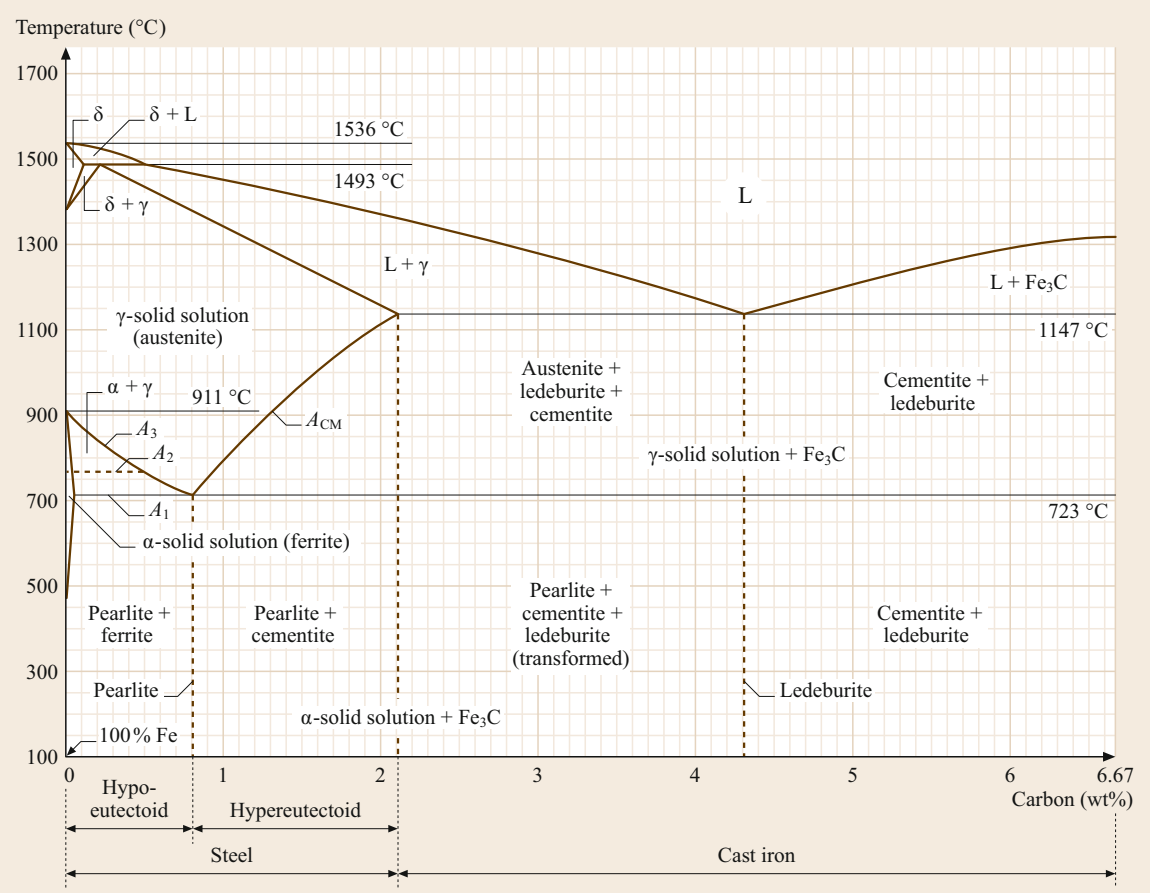

Fig. 8.1 The metastable Fe-Fe_3C (6.67% C) diagram

1. Steels or steel castings, which are forgeable iron-carbon alloys with up to about 2.06% C
2. Gray iron or pig iron with more then 2.06% C (in practice 2.5–5%), which cannot be forged and can be brought into the final form only by casting.

These two groups of Fe-C alloys divide the iron-carbon diagram (Fig. 8.1) into two parts, namely a eutectoid (steel) part and a eutectic (cast iron) part. In the thermally stable condition, carbon prevails in the form of graphite. Although graphite, or more precisely its shape and proportion, plays a major role in adjusting the properties of cast irons, this equilibrium phase is usually not obtained in common steels. Instead, carbon in steels emerges in the form of metastable iron carbide (Fe_3C cementite). Therefore, the metastable equilibrium (Fig. 8.1) between iron and iron carbide is relevant to the behavior of most steels in practice. A closer look at the Fe-Fe_3C phase diagram reveals the three fundamental ideal diagrams introduced in Sect. 4.1.5, namely a peritectic and a eutectoid system in the steel part and a eutectic system in the cast-iron part of the diagram.

Pure iron appears in three different allotropic forms, for which the following notations are used:

- α-Fe with body-centered cubic (bcc) structure, which is stable at temperatures below 911 °C; note that, from 769 °C (A_2 line) to lower temperatures, α-Fe is ferromagnetic without a lattice transformation;
- γ-Fe with face-centered cubic (fcc) structure, which is stable between 911 and 1392 °C;
- δ-Fe with bcc structure, which exists from 1392 °C to the melting point at 1536 °C.

With its significantly smaller atomic radius, carbon occupies interstitial lattice sites (see Sect. 4.1.5) in the iron phases. Its solubility, however, depends on the size of the lattice gap and therefore on the lattice type of the specific Fe phase (Fig. 8.1). These differences in the maximum solubility of carbon are the basis for the

Table 8.2 Phases and phase mixtures of the Fe-Fe_3C diagram. Carbon content means maximum carbon content for single-phase regions or percentage of particular phase for phase mixtures (SS: solid solution)

Phase and phase mixture	Carbon content	Designation
α-Fe	0.02% (at 723 °C)	Ferrite
γ-Fe	2.06% (at 1147 °C) 0.8% (at 723 °C)	Austenite
δ-Fe	0.1% (at 1493 °C)	δ-Ferrite
Fe_3C	6.67%	Cementite
(α-Fe + Fe_3C)	88% α-SS + 12% Fe_3C	Pearlite (eutectoid)
(γ-Fe + Fe_3C)	51.4% γ-SS + 48.6% Fe_3C	Ledeburite I (eutectic)
(α-Fe + Fe_3C)	35.5% α-SS + 64.5% Fe_3C	Ledeburite II

enormous variability of the mechanical properties of steels. In Table 8.2, the phases and phase mixtures of the Fe-Fe_3C system, their corresponding (maximum) carbon content at different temperatures, and their microstructural nomenclature are summarized.

The intermetallic compound Fe_3C (*cementite*), or more accurately its microstructural appearance, plays a crucial role in the adjustment of the mechanical properties of steels. Cementite with 6.67% carbon is based on an orthogonal lattice where dislocation glide at low temperatures is nearly impossible. It therefore exhibits very high hardness (1400 HV) and brittleness. However, in the form of finely distributed particles or lamellae in the grain interiors, it can hinder dislocations from glide very effectively. At the carbon content of about 0.8% at which the eutectoid reaction occurs, a phase mixture of 88% α-Fe and 12% Fe_3C (eutectoid) is formed from γ-Fe(C) solid solution (Table 8.2). The typical arrangement of the eutectoid in contiguous lamellae (Fig. 8.2) is the result of fast decomposition, and the designation "pearlite" is used for this microstructure.

Likewise, the eutectic microstructure at about 4.3 wt% C, i.e., a phase mixture of 51.4% γ-Fe and 48.6% Fe_3C, is called "ledeburite". At carbon concentrations that differ from the exact eutectoid or eutectic composition, the microstructure contains more than one component. This is shown in Fig. 8.3 for *hypo-* and *hypereutectoid* steels.

On slow cooling of hypoeutectoid compositions, i.e., of alloys containing less than 0.8% C, the austenite partly transforms to ferrite in the temperature range of 911–723 °C. Since the solubility of carbon in α-Fe is significantly lower than in γ-Fe, the residual austenite simultaneously enriches in carbon along the A_3 line, until at 723 °C the remaining austenite, now exactly at the eutectoid composition, transforms to pearlite as a second microstructural component (Fig. 8.3). Hypereutectoid alloys with 0.80–2.06% carbon first form cementite at γ-Fe grain boundaries on cooling in the temperature interval from 1147 to 723 °C, while the austenite depletes in carbon. The carbon concentration of the austenite reaches in turn 0.8% at 723 °C, and it transforms to pearlite on further cooling. The microstructural composition of Fe-C alloys in the thermodynamic equilibrium can easily be derived from microstructure diagrams such as that shown in Fig. 8.4.

8.1.2 Heat Treatments

Since modification of the atomic configuration requires diffusion (Sect. 4.1.3) of the atoms to occupy appropriate lattice sites, phase transitions in the solid state are typically time dependent. Therefore, the equilibrium phases of the Fe-C phase diagram only appear upon slow cooling or after sufficiently long heat treatments.

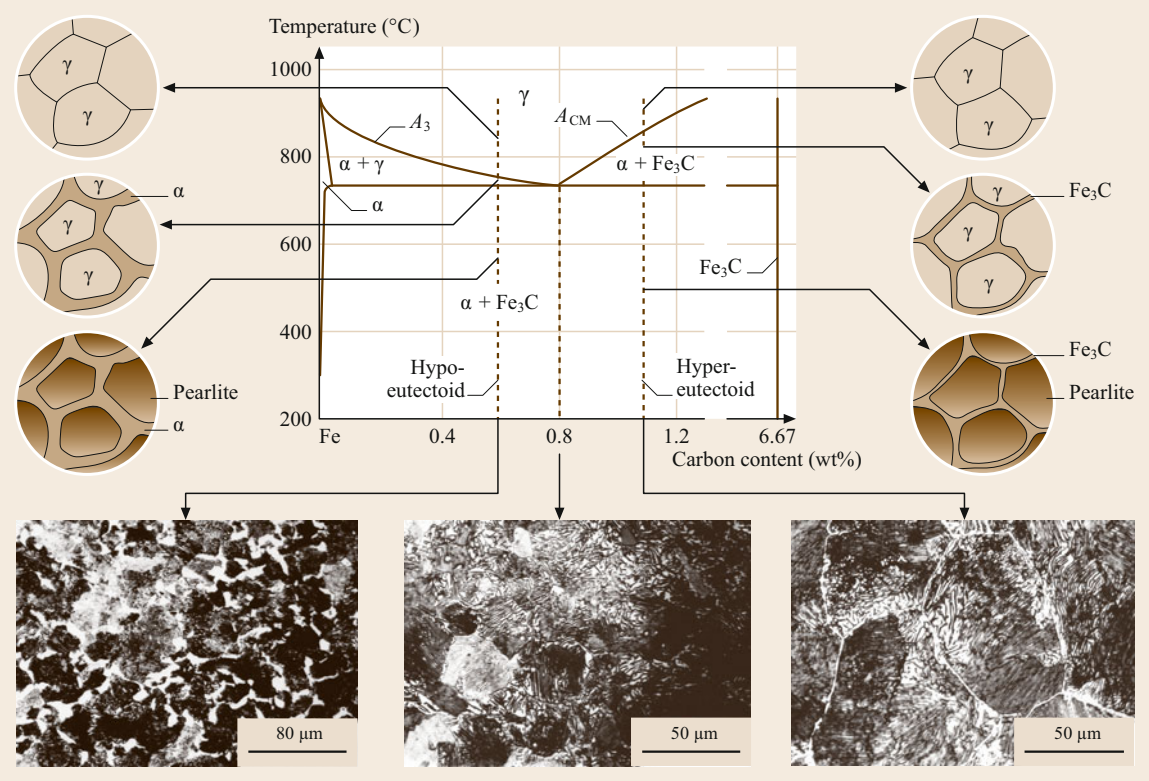

Fig. 8.3 Microstructural evolution of hypo- and hypereutectoid steels upon cooling from the austenitic region of the Fe-C diagram (after [8.13])

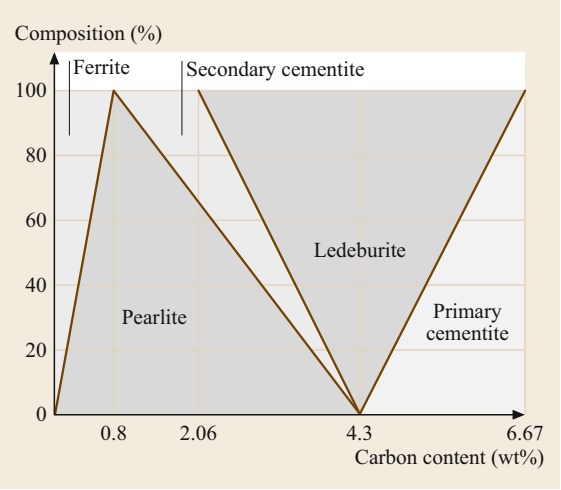

Fig. 8.4 Composition of Fe-C alloys depending on carbon content

The microstructures shown in Fig. 8.3, on the other hand, arise only under specific cooling conditions. By altering the time–temperature path, metastable phases as well as totally different microstructures can be formed. Heat treatment procedures differ with regard to the following parameters:

- Heating method
- Holding temperature
- Holding time
- Cooling method (for example, in air, oil, water, or a furnace).

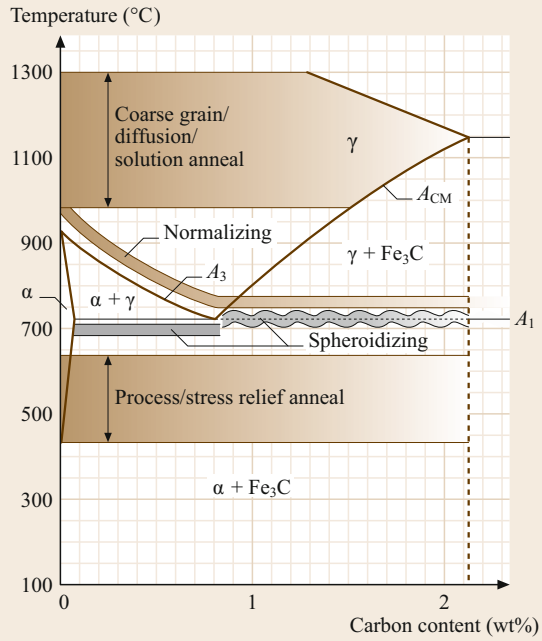
According to the cooling method applied, the following principle division of heat treatment procedures is widely used:

1. Annealing treatments (slow cooling close to equilibrium)
2. Hardening treatments (fast cooling).

In the following, the main parameters and objectives of frequently used heat treatment procedures for steels are summarized using the above scheme.

Annealing Treatments

In Fig. 8.5, the temperatures and main parameters of frequently used annealing treatments of steels are shown [8.8].



Annealing treatments:

- Normalizing:
  30–50 K above A_3
  for 20–60 min
  cooling in air
- Spheroidizing:
  below/around A_1
  for up to 5 h
  slow cooling in furnace
- Stress relief anneal:
  450–650 °C
  for 2–4 h
  slow cooling in furnace

Hardening:

- Solution annealing:
  30–50 K above A_3
  for 20–60 min
- Quenching to room temperature:
  media: oil, water, ice water or salt solutions

Tempering:

- Heat treatment between 100 and 650 °C, outdiffusion of carbon

Fig. 8.5 Annealing treatments of steels

Normalizing. Due to the heat flow during cooling of castings, in the heat-affected zone of welding joints as well as after cold or warm rolling, the microstructure of steels can be extremely inhomogeneous. Normalizing, therefore, first of all serves to homogenize the steel and should result in a fine-grained microstructure (grain size $< 100\,\mu m$). To do so, the workpiece is austenitized by heating to temperatures 30–50 K above the A_3 line, i.e., into the region of the γ-Fe solid solution, or above the A_1 line in case of hypereutectoid steels. Subsequent cooling in air leads to complete new formation of fine-grained pearlitic-ferritic or pearlitic-cementitic microstructures (Fig. 8.6a) with high strength and high toughness. The strength and toughness of steels in the normalized condition strongly depend on the carbon content. As shown in Fig. 8.7, the strength reaches its maximum at about 1.0% carbon. Toughness, as characterized by the impact energy in Charpy tests, gives the steel a brittle behavior at carbon concentrations as low as 0.8%.

Spheroidizing. The cold workability of normalized steels is normally insufficient to achieve the desired degree of deformation. However, since the lamellar arrangement of α-Fe and Fe_3C in pearlite is energetically unstable, on heat treatment slightly below the A_1 transformation temperature (or in the case of hypereutectoid steels by oscillating around A_1 to accelerate spheroidization of the cementite network), the cementite lamellae rearrange to form stable spherical particles (Fig. 8.6b). Dislocation movement, which is restricted in pearlite to the region within the small α-Fe lamellae, is now possible in the whole grain interior, thus the steel can be deformed more severely. After annealing, the workpiece is cooled slowly (in the furnace) to prevent heat stresses from arising.

Process Annealing. Cold deformation as well as hot deformation to a high degree result in the formation of a dense dislocation network, which hinders dislocation movement and therefore further material deformation. A high dislocation density, on the other hand, stores high levels of energy, which encourages the formation of a completely new grain structure (recrystallization) upon annealing at temperatures exceeding $T_p = 0.4T_m$ (T_p = recrystallization temperature, T_m = melting temperature). As a consequence the strength and toughness of the recrystallized state reach levels which are close to the undeformed condition, and the material can therefore be further deformed.

Coarse-Grain Annealing. Coarse grains are beneficial when the material is machined by chip-removal methods, because short fragile shear chips are formed. Such a microstructure is the result of heat treatment at temperatures between 950 and 1200 °C, i.e., in the austenitic region well above the A_3 line. On subsequent cooling in a furnace, the coarse-grained γ-Fe solid solution transforms into a coarse-grained ferritic-pearlitic microstructure. Since the accompanying decrease in toughness deteriorates the properties of the steel, a final heat treatment (hardening, tempering, etc.) must be applied to retransform the microstructure to a fine-grained state.

Stress-Relief Annealing. Stress-relief annealing serves to relieve stresses in the workpiece which are caused by cold deformation, microstructural transformations, thermal loading, or chip-removal working. Stress-relief annealing is usually carried out at temperatures between 450 and 650 °C for several hours,

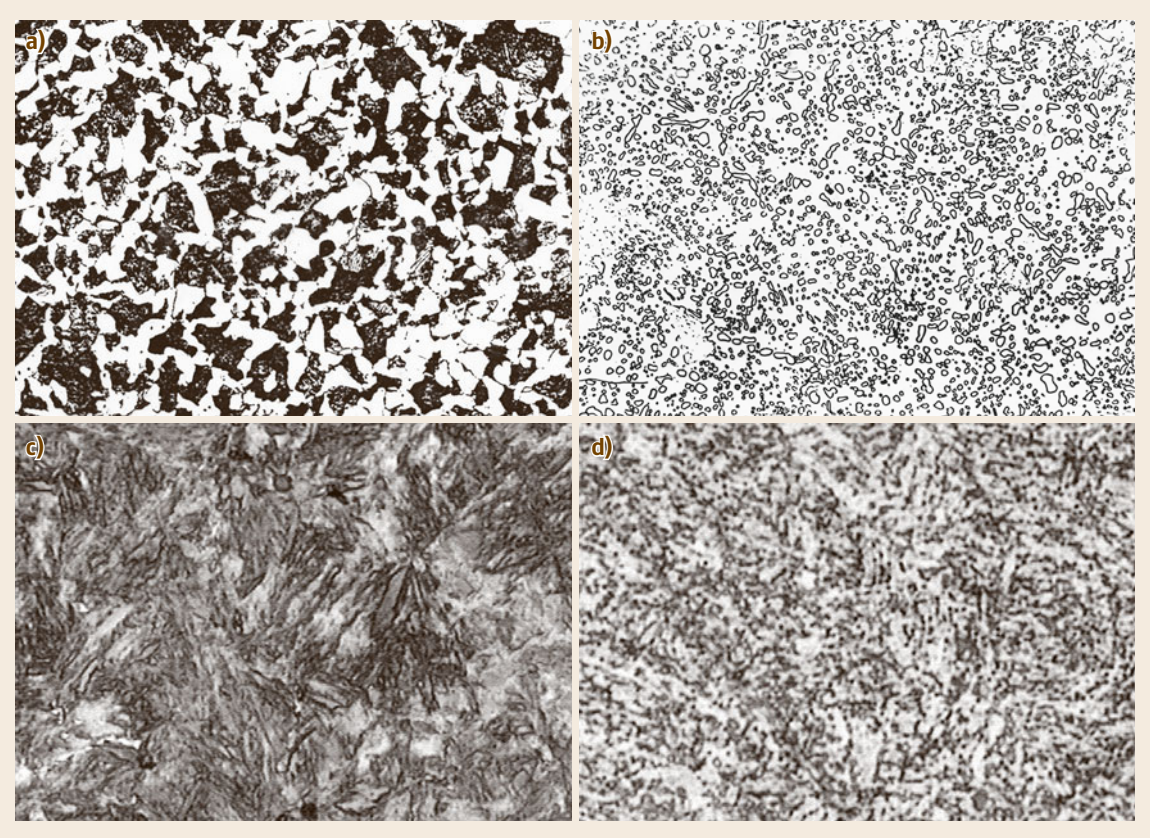


Fig. 8.6a–d Microstructures of steel after different heat treatments: **(a)** C45: normalized, **(b)** C60: spheroidized, **(c)** C45: hardened, and **(d)** C45: hardened and tempered at 550 °C

followed by slow cooling. It does not lead to apparent changes in the microstructure, nor does it change the mechanical properties significantly.

Diffusion Annealing. Diffusion annealing is applied when segregation (local variations of the chemical composition) must be compensated; it requires temperatures as high as 1000–1300 °C and annealing times as long as 50 h. Since this treatment is very expensive, segregation should be prevented by optimizing the cooling conditions after casting.

Solution Annealing. Solution annealing is predominantly applied for austenitic steels and serves to solve (large) precipitates in steels. Annealing at temperatures between 950 and 1200 °C and fast cooling results in a supersaturated solid solution at room temperature. Subsequent aging leads to the formation of small precipitates which lead to a significant strength increase at moderate toughness values.

While the annealing treatments introduced above lead to phase compositions which are close to equilibrium with increasing cooling rate, the transformation behavior of austenite can be completely different. Since the formation and growth of nuclei are diffusion-controlled processes, fast cooling from the γ-Fe phase region may suppress the formation of the temperature-equivalent equilibrium phases. At increasing cooling rates, the transformation temperatures A_1 and A_3 decrease until they coincide at the point of the lower critical cooling rate (Fig. 8.8). At even faster cooling rates, *bainite* (consisting of aggregates of plates of ferrite, so-called sheaves, separated by untransformed austenite), *martensite* (see below), or cementite is formed; for a more comprehensive review of bainite, see [8.15]. Due to the high cooling rate, the diffusivity of Fe is reduced so strongly that the formation of cementite only occurs by diffusion of carbon, while iron transforms from fcc to bcc via a diffusionless shear process. When the cooling rate reaches the upper critical limit, the diffusivity of carbon is completely suppressed as well. Due to the supersaturated solution of carbon in α-ferrite, a distorted body-centered tetragonal (bct) lattice, so-called martensite, is now formed as the product

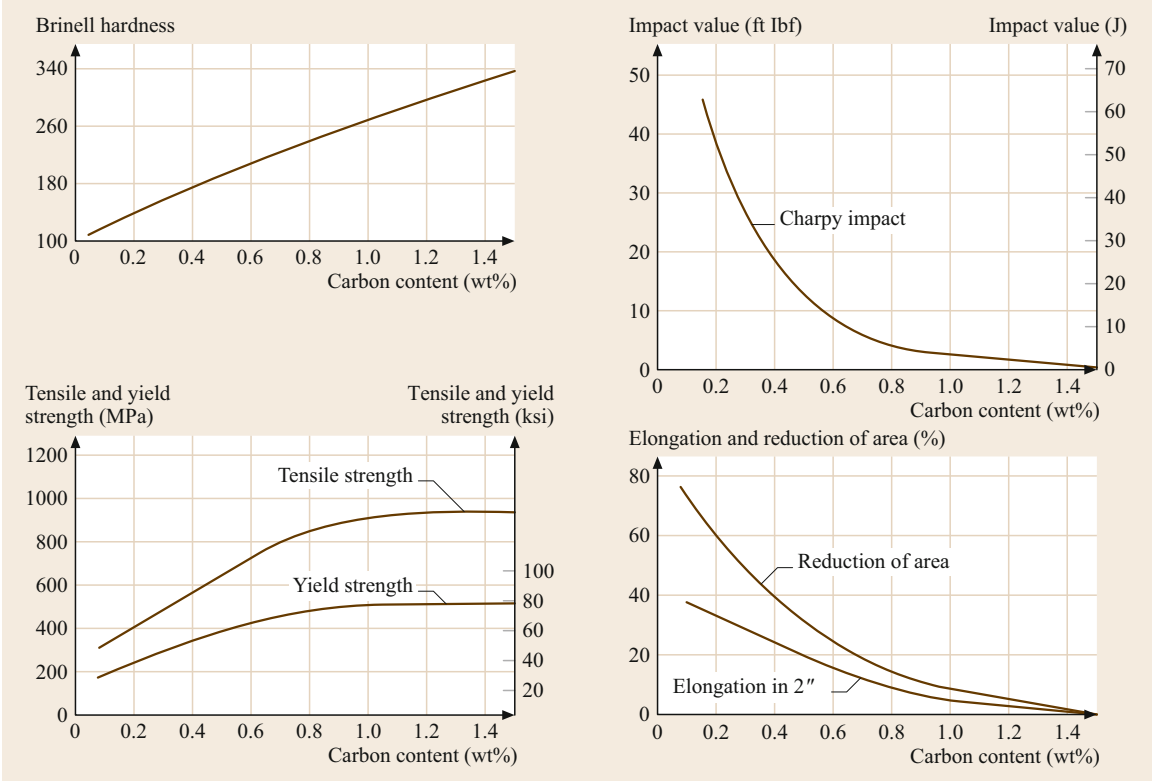

Fig. 8.7 Mechanical properties of Fe-C alloys depending on carbon content (after [8.14])

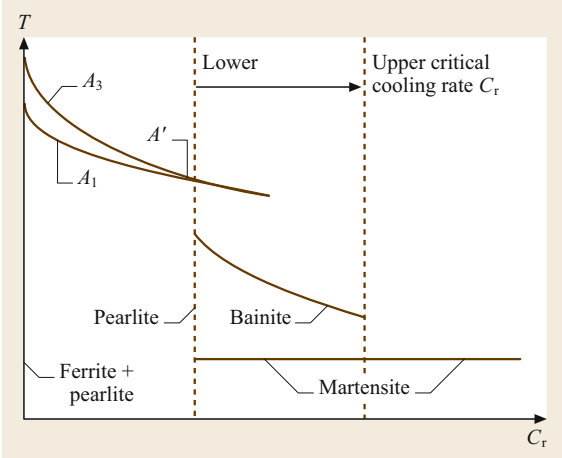

Fig. 8.8 Transition temperatures and products in steels as functions of cooling rate (C_r)

of a phase transition from the fcc γ-lattice. This results in a steel with very high strength, but at the expense of low ductility.

The kinetics of the phase transitions from the γ-Fe phase region can be visualized in time–temperature transition (TTT) diagrams obtained under isothermal holding conditions, or in continuous cooling transition (CCT) diagrams for varying (but fixed) cooling rates. One example for steels is given in Fig. 8.9, which shows the CCT diagram of 42MnV7. Depending on the cooling rate, the transition of γ-Fe leads to the formation of martensite, bainite, pearlite, or a mixture thereof at room temperature. The transformation quantity after crossing a transformation region is given in Fig. 8.9, as well as the hardness values of the resulting microstructure at room temperature.

Hardening

The basis of hardening is the mechanism of martensitic transformation, which results in a massive increase in hardness. In the case of hypoeutectic steels, austenitization is done above the A_3 line in the Fe-Fe_3C diagram; in the case of hypereutectic alloys, annealing in the two-phase region γ-Fe + Fe_3C is usually sufficient. The distortion caused by the supersaturation of carbon in the α-ferrite increases with increasing carbon content. On the other hand, at least about 0.3% C is necessary to yield a significant increase in strength. The temperature to which the material has to be cooled from the austenite region (without any other nucleus formation to apply during cooling) to form martensite M_s

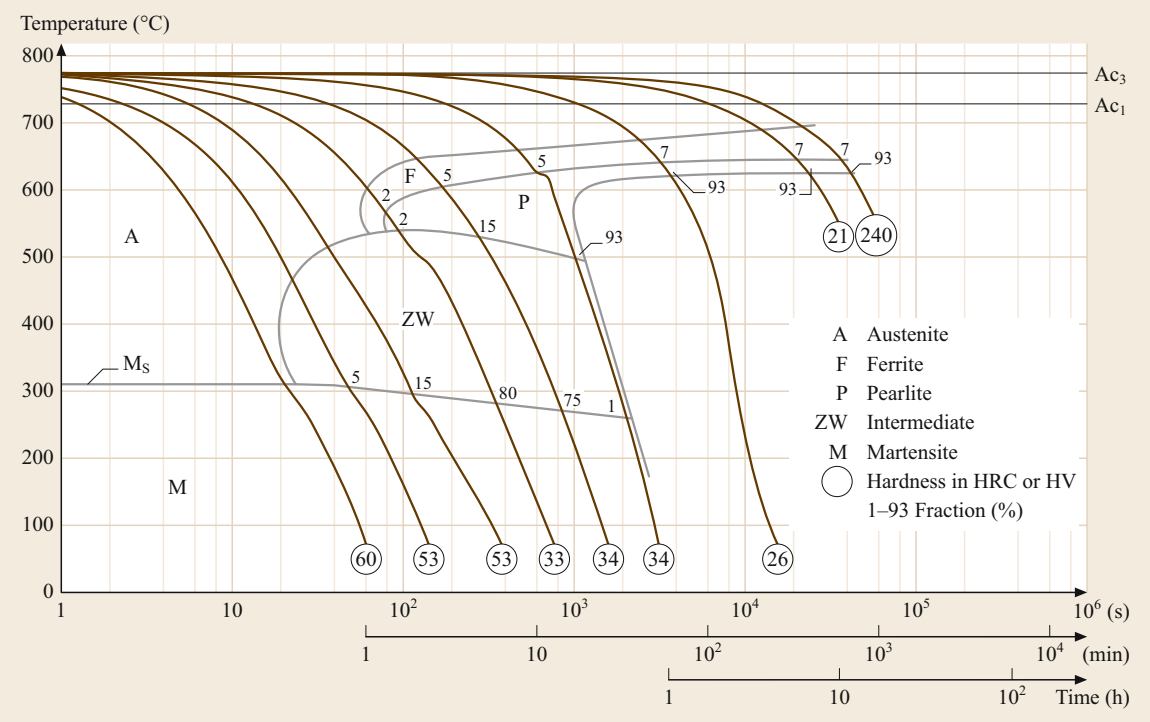

Fig. 8.9 Continuous cooling transition (CCT) diagram of 42MnV7: austenite-forming temperature 1050 °C (holding period 8 min) heat-up in 2 min

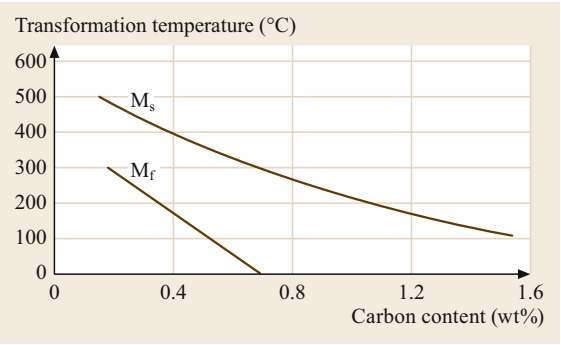

Fig. 8.10 Dependence of martensite transformation temperatures on carbon content (after [8.6])

(the *martensite start*) as well as the temperature where the whole microstructure consists of martensite M_f (the *martensite finish*) decrease with increasing carbon content (Fig. 8.10).

Therefore, hardening through the whole cross section of a workpiece with higher carbon content is possible only for low dimensions, and the hardening depth can be increased by accelerated cooling or by alloying. The cooling media commonly used are oil, water, ice-water, or salt solutions. Alloying with Mn, Cr, Mo, and Ni in the concentration range of 1–3% can improve the through-hardening capability of the steel. Thermal stresses caused by high temperature gradients superimpose onto transformation-induced stresses and can lead to hardening cracks. The crack sensibility can be reduced by warm-bath hardening, in which a temperature-balancing step above the M_s temperature is done before final quenching to martensite.

Tempering. To achieve technically relevant properties, especially suitable toughness values, a final heat treatment after the hardening process step is required. This tempering step is done below the A_1 line and serves to reduce the brittleness of martensite by means of outdiffusion of carbon from the distorted ferrite lattice. In the temperature range up to about 300 °C, diffusion of carbon leads to a decrease of the lattice distortion, which reduces the brittleness but does not lead to a significant change of the strength. This is ensured by the formation of small metastable ϵ-carbides and the disintegration of residual austenite. Tempering above 300 °C leads to disintegration of the remaining martensite to form ferrite with finely distributed spherical cementite, while the ϵ-carbide transforms to cementite as well. Consequently, the strength is lowered significantly while the toughness increases considerably. Tempering above 450 °C yields a homogeneous, fine-grained

microstructure with high toughness and strength, as desired for many structural parts.

In the case of alloyed steels containing Mo, W, and/or V, i.e., tool steels or heat-resistant steels, tempering at temperatures between 450 and 600 °C leads to the formation of small, homogeneously distributed carbide precipitates which counteract the strength decrease during annealing (so-called secondary hardening).

Surface Hardening. In many practical applications such as crankshafts, spigots, rolls, or gears, high hardness and wear resistance may be required at the surface, and there only in some regions, but at the same time, high fracture toughness of the bulk part is required in order not to trade off fatigue strength. Therefore, for these applications, hardening is done only in the near-surface areas of the workpiece. Steels that are suitable for this treatment are plain carbon steels and low-alloy steels with carbon content of 0.3–0.7%. The following treatments are commonly used for direct hardening:

1. Flame hardening, in which the surface of the workpiece is heated to the austenitization temperature using a gaseous oxygen flame
2. Induction heating, in which a high-frequency coil is used to heat the material surface via the skin effect
3. Beam hardening (electron and laser beam), by which small areas of the workpiece can be treated selectively
4. Dip hardening, which is especially suitable for pieces with curved surfaces for which other treatments would be too costly.

In the case of steels with less than about 0.25% C, the surface has to be enriched in carbon prior to hardening and the workpiece is heated to temperatures between 850 and 950 °C in a carbon-rich atmosphere (e.g., methane). It has to be kept in mind that the enriched (up to 0.9% C) surface shows a lower transition temperature then the core with a lower carbon content. Therefore, hardening can be done from the transition temperature of either the core or the surface. If only the surface region is austenitized, the core is not completely transformed to γ-Fe. This can lead to significant grain growth, and lower toughness values are expected. If, however, the core is fully austenitized, a fine-grained core with significantly higher toughness results after hardening. After surface hardening, a tempering treatment at 150–250 °C is usually done.

Nitriding. Nitriding is a thermochemical treatment of steels. The surface area of steels is enriched in nitrogen (usually in an ammonia atmosphere). Nitriding is carried out at relatively low temperatures (495–565 °C), and no quenching is required after the process. Hence, this process leads to relatively little distortion but produces, on the other hand, a relatively shallow (0.2–0.3 mm) casing. In contrast to carbon-enriched surface layers, nitride layers provide significantly higher temperature resistance (up to 500 °C).

8.1.3 Steel Grades

Effect of Alloying Elements

Besides carbon as the main alloying element, steels generally contain further alloying additions [8.16]. A semantic distinction can be made between:

1. Residual elements, which are not intentionally added to the steel but result from raw materials and steel-making practices
2. Alloying elements, which are added to cause changes in the properties of steels.

To the residual elements in group (1) belong predominantly phosphorus, sulfur, oxygen, hydrogen, manganese, and silicon. Phosphorus, sulfur, oxygen, and hydrogen are usually undesired, because they reduce ductility and toughness. Their content has to be reduced to a harmless level by secondary metallurgy. The only exception is the group of free-machining steels, where sulfur or phosphorus may be added deliberately to improve machinability. The effect of alloying elements of group (2) can be separated into four different fundamental mechanisms:

1. Change of the phase equilibria in the Fe-C phase diagram
2. Solid-solution hardening by elements such as Mn, Si, Ni, Co, Cu, and Al in Fe
3. Formation of carbides
4. Influencing the composition of oxides at the surface.

Alloying elements can influence the equilibrium diagram in two principal ways:

- By expanding (or opening) the γ-phase field, thereby facilitating the formation of austenite over a wider compositional range. These elements are referred to as γ-stabilizers (Fig. 8.11a,b).
- By contracting (or closing) the γ-phase field, which encourages formation of ferrite over a wider compositional range; these elements are termed α-stabilizers (Fig. 8.11c,d).

Consequently, elements such as Mn and Ni, which open the γ-phase field, lead to a decrease of the eutectoid temperature, which facilitates hardening; others

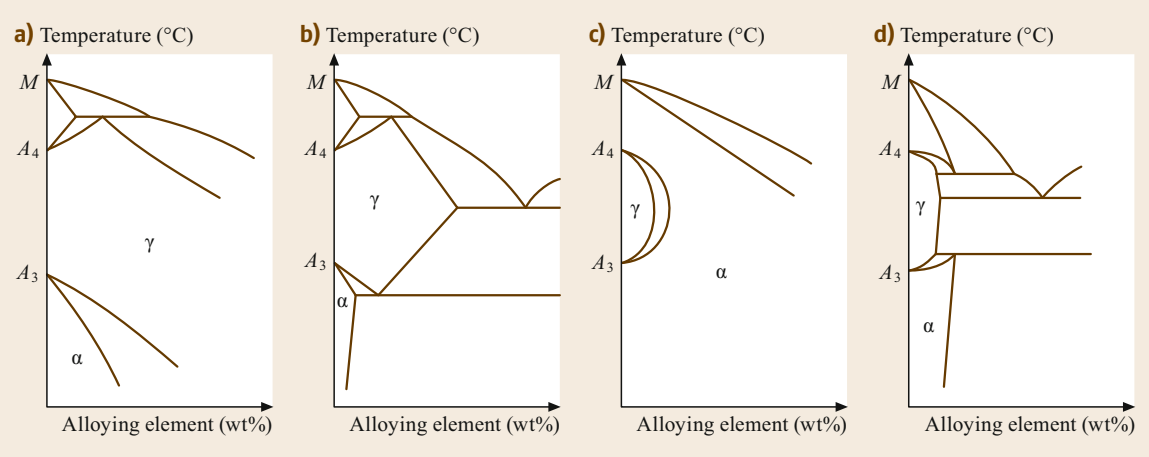

Fig. 8.11a–d Classification of iron alloy phase diagrams: **(a)** opened γ-phase field, **(b)** expanded γ-phase field, **(c)** closed γ-phase field, and **(d)** contracted γ-phase field (after [8.7])

such as Ti and Mo lead to an increase of the eutectoid temperature (Fig. 8.12). However, most of the alloying elements in steels have in common that they help to decrease the carbon concentration in the eutectoid, which provides better hardenability for low-carbon steel grades.

Alloying elements can be separated according to their impact on the iron-carbon phase diagram into four groups [8.7]:

- *Class 1*: These elements open the γ-phase field. To this group belong the most important alloying additions in steels: *manganese* and *nickel*. Cobalt and the inert metals ruthenium, rhodium, palladium, osmium, iridium, and platinum show a similar behavior. With a sufficient amount of nickel or manganese, the formation of α-Fe under normal cooling conditions can be suppressed down to room temperature, allowing the formation of austenitic steels. At least 0.3% *manganese* is present in all commercial steel grades. It serves primarily to deoxidize the melt and counteracts the harmful influence of iron sulfide via the formation of manganese sulfide stringers. Excess content of manganese can partly dissolve in the iron lattice, leading to the mentioned solid-solution hardening effect and partly form Mn_3C. Through the opening of the γ-phase field, the critical cooling rate is considerably decreased, allowing better hardenability of the steel. With increasing Mn content, the amount of C in the steel can be reduced while retaining a constant strength level, which finally leads to improved ductility. The hot working capability is improved at Mn contents up to 2%, since it reduces the susceptibility to hot shortness. However, if the manganese content is increased above 1.8%, the steel tends to become air-hardened, with resulting impairment of the ductility. With 5–12% Mn, the steel becomes martensitic even after slow cooling. At Mn contents

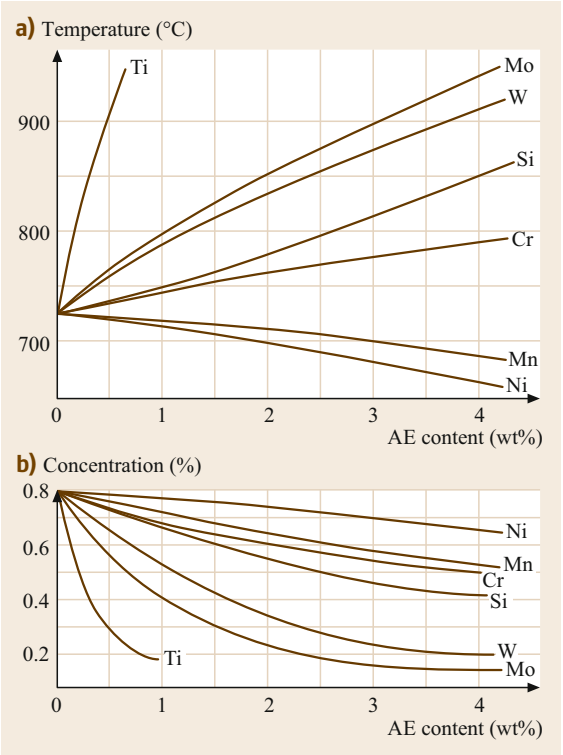

Fig. 8.12a,b Effect of alloying additions (AE content: content of alloying element) on **(a)** eutectoid temperature and **(b)** carbon concentration of eutectoid in steels (after [8.16])

above 12% and high C contents, the austenite phase is retained down to room temperature. Under impact loading, such steels can be strongly cold worked at the surface while the core remains ductile. In contrast to manganese, *nickel* does not form any carbon compounds in steel. Up to content of about 0.5%, it is primarily an efficient ferrite strengthener. This is additionally intensified by a refinement of the pearlite lamellae. As in the case of manganese, with increasing Ni content and hence decreasing transition temperature, the hardenability is improved (Fig. 8.13). The sudden drop in the Ar_1 temperature at 8–10% nickel encourages the formation of martensite, while above 24% Ni this transformation is depressed below room temperature. As shown in the lower part of Fig. 8.13, the mechanical properties behave accordingly: while steels with more than 10% nickel have high tensile strength, the elongation drops from about 20% at nickel contents below 8% to about 10% in the martensitic region. Above 24% Ni and thus stabilization of austenite at room temperature, the tensile strength decreases and the material becomes ductile, tough, and workable. The effect of increasing the Ni and C contents on the microstructure is shown in the *Guillet* diagram for a constant cooling rate in Fig. 8.13. Steels with high nickel content also show a low coefficient of thermal expansion (CTE). The so-called *Invar* alloy, containing 36% Ni, 0.2% C, and 0.5% Mn, has a coefficient of thermal expansion which is nearly zero over the temperature range 0–100 °C. These alloys are therefore used in clocks, tapes, and wire measurements.

- *Class 2*: These elements expand the γ-phase field. The most important elements belonging to this group are carbon and nitrogen. Copper, zinc, and gold show a similar effect. Cu in amounts exceeding 0.2% enhances the atmospheric corrosion resistance of carbon and low-alloy steels. Those steels are referred to as weathering steels and are used in the building industry. Furthermore, copper increases the yield strength, and at content above 0.3%, age hardening is possible. However, copper exaggerates surface defects (grain boundaries), leading to high surface sensitivity during hot rolling. It is therefore sometimes regarded as a *steel pester*.
- *Class 3*: These elements close the γ-phase field. Elements which restrict the formation of γ-Fe to a small area appearing like a loop include silicon, aluminum, beryllium, and phosphorus as well as the carbide"0forming elements titanium, vanadium, molybdenum, tungsten, and chromium. In other words, there are more elements which encourage the formation of bcc iron. Note that the normal heat treatment processes which are based on a γ–α transformation are no longer available. When adding *chromium* to steel, most often its capability to increase the resistance to corrosion and oxidation is considered. However, chromium also improves the hardenability by decreasing the critical hardening rate. Furthermore, it raises the high-temperature strength and improves the abrasion resistance of high-carbon compositions through carbide formation. Since carbides are stable at high temperatures, the solution annealing temperature has to be increased. In combination with nickel, chromium stabilizes austenite, resulting in a steel that superimposes the positive properties of chromium, i.e., high hardness and resistance to wear, and those of nickel, i.e., high strength, ductility, and toughness. The effect of tempering nickel-chromium steel on the room"0temperature mechanical properties is shown in Fig. 8.14. Note that there is a distinct minimum in the Izod impact curve in the temperature range of 250–450 °C, which is known as embattlement. This is caused by the enrichment of grain boundaries with alloying elements such as Mn and Cr during austenitization, which leads to enhanced segregation of em-

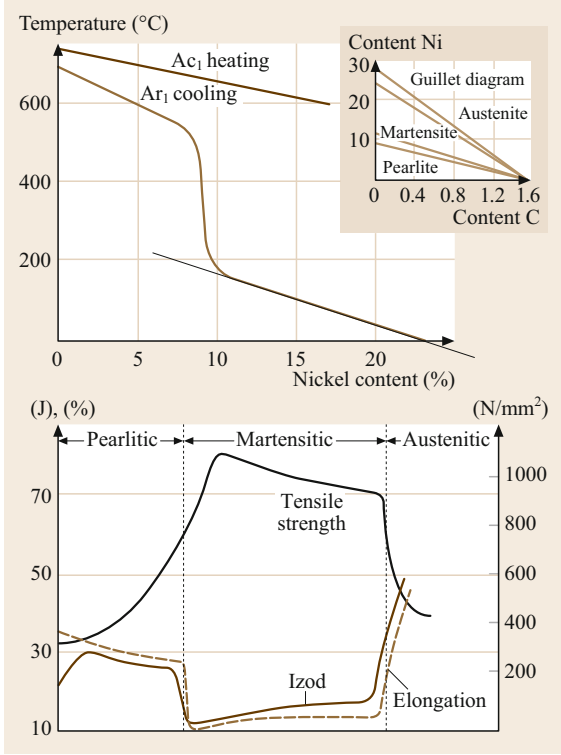

Fig. 8.13 Effect of nickel on transition temperatures (*inset*: Guillet diagram) and mechanical properties of 0.2% carbon steels cooled at constant rate (after [8.12])

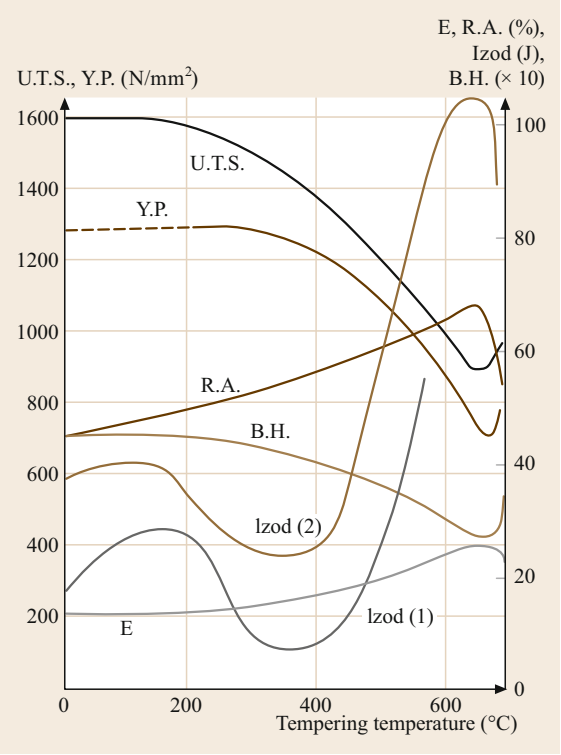

Fig. 8.14 Effect of tempering on mechanical properties of nickel-chromium steel (0.26% C, 3% Ni, 1.2% Cr), 29 mm-diameter bars hardened in oil from 830 °C. Izod (2) for steel with 0.25% Mo added (U.T.S.: ultimate tensile strength; Y.P.: yield point; E.: elongation; R.A. reduction in area; B.H.: Brinell hardness) (after [8.12])

battling elements such as P, Sn, Sb, and As on slow cooling from 600 °C. This can be prevented by increasing the cooling rate during hardening. However, as shown in Fig. 8.14, Izod (2) addition of *molybdenum* significantly reduces the tempering embrittlement at intermediate temperatures and increases the high-temperature tensile and creep strength of the steel. Ni-Cr-Mo steels are therefore widely used for ordnance and turbine rotors. Aluminum, silicon, and titanium are commonly used as deoxidizers. Furthermore, aluminum and titanium can limit grain growth when added to steel in specific amounts. This is critical for preventing grain coarsening during solution annealing prior to hardening. Titanium is, however, one of the strongest carbide formers (Fig. 8.15), and since its carbides are quite stable, they may not dissolve in austenite and can therefore have adverse effects on the hardenability. It is used as a stabilizer in corrosion-resistant steels.

- *Class 4*: These elements contract the γ-phase field. This is observed when carbide-forming elements

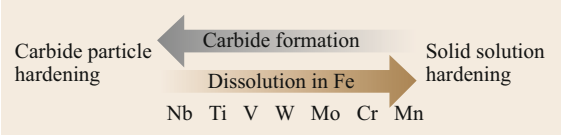

Fig. 8.15 Tendency of alloying elements to form carbides in steels, and vice versa dissolution in Fe lattice

such as tantalum, niobium, and zirconium are present. Boron also belongs to this class of alloying additions. Zirconium is primary used in so-called high-strength low-alloy (HSLA) steels to improve their hot-rolling properties.

Classification and Designations

A variety of steel classification systems are in use; they subdivide, for example, with regard to chemical composition, application area, required strength level, microstructure, manufacturing methods, finishing method, or the product form (a comprehensive comparison of steel standards is given in [8.17, 18]). Chemical composition is, however, by far the most widely used basis for classification and/or designation of steels. The most commonly used system of designation is that of the American Iron and Steel Institute (AISI) and Society of Automotive Engineers (SAE), which is based upon a four- or five-digit number, where the first two digits refer to the main alloying elements and the latter two or three digits give the carbon content in wt%.

The designation 1020 according to the SEA-AISI classification is used, for example, for a carbon steel with nominally 0.2 wt% C, while the steel 10120 according to SEA-AISI contains 1.2 wt% C. The various grades of carbon and alloy steels are presented in Table 8.3.

The unified numbering system (UNS) for metals and alloys is being used with increasing frequency. It was developed by ASTM and SAE and other technical societies, trade associations, individual users and producers of metals and alloys, and US government agencies. The system helps to avoid confusion, preventing the use of more than one identification number for the same metal or alloy. Each UNS designation consists of a single-letter prefix followed by five digits. The prefix usually indicates the family class of metals: for example, "T" for tool steel, "S" for stainless steel, or "F" for cast irons, while "G" is used for carbon and alloy steels. Existing designation systems, such as the AISI-SAE system, were incorporated into the UNS system wherever feasible. More information on the UNS system and an in-depth description can be found in SAE J1086 and ASTM E 527. Table 8.4 presents an overview of the main groups of UNS designations for iron-based materials.

Table 8.3 SAE-AISI system of designation for carbon and alloy steels [8.12]

Numerals and digits	Type of steel and nominal alloy content (%)
Carbon steels	
10xx[a]	Plain carbon
11xx	Resulfurized
12xx	Resulfurized and rephosphorized
15xx	Plain carbon (max. Mn 1.00–1.65)
Manganese steels	
13xx	Mn 1.75
Nickel steels	
23xx	Ni 3.50
25xx	Ni 5.00
Nickel-chromium steels	
31xx	Ni 1.25; Cr 0.65 and 0.80
32xx	Ni 1.75; Cr 1.07
33xx	Ni 3.50; Cr 1.50 and 1.57
34xx	Ni 3.00; Cr 0.77
Molybdenum steels	
40xx	Mo 0.20 and 0.25
44xx	Mo 0.40 and 0.52
Chromium-molybdenum steels	
41xx	Cr 0.50, 0.80, and 0.95; Mo 0.12, 0.20, 0.25, and 0.30
Nickel-chromium-molybdenum steels	
43xx	Ni 1.82; Cr 0.50 and 0.80; Mo 0.25
43BVxx	Ni 1.82; Cr 0.50; Mo 0.12 and 0.25; V 0.03 (min)
47xx	Ni 1.05; Cr 0.45; Mo 0.20 and 0.35
81xx	Ni 0.30; Cr 0.40; Mo 0.120
86xx	Ni 0.55; Cr 0.50; Mo 0.20
87xx	Ni 0.55; Cr 0.50; Mo 0.25
88xx	Ni 0.55; Cr 0.50; Mo 0.35
93xx	Ni 3.25; Cr 1.20; Mo 0.12
94xx	Ni 0.45; Cr 0.40; Mo 0.12
97xx	Ni 0.55; Cr 0.20; Mo 0.20
98xx	Ni 1.00; Cr 0.80; Mo 0.25
Nickel-molybdenum steels	
46xx	Ni 0.85 and 1.82; Mo 0.20 and 0.25
48xx	Ni 3.50; Mo 0.25
Chromium steels	
50xx	Cr 0.27, 0.40, 0.50, and 0.65
51xx	Cr 0.80, 0.87, 0.92, 0.95, 1.00, and 1.05
50xx	Cr 0.50; C 1.00 (min)
51xx	Cr 1.02; C 1.00 (min)
52xx	Cr 1.45; C 1.00 (min)
Chomium-vanadium steels	
61xx	Cr 0.60, 0.80, and 0.95; V 0.10 and 0.15 (min)
Tungsten-chromium steels	
72xx	W 1.75; Cr 0.75
Silicon-manganese steels	
92xx	Si 1.40 and 2.00; Mn 0.65, 0.82, and 0.85; Cr 0 and 0.65
Boron steels	
xxBxx	B denotes boron steel
Leaded steels	
xxLxx	L denotes leaded steel
Vanadium steels	
xxVxx	V denotes vanadium steel

[a] The last two digits "xx" of these designations indicate the carbon content (in hundredths of a percent)

Table 8.4 Main groups of UNS designations for iron-based materials

D00001–D99999	Steels with specified mechanical properties
F00001–F99999	Cast irons
G00001–G99999	AISI and SAE carbon and alloy steels (except tool steels)
H00001–H99999	AISI and SAE H-steels
J00001–J99999	Cast steels (except tool steels)
K00001–K99999	Miscellaneous steels and ferrous alloys
S00001–S99999	Heat- and corrosion-resistant (stainless) steels, valve steels, iron-based *superalloys*
T00001–T99999	Tool steels, wrought and cast

The American Society for Testing and Materials (ASTM) standard contains full specifications of specific products, such as A 574 for alloy steel socket-head cap screws, and is oriented towards the performance of the fabricated end product. These commonly used steels are not initially included in the SAE-AISI designations.

From a user's viewpoint, steels can generally be divided into two main categories, namely *standard steels* and *tool steels*. It is useful to further subdivide *standard steels* according to their chemical composition into three major groups:

1. Carbon steels
2. Alloy steels
3. Stainless steels.

Carbon Steels. Carbon steels contain less than 1.65% Mn, 0.6% Si, and 0.6% Cu. According to the SAE standard J142 *General Characteristics and Heat Treatments of Steels*, plain carbon steels of the 10xx and 15xx series in Table 8.3 can be divided into four groups [8.14]:

- Group I steels with carbon content below 0.15%, providing enhanced cold formability and drawability. These steels are therefore used as cold-rolled sheets in automobile panels and appliances and are suitable for welding and brazing. Note, however, that these alloys are susceptible to grain growth upon annealing after cold working and, as a consequence, exhibit a tendency to embrittlement (strain-age embrittlement).
- Group II steels with carbon content of 0.15–0.3%, which show increased strength and hardness and are less suitable for cold forming. These steels are applicable for carburizing or case hardening. As shown above, increasing the manganese content enhances the hardenability of the core and case, and intermediate manganese levels (0.6–1.0%) are preferred for machining. Carburized plain carbon steels are used for parts which require a hard wear-resistant surface but a *soft* core, for example, small shafts, plungers, and lightly loaded gears.
- Group III steels with medium carbon content of 0.3% to nearly 0.55%, which can be directly hardened by induction or flame hardening or by cold working. These steels are found in automotive applications and can be used for forgings and for parts which are machined from bar stock.
- Group IV steels with high carbon levels of 0.55% to nearly 1.0%, which offer improved wear characteristics and high yield strength and are generally heat treated before use. Since cold-forming methods are not practical for this group of alloys, application parts such as flat stampings and springs are coiled from small-diameter wire. Considering their good wear properties, typical applications are found in the farm implement industry as plow beams, plow shares, scraper blades, discs, mower knives, and harrow teeth.

The so-called *free-machining grades* are either resulferized (group 11xx steels) or resulferized and rephosphorized carbon steels (group 12xx). These additives enhance their machining characteristics and lower machining costs.

The chemical compositions as well as mechanical properties of some carbon steels are presented in Table 8.5.

Alloy Steels. Alloy steels constitute a category of ferrous metals that exceed the element limits for carbon steels. They contain elements not found in carbon steels such as nickel, molybdenum, chromium (up to 3.99%), cobalt, etc. The primary function of these alloying elements is to increase the hardenability and optimize the mechanical properties such as toughness after the final heat treatment. Table 8.6 summarizes the mechanical properties of selected alloy steels in the normalized, annealed, and quenched-and-tempered condition. In the following, alloy steels are divided into five major groups according to their application area [8.14].

According to the SAE-AISI system, structural steels include carburized, through-hardening, and nitriding grades.

Carburizing grades with low alloying combinations such as SAE-AISI 4023 or 4118 have better core properties than plain carbon steels and are hardenable in oil in small cross-sections, resulting in less distortion compared with water-quenched alloys. These alloys are applied as cam shafts, wrist pins, clutch fingers, and other automotive parts. For applications requiring higher core and case hardness such as automotive gears, universal joints, small hand tools, piston pins, bear-

ings, etc., higher-alloy carburizing steels such as Ni-Mo (SAE-AISI 4620), plain Cr (SAE-AISI 5120), or Ni-Cr-Mo (SAE-AISI 8620) steels are used. Aircraft engine parts, truck transmissions and differentials, rotary rock-bit cutters, and large antifriction bearings are made from high-alloy steels as SAE-AISI 4820 and 9310.

Through-hardening grades in principle contain higher carbon levels than carburized grades. In this group, the lower-alloy steels are used for applications in small sections or in larger sections that may not have optimal properties but allow weight savings due to the higher strength of the alloys. Typical examples are manganese steels (SAE-AISI 1330–1345), which are used for high-strength bolts, molybdenum steels (SAE-AISI 4037–4047) and chromium steels (SAE-AISI 5130–5150), which are used for automotive steering parts, and low-Ni-Cr-Mo steels (SAE-AISI 8630–8650), which are used for small machinery axles and shafts. Heavy aircraft or truck parts or ordnance materials require higher-alloy structural steels, such as SAE-AISI 3430 or 86B45. There are several constructional alloy steels which are used for specialized applications; for exam-

ple, SAE-AISI 52100 steels are used almost exclusively for ball-bearing applications, and the chromium steels SAE-AISI 5150 and 5160 were developed for spring steel applications.

Steels that belong to the *nitriding grades* are in most cases either medium-carbon and chromium-containing low-alloy steels, which are covered by the SAE-AISI (for example, the 4100, 4300, 5100, 6100, 8600, 9300, and 9800 groups), or Al-containing (up to 1%) low-alloy steels, which are not described by SAE-AISI designations but have simple names such as "Nitralloy." Typical applications for nitride grades include gears designed for low contact stresses, spindles, seal rings, and pins.

Low-carbon quenched-and-tempered steels typically contain less than 0.25% C and less than 5% alloy additions. Economics has driven the development of these steels and the choice of alloying additions accordingly. With their low carbon content, these steels exhibit high ductility and notch toughness and are suitable for welding while still offering high yield strength (approximately 340–900 MPa). In addition, they show two to six times higher corrosion resistance compared with plain carbon steels. Depending on the final treatment, these steels can be either martensitic, bainitic, and, for some compositions, ferritic. These steels are not covered by SAE-AISI designations, although most of them can be found in ASTM specifications such as A514, A517, and A543. Thanks to their high strength and toughness values, these steels can be applied at lower final costs than plain carbon steels, which leads to a wide variety of applications. They are used as major members of large steel constructions, pressure valves, and in earth-moving and mining equipment.

Ultrahigh-strength steels are a group of alloy steels with yield strength in excess of 1300 MPa; some have plain-strain fracture toughness levels exceeding 100 MPa $\sqrt{\text{m}}$. Some of these steels are included in the SAE-AISI designation system and have medium carbon contents with low-alloy additions. Examples are steels in the SAE-AISI 4130 series, the higher-strength 4140, and the deeper hardening higher-strength 4340 steels. Starting from the 4340 alloy series, numerous modifications have been developed. Addition of silicon, for example, reduces the sensitivity to embrittlement on tempering at low temperatures (required to retain high strength levels). Addition of vanadium leads to grain refinement, which improves the strength and toughness of the material. Medium-carbon alloys can be welded in annealed or normalized condition, requiring a further heat treatment to recover the desired strength. If high fracture toughness as well as high strength is specifically desired, as for aircraft structural components, pressure vessels, rotor shafts for metal-forming equipment, drop hammer rods, and high-strength shock-absorbing automotive parts, high nickel (7–10.5%) and Co (4.25–14.50%) contents are used as primary alloying elements. While offering plane-strain fracture toughness of 100 MPa $\sqrt{\text{m}}$, HP-9-4-30 steel can exhibit tensile strength as high as 1650 MPa. Furthermore, this steel can be hardened to martensite in sections up to 150 mm thick. AF 1410 steel (developed by the US Air Force) has an ultimate tensile strength (UTS) of 1615 MPa and a K_{IC} value of 154 MPa $\sqrt{\text{m}}$.

The group of *alloy steels for elevated- or low-temperature applications* includes two different alloying systems. For high-temperature applications, chromium-molybdenum steels offer a good combination of oxidation and corrosion resistance (provided by the chromium content of up to 9%) on the one hand and high strength at elevated temperatures (provided by the molybdenum content of 0.5–1.0%) on the other. These steels can be applied at temperatures up to 650 °C for pressure vessels and piping in the oil and gas industries and in fossil-fuel and nuclear power plants. In low-temperature service applications such as storage tanks for liquid hydrocarbon gases and structures and machinery design for use in cold regions, ferritic steels with high nickel content (approximately 2–9%) are typically used.

Another important category of alloy steels are the *high-strength low-alloy steels* (HSLA). HSLA steels, or microalloyed steels, are designed to achieve specific mechanical properties rather than a chemical composition. So, the chemical composition can vary for different end-product thicknesses while still retaining specific mechanical properties. The low carbon content (0.05–0.25%) of these steels allows good formability and excellent weldability. Further alloying elements are added to meet the application requirements (Table 8.7), resulting in a division into six categories, as follows:

- Weathering steels, where small amounts of copper and phosphorus are added to improve the atmospheric corrosion resistance;
- Microalloyed ferritic-pearlitic steels, with small amounts (< 0.1%) of carbide-forming elements such as niobium, vanadium, or titanium, which enable precipitation strengthening and grain refinement;
- As-rolled pearlitic steels, with high strength, toughness, formability, and weldability, which have carbon, manganese, and further additions;
- Acicular ferrite (low-carbon bainite) steels (< 0.08%), which offer an excellent combination of high yield strength, weldability, formability, and good toughness;

Table 8.7 Characteristics and uses of HSLA steels according to ASTM standards [8.14]

ASTM specification[a]	Title	Alloying elements[b]	Available mill forms	Special characteristics	Intended uses
A 242	High-strength low-alloy structural steel	Cr, Cu, N, Ni, Si, Ti, V, Zr	Plate, bar, and shapes ≤ 100 mm in thickness	Atmospheric corrosion resistance four times that of carbon steel	Structural members in welted, bolted, or riveted construction
A 572	High-strength low-alloy niobium-vanadium steels of structural quality	Nb, V, N	Plate, bar, and sheet piling ≤ 150 mm in thickness	Yield strength of 290–450 MPa in six grades	Welded, bolted, or riveted structures, including many bolted or riveted bridges and buildings
A 588	High-strength low-alloy structural steel with 345 MPa minimum yield point ≤ 100 mm in thickness	Nb, V, Cr, Ni, Mo, Cu, Si, Ti, Zr	Plate, bar, and shapes ≤ 200 mm in thickness	Atmospheric corrosion resistance four times that of carbon steel; nine grades of similar strength	Welded, bolted, or riveted structures, but primarily welded bridges and buildings in which weight savings or added durability is important
A 606	Steel sheet and strip hot-rolled steel and cold-rolled, high-strength low-alloy steel with improved corrosion resistance	Not specified	Hot-rolled and cold-rolled sheet and strip	Atmospheric corrosion twice that of carbon steel (type 2) or four times that of carbon steel (type 4)	Structural and miscellaneous purposes for which weight savings or added durability is important
A 607	Steel sheet and strip hot-rolled steel and cold-rolled, high-strength low-alloy niobium and/or vanadium	Nb, V, N, Cu	Hot-rolled and cold-rolled sheet and strip	Atmospheric corrosion twice that of carbon steel, but only when copper content is specified; yield strength of 310–485 MPa in six grades	Structural and miscellaneous purposes for which greater strength or weight savings are important
A 618	Hot-formed welded and seamless high-strength low-alloy structural tubing	Nb, V, Si, Cu	Square, rectangular, round, and special-shape structural welded or seamless tubing	Three grades of similar yield strength; may be purchased with atmospheric corrosion resistance twice that of carbon steel	General structural purposes include welded, bolted, or riveted bridges and buildings
A 633	Normalized high-strength low-alloy structural steel	Nb, V, Cr, Ni, Mo, Cu, N, Si	Plate, bar, and shapes ≤ 150 mm in thickness	Enhanced notch toughness; yield strength of 290–415 MPa in five grades	Welded, bolted or riveted structures for service at temperatures at or above −45 °C
A 656	High-strength low-alloy, hot rolled structural vanadium-aluminum-nitrogen and titanium-aluminum steels	V, Al, N, Ti, Si	Plate, normally ≤ 16 mm in thickness	Yield strength of 552 MPa	Truck frames, brackets, crane booms, mill cars, and other applications where weight savings are important
A 690	High-strength low-alloy steel H-piles and sheet piling	Ni, Cu, Si	Structural-quality H-pills and sheet piling	Corrosion resistance two to three times greater than that of carbon steel in the splash zone of marine structures	Dock walls, sea walls, bulkheads, excavations, and similar structures exposed to seawater
A 709, grade 50 and 50 W	Structural steel	V, Nb, N, Cr, Ni, Mo	All structural shape groups and plate ≤ 100 mm thickness	Minimum yield strength of 345 MPa; grade 50 W is a weathering steel	Bridges

Table 8.7 (continued)

ASTM specification[a]	Title	Alloying elements[b]	Available mill forms	Special characteristics	Intended uses
A 714	High-strength low-alloy welded and seamless steel pipe	V, Ni, Cr, Mo, Cu, Nb	Pipe with nominal diameter of 13–660 mm	Minimum yield strength of ≤ 345 MPa and corrosion resistance two or four times that of carbon steel	Piping
A 715	Steel sheet and strip hot-rolled, high-strength low alloy with improved formability	Nb, V, Cr, Mo, N, Ti, Zr, B	Hot-rolled sheet and strip	Improved formability[c] compared with A 606 and A 607; yield strength of 345–550 MPa in four grades	Structural and miscellaneous applications for which high strength, weight savings, improved formability, and good weldability are important
A 808	High-strength low-alloy steel with improved notch toughness	V, Nb	Hot-rolled plate ≤ 65 mm in thickness	Charpy V-notch impact energies of 40–60 J (40–60 ft lfb) at −45 °C	Railway tank cars
A 812	High-strength low-alloy steel	V, Nb	Steel sheet in coil form	Yield strength of 450–550 MPa	Welded layered pressure vessels
A 841	Plate produced by thermomechanical controlled processes	V, Nb, Cr, Mo, Ni	Plates ≤ 100 mm in thickness	Yield strength of 310–345 MPa	Welded pressure vessels
A 847	Cold-formed, welded, and seamless high-strength low-alloy structural rubbing with improved atmospheric corrosion resistance	Cu, Cr, Ni, Si, V, Ti, Zr, Nb	Welded rubbing with maximum periphery of 1625 mm and wall thickness of 16 mm, or seamless tubing with maximum periphery of 810 mm and wall thickness of 13 mm	Minimum yield strength ≤ 345 MPa with atmospheric corrosion twice that of carbon steel	Round, square, or specially shaped structural tubing for welded, riveted, or bolted bridges and buildings
A 860	High-strength butt-welding fittings of wrought high-strength low-alloy steel	Cu, Cr, Ni, Mo, V, Nb, Ti	Normalized or quenched-and-tempered wrought fittings	Minimum yield strength ≤ 485 MPa	High-pressure gas and oil transmission lines
A 871	High-strength low-alloy steel with atmospheric corrosion resistance	V, Nb, Ti, Cu, Mo, Cr	As-rolled plate ≤ 35 mm thickness	Atmospheric corrosion resistance four times that of carbon structural steel	Tubular structures and poles

[a] For grades and mechanical properties
[b] In addition to C, Mn, P, and S. A given grade may contain one or more of the listed elements but not necessarily all of them; for specified compositional limits
[c] Obtained by producing killed steel, made to fine-grain practice, and with microalloying elements such as niobium, vanadium, titanium, and zirconium in the composition

Table 8.8 Compositions and properties of some widely used stainless steels [8.19]

AISI-SAE grade	Nominal composition (wt%) C	Cr	Ni	Others	Condition	Yield strength (MPa)	Tensile strength (MPa)	Elongation (%)
Austenitic grades

17–7	0.09	17	7	Al 1.0	Age-hardened	1585	1650	6

- Dual-phase steels, with martensitic portions finely dispersed in a ferritic matrix. These steels have high tensile strength and sufficient toughness;
- Inclusion-shape-controlled steels, in which the shape of sulfide is changed from elongated stringers to small, dispersed, near-spherical globules to improve ductility and toughness; elements which are suitable are, e.g., Ca, Zr, and Ti.

The allocation to a specific group is not rigorous; many of these steels have properties which would also allow their allocation to other groups mentioned.

Stainless Steels. Stainless steels in general contain at least 12% Cr, which forms a thin protective layer at the surface (Cr-Fe oxide) when exposed to air [8.19]. As shown above, chromium stabilizes the ferrite to remain stable up to the melting point, presuming, however, a low carbon content. Stainless steels can be differentiated depending on their crystal structure or the strengthening mechanisms according to Table 8.8. Ferritic stainless steels are relatively inexpensive and contain as much as 30% chromium but typically less than 0.12% C. They show good strength and intermediate ductility. Martensitic stainless steels typically contain less than 17% chromium to contract the austenitic region not too strongly but have higher C content of up to 1.0%. These alloys are used for high-quality knifes, ball bearings, or fittings.

Austenitic stainless steels are formed by the addition of nickel, offer high ductility, and are intrinsically not ferromagnetic. These alloys are well suited for high-temperature applications because of their high creep resistance and, thanks to their high toughness at low temperatures, for cryogenic service as well.

Precipitation-strengthened stainless steels contain additions such as Al, Nb, or Ta, which form precipitates such as Ni_3Al during heat treatment and can have very high strength levels.

Stainless steels with duplex microstructure consist of about 50% ferrite and austenite each. They show an ideal combination of strength, toughness, corrosion resistance, formability, and weldability, which no other stainless steel can supply.

Tool Steels. *Tool steels* are made to meet special quality requirements, primarily due to their use in manufacturing processes as well as for machining metals, woods, and plastics [8.20]. Some examples are cutting tools, dies for casting or forming, and gages for dimensional tolerance measurements. Tool steels are very clean ingot-cast wrought products with medium (minimum 0.35%) to high carbon content and high alloy (up to 25%) contents, making them extremely expensive. They must withstand temperatures up to 600 °C and should in addition have the following properties:

- Generally a high hardness to resist deformation.
- Resistance to wear for economical tool life, which depends directly on hardness; this can be increased by alloying with carbide-forming elements such as W and Cr.
- Dimensional stability. Dimensional changes of tools can be caused by microstructural alteration, by

exceeding the elastic limit, by transformation of the remaining austenite, and by changes of the grain dimensions. The highest dimensional stability is exhibited by ledeburitic cut steels with 12% chromium, which are used for precise cutting and punch tools.

- Working capability. To guarantee fault-free operation, tools must have a certain working capability, meaning that they should be able to collect elastic distortion energy to a certain degree. Therefore, steels with high toughness and at the same time high yield strength are required.
- Through hardening. The through-hardening capability can be improved by alloying with carbide formers such as Cr, Mo, and Mn, which additionally increase wear resistance.

Tool steels can be categorized into five principal groups; compositions and application examples are given in Table 8.9:

1. Cold-work tool steels, which include the oil-hardening O alloys, the water-hardening W alloys, the high-chromium class D (stainless steel), and the medium-alloy air-hardening class A alloys. Water-hardening grades have high resistance to surface wear but are not suited for high-temperature applications.
2. Shock-resistant tool steels in the S group of alloys, which are the toughest of the tool steels due to the presence of only 0.5% C and low-alloying additions.
3. Hot-work tool steels are class H alloys and include chromium, tungsten, and molybdenum alloying elements.
4. High-speed steels are either tungsten (T class) or molybdenum (M class) alloys. They have high hardness of 62–67 HRC and maintain this hardness at service temperatures as high as 550 °C.
5. Special-purpose tool steels are low-alloy (L) or mold tool steels (P).

From the compositions given in Table 8.9, it is obvious that the main alloying elements in tool steels are:

1. Chromium to increase hardenability, which if alloyed in excess forms $Cr_{23}C_6$ for high wear resistance.
2. Molybdenum and tungsten, which are strong hard carbide formers $(Mo,W)_6C$ that can be dissolved in austenite, and precipitate as fine particles in martensite upon annealing (secondary hardening, Fig. 8.16). Furthermore, they resist growth at low red heat.

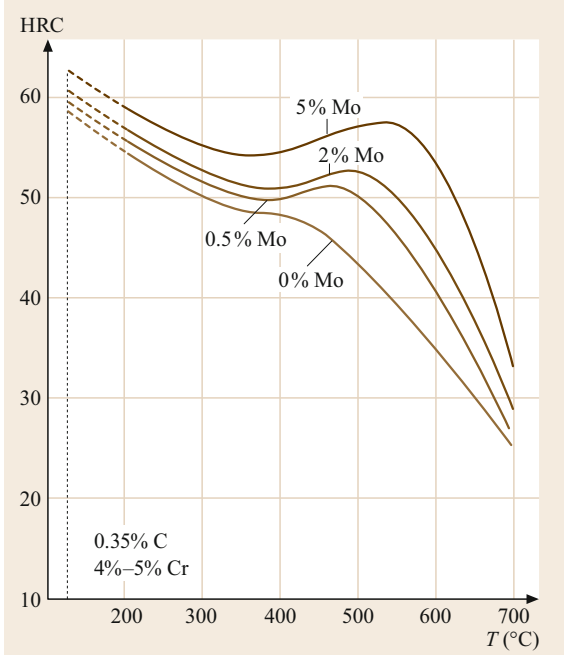

Fig. 8.16 Influence of molybdenum content on occurrence of a secondary hardening maximum during tempering (after [8.21])

3. Vanadium, which forms the hardest carbide V_4C_3, resists solution in austenite, and remains unchanged through heat treatment cycles .

8.1.4 Steel Castings and Cast Iron

Steel castings and cast iron are preferable for the manufacture of complex geometries at relatively low cost because expensive reworking steps are not necessary or only a few processing steps are required to obtain the final product [8.23]. Against this advantage there are two important restrictions, namely:

1. The appearance of cast defects and, in conjunction
2. Inferior mechanical properties compared with components prepared by deformation.

Iron-carbon cast materials can be roughly divided according to their carbon content into: 1. Steel castings (C < 2%) and 2. Cast iron (C > 2%).

Steel castings have a better combination of high strength and ductility compared with cast iron. However, because of their high melting point and strong shrinkage (about 2%) upon cooling, the castability of steel castings is poor and their affinity for cavity formation more pronounced. Therefore, steel castings are only used when high strength and toughness are

Table 8.9 Chemical composition and usage of selected tool steels [8.19]

Designation		Composition in % (with emphasis to show differences between steels belonging to each group)								Typical uses
AISI-SAE	UNS No.	C	Mn	Si	Cr	V	W	Mo	Co	
Water-hardening grades										
W1	T72301	0.7–1.5				0.1 max				Cold-heading dies, wood-working tools, etc.
W2	T72302	0.85–1.5				0.15–0.35				
Shock-resisting tool steels										
S1	T41901	0.4–0.55	0.1–0.4	0.15–1.2	1.00–1.80		1.50–3.00	0.5 max		Chisels, hammers, rivet sets, etc.

Tungsten high-speed steels										
T1	T12001	0.65–0.8			3.75–4.5	0.9–1.3	17.25–18.75			Original high-speed cutting steel, most wear-resistant grade
T15	T12015	1.5–1.6			3.75–5	4.5–5.25	11.75–13.0	1.0 max	4.75–5.25	
Molybdenum high-speed steels										
M1	T11301	0.78–0.88			3.5–4.0	1–1.35	1.4–2.1	8.2–9.2		Lower cost than T-type tools
M2	T11302	0.78–0.88			3.75–4.5	1.75–2.2	5.5–6.75	4.5–5.5		
M3	T11313	1.0–1.1			3.75–4.5	2.25–2.75	5.5–6.75	4.75–6.5		
M10	T11310	0.84–0.94			3.75–4.5	1.8–2.2				

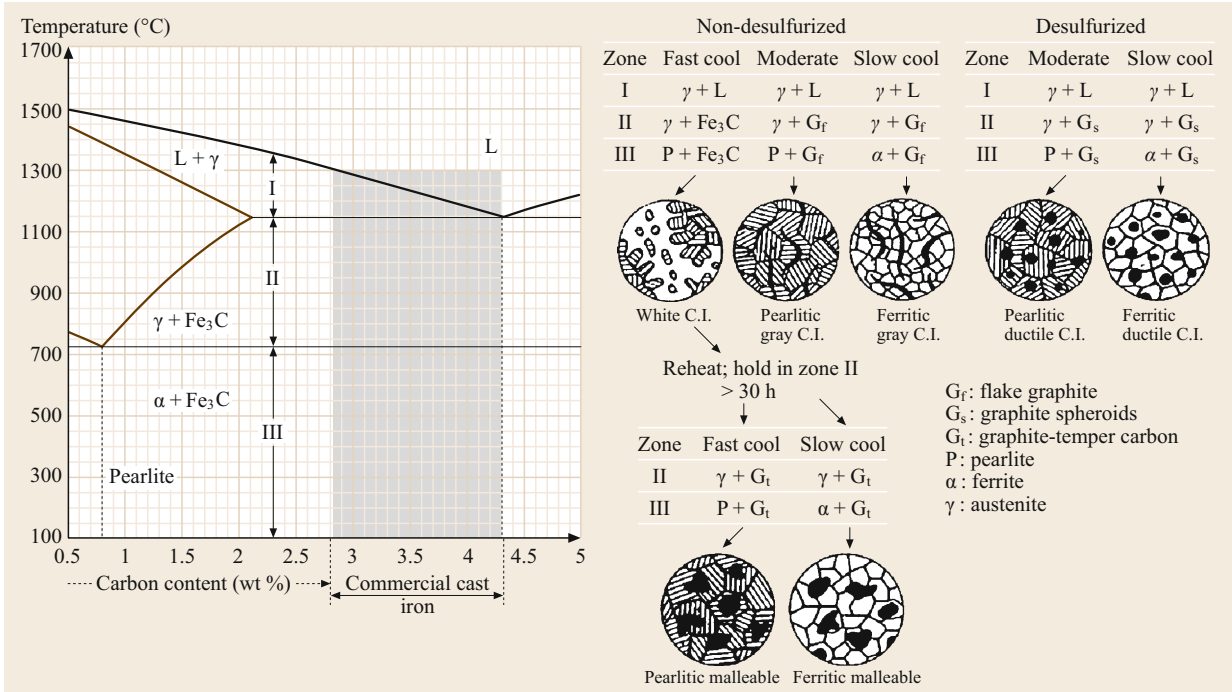

Fig. 8.17 Influence of casting conditions on resulting microstructure of cast irons (after [8.22])

a must, as in the case of permanent magnet castings and manganese hard castings. A far broader spectrum of applications exists for cast irons, based of the advantage that they are also very cost-efficient construction materials. The precipitation of carbon (as graphite) during solidification counteracts the normal shrinkage of the solidified metal.

Classification of Cast Irons

Cast irons solidify by the eutectic reaction and are generally ternary alloys of Fe with 2–4% C and 0.5–3% Si. With increasing contents of C and Si and decreasing cooling rate, the formation of stable graphite instead of unstable cementite is favored. Furthermore, their high carbon and silicon contents give cast irons excellent castability with melting points appreciably lower than those of steel. Pattern-making is no longer a necessary step in manufacturing cast-iron parts. Many gray, ductile, and alloy-iron components can be machined directly from bars that are continuously cast to near-net shape. Not only does this *parts without patterns* method save the time and expense of pattern-making, but continuous-cast iron also provides a uniformly dense, fine-grained structure, essentially free from porosity, sand, or other inclusions. Cast irons are usually not classified according to their chemical composition. The microstructure of the final product depends strongly upon foundry practice and the shape and size of the castings, which influence the cooling rate; so several entirely different types of iron may be produced starting with the same nominal composition. Thus, cast irons are usually specified by their mechanical properties. A principal classification can be made concerning their microstructure, which depends on the casting conditions:

1. Gray cast iron
2. Ductile cast iron
3. White cast iron
4. Compacted graphite iron
5. Malleable cast iron
6. High-alloy cast irons.

Gray cast iron is formed when excess carbon graphitizes during solidification to form separate graphite flakes. The resulting microstructure depends on the cooling rate from the eutectoid temperature downwards (region II in Fig. 8.17). If cooling is fast, pearlite (α-Fe + Fe_3C) is formed from the γ-Fe. If the cooling rate is slow, ferrite is formed during transformation and the material has lower strength compared with pearlitic gray cast iron. Depending on the cooling rate, a mixture of ferrite (surrounding the graphite flakes) and pearlite may be formed as well. The flake-type shape of the graphite in gray cast iron leads to generally brittle behavior. Furthermore, the impact strength of gray cast iron is low, and it does not exhibit a distinct yield

point. On the other hand, excellent damping against vibrations, excellent wear resistance, and acceptable fatigue resistance are desirable properties of gray cast iron. Typical applications are engine blocks, gears, flywheels, brake discs and drums, and machine bases.

In *ductile iron*, the form of the graphite is nodular or spheroidal instead of flake type. This is achieved by the addition of trace amounts Mg and/or Ce, which react with sulfur and oxygen. However, in ductile iron, the impurity level has to be controlled more precisely than in gray cast iron, since it affects nodule formation. Ductile cast iron exhibits improved stiffness and shock resistance. It exhibits good machinability and fatigue strength as well as high modulus of elasticity, yield strength, wear resistance, and ductility. Its damping capacity and thermal conductivity are lower than those of gray iron. By weight, ductile gray iron castings are more expensive than gray iron. Ductile iron is used in applications such as valve and pump bodies, crankshafts, heavy-duty gears or automobile door hinges, and nowadays with increasing frequency also as engine blocks.

Austempered ductile cast iron (ADI) is a subgroup of the ductile iron family but could be treated as a separate class of engineering materials. In contrast to the former, the matrix of this spheroidal graphite cast iron is bainitic (not pearlitic). This microstructure is obtained by isothermal transformation of austenite at temperatures below that at which pearlite forms. In terms of properties, the bainitic matrix has almost twice the strength of pearlitic ductile iron while retaining high elongation and toughness. While exhibiting superior wear resistance and fatigue strength, the castability of ADI is not very different from that of other ductile irons, but heat treatment is a critical issue to fully exploit its beneficial properties; For example, the yield strength of ADI is more than three times that of the best cast or forged aluminum. In addition ADI castings weigh only 2.4 times more than Al alloys and are 2.3 times stiffer. ADI is also 10% less dense than steel. Furthermore, for a typical component, ADI costs 20% less per unit weight than steel and half that of Al. A comparison of forged steel, pearlitic ductile iron, and ADI is presented in Table 8.10.

White cast irons are formed trough fast cooling and consist of Fe_3C and pearlite. The origin of this designation is the white-appearing crystalline fracture surface. While exhibiting excellent wear resistance and high compressive strength, the principal disadvantage of white cast iron is its catastrophic brittleness. Therefore, in most applications, white cast iron is only formed on the surface of cast parts, while the core consists of either gray cast iron or ductile iron. Examples of the application of white cast iron are mill liners and shot-blasting nozzles, as well as railroad brake shoes, rolling-mill rolls, and clay-mixing and brick-making equipment, crushers, and pulverizers.

Table 8.10 Mechanical properties of forged steel, pearlitic ductile iron, and ADI [8.23]

Mechanical property	Forged steel	Pearlitic ductile iron	Grade 150/100/7 ADI
Tensile strength (MPa)	790	690	1100
Yield strength (MPa)	520	480	830
Elongation (%)	10	3	10
Brinell hardness	262	262	286
Impact strength (ft-lb)	130	40	120

Compacted graphite iron (CGI), also known as vermicular iron, can be considered to be an intermediate between gray and ductile iron, possessing many of the favorable properties of each. CGI is difficult to produce successfully on a commercial scale because the alloy additions must be kept within very tight limits. The advantages of CGI compared with gray cast iron are its higher fatigue resistance and ductility, which are at the same levels as those of ductile iron. Its machinability, however, is superior to that of ductile iron, and its damping capacity almost as good as that of gray iron. This combination and the high thermal conductivity of CGI suggest applications in engine blocks, brake drums, and exhaust manifolds of vehicles.

Malleable iron is white iron that has been converted by a two-stage heat treatment to a condition in which most of its carbon content is in the form of irregularly shaped nodules of graphite, called temper carbon. In contrast to white iron, it is malleable and easily machined. The matrix of malleable cast iron may be ferritic, pearlitic, or martensitic. Ferritic grades are more machinable and ductile, whereas pearlitic grades are stronger and harder. Malleable iron castings are often used for heavy-duty bearing surfaces in automobiles, trucks, railroad rolling stock, and farm and construction machinery. Their applications are, however, limited to relatively thin-sectioned castings because of the high shrinkage rate and the need for rapid cooling to produce white iron.

High-alloy irons are ductile, gray, or white irons that contain 3% to more than 30% alloy content. The properties achieved by specialized foundries are significantly different from those of unalloyed irons. These irons are usually specified by chemical composition as well as by various mechanical properties. White high-alloy irons containing nickel and chromium develop a microstructure with a martensitic matrix around primary chromium carbides. This structure provides high hardness with extreme wear and abrasion resistance. High-chromium irons (typically, about 16%) combine

wear and oxidation resistance with toughness. Irons containing 14–24% nickel are austenitic; they provide excellent corrosion resistance for nonmagnetic applications. The 35% nickel irons have an extremely low coefficient of thermal expansion and are also nonmagnetic and corrosion resistant.

8.2 Aluminum and Its Alloys

8.2.1 General Properties

Despite the ten times higher cost of preparation of primary aluminum compared with pig iron, aluminum-based materials are today the second most widely used metallic materials. For structural applications in mechanical engineering, their most important advantage is an excellent combination of intrinsically good corrosion and oxidation resistance and high specific strength (strength-to-density ratio; Table 8.1) compared with stainless steels. However, with strength values as low as 45 MPa (1199-O), technically pure aluminum is very soft and requires the addition of alloying elements for most applications. In doing so, the strength can be increased considerably to almost 700 MPa (alloy 7055-T77). Because the specific stiffness (stiffness-to-density ratio) of aluminum alloys ($E \approx 70$ GPa) is comparable to that of steels ($E \approx 210$ GPa), components must have significantly larger dimensions (volume) in order to achieve a stiffness equal to that of their steel counterparts. However, various constructive arrangements, such as tabular or box-shaped hollow sections, locally strengthened rips, flanges welts, and coils, are known and can be used as an alternative to larger components. In contrast to steels, Al does not exhibit an endurance limit in fatigue. Moreover, the low hardness of aluminum leads to generally poor wear resistance.

Further important properties, which contribute to the still-growing applications of aluminum and its alloys, are their high electrical and thermal conductivity as well as good formability. Furthermore, the high chemical affinity of aluminum to oxygen leads to very acceptable corrosion and oxidation resistance but causes at the same time the high production costs mentioned. To manufacture primary aluminum based on aluminum oxide, a costly reduction (mostly smelting electrolytic reduction) is necessary. Bauxite with hydrated forms of aluminum oxide serves as the primary mineralogical source of alumina, since its reduction is economically most efficient amongst the different types of aluminum ore.

Al alloys can be very well machined by chip removal, and additions of Pb can prevent the formation of long chips in the case of pure aluminum or soft Al alloys. Joining of Al-based components can be done by all common procedures. Fusion welding is predominantly done by inert gas welding. Adhesion joints are also gaining in importance. Aluminum and its alloys do not show a sharp ductile-to-brittle transition temperature; rather they remain ductile even at very low temperatures. Comprehensive treatments of Al-based materials are given in [8.24–26].

8.2.2 Pure Aluminum

Commercial-purity aluminum, mainly manufactured by modified Hall–Héroult electrolysis, usually reaches a purity of 99.5–99.8%. On further electrolytic refinement (the three-layer method [8.24]) of commercially pure aluminum or secondary aluminum, superpurity aluminum (99.95–99.99%) can be prepared. Finally, for special purposes, aluminum can be further purified by zone melting to obtain aluminum with extreme purity of up to 99.999 95%. A classification of pure aluminum is presented in Table 8.11 from [8.24].

In the annealed condition, aluminum possesses only low strength at room temperature. By cold deformation, however, it is possible to improve its strength significantly, whereas the elongation is reduced considerably (Fig. 8.18).

Traditionally, pure aluminum is used in wrought condition for electrical conductors (EC aluminum).

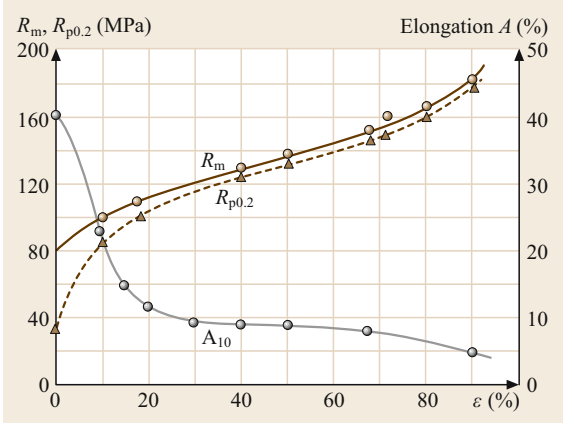

Fig. 8.18 Hardening of Al 99.5 strip (0.15 wt% Si, 0.28 wt% Fe) after recrystallization annealing and subsequent cold rolling. R_m – tensile strenght, $R_{p0.2}$ – 0.2% proof stress, A – elongation, ε – degree of cold work (after [8.6])

Table 8.11 The various degrees of purity of pure aluminum [8.24] as mentioned by the International Organization for Standardization (ISO), and the Aluminum Association (AA)

Aluminum (%)	Examples (ISO)	Examples (AA)	Designation
99.5000–99.7900	A 199.5–A 199.8	1050–1080, 1145	Commercial purity
99.8000–99.9490	A 199.8–A 199.95R	1080–1090, 1185	High purity
99.9500–99.9959	A 199.95R–A 199.99R	1098, 1199	Superpurity
99.9960–99.9990	A 199.99R	–	Extreme purity
> 99.9990	–	–	Ultra purity

Further important applications of aluminum are as foils for the food processing industries and in packaging practice (alloy 1145), as case components, boxes in tool-building, in the building industry as well as claddings, and to improve resistance to corrosion with heat-treatable Al alloys.

8.2.3 Aluminum Alloys

The major alloying elements of aluminum are copper, manganese, magnesium, silicon, and zinc. Depending on the production route to its final form, aluminum alloys may in principle be divided into wrought alloys and cast alloys. The wrought alloys can be classified into two main groups: 1. Age-hardenable alloys and 2. Non-age-hardenable alloys.

The nomenclature used for wrought alloys consists of four digits in the form 2xxx–8xxx, where the last two digits are the alloy identifier (Table 8.12). The second digit indicates certain alloy modifications (0 stands for the original alloy). A second designation is usually used, and describes the final temper treatment (Table 8.13).

Aluminum responds readily to strengthening mechanisms (Sect. 4.1) such as age hardening, solution hardening, and strain hardening, resulting in 2–30 times higher strength compared with pure aluminum (Table 8.14). Age hardening is the most effective hardening mechanism. It is based on the fact that the solubility of certain elements increases with increasing temperature. In the case of Cu as the alloying element, the maximum solubility is reached at about 550 °C (Fig. 8.19). For age hardening, the material is solution annealed in the single-phase region, quenched to room or low temperature, and finally age-hardened at higher temperatures (100–200 °C) to facilitate the formation of small precipitates. On further age hardening, the precipitates continue to grow, resulting in overaging (Fig. 8.19), which is accompanied by a loss in material strength.

The strength increase $\Delta\sigma$ is inversely proportional to the separation distance l of the precipitates and is giving in the peak-aged condition (Fig. 8.20) by $\Delta\sigma \approx 2Gb/l$, where G is the shear modulus and $\boldsymbol{b}$ is the Burgers vector.

Table 8.12 Constitution of aluminum alloys

Wrought alloys	
1xxx Commercially pure Al (> 99% Al)	Not aged
2xxx Al-Cu	Age hardenable
3xxx Al-Mn	Not aged
4xxx Al-Si and Al-Mg-Si	Age hardenable if Mg is present
5xxx Al-Mg	Not aged
6xxx Al-Mg-Zn	Age hardenable
7xxx Al-Mg-Zn	Age hardenable
8xxx Other elements (for example Al-Li)	Depends on additions
Casting alloys	
1xx.x Commercially pure Al	Not aged
2xx.x Al-Cu	Age hardenable
3xx.x Al-Si-Cu or Al-Mg-Si	Some are age hardenable
4xx.x Al-Si	Not aged
5xx.x Al-Mg	Not aged
7xx.x Al-Mg-Zn	Age hardenable
8xx.x Al-Sn	Age hardenable
9xx.x (Other elements)	Depends on additions

However, on further annealing, the precipitates can grow by Ostwald ripening; i.e., small precipitates are consumed while larger particles grow continuously at their expense. This process results in a severe strength decrease when the material is exposed to high temperatures during service (Fig. 8.21).

Depending on the alloying additions, different strengthening mechanisms are activated:

- 2xxx: Precipitation of Cu-rich phases allows the formation of high-strength alloys at the expense of weldability. Precipitation from the α-solid solution appears in the following order: $\alpha_{ss} \rightarrow \alpha +$ GP-I $\rightarrow \alpha +$ GP-II $\rightarrow \alpha + \theta' \rightarrow \alpha + \theta$ with GP = Guinier–Preston zone. As shown in Fig. 8.22, the highest strength is reached when coherent GP-II zones have been formed, where Orowan bypassing and precipitation cutting require almost the same amount of energy.
- 3xxx: These alloys are single-phase alloys except for the presence of inclusions or intermetallic compounds. Their strength is achieved by a solid solu-

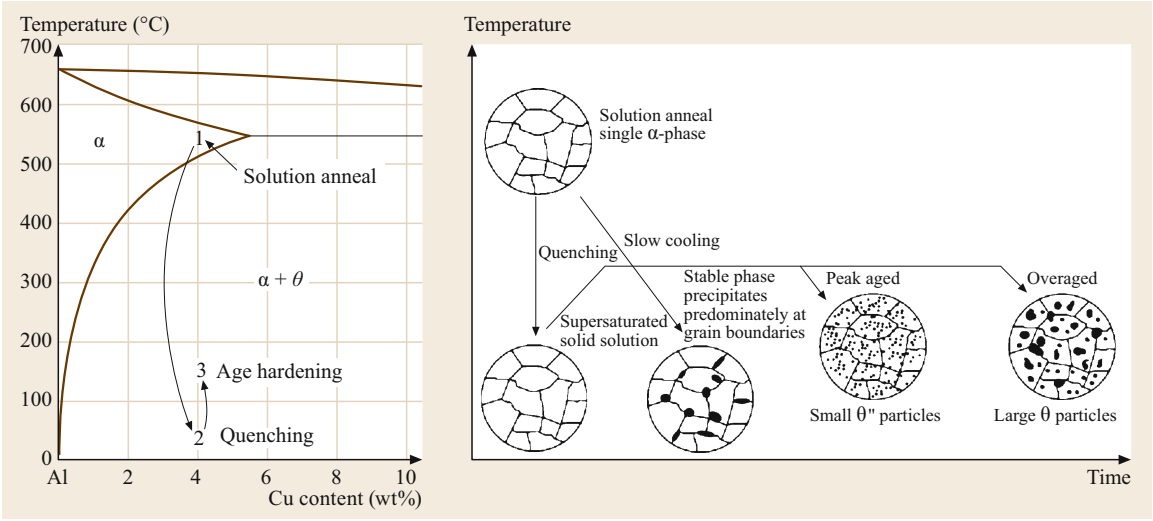

Fig. 8.19 Principle of age hardening in Al-based alloys

Table 8.13 Heat treatments of aluminum alloys

F	As-fabricated (hot worked, forged, cast, etc.)	
O	Annealed (in the softest possible condition)	
H	Cold worked	
	H1x	cold worked only ("x" refers to the amount of cold work and strengthening)
	H-12	cold work that gives a tensile strength midway between the O and H14 tempers
	H-14	cold work that gives a tensile strength midway between the O and H18 tempers
	H-16	cold work that gives a tensile strength midway between the H14 and H18 tempers
	H-18	cold work that gives about 75% reduction
	H-19	cold work that gives a tensile strength greater than 2000 psi of that obtained by the H18 temper
	H2x	cold worked and partly annealed
	H3x	cold worked and stabilized at low temperature to prevent age hardening of the structure
W	Solution treated	
T	Age hardened	
	T1	cooled from the fabrication temperature and naturally aged
	T2	cooled from the fabrication temperature, cold worked, and naturally aged
	T3	solution treated, cold worked, and naturally aged
	T4	solution treated and naturally aged
	T5	cooled from the fabrication temperature and artificially aged
	T6	solution treated and artificially aged
	T7	solution treated and stabilized by overaging
	T8	solution treated, cold worked, and artificially aged
	T9	solution treated, artificially aged, and cold worked
	T10	cooled from the fabrication temperature, cold worked, and artificially aged

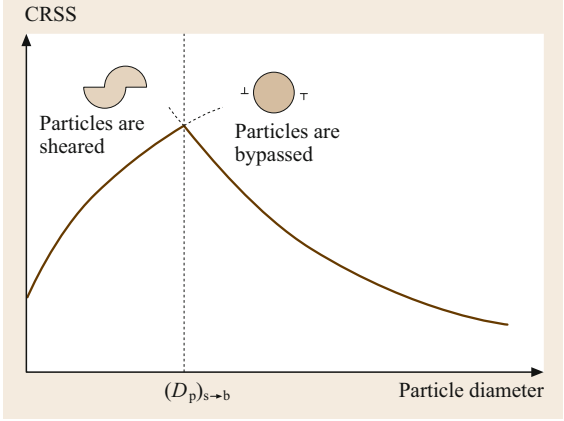

Fig. 8.20 Change in critical resolved shear stress (CRSS – at which dislocations glide freely in single crystals) as a function of particle (precipitate) size. Maximum strength is obtained when the dislocation interaction changes from shearing to Orowan bypassing. In the peak-aged condition, the average particle size corresponds to D_p and the particle size variation should be marginal (after [8.24])

tion of Mn and is not as high as for 2xxx alloys, but they exhibit excellent corrosion and oxidation resistance and are weldable.

- 4xxx: The high strength of this group of wrought alloys is achieved via a solid solution of Mg and in the case of the presence of Si by the formation of finely dispersed Mg_2Si particles as well.
- 5xxx: These alloys are strengthened by a solid solution of Mg and contain a second phase: Mg_2Al_3 particles, a hard and brittle intermetallic compound.

Table 8.14 Effect of strengthening mechanisms on mechanical properties of aluminum alloys (after data in [8.26])

Material	Tensile strength (MPa)	Yield strength (MPa)	Elongation (%)	Yield strength (alloy) / Yield strength (pure)
Pure annealed Al (99.999% Al)	45	17	60	
Commercially pure Al (annealed, 99% Al)	90	34	45	2.0
Solid-solution strengthened (1.2% Mn)	110	41	35	2.4
75% cold-worked pure Al	165	152	15	8.8
Dispersion strengthened (5% Mg)	290	152	35	8.8
Age hardened (5.6% Zn, 2.5% Mg)	570	503	11	29.2

Table 8.15 Mechanical properties and applications of selected aluminum alloys (after [8.26])

Alloy	Chemical composition	Condition	Tensile strength (MPa)	Yield strength (MPa)	Elongation (%)	Typical applications
3003	1.2 Mn	Annealed (-O) Half-hard (-H14)	110 150	40 145	30 8	Pressure vessels, builders' hardware, sheet metal work
5052	2.5 Mg, 0.25 Cr	Annealed (-O) Half-hard (-H32)	195 230	90 195	25 12	Sheet metal work, hydraulic tubes, appliances

formation of $MgZn_2$ particles in the followingsequence: $\alpha_{ss} \rightarrow \alpha + \text{GP zones} \rightarrow \alpha + \eta\,(MgZn_2) \rightarrow \alpha + \eta\,(MgZn_2)$. Most alloys of this group are not weldable. An exemption is the alloy 7005, which is used as a standard alloy for bike frames.

Mechanical properties and some typical applications of selected aluminum alloys are presented in Table 8.15.

Cast aluminum alloys are developed to have good fluidity and feeding ability during casting. Their designation (Table 8.12) is based on three major digits of the form 2xx–9xx, giving the alloy group, and a further digit following a dot, which indicates the material form (casting/ingot). The most widely used casting alloys belong to the 300 series (319 and 356), where hardening is done by Cu or Mg_2Si precipitates. Examples of casting alloys are presented in Table 8.16.

8.3 Magnesium and Its Alloys

8.3.1 General Properties

Magnesium is the lightest structural metal, with a density close to that of polymers (plastics). It is therefore not surprising that Mg alloys are especially found in applications where the weight of a workpiece is of paramount importance, as is generally the case in the transportation industry. In recent years, magnesium cast alloys have particularly becoming increasingly important and have partly replaced well-established Al-based alloys. The main reason is the excellent die-filling characteristics of magnesium, which allow large, thin-walled, and unusually complex castings to be produced economically. Magnesium can be cast with thinner walls (1−1.5 mm) than plastics (2−3 mm) or aluminum (2−2.5 mm) and, by designing appropriately located ribs, the stiffness disadvantage of magnesium versus aluminum can be compensated without increasing the wall thickness of the overall magnesium part.

Further positive properties to be noted are the excellent machinability, high thermal conductivity (Chap. 5), and good weldability. However, Mg alloys suffer from poor corrosion resistance, and their manufacturing costs are comparatively high. With its hexagonal close-packed crystal structure, the room-temperature deformation behavior of Mg alloys is moderate, resulting in poor cold workability. Thus, all current applications are manufactured through casting. Furthermore, Mg is a very reactive metal and readily oxidizes when exposed to air. Since pure Mg is only of minor importance for structural applications, it appears almost always in

Table 8.17 Designation of Mg alloys

1.	Two letters which indicate the major alloying additions (A for Al; Z for Zn; M for Mn; K for Zr; T for Sn; Q for Ag; C for Cu; W for Y; E for rare earths)
2.	Two or three numbers which indicate the nominal amounts of alloying elements (rounded off to the nearest percent)
3.	A letter which describes the variation from the normal alloy
4.	If needed, the temper treatment according to Table 8.18

Table 8.18 Temper designations (after [8.6])

General designations	
F	As fabricated
O	Annealed, recrystallized (wrought products only)
H	Strain-hardened
T	Thermally treated to produce stable tempers other than F, O, or H
W	Solution heat-treated (unstable temper)
Subdivisions of H	
H1, Plus one or more digits	Strain-hardened only
H2, Plus one or more digits	Strain-hardened and then partially annealed
H3, Plus one or more digits	Strain-hardened and then stabilized
Subdivisions of T	
T2	Annealed (cast products only)
T3	Solution heat-treated and cold worked
T4	Solution heat-treated
T5	Artificially aged only
T6	Solution heat-treated and artificially aged
T7	Solution heat-treated and stabilized
T8	Solution heat-treated, cold worked, and artificially aged
T9	Solution heat-treated, artificially aged, and cold worked
T10	Artificially aged and cold worked

alloyed condition with additions such as Al and Zn. A comprehensive treatment of Mg and its alloys is given in [8.29].

8.3.2 Magnesium Alloys

Major alloying elements of Mg are Al, Zn, and Mn, while elements such as Sn, Zr, Ce, Th, and B are occasionally of importance. Impurities in Mg alloys are commonly Cu, Fe, and Ni. Mg alloys are designated based on the main alloying elements (such as AZ for aluminum and zinc) followed by the amount of additives and a letter that indicates the variation with respect to the normal alloy (Table 8.17). When referring to mechanical properties, it is useful to indicate the temper treatment as well (Table 8.18). The alloy AZ91A, for example, is a Mg-based alloy with nominally about 9% Al and 1% Zn, while the letter A indicates that only minor changes to the normal alloy were carried out.

An overview of the general effect of certain alloying additions is presented in Table 8.19 [8.6, 29–31]. The addition of up to 10% aluminum (Mg-Al alloys) increases the strength (age hardenable), castability, and corrosion resistance. During precipitation heat treatment, the intermetallic phase $Mg_{17}Al_{12}$ is formed and is usually not finely distributed enough to lead to a strong strengthening effect. The supplementary addition of zinc (Mg-Al-Zn alloys) improves the strength of Mg-Al alloys by refining the precipitates and by solid-solution strengthening. The frequently used alloy AZ91, for example, offers yield strength and ductility levels that are comparable to those of its aluminum counterpart

Table 8.19 General effects of alloying elements in magnesium materials (after [8.6], see also [8.29–31])

Series	Alloying elements	Melting and casting behavior	Mechanical and technological properties
AZ	Al, Zn	Improve castability; tendency to microporosity; increase fluidity of the melt; refine weak grains	Solid-solution hardener; precipitation hardening at low temperatures (< 120 °C); improve strength at ambient temperatures; tendency to brittleness and hot shortness unless Zr is refined
QE	Ag, rare earths	Improve castability; reduce microporosity	Solid-solution and precipitation hardening at ambient and elevated temperatures; improve elevated-temperature tensile and creep properties in presence of rare-earth metals
AM	Al, Mn	Improve castability; tendency to microporosity; control of Fe content by precipitating Fe-Mn compound; refinement of precipitates	Solid-solution hardener; precipitation hardening at low temperatures (< 120 °C); increase creep resistivity
AE	Al, rare earth	Improve castability; reduce microporosity	Solid-solution and precipitation hardening at ambient and elevated temperatures; improve elevated-temperature tensile and creep properties; increase creep resistivity
AS	Al, Si	Tendency to microporosity; decreased castability; formation of stable silicide alloying elements; compatible with Al, Zn, and Ag; refine weak grains	Solid-solution hardener, precipitation hardening at low temperatures (< 120 °C); improves creep properties
WE	Y, rare earths	Grain refining effect; reduce microporosity	Improve elevated-temperature tensile and creep properties; solid-solution and precipitation hardening at ambient and elevated temperatures

Table 8.20 Typical tensile properties and characteristics of selected cast Mg alloys (after [8.6], see also [8.29–31])

ASTM designation	Condition	Tensile properties			Characteristics
		0.2% proof stress (MPa)	Tensile strength (MPa)	Elongation to fracture (%)	
AZ63	As-sand cast	75	180	4	Good room-temperature strength and ductility
	T6	110	230	3	
AZ81	As-sand cast	80	140	3	Tough, leak-tight casting with 0.0015 Be, used for pressure die casting
	T4	80	220	5	
AZ91	As-sand cast	95	135	2	General-purpose alloy used for sand and die casting
	T4	80	230	4	
	T6	120	200	3	
	As-chill cast	100	170	2	
	T4	80	215	5	
	T6	120	215	2	
AM50	As-die cast	125	200	7	High-pressure die casting
AM20	As-die cast	105	135	10	Good ductility and impact strength
AS41	As-die cast	135	225	4.5	Good creep properties up to 150 °C
AS21	As-die cast	110	170	4	Good creep properties up to 150 °C
ZK51	T5	140	253	5	Sand casting, good room-temperature strength and ductility
ZK61	T5	175	275	5	As for ZK51
ZE41	T5	135	180	2	Sand casting, good room-temperature strength, improved castability
ZC63	T6	145	240	5	Pressure-tight casting, good elevated-temperature strength, weldable
EZ33	Sand cast T5	95	140	3	Good castability, pressure-tight, weldable, creep resistant up to 250 °C
	Chill cast T5	100	155	3	
HK31	Sand cast T6	90	185	4	Sand casting, good castability, weldable, creep resistant up to 350 °C
HZ32	Sand or chill cast T5	90	185	4	As for HK31
QE22	Sand or chill cast T6	185	240	2	Pressure-tight and weldable, high proof stress up to 250 °C
QH21	As-sand cast T6	185	240	2	Pressure-tight, weldable, good creep resistance and stress-proof to 300 °C
WE54	T6	200	285	4	High strength at room and elevated temperatures, good corrosion resistance
WE43	T6	190	250	7	Weldable

A380. However, in terms of high-temperature creep resistance (applications limited to about 125 °C), fatigue strength, and corrosion resistance, the alloy AZ91 is inferior to Al alloys. Its application is therefore restricted to nonstructural components such as brackets, covers, cases, and housings. With the development of the low-impurity AZ91D alloy (Fe < 0.005%; Ni < 0.001%, Cu < 0.015%), the corrosion resistance has been dramatically improved. For structural applications where crashworthiness is important, such as instrument panels, steering systems, and seating structures, magnesium die-cast alloys with small amounts of manganese (Mg-Al-Mn alloys) such as AM50 or AM60 are used, as they offer higher ductility (expensive to failure 10–15%). These alloys are less expensive than Al alloys. The poor high-temperature creep resistance of Mg alloys is the reason why these alloys are rarely found in automotive powertrains. The high operating temperatures (transmission cases: 175 °C, engine blocks: > 200 °C) are already a challenge for aluminum alloys, which have higher creep resistance. For this application, Mg alloys containing rare-earth elements are under development to improve the creep resistance by precipitation strengthening (some examples such as QE22 and WE43 are given in Tables 8.20, 8.21 [8.6, 29–31]).

Table 8.21 Typical tensile properties and characteristics of selected wrought Mg alloys (after [8.6], see also [8.29–31])

ASTM designation	Condition	Tensile properties			Characteristics
		0.2% proof stress (MPa)	Tensile strength (MPa)	Elongation to fracture (%)

8.4 Titanium and Its Alloys

8.4.1 General Properties

With a density below 5 g/cm^3 (Table 8.1), titanium, like aluminum and magnesium, belongs to the light structural materials. However, in contrast to Al and Mg, it also offers a high melting point of $T_m = 1670\,°C$, which is even higher than that of pure iron. Furthermore, amongst the materials which are under consideration for light structural constructions, Ti-based alloys have the highest specific strength (Table 8.1) and excellent corrosion resistance in oxidizing acids, chloride media, and most neutral environments. Titanium is well known for its biocompatibility, low thermal conductivity ($\kappa = 21\,W\,m^{-1}\,K^{-1}$), and low coefficient of thermal expansion ($\lambda = 8.9 \times 10^{-6}\,K^{-1}$). Beside a slightly lower specific stiffness compared with iron-based materials, the most annoying disadvantage of Ti and its alloys is the high manufacturing cost, which is about six times that of aluminum and ten times that of stainless steels. Therefore, Ti alloys are primary used in areas where strength-to-weight ratio and elevated-temperature properties are of prime importance, i.e., in aerospace applications (Fig. 8.23 [8.26]).

As an allotropic material, Ti undergoes a structural phase transformation at 883 °C from an (almost) closed-packed hexagonal structure (α) to a body-centered cubic high-temperature phase (β). By alloying additions and applying appropriate heat treatments, titanium alloys can be age hardened to form a two-phase (α + β) alloy. The solubility of interstitials such as O, N, C, and H is very high, on the one hand allowing the strength to be increased by solid-solution hardening, but on the other hand leading to a severe reduction of toughness when the material is penetrated by gases. Comprehensive treatments on Ti and its alloys can be found in [8.30, 32, 33].

8.4.2 Commercially Pure and Low-Alloy Grades of Titanium

Commercially pure grades of titanium in the purity range of 99.0–99.5% can actually be considered to be

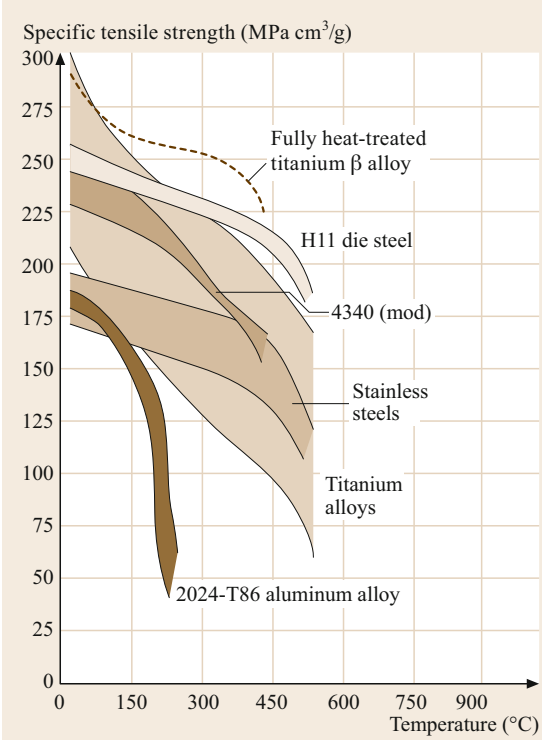

Fig. 8.23 High-temperature properties of Ti alloys compared with those of steels and aluminum alloys (after [8.26])

α-phase alloys, since they contain certain levels of O, N, C, and Fe, resulting from the manufacturing process. Furthermore, oxygen may be added deliberately for solid-solution strengthening. Interstitials in titanium are very effective strengtheners; a 0.1% oxygen equivalent (% O equivalent = % O + 2% N + 0.67% C) in pure titanium increases the strength by about 120 MPa. However, interstitials counteract the fracture toughness; some applications, especially at low temperatures, may therefore require titanium grades with extralow interstitials (ELI). Despite its hcp structure, Ti exhibits surprisingly high room-temperature ductility and can be cold-rolled to > 90% without crack formation. This behavior is attributed to the relative ease of activating slip systems and the availability of twinning planes in the crystal lattice. The chemical composition and mechanical properties of commercially pure and low-alloy grades of titanium are presented in Table 8.22.

8.4.3 Titanium Alloys

Alloying additions, which are usually added to improve the mechanical properties of Ti, influence the phase stability in different manners. The low-temperature hexagonal α-phase is stabilized by the impurities O, N, and C as well as by Al and Sn (Table 8.23), whereas elements such as V, Mo, and Cr expand the β-phase stability region (the Ti-rich part of the Ti-Al and the Ti-Mo phase diagram are shown in Fig. 8.24 [8.34]).

By varying the alloying content, pure α- or β-phase alloys can be stabilized at room temperature, as well as a mixture of both phases. α-Phase Ti alloys have high solid solubility at room temperature and are weldable. The most widely used α-Ti alloy is Ti-5Al-2.5Sn (Table 8.24). While offering the highest strength levels

Table 8.23 Alloying elements in Ti alloys [8.26, 30, 32]

Alloying element	Range (approx.) (wt%)	Effect on structure
Carbon, oxygen, nitrogen	–	α stabilizer
Aluminum	2–7	α stabilizer
Tin	2–6	α stabilizer
Vanadium	2–20	β stabilizer
Molybdenum	2–20	β stabilizer
Chromium	2–12	β stabilizer

among the Ti alloys and the ability for cold working, the usage of β-phase alloys is rather limited compared with pure α- or α + β-alloys. Besides costs, the reasons for this include the higher density, caused by the addition of V or Mo, the low ductility in the high-strength condition, and the poor fatigue performance in thick sections, which is caused by segregations at grain boundaries. The most widely used group (about 60%) of Ti alloys are two-phase α + β-alloys, with Ti-6Al-4V being the most prominent representative. These alloys are heat treatable and allow large variations of the microstructure by altering the cooling and heat-treatment conditions. Some typical applications of α + β-alloys and the conditions of their usage are presented in Table 8.25.

8.4.4 Two-Phase Intermetallic Ti-Al Alloys

With density as low as 3.5 g/cm^3 and specific stiffness as high as 45 GPa cm^3/g (steel: 27 GPa cm^3/g), intermetallic compounds in the Ti-Al system are attractive candidates for use in high-temperature applications [8.36], mainly because of their unique combination of very low density and high melting point (> 1350 °C). The most promising alloys are Ti-rich two-phase (γ-TiAl and α_2-Ti_3Al) Ti-Al alloys with lamellar or duplex microstructures, which can be adjusted by adequate heat treatments (Fig. 8.25). Additions such as Cr and Nb lead to further enhancement of the mechanical properties and allow elongations of up to about 3%, while the room-temperature toughness values of 10–35 MPa $\sqrt{m}$ underline their principal suitability as constructional materials.

8.4.5 Ti-Ni Shape-Memory Alloys

Ti-Ni alloys are the most prominent representatives of shape-memory alloys [8.37]. The shape-memory effect, allowing the return of a highly deformed material to its starting shape, is based on a reversible martensitic trans-

formation. In the case of Ti-Ni, this effect is provided by a transition of the cubic, high-temperature B2 structure to the monoclinic low-temperature B19 structure upon cooling or by deformation. The transformation start (M_s) temperature can be varied between −200 and 110 °C by altering the Ni content. Therefore, the transformation can be reversed either on heating or on releasing the stress isothermally. For further reading, see [8.6, 37].

8.5 Ni and Its Alloys

8.5.1 General Properties

Due to its similarity to Fe with respect to the most relevant physical (and chemical) properties such as density, Young's modulus, melting point, thermal conductivity, and CTE (Chap. 5), it is straightforward to conclude that nickel is one of the major alloying elements in Fe-based alloys. Since Ni possesses an fcc crystal structure, it stabilizes the austenite in Fe-based alloys at higher concentrations. In fact, over 60% of the annual Ni consumption is devoted to alloying of stainless steels and a further 10% is used in (ferritic) alloy steels.

Nickel forms extensive solid solutions with many other elements: complete solid solutions with Fe and Cu (such as those exemplified by the phase diagrams in Figs. 3.30 and 3.31) and limited solid solutions with 35 wt% Cr, 20 wt% Mo, 10 wt% Al, Ti, to mention only the most important. Based on the fcc crystal structure, Ni and its solid solutions show high ductility, fracture toughness, and formability.

Ni-Fe alloys exhibit ferromagnetism over a wide range of compositions which, in combination with their other intrinsic properties, gives rise to alloys with soft magnetic [8.38] and controlled thermal expansion properties (*Invar alloy*, Sect. 8.1.3, *Effect of Alloying Elements*). Ti-Ni shape-memory alloys are briefly discussed in Sect. 8.4.5. Finally, nickel plating is widely used for decorative applications. Most frequently, electroless deposition of either Ni-P or Ni-B binary solutions is carried out by autocatalytic reduction of Ni ions from aqueous solutions. For more details, see [8.39].

Besides these functional applications, structural applications of nickel and its alloys can be essentially grouped into two categories, namely: 1. Corrosion-resistant alloys and 2. High-temperature alloys.

These are briefly described in the following two subsections. A survey on commonly used alloying additions in nickel and their effects on its properties and applications is shown in Fig. 8.26.

8.5.2 Corrosion-Resistant Alloys

The main application of commercially pure nickel is to combine corrosion resistance with outstanding formability. The 200 alloy series typically contains minor amounts of less than 0.5 wt% Cu, Fe, Mn, C, and Si. According to Fig. 8.23, the intrinsically good corrosion resistance of nickel 200 can be substantially improved by high alloying in solid solution with:

- Cu for increased resistance against seawater and reducing acids, leading to the Monel alloys (e.g., 400, K-500)
- Mo for increased resistance against reducing acids and halogens, leading to the Hastelloy alloys (B2, B3)
- Cr for increased high-temperature strength and resistance to oxidizing media, leading to alloy 600 (which also contains about 8 wt% Fe, mainly for economic reasons).

Alloy 600 can be considered to be the base alloy for a series of further high-alloyed Ni-base alloys for use in various applications in aggressive environments, as displayed in Fig. 8.26. An extensive compilation of chemical compositions and mechanical properties can be found in [8.6], while some typical examples of Ni alloys are presented in Table 8.26 together with their corresponding fields of application.

8.5.3 Ni-Based Superalloys

The term "superalloy" is generally used for metallic alloy systems which can operate under structural loading conditions at *elevated temperatures* above 1200 °F (or around 650 °C correspondingly). Note that this is synonymous with operating under creep conditions since $T_{app} > 0.5T_m$ (Chap. 5). As displayed in Fig. 8.27, superalloys can be grouped into three main subcategories according to the strengthening mechanism (Sect. 4.1.2) employed. One distinguishes:

1. Solid-solution-strengthened Fe, Ni and Co alloys
2. Carbide-strengthened Co alloys (see next section) and most prominently
3. Precipitation-strengthened Ni and Ni-Fe alloys.

The paramount importance of the latter group regarding high-temperature creep strength stems from alloying with Al and Ti, which leads to the formation

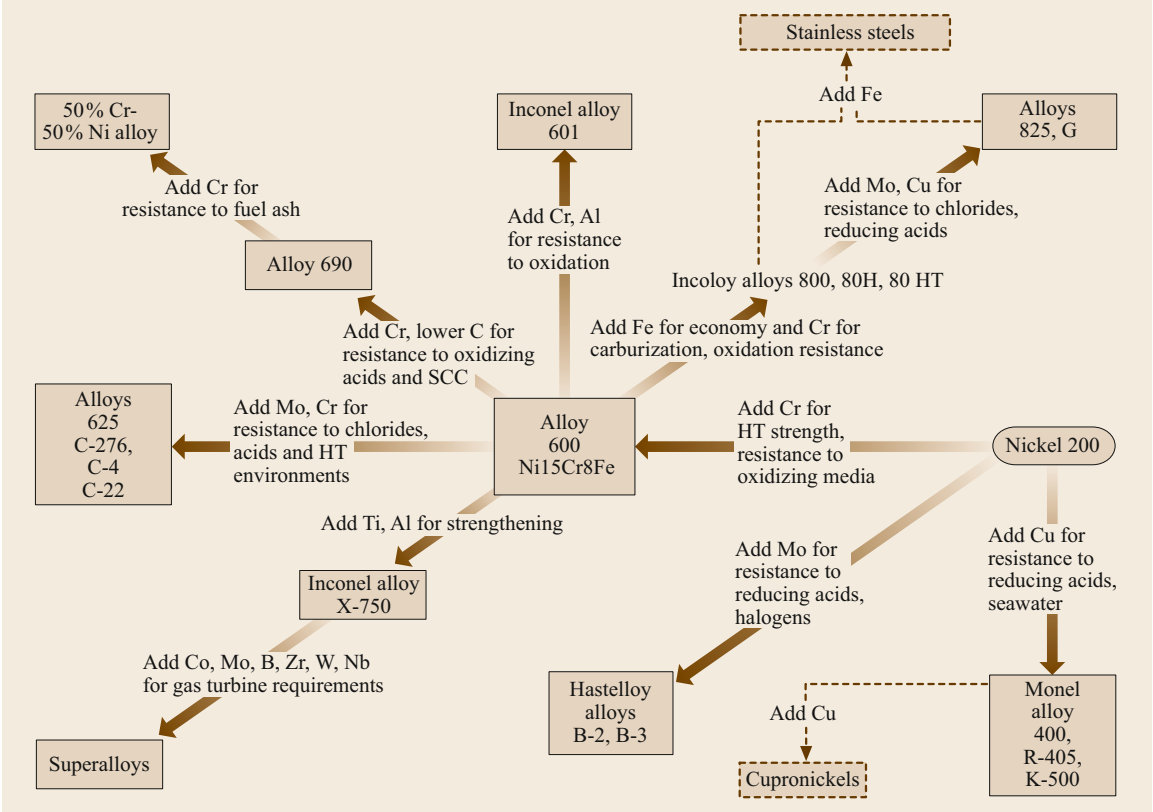

Fig. 8.26 Effects of alloying additions on corrosion resistance of nickel alloys (HT denotes high temperature, SCC denotes stress corrosion cracking) (after [8.6])

Table 8.26 Typical applications and properties of Ni-based alloys and superalloys

Material	Tensile strength (MN/m^2)	Yield strength (MN/m^2)	Elongation (%)	Strengthening mechanism	Application
Pure Ni (99.9% Ni)	345	110	45	Annealed	Corrosion resistance
	655	620	4	Cold-worked	Corrosion resistance
Ni-Cu alloys					
Monel 400 (Ni-31.5% Cu)	540	270	37	Annealed	Valves, pumps, heat exchangers
Monel K-500 (Ni-29.5% Cu-2.7% Al-0.6% Ti)	1030	760	30	Aged	Shafts, springs, impellers
Ni superalloys					
Inconel 600 (Ni-15.6% Cr-8% Fe)	620	200	49	Carbides	Heat-treatment equipment
Hastelloy B-2 (Ni-28% Mo)	900	415	61	Carbides	Corrosion resistance
DS-Ni (Ni-2% ThO_2)	490	330	14	Dispersion	Gas turbines
Fe-Ni superalloys					
Incoloy 800 (Ni-46% Fe-21% Cr)	615	258	37	Carbides	Heat exchangers
Co superalloys					
Stellite 6B (60% Co-30% Cr-4.5% W)	1220	710	4	Carbides	Abrasive wear resistance

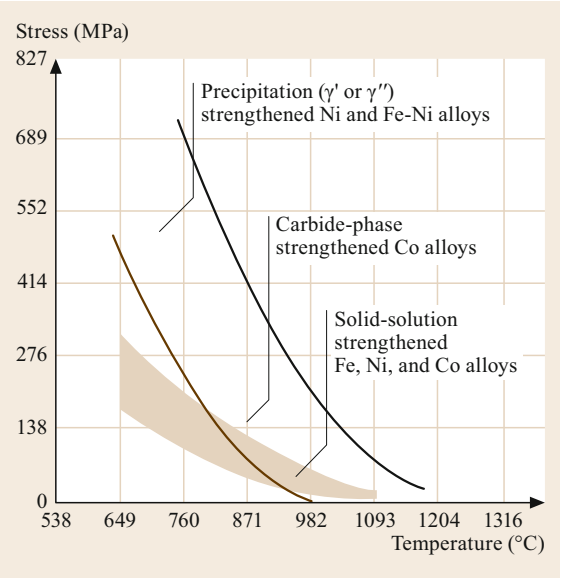

Fig. 8.27 Temperature dependence of 100-h stress-rupture characteristics of wrought superalloys (after [8.6])

of a coherent ordered intermetallic γ′-Ni_3(Al,Ti) phase. This $L1_2$ crystal structure has a superlattice structure with regard to the disordered fcc structure of the γ phase. The binary Al-Ni phase diagram (Fig. 8.28) clearly demonstrates that the γ′ phase is stable up to its melting point close to 1400 °C. Since the γ phase exhibits a decreasing solubility for Al with decreasing temperature, precipitation strengthening by age hardening can be carried out in analogy to the Al-Cu system (Fig. 8.18). The maximum fractions of γ′-phase exceed 60% by volume in single-crystal cast alloys such as CMSX 4 (Fig. 8.29). The pronounced hardening effect of the precipitate phase is mainly due to the γ/γ′ lattice mismatch, which causes dislocation reactions at the interphase and an anomalous temperature dependence of the strength of the γ′ phase [8.40]. This strength anomaly is also the reason why forming and machining operations on wrought superalloys require special attention and tools and restrict γ′ volume fractions to below 50%.

Another major alloying element is carbon, which forms carbides (of type MC, M_7C_3, $M_{23}C_6$, and M_6C) with Ti, Cr, Nb, Mo, and W in order to stabilize the microstructure (grain structure) against creep deformation. The latter *heavy* elements are added also for γ matrix solid-solution strengthening, since they segregate preferentially there. This effect has been further accentuated recently with noble elements such as rhenium and ruthenium (Fig. 8.29). Finally, Cr is deliberately

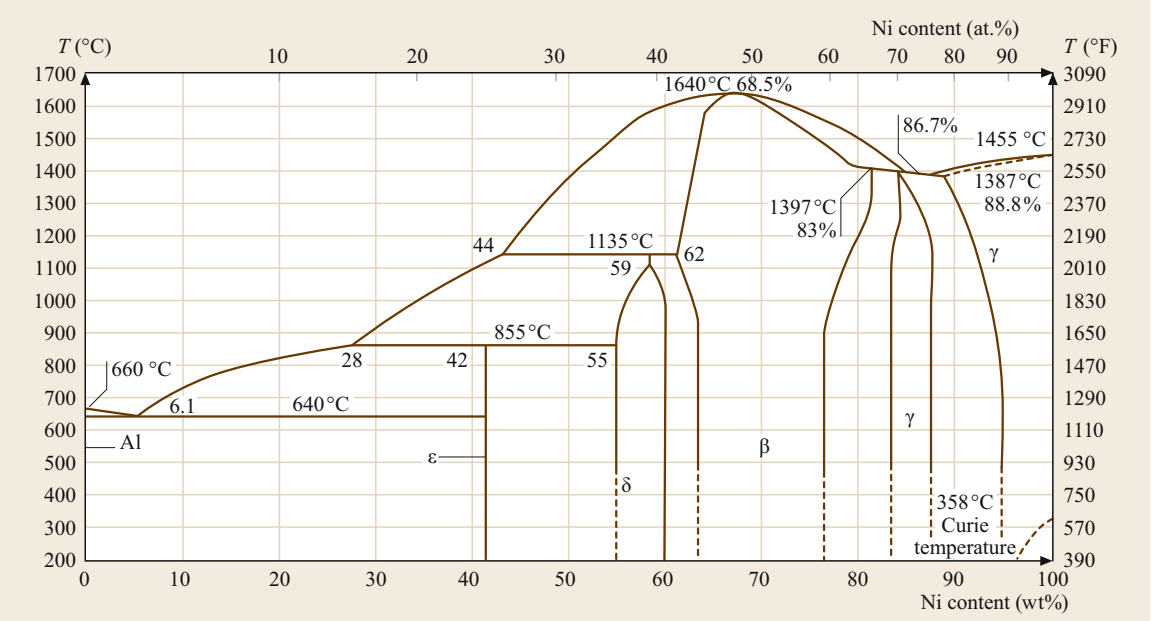

Fig. 8.28 Al-Ni phase diagram, the phases of interest are the Ni solid solution γ and the $L1_2$ ordered coherent Ni_3Al γ phase. Considerable interest has also been given to the B2 ordered NiAl β phase as a high-temperature structural material due to its very high melting point (after [8.6])

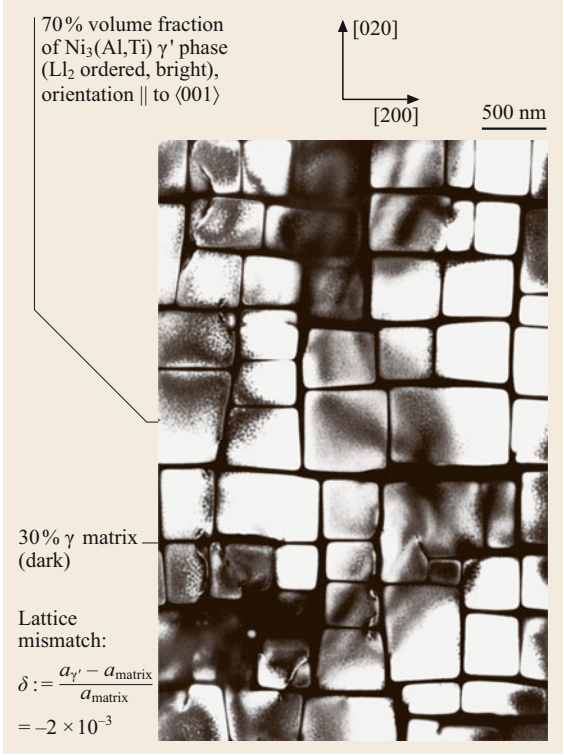

Fig. 8.29 Transmission electron microscopy (TEM) micrograph of a second-generation Ni-based single-crystalline superalloy CMSX 4 (courtesy of U. Glatzel, University of Bayreuth, Germany) ►

added in large concentrations of > 10 wt%, typically around 20 wt%, for chromia scale formation and protection against oxidation up to about 1000 °C.

A compilation of the most commonly employed wrought and cast Ni-based superalloys and their chemical composition can be found in [8.6]. Data for mechanical properties as a function of temperature are also extensively tabulated in [8.6]; some characteristic examples for superalloys and their fields of application are also presented in Table 8.26. Figure 8.30 illustrates some typical results of long-term stress-rupture tests, demonstrating the suitability of Ni-based superalloys for application in gas turbines and related power-generation applications.

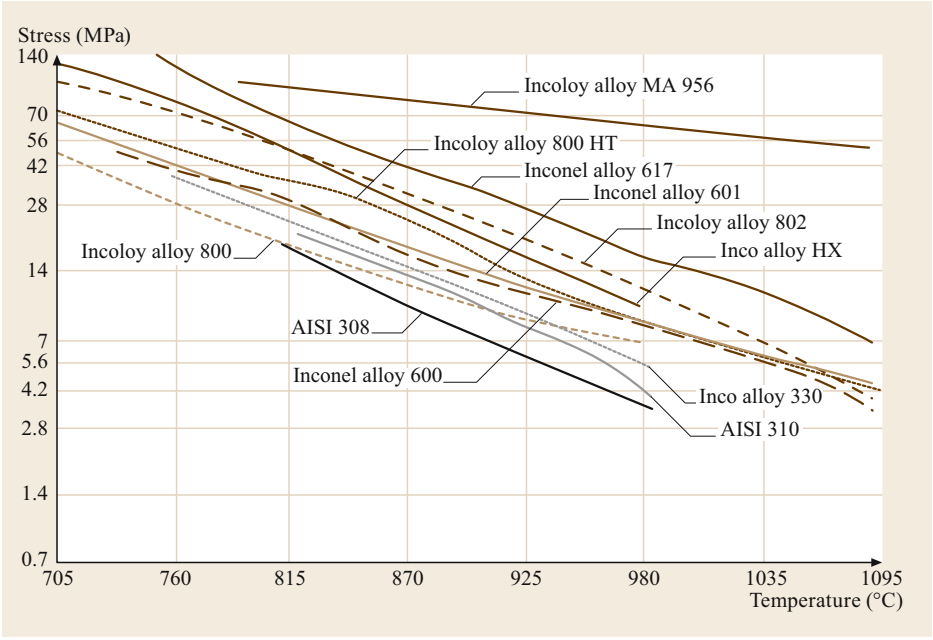

Fig. 8.30 Rupture strength (10 000 h) of Ni-based superalloys in comparison with selected stainless steels (after [8.6])

8.6 Co and Its Alloys

8.6.1 General Properties

Due to their proximity in the Periodic Table, there are many analogies between Co and Ni. Like Ni, cobalt also possesses physical properties that are similar to those of Fe [8.6]. However, at room temperature, it exhibits a hcp crystal structure like Mg, which undergoes an allotropic transformation into an fcc crystal structure above approximately 660 K. Therefore, wrought deformation requires elevated temperatures, and structural applications rely on the intrinsically high hardness of Co alloys, mainly manufactured via casting or powder-metallurgical technologies. Besides its use as an alloying element in steel, Co is frequently used as a component for many inorganic compounds such as a colorizer for glass and ceramics or in battery applications. While applications as surgical implant alloys and corrosion-resistant alloys are not treated further here, Co-based alloys may be grouped according to their field of application into the following three main categories:

8.6.2 Co-Based Hard-Facing Alloys

Co-based alloys with carbon content in the range of 1–3 wt% C are widely used as wear-resistant hard-facing materials and weld overlays. In analogy to Ni-base alloys, carbides of the type $M_{23}C_6$, M_6C, and MC are formed depending on the composition and heat treatment, and *heavy* elements such as Mo, Ta, and W are deliberately added for solid-solution strengthening. Finally, a high Cr content of typically > 15 wt% provides oxidation and hot corrosion resistance by chromia scale formation. To provide the necessary wear resistance under abrasive conditions, the microstructure of hard-facing Co-based alloys consists of a rather coarse dispersion of hard carbide phases embedded in a tough Co-rich metallic matrix. Due to the high C content of up to 3 wt%, the carbide volume fraction can exceed 50%. As a consequence, hot hardness values can exceed 500 HV at 650 °C (1200 °F) and compressive strength can approach 2000 MPa, albeit trading off for tensile ductility (< 1%) and UTS (around 800 MPa). Among some others, the most commonly known family of hard-facing Co-based alloys is designated *stellites*. For further details, see [8.6] and Chap. 9 on tribology.

8.6.3 Co-Based Superalloys

Both wrought and cast Co-based superalloys differ significantly in chemical composition from their hard-facing counterparts as follows: First, they are based on the high-temperature fcc crystal structure, which is stabilized between room temperature (RT) and the melting point by alloying with > 10 wt% Ni. Second, to enable wrought deformation, the carbon content is reduced to below 0.5 wt%, which forms fine and homogeneously distributed carbides for dispersion strengthening. Finally, like for many Ni-based superalloys, in some Co-based superalloys, addition of Al and Ti serves to form the coherent ordered $Co_3(Al,Ti)$ phase, thus leading to precipitation strengthening by age hardening. These (often investment-cast) alloys are used in the very hot parts of gas turbines because of their excellent oxidation resistance. By contrast, they are inferior to Ni-based superalloys regarding creep strength (Fig. 8.27). A survey of the temperature dependence of the 1000-h rupture stress of typical Co-based superalloys is shown in Fig. 8.31.

8.6.4 Cemented Carbides

Cemented carbides, also called *hardmetals*, can be considered to be powder-metallurgically manufactured composite materials consisting of (rather coarse) carbide particulates embedded in a metallic Co-based matrix (*binder*). Most commonly, tungsten carbide (WC)

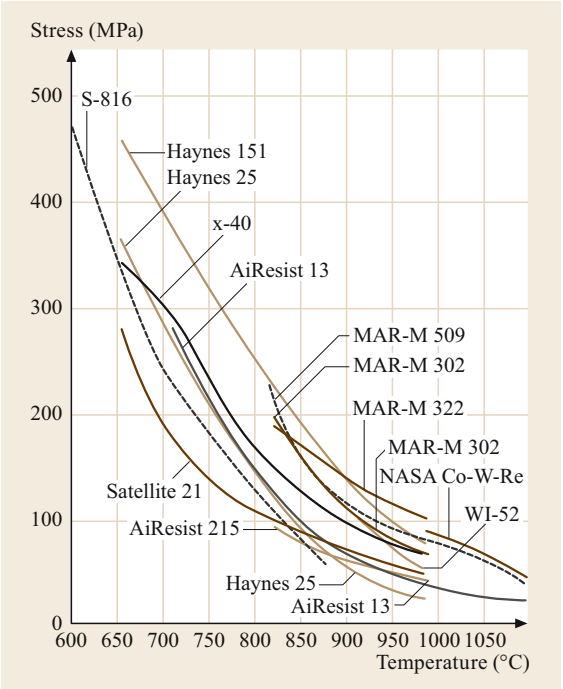

Fig. 8.31 Temperature dependence of 1000-h rupture stress of cast Co-based superalloys (after [8.6])

Table 8.27 Composition, microstructure, and properties of representative Co-bonded cemented carbides (after [8.6, p. 279])

[a] Based on a value of 100 for the most abrasion-resistant material

is used for the particulates, while the elements Ta, Nb, and Ti are deliberately added for economic reasons and to form complex multigrade cemented carbides. Then, the term "cermets" is used occasionally. Cobalt is the element of choice for the binder, since it wets the carbides particularly well. Usually, Ni is added to the binder phase to increase the corrosion and oxidation resistance. The main field of application is as grinding and turning tools for *difficult-to-machine* materials. Table 8.27 lists selected relevant hardmetals and their main properties.

8.7 Copper and Its Alloys

The most striking evidence of the presence of copper in constructions is in rooftops, where it is distinctively marked (after 10–15 years) by a green-colored layer of copper acetate, which prevents further corrosion (the statue of liberty is referred to as a prominent example). Copper and copper alloys have been in use for about 11 000 years, with Cu-Sn (bronze) probably being the first alloy of all. They generally show good corrosion resistance with excellent electrical and thermal conductivity, and their fabrication is easy due to their excellent formability (ductility). This favorable combination of electrical, mechanical, and corrosion properties aided the establishment of Cu as a structural material. On the other hand, Cu is susceptible to hydrogen embrittlement and stress corrosion cracking and has a relatively low strength-to-weight ratio. Comprehensive treatments and data of copper and copper alloys are given in [8.41–43]. The designation system of Cu alloys is presented in Table 8.28.

Table 8.28 Designation of Cu and its alloys (according to UNS)

Wrought alloys	
C100xx–C159xx	Commercially pure Cu
C160xx–C199xx	Nearly pure Cu, age hardenable
C2xxxx	Cu-Zn (classical brass)
C3xxxx	Cu-Zn-Pb (leaded brass)
C4xxxx	Cu-Zn-Sn (tin bronze)
C5xxxx	Cu-Sn (classical bronze) and Cu-Sn-Pb (phosphor bronze)
C6xxxx	Cu-Al (aluminum bronze), Cu-Si (silicon bronze), Cu-Zn-Mn (manganese bronze)
C7xxxx	Cu-Ni (cupronickel), Cu-Ni-Zn (nickel silver)
Cast alloys	
C800xx–C811xx	Commercially pure Cu
C813xx–C828xx	95–99% Cu
C833xx–C899xx	Cu-Zn alloys containing Sn, Pb, Mn, or Si
C9xxxx	Other Cu alloys, including tin bronze, aluminum bronze, cupronickel, and nickel silver

8.7.1 Pure Copper

Due to its high electrical conductivity, pure copper is primarily used for cables, wires, electrical contacts, and other electrical devices. A conductivity of 100% International Annealed Copper Standard (IACS) corresponds to a resistivity of 1.724 38 μΩ cm. However, the properties of Cu are subject to dramatic changes with varying alloy content; i.e., the conductivity decreases substantially with increasing impurity content. Small oxygen additions of up to about 0.04% (electrolytic tough pitch copper) can bind metallic impurities to form oxides, thus leading to an increase of the conductivity (Table 8.29), on the one hand. On the other hand, the presence of oxygen in Cu diminishes its weldability, since hydrogen diffuses into the metal and interacts with oxide to form steam, which leads to cracking. For torch welding and brazing, copper must be deoxidized, for example, by addition of a small amount of phosphorus; this lowers the electrical conductivity substantially but allows the material to be used in plumbing devices.

8.7.2 Copper Alloys

Elements which are solid-solution strengtheners in copper include Zn, Sn, Al, and Si, whereas Be, Cd, Zr, and Cr are suitable for age hardening. *Age-hardenable*

Table 8.29 Composition and properties (yield stress, ultimate tensile strength, fracture strain, thermal conductivity, and electrical resistivity) of characteristic unalloyed coppers (after [8.6])

Material	UNS No.	Composition (wt%)	$R_{p0.2}$ (MPa)	R_m (MPa)	A_f (%)	κ (W m^{-1} K^{-1})	ρ (μΩ cm)
Pure Cu (oxygen-free electronic)	C10100	99.00Cu	69–365	221–455	4–55	392	1.741
Pure Cu (oxygen free)	C10200	99.95Cu	69–365	221–455	4–55	397	1.741
Electrolytic tough pitch Cu	C11000	99.90Cu-0.04O	69–365	224–455	4–55	397	1.707
Oxygen-free low phosphorus Cu	C10800	99.95Cu-0.009P	69–345	221–379	4–50	397	2.028
Phosphorus deoxidized arsenical Cu	C14200	99.68Cu-0.35As-0.02P	69–345	221–379	8–45	397	3.831

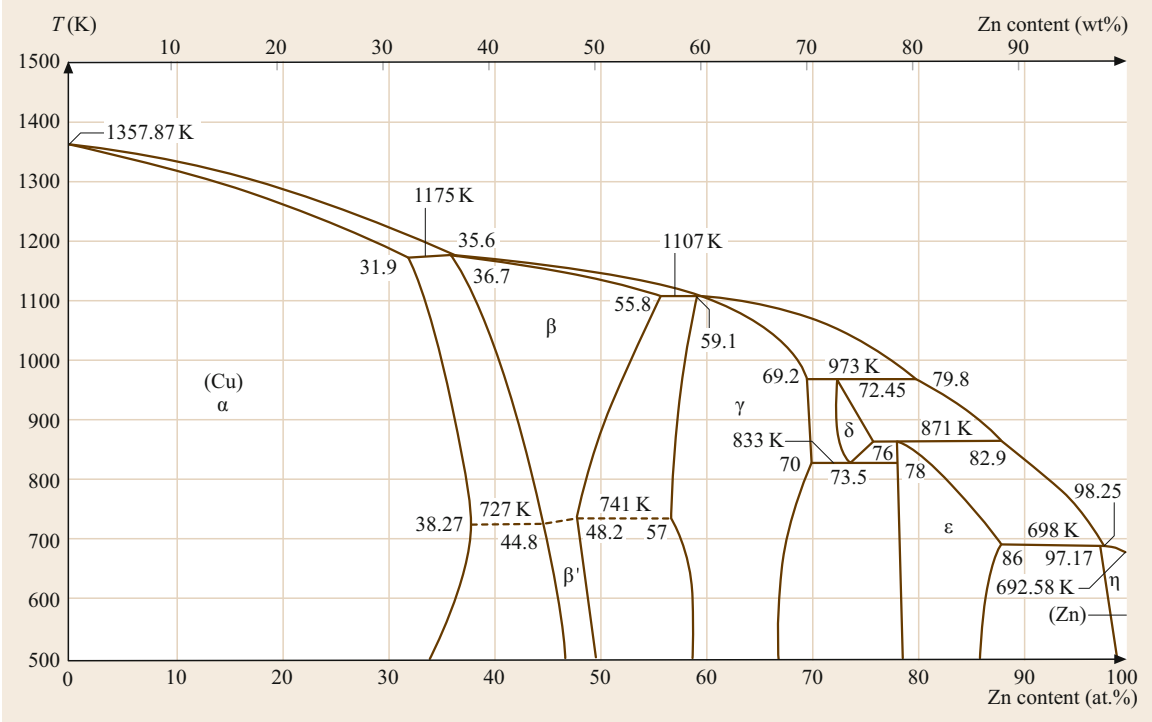

Fig. 8.32 Cu-Zn phase diagram (after [8.6])

alloys with small amounts of alloying additions (up to about 3%) can reach very high strength levels (yield stress $R_{p0.2} > 1300$ MPa at RT in the case of copper beryllium), offer high stiffness, and are nonsparking.

The term "brass" has been established for binary Cu-Zn alloys (Fig. 8.32) but is nowadays used for alloys containing additional components such as Pb, Fe, Ni, Al, and Si as well. Brasses are less expensive than pure Cu and can have different microstructures which depend on the Zn content. Pure α-(Cu) solid solutions (up to about 38% Zn) are cold-working alloys. As the Zn content is increased, the natural color of brass changes from copper-like red (5% Zn) to yellow-gold (40% Zn) (Table 8.30). *Muntz metal brass* is a binary α + β alloy with high strength and still reasonable ductility.

The most important properties of selected commonly used brasses are summarized in Table 8.31.

Wrought products of brasses and bronzes are used in automobile radiators, heat exchangers, and home heating systems, as pipes, valves, and fittings for carrying potable water, and as springs, fasteners, hardware, small gears, and cams, to give a few examples. Cast leaded red and semired brasses find applications as lower-pressure-rating valves, fittings, and pump components, as well as commercial plumbing fixtures, cocks, faucets, and certain lower-pressure valves.

Table 8.30 Designation, composition, and natural color of some brasses

Brass designation	Zn content (%)	Color
Gilding metal	5	Copper red
Commercial bronze	10	Golden
Red brass	15	Red gold
Yellow brass	35	Yellow
Muntz metal (α + β)	40	Yellow gold

General hardware, ornamental parts, parts in contact with hydrocarbon fuels, and plumbing fixtures are made from yellow leaded brass, while high-strength (manganese-containing) yellow brass is suitable for structural, heavy-duty bearings, hold-down nuts, gears, valve stems, and some marine fittings.

Bronzes are Cu-Sn- (Fig. 8.33), Cu-Al-, and Cu-Si-based alloys. Tin and aluminum are the most effective solid-solution strengtheners in copper. Cast products of tin bronzes are used as high-quality valves, fittings, and pressure vessel for applications at temperatures of up to 290 °C, special bearings, pump parts, gears, and steam fittings. Aluminum and silicon bronzes have very good strength, excellent formability, and good toughness. They are used as gears, slides, gibs, cams, bushings, bearings, molds, forming dies, combustion engine components, valve stems, spark-resistant tools,

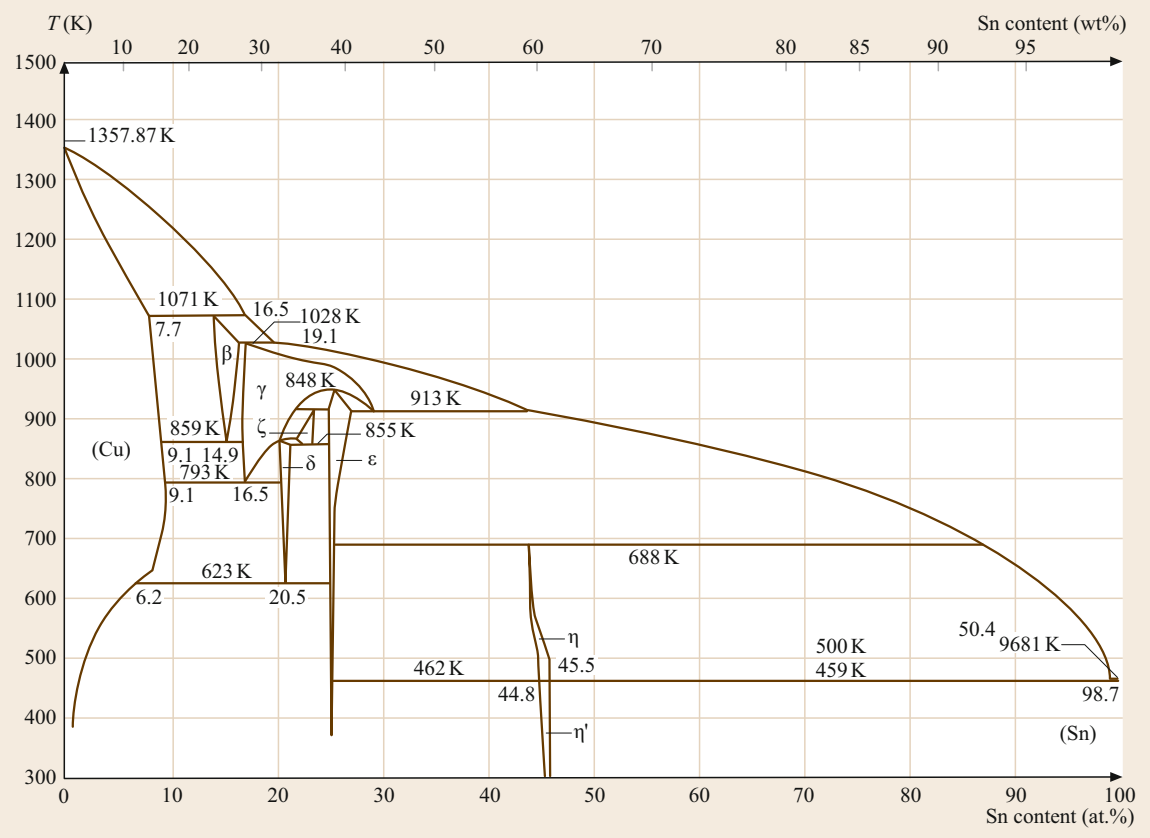

Fig. 8.33 Cu-Sn phase diagram (after [8.6])

Table 8.31 Composition and properties of characteristic brasses, bronzes, and Cu-Ni and Cu-Ni-Zn alloys (after [8.6])

Material	UNS No.	Composition	Yield strength (MPa)	Tensile strength (MPa)	Elongation (%)	Thermal conductivity ($W\,m^{-1}\,K^{-1}$)	Electrical resistivity ($\mu\Omega$ cm)
Gilding metal (cap copper)	C21000	95Cu-5Zn	69–400	234–441	8–45	234	3.079

and in marine applications such as propellers, impellers, and hydrofoils. The properties of some widely used bronzes are given in Table 8.31.

Copper-nickel alloys show excellent corrosion resistance against seawater. Accordingly, they are used in shipboard components, power plants in coastal areas, and saline-water conversion installations. Since Ni in Cu leads to a drastic decrease in its electrical and thermal conductivity, Cu-Ni alloys are also suitable for cryogenic applications.

8.8 Polymers

Polymers (polymer materials, polymeric materials, solid polymers, or macromolecular materials) consist of very large molecules (chain molecules and macromolecules) which are synthesized from small molecules (monomers or monomer units) by a chemical reaction called polymerization (e.g., polyethylene, polyvinylchloride, polyurethane, and polyamide) or are modified natural products (modified silk and regenerated cellulose) [8.44, 45]. In this section, only polymers with carbon as the main component within the molecule chain are considered (organic polymers).

Polymerization reactions can be classified into four groups [8.46]. *Chain polymerization* proceeds by the reaction of a monomer unit with the reactive site at the end of a polymer chain. These are mostly reactions via a radical mechanism [8.47]. Terminus *condensation chain polymerization* is used in cases where a low-molar-mass byproduct is formed during polymerization. In *polycondensation*, pregenerated polymer chains react with each other or with a monomer unit to generate a low-molar-mass byproduct, for example, the reaction of an −OH (alcohol) group with a −COOH (organic acid) group, resulting in an ester group with water as the byproduct. During *polyaddition*, the growth of the polymer chains proceeds by an addition reaction between molecules of all degrees of polymerization or monomer units.

The annual world production of polymer materials is about 150–200 Mt. Some polymer materials are produced in amounts of > 1 Mt/year (polypropylene ≈ 14 Mt/year, which is about the same amount as for cotton), whereas others are polymer materials for special purposes with only small production volumes. Beside the use of bulk polymers as engineering materials, a great amount of polymers is fabricated in the shape of fibers for manufacturing fabric, packaging films, paintings, thermal isolation materials (foam), and, for example, artificial leather.

8.8.1 Chemical Composition and Molecular Structure

In the presentation of a polymer molecule, the monomer unit is enclosed in brackets with an index n showing that a certain number of monomer units react to form the backbone of the polymer molecule. The polymerization of ethylene to polyethylene, for example, is written as $n\,CH_2{=}CH_2 \rightarrow [-CH_2-CH_2-]_n$, where the last part represents the whole molecule $CH_3-CH_2-CH_2\cdots CH_2-CH_2-CH_3$, with n being between some hundreds and some millions.

Most polymers that are used as engineering materials are organic polymers with backbones (main chains) consisting of C–C bonds, or they contain bondings between C and other chemical elements (Table 8.32). Polymers with a backbone containing noncarbon atoms are called inorganic polymers. For most polymers, common abbreviations are used and trademarks exist (Table 8.32).

Polymer materials can be classified, e.g., by their specific molecular structure and the resulting mechanical properties at different temperatures into *thermoplastics*, *elastomers*, and *duromers* [8.48].

Table 8.32 Examples of widely used polymer materials and their abbreviations, characteristic backbone units, element groups within the backbone, and trademarks

Polymer	Backbone unit	Backbone	Trademarks
Organic polymers			
Polyethylene (PE)	$-CH_2-CH_2-$	–C–C–C–C–	Polythen, Lupolen, Hostalen
Polypropylene (PP)	$-CH_2-(CH_3)-CH_2-$	–C–C–C–C–	Hostalen, PPH, Luparen
Polyvinylchloride (PVC)	$-CH_2-CHCl-$	–C–C–C–C–	Hostalit, Vinidur, Vinylite
Polystyrene (PS)	$-CH_2-CH(C_6H_5)-$	–C–C–C–C–	Styroflex, Vestyron, Styropor (foam)
Polytetrafluoroethylene (PTFE)	$-CF_2-CF_2-$	–C–C–C–C–	Teflon, Hostaflon
Polyamide (PA)	$-(CH_2)_6-NH-CO-(CH_2)_6-$	–C–N–C–C–	Nylon, Perlon
Polyethylene terephthalate (PET)	$-O-CO-C_6H_4-CO-O-CH_2-CH_2-$	–C–O–C–C–C–	Trevira (fiber), Diolen, Mylar (foil)
Polyurethane (PUR)	–NH–CO–O–	–C–C–N–C–O–C–C	
Polycarbonate (PC)	–O–CO–O–R	–C–O–C–C–	
Polyphenylene sulfide (PPS)	$-C_6H_4-S-$	–C–S–C–	Noxon, Ryton, Sulfar (fiber)
Inorganic polymers			
Polyphosphazene	$-N{=}PCl_2-$	–N=P–	
Polysiloxane (polydimethylsiloxane)	$-Si(CH_3)_2-O-$	–Si–O–Si–O–	
Polysilane		–Si–Si–Si–Si–	

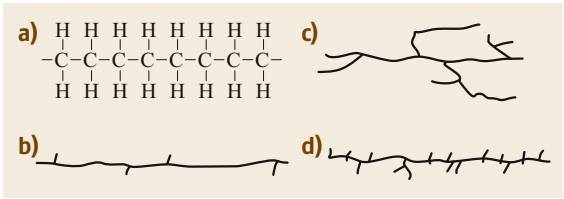

Fig. 8.34a–d Examples of linear polymer molecules: **(a)** theoretical backbone with carbon–carbon bonds and no side chains, **(b)** backbone with only a few small side chains (≈ 10 side chains/1000 C atoms, for example, high-density PE), **(c)** backbone with longer side chains/branches (for example, low-density PE), and **(d)** a great number of side chains attached to the backbone (for example, very low-density PE)

Thermoplastics

Thermoplastics show good strength and high Young's modulus at RT, and they are plastically deformable at elevated temperatures, in most cases above 100 °C. They consist in their simplest molecule structure of linear molecules with no branches (Fig. 8.34). In technical products, small (e.g., $-CH_3$ groups) or larger side chains (short −C−C− chains) are attached to the main chain, forming a branched polymer. The degree of branching determines the density of solid polymers, because with increasing branching the possibility of a dense arrangement of macromolecules decreases.

A typical example is polyethylene, with a density of 0.91–0.94 g/cm^3 for the strongly branched low-density PE (LDPE) and a density of 0.94–0.97 g/cm^3 for the weakly branched high-density PE (HDPE). In thermoplastics, very strong intramolecular covalent bonds (with a bonding energy of 348 kJ/mol for the −C−C bond) exist within the chain molecules, whereas only weak intermolecular bonds with small bonding energies (0.5–5 kJ/mol for van der Waals bonds, ≈ 7 kJ/mol for hydrogen bonds) are present between neighboring molecule chains. The chain molecules can therefore, already at around room temperature (rubber-like polymers, elastomers) or at elevated temperatures (thermoplastics), move with respect to one another, and such polymer solids can be deformed elastically or plastically. The molecular structure of thermoplastics can be distinguished by the kind of atoms forming the backbone or the kind of atoms or chemical groups attached to the backbone (Table 8.33). The side groups determine the polymer properties to a large extent, because they influence the strength of the intermolecular bonding.

Other significant parameters that determine the properties of polymer solids are based on the mean size of the macromolecules (degree of polymerization, mean chain length, or mean molar mass) and, because the polymer molecules show no unit length, the deviation of the molecule size, which depends on the production parameters.

Table 8.33 Examples of chemical groups/atoms on the backbone of linear polymers

X	Y	Polymer
H	H	Polyethylene
CH_3	H	Polypropylene
Cl	H	Polyvinylchloride
C_6H_5	H	Polystyrene
CH_3	$COOCH_3$	Polymethylmethacrylate (PMMA)

Elastomers

Elastomers (rubber-like polymers) consist, similarly to thermoplastics, of linear molecules, but the molecule chains are bridged by small-molecule segments via covalent bondings. The molecules can thus undergo strong elastic deformation at *room temperature*. This effect is due to the stretching of the molecules out of the disordered state if a load is applied, followed by a redeformation into a random tangle of molecules due to the increased entropy after the load is released.

Duromers

Duromers consist of a three-dimensional molecule network, bridged by covalent bondings. Even at elevated temperatures, they undergo no plastic deformation and can, in most cases, be heated up to their decomposition temperature without any elastic or plastic deformation. Most duromers are thermosets (phenolics, unsaturated polyesters, epoxy resins, and polyurethanes) which solidify by an exothermal chemical reaction (curing). Thermosets are obtained by molding a thermoplastic material into the desired shape, which is then cross-linked. The curing reaction can be initiated at RT by mixing the components, or it starts at an elevated temperature, or irradiation by energetic radiation (ultraviolet light, laser beam, or electron beam) is applied.

Most polymers are formed by chain polymerization from one type of monomer (e.g., PE, PP, PVC, and PS); For example, PE is obtained by polymerization of ethylene: $n\,[CH_2{=}CH_2] \rightarrow [-CH_2{-}CH_2-]_n$. Another possibility is that two different monomers containing different types of chemical groups react with each other (e.g., PA, PC, PET, and polyurethane), thus forming a polymer unit built by two molecules; for example, PET is obtained by polycondensation of ethylene glycol with terephthalic acid with water generated as a byproduct, as exemplified in Fig. 8.35.

In copolymers, the polymer chain is composed of two or more types of monomer. The monomers can be arranged randomly, alternating, or as blocks (short molecule chains, consisting of the same monomer

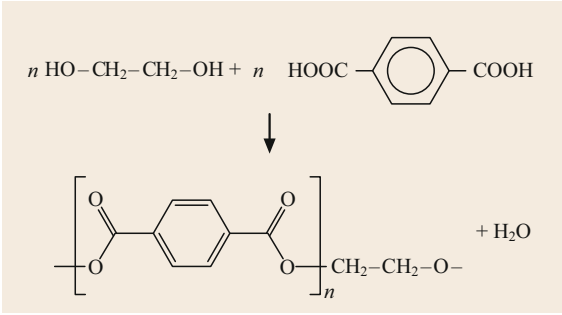

Fig. 8.35 PET formation by polycondensation of ethylene glycol with terephthalic acid

units). Another variant is where blocks built from one type of monomer are fixed as side chains onto a backbone built from another monomer type. Common copolymers are polystyrene-butadiene rubber (SBR) and acrylonitrile-butadiene-styrene (ABS).

The properties of polymeric materials can be further tailored by mixing or blending two or more polymers [8.49]. One goal of such blending is to obtain materials with greater impact toughness than the pure polymers, whereby one component functions as a toughener for the other. In high-impact polystyrene, the high modulus of polystyrene is combined with the high impact strength of rubber particles (polybutadiene). Other example blends are PP-PC, PVC-ABS, and PE-PTFE.

The toughness of otherwise stiff polymers and the glass-transition temperature (see below) can be increased by mixing low-molar-mass substances (plasticizers) into them. The most common case is dioctyl phthalate as a plasticizer for PVC. A similar effect results if up to 3% water is incorporated into polyamide, when in contact with water or high humidity.

In a process known as cross-linking, molecules are linked to one another to increase the temperature resistance, long-time creep strength, and insensitivity to stress cracks. Cross-linking can be achieved very precisely by irradiating plastics with high-energy electron beams or gamma rays. This optimization can be applied even to pure and widely used plastics, such as PE and PVC. Another approach is to add special compounds which are cross-linkable by irradiation, thus fixing two polymer chains to each other. The advantages of the cross-linking technique are that the properties are modified after the components have been formed into parts and that the process takes place at room temperature and normal pressure.

Fig. 8.36 Amorphous and crystalline regions in the morphology of a semicrystalline polymer

8.8.2 Microstructure of Polymer Materials

Linear polymers can have a disordered state (amorphous) or a semicrystalline arrangement of the molecules (Fig. 8.36).

The amorphous state is characterized by a random tangle of molecules. In semicrystalline polymers, some parts of the polymer molecules are ordered in the shape of folded-chain lamellae, which are eventually arranged to form blocks. The degree of crystallinity can be estimated by density measurements, thermal analysis/differential scanning calorimetry (DSC), or x-ray diffraction (XRD) analysis. It depends on the number and length of the side chains on the molecule backbone (degree of branching) and determines the density and elastic moduli of the polymer material. For polyethylene, the degree of crystallinity varies from 45% for LDPE to 95% for HDPE (Table 8.34).

In some semicrystalline polymers, the folded-chain lamellae grow, starting at a nucleus, outwards, yielding globules/spherulites [8.50]. The size of the spherulites can be modified by the addition of nucleants. The toughness and light transparency decrease with increasing spherulite size. Spherulites are visible under polarized-light microscopy of microtome sections (about 25 μm thick) (Fig. 8.37).

Table 8.34 Degree of crystallinity of common polymer materials

Polymer	Degree of crystallinity (%)
LDPE	45–75
HDPE	65–95
PP fiber	55–60
PET fiber	20–60

Fig. 8.37 Spherulites in polypropylene; transmission light microscopy of a microtome section; polarized light

Polymer molecules can be strongly oriented parallel to the flow direction during production processes such as injection molding due to the high viscosity of the melt. This occurs especially if metallic parts are used as inserts, by which the melt flow is divided and then reunited after the flow around the insert [8.51, 52]. As a result, regions that show strongly anisotropic mechanical properties can be found within normally isotropic polymer solids [8.53]. The aligned molecules can result in substantial residual stresses and give rise to crack initiation even when a low external load is applied. This molecular alignment effect can be reduced by relaxation at elevated temperatures, whereby changes of the shape can occur. This effect has to be taken into account if parts made from polymer materials are to be heated during further manufacturing or while in use. One application of this relaxation effect is the use of polymer films for shrink packaging, where an article is wrapped at room temperature and the film shrinks upon heating.

8.8.3 Thermal Properties

The strength of duroplastic materials does not change much with increasing temperature. They do not melt at all due to the three-dimensional molecule network, but rather start to decompose. During heating of thermoplastic and elastomeric polymers, temperature ranges with different polymer properties are observed: strong, hard, and brittle at low temperatures, but ductile and deformable at increased temperatures, finally changing

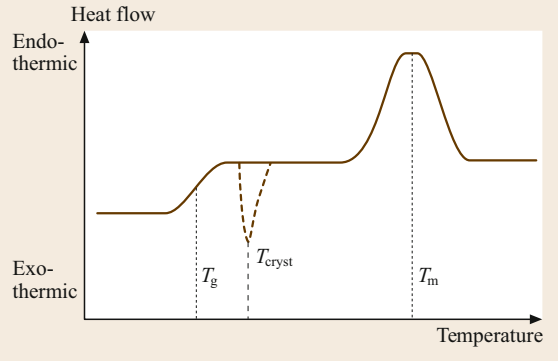

Fig. 8.38 DSC results for a partially crystalline polymer; schematic heating curve with characteristic transition points: glass transition T_g, crystallization temperature T_{cryst}, and melting point T_m

from a solid to the state of a viscous melt. The transitions between the different states, which are due to the arrangement and mobility of the molecules, can be investigated by differential scanning calorimetry (DSC) [8.54], whereby the exothermic and endothermic heat flux is registered (Fig. 8.38).

At a material-specific temperature, an endothermic hump appears, extending over a certain temperature range. This is the transition into the glassy state due to the increased mobility of the molecule segments in the amorphous parts of the microstructure and is accompanied by an enormous decrease of viscosity and, thus, strength. The glass-transition temperature (T_g), which can be defined as the temperature at the first inflection point of the graph, is heating rate dependent and specific to each material (Table 8.35). The high level of heat flux is maintained because the specific heat of the glassy polymer is greater than that of the solid polymer.

In very few cases and at very low temperatures, partial crystallization of the polymer can follow the transition into the glassy state, connected with an exothermic heat flow (dashed line in Fig. 8.38). With increasing

Table 8.35 Typical glass-transition temperatures and melting temperatures of polymers

Polymer	T_g (°C)	T_m (°C)
PE	−120	130
PP	−15	170
PS	90	200
PVC (amorphous)	80	–
PVC (partially crystalline)	80	210
PTFE	−115	330
PMMA	45	160
PA6 (polyamide 6)	75	230
PET	75	280

temperature, the crystalline regions of semicrystalline polymers will melt, which is indicated by another endothermic event, which represents the melting temperature (T_m) (Table 8.35). The large peak width, as compared with metals, is related to the nonuniformity of the polymer molecules and the high degree of imperfection of the polymer crystals. After that temperature range, the polymer behaves like a high-viscosity melt.

Usually, technical applications of polymer materials are restricted to temperatures below the glass transition (PS, PMMA, and PET). However, in some cases, polymers are also used above that temperature (polyisoprene, polybutadiene, and polyethylene); then some polymers exhibit rubber-like properties.

Polymeric materials start to decompose or to be oxidized in air if heated above a certain temperature. In some cases (PE, PP, and PS), they burn with a characteristic flame color. The decomposition is a process of thermal cracking of the material and/or an oxidation, whereby sometimes a fume with a characteristic smell occurs when the flame is blown out (PE: like burning candle or wax; PA: like burned hair or horn; PVC: stinging, acidic; PS: fruity). In some cases, chemicals which are dangerous to humans or can alter other materials are released. Burning PUR generates toxic hydrocyanic acid. Overheating or burning of PVC yields hydrochloric acid (HCl) vapor, which leads to the corrosion of parts made from Cu or other metals and is toxic to humans.

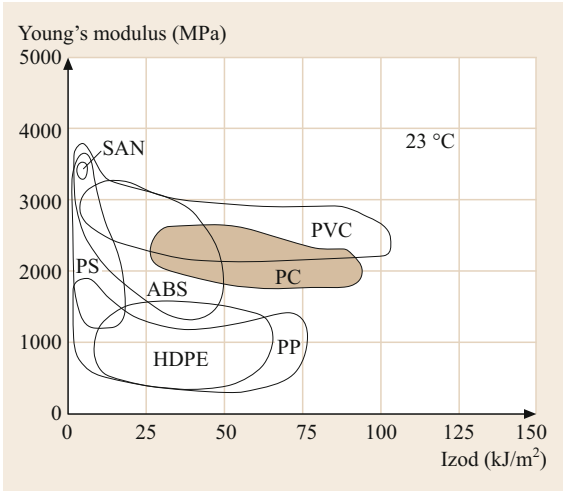

Fig. 8.40 Young's modulus versus notch impact strength (Izod) for thermoplastics (after [8.56])

8.8.4 Mechanical Properties of Polymer Materials

As stated above, the three basic types of polymer – thermoplastics, elastics, and duromers – show very different properties with different temperature dependences, which can be a reason for selecting a certain polymer. The choice of a polymeric material for a specific application [8.55] can be based on the difference in mechanical properties, such as tensile strength, impact, and elastic behavior, but also often other properties have to be considered, such as density, corrosion resistance, or formability. The ratio of the density to the Young's modulus (Fig. 8.39) can be a potential criterion for selecting a polymer material for a certain application. Alternatively, the ratio of the Young's modulus to the impact strength of a polymer material may be taken into account (Fig. 8.40).

Standardized mechanical testing methods for polymer materials (Table 8.36) in most cases differ from those applied to other materials (Chap. 5.). This is especially true for the size and shape of the specimens and the applied load [8.57].

Tensile stress–strain curves can be very different for polymer materials (Fig. 8.41) and are strongly dependent on the testing temperature (Fig. 8.42). No linear region of the stress–strain curve of polymer materials exists from which the Young's modulus could be obtained. Therefore, a *secant modulus* is calculated based on the slope of the stress–strain curve within a certain range of elongation, e.g., between 0.05% and 0.25% elongation

$$E_t = \frac{\sigma_{0.05} - \sigma_{0.25}}{\varepsilon_{0.05} - \varepsilon_{0.25}} \,. \tag{8.1}$$

In general, the values of the mechanical properties of polymer materials are inferior to those of metallic materials (Table 8.38).

The tensile strength generated by stretching the polymer chains during the manufacturing process can yield values of the ultimate tensile strength which

are greater than those known for steel (for example, $\approx 400\,N/mm^2$ for steel S355) (Table 8.39). An outstanding high tensile strength is exhibited by Aramid (polyparaphenylene terephthalamide; Kevlar), which is used as a fiber.

The orientation of segments of the molecule chains as generated by the shaping process [8.60] (see above) has a significant influence on the mechanical properties (Fig. 8.43). For the determination of the dynamic mechanical properties of polymers, a torsion pendulum is used [8.61, 62]. As a result, the elastic shear modulus G and $\tan\delta$ are obtained. The shear modulus is strongly dependent on temperature (Fig. 8.44).

The mechanical properties of polymer materials can be further improved by fiber reinforcement ([8.63, 64], Sect. 8.10).

8.8.5 Polymer Interaction with Solvents

The dissolution of solid polymers in organic solvents or water starts with swelling, whereby the macromolecules are not degraded, which means that the chain length is not changed [8.65]. Only in some polymers are the chain molecules shortened by a chemical reac-

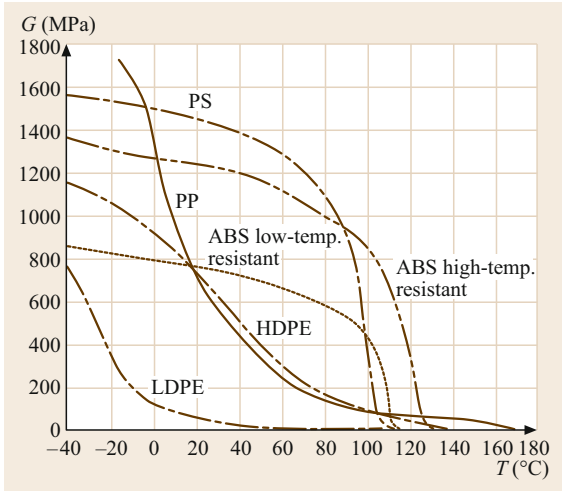

Fig. 8.44 Shear modulus versus temperature for several common polymer materials (after [8.56])

tion with a chemical substance contained in a solvent; For example, the amide groups in polyamides undergo hydrolysis under basic conditions (saponification), resulting in the generation of chain molecule fragments of different lengths. The swelling and subsequent dissolution are due to competition between the intermolecular bonding forces between the chains of the polymer versus the bonding forces between the macromolecules and the small solvent molecules, respectively. As a re-

sult, increasing numbers of solvent molecules penetrate the tangled polymer chain arrangement and lead to an increase of the volume of the polymer solid. This is accompanied by a lowering of the interaction forces between adjacent macromolecule segments and an increase of the mobility of the molecules with respect to each other, with a loss of strength. The swelling and dissolution process may take up to several days or weeks at ambient temperature. For the same reason, the contact of many polymers with mineral oils must be avoided. Swelling often results in a sticky substance before true dissolution occurs. In some cases, polymer solutions can be used as glue which will have the strength of the starting polymer after the solvent has evaporated.

Some polymers can only incorporate a limited fraction of solvent into the solid. The interaction between a polymer and a selected solvent and therefore the solubility of the polymer can be predicted using the solubility parameter δ (Table 8.39), which is based on the cohesion forces, beside other factors [8.59]. As a rule, a substance can be regarded as a solvent if the difference of δ values is < 2.

8.8.6 Aging and Corrosion

Aging of polymers is mainly due to chemical changes of the structure of the macromolecules accompanied by a shortening of the chain molecules, branching, crosslinking, and the generation of new chemical groups. A prerequisite for aging is the influence of light, especially ultraviolet (UV) light, and eventually oxygen from the air. As a result, the polymer becomes brittle, cracks are generated, the quality of the surface is changed, and a loss of electrical insulation behavior will appear. Loss of plasticizer by diffusion also lowers the elasticity and ductility, especially at lower temperatures. An especially dangerous situation is the interaction of a solvent or a solution and the mechanical stress of a polymer part, leading to stress-corrosion failure.

8.9 Glasses and Ceramics

Glass and ceramic materials are complex compounds and solid solutions containing metallic and nonmetallic elements, being composed of either ionic or covalent bonds. Typical properties of glasses and ceramics include high hardness, high compressive strength, high brittleness, high melting point, and low electrical and thermal conductivity. There are several ways in which ceramics can be classified, such as by chemical composition, properties, or applications. In Fig. 8.45, this classification is made on the basis of chemical composition [8.6].

In the following, we take a closer look at some of the ceramic materials listed in Fig. 8.45. Detailed treatments of ceramics are given in [8.66, 67].

8.9.1 Glasses

Glasses are solid materials which have become rigid without crystallization (Sect. 4.1.1). The microstructure is based on SiO_4 tetrahedral units which possess short-range order and are connected to each other by bridging oxygen, resulting in a three-dimensional framework of strong Si–O–Si bonds. The main advantages of glasses are their optical transparency, pronounced chemical resistance, high mechanical strength, and relatively low fabrication costs. Glasses usually contain other oxides, notably CaO, Na_2O, K_2O, and Al_2O_3, which influence the glass properties. Besides about 70% SiO_2, soda-lime glasses, which are used for windows and containers, additionally consist of Na_2O (soda) and CaO (lime). Further applications of glasses are as lenses (optical glasses), fiberglass, industrial and laboratory ware, and for metal-to-glass sealing and soldering. The compositions of some commercial glass materials are described in Table 8.40 [8.68].

8.9.2 Glass Ceramics

Glass ceramics contain small amounts of nucleating agents (such as TiO_2 and ZrO_2) which induce crys-

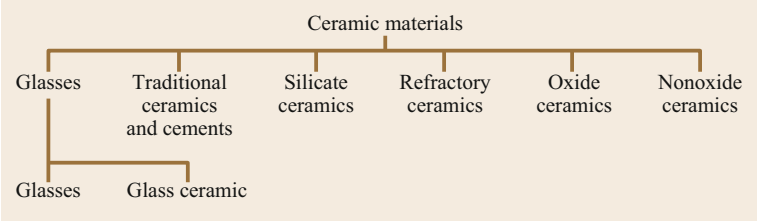

Fig. 8.45 Classification of ceramic materials based on chemical composition (after [8.6])

Table 8.40 Compositions and characteristics of some common commercial glasses (after [8.68])

Glas type	Composition (wt%)						Characteristics and applications
	SiO_2	Na_2O	CaO	Al_2O_3	B_2O_3	Other	
Fused silica	> 99.5						High melting temperature, very low coefficient of expansion (shock resistant)
96% Silica (Vycor)	96				4		Thermal shock and chemically resistant (laboratory ware)
Borosilicate (Pyrex)	81	3.5		2.5	13		Thermal shock and chemically resistant (ovenware)
Container (soda lime)	74	16	5	1		4MgO	Low melting temperature, easily worked, also durable
Fiberglass	55		16	15	10	4MgO	Easily drawn into fibers (glass–resin composites)

tallization of glasses when exposed to high temperatures. After melting and shaping of the glassy material, it is partly crystallized using a specific heat treatment at temperatures between 800 and 1200 °C. The residual glass phase occupies 5–50% of the volume, and the crystalline phase has a grain size of 0.05–5 μm. In contrast to conventional ceramics, e.g., prepared by powder processing routes, glass ceramics are fully dense and pore free, resulting in relatively high mechanical strength. Glass ceramics of the system Li_2O-Al_2O_3-SiO_2 show near-zero linear thermal expansion, so such glass ceramic ware will not experience thermal shock. These materials also have a relatively high thermal conductivity and show exceptionally high dimensional and shape stability, even when subjected to considerable temperature variations. Glass ceramics are used in astronomical telescopes, as mirror spacers in lasers, as ovenware and tableware, as electrical insulators, for architectural cladding, and in heat exchangers and regenerators.

8.9.3 Silicate Ceramics

Silicates are the most important constituents of the Earth's crust. Their structure, which is based on SiO_4 tetrahedrons (glasses are a derivative of silicates), depends on the actual composition. A three-dimensional network (quartz) is only stable when the ratio of O/Si is exactly 2. The addition of alkali or alkali-metal oxides to silica increases the overall O/Si ratio of the silicate and results in the progressive breakdown of the silicate structure into smaller units. The relationship between the O/Si ratio and the silicate structure is presented in Table 8.41. Silicates are particularly useful for electrotechnical, electronic, and high-temperature applications as well as in the processing of materials.

8.9.4 Refractory Ceramics

Refractory ceramics are another important group of ceramics that are utilized in large tonnages. These materials must withstand high stresses at high temperatures without melting or decomposing and must remain nonreactive and inert when exposed to severe environments. Refractory ceramics are composed of coarse oxide particles bonded by a finer refractory material. The finer material usually melts during firing and bonds the remaining material. Refractory ceramics generally contain 20–25% porosity as an important microstructural variable that must be well controlled during manufacturing. They are used for various applications ranging from low- to intermediate-temperature building bricks to high-temperature applications, where magnesite, silicon carbide, and stabilized zirconia (also used as thermal barrier coatings on nickel-based turbine components) are suitable. Typical applications include furnace linings for metal refining, glass manufacturing, metallurgical heat treatment, and power generation. Depending on their chemical composition and reaction, oxide refractories can be classified into acidic, basic, and neutral refractories. Fireclays are acidic refractories and are formable with the addition of water (castable and cements). Very high melting points are provided by chromite and chromite-magnesite ceramics, which are neutral refractories. Examples of commercial refractories are presented in Table 8.42.

8.9.5 Oxide Ceramics

Oxide ceramics are treated as a separate group of ceramics in [8.6] since they are the most common constituents of ceramics. The properties and applications of some important members are summarized in Table 8.43. For further reading, the extensive treatment in [8.69] is recommended.

Table 8.41 Relationship between silicate structure and O/Si ratio

Structure	O/Si ratio	O atoms per Si atom		Structure and examples
		Bridging	Nonbridging	
	2.00	4.0	0	Three-dimensional network quartz, tridymite, and cristobalite are all polymorphs of silica
 Repeat unit $(Si_4O_{10})^{4-}$	2.50	3.0	1.0	Infinite sheets $Na_2Si_2O_5$, clays (kaolinite)
 Repeat unit $(Si_4O_{11})^{6-}$	2.75	2.5	1.5	Double chains, e.g., asbestos
 Repeat unit $(SiO_3)^{2-}$	3.00	2.0	2.0	Chains $(SiO_3)_n^{2n-}$, Na_2SiO_3, $MgSiO_3$
 $(SiO_4)^{4-}$	4.00	0	4.0	Isolated $(SiO_4)^{4-}$, tetrahedra Mg_2SiO_4 olivine, Li_4SiO_4

The simplest way to determine the number of nonbridging O atoms per Si atom is to divide the charge on the repeat unit by the number of Si atoms in the repeat unit

Table 8.42 Properties of fired refractory brick materials (after [8.6])

Brick (major chemical components)	ρ (kg/m^3)	T_m (°C)	κ (W/(m K))
Building brick	1842	1600	0.72
Chrome-magnesite brick (52 wt% MgO, 23 wt% Cr_2O_3)	3100	3045	3.5
Fireclay brick (54 wt% SiO_2, 40 wt% Al_2O_3)	2146–2243	1740	0.3–1.0
High-alumina brick (90–99 wt% Al_2O_3)	2810–2970	1760–2030	3.12
Silica brick (95–99 wt% SiO_2)	1842	1765	1.5
Silicon carbide brick (80–90 wt% SiC)	2595	2305	20.5
Zirconia (stabilized) brick	3925	2650	2.0

Table 8.43 Properties of commercial oxides according to DIN EN 60672: density, Young's modulus, bending strenght, coefficient of thermal expansion (at room temperatur), thermal conductivity (at room temperatur) [8.6]

Oxide	ρ ($g\,cm^{-3}$)	E (GPa)	σ (MPa)	α ($10^{-6}\,K^{-1}$)	κ ($W\,m^{-1}\,K^{-1}$)	Application examples
MgO (C 820; 30% porosity)	2.5	90	50	11–13	6–10	For insulation in sheathed thermocouples; in resistive heating elements
Al_2O_3 (> 99.9)	3.97–3.99	366–410	550–600	6.5–8.9	38.9	In insulators; in electrotechnical equipment; as wear-resistant machine parts; in medical implants
TiO_2 (C 310)	3.5	–	70	6–8	3–4	In powder form as a pigment and filler material; in optical and catalytic applications
BeO (C 810)	2.8	300	150	7–8.5	150–220	In heat sinks for electronic components
ZrO_2 (partially stabilized)	5–6	200–210	500–1000	10–12.5	1.5–3	As thermal barrier coating of turbine blades

Table 8.44 Properties and applications of advanced ceramics

Property	Application examples
Thermal	
Insulation	High-temperature furnace linings for insulation (oxide fibers such as silica, alumina, and zirconia)
Refractoriness	High-temperature furnace linings for insulation and containment of molten metals and slags
Thermal conductivity	Heat sinks for electronic packages (AlN)
Electrical and dielectric	
Conductivity	Heat elements for furnaces (SiC, ZrO_2, $MoSi_2$)
Ferroelectricity	Capacitors (Ba-titanate-based materials)
Low-voltage insulators	Ceramic insulation (porcelain, steatite, forsterite)
Insulators in electronic applications	Substrate for electronic packaging and electrical insulators in general (Al_2O_3, AlN)
Insulators in hostile environments	Spark plugs (Al_2O_3)
Ion-conducting	Sensors, fuel cells, and solid electrolytes (ZrO_2, β-alumina, etc.)
Semiconducting	Thermistors and heating elements (oxides of Fe, Co, and Mn)
Nonlinear I–V characteristics	Current surge protectors (Bi-doped ZnO, SiC)
Gas-sensitive conductivity	Gas sensors (SnO_2, ZnO)
Magnetic and superconductive	
Hard magnets	Ferrite magnets [$(Ba,Sr)O \times 6Fe_2O_3$]
Soft magnets	Transformer cores [$(Zn,M)Fe_2O_3$, with M = Mn, Co, Mg]; magnetic tapes (rare-earth garnets)
Superconductivity	Wires and SQUID magnetometers ($YBa_2Cu_3O_7$)
Optical	
Transparency	Windows (soda-lime glasses), cables for optical communication (ultrapure silica)
Translucency and chemical inertness	Heat- and corrosion-resistant materials, usually for Na lamps (Al_2O_3, MgO)
Nonlinearity	Switching devices for optical computing ($LiNbO_3$)
Infrared transparency	Infrared laser windows (CaF_2, SrF_2, NaCl)
Nuclear applications	
Fission	Nuclear fuel (UO_3, UC), fuel cladding (C, SiC), and neutron moderators (C, BeO)
Fusion	Tritium breeder materials (zirconates and silicates of Li, Li_2O); fusion reactor lining (C, SiC, Si_3N_4, B_4C)
Chemical	
Catalysis	Filters (zeolites); carrier for catalytic active components, purification of exhaust gases
Anticorrosion properties	Heat exchangers (SiC), chemical equipment in corrosive environment
Biocompatibility	Artificial joint prostheses (Al_2O_3)
Mechanical	
Hardness	Cutting tools (SiC whisker-reinforced Al_2O_3, Si_3N_4)
High-temperature strength retention	Stators and turbine blades, ceramic engines (Si_3N_4)
Wear resistance	Bearings (Si_3N_4)

8.9.6 Nonoxide Ceramics

The *nonoxide ceramics* include essentially borides, carbides, nitrides, and silicides. A comprehensive overview of these materials is given in [8.6, 66, 67]. A few application examples will be given in the following. In recent years, some effort has been made in the construction of ceramic automobile engine parts such as engine blocks, valves, cylinder liners, rotors for turbochargers, etc. Ceramics under consideration for use in ceramic turbine engines include silicon nitride Si_3N_4, and silicon carbide SiC, which possess high thermal conductivity and thus excellent thermal shock resistance. Boron carbide (B_4C), silicon carbide (SiC), and titanium diboride (TiB_2) are also being considered for armor systems to protect military personnel and vehicles from ballistic projectiles. The low density of ceramics makes them very attractive in this field. High-purity ceramics with simple crystal structures such as boron nitride (BN), silicon carbide (SiC), and aluminum nitride (AlN) may be used as substrates for integrated circuits (ICs), since they have better thermal conductivity and thermal expansion coefficients which are closer to those of silicon IC chips compared with the presently used alumina. Further applications of nonoxide ceramics as well as advanced oxide ceramics are given in Table 8.44.

8.10 Composite Materials

Composite materials are formed when two materials which belong to different material classes are combined to obtain properties which are not provided by the original materials. Possible combinations are:

- Metal-ceramic
- Metal-polymer
- Ceramic-polymer
- Polymer-glass fiber
- Polymer-carbon fiber.

Either the second phase can be introduced into the matrix material in the form of homogeneously distributed particles or fibers, or the materials form a laminate structure (Fig. 8.46).

In *dispersion-strengthened* alloys, a small amount (usually $< 10\%$ volume fraction) of second-phase particles (metallic oxide or ceramic) is homogeneously distributed into the matrix material, commonly by mechanical alloying techniques [8.70]. These dispersoids are generally not coherent and, thus, effectively inhibit dislocation motion (Orowan circumvention at room temperature or by lowering dislocation line energy at higher temperatures [8.40]) when their distance is typically about 100 nm. The most important advantage over age-hardened alloys is the excellent elevated-temperature stability. Due to their insolubility in the metallic matrix, no significant coarsening of the dispersoids is observed even after long-term exposure at temperatures close to the melting point of the matrix. Prominent examples are the oxide-dispersion-strengthened (ODS) nickel- and iron-based superalloys [8.71]. When the particles are large so that they do not interact significantly with moving dislocations, the rule of mixtures can be applied for property determination; i.e., the properties can be directly determined by adding the percentage contribution of each phase. Hence, the term "particulate-reinforced material" is more appropriate, and the volume fraction of the reinforcement phase can exceed 50%. Applications are, e.g., cemented carbides in a Co matrix for wear and cutting tools (Sect. 8.6), abrasives such as Al_2O_3, SiC, and BN, which are added to grinding and cutting wheels, and electrical contacts such as tungsten or oxide particle-reinforced silver.

The fibers in *fiber-reinforced* composites can be continuously (as in Fig. 8.46), orthogonally, or randomly distributed. The properties of the fiber, i.e., strength, stiffness, etc., the aspect ratio l/d, where l is the fiber length and d is the diameter, and the volume fraction of the fibers play a decisive role in the final performance

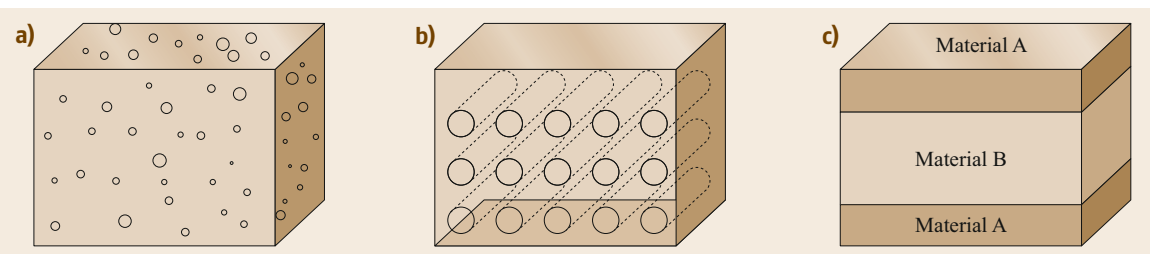

Fig. 8.46a–c Types of composites (schematic): **(a)** particulate, **(b)** fiber, and **(c)** laminated

Table 8.45 Typical longitudinal and transverse tensile strengths for three unidirectionally fiber-reinforced composites. The fiber content in each is ≈ 50 vol.% (after [8.72])

Material	Longitudinal tensile strength (MPa)	Transverse tensile strength (MPa)
Glass-polyester	700	20
Carbon (high modulus)-epoxy	1000	35
Kevlar-epoxy	1200	20

of the reinforced composite. In the longitudinal direction (along the fiber axis), the strength is much higher than in the transverse direction (Table 8.45).

The matrix of fiber-reinforced materials should be tough enough to support the fibers and prevent cracks in broken fibers from propagating, and one has to be aware of chemical reactions when the matrix is a metallic material. If the fibers are to be exposed to high temperatures, the coefficient of thermal expansion should not differ substantially from that of the matrix. Fiber composites may be used as fan blades in gas turbine engines and other aircraft and aerospace components, in lightweight automotive applications such as fiber-reinforced Al-matrix pistons, sporting goods (such as tennis rackets, golf club shafts, and fishing rods), and as corrosion-resistant components, to name some of the possible applications.

Laminar compositions could be very thin coatings such as thermal barrier coatings to protect Ni-based superalloys in high-temperature turbine applications (Sect. 8.5), thicker protective layers, or two-dimensional sheets or panels that have a preferred high-strength direction. The layers are stacked and joined using organic adhesives. Examples of laminar structures are adjacent wood sheets in plywood, capacitors composed of alternating layers of aluminum and mica, printed circuit boards, and insulation for motors, to mention a few.

Ulrich Wendt

Freelance Materials Science Consultant
c/o Otto-von-Guericke University,
Department of Materials and Joining Technology
Magdeburg, Germany
wendt@ovgu.de

Professor Ulrich Wendt studied chemistry and earned a diploma degree with a thesis on organic synthesis, a doctoral degree RNDr on heterogeneous catalysis, and a habil. degree on polymer melt crystallization. For more than 30 years he headed the Microscopy and Stereology Laboratory at the Department of Materials and Joining Technology, University Magdeburg. He lectured on microscopic and spectroscopic characterization, image analysis, topometry, and failure analysis of materials. He is now a freelance Materials Science consultant.

9. Tribology

Ludger Deters, Dirk Bartel

The main subjects of this chapter are the tribological system, friction, wear and lubrication. Regarding the tribological system essential information on structure, real contact geometry, tribological loads, operating and loss variables are provided. Concerning friction, the different friction types, states and mechanisms are discussed. In the sections on wear a lot of details on types and mechanisms of wear, wear profiles and the determination of wear and the average lifetime are introduced. The sections on lubrication contain relevant expositions on the lubrication states, like hydrodynamic, elastohydrodynamic, hydrostatic, mixed and boundary lubrication and lubrication with solid lubricants. Lubricants like mineral, synthetic and biodegradable oils and additives, lubricating greases and solid lubricants are also considered, as are the properties of lubricants, like the dependence of oil viscosity on temperature, pressure and shear rate, and the consistency of lubricating greases.

9.1 Importance of Tribology

Tribology is the science and technology of interacting surfaces in relative motion. Tribology includes boundary-layer interactions both between solids and between solids and liquids and/or gases. Tribology encompasses the entire field of friction and wear, including lubrication [9.1].

Tribology aims to optimize friction and wear for a particular application case. Apart from fulfilling the required function, this means assuring high efficiency and sufficient reliability at the lowest possible manufacturing, assembly, and maintenance costs.

Friction and wear are frequently undesirable. While friction impairs the efficiency of machine elements, machines, and plants and thus increases the energy demand, wear diminishes the value of components and assemblies and can lead to the failure of machines and plants. On the other hand, many technical applications strive for high friction, e.g., brakes, clutches, wheels/

K.-H. Grote, H. Hefazi (Eds.), *Springer Handbook of Mechanical Engineering*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-47035-7_9

rails, car tires/road, friction gears, belt drives, bolted joints, and press fits. To a limited extent, wear can also be advantageous in special cases, e.g., in breaking-in processes.

Friction and wear are not properties specific to the geometry or substance of only one of the elements involved in friction and wear, e.g., external dimensions, surface roughnesses, thermal conductivity, hardness, yield point, density or structure, but rather are properties of a system. The system's friction and/or wear behavior can already change seriously when one influencing variable of the tribological system is marginally modified.

Lubrication is employed to lessen friction and minimize wear or to prevent them entirely. In the case of circulatory lubrication, the lubricant can additionally remove wear particles and heat from the friction contact. Other important tasks of lubrication are preventing corrosion (rusting) and, in the case of grease lubrication, sealing the friction points.

9.2 Tribological System (Tribosystem)

Friction and wear occur within a tribological system (TS). To delimit a TS, a system envelope is appropriately placed around the components and materials directly involved in friction and wear, thus virtually isolating these from the remaining components. The materials and components involved in friction and wear are the elements of the TS and are characterized by their material and shape properties. A tribological system is described by the function to be fulfilled, the input variables (operating variables), the output variables, the loss variables, and the structure (Fig. 9.1).

Apart from desired *input variables*, undesired input variables, so-called *disturbance variables*, also arise. Together with the structure, they influence the *output* and *loss variables* of the TS.

The function of a TS is to use the system structure to convert input variables (e.g., input torque, input speed, input type of motion, and sequence of motions) into technically utilizable output variables (e.g., output torque, output speed, output motion) (Fig. 9.1).

9.2.1 Structure

The elements involved, their properties, and the interactions between the elements describe the structure of a TS. The basic structure of every TS consists of four elements: the base body, counterbody, interfacial medium, and ambient medium (Fig. 9.1). Table 9.1 displays some TS with different elements. While the base body and counterbody are found in every TS, the interfacial medium and, in a vacuum, even the ambient medium can be absent.

In transport and machining processes, the base body is constantly stressed by new material zones of the counterbody. Such systems are called an *open* TS. By contrast, the stressed zones of the base body and counter-

body in a *closed* TS are repeatedly in contact. Examples of open and closed systems can also be found in Table 9.1. The function in open systems mainly depends on the wear of the base body. The counterbody generates the load; as a rule, the wear on it is not of interest. By comparison, when systems are closed, the ability to operate depends on the wear of both friction bodies. The elements of the TS are characterized by a large number of *properties*, largely listed in Table 9.2.

A difference is made principally between geometric and material properties in the base body and counterbody, which are supplemented by physical variables. The interfacial medium and ambient medium can appear in different aggregate states, on which other important tribological properties depend. A difference in the material properties of the base body and counterbody is made between bulk material and the near-surface zone. The properties of the near-surface zone, e.g., structural composition, hardness, and chemical composition, are particularly important for the tribological processes. In addition, the surface roughness's play an important role.

Figure 9.2 shows a diagram of the possible composition of *boundary layers* in metallic materials. The undisturbed *basic structure* generally has attached to it a hardened composition of machined or deformed layers endowed with a structure that is fine-grained compared with the basic structure. A reaction layer and an adsorption layer lie on top of this. Taken together they are also called the *outer boundary layer*. Wear is generally acceptable as long as it occurs in the outer boundary layer.

As a rule, not only the near-surface zone's material structure but also its chemical composition differs from those of the bulk material. This is apparent in Fig. 9.3. The material beneath the surface already changes during manufacturing in terms of the concentration of elements present compared with the bulk material. Other considerable changes undergone by the near-surface zone's element concentrations are caused by breaking-in or occur after a short running time.

9.2.2 Contact Geometry

It is not only the input variables, the material properties and the physical variables of the base body and counterbody, the interfacial medium, and the ambient medium but also the contact areas that greatly influence friction

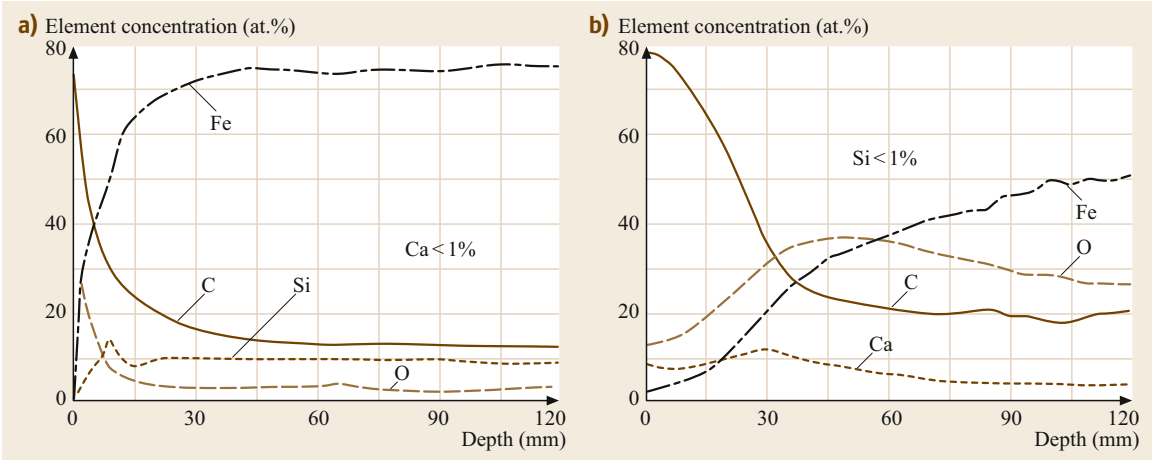

Fig. 9.3a,b Auger electron spectroscopy depth profiles as element concentration in the cylinder wall at top dead center in a diesel engine **(a)** before running in and **(b)** after 15 h running time (oil: SAE 15W-40) [9.4]

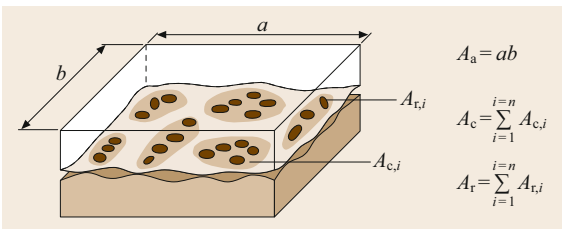

Fig. 9.4 Various types of contact areas

and wear of the base body and counterbody and the tribological system's lubrication state.

In turn, the contact areas appearing during operation depend on the form of contact (Table 9.3), the input variables, the geometric properties of the base body and counterbody (Table 9.1), and the other system properties.

In the contact areas, a difference is made between the *nominal or apparent contact area* and the *real contact area* (Fig. 9.4).

The nominal or apparent contact area A_a corresponds to the macroscopic contact area of the bodies in contact, e.g., of the contact area ab of a cuboid on one plane or the Hertzian contact area between a cylinder and a plane. Not only the apparent contact area but also the real contact areas $A_{r,i}$ play a key role when the asperities of the friction bodies meet in the apparent contact area.

The real contact areas result from the asperity contacts, which occur when the friction bodies are not completely separated by a lubricating film or in the cases of application in which no lubricant is used (dry friction). Not only the roughness but also the waviness on the friction body surfaces have to be taken into account when analyzing the real contact areas. The waviness causes so-called *contour areas* $A_{c,i}$ to form as well as the real contact areas on the asperity contacts within the contour areas.

As a rule, the sum of the real contact areas A_r, which is dependent on the roughness distributions and the separation of the two friction body surfaces, is substantially smaller than the apparent contact area ($A_r \approx 10^{-1}$–$10^{-4} A_a$). Hence the real contact pressures in the asperity contacts are substantially higher than the nominal pressure. While the nominal pressure displays elastic macromaterial behavior, plastic deformation may already have begun for a majority of the microcontacts (real contact areas). Results of calculations have yielded that the sum of the real contact areas is nearly proportional to the normal force F_n [9.5]. In addition, as the normal force increases, the number of real individual contacts increases, while the real individual contact area $A_{r,i}$ remains roughly constant.

Apart from the real contact area, the *overlap ratio* ε also plays an important role as well. It represents the ratio of the apparent contact area A_a to a friction body's friction area A_f. Thus, for example, the nonrotating bush of a sliding bearing with bearing clearance has an overlap ratio of $\varepsilon = 1$, since the apparent contact area A_a for the bearing bush corresponds to the friction area A_f. For the rotating shaft however, the friction area $A_f = \pi db$, with shaft diameter d and bearing bush width b, is larger than the apparent contact area $A_a = db\gamma/2$, with contact angle γ, so that the overlap ratio is $\varepsilon < 1$. For a constantly loaded friction body, an overlap ratio $\varepsilon = 1$ means permanent contact, no cyclical mechanical loads (macroscopic), permanent frictional heat absorption, and limited microchemical reaction with the ambient medium. For the friction body concerned, an overlap ratio of $\varepsilon < 1$ leads to an intermittent contact, to cyclical mechanical loading, to intermittent frictional heat absorption, and to

tribochemical reactions with the ambient medium in the range A_f–A_a. When both friction bodies (the base body and counterbody) have an overlap ratio of $\varepsilon \approx 1$, the wear particles can remain in the contact area and hence adversely influence the further wear profile.

9.2.3 Tribological Loads and Interactions

Tribological loads in a TS are generated by the input and disturbance variables' action on the system structure. They chiefly include contact, kinematic, and thermal processes [9.2]. According to [9.1], the tribological load represents "the loading of the surface of a solid caused by contact and relative motion of a solid, liquid or gaseous counterbody." It is introduced via the real contact areas. Plastic deformation and wear can cause the real contact areas to change during TS operation.

When mechanical energy is converted by friction, energy dissipates, which makes itself noticeable by changing the thermal situation. Since the thermal behavior also continuously adapts to the new conditions as a result of wear, changes to the contact geometry, and resulting changes in the friction, dynamic rather than static influencing variables determine the tribological loading in a real contact.

The contact geometry, the processes occurring in the contact, and the thermal behavior of a TS are influenced by, among other things, the load, the motion conditions, the element properties, and the friction state.

While the apparent contact area alone is decisive in fluid lubrication, according to [9.6], in mixed lubrication, i.e., when the dimensionless film thickness parameter

$$\Lambda = \frac{h_{\min}}{\left(R_{q1}^2 + R_{q2}^2\right)^{1/2}}\,, \tag{9.1}$$

with the minimum lubrication film thickness $h_{\min}$ and the root-mean-square (rms) surface roughnesses R_{q1} and R_{q2} of the base body and counterbody, is in the range $\Lambda < 3$, in boundary lubrication with $\Lambda < 1$ and for dry friction, both the apparent contact area and the real contact areas must be considered and allowed for (Fig. 9.4).

When there are contacts between the friction bodies, *interactions* occur in the real contact areas and in the near-surface zones. *Atomic/molecular* interactions occur on the one hand and *mechanical* interactions on the other. Whereas the former cause adhesion on solid–solid boundary layers or are extremely important technically in the form of physisorption and chemisorption on solid–fluid boundary layers, the latter lead to elastic and plastic contact deformations and to the development of the real contact areas.

Table 9.3 Contact geometry (form of contact) of tribological systems

Form of contact	Base body	Counterbody	Sketch	Example application
Conformal				
Areal	Plane	Plane		Thrust bearings
	Hollow cylinder	Solid cylinder		Sliding bearings, round fittings, cylinder races
Nonconformal				
Line contact	Plane	Cylinder		Thrust roller bearings
	Cylinder	Cylinder		Roller, roller bearings
	Pinion tooth	Gear tooth		Gears
Point contact	Plane	Ball		Thrust ball bearings
	Inner ring (circumferential direction)	Ball		Ball bearings

The type of interaction that primarily occurs depends greatly on the friction state. Thus, when a lubricant is present the atomic/molecular interaction can be disregarded more often than the mechanical.

Friction and wear in a given TS ultimately depend on the interactions between the elements. The friction state, the effective mechanisms of friction and wear, and the contact state can be used to describe the interactions.

The tribological loads occurring in the real contact areas produce *tribological processes*. These subsume the dynamic physical and chemical mechanisms of friction and wear and boundary-layer processes that can be attributed to friction and wear.

9.2.4 Operating Variables (Input Variables)

According to [9.1], the operating variables are: the type of motion, the time sequence of motions of the elements contained in the system structure, and a number of technical-physical load parameters, which act on the system structure when the function is executed. The operating variables originate from:

- Type of motion and time sequence of motions
- Load
- Velocities
- Temperatures
- Loading time.

The type of motion can frequently be attributed to one of the basic types of motion *sliding*, *rolling*, *spin*, *impact* or *flowing* or can be composed from these. The time sequence of motions can occur regularly, irregularly, back and forth, or intermittently. The sequence of motions frequently also consists of different components. As a rule, the normal force F_n is decisive for the load.

Both the relative velocity between the friction bodies and the entraining velocity of the lubricant in the

contact and the slippage as a ratio of the relative velocity to the average circumferential velocity play a role for the velocities. The friction body temperatures and the effective contact temperature produced in operation are critically important for the temperature variables. It is normally not possible to measure the contact temperatures. Apart from these desired input variables, which as a rule are specified by a technical function, *disturbance variables* such as vibrations or dust particles must be considered under certain circumstances.

9.2.5 Output Variables (Useful Variables)

The TS provides output variables for subsequent utilization. These useful variables reflect the performance of a function of the TS. The useful variables can differ over extremely wide ranges depending on the main task of the TS. In an energy-determined system, for example, the following output variables may be desired:

- Force
- Torque
- Velocity
- Motion
- Mechanical energy.

Particular material or signal variables could be interesting as useful variables in a material- or signal-determined TS.

9.2.6 Loss Variables

The loss variables of a TS are essentially represented by friction and wear. While friction leads to losses of force, torque or energy, wear means a progressive loss of material.

The energy losses produced when there is friction are converted into heat for the most part. This process is irreversible and is called energy dissipation. Along with the conversion of friction into heat and the generation of wear particles, the tribological process generates other tribologically induced loss variables such as vibrations that frequently become apparent through sound waves, photon emission (triboluminescence), electron, ion emission, etc.

9.3 Friction

Friction can be ascribed to the interactions between bodies' material zones that are in contact or moving relative to one another; it counteracts relative motion. External and internal friction are differentiated. When friction is external, the different friction bodies' material zones are in contact; when friction is internal, material zones that are in contact belong to one friction body or the interfacial medium.

A number of parameters can characterize friction. Thus, depending on the application, friction is characterized by the friction force F_f, the friction torque M_f or the coefficient of friction f. Instead of f the symbol μ is also frequently used for the coefficient of friction. The coefficient of friction f is formed from the ratio of the friction force F_f to the normal force F_n

$$f = \frac{F_f}{F_n} . \tag{9.2}$$

The work of friction or friction energy W_f is used to calculate the frictional heat or the amount of deformation of the friction force in solid friction. It is calculated as

$$W_f = F_f s_f , \tag{9.3}$$

with the friction distance s_f. The friction power P_f is of interest for an energy balance or efficiency calculation. The friction power is a power loss and, disregarding signs, the following applies

$$P_f = F_f \Delta v , \tag{9.4}$$

with the relative velocity Δv. (The power loss is frequently defined negatively.)

9.3.1 Types of Friction

Friction can be classified according to various features. Types of friction are distinguished depending on the type of relative motion between the friction bodies. Figure 9.5 presents the most important types of friction with sample applications. There are three main types of friction:

- Sliding friction
- Rolling friction
- Spin friction.

Apart from these three kinematically defined types of friction, there can be overlaps (mixed forms), namely:

- Sliding-rolling friction (rolling friction)
- Sliding-spin friction
- Rolling-spin friction.

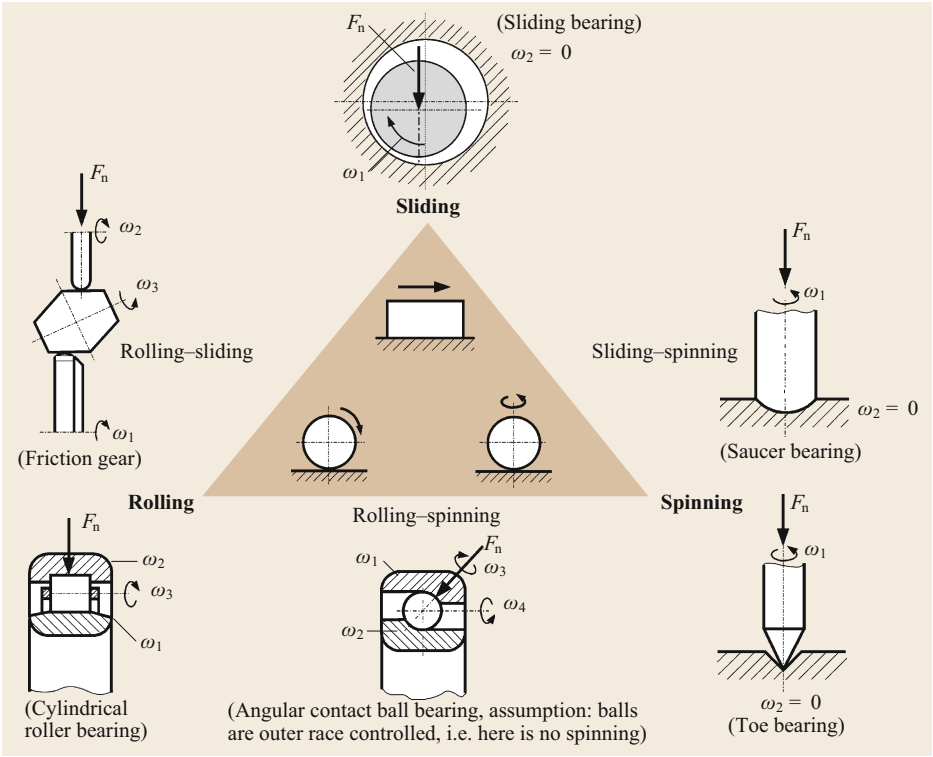

Fig. 9.5 Types of dynamic friction

Along with the types of friction shown in Fig. 9.5, another type of friction is impact friction, which applies when a body strikes another body perpendicular or oblique to the contact surface and possibly withdraws again. The angular contact ball bearing is a machine element in which sliding and rolling and spin friction appear.

9.3.2 Friction States

Various friction states can be defined if friction is classified as a function of the aggregate state of the material zones involved. To illustrate this, Fig. 9.6 presents different states of friction based on the Stribeck curve using a radial sliding bearing as an example. Generally, the following friction states are differentiated:

- Solid friction
- Fluid friction
- Gas friction
- Mixed friction.

In *solid friction* the friction acts between material zones that exhibit solid properties and are in direct contact. If the friction occurs between solid boundary layers with modified properties compared with the bulk material, e.g., between reaction layers, then this is *boundary-layer friction*. If the boundary layers on the contact surfaces each consist of a molecular film coming from a lubricant, then this is called *boundary friction*. In boundary friction, the lubricant's hydrodynamic effect can be disregarded because the velocity is very low and/or only a very small quantity of lubricant, insufficient to fill the lubrication gap, is present.

Fluid friction is internal friction in a lubricating film with fluid properties and is present in a hydrodynamically, elastohydrodynamically or hydrostatically produced lubricating film.

Gas friction is internal friction in a lubricating film with gas properties and is present in an aerodynamically or aerostatically produced lubricating film.

Mixed friction is any mixed form of the friction states. The term is primarily used in the simultaneous presence of boundary and liquid friction.

9.3.3 Friction Mechanisms

Solid friction can be ascribed to interactions between the elements. As already addressed before, there are essentially two different types of interaction, i.e., atomic/molecular and mechanical. *Kragelski* [9.7] speaks of friction's "dual nature". Hence, the friction mechanisms can be divided into two groups. Generally a difference can initially be made between the following four fric-

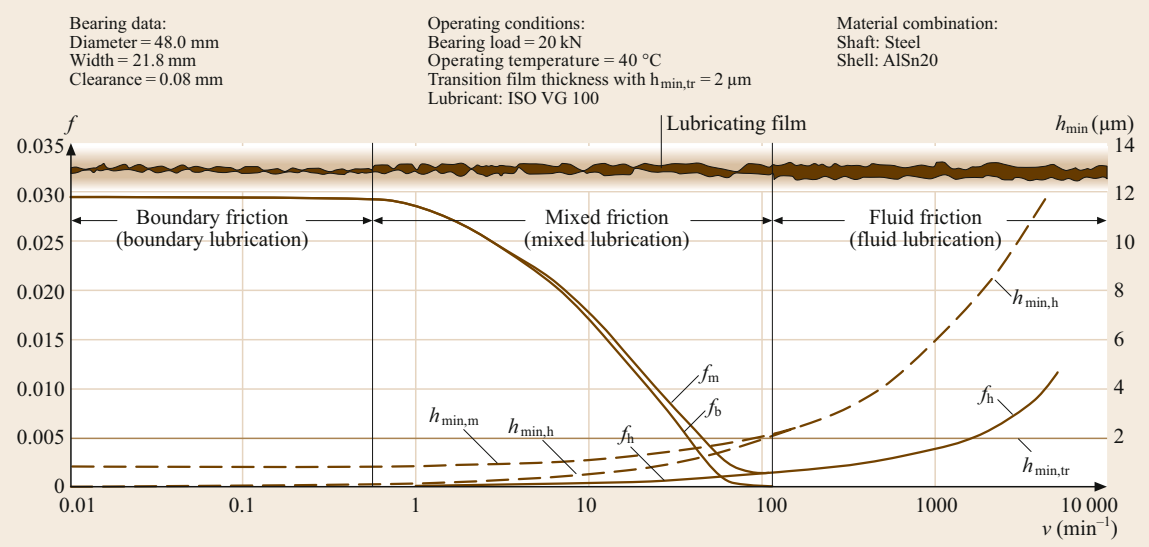

Fig. 9.6 Stribeck curve, minimum lubrication film thickness, and friction states in a radial sliding bearing (f_m friction coefficient in mixed friction, f_b friction coefficient in boundary friction, f_h friction coefficient in fluid friction, $h_{min,tr}$ minimum lubrication film thickness during the transition from fluid to mixed friction, $h_{min,h}$ minimum lubrication film thickness during fluid friction, $h_{min,m}$ minimum lubrication film thickness during mixed friction)

tion mechanisms, compiled schematically in Fig. 9.7:

- Adhesive bond shearing
- Plastic deformation
- Abrasion
- Hysteresis losses in elastic deformation.

Adhesion is an atomically/molecularly based friction mechanism. Its frictional effect is based on the bonds formed atomically or molecularly in the real contact areas that separate again when relative motion occurs, as a result of which energy loss occurs.

Deformation, abrasion, and hysteresis can be classified as mechanically based friction mechanisms. The action of friction in deformation and abrasion can above all be ascribed to the displacement of overlaps of asperities. Hysteresis is based on internal friction and has a damping effect. Different friction mechanisms frequently appear at the same time. The friction mechanisms that are principally acting depends on the state of friction.

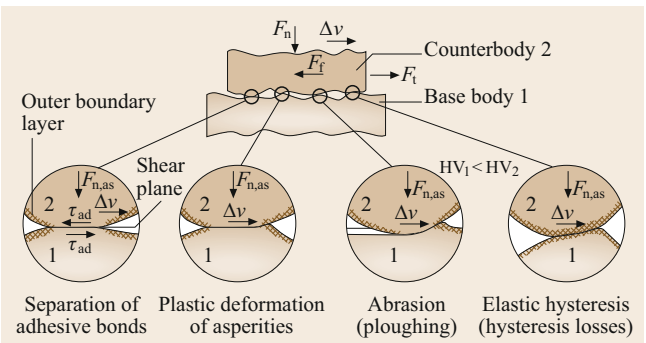

Fig. 9.7 Basic friction mechanisms viewed microscopically (F_n normal force on apparent contact area, F_f friction force between base body and counterbody, F_t tangential force, $F_{n,as}$ normal force on asperity contact, Δv relative velocity, τ_{ad} shear stress for shearing an adhesive bond, HV Vickers hardness)

9.3.4 Coefficient of Friction

Table 9.4 reproduces ranges of friction coefficients in various types and states of friction [9.8]. It should however be recalled that friction does not represent a constant property of a material or a combination of material properties but rather depends on the operating variables and the system structure, i.e., on the load and the elements involved in the friction process with their properties and interactions.

Table 9.4 Coefficients of friction for different types and states of friction

Type of friction	Friction state	Coefficient of friction f
Sliding friction	Solid friction	0.1–1
	Boundary friction	0.1–0.2
	Mixed friction	0.01–0.1
	Fluid friction	0.001–0.01
	Gas friction	0.0001
Rolling friction	(Grease lubrication)	0.001–0.005

9.4 Wear

As soon as the base body and counterbody come into contact, i.e., when the lubrication film thickness becomes too small or lubricant is unavailable, wear occurs. Wear is a progressive loss of material from the surface of a solid, brought about by mechanical causes, i.e., by contact and relative motion of a solid, fluid or gaseous counterbody [9.1]. Signs of wear are small detached wear particles, material removal from one friction body to the other, and material and shape changes of the tribologically loaded material zone of one or both friction partners.

9.4.1 Types and Mechanisms of Wear

Wear processes can be classified into different types according to the type of tribological load and the materials involved, e.g., sliding wear, fretting wear, abrasive wear, and material cavitation. Wear is caused by a number of mechanisms, the following four being especially important:

- Surface fatigue
- Abrasion
- Adhesion
- Tribochemical reaction.

Table 9.5 provides a breakdown of wear according to types of wear and wear mechanisms based on [9.1].

Figure 9.8 presents a chart of the effective wear mechanisms. The wear mechanisms can occur individually, successively or concomitantly.

Surface fatigue manifests itself through cracking, crack growth, and detachment of wear particles, brought about by alternating loads in near-surface zones of the base body and counterbody.

In *abrasion* microcuttings, fatigue due to repeated ploughing, and fracture of the base body caused by the

Table 9.5 Types and mechanisms of wear (after [9.1])

System structure	Tribological load (types of motion and simplified symbols)	Type of wear	Effective wear mechanism			
			Surface fatigue	Abrasion	Adhesion	Tribochemical reactions
Solid ● Interfacial medium (complete solid separation) ● Solid	Sliding Rolling Bouncing Impacting 	–	×			×

Solid ● Fluid and particles	Flowing 	Particle erosion (erosion wear)	×	×		×

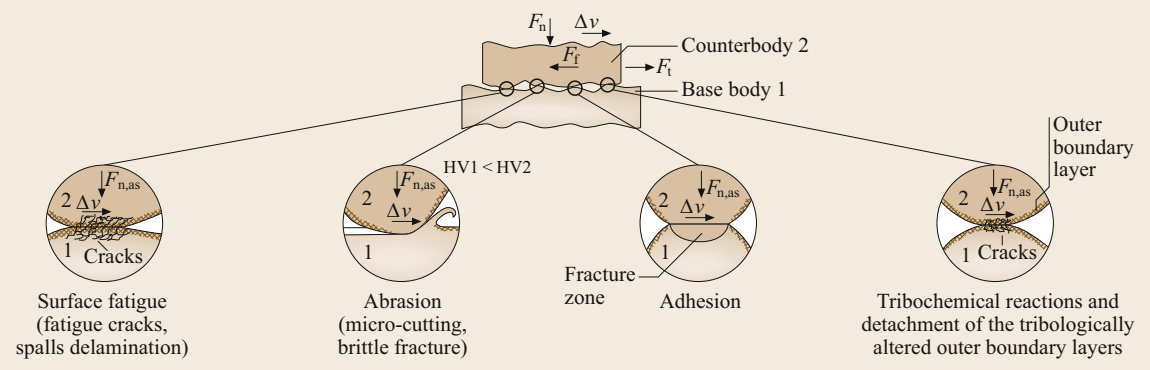

Fig. 9.8 Basic wear mechanisms viewed microscopically (F_n normal force on apparent contact surface, F_f friction force between base body and counterbody, $F_{n,as}$ normal force on asperity contact, Δv relative velocity, HV Vickers hardness)

Table 9.6 Typical wear phenomena caused by the main wear mechanisms (after [9.1])

Wear mechanism	Wear phenomenon
Adhesion	Scuffing or galling areas, holes, plastic shearings, material transfer
Abrasion	Scratches, grooves, ripples
Surface fatigue	Cracks, pitting
Tribochemical reactions	Reaction products (layers, particles)

counterbody's hard asperities or by hard particles in the interfacial medium lead to wear.

In *adhesion*, after possibly extant protective surface layers have been broken through, atomic bonds (microwelds) form above all on the plastically deformed microcontacts between the base body and counterbody. If the strength of the adhesive bonds is greater than that of the softer friction partner, material eventually detaches from the deformed surface of the softer friction partner and is transferred to the harder one. The transferred material can either remain on the harder friction partner or detach, or even return.

In *tribochemical reactions*, friction-induced activation of loaded near-surface zones causes elements of the base body and/or counterbody to react chemically with elements of the lubricant or ambient medium. Compared with the base body and counterbody, the reaction products exhibit changed properties and, after reaching a certain thickness, can be subject to brittle chipping or even exhibit properties reducing friction and/or wear.

Apart from the types and mechanisms of wear, *wear phenomena* are also extremely interesting for interpreting the result of wear (Table 9.6). These mean the changes of a body's surface layer resulting from wear and the type and shape of the wear particles accumulating. Light or scanning electron microscope images can present this extremely clearly.

9.4.2 Wear Profiles and Measurable Variables

Estimating the service life of components necessitates knowing the wear profile over the loading time and/or the rate of wear (amount of wear per loading time). According to [9.1, 8], different wear profiles are frequently generated depending on the effective wear mechanism (Fig. 9.9).

Three phases are distinguished: break-in, steady state, and failure. During breaking-in, increased wear, so-called break-in wear, with a degressive profile can occur and, for example, switch over into a long-lasting state with a constant increase of the amount of wear (constant rate of wear) until failure is announced by a progressive increase of wear (Fig. 9.9a).

If surface fatigue takes effect as the primary mechanism of wear, then measurable wear after break-in frequently only becomes noticeable after a certain incubation period during which microstructural changes, cracking, and crack growth commence. Wear particles only detach after the incubation period (Fig. 9.9b). A negative amount of wear is even occasionally measured at the beginning of the wear process. This is caused by material transfer from the wear partner (Fig. 9.9c).

In principle, the profile of the amount of wear W over the loading time t can be progressive, linear or digressive (Fig. 9.9d).

A difference is made between directly measurable wear variables, such as linear, planimetric, volumetric and mass amount of wear, and related measurable wear variables (wear rates), such as rate of wear, wear–distance ratio, and wear–throughput ratio. As a rule, the amount of wear can be measured. It is advisable to use specific or relative amounts of wear in comparative wear tests whenever the operating variables or the

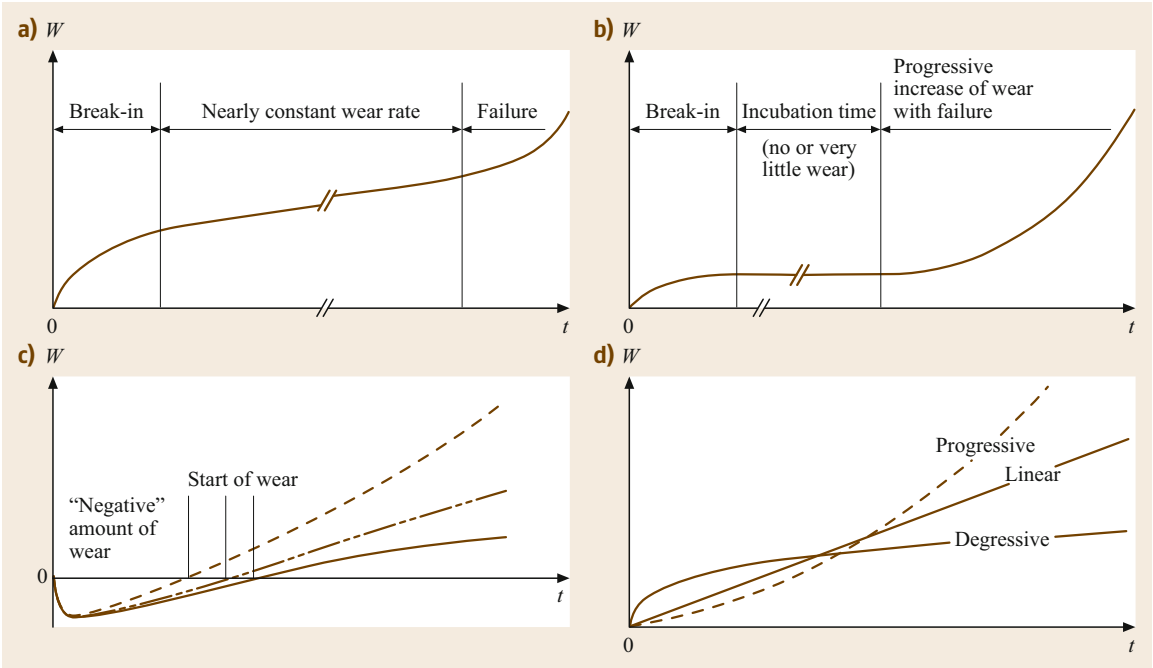

Fig. 9.9a–d Amount of wear as a function of loading time: **(a)** typical wear profile with a nearly constant wear rate; **(b)** wear profile with an incubation time; **(c)** wear profile with negative amount of wear; **(d)** different wear profiles

properties of the elements involved in the wear cannot be kept constant or are intentionally changed.

9.4.3 Determination of Wear and Lifetime

In unlubricated tribological systems and in systems operated in the boundary or mixed lubrication range, practically usable information about friction and wear can frequently only be found through experimentation since the physical and chemical mechanisms occurring here frequently cannot be described sufficiently exactly theoretically so that a precise calculation of friction and wear is often impossible.

However, mathematical equations for an approximate preliminary determination of friction and wear provide the energy balance of the friction process. If friction is approached as an energetic problem, the energy balance forms the basis for determining the friction and wear [9.9]. The friction force F_f and the friction coefficient f can be determined from the friction energy W_f

$$W_f = W_{el,hys} + W_{pl} + W_{abr} + W_{ad} = fF_n s_f = fF_n \Delta v t \,, \quad (9.5)$$

where $W_{el,hys}$ is the proportion of the work of friction from the hysteresis during elastic deformation, W_{pl} is the work of friction from plastic deformation, W_{abr} is the work of friction caused by abrasion, W_{ad} is the work of friction caused by separation of adhesive bonds, f is the friction coefficient, F_n is the normal force, s_f is the friction distance, Δv is the relative velocity between the friction bodies, and t is the friction time [9.9].

The action time of a friction pair usually depends on the wear. The anticipated lifetime L_h under specific operating conditions is frequently determined by calculation. A function-based maximum allowable wear is assumed. Thus, the lifetime L_h corresponds to the action time for which the friction pair can be safely operated.

Wear properties as a function of the friction time are presented in Fig. 9.10. The development of wear with its scatter as a function of the friction time is shown for various operating conditions. The wear height h_w serves as the gauge of wear. The function-based wear limit is characterized by the maximum allowable wear height $h_{w,al}$. As a rule, a wear profile exists, which is composed of a break-in process and a steady state (Fig. 9.10, cases 2 and 3). In addition, Fig. 9.10 also shows the distribution densities $f(t)$ for the lifetimes L_h defined by $h_{w,al}$.

Despite a large allowable wear height, case 1 is not practicable since the friction pair here fails early and

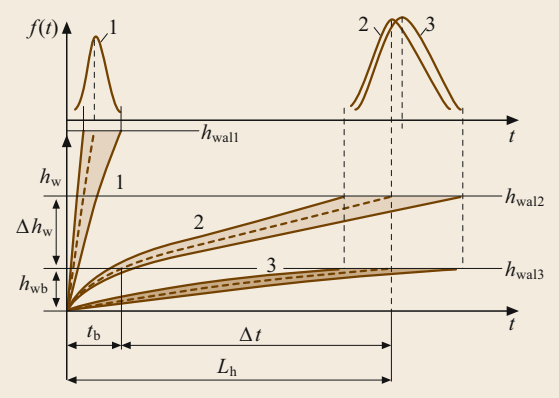

Fig. 9.10 Courses of wear height h_w and distribution density $f(t)$ as a function of the friction time t when allowable wear height values have been reached for different high stresses and different frictional states (after [9.10])

does not reach a steady state. Case 2 shows a normal progression in pure solid friction. More favorable conditions exist in case 3 (e.g., mixed friction), but the allowable wear height is small.

The average lifetime (action time) for the median of the distribution density results from the expression

$$L_h = t_b + \Delta t = t_b + \frac{h_{w,al} - h_{w,b}}{I_h \Delta v} , \qquad (9.6)$$

with the linear wear intensity I_h formed from the ratio of the wear height h_w to the friction distance s_f ($I_h = \Delta h_w / \Delta s_f$), the break-in time t_b, and the break-in wear height $h_{w,b}$. If it is assumed that the wear volume V_w and the work of friction W_f are proportional ($W_f \propto V_w$), and the value e_w as a proportionality factor is introduced as the wear energy density, as a result of which the basic wear equation becomes $W_f = e_w V_w$, and if the probabilistic nature of real operation is allowed for (through the introduction of $L(\gamma)_h$ as γ percentage lifetime, x as the quantile (random variable) of the standardized normal distribution, and v as an empirical coefficient of variation that represents a measure of the scatter of the wear rate), then the following expression can be set up for the lifetime [9.10]

$$L(\gamma)_{h1,2} = t_{b1,2} + \frac{(h_{w,al1,2} - h_{w,b1,2})\, e_{w1,2}}{\alpha_{f1,2} \tau_f \Delta v\, (1 - x v_{1,2})} , \qquad (9.7)$$

with the friction shear stress $\tau_f = f F_n / A_a$, where A_a stands for the apparent contact area, and the energy proportion factor $\alpha_{f1,2}$ is used to quantify the share of the work of friction induced in friction body 1 or 2.

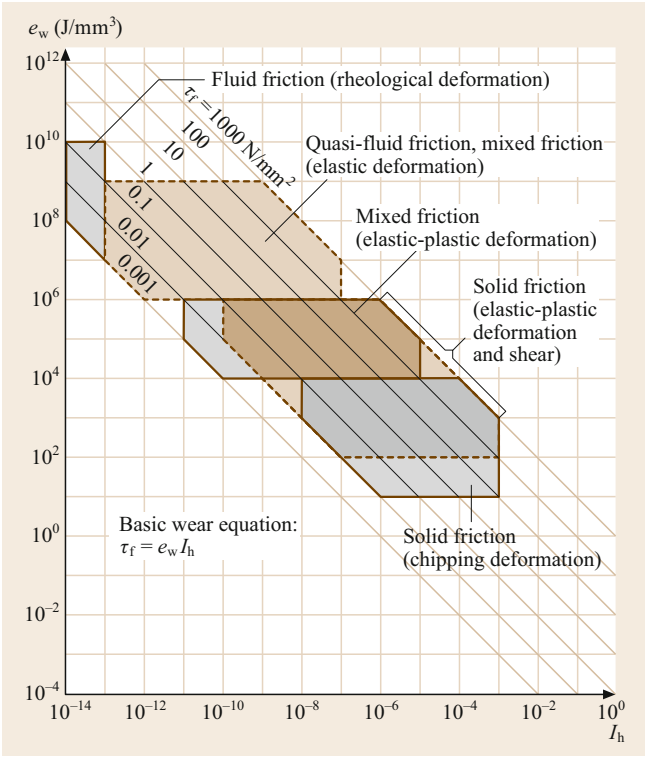

Fig. 9.11 Wear energy density e_w as a function of the linear intensity of wear I_h and the friction shear stress τ_f (after [9.9])

For a survival probability of $\gamma = 50\%$, when there is a standardized normal distribution, the quantile is $x = 0$, whereas $x = -1.28$ applies for $\gamma = 90\%$. The coefficient of variation depends on the operating conditions (common values based on [9.11] are $v = 0.2$–0.8; when there is fatigue wear, $v = 0.2$–0.4).

Determining the lifetime by using (9.7) not only requires knowledge of the break-in time t_b, the allowable wear height $h_{w,al}$, the break-in wear height $h_{w,b}$, the energy proportion factor α_f, the normal force F_n, the apparent contact surface A_a, the relative velocity Δv, and the statistical variables quantile x and coefficient of variation v but above all also information about the friction coefficient f and the wear energy density e_w appearing in the contact.

The friction coefficient can be determined experimentally or estimated through calculations [9.3, 12]. Values for the wear energy density e_w are either determined in tests or taken out of [9.9–11]. Figure 9.11 presents the nomogram of the basic wear equation $W_f = e_w V_w$, with ranges for typical friction and wear states for evaluating and classifying the tribological behavior of friction pairs.

9.5 Fundamentals of Lubrication

Lubrication completely or partially separates the surfaces of the friction bodies by selectively introducing an interfacial medium (lubricant) that minimizes friction and wear. Most lubricants are fluids (mineral oils, synthetic oils, water, etc.), yet they can also be solid, e.g., for use in dry sliding bearings (polytetrafluoroethylene (PTFE), graphite, molybdenum disulfide (MoS_2), etc.). Greases are also applied, e.g., in ball bearings and sliding bearings and occasionally in gears too. Gases (air) are also employed, e.g., in gas-lubricated bearings. Figure 9.12 reproduces the areas of application of different lubricants. Powders, lubricating varnishes, and pastes can be classified as solid lubricants [9.13].

Similar to friction states, different lubrication states can also be defined (Table 9.7), to be precise: fluid film lubrication, mixed lubrication, boundary lubrication, and solid lubrication (lubrication with solid lubricants and surface coatings).

9.5.1 Fluid Film Lubrication

Fluid film lubrication, i.e., the complete separation of the frictional surfaces by a lubricating film, can be achieved by hydrodynamic, elastohydrodynamic or hydrostatic lubrication (Table 9.8). A load-dependent pressure is developed in the lubricating film, as a result of which the load can be carried.

9.5.2 Hydrodynamic Lubrication

The following conditions must be met to produce hydrodynamic lubrication. A viscous lubricant that adheres to both the moving and the fixed friction body must be used (adhesive effect of the lubricant). Furthermore, the friction body surfaces must be converging and the lubricant must be dragged into the converging gap. The entraining velocity depends on the velocity at which the lubricant is dragged into the contact and is frequently confused with the relative velocity. The latter is decisive for friction, while the entraining velocity is essential for load-carrying capacity.

The lubricant adhering to the surface is dragged into the lubrication gap by the friction bodies moving relative to the minimum lubrication film thickness. Since the gap converges in the direction of motion, the quantity of oil dragged by the friction bodies accumulates in front of the narrowest gap cross section and cannot be completely transported by the moving friction bodies' drag effect alone through the minimal cross section.

Thus, overpressure is inevitably produced in the converging zone in between the sliding surfaces, which grows to be just large enough that the difference between the quantities supplied and discharged by the drag flow are squeezed out of the lubricant gap as a result of compressive flows (satisfaction of the condition of continuity). The overpressure produces the friction contact's load-carrying capacity in equilibrium with the external load.

Figure 9.13 presents examples of velocity distributions at various points in the lubrication gap and the pressure distribution for an inclined plane bearing pad. The level of the average pressure developed (normally < 7 MPa) is usually not high enough to cause significant elastic deformation of the surfaces. The

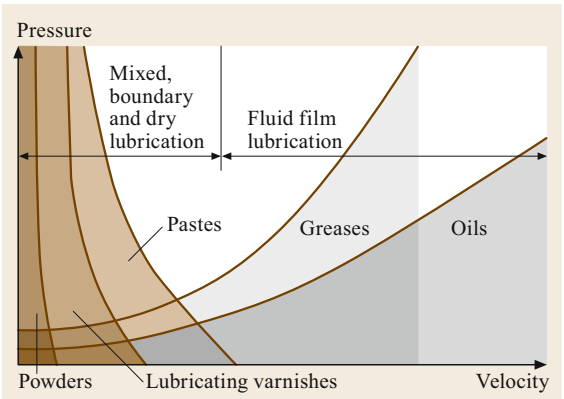

Fig. 9.12 Areas of lubricant application (after [9.13])

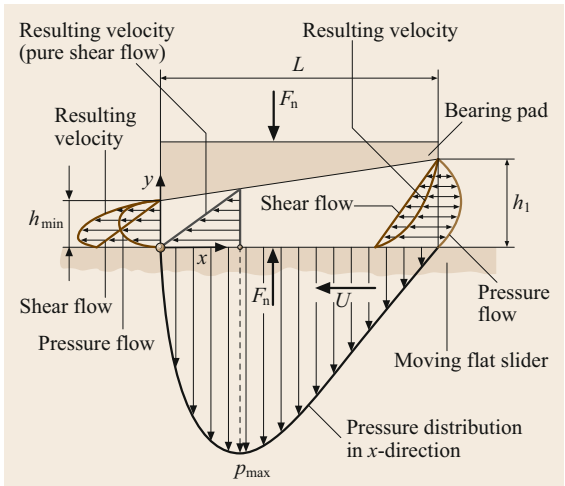

Fig. 9.13 Velocity distributions and pressure distribution in a bearing pad

Table 9.7 Friction and lubrication states

	Friction/lubrication states
	1. Solid friction/no lubrication ● Direct contact of friction partners ● Formation of oxide reaction layers and adsorption of gases ● High wear rates probable, risk of seizing ● Friction coefficients (reference values): $f \approx 0.35$ to > 1 ● Special cases *Boundary-layer friction* Friction between solid boundary layers with modified properties compared with the bulk material (e.g., oxide layers) *Friction of pure metallic surface* Direct contact of pure metallic surfaces (e.g., in machine or scuffing processes)
	2. Boundary friction/boundary lubrication ● Surfaces of the friction partners covered with a thin friction minimizing lubrication film ● Physisorption, chemisorption, and tribochemical reaction with additives from the lubricant form friction-minimizing, lightly shearing layers on the surfaces ● Lower wear rates than for solid friction ● Friction coefficients (reference values): $f \approx 6 \times 10^{-2}$–$2 \times 10^{-1}$
	3. Mixed friction/mixed lubrication ● Lubrication film not thick enough to separate surfaces from each other completely; consequence: roughness contacts ● Load is partially carried by lubricating film through hydrodynamic effect and partly by the roughness contacts ● As in boundary friction, use of additives in lubricant is also important to generate friction-minimizing absorption and reaction layers on the surfaces ● Wear rates are smaller, the larger the hydrodynamic part of the load-carrying capacity ● Friction coefficients (reference values): $f \approx 10^{-3}$–10^{-1}
	4. Fluid friction/fluid film lubrication ● Friction partners are completely separated from each other by a fluid film that can be generated, hydrodynamically or hydrostatically ● Virtually wear-free operation ● Friction coefficients (reference values): $f \approx 6 \times 10^{-4}$–$5 \times 10^{-3}$

hydrodynamic pressure is dependent on the friction bodies' geometry, the inclination of the surfaces to each other, the viscosity of the lubricant, the load, and the velocity of the lubricant dragged into the converging lubrication gap.

Table 9.8 specifies the correlation between the minimum lubrication film thickness h_{min} and the entraining velocity, the viscosity of the lubricant, and the load. It is evident that the minimum lubrication film thickness increases as the entraining velocity increases and the viscosity becomes greater, and that it decreases as the load grows, although only with an exponent of 0.5 in each case. The minimum lubrication film thickness is normally greater than 1 μm.

Above all, it is the lubricant's viscosity that determines the lubricating effect in hydrodynamic lubri-

Table 9.8 Different types of fluid film lubrication

	**Hydrodynamic** [9.14] For a given geometry $h_{min} \approx \sqrt{\frac{\overline{v}\eta}{F_n}} = (\overline{v}\eta)^{0.5} F_n^{-0.5}$, $\overline{v} = \frac{v_1+v_2}{2}$ entraining velocity, η average viscosity of the lubricant in the lubricating film, F_n load
	**Elastohydrodynamics** [9.6] a) *Hard material surfaces (hard EHL)* Elliptical contact surfaces, given geometry $h_{min} \approx (\overline{v}\eta_0)^{0.68} \alpha^{0.49} E^{*-0.117} F_n^{-0.073}$, $\frac{h_{min}}{h_c} \approx 0.56$ $\overline{v} = \frac{v_1+v_2}{2}$ entraining velocity, η_0 viscosity of the lubricant at gap entry at $p = 0$, α viscosity–pressure coefficient, $\frac{1}{E^*} = \frac{1}{2}\left(\frac{1-\upsilon_1^2}{E_1} + \frac{1-\upsilon_2^2}{E_2}\right)$ reduced modulus of elasticity, E_1 and E_2 Young's modulus of friction bodies 1 and 2, υ_1 and υ_2 Poisson's ratio of friction bodies 1 and 2, F_n load b) *Soft material surfaces (soft EHL)* Elliptical contact surfaces, given geometry $h_{min} \approx (\overline{v}\eta_0)^{0.65} E^{*-0.44} F_n^{-0.21}$; $\frac{h_{min}}{h_c} \approx 0.77$
	**Hydrostatic** [9.14] For a given geometry and constant lubricant volumetric flow ($\dot{V} = \text{const.}$) $h_{min} \approx \sqrt[3]{\frac{\eta}{F_n}} = \eta^{0.33} F_n^{-0.33}$, F_n load, η average viscosity of the lubricant in the lubricant cap

cation. Friction is only generated by the shear of the viscous lubricant. Apart from the viscosity, the relative velocity between the moving bodies' lubrication gap surfaces and the lubrication gap height are decisive for friction. If both surfaces slide with the same sliding velocity, the relative velocity is $\Delta v = 0$, i.e., friction does not occur. However, when the sliding conditions are identical, the entraining velocity in the lubrication gap can be high (e.g., in the case of radial sliding bearings, in which the shaft and bushing rotate with the same speed in the same direction) so that the tribological system then has a high load-carrying capacity and a friction force of zero.

Elastohydrodynamic Lubrication

Elastohydrodynamic lubrication (EHL) is a form of hydrodynamic lubrication in which elastic deformations of the lubricated surfaces become significant. The essential prerequisites for hydrodynamic lubrication, such as a converging lubricating film, the lubricant entraining

velocity in the converging gap, and a viscous lubricant between the surfaces, are also important in EHL. Elastohydrodynamic lubrication is normally connected with nonconformal surfaces (Table 9.3). There are two different forms of EHL: for hard surfaces (hard EHL) and soft surfaces (soft EHL).

Hard EHL. Elastohydrodynamic lubrication for hard surfaces (hard EHL) refers to materials with high moduli of elasticity, e.g., metals. Both the elastic deformations and the viscosity's pressure dependence are equally important in this type of lubrication. The maximum occurring lubricating film pressure is typically between 0.5 and 4 GPa. The minimum lubrication film thickness normally exceeds 0.1 μm. When the loads are those normally occurring in nonconformal contacts of machine elements, the elastic deformations in hard EHL exhibit values several magnitudes greater than the minimum lubrication film thicknesses. Furthermore, the lubricant viscosity in the lubrication film can change by a magnitude of 3–4 or more, depending on the lubricant, pressure, and temperature.

The minimum lubrication film thickness h_{min} is a function of the same parameters as in hydrodynamic lubrication, but these must be augmented by the effective Young's modulus E^* and the lubricant's viscosity–pressure coefficients α. Table 9.8 indicates that, in the relationship for the minimum lubrication film thickness, the exponent for the normal load in hard EHL is approximately seven times smaller than it is in hydrodynamic lubrication. This means that, in contrast to hydrodynamic lubrication, the load only marginally influences the lubrication film thickness in hard EHL. The reasons are to be found in the increase of the contact area as the load increases in hard EHL, as a result of which a larger lubrication area is provided to bear the load. The exponent for the lubricant entraining velocity in hard EHL is greater than in hydrodynamic lubrication. Typical applications for hard EHL are toothed gears, rolling element bearings, and cam–follower pairs.

Soft EHL. Elastohydrodynamics for soft surfaces (soft EHL) refers to materials with low moduli of elasticity, e.g., rubber. In soft EHL, sizeable elastic deformations occur even at low loads. The maximum occurring pressures in soft EHL are typically 1 MPa, in contrast to 1 GPa for hard EHL. This low lubricating film pressure only negligibly influences the viscosity during the flow through the lubrication gap. The minimum lubrication film thickness is a function of the same parameters as in hydrodynamic lubrication with the addition of the effective modulus of elasticity E^*. The minimum lubricating film thickness in soft EHL is typically 1 μm. Applications for soft EHL are seals, artificial human joints, tires and nonconformal contacts in which rubber is used.

A common feature that hard and soft EHL exhibit is the generation of coherent lubricating films as a result of local elastic deformations of the friction bodies and thus the prevention of interactions between asperities. Hence, only the lubricant's shear generates frictional resistance to motion.

Hydrostatic Lubrication

In hydrostatic lubrication of friction bodies, a pocket or recess is incorporated in one friction body's loaded surface into which a fluid is forced from outside at constant pressure. A pump outside the bearing generates the lubricant pressure. Hence, the lubricant pump and the lubricating pocket into which the lubricant is fed under pressure are the most important features of hydrostatic lubrication. The lubricating pocket is normally positioned opposite the external load. The load-carrying capacity of a contact with hydrostatic lubrication is also assured when surfaces are not moving. When the volumetric flow of lubricant into the lubricating pocket is constant, the minimum lubrication film thickness is proportional to the cube root of the ratio of the average lubricant viscosity in the lubrication gap and the load, i.e., the minimum lubrication film thickness is less dependent on the viscosity and the load than is the case in hydrodynamic lubrication.

Hydrostatic lubrication is mainly used: where the friction partners' surfaces do not have any metallic contact, i.e., wear may not occur, not even when ramping up and ramping down a machine or at low speed; where as low a friction coefficient as possible must be produced at low speeds; and where, as a result of less effective lubricant entraining velocities in the lubrication gap, the wedge effect cannot produce any bearing lubricating film hydrodynamically.

9.5.3 Boundary Lubrication

In *boundary lubrication*, the friction bodies are not separated by a lubricant, the hydrodynamic lubricating film effects are negligible, and there are extensive asperity contacts. The physical and chemical properties of thin surface films of molecular thickness control the lubricating mechanisms in the contact. The base lubricant's properties are of little importance. The coefficient of friction is on the whole independent of the lubricant's viscosity. The frictional characteristic is determined by the properties of the solids involved in the

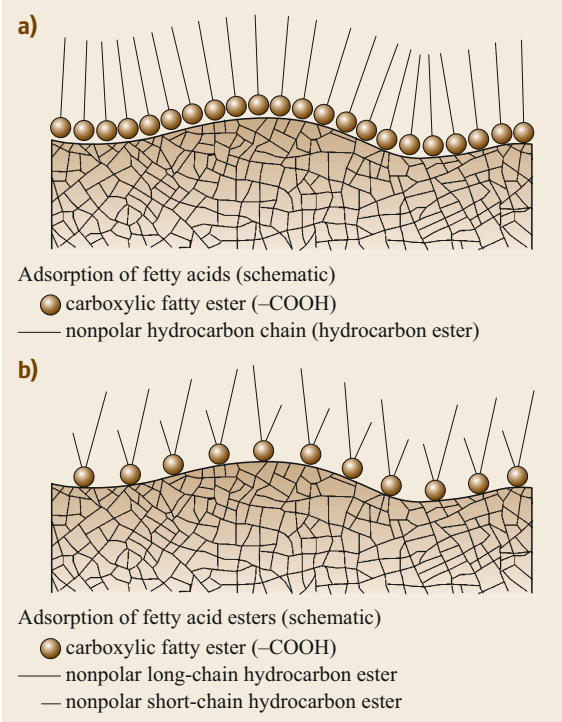

Fig. 9.14 Adsorption on metal surfaces (after [9.15])

friction process and the boundary layers forming on the material surfaces, which primarily depend on the lubricant's properties, particularly the lubricant additives, as well as the material surfaces' properties. These boundary layers are formed by physisorption, chemisorption, and/or tribochemical reaction. The thickness of the surface boundary layer varies between 1 and 10 nm, depending on the molecule size.

In *physisorption*, additives contained in the lubricant (e.g., antiwear (AW) additives) such as saturated and unsaturated fatty acids, natural and synthetic fatty acid esters, and primary and secondary alcohols are adsorbed on the tribologically loaded surfaces. Such materials have in common a high dipole moment because of at least one polar group in the molecule (Fig. 9.14).

The coverage of the surfaces follows the laws of adsorption and is dependent on temperature and concentration. A prerequisite for the adsorption of polar groups is that the material surface exhibits a polar character so that van der Waals bonds can form. This is usually attained for metallic materials by oxide films forming on the surfaces. Problems can arise for ceramic materials however. While, for example, adsorption of fatty acids with polar end groups occurs easily on aluminum oxide with ionic bonding so that friction is diminished from a certain chain length onward, adsorption apparently does not occur on silicon carbide with covalent bonds so that the friction coefficient is not influenced [9.2].

In *chemisorption*, molecules are bonded to the surface. Substantially more-stable boundary layers develop because chemical bonds with greater bonding force are formed on the surface (e.g., the reaction of stearic acid with iron oxide when water is present, as a result of which metallic soap forms as iron stearate). Chemisorbed layers have excellent lubricating properties up to their melting point. At medium loads, temperatures, and velocities, they produce a sustained reduction of friction.

Tribochemical reactions between elements of the lubricant and the metallic material surface form reaction layers that generally have more thermal and mechanical load-carrying capacity than layers formed by physisorption or chemisorption. For this, chlorine, phosphorous or sulfur compounds are added to the lubricants as additives (extreme-pressure (EP) additives). The effectiveness of such EP additives depends on the speed of reaction layer formation, which is influenced by the reaction's activation energy, the surface temperature, and the concentration of the additive. EP active ingredients themselves, or their thermal cleavage products, react with the surface metallic oxide in very short time (10^{-6}–10^{-7} s), forming a reaction layer that adheres well and shears easily (Fig. 9.15).

While only very little or no wear appears in hydrodynamic and elastohydrodynamic lubrication because there are no asperity contacts, the number of asperity contacts grows in boundary lubrication and thus so does the rate of wear as the load increases. However, compared with unlubricated conditions, the rates of wear in boundary lubrication are substantially lower.

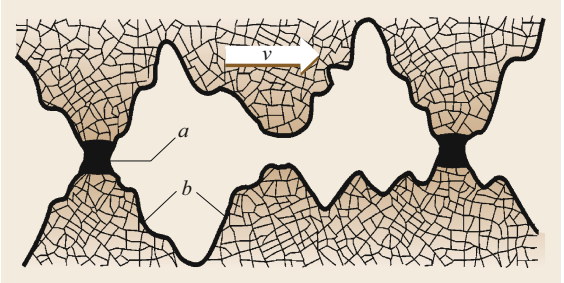

Fig. 9.15 Formation of a protective layer by EP active ingredients of sulfur compounds. *a*: metal-sulfide compound; *b*: metal surface (after [9.15])

9.5.4 Mixed or Partial Lubrication

If the load in hydrodynamically or elastohydrodynamically lubricated machine elements grows too large or the lubricant entraining velocity in the lubrication gap is too small, the lubricating film becomes too thin so that asperity contacts appear at some points. This is mixed friction, in which the states of boundary friction and fluid friction coexist. The lubricating film is no longer coherent because individual surface asperities of the paired parts penetrate it and cause direct contact of the sliding surfaces. In partial or mixed lubrication, the normal load is partly carried by hydrodynamic film pressures and partly by contact of the frictional surfaces at the asperity contacts. The transition from hydrodynamic or elastohydrodynamic lubrication to partial lubrication does not happen suddenly when the load is increased but rather the share of the load carried by the hydrodynamic pressure buildup decreases gradually, while the share carried by the asperities grows in equal measure.

9.5.5 Lubrication with Solid Lubricants and Surface Coatings

In lubrication with solid lubricants and in coatings, the most important measures for improving friction, preventing scuffing or seizing, and minimizing wear are applying metallic (e.g., indium) or nonmetallic layers (e.g., synthetic resin coatings), forming reactionlayers through chemical transformation (e.g., phosphatizing),

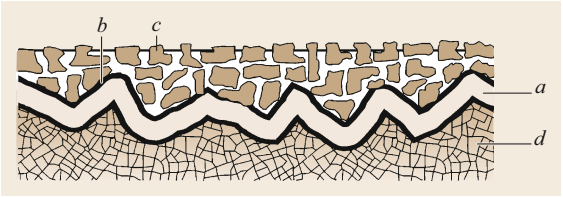

Fig. 9.16 Solid lubrication made of lubricating varnish: *a*: phosphate layer (3 µm); *b*: binder; *c*: solid lubricant; *d*: base metal (after [9.15])

and using solid lubricants. Nonmetallic layers also include layers obtained by physical vapor deposition (PVD) or chemical vapor deposition (CVD) from the gas phase; the layer has a thickness in the micrometer range and can be made of, for example, titanium nitride (TiN), titanium aluminum nitride (TiAlN), chromium nitride (CrN) or tungsten carbide/carbon (WC/C).

Among the solid lubricants, crystalline solids with layer lattices (lamina structure) appear particularly suitable. Their structure is characterized by lamellae that can be displaced slightly with respect to each other along glide planes. Typical representatives are graphite (C) and molybdenum disulfide (MoS_2). Certain plastics such as PTFE are also used as solid lubricants.

Apart from these, coating layers on metals, which are adhesive, act as lubricants, and are firm to the touch, so-called lubricating varnishes, also play a role (Fig. 9.16). They have a large proportion of solid lubricants and can be used as dry films over a wide range of temperatures.

9.6 Lubricants

Gaseous, fluid, consistent or solid lubricants are used in mechanical engineering. Gaseous lubricants are utilized, for example, in high-speed, lightly loaded machines (e.g., ultracentrifuges, gas pumps for nuclear power plants) or in equipment technology. The most important group of substances for fluid lubricants are the mineral oils, as well as synthetic, animal, and vegetable oils and even water in special applications. Greases and adhesive lubricants are consistent lubricants. Greases consist of mineral or synthesis oils that are thickened with, for instance, soaps. There are bitumen-based adhesive lubricants as well as bitumen-free adhesive spray lubricants. These are principally used to lubricate larger, open-toothed gears. Solid lubricants are frequently introduced into fluid or consistent carrier substances. Solid lubricants are used in pure form only under special operating conditions. Among others substances, solid lubricants include graphite, molybdenum disulfide, PTFE, etc.

During operation, pressure and shear stresses, among others, act on a lubricant at different temperatures. The lubricant comes into contact with gases (e.g., air), liquids (e.g., water), and solids (e.g., metals, sealing materials, wear particles). In addition, contact with human skin cannot be ruled out. This results in a number of requirements that a good lubricant should have. For a particular application, it should have an appropriate viscosity–temperature and viscosity–pressure behavior, a low pour point, and preferably not be volatile, exhibit high-temperature, shear, and oxidation stability, and be hydrolysis and radiation resistant in special cases. Beyond this, a good lubricant should be compatible with the constructional materials used and be nontoxic and not cause any disposal problems.

9.6.1 Lubricating Oils

Among the fluid lubricants, a difference is made between mineral oils and synthetic oils.

Mineral Oils

Mineral oils are obtained from naturally deposited crude oil with the aid of distillation and refining. Crude oils chiefly consist of hydrocarbons and organic oxygen, sulfur, and nitrogen compounds. The exact composition of a crude oil depends on its origin (provenance). When mineral oils are manufactured, systematic selection of the base oil and control of the manufacturing process can produce particular compositions and thus influence desired properties. Mineral oils are mixtures of hydrocarbons, which can be subdivided as a function of their structure into open-chain hydrocarbons (paraffins) and cyclic hydrocarbons (naphthalenes, aromatics), which can each be saturated or unsaturated.

Mineral oils' performance characteristics change as their working life increases. A primary reason for diminished performance is gradual oxidization of hydrocarbon chains, with aromatics reacting more than naphthenes and naphthenes more than paraffins. As a result, sludge-like deposits can form, which impede the oil supply by clogging oil feed lines and filters. Moreover, the formation of organic acids can be boosted, which can cause corrosion of machine parts. This can be prevented in part by admixing additives (e.g., antioxidants, detergent, and dispersant agents). More information on their effect and the use of additives can be found in Sect. 9.6.1, *Additives*.

Synthetic Oils

Synthetic-base lubricating oils are produced by chemical synthesis from chemically defined structural elements (e.g., ethylene). Their development has made it possible to systematically satisfy even extreme requirements (e.g., lubricant temperature > 150 °C). According to their chemical composition, synthetic lubricants are subdivided into synthetic hydrocarbons, which only contain carbon and hydrogen (e.g., polyalphaolefines (PAO), dialkylbenzenes (DAB), polyisobutenes (PIB)), and synthetic fluids (e.g., polyglycols, carboxylic acid esters, phosphoric acid esters, silicon oils, polyphenyl ethers, fluorine-chlorine-carbon oils). Typical characteristics of synthetic oils are provided in Table 9.9 and a comparison of the properties of synthesis oils with those of mineral oil is presented in Table 9.10.

Synthetic oils have a number of advantages over mineral oils. They have better resistance to aging (thermal and oxidative stability) and thus their useful life is three to five times longer. They exhibit a more favorable viscosity–temperature behavior (with a significantly lower dependence of viscosity on temperature), display better flow properties at low temperatures and lower volatility at high temperatures, can cover applications operating at a substantially expanded range of temperature, and are radiation and flame resistant. Moreover, synthetic lubricants can be used to obtain

Table 9.9 Characteristics of various synthetic oils (after [9.16])

specific frictional properties, e.g., lower friction coefficients to minimize power loss in ball bearings or gears, or higher friction coefficients to increase the transmittable torque in friction gears.

On the other hand, synthetic lubricants often cannot be used as universally as mineral oils since they have been developed for specific properties. In addition, they are more strongly hydroscopic (water attracting), display only slight air release characteristics (risk of foaming), mix poorly or not at all with mineral oils, are toxic to a large extent, and are characterized by poor compatibility with other materials (risk of chemical reaction with seals, paints, and nonferrous metals) and by poor solubility for additives. They are not always available, most notably in certain viscosity classes, and they frequently cost substantially more. Table 9.11 details examples of typical areas of application of synthetic oils.

Biodegradable Oils

Environmentally compatible lubricating oils are increasingly being used, for example, in motor vehicles and equipment in water protection areas and in hydraulic engineering, in vehicles for agriculture and forestry, and in openly running gears with loss lubrication (excavators, mills). They are readily and rapidly degradable, have a low water hazard class, and are toxicologically harmless. Their base substances have to be degraded in a degradability test (e.g., CEC L-33-T-82) by a defined amount within a specified time and the additives used (up to a maximum of 5%) should be potentially degradable. Native oils and native base synthetic esters as well as fully synthetic esters and polyglycols are used. Native oils (e.g., rape oil and natural esters) are unsuitable for high temperatures (>70 °C) and additionally have low thermal stability and resistance to aging. The synthetic oils suitable for continuous high temperatures are often used as hydraulic oils in agricultural and forestry machines. Polyglycols are used, for example, as readily biodegradable oils in water engineering.

Additives

Additives are substances that either give new characteristics to mineral, synthesis or vegetable oils or enhance already existing positive properties. The quantity of ad-

Table 9.11 Examples of use of the most important synthetic lubricants (after [9.17])

Product group	Examples of use
PAO (synthetic hydrocarbons)	● High-performance oils for diesel engines ● Multigrade engine oils ● Gear lubrication at high thermal stress ● Compressor oils
Carboxylic acid esters	● Aircraft engine oils ● Fuel economy oils (low-friction engine oils) ● Base oil for high- and low-temperature greases ● Applications requiring good and fast biodegradability
Neopentyl polyol esters	● Applications similar to those for carboxylic acid esters but especially wherever oxidation stability and better additive solubility are required
Polyalkylglycols (polyglycols)	● Metalworking fluids ● Gear oils (worm gears) ● Hydraulic fluids (flame resistant) ● Lubricant for compressors and pumps
Polyphenyl ethers	● High-temperature lubricants (up to 400 °C) ● Applications requiring resistance to ionizing radiation (γ rays and thermal neutrons)
Phosphoric acid esters	● Plasticizers ● Flame-resistant hydraulic oils ● Safety lubricants for air and gas compressors ● EP additives
Silicone oils	● Special lubricants for high temperatures ● Base oil for lifetime lubricating greases (e.g., for clutch release bearings for motor vehicle clutches, starters, brakes, and axle components)
Silicate esters	● Hydraulic oils for lower temperatures ● Heat exchange fluids
Fluorine-chlorine-carbon oils	● Lubricants for oxygen compressors and for pumps for aggressive fluids

ditive used differs greatly. Thus, circulating or hydraulic oils may only contain 0.1%, whereas special engine and gear oils may contain up to 30% additives.

All properties of lubricants cannot be changed by additives. However, by using additives a clear improvement in lubrication can be obtained by modifying some properties. Thus, for example, heat dissipation, viscosity–density properties, and temperature resistance cannot be influenced by additives. Improvements brought about by additives are obtained for low-temperature performance, aging stability, viscosity–temperature properties, and corrosion protection. Only additives can attain good cleaning performance, favorable dispersion behavior, antiseizing properties, and foam inhibition.

Additives have to be matched to the base oil in terms of quantity and composition and the presence of other additives since they respond differently to the base oil and are not mutually compatible in every case. For example, there are antagonistic effects between viscosity index improves and antifoam additives, between detergent/dispersant additives and antiwear, antiseizing, and antifoam additives, and between corrosion inhibitors and antiwear and antiseizing additives [9.15].

A difference can be made between additives that form surface layers and those that change the properties of the lubricant itself. Additives forming surface layers act as a lubricating film above all when there is insufficient lubrication, as a result of which friction is reduced and the load-carrying capacity of sliding–rolling pairs is improved. Among others, this group of additives includes antiwear (AW) additives, extreme pressure (EP) additives, and friction modifiers. Adding additives that form surface layers also has drawbacks though. Thus, lubricants with additives oxidize faster than normal mineral oils and corrosive acids and insoluble residues frequently form. Hence these additives should only be used when necessitated by the operating conditions. Additives that modify lubricants influence, for example, foaming behavior, corrosion behavior, sludging, and pour point. Table 9.12 provides an overview of the most important types of additives and their applications.

During operation, the effectiveness of some additives can decrease (exhaustion) since reaction with the

Table 9.12 Additives, typical types of additives, applications, and active mechanisms (after [9.18])

Additive	Types of additive	Application	Active mechanisms
AW additive	Zinc dialcyldithiophosphates, tricresylphosphates	Decrease of inordinate wear metal surfaces	Reaction with metal surfaces produces layers that are plastically deformed and improves the contact pattern
EP additives	Sulfurized greases and olefines, chlorohydrocarbons, lead salts of organic acids, aminophosphates	Prevention of microwelding between metal surfaces at high pressures and temperatures	Reaction with metal surfaces produces new bonds with lower shear resistance than the base metal. There is constant shearing off and reformation
Friction modifiers	Fatty acids, fat amines, solid lubricants	Reduction of friction between metal surfaces	Highly polar molecules are absorbed on metal surfaces and separate the surfaces, solid lubricants form friction-reducing surface film
Viscosity index improvers	Polyisobutylenes, polymethylacrylates, polyacrylates, ethylenepropylene, styrene maleic acid esters, copolymers, hydrogenated styrene-butadiene-copolymers	Reduction of dependence of viscosity on temperature	Polymer molecules are strongly balled in cold oil (poor solvent) and take on greater volume in warm oil (good solvent) by unballing. This produces a relative thickening in oil
Pour point depressants	Paraffin-alkylated naphthalenes and phenols, polymethylacrylates	Decrease of pour point of the oil	Encasing prevents the agglomeration of paraffin crystals
Detergent additives	Normal or alkaline calcium, barium or magnesium-sulfinates, phenates or phosphonates	Reduction or prevention of deposits in engines at high operating temperatures	Reaction with the oxidation products controls the formation of coating and sludge. Products are produced that are oil soluble or suspended in oil
Dispersant additives	Polymers such as nitrogenous polymethylacrylates, alkyl succunimides and succinate esters, high molecular weight amines and amides	Prevention or delay of the development and deposition of sludge at low operation temperatures	Dispersants have a pronounced affinity for impurities and encase these with oil soluble molecules that suppress the agglomeration and deposition of sludge in the engine
Oxidation inhibitors	Inhibited phenols, amines, organic sulfides, zinc dithiophosphates	Minimization of the formation of resin, coating, sludge, acid, and polymer-like compounds	Reducing the organic peroxides ends the oxidation chain reaction. reduced oxygen intake by the oil decreases the acid formation. Catalytic reactions are prevented
Corrosion inhibitors	Zinc dithiophosphates, sulfurized terpenes, phosphorized, sulfurized olefines	Protection of bearing and other metal surfaces against corrosion	Acts as an anticatalyst; film forms on metal surfaces as protection against attacks from acids and peroxides
Rust inhibitors	Amine phosphates, sodium, calcium, and magnesium sulfates, alkyl succinic acid, fatty acids	Protection of ferrous surfaces against rust	Metal surfaces prefer to adsorb polar molecules and they serve as a barrier against water neutralization by acids
Metal deactivators	Triarylphosphate, sulfur compounds, diamines, dimercaptothiadiazop deriviatives	Suppression of the catalytic influence on oxidation and corrosion	A protective film is adsorbed an metal surfaces, which inhibits the contact between the bases metal and the corrosive substance
Foam inhibitors	Silicon polymers, tributylphosphates	Protection of the development of stable foam	Attacking the oil film surrounding every air bubble reduces the boundary surface stress. As a result smaller bubbles coalesce into larger bubbles that rise to the surface
Adhesion improvers	Soaps, polyisobutylenes and polyacrylate polymers	Increase of the oils's adhesive ability	Viscosity is increased. Additives are viscous and sticky
Emulsifier	Sodium salts of sulfonic acids and other organic acids, fat amine salts	Emulsification of oil in water	Adsorbing the emulsifier in the oil/water boundary surface reduces boundary surface stress, as a result of which one fluid disperses into another
Demulsifier	Anionic sulfon acid compounds (dinonylnaphthalinsulfonate)	Demulsification of water	A boundary layer develops between water and oil form substances active in the boundary surface
Bactericide	Phenols, chlorine compounds, formaldehyde derivatives	Increase of the emulsion's working life, prevention of unpleasant odors	The growth of microorganisms is prevented or delayed

materials or atmospheric oxygen causes their concentration to drop. Once the concentration of the additive falls below a certain value, an oil change is necessary.

9.6.2 Lubricants (Lubricating Greases)

Consistent lubricants have a flow limit. No movement occurs below a shear stress that is specific to the lubricant. Only when this flow limit has been exceeded does the viscosity drop from a virtually infinitely high to a measurable value.

Lubricating greases consist of three components: a base oil (75–96 wt%), a thickener (4–20 wt%), and additives (0–5 wt%). Suitable thickeners can be dispersed both in mineral oils and in synthetic or vegetable oils so that consistent lubricants are produced. By far, most greases are manufactured using soaps (metallic salts from fatty acids) as thickeners. Thus, fatty acids are dissolved in the base oil at relatively high temperatures and a suitable metal hydroxide (e.g., hydroxides of sodium, lithium, and calcium or to a lesser extent barium and aluminum) is added subsequently. Long-chain fatty acids come from vegetable or animal oils and can be hydrogenated. Occasionally, not only long-chain fatty acids but also short-chain acids such as acetic, propionic, benzoic acid, etc. are used. Then so-called complex soaps are produced [9.15]. Most soap compounds form a fibrous matrix of interlocking particles, which retains the base oil (Fig. 9.17).

By contrast, aluminum soaps contain a spherical gel structure. The grease's lubricating action is based on the base oil being dispensed slowly and sufficiently in operation under load. The delivery of the base oil depends strongly on the temperature. The lubricating grease releases less and less oil as the temperature drops and the grease becomes stiffer and stiffer (consistency). Beyond a certain temperature limit, this eventually leads to insufficient lubrication in the friction contact. As the temperature increases, more and more oil is released. Simultaneously, the grease ages and oxidizes faster and the deterioration products produced have an adverse effect on the lubrication. A standard value is to cut the grease's working life and thus the relubrication interval in half for every 15 °C rise in temperature above approximately 70 °C. Below 70 °C, the grease's working life and consequently the relubrication interval can be extended unless the temperature drops below the lower limit. The type of base oil, its viscosity, and the additives it contains are decisive for the lubricating properties.

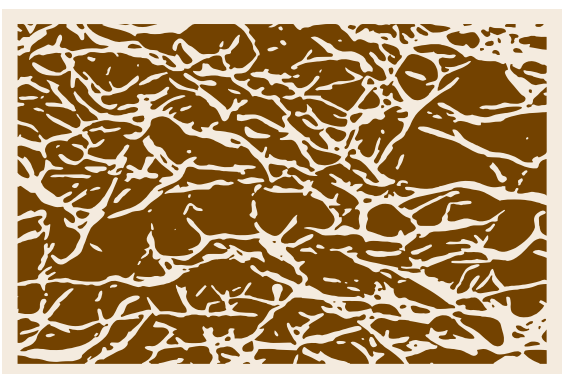

Fig. 9.17 Fiber structure of a grease with soap thickener [9.19]

Lubricating greases are predominantly used at low speeds since the lubricant results in lower frictional heat transportation than oil lubrication. The relevant temperature ranges are generally from −70 to +350 °C. Lubricating greases also frequently have the job of protecting lubricating points from the infiltration of water and dirt and keeping out small quantities of dirt without disrupting the function. Tables 9.13 and 9.14 present performance the characteristics and applications of different lubricating greases.

Additives mainly serve to improve particular performance characteristics of the base oils. They must be uniformly distributed and be dissolved. Additives can improve the following properties of greases in particular: oxidation stability, corrosion protection, water resistance, adhesiveness, and antiwear properties.

The greatest care is necessary when mixing different types of lubricating greases since not all types of lubricating greases are mutually compatible (Table 9.15). Thus, for example, sodium soap grease is incompatible with nearly all other lubricating greases with the exception of barium complex soap grease. Lithium soap grease is incompatible with sodium soap grease, aluminum complex soap grease, and bentonite grease. In turn, bentonite grease is incompatible with all other types of grease.

9.6.3 Solid Lubricants

Solid lubricants are used especially whenever fluid and consistent lubricants cannot provide the lubricating action required. This is frequently the case under the following operating conditions: low sliding speeds, oscillating motions, high specific loads, high or low operating temperatures, extremely low ambient pressures (vacuum), and aggressive ambient atmospheres. Solid lubricants are also used to improve particular properties of fluid and consistent lubricants, i.e., as additives, for example, to minimize friction and wear and to guar-

antee antiseizure performance. Solid lubricants in the form of powders, pastes or lubricating varnishes contribute directly to the build up of the lubricating film on the one hand or improve the lubricating properties in oils, greases or bearing materials on the other hand.

Substances with a layer lattice structure (graphite, the sulfides MoS_2 and WS_2), selenides (WSe_2), organic substances (PTFE, amides, imides), soft nonmetals (lead sulfide, iron sulfide, lead oxide, and silver iodide), soft nonferrous metals (gold, silver, lead, copper, and indium), and reaction layers on the surface (oxide, sulfide, nitride, and phosphate layers) are used as solid lubricants. Graphite needs water to adhere and to reduce shear strength (low friction) and hence is unsuitable for use in a dry atmosphere or vacuum. Molybdenum disulfide adheres well to all metal surfaces with the exception of aluminum and titanium. It is a highly suitable solid lubricant for temperatures up to 350 °C but costs more than graphite. Polytetrafluoroethylene (PTFE or Teflon) exhibits a low friction factor at low speeds and high loads and is suitable for temperatures from −250 to +250 °C.

Their high proportion of solid lubricants (graphite, molybdenum disulfide or PTFE) distinguishes lubricating varnishes from decorative industrial varnishes. They can be used as a dry film at temperatures between −180 and +450 °C. Lubricating varnishes with oil-resistant binders can also be used in oily systems and are suitable, for example, for bypassing the critical break-in phase without damage or for shortening the break-in time.

9.6.4 Properties of Lubricants

The properties of fluid and consistent lubricants are specified by data predominantly determined with standardized test procedures. It should be noted that not all results from laboratory tests are meaningful for lubrication applications. Along with viscosity, other properties of lubricants are density, specific heat, thermal conductivity, pour point, flashpoint, fire point, foaming behavior, compatibility with sealing materials, and consistency in the case of lubricating grease. Furthermore, aging resistance is vital since it characterizes the abatement of the lubricity and thus the useful life of lubricating oils and determines the oil change interval (Fig. 9.18).

Viscosity

One of a lubricant's most important rheological properties is its viscosity. A fluid's dynamic (or absolute) viscosity η is a measure of the amount it resists a relative motion. The dynamic viscosity η is defined as the shear force F required to realize the relative movement between two planes, acting in the direction of the lubricant flow between the two planes and related to the friction area A and the velocity gradient $\mathrm{d}v/\mathrm{d}y$ between the planes (Fig. 9.19).

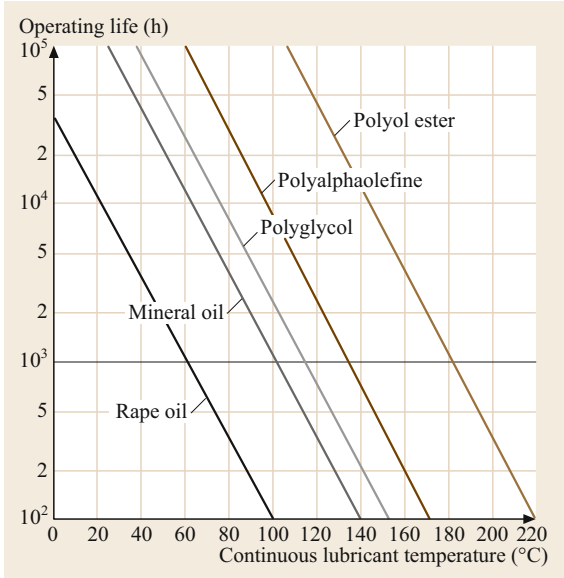

Fig. 9.18 Influence of the lubricant continuous temperature on the approximate useful life of mineral-oil-based and synthetic lubricants (after [9.17])

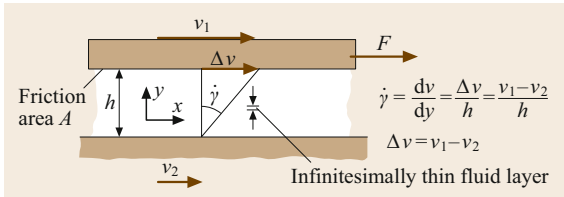

Fig. 9.19 Gap flow and velocity gradient for a Newtonian fluid

Since the shear force per friction area corresponds to the shear stress τ and the velocity gradient to the local shear strain rate $\dot{\gamma}$ (also called shear rate), the following relationship applies

$$\eta = \frac{F/A}{\mathrm{d}v/\mathrm{d}y} = \frac{\tau}{\dot{\gamma}}\,, \tag{9.8}$$

with $\dot{\gamma} = \mathrm{d}v/\mathrm{d}y = \Delta v/h$, where Δv stands for the relative velocity between the two friction bodies and h is the lubrication gap height. The absolute value of the shear force F equals that of the frictional force F_f.

Fluids that can be characterized with (9.8) at constant temperatures and pressures are also called *Newtonian fluids*. Many common fluids, especially those with relatively simple molecular structures, fall into this group (e.g., undoped mineral oils, synthetic fluids, vegetable oils, water, and gases). The unit for dynamic viscosity η is $\mathrm{N\,s/m^2} = \mathrm{Pa\,s}$. Engineering gen-

erally uses mPa s however, which corresponds to cP (centipoise), which was common earlier.

The viscosity is measured with commercially available viscometers, which are standardized as rotation, capillary, falling ball, and falling rod viscometers. Rotation and falling ball viscometers determine the dynamic viscosity η, while the capillary viscometer used most determines the ratio of the dynamic viscosity η and the density ρ. This ratio is known as the kinematic viscosity ν, so that the following applies

$$\nu = \frac{\eta}{\rho} . \tag{9.9}$$

The kinematic viscosity ν is a mathematical value, i.e., it is not a material property. Its units are m^2/s. Usually however mm^2/s is used, corresponding to cSt (centistokes), which was used earlier. The kinematic viscosity is the basic of the standardization of oils. Table 9.16 shows the 20 ISO viscosity groups (ISO VG) by ISO 3448. The basic of the viscosity groups is the middle kinematic viscosity ν_m at 40 °C. Oils of a viscosity group can vary ± 10% around the middle viscosity.

The viscosity of substances that do not behave like a Newtonian liquid is dependent on the temperature, pressure, shear rate, and mean molecular weight. In addition, shear strains are dependent not only on the instantaneous shear rate but also on the past shear history (the lubricant's *memory properties*).

Table 9.16 Viscosity groups by ISO 3448

ISO VG	Middle kinematic viscosity at 40 °C (mm^2/s)	Minimum kinematic viscosity at 40 °C (mm^2/s)	Maximum kinematic viscosity at 40 °C (mm^2/s)
2	2.2	1.98	2.42
3	3.2	2.88	3.52
5	4.6	4.14	5.06
7	6.8	6.12	7.48
10	10	9.00	11.0

32	32	28.8	35.2
46	46	41.4	50.6
68	68	61.2	74.8
100	100	90.0	110
150	150	135	165
220	220	198	242
320	320	288	352
460	460	414	506
680	680	612	748
1000	1000	900	1100
1500	1500	1350	1650
2200	2200	1980	2420
3200	3200	2880	3520

9.6.5 Dependence of Viscosity on Temperature and Pressure

The viscosity of lubricating oils greatly depends on the operating temperature. As the temperature increases, the viscosity of the lubricating oil decreases considerably.

To design lubricated tribological contacts it is important to know the viscosity at the operating temperature since this decisively influences the lubrication film thickness between the surfaces to be separated. The lubricant's viscosity–temperature behavior (η–T behavior) is determined metrologically with viscometers and is frequently specified by simple power and exponential equations. The following equation from Vogel has proven to be valuable for lubricating oils used in the field

$$\eta(T) = A \exp\left(\frac{B}{C+T}\right) . \tag{9.10}$$

In this equation, η stands for the dynamic viscosity in Pa s, A, B, and C are values specific to lubricants that have to be determined for every lubricant, and T is the operating temperature in °C.

Figure 9.20 shows an example for the viscosity–temperature behavior for liquid industrial lubricants in accordance with ISO 3448. The selection of a logarithmic scale on the ordinate axis and a hyperbolic scale on the abscissa gives the viscosity curves a straight gradient. This makes it possible to determine the η–T behavior with only two measurements.

The viscosity index (VI) is also frequently used in practice to specify viscosity–temperature behavior. The viscosity index is a measure of the slope of the *straight lines* of viscosity–temperature compared with a reference lubricant. The higher the VI, the more favorable the η–T behavior. A high VI is characterized by a relatively mild change of viscosity as temperature changes and a low VI by a relatively intense change. Oils that hardly tend to thicken at low temperatures and that do not become low viscosity too fast at high temperatures, i.e., oils with a high VI, should be preferred when machine parts to be lubricated have to operate over a wide range of temperatures. Common paraffin basic oils exhibit a VI of 90−100, synthetic lubricants have a VI of approximately 200 and above.

The viscosity of lubricating oils increases as the pressure rises. The viscosity's pressure dependence only really becomes noticeable at high pressure though. The influence of the pressure decreases as the temperature increases. The viscosity of mineral oil increases more strongly as the pressure increases as the viscosity–temperature curve becomes steeper. The viscosity–pressure behavior can be approximated by

$$\eta(p) = \eta_0(T) \exp\left[\alpha\,(p - p_u)\right] . \tag{9.11}$$

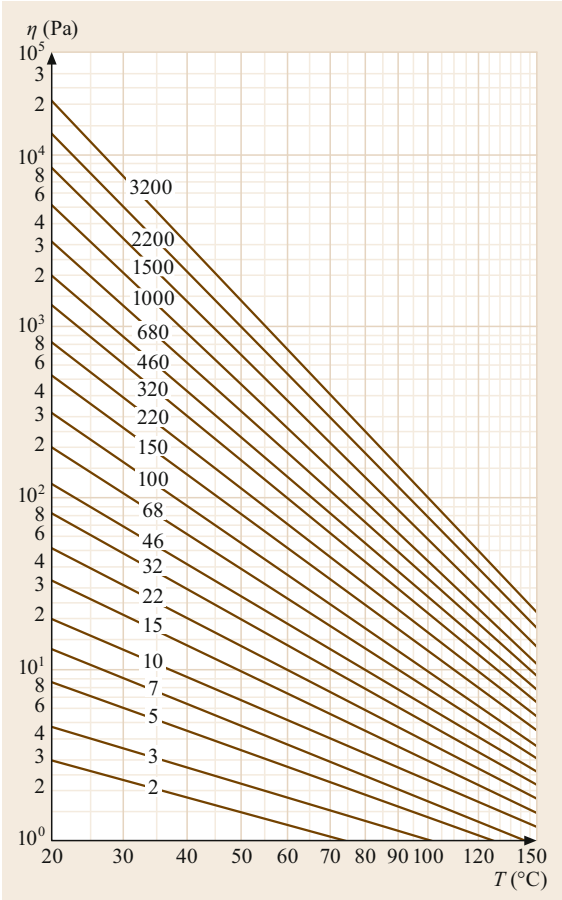

Fig. 9.20 Dependence of the dynamic viscosity η on the temperature T for the ISO VGs (Table 9.16) at density $\rho = 900\,\mathrm{kg/m^3}$ and VI = 95 in accordance with ISO 3448

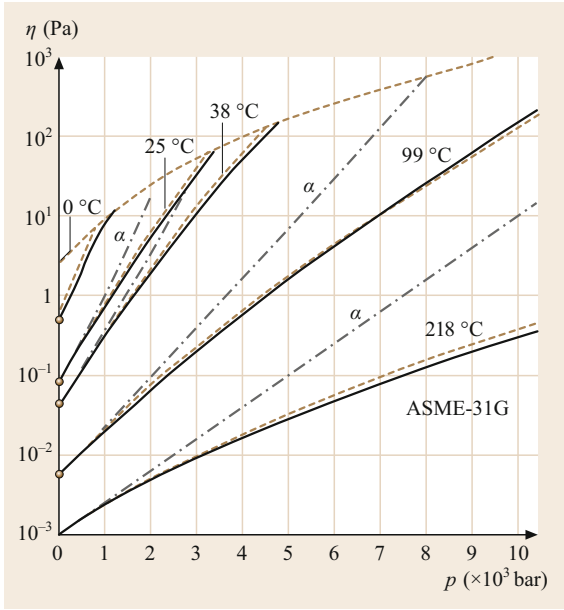

Fig. 9.21 Viscosity of the lubricating oil ASME-31G as a function of pressure and temperature [9.21] (ASME-31G is roughly equivalent to a lubricating oil ISO VG 46). *Dash-dotted lines*: calculations based on (9.11), *dashed lines*: calculations based on (9.12), *continuous lines*: ASME measurements

In the equation, $\eta_0(T)$ is the viscosity at 1 bar and the corresponding operating temperature, α is the viscosity–pressure coefficient, and p_u is the ambient pressure; α is dependent on the base oil (mineral or synthetic) and the additives (Tables 9.12 and 9.17).

Reference [9.1] provides an expression that simultaneously reproduces the dependence of the dynamic viscosity η on the state variables pressure p and temperature T

$$\eta(T,p) = A \exp\left[\frac{B}{C+T}\left(\frac{p-p_u}{2000}+1\right)^{\left(D+E\frac{B}{C+T}\right)}\right]. \tag{9.12}$$

The dependence of the dynamic viscosity on the temperature is represented by the coefficients A, B, and C (Vogel equation) and the dependence on the pressure is described by the coefficients D and E. Tests are employed to determine the coefficients A–E. Figure 9.21 presents the viscosity of a lubricating oil as a function of pressure and temperature.

Table 9.17 Viscosity–pressure coefficient α and examples of increasing viscosity for different lubricants [9.20]

Type of oil	$\alpha_{25\,°C}$ ($\times 10^8\,m^2/N$)	$\frac{\eta_{2000\,bar}}{\eta_0}$ at 25 °C	$\frac{\eta_{2000\,bar}}{\eta_0}$ at 80 °C
Paraffin basic mineral oils	1.5–2.4	15–100	10–30
Naphthene basic mineral oils	2.5–3.5	150–800	40–70
Aromatic solvent extracts	4.0–8.0	1000–200 000	100–1000
Polyolefines	1.3–2.0	10–50	8–20
Ester oils (diester, dendritic)	1.5–2.0	20–50	12–20
Polyether oils (aliph.)	1.1–1.7	9–30	7–13
Silicon oils (aliph. subst.)	1.2–1.4	9–16	7–9
Silicon oils (arom. subst.)	2.0–2.7	300	–
Chlorinated paraffin (depending on level of halogenation)	0.7–5.0	5–20 000	–

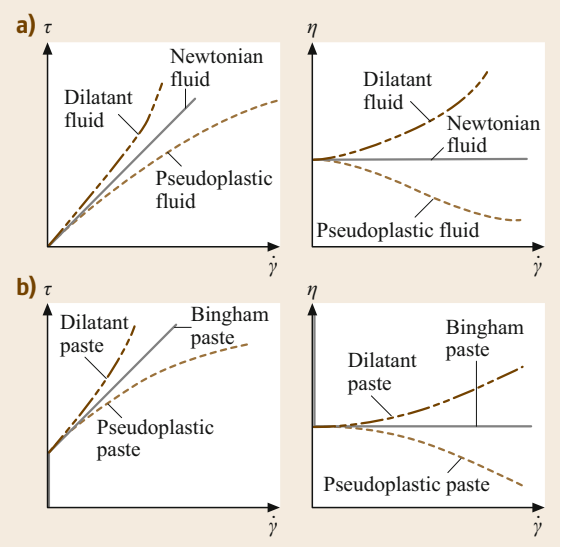

Fig. 9.22a,b Typical flow curves of different lubricants. **(a)** Newtonian, dilatant and pseudoplastic fluid; **(b)** Bingham paste, dilatant and pseudoplastic paste

9.6.6 Dependence of Viscosity on Shear Rate

When the rheological properties are independent of time, the flow properties of viscous lubricants can be easily described. Then the shear stress τ in the lubricant is a simple function of the local shear rate $\dot{\gamma}$, i.e., $\tau = f(\dot{\gamma})$. If this function is linear so that the shear stress is proportional to the shear rate, then a Newtonian fluid exists and the proportionality coefficient is the dynamic viscosity, which also remains constant when shear rates vary (Fig. 9.22a). Pure mineral oils generally exhibit Newtonian properties up to relatively high shear rates of 10^5–$10^6\ s^{-1}$. At higher shear rates, which occur relatively often in tribological contacts such as toothed gears, ball bearing, cam-follower pairs, etc., the viscosity's constancy frequently disappears and the viscosity decreases as the shear rate increases. The lubricant begins to behave like a non-Newtonian fluid, i.e., the viscosity now depends on the shear rate.

Pseudoplastic behavior, also known as shear thinning, is characterized by a decrease of viscosity as the shear rate increases (Fig. 9.22a). Dilatant fluids manifest the opposite of pseudoplastic behavior, i.e., thickening of the lubricant as the shear rate increases (Fig. 9.22a). Dilatant fluids are normally suspensions with a high solid content.

The flow properties of greases can be compared with those of a Bingham substance. In order to generate a flow, a threshold shear stress must first be overcome (Fig. 9.22b). This means that grease behaves like a solid at first. Once the threshold shear stress τ_0 is exceeded, the lubricating grease then flows, for example, with constant viscosity like a Newtonian fluid or even pseudoplastically or dilatantly.

Consistency of Lubricating Greases

The behavior of a lubricating grease is frequently described by its consistency (plasticity). Penetration according to ASTM D-217 and ASTM D-1403 is used as a characteristic. To determine the penetration, the penetration depth of a standard cone with predetermined dimensions into the surface of a lubricating grease is measured in a penetrometer after a penetration time of 5 s at a temperature of 25 °C (in units of 0.1 mm). A difference is made between unworked and worked penetration. Unworked penetration is measured in the unused lubricating grease, whereas worked penetration in measured in already sheared grease that has been worked under standardized conditions in a standard lubricating grease mixer. The higher the worked penetration, the softer the grease. Table 9.18 shows the relationship between penetration and consistency class.

Table 9.18 NLGI consistency classes and applications of lubricating greases (after [9.2]) (NLGI – National Lubricating Grease Institute)

NLGI class	Penetration (0.1 mm)	Consistency	Sliding bearings	Ball bearings	Centralized lubricating systems	Gears	Water pumps	Block greases
000	445–475	Almost fluid			+	+		
00	400–430	Semifluid			+	+		
0	355–385	Extra soft			+	+		
1	310–340	Very soft			+	+		
2	265–295	Soft	+	+				
3	220–250	Medium	+	+				
4	175–205	Relatively firm		+			+	
5	130–160	Firm					+	
6	85–115	Very firm						+

Ludger Deters

Institute of Machine Design
Otto von Guericke University Magdeburg
Magdeburg, Germany
ludger.deters@ovgu.de

Ludger Deters was Professor of machine elements and tribology at the Otto von Guericke University Magdeburg for almost 23 years. He retired at end of September 2016. Prof. Deters received his PHD degree from the mechanical engineering department of the University of Clausthal in 1983. From 1983 to 1994 he worked in executive positions in different development and design departments of the machine-building industry. His main research activities at the University of Magdeburg include tribology, lubrication, slider and rolling bearings, wheel/rail contacts, and friction and wear of combustion engine parts.

Dirk Bartel

Institute of Machine Design
Otto von Guericke University Magdeburg
Magdeburg, Germany
dirk.bartel@ovgu.de

Dirk Bartel is Professor at the Otto von Guericke University Magdeburg. In 2000 he completed his PhD and in 2009 his habilitation. Since 2016 he is the head of the institute of competence in mobility (IKAM) and the chair of machine elements and tribology and since 2018 managing director of the Tribo Technologies GmbH. Scientifically, he and his team deal with the development of models for the simulation of lubricated and unlubricated tribosystems and the experimental study of these at the model, component and assembly level.

10. Casting

Casting

Klaus Herfurth, Stefan Scharf

Primary shaping, by definition the production of a solid body from formless material while creating a material cohesion, forms one of the six main groups of production technology according to DIN 8580. It is upstream of all other production processes and creates the precondition for their application. In addition to state-of-the-art manufacturing technologies, such as additive manufacturing, classical casting is still the main application of primary shaping processes. In particular, the casting of metals has a long history of development that goes back to the beginnings of human metallurgical activity. Over time, castings often have been and continue to be decisive for the cultural, technological and economic progress of mankind. Although it has been used for more than 5000 years, the casting process, which has been continuously developed through continuous innovation, is still of central importance within the most modern production processes. Last but not least, a wide variety of casting processes as well as casting materials offer unique conditions for manufacturing high-quality components in a very economical manner. The extraordinary range of applications for cast components extends from one-off production in the arts and crafts sector to highly stressed components for the aerospace industry and up to millionfold mass production in the automotive industry. The following chapter gives an overview of common casting materials and the special features of individual variants of these fascinating manufacturing processes.

Manufacturing is the production of workpieces of a geometrically defined shape. Unlike other production technologies, manufacturing technology produces products distinguished by material and geometric characteristics.

According to DIN 8580 [10.1] today's and tomorrow's many and varied manufacturing processes can be classified into six main groups (Fig. 10.1) according to the criteria *changing of material cohesion* (creation, preservation, increase, and reduction). These main groups are: primary shaping, forming, cutting, joining, coating, and changing of material properties. The main groups are subdivided into groups. Within these groups, the manufacturing processes themselves are distinguished by subgroups.

Fig. 10.1 Classification of manufacturing processes (DIN 8580) ◄

Casting is an important group of the main group *primary shaping*. The products of casting are so-called castings from metallic materials, so-called cast alloys. The foundry industry produces the castings.

10.1 The Foundry Industry

The foundry industry produces castings from metallic materials. Castings in various shapes and materials are to be found in all branches of engineering, such as in road and rail vehicles, machinery, the aerospace industry, electric power engineering, shipbuilding, pumps and fittings, electrical engineering, fine mechanics, architecture, electronics, medicine and optics, as well as office machines and cast art. Most technical products are not conceivable without castings.

10.1.1 Advantages of Casting Production

The following outlines the economical advantages resulting from the use of castings. It is based on two fundamental aspects. Firstly, the overall consideration from melting to recycling, [10.1]. The advantages are the following:

- Exceptional freedom in the choice of shape
- Castability of all technically important metals
- Mechanical properties of cast materials that are no longer governed by those of the wrought materials
- Optimal components through the combination of material properties and shape
- Near net shape castings, i.e., reduced machining costs
- Integral castings, i.e., reduced assembly costs
- Tailored castings
- A high recycling rate, no down-cycling
- Material savings through the use of castings
- Ecological benefits
- When considered in overall terms, a lower specific use of energy on the whole.

Production from the shapeless condition, i.e., the melt, and solidification in the prescribed cavity, i.e., sand or a permanent mold, naturally enables great freedom in the choice of shape. It is possible to produce castings weighing less than 1 g and as much as 200 t, the weight only being restricted by handling and transport facilities.

There are very few restrictions with regard to the geometry of castings. All that can be drawn is also castable, but it is sometimes difficult to draw what is easy to cast.

High quality casting designs increasingly result from the incorporation of numerical simulation of mold filling and solidification, rapid prototyping, and simultaneous engineering. This takes place through close cooperation between foundrymen and designers. In the future it is expected that bionic and biological designing will provide new impulses for shaping. This will enable a large amount of freedom in the choice, thereby leading to full utilization of modern computer technology in the foundry industry.

10.1.2 Properties of Castings

Castings are produced from the following material groups: Iron alloys (cast steel, cast iron), aluminum, magnesium, titanium, copper, zinc, tin, nickel, and cobalt alloys. All of these are cast alloys.

Independent of the type of production process, in the manufacture of metallic components by casting, differentiation is always to be made between the material properties and the properties of the casting itself. In order to achieve a prescribed component characteristic the material and the geometry determine and complement each other in the properties of the component. These properties depend on the following:

- The geometry of the part
- The chemical composition of the cast material
- The treatment of the melted material (inoculation, modification, desulfurization, deoxidation, magnesium treatment, grain refinement, etc.)

- The type of molding and casting process
- The rate of cooling from casting to the ambient temperature
- The subsequent heat treatment
- The subsequent treatment of the outer layer (chemical-thermal process, surface deformation, surface alloying, surface remelting, etc.)
- Changes in the surface layer through machining
- The type of coating (painting, galvanizing, enameling etc.)

During the past decades the properties of cast alloys have also been further developed and considerably improved. For example, whereas in the 1950s only steel casting was able to achieve tensile strengths of more than $400\,N/mm^2$, today the designer has the choice of three higher strength groups of ferrous materials, i.e., spheroidal graphite cast iron, malleable cast iron, and cast steels. In many cases, this has enabled the highly economical substitution of forged and rolled steels.

There have also been further developments in nonferrous metal cast alloys, especially in the fields of aluminum and magnesium materials, which increasingly enable the use of these alloys in automotive manufacturing.

Consequently, the last decade has seen substantial rates of growth in the production of spheroidal graphite cast iron, as well as in aluminum and magnesium alloy castings. This is directly associated with the efforts towards light construction but also towards the reduction of total production costs.

The trend towards light construction is not only being realized with less dense cast materials, e.g., aluminum, but is also being achieved with higher density materials, e.g., spheroidal graphite cast iron. This is the result of the combined effect of material and shape as well as further development of casting technology.

In the selling of castings the material properties were traditionally (and often still are) taken as a basis for the contract, i.e., such material characteristics as yield strength, tensile strength, elongation at fracture, fatigue strength etc., which were determined from separately quasi simple geometrical samples. However, these samples only partially reflect the capabilities of the cast materials. Cast components are increasingly being designed on the basis of fracture mechanics. This shows that cast components are frequently unbeatable.

10.1.3 The Development of Casting Processes

The development of molding and casting processes over recent decades has led to the fact that the casting more closely approaches the shape of the finished part. The best results have been achieved with investment casting (lost wax molding process) and high pressure die casting, which can produce almost finished parts. These often require only minimum machining, e.g., fine machining of operating surfaces. Additionally, the development of weldable aluminum pressure die castings has enabled further possibilities of use.

Mechanical machining requires a relatively high amount of energy, the generation of 1 t of chips requiring the same amount of energy as that for the melting of 1 t of material.

The chips produced in machining the casting to the complete product, which can often result in a material utilization of less than 50%, should now be a thing of the past. The future lies in the production of near net shape castings with the resultant large savings in energy.

In many cases, groups of parts were and are being assembled from numerous individual components (turned, milled, and sheet metal components) by means of welding, riveting, bolting, etc. This type of assembly not only necessitates expensive manufacture of individual parts but also gives rise to considerable assembly costs.

The casting of integral components (one-piece-castings), through which the numerous previously necessary individual parts are combined in one casting, is an ideal way towards a new generation of parts. These integral castings can additionally better incorporate specific functional elements, resulting in considerable savings in material and energy.

Recycling is understood to be the return of material into the production process. In doing so, the aim is not to leave industrial production open-ended but, as with nature, to close the circuit, where material flows.

Recycling is in no way a new term for metallic materials but is rather a thousands of years old practice of returning metallic waste into the production process. Recycling of cast steel, cast iron, and cast nonferrous metals is a worldwide normal practice. Recycling of metallic materials leads to the saving of energy, preservation of our raw materials reserves, and thus to relief of our environment.

Development of the properties of the cast materials and the improvement of the molding and casting processes in the foundry industry have not only led to higher productivity but also material saving through:

- The reduction of wall thicknesses as a result of better pouring possibilities
- The use of higher strength materials
- Optimal casting design with, for example, ribbing or realization of hollow structures
- The reduction of machining allowances

- Material substitution, e.g., spheroidal graphite cast iron instead of forged steel and aluminum alloys instead of cast iron

These savings in materials reduce the weight of the components as well as the amount of machining. They also result in energy savings and thus preservation of the environment.

Overall consideration of component manufacture from the raw material to the finished part and taking account of recycling of metallic materials, i.e., an economic balance, illustrated that, by comparison with the other main production processes, the manufacture and use of castings results in substantial energy savings and thus ecological advantages, e.g., the reduction of CO_2.

From case studies, it is a well-known fact that, by comparison with other process variants, near net shape castings are clearly advantageous with regard to specific energy requirements for the finished components, especially with respect to machining from solid semiproducts. Component manufacture by casting is also clearly preferential when considering ecological aspects such as CO_2 emission.

Foundries pursue objective environmental management and confront public option with declarations of their achievements.

10.2 Cast Alloys

Cast alloys are metallic materials manufactured by primary shaping in a foundry. Cast alloys can be classified into two main groups: Cast ferrous materials (cast irons and cast steels) and cast nonferrous materials (cast aluminum, cast magnesium, cast copper, and cast zinc alloys).

10.2.1 Cast Iron Alloys

Cast iron alloys can be classified into seven groups:

- Gray cast iron
- Spheroidal graphite cast iron
- *Solid solution strengthened cast iron*
- Ausferrite spheroidal graphite cast iron
- Compacted graphite cast iron
- Malleable cast iron
- Austenitic cast iron
- Abrasion resisting alloyed cast iron
- *Continuous cast iron*.

Cast Iron

The term *cast iron* designates an entire family of metallic materials with a wide variety of properties. It is a generic term like steel, which also designates a family of metallic materials. Steels and cast irons are both primarily iron with carbon as the main alloying element. Steels contain less than 2%, while all cast irons contain more than 2% carbon. About 2% is the maximum carbon content at which iron can solidify as a single phase alloy with all of the carbon in solution in austenite. Thus, the cast irons by definition solidify as heterogeneous alloys and always have more than one constituent in their microstructure.

In addition to carbon, cast irons also must contain appreciable silicon, usually from 1 to 3%, and thus they are actually iron-carbon-silicon alloys. The high carbon content and the silicon in cast irons make them excellent casting alloys. Their melting temperatures are appreciably lower than those of steel. Molten cast irons are more fluid than molten steel and less reactive with molding materials. Formation of lower density graphite in cast iron during solidification reduces the change in volume of the metal from liquid to solid and makes production of more complex castings possible.

The various types of unalloyed cast irons cannot be designated by chemical composition because of similarities between the types. Unalloyed cast irons are designated by their mechanical properties. High-alloy cast irons are designated by their chemical composition and mechanical properties. These have a wide range in chemical composition and also contain major quantities of other elements.

The presence of certain minor elements is also vital for the successful production of each type of cast iron. For example, nucleating agents, called inoculants, are used in the production of gray cast iron to control the graphite type and size. Trace amounts of bismuth and tellurium in the production of malleable cast iron, and the presence of a few hundredth of a percent of magnesium causes the formation of spheroidal graphite cast iron.

In addition, the composition of a cast iron must be adjusted to suit particular castings. Small castings and large castings of the same grade of cast iron cannot be made from the same composition of alloy. For this reason, most cast iron castings are purchased on the basis of mechanical properties rather than composition. The common exception is for castings that require special properties such as corrosion resistance or elevated temperature strength.

The various types of cast iron can be classified according to their microstructure. This classification is based on the form and shape in which the major portion

of carbon occurs in the cast irons. This system provides for five basic types of gray cast iron, spheroidal graphite cast iron, malleable cast iron, compacted graphite cast iron, and white cast iron. Each of these types may be moderately alloyed or heat treated without changing its basic classification. The high-alloyed cast irons, generally containing over 3% of added alloying element, can also be individually classified as gray or spheroidal graphite cast iron or white cast iron, but the high-alloyed cast irons are classified as a separate group.

Gray Cast Iron. When the composition of a molten cast iron and its cooling rate are appropriate, the carbon in the cast iron separates during solidification and forms separate graphite flakes that are interconnected within each eutectic cell (EN 1561). The graphite grows edgewise into the liquid and forms the characteristic flake shape. When gray cast iron is broken, most of the fracture occurs along the graphite, thereby accounting for the characteristic gray color of the fractured surface.

Because the large majority of iron castings produced are of gray cast iron, the generic term is often improperly used to mean gray cast iron specifically.

The properties of gray cast iron are influenced by the size, amount, and distribution of the graphite flakes, and by the relative hardness of the matrix metal around the graphite. These factors are controlled mainly by the carbon and silicon contents of the metal and the cooling rate of the casting. Slower cooling and higher carbon and silicon contents tend to produce more and larger graphite flakes, a softer matrix structure, and lower strength. The flake graphite provides gray cast iron with unique properties such as excellent machinability at hardness levels that produce superior wear-resisting characteristics, the ability to resist galling, and excellent vibration damping.

The amount of graphite present, as well as its size and distribution, are important to the properties of the cast iron. Wherever possible, it is preferable to specify the desired properties rather than the factors that influence them.

Microscopically, all gray cast irons contain flake graphite dispersed in an iron-silicon matrix. How much graphite is present, the length of the flakes, and how they are distributed in the matrix directly influence the properties of the cast iron.

The basic strength and hardness of the cast iron is provided by the metallic matrix in which the graphite occurs. The properties of the metallic matrix can range from those of a soft, low-carbon steel to those of hardened, high-carbon steel. The matrix can be entirely ferritic for maximum machinability, but the cast iron will have reduced wear resistance and strength. An entirely pearlitic matrix is characteristic of high-strength gray cast iron, and many castings are produced with a matrix microstructure of both ferrite and pearlite to obtain intermediate hardness and strength. Alloying element additions and/or heat treatment can be used to produce gray cast iron with very fine pearlite or with an acicular matrix structure.

Graphite has little strength or hardness, so it decreases these properties of the metallic matrix. However, graphite provides several valuable characteristics to gray cast iron: the ability to produce sound castings economically in complex shapes, good machinability, even at wear-resisting hardness levels and without burring, dimensional stability under different heating, high vibration damping, and borderline lubrication retention.

The properties of gray cast iron primarily depend on its chemical composition. The lower strength grades of gray cast iron can be produced consistently by simply selecting the proper melting stock. Grey cast iron castings in the higher strength grades require close control of their processing and chemical composition.

The majority of the carbon in gray cast iron is present as graphite. Increased amounts of graphite result from an increased total carbon content in the gray cast iron. This decreases the strength and hardness of the gray cast iron, but increases other desirable characteristics.

An appreciable silicon content is necessary in gray cast iron because this element causes the precipitation of the graphite in the material. The silicon also contributes to the distinctive properties of the gray cast iron. It maintains a moderate hardness level, even in the fully annealed condition, and thus assures excellent machinability. Also, silicon imparts corrosion resistance at elevated temperature and oxidation resistance in gray cast iron.

Gray cast iron can be alloyed to increase its strength and hardness as-cast or its response to hardening by heat treatment.

A very important influence on gray cast iron properties is the effective section thickness in which it is cast. The thicker the wall and the more compact the casting, the lower the temperature at which liquid metal will solidify and cool in the mold. As with all metals, slower solidification causes a larger grain size to form during solidification. In gray cast iron, slower solidification produces a larger graphite flake size.

Gray cast iron is commonly classified by its minimum tensile strength or by hardness (Table 10.1). The mechanical properties of gray cast iron are determined by the combined effect of its chemical composition, processing technique in the foundry, and the solidification and cooling rates. Thus, the mechanical properties

Table 10.1 Mechanical properties of gray cast iron

Tensile strength (N/mm^2)	100–350
Brinell hardness	155–265

of the gray cast iron in a casting will depend on its shape, size and wall thickness as well as on the gray cast iron that is used to pour it. Five grades of gray cast iron are classified by their tensile strength in EN 1561. The grades of gray cast iron also can be specified by Brinell hardness only. The chemical composition and heat treatment, unless specified by the purchaser, shall be left to the direction of the manufacturer, who shall ensure that the casting and heat treatment process is carried out with the same process parameters.

Spheroidal Graphite Cast Iron. Spheroidal graphite cast iron or ductile iron (EN 1563) is characterized by the fact that all of its graphite occurs in microscopic spherolites. Although this graphite constitutes about 10% by volume of this material, its compact spheroidal shape minimizes the effect on mechanical properties.

The difference between the various grades of spheroidal graphite cast irons is in the microstructure of the material around the graphite, which is called the matrix. This microstructure varies with the chemical composition and the cooling rate of the casting. It can be slowly cooled in the sand mold for a minimum hardness as-cast condition or, if the casting has sufficiently uniform sections, it can be shaken out of the mold while still at a temperature above the critical and normalized.

The matrix microstructure and hardness can also be changed by heat treatment. The high ductility grades are usually annealed so that the matrix structure's ferrite is entirely free of carbon. The intermediate grades are often used in the as-cast condition without heat treatment and have a matrix structure of ferrite and pearlite. The ferrite occurs as rings around the graphite spheroids. Because of this, it is called bull-eye ferrite. The high-strength grades are usually given a normalizing heat treatment to make the matrix all pearlite, or they are quenched and tempered to form a matrix of tempered martensite. However, spheroidal graphite cast iron can be moderately alloyed to have an entirely pearlitic matrix as-cast condition.

The chemical composition of spheroidal graphite cast iron and the cooling rate of the casting directly affect its tensile properties by influencing the type of matrix structure that is formed. All of the regular grades of the spheroidal graphite cast iron can be made from the same cast iron provided that the chemical composition is appropriate so that the desired matrix microstructure can be obtained by controlling the cooling rate of the casting after it is poured or by subsequent heat treatment. For most casting requirements, the chemical composition of the spheroidal graphite cast iron is primarily a matter of facilitating production.

Table 10.2 Mechanical properties of spheroidal graphite cast iron

Tensile strength (N/mm^2)	350–900
Yield strength (N/mm^2)	220–600
Elongation (%)	6–22
Brinell hardness	130–330

The common grades of spheroidal graphite cast iron differ primarily in the matrix structure that obtains the spheroidal graphite. These differences are the result of differences in the chemical composition, in the cooling rate of the casting, or the result of heat treatment.

Solid Solution Strengthened Cast Iron. Solid solution strengthened ferritic spheroidal graphite cast iron [10.2] has a matrix of predominantly ferrite with a maximum pearlite of 5%. The amount of free cementite should not exceed 1%. In order to fulfil the requirements for the mechanical properties, a ferritic structure solid solution strengthened by silicon is recommended. The silicon content is for tensile strength of $450\,N/mm^2$ approx. 3.20%, for tensile strength of $500\,N/mm^2$ approx. 3.80% and for tensile strength of $600\,N/mm^2$ approx. 4.30%. These solid solution strengthened ferritic spheroidal graphite iron grades are used for applications where good machinability, high ductility and high proof strength are required. The solid solution strengthened cast iron grades were included in EN 1563.

All in all 16 grades of spheroidal graphite cast iron are classified by their tensile properties or hardness in EN 1563 (Table 10.2). The common grades of spheroidal graphite cast iron also can be specified only by Brinell hardness. The method of producing spheroidal graphite, the chemical composition and heat treatment will be specified by the purchaser.

Ausferrite Spheroidal Graphite Cast Iron. This group of spheroidal graphite cast iron (EN 1564) is well known as ACI (austempered cast iron), and recently as ausferrite spheroidal graphite cast iron. The development of ausferrite spheroidal graphite cast iron has given the design engineer a new group of cast ferrous materials that offer the exceptional combination of mechanical properties (Table 10.3) equivalent to cast and forged steels, and production costs similar to those of conventional spheroidal graphite cast iron.

Ausferrite spheroidal graphite cast iron provides a wide range of properties, all produced by varying

Table 10.3 Mechanical properties of ausferrite spheroidal graphite cast iron

Tensile strength (N/mm^2)	800–1400
Yield strength (N/mm^2)	500–1100
Elongation (%)	1–10

Yield strength (N/mm^2)	200–600
Elongation (%)	1–10
Brinell hardness	150–320

the heat treatment (austempering) of the same castings. Austempering is a special heat treatment process, which consists of three steps:

- Austenitize in the temperature range of 840–950 °C for a time sufficient to produce a fully austenitic matrix that is saturated with carbon.
- Rapidly cool the entire part to an austempering temperature in the range of 230–400 °C without forming pearlite or allowing the formation of ausferrite to begin.
- Isothermally treat at the austempering temperature to produce ausferrite with an austenite carbon content in the range of 1.8–2.2%.

After heat treatment (austempering) the matrix consists of acicular ferrite and residual austenite without carbides.

Six grades of ausferrite spheroidal graphite cast iron are classified by their tensile properties in ISO/WD 17804 and two abrasion resistant grades are classified by Vickers hardness.

Compacted Graphite Cast Iron. Compacted graphite cast iron (vermicular graphite cast iron, EN 16079) is a recent addition to the family of commercially produced cast irons (Table 10.4). Its characteristics are between that of the gray cast iron and spheroidal graphite cast iron. The graphite in compacted graphite cast iron is in the form of interconnected flakes. The short span and blunted edges of graphite in this material provide improved strength, some ductility and a better machined finish than gray cast iron. The interconnected compacted graphite cast iron provides slightly higher thermal conductivity, more damping capacity, and better machinability than those obtained with spheroidal graphite cast iron.

Compacted graphite cast iron provides similar tensile and yield strengths to ferritic spheroidal graphite cast iron and malleable cast iron, although the ductility is less.

Table 10.4 Mechanical properties of compacted graphite cast iron

Tensile strength (N/mm^2)	300–500
Yield strength (N/mm^2)	220–380
Elongation (%)	0.5–1.5
Brinell hardness	140–260

Malleable Cast Iron. The starting point is a cast iron in which the carbon and silicon contents are arranged so that the casting is graphite-free after solidification, the entire carbon content being bonded to the iron carbide (cementite). If the casting is then heat-treated (tempered), the cementite decomposes without residue.

Two kinds of malleable cast iron are distinguished (Table 10.5):

- White malleable cast iron, which is decarbonized during heat treatment; and
- black malleable cast iron, which is not decarbonized during heat treatment.

White malleable cast iron (EN 1562) is produced by heating for 50–80 h at about 1050 °C in a decarburizing atmosphere (CO, CO_2, H_2, H_2O). In this process carbon is removed from the casting, so that after cooling a purely ferritic microstructure is in the casting. White malleable cast iron with small cross sections welds easily.

Black malleable cast iron is produced by heating in a neutral atmosphere, first for about 30 h at 950 °C. In this process the cementite of the ledeburite decomposes into austenite and graphite (temper carbon), which is precipitated in fluky clusters. In a second step of the heat treatment the austenite is converted during slow cooling from 800 to 700 °C into ferrite and temper carbon or transformed during quick cooling into pearlite and temper carbon.

In EN 1562 five grades of white malleable cast iron and nine grades of black malleable cast iron are classified by tensile strength.

Table 10.6 Mechanical properties of austenitic cast iron

With flake graphite	
Tensile strength (N/mm^2)	140–220
Elongation (%)	2
Brinell hardness	120–150
With spheroidal graphite	
Tensile strength (N/mm^2)	370–500
Yield strength (N/mm^2)	210–290
Elongation (%)	1–45
Brinell hardness	120–255

Austenitic Cast Iron. High-alloy cast iron is used to produce components that require resistance to corrosives in the operating environment such as seawater, sour well oils, commercial organic and inorganic acids, and alkalis. The ability to easily cast it into complex shapes and the ease of machining some types of this material, make high-alloy cast iron an attractive material for the production of components for chemical processing plants, petroleum refining, food handling, and marine service. Two types dominate high alloy corrosion resistant cast iron: nickel-alloyed cast iron (austenitic cast iron, EN 13835) and high-Si cast iron.

Nickel-alloyed cast iron owes its excellent corrosion resistance to the presence of nickel in concentrations of 12.0–36.0%, a chromium content of 1.0–5.5% and, in one type, s copper content of 5.5–7.5%. These cast irons have an austenitic matrix.

Ten grades of austenitic cast iron with spheroidal graphite and two grades of austenitic cast iron with flake graphite are classified in EN 13835 by chemical composition and mechanical properties, like austenitic steels.

The mechanical properties of austenitic cast iron with spheroidal graphite and with flake graphite are shown in Table 10.6.

Abrasion Resisting Alloyed Cast Iron. High-alloy white cast iron (EN 12513) is specially qualified for abrasion-resistant applications. The predominant carbides in its microstructure provide the high hardness necessary for crushing and grinding other materials without degradation. The supporting matrix structure may be adjusted by alloy content and/or heat treatment to develop the most cost-effective balance between resistance to abrasive wear and the toughness required to withstand repeated impact loading. High-alloy white cast iron is easily cast into shapes required for crushing and grinding or the handling of abrasive materials.

Abrasion resistance concerns the conditions under which a metal or alloy is used. The ability of a part to resist a weight loss due to abrasion depends upon its microstructure, the actual mechanical operations of the part, and the kind and size of material being moved, crushed or ground.

Most of the white cast iron designated for abrasion-resistant applications falls within the high-alloy cast iron category, but unalloyed white cast iron is common and provides satisfactory service where the abrading material is not fine or where replacement is not frequent or expensive. All alloyed cast iron contains chromium to prevent the formation of graphite and to ensure the stability of the carbides in the microstructure. Alloy white cast iron also may contain nickel, molybdenum, copper, or a combination of these alloying elements to prevent or minimize the formation of pearlite in the microstructure.

Unalloyed white cast iron castings develop hardnesses in the range 350–550 BHN. Their microstructures consist of primary iron carbides with a microhardness of 900–1200 VHN in a pearlitic matrix with a microhardness of 220–300 VHN. Alloyed martensitic white cast iron, however, develops Brinell hardnesses in the 500–700 range. The carbide hardness remains 900–1200 VHN, but martensitic, always associated with some retained austenite, exhibits a microhardness of 600–700 VHN. For many abrasion-resistant applications; the more costly alloyed white cast iron with martensitic matrix structures provide the most economical service.

EN 12513 covers the composition and hardness of abrasion-resistant white cast iron. Martensitic white cast iron falls into two major groups:

- The low-chromium group with 1–4% chromium and 3–5% nickel
- The high-chromium white cast iron containing 14–28% chromium with 1–3% of molybdenum, often alloyed further with additions of nickel and copper

A third but minor category comprise the straight 25–28% chromium white cast iron.

Continuous Cast Iron. In the manufacture of continuous cast iron (EN 16482) solidification begins in a water-cooled, open-ended die. Because the thermal conditions are different from those for sand casting, solidification is faster. Depending on the process, the results in properties that differ from those obtained by sand casting and a particularly close-grained, dense material structure. Very high pressure tightness in respect of liquids and gases is a feature of continuous cast iron. Continuous cast grey and spherolitic graphite iron is manufactured using the horizontal continuous casting method. The mechanical properties of grey iron and spherolitical graphite cast iron are described in

EN 16482 [10.3]. It gives four grades of grey cast irons and 14 grades of spherolitic graphite cast iron. Continuous cast irons are semifinished cast products. The products of continuous cast irons are round, quadratic, rectangular or half round bars.

10.2.2 Cast Steel

Cast steels can be classified into four groups:

- Cast carbon and cast low-alloy steel
- Cast high-alloy steel
- Cast stainless steel
- Cast heat-resisting steel.

Cast Carbon and Cast Low-Alloy Steel

This group of cast steels consists of many subgroups: steel castings for general purposes (DIN 1681, EN 10293 steel casting for general engineering uses), steel casting for pressure purposes (partially EN 10213), steel castings with improved weldability and toughness for general purposes (DIN 17182, EN 10293 steel castings for general engineering uses, draft), quenched and tempered steel castings for general purposes (DIN 17205, EN 10293 steel castings for general engineering uses, draft), steel castings for use at room temperature and elevated temperatures (EN 10213-2), and steel castings for use at low temperatures (EN 10293-3).

Carbon steel is considered to be steel in which carbon is the principal alloying element. Other elements that are present and that, in general, must be reported are manganese, silicon, phosphorus, and sulfur. In a sense, all of these elements are *residuals* from the raw materials (coke, iron ore) used in the manufacture of the steel, although the addition of manganese is often made during the steel making process to counter the deleterious effect of sulfur.

Low-alloy cast steels are considered to be those steels to which elements (other than carbon) are added deliberately to improve mechanical properties.

For all cast carbon and cast low-alloy steels, the mechanical properties are controlled by the chemical composition, the heat treatment and the microstructure of these cast steels. Among the exceptions are the effect of carbon on increasing hardness, the effect of nickel on increasing toughness, and the effect of combinations of chromium, molybdenum, vanadium, and tungsten on increasing elevated temperature strength. The major reason for using alloying elements in low-alloy cast steels is to make the role of heat treatment on increasing strength effective over a wide range of material thickness by quenching and tempering. This effectiveness is termed *hardenability*.

Table 10.7 Mechanical properties of steel castings for general engineering uses

Tensile strength (N/mm^2)	380–1250
Yield strength (N/mm^2)	200–1000
Elongation (%)	7–25

Table 10.8 Mechanical properties of cast stainless steels

Tensile strength (N/mm^2)	430–1100
Yield strength (N/mm^2)	175–1000
Elongation (%)	5–30

Thirty grades of steel castings for general engineering uses (five grades of carbon cast steels, 20 grades of low alloy cast steels, and five grades of high alloy cast steels) are classified by their chemical composition, heat treatment processes (austenitizing, air cooling/austenitizing, quenching, tempering), and mechanical properties in EN 10293 (Table 10.7).

EN 10213 consists of steel castings for pressure purposes, in specially cast steel grades for use at room temperature and elevated temperatures (carbon cast steels, low alloy cast steels, high alloy cast steels), cast steel grades for use at low temperatures (low alloy cast steels, high alloy cast steel), and cast austenitic and austenitic-ferritic steel grades (high alloy cast steel grades).

High-Alloy Cast Steel

There are two main groups of high-alloy cast steels: Cast stainless steels and cast heat-resisting steels.

Corrosion Resistant Cast Steel. Cast stainless steels (EN 10213, EN 10283, SEW 410) are distinguished by their special resistance to chemically corrosive substances; in general, they have a chromium content of at least 12 wt %. The cast stainless steels in EN 10213, EN 10283, and SEW 410 are subdivided into martensitic, ferritic-carbidic, ferritic-austenitic, austenitic, and full austenitic steels. Cast stainless steels are suitable for welding. Their resistance to intercrystalline corrosion in mill finishing is an important property of cast stainless steels (Table 10.8).

A special kind of cast stainless steels are the duplex-steels (dual phase steels) with about 50% austenite and 50% soft martensite, in which the two phases fulfil different functions: The austenite guarantees corrosion protection, e.g., seawater resistance in this case, and the soft martensite guarantees component strength.

In EN 10213, EN 10283, and SEW 410 44 grades of cast stainless steels are classified by chemical composition and mechanical properties. The main alloying elements are chromium, nickel, and molybdenum.

Table 10.9 Mechanical properties of heat-resistant cast steel at room temperature

Tensile strength (N/mm^2)	400–440
Yield strength (N/mm^2)	220–230
Elongation (%)	5–15

Heat-Resisting Cast Steel. The chief requirement for heat-resisting cast steels (EN 10295, SEW 471, SEW 595) is not especially good high-temperature strength but sufficient resistance to hot gas corrosion in the temperature range above 550 °C. The highest temperature at which a heat-resisting steel can be used depends on operational conditions. Recommended temperatures for air and hydrogen atmospheres are up to 1150 °C depending on the chemical composition.

The scaling limit temperatures for the heat-resisting steels is defined as the temperature at which the material loss in clean air is 0.5 mg cm^{-2} h^{-1}.

The scale resistance of heat-resisting cast steels is based on the formation of dense, adhesive surface layers of oxides of the alloying elements chromium, silicon, and aluminum (Table 10.9). The protective effect starts when the chromium content is 3–5%, but chromium contents up to 30% can be alloyed. The protective effect of these layers is limited by the corrosive low-melting-point eutectics and by carburizing. To increase the heat resistance the alloying element nickel is added in addition to chromium (Cr + Ni = 25–35%).

In EN 10295, SEW 471, and SEW 595, 25 grades of heat-resistant cast steels are classified by the chemical composition and the mechanical properties. The main alloying elements are chromium, silicon, and nickel.

The creep behavior with the creep rupture strength and the creep limit in the temperature range of 600 up to 1100 °C is the most important property.

10.2.3 Cast Nonferrous Alloys

The cast nonferrous alloys are classified into four main groups:

- Cast aluminum alloys
- Cast magnesium alloys
- Cast copper alloys
- Cast zinc alloys.

There are other groups, for example cast titanium alloys, cast tin alloys, cast lead alloys, cast nickel alloys, cast cobalt alloys, etc.

Cast Aluminum Alloys

The specification of a cast aluminum alloy (EN 1706) for a cast component is based upon the mechanical properties it can achieve. These properties are obtained from one particular combination of cast alloy, melt treatment (grain refining, modification) foundry practice, and thermal treatment. In all cast aluminum alloys the percentage of alloying elements and impurities must be carefully controlled.

The main alloying elements of the cast aluminum alloys are copper, silicon, magnesium, and zinc. Grain refiners, which are usually materials that liberate titanium, boron, or carbon, are generally added in the form of a master-alloy to the melt. In casting alloy this is a well-proven method to influence the nucleation conditions in a melt, so that it solidifies with as fine-grained and dense a structure as possible. Hypereutectic aluminum-silicon alloys can be grain-refined with additions that release phosphorus, which promotes the nucleation of primary silicon. Modifying aluminum-silicon alloys of eutectic and hypereutectic composition means treating the melt to binder primary silicon from precipitating to form coarse, irregularly shaped particles. The melt can be modified by adding capsules of metallic sodium or compounds that release sodium. Alternatively, the addition of strontium has proved successful in castings. In contrast to sodium, which burns off and is lost fairly quickly, strontium lasts longer.

Industrial casting processes consist of traditional sand casting, low-pressure sand casting, investment casting, lost-foam casting, permanent mold casting, high pressure die casting, low-pressure permanent mold casting, back-pressure die casting, vacuum die casting, squeeze casting, and thixocasting.

Sand and permanent mold castings may be heat treated to improve mechanical and physical properties. The following thermal treatments are used in industry:

- Stress relief or annealing
- Solution heat treatment and quenching, artificial aging
- Solution heat treatment, quenching and natural aging and
- Solution heat treatment, quenching, and artificial overaging (for the groups 1, 2 and 4 in Table 10.10).

In EN 1706 37 grades of cast aluminum alloys are classified by their chemical composition and mechanical properties (Table 10.10). The mechanical properties depend on the chemical composition of the cast aluminum alloys, the casting technology, and the heat treatment process.

Cast Magnesium Alloys

Magnesium combines a density two-thirds that of aluminum and only slightly higher than that of fiber-

Table 10.10 Mechanical properties of aluminum cast alloys (sand molding—1, permanent mold casting—2, high pressure die casting—3, investment casting—4)

Tensile strength (N/mm^2)	140–300	150–330	200–240	150–300
Yield strength (N/mm^2)	70–210	70–280	120–140	80–240
Elongation (%)	1–5	1–8	1–2	1–5
Brinell hardness	40–100	45–100	55–80	50–90

reinforced plastics with excellent mechanical and physical properties as well as processability and recyclability.

Cast magnesium alloys (EN 1753) can be divided into two groups: the sand-casting alloys that have a fine grain structure due to a melt treatment with small additions of zirconium, and the die casting alloys, in which aluminum is the principal alloying element. The alloys can also be classified as general purpose (Table 10.11), high ductility, and high temperature alloys. Most of the alloys are produced as high-purity versions to reduce potential corrosion problems associated with higher levels of iron, nickel, and copper.

Aluminum improves the mechanical strength, corrosion properties, and castability of the castings. Ductility and fracture toughness are gradually reduced with increasing aluminum content.

Manganese is added to control the iron content of the alloys. The level of manganese additions varies from one alloy to the next, depending on the mutual solubilities of iron and manganese in the presence of other alloying elements. A basic requirement of high-purity alloys is that the iron content of diecast parts is limited to a maximum of 0.005 wt%. Other impurities like nickel and copper also must be strictly controlled. Other alloying elements are zinc, manganese, silicon, copper, zirconium, and rare earth elements.

Following are some of the advantages magnesium alloys offer casting designers:

- *Light weight*—The lightest of all structural alloys, magnesium alloys preserves the light weight of a design without sacrificing strength and rigidity.
- *High stiffness to weight ratio*—This characteristic is important where resistance to deflection is desired in a light-weight component.
- *Damping capacity*—Magnesium is unique among metals because of its ability to absorb energy inelastically. This property yields the vibration absorption capacity to ensure quieter operation of equipment.

Table 10.11 Mechanical properties of cast magnesium alloys

Tensile strength (N/mm^2)	140–250	160–250	150–260
Yield strength (N/mm^2)	90–175	90–175	80–160
Elongation (%)	2–8	2–8	1–18
Brinell hardness	50–90	50–90	50–85

- *Dimensional stability*—Annealing, artificial aging or stress-relieving treatments normally are not necessary to achieve stable final dimensions.
- *Impact and dent resistance*—The elastic energy absorption characteristics of magnesium alloys result in a good impact and dent resistance and energy management.
- *Anti-galling*—Magnesium alloys possess a low galling tendency and can be used as a bearing surface in conjunction with shaft hardness above 400 HB.
- *High conductivity*—Magnesium alloys have a high thermal conductivity and a good electrical conductivity.
- *Wall thickness*—Magnesium alloy die castings are commonly produced with a wall thickness from 0.15 to 0.4 cm.

Magnesium alloys can be cast by a variety of methods, including high-pressure die casting, low pressure permanent mold casting, sand casting, plaster/investment casting, and thixocasting and squeeze casting.

Different alloys may be specified for the different processes. In cases where the same alloy is used with different casting processes, it is important to note that the properties of the finished castings will depend on the casting method. The most prevalent casting method for magnesium alloys is die casting. In this process, thin-walled parts are produced at high production rates with reduced tool wear compared to aluminum alloys, due to the lower heat content per volume of molten metal. Both hot chamber and cold camber machines are currently used for magnesium alloys. Thixocasting is another casting method that has shown progress with magnesium alloys.

There are seven cast magnesium alloys in EN 1753.

Cast Copper Alloys

Cast copper alloys (EN 1982) are known for their versatility. They are used in a wide range of applications because they are easily cast, have a long history of successful use, are readily available from a multitude of sources, can achieve a range of physical and mechanical properties, and are easily machined, brazed, soldered, polished, or plated.

Table 10.12 Mechanical properties of cast copper alloys

Tensile strength (N/mm^2)	150–750
Yield strength (N/mm^2)	40–480
Elongation (%)	5–25
Brinell hardness	40–190

Table 10.13 Mechanical properties of cast zinc alloys

Tensile strength (N/mm^2)	220–425
Yield strength (N/mm^2)	200–370
Elongation (%)	2.5–10
Brinell hardness	83–120

The following lists the physical and mechanical properties common to cast copper alloys:

- Good corrosion resistance, which contributes to the durability and long-term cost-effectiveness.
- Favorable mechanical properties ranging from pure copper, which is soft and ductile, to manganese-bronze, which rivals the mechanical properties of quenched and tempered steel. In addition, all cast copper alloys retain their mechanical properties, including impact toughness at low temperatures.
- High thermal and electrical conductivity, which is greater than any metal except silver. Although the conductivity of copper drops when alloyed, cast copper alloys with low conductivity still conduct both heat and electricity better than other corrosion-resistant materials.
- Bio-fouling resistance, as copper inhibits marine organism growth. Although this property (unique to copper) decreases upon alloying, it is retained at a useful level in many alloys, such as copper-nickel.
- Low friction and wear rates, such as with the high-leaded tin-bronzes, which are cast into sleeve bearings and exhibit lower wear rates than steel; good castability, as all cast copper alloys can be sand cast and many can be centrifugally, continuously, and permanent mold cast, as well as diecast.
- Good machinability, as the leaded copper alloys are free-cutting at high machining speeds, and many unleaded alloys such as nickel-aluminum bronze are readily machinable at recommended feeds and speeds with proper tooling.
- Ease of post-casting processing, as good surface finish and high tolerance control is readily achieved. In addition, many cast copper alloys are polished to high luster, and platting, soldering, and welding also are routinely performed.
- Large alloy choice, since several alloys may be suitable candidates for any given application depending upon design loads and corrosivity of the environment.
- Comparable costs to other metals due to their high yield, low machining costs, and little requirement for surface coatings such as paint.

In EN 1982 the cast copper alloys are divided into cast copper, cast copper-chromium, cast copper-zinc, cast copper-tin, cast copper-tin-lead, cast copper-aluminum, cast copper-manganese-aluminum, and cast copper-nickel alloys.

Thirty five grades of cast copper alloys are classified by their chemical composition and mechanical properties in EN 1982.

Cast Zinc Alloys

Cast zinc alloys (EN 1774 and EN 12844) are assigned to three alloy groups. The first group of alloys have 4% aluminum as the primary alloying element with 0.099% or less magnesium to control intergranular corrosion. Another alloying element is copper. The alloys with the highest copper content have the highest hardness. The mechanical properties can be improved with 0.005–0.2% nickel as the alloying element. The second group has higher aluminum contents (8–27%) These alloys have superior hardness, wear and creep resistance that increase with the aluminum content. The third group is a cast zinc alloy that has copper as the primary alloying element. Castings of the cast zinc alloys are manufactured by the high pressure die casting.

In EN 12844 8 grades of cast zinc alloys are classified by their chemical composition and mechanical properties.

10.3 Primary Shaping

According to DIN 8580 [10.4], primary shaping is the manufacturing of a solid body from a shapeless material by creating cohesion. Thus primary shaping serves to give a component made from a material in shapeless condition an initial form. Shapeless materials are gases, liquids, powders, fibers, chips, granules, solutions, melts, and the like. Primary shaping may be divided into two groups with regard to the form of the products and their further processing:

- Products produced by primary shaping, which will be further processed by forming, severing, cutting,

and joining. The final product no longer resembles the original product of primary shaping in form and dimensions, i.e., a further material change in shape and dimensions is accomplished by means of other main groups of manufacturing processes.

- Products produced by primary shaping, which essentially have the form and dimensions of finished components (e.g., machine parts) or end-products, i.e., their shape essentially corresponds to the purpose of the product. The attainment of the desired final form and dimensions usually requires only operations that fall into the main process group *cutting* (machining).

Most powders are produced by primary shaping, whereby the powders are atomized out of the melt, and rapid solidification is followed. From powder, sintering parts are produced as a result of powder metallurgical manufacturing.

The production of cast parts from metallic materials in the foundry industry (castings), from metallic materials in powder metallurgy (sintered parts), and from high-polymer materials in the plastics processing industry has major advantages for economic efficiency.

The production of cast parts is the shortest route from the raw material to the finished part. It bypasses the process of forming and all the associated expense. The final form of a finished component with a mass ranging from a few grams to several hundred tonnes is practically achieved in one direct operation.

The production of cast parts by primary shaping from the liquid state allows the greatest freedom of design. This cannot be achieved by any other manufacturing process.

Primary shaping also enables processing of materials that cannot be achieved by means of other manufacturing methods. The direct route from the raw material to the preform or the end-product results in a favorable material and energy balance.

The continual further development of primary shaping processes increasingly permits the production of components and end-products with enhanced practical characteristics, i.e., cast parts with lower wall thicknesses, lower machining allowances, narrower dimensional tolerances, and improved surface quality.

In the following, primary shaping of metallic materials from the liquid state in foundry technology, of metallic materials from the solid state in powder metallurgy, and of high-polymer materials (plastics) from the plasticized state or from solutions is discussed on a common basis with regard to the fundamental technological principles. The discussion is restricted to subjects relevant to mechanical engineering.

For a better appreciation of the relevant principle of action, many detailed technological operations are omitted, which although vital to the specific manufacturing technology, are of minor importance. Furthermore, when discussing the specific primary shaping processes, only products with a simple form are referred to, because the diversity of the possible geometric forms cannot be described here.

Only the most important primary shaping processes are selected, as the large number of technological processes and process variables means that it is impossible to provide anything like a complete description. The processes are selected first according to their technical importance and second according to the principle of action.

Materials technology problems will only be mentioned briefly, although they are vital in order to understand the technological processes, their applicability and efficiency, and the changes in material properties brought about by the technological processes.

10.3.1 Process Principle in Primary Shaping

In the processes of primary shaping, the technological manufacturing process essentially comprises the following steps:

- Supply or production of the raw material as an amorphous substance
- Preparation of a material state ready for primary shaping
- Filling of a primary shaping tool with the material in a state ready for primary shaping
- Solidification of the material in the primary shaping tool
- Removal of the product of primary shaping from the primary shaping tool.

These individual steps are discussed in the following section.

10.3.2 Material State Ready for Primary Shaping

In primary shaping of metallic materials from the liquid state, the raw materials (pig-iron, scrap, ferroalloys and the like) are melted in a metallurgical melting furnace by means of thermal energy. The melting furnaces are usually physically separated from the primary shaping tool. The molten metal is carried by means of transfer vessels (ladles) to the primary shaping tools, termed molds in the foundry industry, and cast there.

In primary shaping of high-polymer materials from the plasticized state, bulk raw materials (granules, pow-

der) are fed after proportioning into a preparation device, which is usually integral with the primary shaping tool. There, thorough mixing, homogenizing and plasticizing of the material to be processed are accomplished under the action of heat and pressure. When solutions are used, these are produced in a mixing unit and then poured into the primary shaping tool. In primary shaping of metallic and also high-polymer materials from the solid state, the bulk raw materials (metal powder, plastic powder, or plastic granules) are poured straight into the primary shaping tool, where they sinter, or first become plastic and then solidify under the action of pressure and thermal energy.

10.3.3 Primary Shaping Tools

The primary shaping tool contains a hollow space which, with the allowance for contraction, usually corresponds to the form of the product (unmachined part) to be manufactured, but may be smaller or larger than the resulting unmachined part. Furthermore, primary shaping tools often contain systems of channels (runners) for feeding the material in the state ready for primary shaping. The allowance for contraction corresponds to the dimensional changes that occur in the material to be processed from the moment of solidification to its cooling to room temperature.

In the production of cast parts, a distinction is made between primary shaping tools for once-only use and those for repeated use. Primary shaping tools for once-only use are only used for primary shaping of metallic materials from the liquid state in foundry technology. They are termed expendable or *dead* molds. Only one product (casting) can be manufactured, as the mold is subsequently destroyed. However, primary shaping tools for repeated use (permanent molds) are also used in foundry technology. A larger quantity of cast parts can be produced. The primary shaping technologies for processing of high-polymer materials and powder metallurgy use only primary shaping tools for repeated use. Primary shaping tools for repeated use are usually made of metallic, and more rarely of nonmetallic, materials. Primary shaping tools for once-only use (dead molds) are made with the aid of patterns.

10.3.4 Filling the Primary Shaping Tools

Filling of the primary shaping tools with the material ready for primary shaping may be accomplished by means of the following principles of action: under the influence of gravity, elevated pressure or centrifugal force and by displacement. The material to be processed can be put into the primary shaping tools in solid, pourable form (e.g., powder), as molten metal in the case of metallic materials, or in a plasticized condition, as a solution or as a paste in the case of high-polymer materials.

10.3.5 Change of State Ready for Primary Shaping

Shaping into the Solid State of Aggregation

Liquid metallic materials (molten metals) change by crystallization to the solid state of aggregation on cooling owing to the removal of heat.

Thermoplastics are cooled in the primary shaping tool after forming. As a result of temperature reduction, which is accomplished either by heat removal in cooled tools or in downstream equipment (cooling baths), the plastic mass passes through the following states: plastic–rubber like–elastic–solid. In setting by cooling, secondary valency bonds are restored. This process is repeatable; therefore thermoplastics cart be restored to the plastic state by reheating.

Thermosetting plastics or thermosets (cross-linkable plastics) are cured after forming by a hardening process. Primary valency bonds form, and the plasticized mass solidifies directly under the effect of heat and/or pressure. The curing is an irreversible chemical process: thermosets disintegrate on reheating without needing to pass through a plastic state. Fundamental chemical reactions during solidification are polymerization, polycondensation, and polyaddition.

In primary shaping of high-polymer materials, if solutions are used then the transformation to the solid state may be accomplished by the physical process of solvent evaporation.

In primary shaping by sintering, a process of shrinkage of the internal and external surface area of a body formed from powder by pressure takes place. Powder particles that are in contact are joined by the formation or reinforcement of bonds (material bridges) and/or by reducing the pore volume; at least one of the material constituents involved remains solid throughout the process. The bonding of the porous pressed body of powder takes place mainly through diffusion mechanisms.

The description of the technological aspects of primary shaping and details of the processes are not described here but can be found in the relevant literature.

10.4 Shaping of Metals by Casting

10.4.1 Manufacturing of Semifinished Products

This group of primary shaping processes involves the production of initial and intermediate products, which are further processed by, for instance, metal forming (plastic deformation).

The Ingot Casting Process

Here, ingots, slabs, wirebars, etc. are produced in permanent molds made of metal (usually cast iron). These products are converted by metal forming (rolling, forging, pressing, wire drawing, etc.) into a semifinished product (sheet, plate, section, wire) that no longer resembles the original ingot in form and dimensions. In ingot casting a distinction is made between top pouring (downhill casting, Fig. 10.2a), where the mold is filled by directly pouring the molten metal in from above, and bottom pouring (uphill casting, Fig. 10.2b), where one mold or several molds simultaneously (group casting) are filled from below by means of a distribution system (pouring gate and runner bricks).

Procedure: The prepared molds are set up into the teeming box as illustrated. They are filled with the liquid metal, which solidifies in them. The molds are stripped from the ingots, which are taken away.

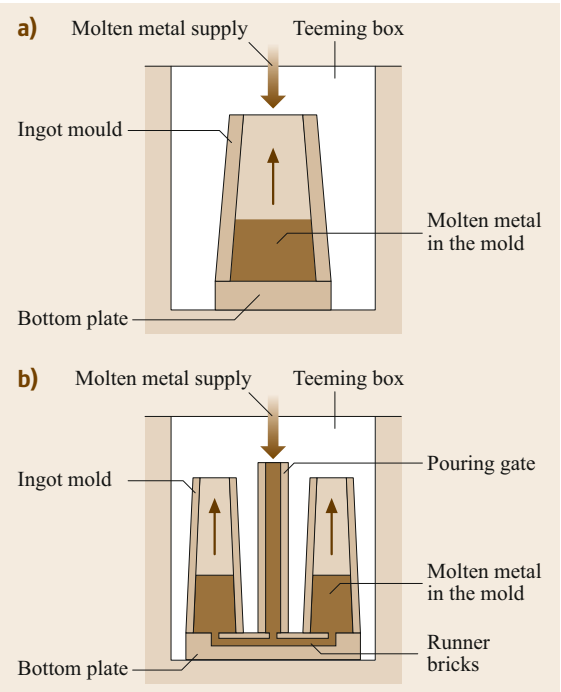

Fig. 10.2a,b Ingot casting methods: **(a)** top pouring, **(b)** bottom pouring [10.1]

Continuous Casting Processes

In these processes, which are used to produce either intermediate products for metal forming or semifinished products, the primary shaping tool (continuous mold, casting roller, casting belt, casting wheel) is always smaller than the product of primary shaping.

Casting with Stationary Molds. Continuous casting with a stationary mold. In this casting process, a bath of molten metal is fed into a stationary continuous mold, where the solidification begins.

Depending on the design, a distinction is made between batch or continuous vertical (Fig. 10.2a) and horizontal continuous casting systems (Fig. 10.2b). On leaving the continuous mold the resulting continuous casting (solid or hollow section) is cooled until it solidifies completely. The continuous casting is usually cut into defined lengths at intervals. Like ingots from ingot casting, these are further processed by metal forming.

Traveling Primary Shaping Tools. In this continuous casting process, metal-forming equipment for rolling or drawing is installed directly following the casting plant, thus dispensing with the manufacturing stages of metal forming. In this case, there is usually no cutting of the continuous castings into sections.

Continuous Casting with Moving Molds. The continuous casting with moving molds is realized with strip and wire rod casting plants.

In vertical uphill casting between two casting rollers (Fig. 10.3a) the molten metal is fed from below between two casting rollers. Solidification takes place between these two rollers, and the finished continuous casting (a strip) emerges vertically upward from these rollers.

In horizontal casting (Fig. 10.3b), both the feeding of the molten metal and the discharge of the solidified continuous casting (strip) take place horizontally. In casting between a casting roller or a casting wheel having the profile of the desired strip or rod and an endless casting belt (Fig. 10.4a, b), the molten metal solidifies between the casting roller/wheel and the casting belt and emerges into the open air. In casting in belt molds (two endless, rotating casting belts), solidification is accomplished with the aid of further rotating equipment to restrict the product laterally between these casting belts (Fig. 10.5a–c); the solidified

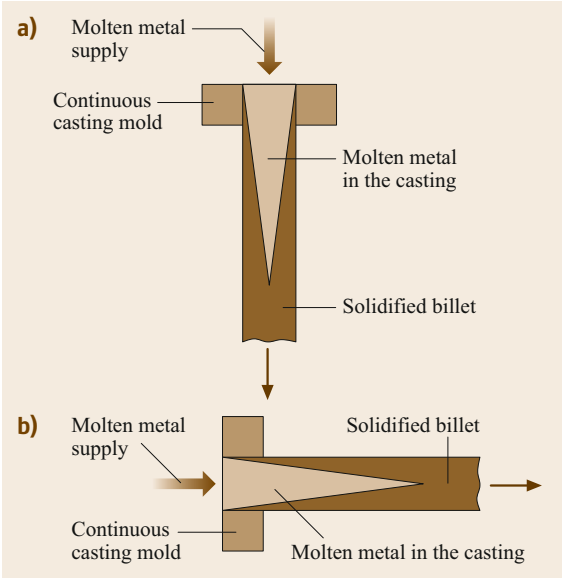

Fig. 10.3a,b Continuous casting: (a) vertical, (b) horizontal continuous casting [10.1]

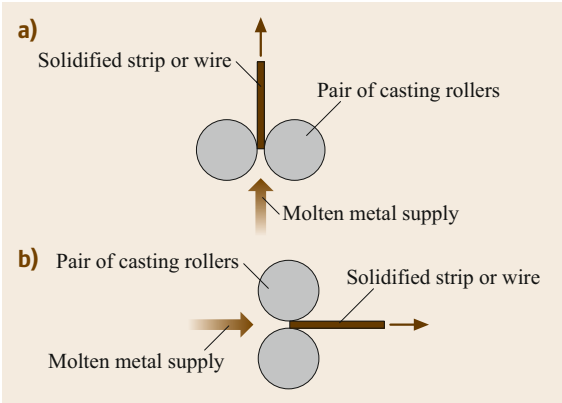

Fig. 10.4a,b Strip casting: (a) vertically uphill, (b) horizontally [10.1]

continuous casting then emerges into the open air as a strip.

10.4.2 Manufacturing of Cast Parts

Manufacturing of cast parts is accomplished with primary shaping processes by means of which a practically finished component, e.g., a machine part or an end-product, is produced without metal forming. The product's shape and dimensions do not undergo any further significant change. However, primary shaping is followed by other manufacturing processes, e.g., cutting (turning, planing, milling, drilling), to obtain a component ready for fitting. The intention is to perfect and

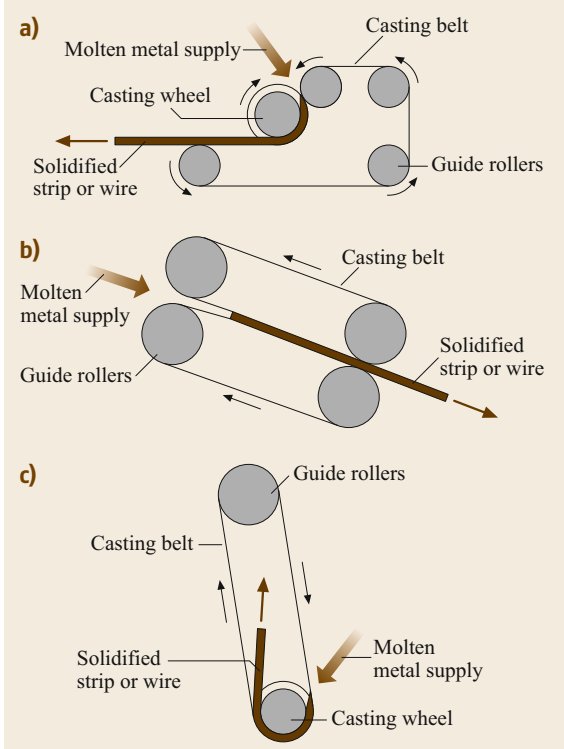

Fig. 10.5a–c Casting machines: (a) strip casting machine (rotary process), (b) strip casting machine (Hezelett process), (c) wire rod casting machine [10.1]

further develop the primary shaping techniques in order to, for instance, reduce the amount of machining work to a minimum. A good view of the manufacturing of cast parts—cast alloys, manufacturing processes and applications of cast parts—is given in [10.1, 5].

Use of Lost Primary Shaping Tools (Lost Molds)

This technique, which is only used in primary shaping of metallic materials from the liquid state in foundry technology, uses a pattern to produce the expendable primary shaping tool. Depending on the type of pattern used, a distinction is made between processes using a permanent pattern and those using an expendable pattern. A permanent pattern can be used to make many expendable molds, but an expendable pattern can only be used for one expendable mold. Expendable patterns are also made in an appropriate primary shaping tool.

The patterns are similar in shape to the case part to be manufactured, but are larger by the allowance for contraction of the material to be cast. They also incorporate the machining allowances, which will subsequently be eliminated by machining of the casting with the aim of achieving accuracy in dimensions, shape and position, as well as tapers to enable the pat-

tern to be removed from the mold. Most patterns have a pattern joint, i.e., they consist of at least two parts (pattern halves). In addition, for castings with hollow spaces the pattern has care marks for insertion of the cores in the mold.

In the case of permanent patterns for making an expendable mold for casting, these patterns or their sections made from metals, high polymers or wood are used to make the molds by the sand molding, template molding, or shell molding process.

Hand Molding. The mold is expendable (i.e., used only once). The medium used may be natural or synthetic sand with bentonite; other molds used sand with a resin binder. It is worked by hand.

Pattern. Patterns for repeated use, and patterns and core boxes, are made of wood or plastics.

Process Characteristics. Hand molding denotes the production of a sand mold without using a molding machine. The mold consists of the external parts for the external profile and the internal parts for the internal profile. Hollow spaces in the casting are formed by cores placed in the mold.

The principle of molding is illustrated in Fig. 10.6. First of all the bottom half of the two-part pattern is molded. After turning the molding box over, the top half of the pattern and the pouring gate and risers are placed in position and the top mold is made. The top box is lifted off, the pattern halves are removed from the mold, and the core is inserted. The halves of the mold are joined and the casting is made.

Casting Materials. All metals and alloys that are castable with the current technology.

Weight of Castings. The maximum transportable weight and the melting capacity determine the maximum weight.

Number of Castings. Single items, small production runs.

Tolerances. From about 2.5 to 5%.

Machine Molding. The mold is expendable (used only once). Natural sand, artificial sand, sand with synthetic resin binders, CO, sand. Preparation on molding and core molding machines. Used in semiautomatic and fully automatic production lines.

Pattern. Patterns and core boxes are made of metal or plastic.

Process Characteristics. Mechanical molding is characterized by a semiautomatic or fully automatic manufacturing operation for efficient production of ready-to-cast sand molds (Fig. 10.7). The casting process is often

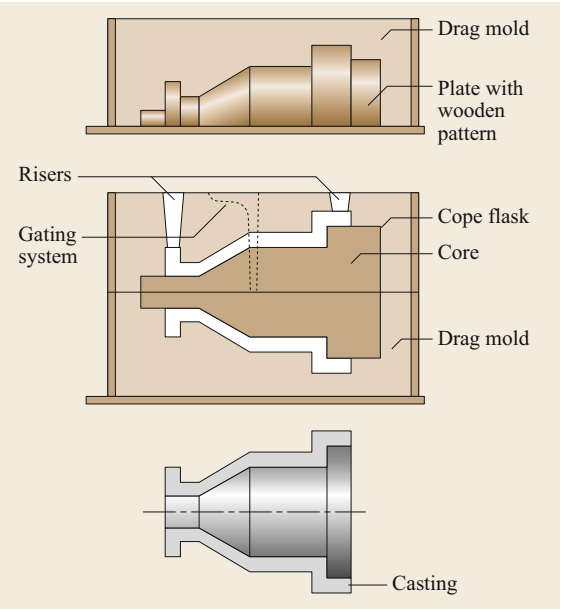

Fig. 10.6 Hand molding [10.1, 6]

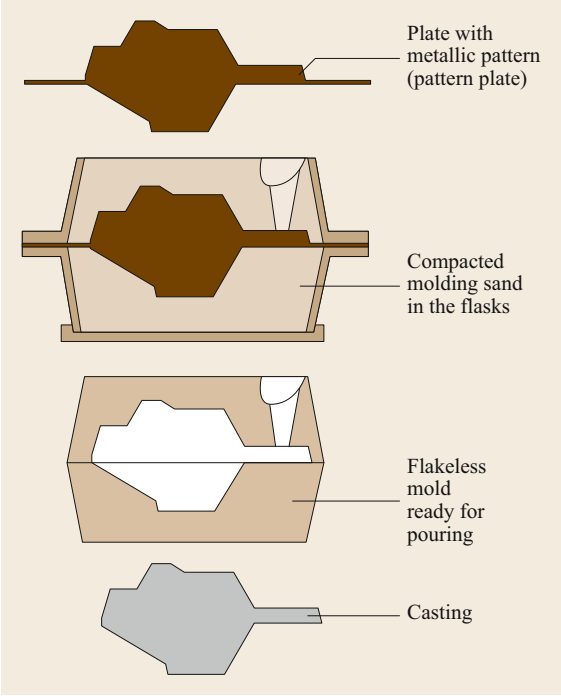

Fig. 10.7 Machine molding [10.1, 6]

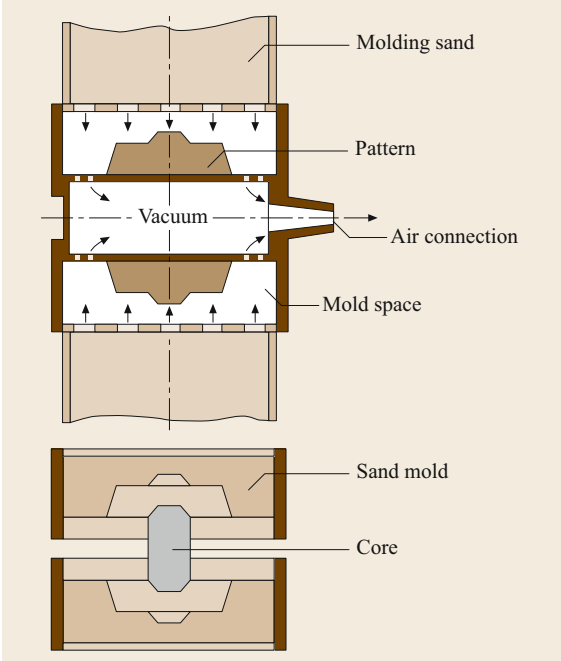

Fig. 10.8 Suction molding [10.1, 6]

incorporated into the production line. The main stages are: Molding station, core insertion section, casting section and cooling section. The emptying station releases the cast molds. The molding station may consist of one automatic molding machine for complete molds or of two or more for making separate top and bottom boxes. There are also boxless molding units, where the molds are made using only a frame, which is withdrawn after compacting the sand.

Casting Materials. All metals and alloys that are castable with the current technology.

Weight of Castings. Limited by the size of the molding machines: up to ≈500 kg.

Number of Castings. Owing to the mechanical preparation, mechanical molding is suitable for series and mass production of quantities of 1000 and multiples thereof.

Tolerances. From about 1.5 to 3%.

Suction Molding. The mold is expendable (used once only), made from wet artificial casting sand (Fig. 10.8).

Pattern. Wood, plastic, metal.

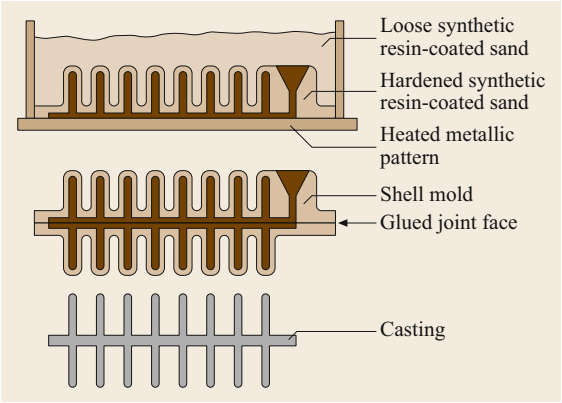

Fig. 10.9 Shell molding [10.1, 6]

Process Characteristics. The process is characterized by the formation of a vacuum by withdrawing air from the mold space and the incoming molding sand. This accelerates the sand, which spreads over the wall of the pattern. The sand can be subsequently pressed against the pattern. Advantages of the process are optimum mold, compaction around the pattern, no shadow effect with plane surfaces, decreasing hardness of compacted sand from the inside to the outside, high surface quality, dimensionally stable castings, reduced cleaning. This process should not be confused with vacuum molding.

Casting Materials. Iron, steel, aluminum.

Weights of Castings. From about 0.1 to 120 kg.

Number of Castings. Small, medium, and large production runs.

Tolerances. Conventional to DIN 1683; maximum offset of compacted sand 0.3 mm.

Shell Molding. The mold is expendable (used only once). Resin-coated sands or sand/resin mixtures (Fig. 10.9).

Pattern. Patterns for repeated use, heatable metal patterns, and metal core boxes.

Process Characteristics. These molds are shell molds with walls only a few mm thick. The mold material is poured onto the heated metal pattern. This cures the synthetic resins in the mold material, solidifying the mold. The result is a self-supporting, stable shell mold. Shell molds are often molded in one piece and then di-

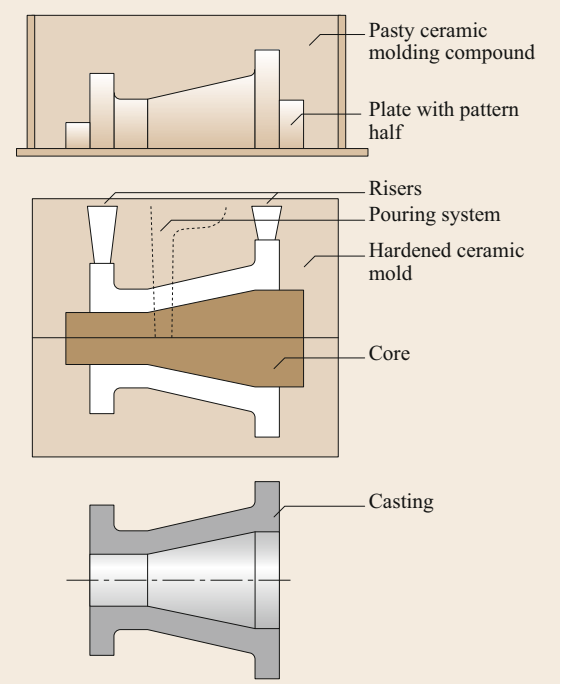

Fig. 10.10 Ceramic molding [10.1, 6]

vided. After putting in the cores, the two halves of the mold are glued together. The shell molding process is used in various stages of mechanization and automation. This process is used not only for making molds for shell casting, but also for producing hollow shell cores for sand and chill casting. These cores are produced on special core molding machines. Shell casting offers high dimensional accuracy with excellent surface quality.

Casting Materials. All metals and alloys that are castable with the current technology.

Weight of Castings. Up to 150 kg.

Number of Castings. Medium to large production runs.

Tolerances. From about 1 to 2%.

Ceramic Molding. The mold is expendable (used only once). This mold is made of highly refractory ceramic similar in kind to mold materials for investment casting (Fig. 10.10).

Pattern. Reusable, made of metal, plastic, or specially varnished wood.

Process Characteristics. A slip consisting of highly refractory substances is poured around the pattern; these substances then harden by chemical reaction. Often only one layer is poured, which is then back-filled with *normal* molding sand. After removing the pattern, the ceramic is fired or skin-dried (Shaw process). To keep ceramic molding, which is relatively expensive, to a minimum, it is usually only the parts of the mold that are made from special ceramic that will be cast in finished or near-finished shape. Castings from ceramic molds have no casting skin in the conventional sense and are among the precision casting processes that, as the technology develops, are becoming more and more widely used owing to their efficiency.

Casting Materials. All metals and alloys that are castable with the current technology, especially iron-based materials.

Weight of Castings. From about 0.1 to 25 kg, depending on the production equipment.

Number of Castings. Single items, small and medium runs, also larger runs in the case of fluid flow machines.

Tolerances. Up to about 100 mm ± 0.2%, over 100 mm ± 0.3–0.8% of nominal dimensions.

Vacuum Molding (V-Process). The mold is expendable (used only once). A plastic foil is vacuum-molded to the contours of the pattern, back-filled with fine-grained, binder-free quartz sand and sealed with a covering foil. Dimensional stability is preserved by means of a vacuum of 0.3–0.6 bar.

Pattern. Permanent patterns, not subject to significant wear. Patterns are made of wood or metal. Core boxes according to the core manufacturing method.

Process Characteristics. (Fig. 10.11). The process is characterized by the use of a vacuum for both deep drawing the pattern sheet over a pattern with nozzle holes and maintaining the stability of the mold. A molding box equipped with suction systems is connected by a pipe to the vacuum grid. The fine, binder-free sand with which the mold box is filled is compacted by vibration. After applying a cover sheet, the air is evacuated from the sand and the mold thus becomes rigid. The mold is constantly connected to the vacuum grid before, during, and after casting. To empty the mold, the vacuum is switched off and the sand and cast parts drop out of the mold box without additional force. The advantages of the process are: high, reproducible di-

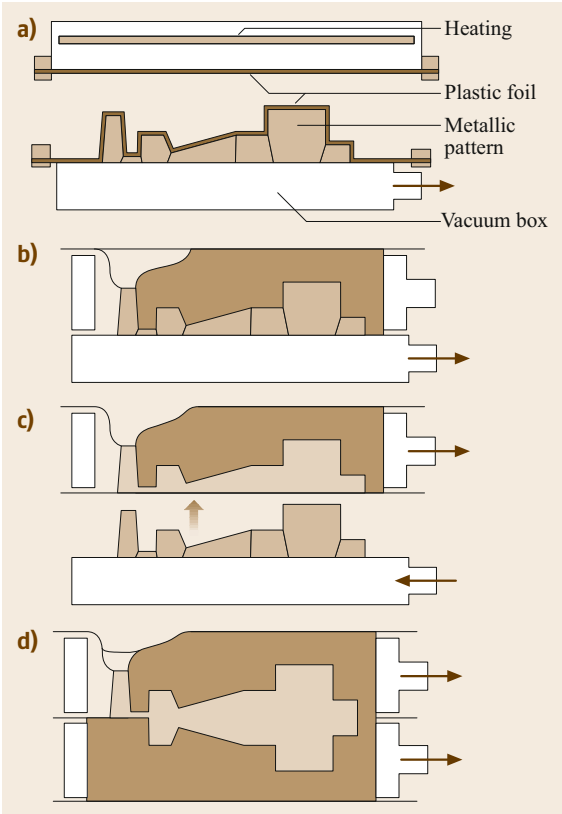

Fig. 10.11a–d Vacuum molding: **(a)** The plastic foil is softened by means of a foil-type heating element and drawn tightly against the pattern by vacuum through holes. **(b)** The mold box is placed on top, filled with binderless sand, precompacted, and the top of the box is covered with plastic foil. **(c)** Vacuum is applied to the mold box, compacting the sand. By switching off the vacuum, the mold box can easily be lifted off the pattern. **(d)** The top and bottom halves of the box are joined. The vacuum is maintained during pouring [10.1, 6]

mensional accuracy with outstanding surface quality; the mold seam at the joins and core marks is very small; tapers can be entirely dispensed with in certain areas of the casting.

Casting Materials. All metals and alloys that are castable with the current technology.

Weight of Castings. Restricted by the equipment available, not by the process.

Tolerances. 0.3–0.6%.

Casting Under Vacuum. The mold is expendable (used once only), shell molds (for investment casting) and precision casting molds made of special mold materials.

Pattern. Wax for investment casting, also of metal, plastic or the like, depending on the type of mold.

Process Characteristics. Titanium and zirconium are among the reactive metals that have high affinities with oxygen, nitrogen, and hydrogen in the molten state. This is even the case when present as alloying constituents in appropriate percentages in, e.g., molten nickel. All these alloys must therefore be produced and cast under defined conditions, normally under high vacuum.

The new mold ceramics, e.g., those made of yttrium and zirconium oxides, resist attack by reactive metals and melts. However, these special ceramics are not (yet) required for nickel-base alloys that are only alloyed with titanium, aluminum, etc.

To optimize quality and structure, the castings are usually isostatically pressed at high temperature by means of the hot isostatic pressing (HIP) process.

Casting Materials. Alloys based on (in order of importance) nickel, titanium, cobalt, iron, and zirconium.

Weight of Castings. Approximately 0.01–100 kg and more, depending on the manufacturing equipment.

Number of Castings. Small series to fairly large production runs.

Tolerances. From 0.3 to ±0.8% of nominal size, depending on the molding process.

Investment Casting (Lost Wax Process). The mold is expendable (used once only), made of highly refractory ceramic, single or group pattern with runners, combined to form casting units (*clusters* or *trees*) (Fig. 10.12)

Pattern. Made by injection molding from special waxes or the like, thermoplastics or mixtures thereof.

Process Characteristics. The distinguishing features are the expendable patterns, the one-piece molds and the casting in hot molds (900 °C for steel). A casting skin in the conventional sense does not form. The patterns are inject ion-molded in single or multiple tools made of aluminum, steel or soft metal, for which an original pattern is required. The most suitable injection molding tool in each particular case is chosen according to the planned total quantity, the form of the casting, and the nature of the pattern material. The formation of certain undercut contours may require the use of water-

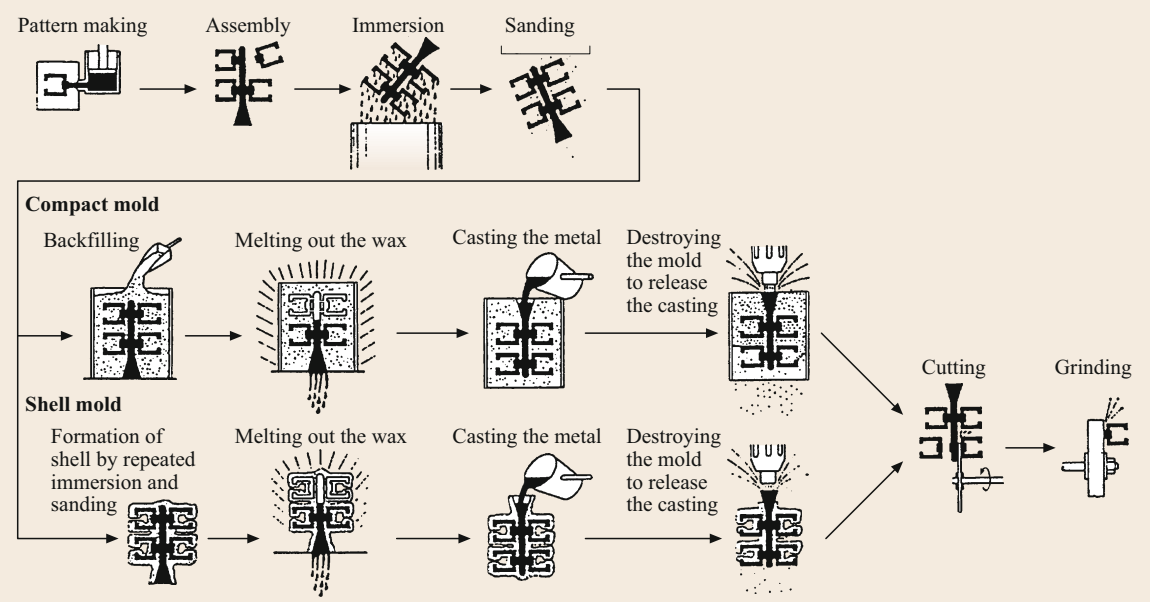

Fig. 10.12 Schematic of manufacturing stages in investment casting [10.1, 6]

soluble or ceramic cores, for which a supplementary tool is used. The patterns are assembled into clusters by means of casting systems, usually again employing injection molding. The method of this assembly is crucial for the quality of the castings and for efficiency. Viscous ceramic coatings which cure by chemical reaction are then applied to these clusters. For aluminum, special plasters are also used. After melting out (lost wax process) or dissolving away the pattern material, the resulting one-piece molds are fired. Casting takes place in molds that are usually still hot from firing, so that narrow cross-sections and fine profiles *turn out* cleanly. Precision casting, with its tight tolerances and high surface quality, is the casting technology that offers the greatest freedom of design coupled with high quality.

Casting Materials (in Order of Importance). Steels and alloys based on iron, aluminum, nickel, cobalt, titanium, copper, magnesium, or zirconium, including aerospace, materials, produced at atmospheric pressure or under vacuum.

Weight of Castings. 0.001 to 0.001–50 kg, also up to 150 kg and over depending on manufacturing equipment.

Number of Castings. Small series to large production runs, depending on the complexity and/or machinability of the workpiece concerned.

Tolerances. From ±0.4 to ±0.7% of nominal dimensions.

Full Mold Casting (Evaporative Pattern Casting, Lost Foam Casting). The mold is lost (used only once), mold material is usually self-curing.

Pattern. Expendable, foam material.

Process Characteristics. (Fig. 10.13). One-piece pattern made of foam material (polystyrene). Shape and dimensions match the part to be cast (taking into account allowance for contraction). The pattern need not be removed from the mold after mold-making. The heat of the molten metal flowing into the full mold vaporizes the pattern, which is continuously replaced by cast metal. Mold joints and cores are usually unnecessary. Bolts, sleeves, lubrication lines, etc. can be integrally cast in. The absence of mold tapers reduces the weight of the casting. The time and cost of manufacture are only a fraction of those encountered with a wooden pattern.

Casting Materials. All metals and alloys that are castable with the current technology, especially those with high casting temperatures.

Weight of Castings. From ≈50 kg up to maximum transportable weight; especially suitable for large components.

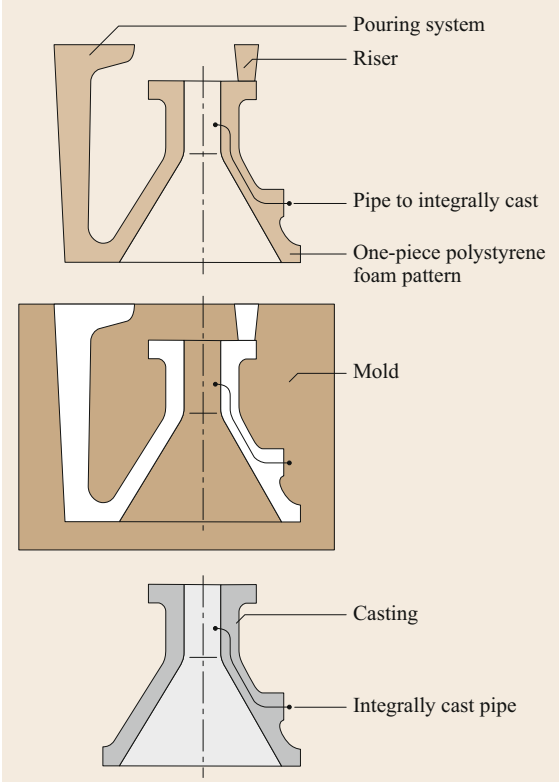

Fig. 10.13 Full mold casting [10.1, 6]

Number of Castings. Single pieces, small production turns.

Tolerances. From about 3 to 5%.

Magnet Molding. The mold is expendable (used once only), iron granules.

Pattern. Expendable, foam material.

Process Characteristics. Magnetic molding is a type of full mold casting. The casting units, prefabricated from foam material (patterns with pouring gates and runner), are coated with a refractory ceramic (similar to shell molds for precision casting). They are then back-filled with pourable iron granules in a mold box. By applying (or switching on) a DC magnetic field, the iron powder becomes rigid and thus supports the casting unit. After casting and solidification of the die metal, the magnetic field is switched off, causing the iron granules to become pourable again. Then the casting is removed. The iron granules can be reused.

Casting Materials. All metals and alloys that are castable with the current technology. As the thermal conductivity of the magnetizable mold material is higher than that of quartz sand, the cooling rate of the castings is higher and leads to a finer metallographic structure. The properties in use are especially improved in the case of steel castings.

Number of Castings. Single items, small production runs.

Tolerances. From about less than 3 to 5%.

Use of Permanent Molds

Permanent Mold Casting (Gravity Die Casting). The mold is a permanent mold from cast iron or steel, cores made of steel.

Pattern. None required.

Process Characteristics. (Fig. 10.14). Casting takes place by gravity in permanent metal molds. These molds are made in two or more parts for removal of the finished casting. The higher thermal conductivity of the metal mold compared with molding sand brings about faster cooling of the solidifying molten metal. The result is a relatively fine-grained, dense structure with better mechanical properties than parts made by sand casting. High dimensional accuracy, excellent surface quality, and good reproduction of contours characterize chill casting. This process fully meets the specifications for gas- and liquid-tight valves, owing to the production of a dense structure. A rapid, efficient casting sequence, with machining generally being unnecessary

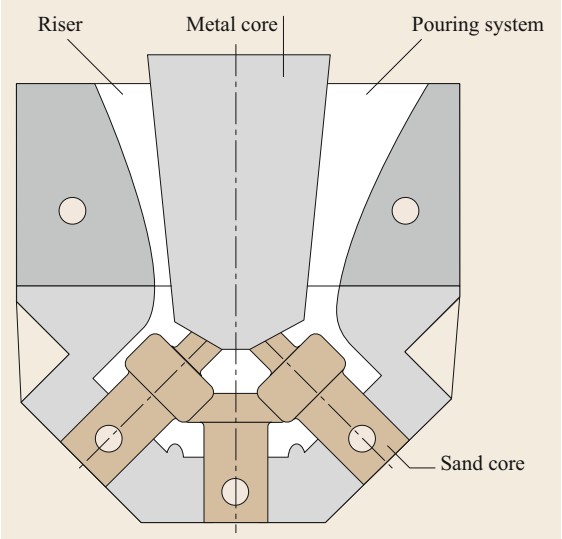

Fig. 10.14 Permanent mold casting (composite mold with metallic and sand cores, the latter for undercuts) [10.1, 6]

or requiring only small machining allowances, are further features of this process.

Casting Material. Copper-zinc alloys, copper-aluminum alloys, aluminum alloys, magnesium alloys, high-grade zinc alloys, also copper, copper-chromium alloys, super-eutectic aluminum-silicon alloys, lamellar and nodular graphite cast iron.

Weight of Castings. Nonferrous metals and cast iron up to ≈100 kg, more depending on equipment. Cast iron for certain purposes up to ≈20 t (=20 000 kg).

Number of Castings. From about 1000 and multiples thereof, depending on the material being cast (e.g., Al ≈ 100 000 castings).

Tolerances. From about 0.3 to 0.6%.

Low-Pressure Permanent Mold Casting. The mold is a permanent mold from cast iron or steel.

Pattern. No pattern required.

Process Characteristics. (Fig. 10.15). Casting is carried out under pressure (usually with compressed air) in permanent metal molds. These molds are made in two or more parts for removal of the finished casting. The higher thermal conductivity of the metal mold compared with molding sand brings about faster cooling of the solidifying molten metal. The result is a relatively fine-grained, dense structure with better mechanical properties than parts made by sand casting. The distinguishing feature is the application of pressure, which dispenses with the need for risers on the casting. High dimensional accuracy, excellent surface quality, and good contour reproduction together with a rapid, efficient casting sequence and considerable machining economies are further features of this process. Gas-tight and liquid-tight valves can be efficiently manufactured owing to the dense structure of the casting.

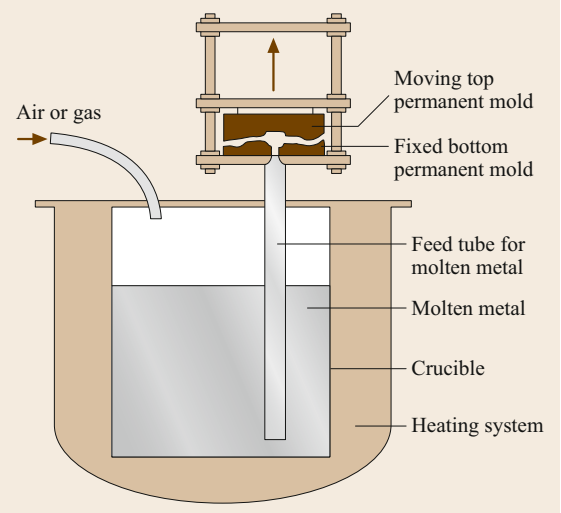

Fig. 10.15 Low-pressure permanent mold casting [10.1, 6]

Casting Materials. Light metal, especially aluminum alloys.

Weight of Castings. Up to 70 kg.

Number of Castings. From about 1000 and multiples thereof.

Tolerances. From about 0.3 to 0.6%.

High-Pressure Die Casting (Die Casting). The mold is a permanent mold, usually from high-tensile hot forming tool steel or special metals.

Pattern. No pattern required.

Process Characteristics. (Fig. 10.16). The distinguishing feature of this process is that the molten metal is forced into the two-part permanent mold at high pressure and relatively high speed in pressure die casting machines. Two types of process are distinguished, namely:

- The hot-chamber process. Here the die casting machine and the holding furnace for the molten metal form a unit. The casting assembly is immersed in the molten metal. In each casting operation, a precisely predetermined volume of molten metal is forced into the mold. The hot-chamber die casting process is especially suitable for lead, magnesium, zinc, and tin. The output of components manufactured by this process is considerable, but varies according to the size of the component and the casting material.
- The cold-chamber process. In this process the die casting machine and the holding furnace for the molten metal are separate. After being taken from the furnace, the molten metal is poured into the cold pressure chamber and forced into the mold. The pressure chamber is mounted directly on the runner-side mold block. This process is chiefly suitable for aluminum-based and copper-based alloys, as these would attack the steel casting assembly when molten if the hot-chamber process were employed. Cold-chamber die casting machines do not achieve the rates of output of hot-chamber ma-

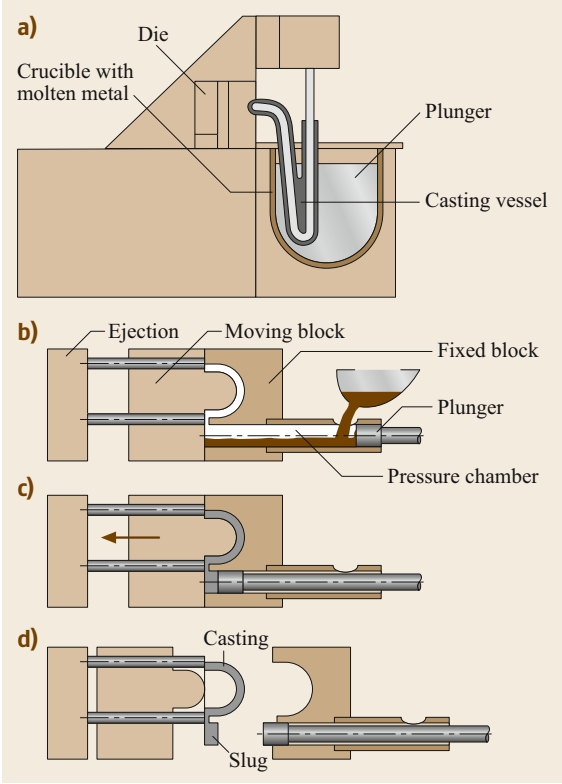

Fig. 10.16a–d High pressure die casting: **(a)** hot chamber process, **(b–d)** cold-chamber process, **(b)** filling of casting chamber, **(c)** plunger for molten metal into die, **(d)** ejection of casting [10.1, 6]

chines, owing to the nature of the process. Pressure die casting is today one of the most efficient casting processes around. The machines are mostly semi-automatic or fully automatic. Pressure die-cast parts have smooth, clean surfaces and edges. They are extremely dimensionally accurate. Therefore, only the fitting and bearing surfaces, at most, require machining. Very low machining allowances result in short machining times.

Special cases of high pressure die casting are squeeze-casting and thixocasting.

Squeeze-Casting and Thixocasting. In the direct squeeze casting, the die is filled with a defined amount of liquid metal via a trough. The die, which has two or more parts, is closed above by hydraulic pressure, forcing the metal to conform to the die surfaces. The pressure is maintained during solidification. Unlike direct squeeze-casting, the indirect version has proved itself in production and has obtained a foothold in foundries producing castings for special applications. The principle of operation differs from the direct process in that the melt is not poured directly into the die, but into a casting chamber situated below it. The bottom of the chamber is sealed by a piston whose actuating cylinder is fixed to a pivot. After filling, the chamber is swung into position under the die and the piston is raised to fill the die.

Thixocasting takes advantage of the thixotropic properties of metal alloys in the partly solidified state (semisolid state). Thixotropic behavior means that the material behaves as a solid when at rest but flows like a liquid when rapidly deformed, its viscosity falling as the stress increases. To bring this about, the alloy has to be heated to a point in its freezing range between solidus and liquidus temperatures. This point is chosen so that, for example, 40% of the volume is liquid, with the rest remaining solid. Aluminum alloys having a long freezing range are suitable for thixocasting. To attain a good thixotropic state, the crystals in the solid solution must be equiaxed in order to ensure the liquid and solid phases flow uniformly and do not separate. Such a structure can be created by so-called *rheocasting*, whereby the melt is mechanically or electromagnetically stirred during solidification at continuous casting. This breaks off or melts off the dendrite arms, which condense to globular shapes when held just above the solidus temperature, resulting in indigenous growth of free-floating crystals with the desired equiaxed structure.

Current practice in thixocasting is as follows: The rheocasted bar is first cut off in pieces having sufficient weight for the part to be casted. The pieces are then preheated to a predetermined temperature in their melting range. This is done automatically using temperature sensors to attain a definite proportion of liquid metal, often between 35 and 50%. It is placed in the casting chamber of the casting machine and is injected into the mold cavity by the casting piston.

Casting Materials. Materials suitable for pressure die casting are copper-zinc alloys, copper-aluminum alloys, aluminum alloys, magnesium alloys, lead alloys, tin alloys, high-grade zinc alloys. For the hot-chamber process: Lead, magnesium, zinc, and tin alloys. For the cold-chamber process: Particularly for aluminum- and copper-based materials.

Weight of Castings. Up to 45 kg for light alloys, up to 20 kg for other materials, depending on the material being cast and the working dimensions of the die casting machines.

Number of Castings. Varies widely depending on the material being cast (e.g., Zn alloys $\approx$ 500 000 castings).

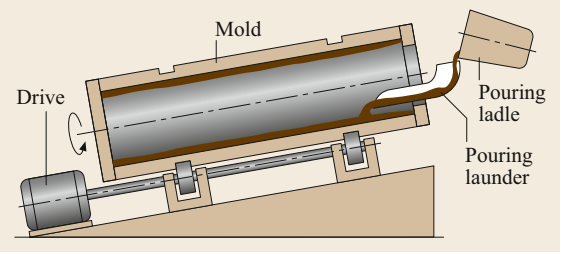

Fig. 10.17 Centrifugal casting (after [10.1, 6])

Tolerances. From about 0.1 to 0.4%.

Centrifugal Casting. The mold is a permanent, water-cooled cast iron or steel mold.

Pattern. None required.

Process Characteristics. (Fig. 10.17). The centrifugal casting process is used to manufacture hollow products having a rotationally symmetrical hollow space and an axis coinciding with the axis of rotation of the centrifugal casting machine. The external form of the casting is determined by the shape of the mold. The internal form is determined by the effect of the centrifugal force of the rotating mold. The wall thickness of the casting depends on the quantity of molten metal supplied. A variant of the process is centrifugal mold casting, which produces finished hollow or even massive castings using rotating molds. Composite centrifugal casting is also possible, as is centrifugal casting with a flange. The condition on delivery of centrifugal cast Fe, Ni and Co-based alloys is normally (at least) preturned.

Casting Materials. Especially cast iron, cast steel, heavy and light metals.

Weight of Castings. Up to about 5000 kg.

Number of Castings. From about 5000 to over 100 000, depending on the mold material and the casting material. In special cases, e.g., castings of stainless steel and the like, also for single pieces and small production runs (from ≈104 mm internal diameter upwards).

Tolerances. About 1%.

Composite Casting (Compound Casting)

The mold is a lost or permanent mold. Metal mold. e.g., for centrifugal composite casting.

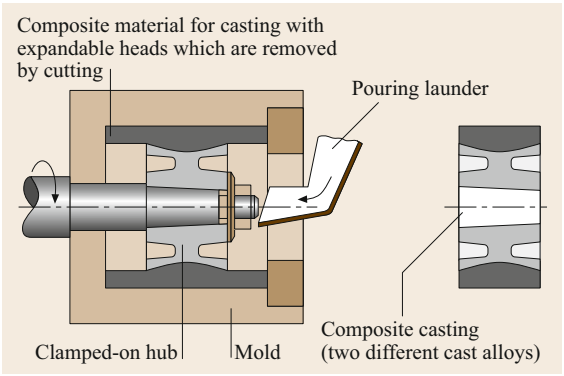

Fig. 10.18 Composite casting [10.1, 6]

Pattern. None.

Process Characteristics. (Fig. 10.18). These types of process are used to cast structural parts from two or more different metallic materials that are firmly joined together. At least one material is poured in the molten state into a mold, which may also be part of a product to be manufactured. For composite casting of various metals and/or alloys in a molten or semisolid condition, e.g., in centrifugal casting and for casting in, casting round and lining solid components, which may be made not only of metal but also of ceramic. The bonding may be formed by shrinkage, diffusion, or both.

Casting Materials. All metals and alloys that are castable with the current technology.

Weight of Castings. Up to about 50 kg and over, depending on the manufacturing equipment.

Number of Castings. Medium and large production runs.

Tolerances. From about 0.1 to 0.6%, depending on the process.

Additive Manufacturing Processes

The basics of these additive manufacturing processes are powders of the materials and a selective acting heat source. The process is a layer manufacturing process that generating complex 3-D parts by consolidating successive layers of powder material in selected areas using a heat source. Each layer is scanned according to its corresponding cross section as calculated from a CAD/CAM model. In the foundry industry selective laser melting, selective laser sintering, selected hardening of polymer and selected clogging of polymer are being used.

Selected Laser Melting. The new innovative selective laser melting technique (SLM-process) is a primary shaping technology. The SLM (selective laser melting) fabrication process is described: A focused laser beam driven by a CAD/CAM-model transmits the contour information of a desired part slice-by-slice into a bed of metallic powder, which locally melts and consolidates. This allows the fabrication of complex-shaped parts with predefined 3-D architecture and near full dense and mechanical properties comparable to those of bulk materials. SLM is reserved for metallic materials. Up until now it has manufactured parts from aluminum-, chromium-, copper-, nickel-, titanium- and precious metal alloys.

Selected Laser Sintering. This sintering method is used for manufacturing of complex inserts from metallic or ceramic powders e.g., helical cooling coil for in dies of high pressure die casting process.

Selected Hardening of Polymers. This method is used for manufacturing of sand molds or sand cores from quartz sand or olivin sand powders with furan or phenolic resin binders. The binder is spread on the molding or core sand corresponding to the CAD/CAM-model. These areas are cold hardened.

Selected Clogging of Polymer. The cores for investment casting process are PMMAs (poly(methyl methacrylate)) are made from PMMA-granulat with an adhesive material (Polypor).

These four techniques were used to successfully manufacture metal parts in the field of rapid prototyping.

10.5 Guidelines for Design

Forming by casting enables design ideas to be turned into reality to a particularly high degree, owing to the extensive freedom of design that it offers. A design appropriate for manufacturing, which contributes decisively to the efficient production of a casting, can generally be achieved only by close collaboration between the design engineer and the founder. Forming by casting differs from other forming processes in that the material only receives its shape, material structure, and quality after cooling; with shrinkage—which may sometimes be considerable—in the liquid state and during solidification, and appreciable contraction in the solid state (Fig. 10.19, Table 10.14). The contraction in the solid state should be accounted for by means of a suitable allowance (allowance for contraction). The alloying specifications often suffer considerable deviations, owing to obstruction of contraction by ribs, projections, more or less flexible cores, and mold parts (Table 10.15). Provided that they fall within the acceptable dimensional variations or are compensated for by machining allowances, as is usually the case with small castings, they do not present a problem. With large castings, though, empirical values for the deviations due to contraction have to be taken into account when making the pattern. If there is a one-sided obstruction of contraction, e.g., due to the mold or even the shape, especially in the case of longer castings (different cross-sections along their length and consequently

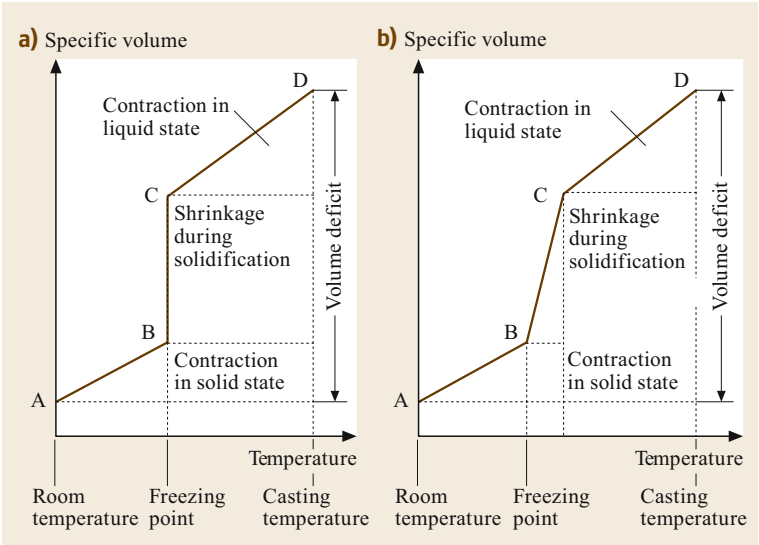

Fig. 10.19a,b Schematic of contraction of metallic materials during cooling from the molten state: **(a)** for pure metals and eutectic alloys, **(b)** for noneutectic alloys [10.7]

Zinc casting alloys	1.3	1.1–1.5
Babbitt (Pb, Sn)	0.5	0.4–0.6

different cooling rates and thermal stresses), the castings would distort unless the pattern is curved in the opposite direction. Large wheel centers, for instance, are not infrequently split, e.g., to prevent unacceptable out-of-roundness. Thermal stresses that are not reduced by plastic deformation may, besides distortion, also result in undesirable *relief by cracking*. Therefore, if insufficient attention is paid to contraction of the material being cast at the design stage, taking into account the possibilities afforded by gating of molds and risering, pipes (shrinkage cavities), shrinkage voids, sinks, hot (pipe) cracks, distortion, and stress cracks may form.

10.5.1 Manufacture-Orientated Design

The correct design of changes in wall thickness with a view to shrinkage during solidification and contraction in the solid state is outlined below:

- Wall thickness graduations should permit directional solidification.

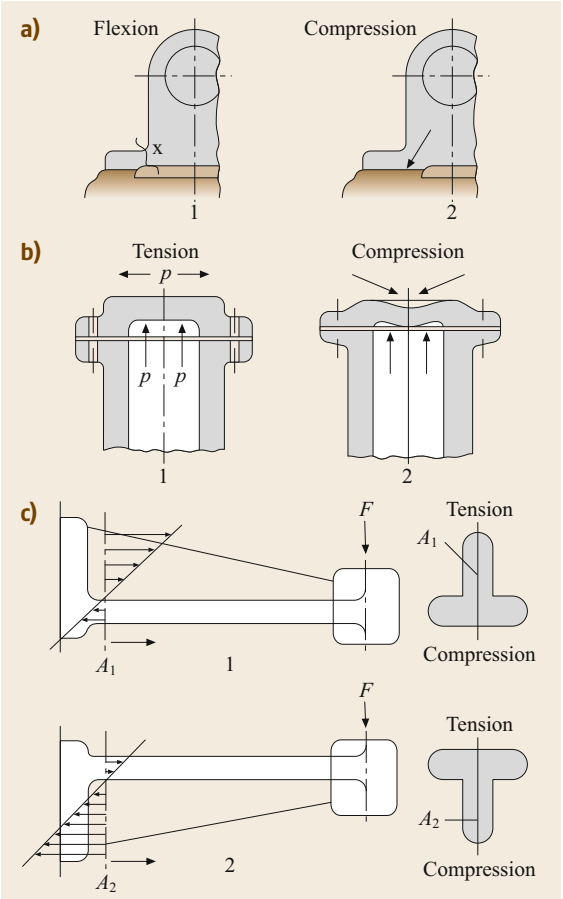

Fig. 10.20a–c Examples for stress-orientated casting design for a material having more compression stress strength than tensile strength according to [10.7]: **(a)** Pedestal (1 flexurally stressed—inadequate bearing surface, 2 compressively stressed—bearing surface widened); **(b)** cylinder cover (1 tensionally stressed—poor design, 2 compressively stressed—bearing surface—good design); **(c)** wall bracket arm (1 poor cross-sectional arrangement, 2 stress-absorbing cross-sectional arrangement) [10.8]

- Junctions formed by the meeting of two or more walls. They should be separated as far as possible, or designed for efficient casting by narrowing the cross-section. Concentrations of material, especially at locations that are inaccessible to feeding, lead to piping.
- Sudden changes in wall thickness should be avoided, as they produce high thermal stresses due to different cooling rates. In addition, there is often increased obstruction of contraction by the mold. The risk of formation of hot cracks (*pipe cracks* between liquidus and solidus temperatures) and stress cracks (during further cooling in the solid state) is

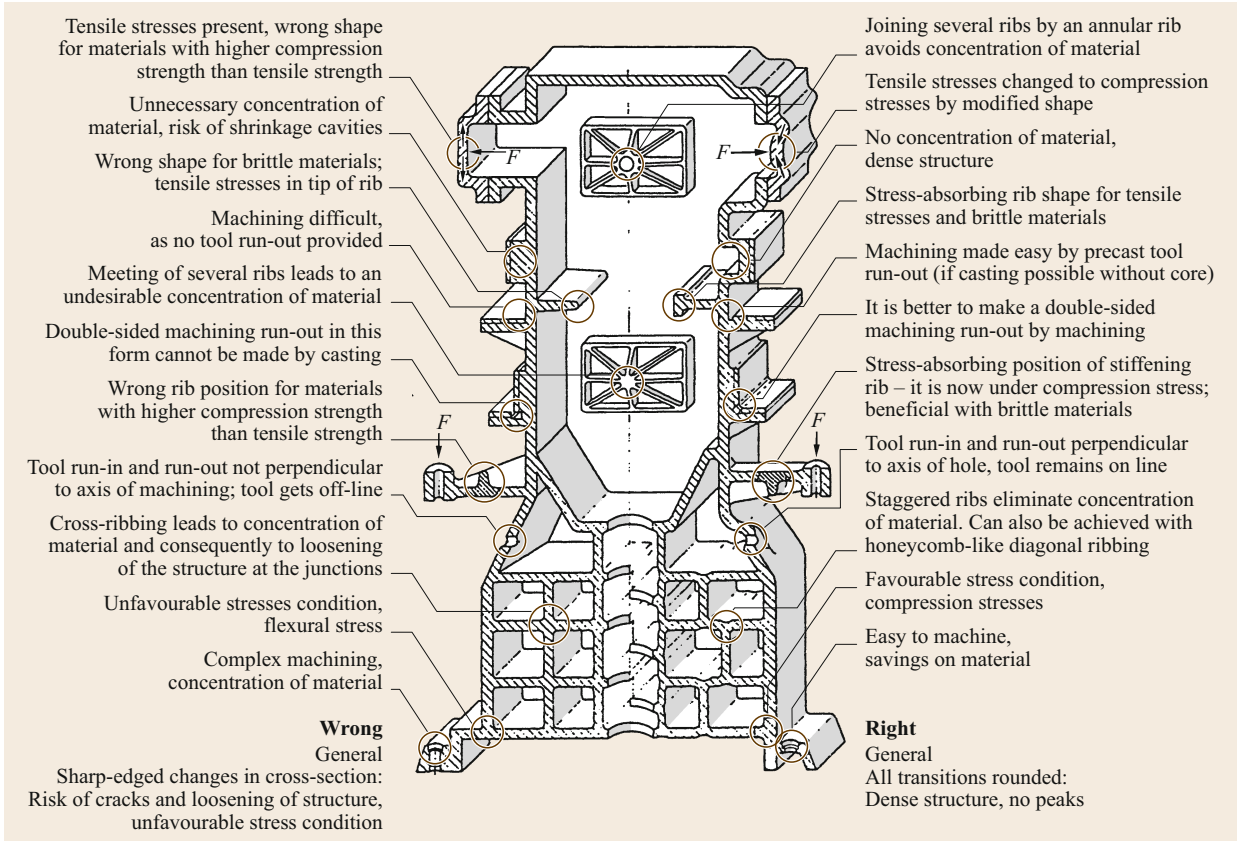

Fig. 10.21 Illustration of important design guidelines [10.9]

therefore high. Locations prone to cracking can be protected by ribs.

- Sharp corners additionally cause a heat build-up (hot sand effect) and, accordingly, not only hot cracks but also porosity due to contraction as well as drawholes.

For a summary of design recommendations see Fig. 10.21.

10.5.2 Stress-Orientated Design

When designing castings, the main stresses occurring during manufacture have to be taken as a basis. Here, the freedom of design offers excellent adaptation to the technical requirements. Forming by casting permits the efficient manufacture of parts of the most complicated kind with high strength in relation to shape. The stress condition of the design can often be made more favorable by suitable ribbing or slight modification (Figs. 10.20 and 10.21).

It is important to know the load-bearing capacity of the materials to be cast. For approximate values for lamellar graphite cast iron see Fig. 10.22.

Examples

A casting made from EN-GJL-150 gray cast iron (top horizontal gray bar) with a wall thickness of 10 mm or a test bar diameter of 20 mm (vertical line) has a tensile strength of $\approx 220\,N/mm^2$, a hardness of ≈ 220 HB, and a modulus of elasticity of $10\,000\,dN/mm^2$. For a wall thickness of 45 mm, on the other hand, the tensile strength is $\approx 100\,N/mm^2$, the hardness is ≈ 130 HB, and the modulus of elasticity almost $8000\,dN/mm^2$.

If however, the tensile strength of this 45 mm thick wall is $220\,N/mm^2$, a hardness ≈ 180 HB and an modulus of elasticity of $\approx 11\,500\,dN/mm^2$ should be expected. The material grade EN-GJL-30 should be selected. For a wall thickness of 10 mm, this cast iron has a tensile strength of $\approx 350\,N/mm^2$, a hardness of ≈ 260 HB, and a modulus of elasticity of $\approx 13\,000\,dN/mm^2$.

10.5.3 Near-Net-Shape Manufacturing and Integral Castings

The main advantage of shaping by casting is the realization of near-net-shape production of castings, thereby minimizing cutting processing and drastically shortening the process chains due to fewer process stages. The process chain is dominated up to the finished part by chip-arm shaping. The calculations of cumulative energy demands were carried out on the basis of the VDI Guideline 4600 [10.11].

Development in shaping by casting is focused on two directions. First, the components become increasingly closer to the finished parts. Second, many single parts are aggregated to one casting (integral casting, one-piece-casting). Both directions of development are realized in all variants of casting technology.

For evaluation, the manufacturing examples in Figs. 10.23 and 10.24 were considered from melting up to a commensurable part.

Fig. 10.23 shows a technical drawing of a flat part that had previously been produced by cutting starting from a bar, that is now made as a casting (malleable cast iron) using the sand-molding principle. In cutting from a semifinished material, material is utilized at only 25.5%. As a result of shaping by casting, utilization of material was increased to 40%. The effects of shaping by casting become evident in the energy balance (primary energy, cumulative energy demand). For cutting the flat part from a semifinished product, 49 362 GJ/t

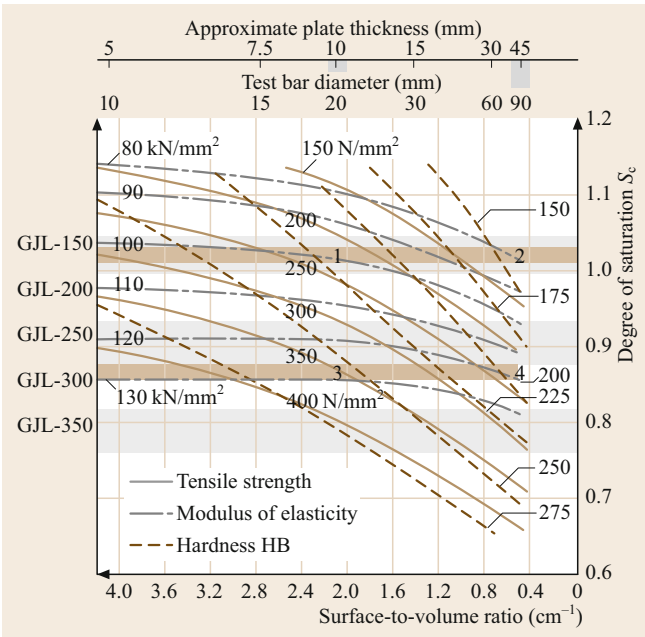

Fig. 10.22 Chart illustrating the mechanical properties of gray cast iron. The relationship between chemical composition, rate of cooling, and mechanical properties (tensile strength, hardness, modulus of elasticity) in the casting (wall thickness) and the separately cast test bar is detailed in[10.10]. Each point on the diagram signifies a specific combination of mechanical properties for a specific material. It also determines the material grade to be selected

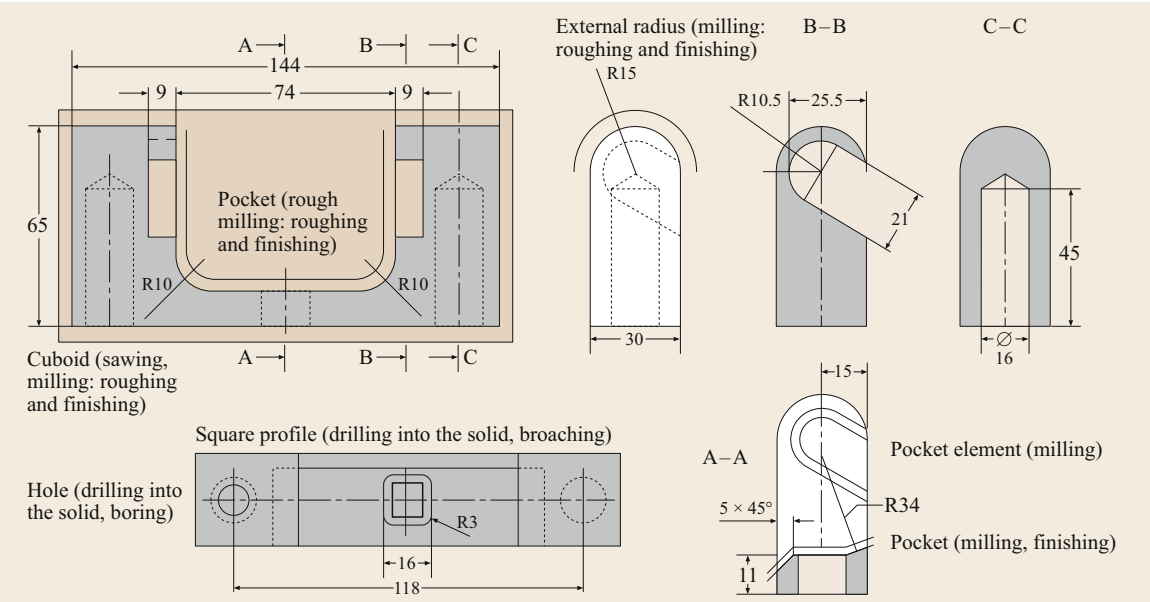

Fig. 10.23 Example: Flat part [10.12]

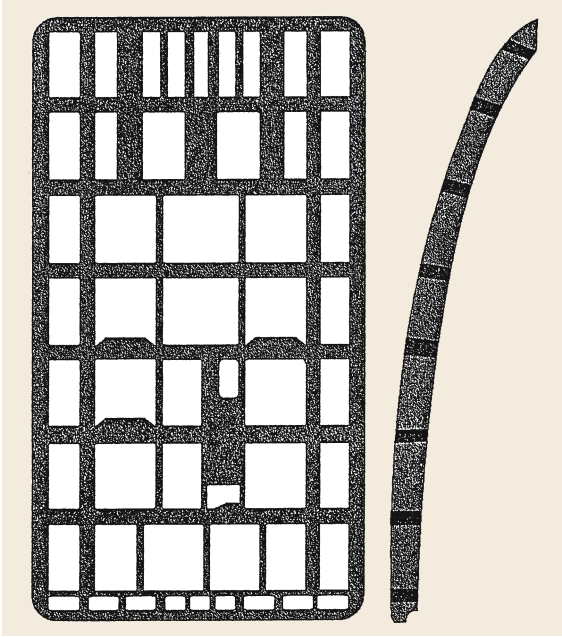

Fig. 10.24 Example: Airbus doorway [10.12]

parts are required. For shaping by casting, 17 462 GJ/t parts are required. Consequently, 64.6% of the energy can be saved. Compared to cutting of semifinished steel material, for part manufacturing about a third as much primary energy is required.

The doorway structure of an Airbus passenger door (height about 2100 mm; width about 1200 mm) is illustrated in Fig. 10.24.

The conventional manufacturing of the doorway structure as practiced until now, apart from the standard parts such as rivets, rings, and pegs, involved 64 milling parts cut from semifinished aluminum materials with very low material utilization. Afterwards, those parts were joined by about 500 rivets.

As an alternative technological variant, it is proposed that the doorway structure be made of three cast segments. Assuming almost the same mass, in production from semifinished materials, the ratio of chips amounted to about 63 kg, whereas in casting, this can be reduced to about 0.7 kg. Thus, in casting, the chip ratio amounts to only 1% in comparison to the present manufacturing strategy. In the method starting from the semifinished material, about 175 kg of material have to be molten; however, in shaping by casting, this value is about 78 kg—that is 44.6%. As a result of the energy balance (primary energy, cumulative energy demand), about 34 483 MJ are required for manufacturing the doorway from the semifinished material. However, in shaping by casting, 15 002 MJ are needed—that is about 46%. The result of having drastically diminished the cutting volume due to near-net shaping can be clearly proven in the energy balance: in the variant starting from the semifinished material, 173 MJ were consumed for cutting, while in casting it was less than 2 MJ.

In contrast to the studies mentioned before, today, the Airbus door constructions that have been cast as one part only are used. 64 parts are aggregated to one casting (integral casting).

10.6 Preparatory and Finishing Operations

10.6.1 Melting of Materials for Casting

For transforming the metal to be cast and the additives into the molten state, a wide variety of melting equipment—e.g., shaft (cupola), crucible, and hearth-type furnaces—is available. These furnaces are heated with coke, gas, oil, or electricity. The most important types of melting equipment are: for cast iron, including malleable cast iron: cupola (shaft) furnaces, induction furnaces, rotary kilns (oil-fired); cast steel: electric arc furnaces, induction furnaces; nonferrous metal castings: Induction furnaces, electrically, gas-heated or oil-heated crucible furnaces.

10.6.2 Cleaning of Castings

The molds are emptied by means of emptying jiggers. The sand adhering to the casting is generally removed by means of abrasive blasting equipment employing, without exception, steel shot or steel grit made from wire.

10.6.3 Heat Treatment

Many materials only obtain the physical and technological characteristics required in use from heat treatment. This treatment requires the use of electrically heated or gas- or oil-fired furnaces in continuous or batch operation. Their size is matched to the size and quantity of the castings and their mode of operation to the wide variety of heat treatment processes.

10.6.4 Inspection and Testing Methods

The diverse demands made on the casting, which become greater with advances in technology, and the trend

towards lightweight construction and thus more efficient use of materials inevitably lead to stringent requirements with regard to casting quality, with particular emphasis on consistency. Inspections of the process and the castings begin with checking of the metallic and nonmetallic feed stocks and end with the final inspection of the castings. Materials and workpieces are mainly tested by means of nondestructive testing methods [10.1] such as radiographic (EN 12681 [10.13]), ultrasonic (EN 12680, part 1, 2 and 3 [10.14–16]), magnetic powder (EN 1369 [10.17]), and liquid penetrant (EN 1371 part 1 and 2 [10.18, 19]) testing. Destructive tests, e.g., tensile, notched-bar impact and bending, are usually carried out with specimens cast either separately or as an appendage to the casting; in exceptional cases, specimens taken from the casting itself may be used.

In the last 20 years the certification of quality management systems on the basis of ISO 9000 etc. and QS (quality management system) 9000 has risen appreciably in the foundry industry.

After studying industrial/mechanical engineering and graduating with a diploma, Stefan Scharf started working at the Otto-von-Guericke University of Magdeburg, Germany, where he developed hybrid compound-material-solutions for the automotive industry. After obtaining his doctorate in 2014, he worked as a project manager at the Institute of Manufacturing Technology and Quality Management at the University of Magdeburg, focusing his research on the development of sustainable and energy-efficient production solutions. In 2015, he completed a research semester at the LMAS of the University of California, Berkeley, as a visiting scientist. Since September 2018 Stefan Scharf has been working at the Fraunhofer Institute for Factory Operation and Automation IFF, Magdeburg, where he is responsible for business development.

11. Metal Forming

A. Erman Tekkaya

Metal forming processes do not only shape workpieces but also set their properties over the whole volume including the surface. They improve the physical properties such as mechanical, electrical, acoustical, etc. of workpieces and hence increase their capabilities in service. Besides the hardness, ductility, residual stresses also the ductile damage level of the formed components can be controlled during forming. Formed metallic components have low imbedded energy per mass thanks the minimal or even none scrap. Hence, metal forming is among the most environmentally friendly manufacturing processes. This chapter starts with an overview of various processes of metal forming. There are over 250 different forming processes and every year new ones are invented showing the vitality of the technology. The metallurgical fundamentals relevant for metal forming processes are described next covering the mechanisms of plastic deformation, strain hardening and heat treatment. The basic concepts of elementary plasticity including the true stress, true strain, flow stress, flow condition and flow rules are followed by simple analytical methods necessary to understand the process mechanics effectively. The technological processes are covered in two groups: Bulk and sheet forming processes. Upsetting, forging, cold extrusion, rolling and shear forming is discussed in detail as bulk forming representatives. Emphasis is placed on the process description, process windows, stress states in the forming region and force displacement curves. Where necessary, tools are included as well. An introduction to sheet metal forming is given through the analytical models (such as membrane theory) and the material characterization for formability. Bending as a basic sheet forming process is studied in detail. This is followed by stretch- and deep drawing processes including hydroforming. The chapter concludes with a summary of typical forming machines including energy-, force- and displacement-controlled machines.

Metal forming is the manufacturing through plastic (permanent) change of the form of a solid body while preserving both its mass and cohesion. The term "forming" should be used for controlled plastic straining with a predefined target shape, whereas the term "deforming" should be used for unwanted or uncontrolled plas-

K.-H. Grote, H. Hefazi (Eds.), *Springer Handbook of Mechanical Engineering*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-47035-7_11

tic straining. The basic advantages of metal-forming processes as compared with alternative processes such as casting and machining are [11.1, 2]:

- High material utilization and hence high energy conservation
- High productivity with short production times
- High dimensional and shape accuracy within certain tolerances
- Superior mechanical material properties of the product (especially for dynamic loadings).

On the other hand, these processes can suffer from the following disadvantages:

- Due to the high loads required for plastic forming, the tools and machines are expensive, requiring minimum batch sizes for economic production.
- The limited formability of metals restricts the range of product geometries.
- The process usually requires a high level of engineering, including analytical modeling, numerical analysis (process simulation), and also extended experience.

Metal-forming processes can be classified according to various criteria. An academic classification is done according to the dominant stress state existing in the deformation zone. Accordingly, forming processes can be classified into compressive, tensile, tensile–compressive, bending, and shearing processes. A more practical classification is according to the type of product, according to which two classes of processes can be identified: bulk forming and sheet forming processes. In bulk forming processes, the workpieces have spatial geometries (i.e., their geometries are more or less balanced in all spatial directions). During forming, large changes in the cross-sections and thickness of the products occur. The material flows in all directions. Generally, multiaxial compressive stress states exist in the deformation zone. Larger relative forming forces are needed. Bulk forming can be done with workpieces at either room temperature (cold forming) or an elevated temperature (warm or hot forming). Where hot forming is done with workpieces heated above their recrystallization temperature, warm forming is performed with workpieces between the room and recrystallization temperature or slightly above the recrystallization temperature. Examples of typical bulk forming processes are given in the following.

Figure 11.1 shows the primary forming process of flat rolling, in which an initial blank is reduced in thickness by means of two rolls. Usually, the width of the workpiece remains approximately constant. The product is then used as the initial workpiece for other basically sheet forming processes. After rolling, the casting microstructure is also changed to a more homogeneous, defect-free microstructure.

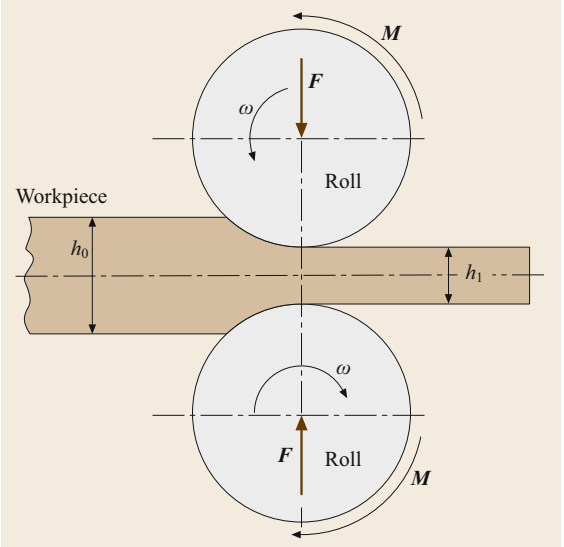

Fig. 11.1 Flat rolling

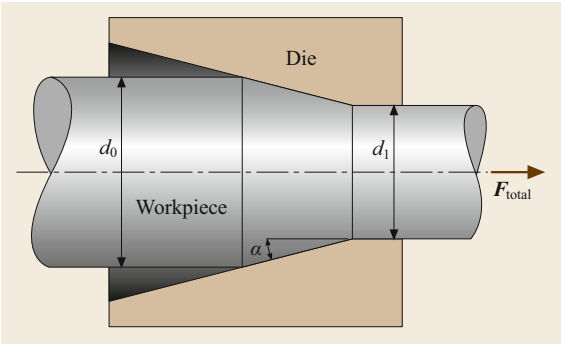

Fig. 11.2 Wire drawing

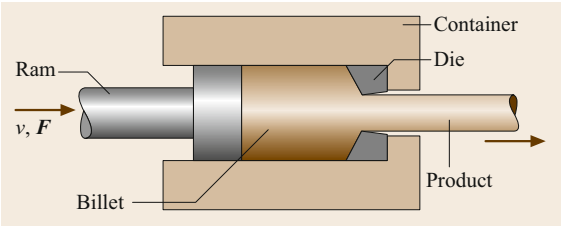

Fig. 11.3 Extrusion

Figure 11.2 shows the basic process of wire drawing, in which an initial rod or wire is forced through a conical die to reduce its diameter. Due to the application of a drawing force, the area reduction is limited to about 20%.

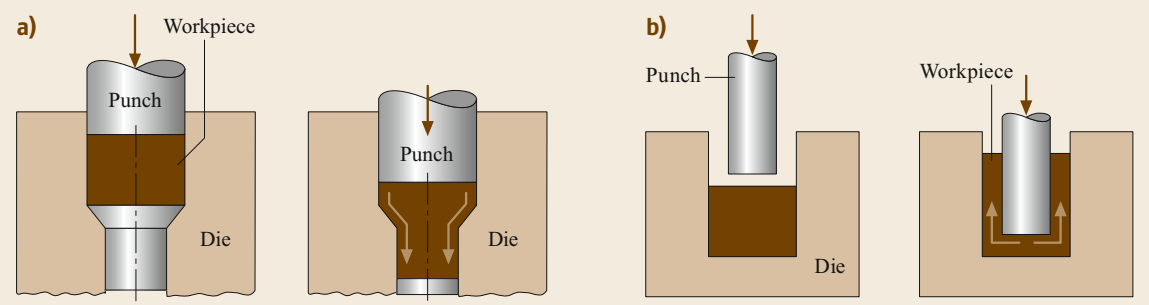

Fig. 11.4a,b Impact extrusion: (a) forward rod extrusion, (b) backward can extrusion

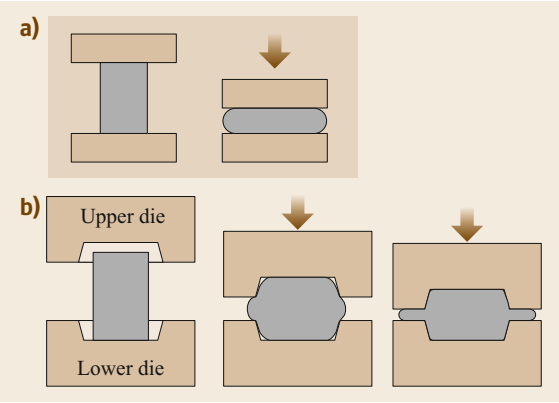

Fig. 11.5a,b Forging: (a) upsetting, (b) impression forging

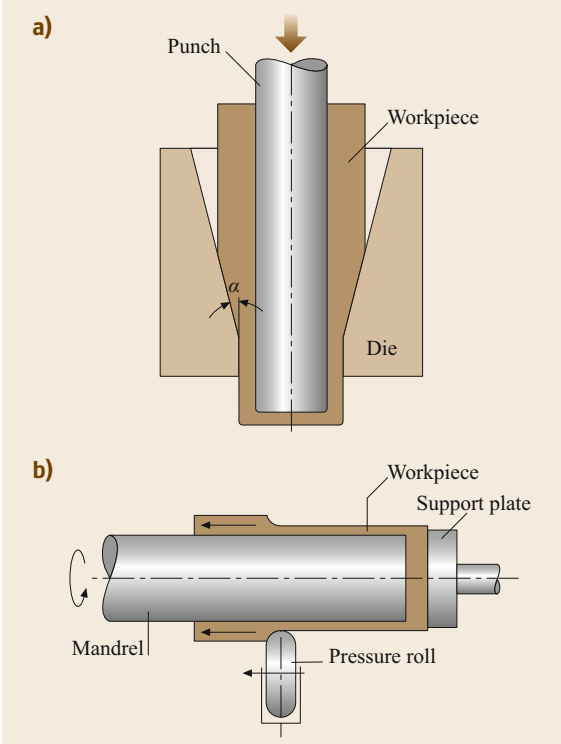

Fig. 11.6 (a) Ironing and (b) flow turning

Extrusion is demonstrated in Fig. 11.3. Similar to wire drawing, the cross-section of a rod is reduced by forcing it through a die opening. However, this time, the workpiece is pushed into instead of pulled through the die. The extrusion process shown in this figure produces continuous profiles with various cross-sections. The resulting semifinished products are then usually processed further in subsequent processes. Whereas the extrusion process in Fig. 11.4, also called impact extrusion or cold forging, aims to produce discrete parts, here net-shaped or near-net-shaped parts, i.e., parts that need no or only minor machining or similar shaping operations, are formed.

Figure 11.5 shows typical forging processes, in which an initial – usually heated – workpiece is formed between two dies. If the dies are flat, this process is called upsetting or open-die forging (Fig. 11.5a). However, if the part is formed between shaped dies and during forging the excess material flows to form a flash, this process is called impression die forging (Fig. 11.5b). Closed die forging is a forging process in which no flash is produced. This is also called trapped-die forging.

Two further bulk forming processes to create sheet-like products are shown in Fig. 11.6. Ironing (Fig. 11.6a) is a process in which the wall thickness of a cup is reduced. This is considered to be a bulk forming process, since the thickness is reduced and the stress state resembles that in a typical bulk forming process. Figure 11.6b shows the flow turning process, where the thickness of a hollow workpiece is again reduced and the stress state is typical of bulk forming.

Sheet forming processes, on the other hand, operate on planar workpieces (sheets, plates) and aim to produce hollow pieces with almost constant wall thickness. Here, a change of the wall thickness is not intended. Generally, two axial stress states exist, viz. tensile–compressive or tensile–tensile, while the third stress component normal to the sheet plane is zero or nearly zero. Sheet forming

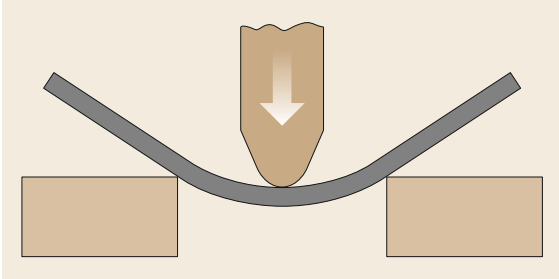

Fig. 11.7 Bending

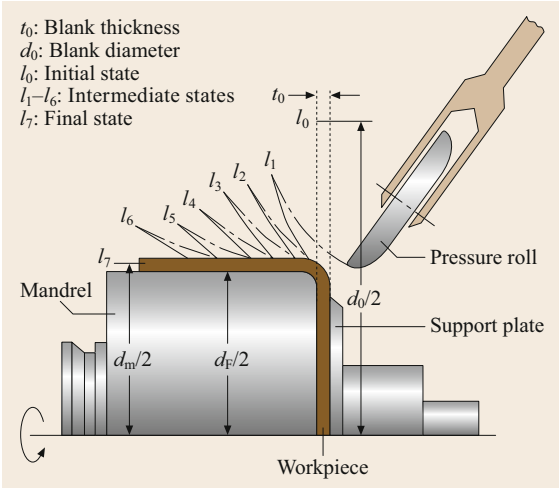

Fig. 11.8 Spinning

processes are usually conducted on workpieces that are not heated. Figures 11.7–11.9 show some examples of typical sheet forming processes. Figure 11.7 describes the bending of sheets. The mechanics of deformation during bending depends greatly on the ratio of the sheet thickness to the bending radius. Mostly, the thickness of the sheet varies only slightly during bending. In the figure, the free bending process is shown. Bending can also be conducted in dies.

The process of stretching (Fig. 11.79) consists of applying tensile forces in the plane of the sheet. The thickness of the sheet is reduced considerably during stretching. Figure 11.80 shows the basic process of deep drawing. During this process, an originally mainly flat sheet is drawn by means of a punch into a die, producing a hollow cup. The basic deformation occurs in the flange of the workpiece, and the stress state here consists of a tensile and a compressive component. The sheet is thickening at the outer rim. In this process, bending at the die radius and stretching in the cup walls also occur.

Figure 11.8 illustrates the process of spinning. Spinning is a typical incremental process in which an

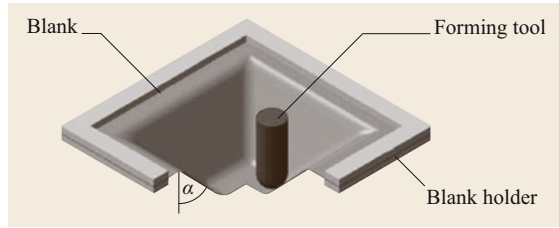

Fig. 11.9 Incremental sheet forming

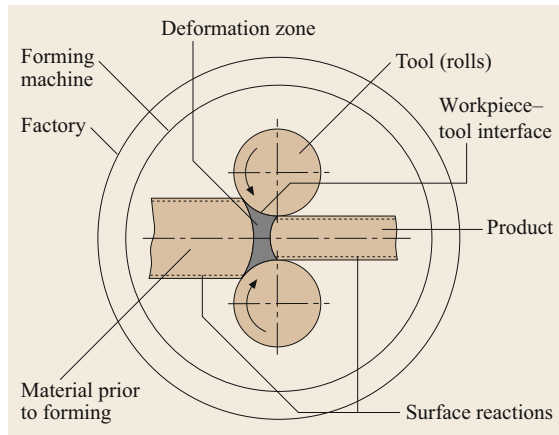

Fig. 11.10 Metal forming system (after [11.1, 2])

originally flat sheet is formed by moving a roll towards a mandrel on which the sheet is rotating while the roll also performs translatory motion.

Another recent incremental sheet formingprocess is sketched in Fig. 11.9. In this process, a punch controllable on three to five axes is used to shape an originally flat sheet incrementally. The process is much slower than the classical deep-drawing or stretching process but offers the advantage of flexibility. Besides solid tools, pressure media can also be used in sheet forming operations (Figs. 11.89–11.91). Hydroforming, aquadrawing, and tube hydroforming are variants in this process family.

Metal forming processes can be analyzed most effectively using a systems approach. The basic items of a metal forming system are shown in Fig. 11.10, for the flat rolling process. The first item is the material prior to forming. The deformation zone is the second item. The material properties of the plastically formed workpiece, the product, constitute the third item. The tools (here the rolls) make up another item. The interface between the workpiece and tools is the fifth item. The surface reactions of the workpiece before and after deformation constitute the sixth item of the metal forming system. The two final items are the forming machine and the factory. All these items influence each other and must, therefore, be considered together.

11.1 Metallurgical Fundamentals

11.1.1 Mechanisms of Plastic Deformation

If a metal crystal is exposed to shear stresses, first the lattice will deform elastically, as shown in Fig. 11.11a. After removal of the shear stress, the lattice will recover its original form. If the shear stress is increased, the crystal will deform elastically and plastically, such that, upon removal of the stresses, the crystal will not recover its original shape completely (Fig. 11.11b). Plastic deformations occur via the movement of atomic layers. Such movement occurs on so-called slip planes along slip directions [11.3].

The theoretical shear stress necessary to move one part of the lattice along a slip plane with respect to the other part can be estimated as

$$\tau_{\text{theoretical}} = \frac{G}{30} \quad \text{to} \quad \frac{G}{2\pi}\,, \tag{11.1}$$

where G is the shear modulus of the metal. For typical metallic materials, the theoretical shear strength calculated using (11.1) is presented in Table 11.1.

A second mechanism for plastic deformation is twinning (Fig. 11.12). During twinning, atoms on one side of the twinning plane are almost instantaneously moved to a mirror position on the other side of the plane. Twinning is a preferred mechanism of plastic deformation in hexagonal closed-packed (hcp) metals such as titanium, magnesium, and zinc alloys. Also, for other metals, twinning is preferred if the strain rates are very high, since plastic deformation by twinning needs much less time than that occurring by sliding.

The actual shear strengths of metals are up to several orders of magnitude less than their theoretical values (Table 11.1). Real metals show crystal defects called dislocations that facilitate another mechanism of slip that requires much less shear stress than the slip in a defect-free crystalline structure. Figure 11.13 shows that this dislocation shear occurs only incrementally over the shear plane and hence requires much lower shear stress values. Dislocations are present in virtually any metal, being introduced during solidifica-

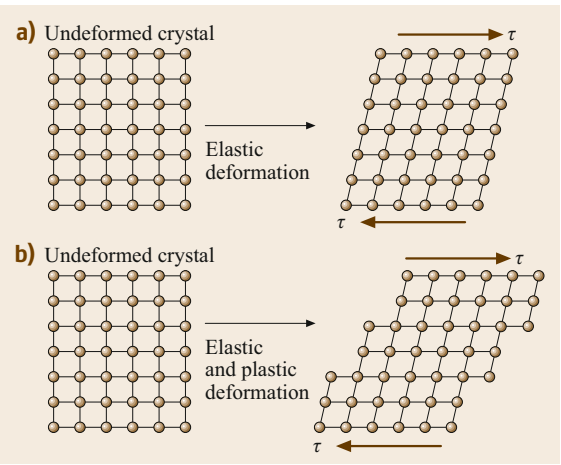

Fig. 11.11a,b Elastic and plastic deformations of the lattice structure

Table 11.1 Theoretical and actual shear strength for typical metallic materials

Material	Shear modulus (MPa)	Theoretical shear strength (MPa)	Actual shear strength (MPa)
Steel	75 800	2527–12 063	150–750
Aluminum alloys	27 500	917–4377	50–150
Copper alloys	41 400	1380–6589	100–250
Titanium alloys	44 800	1493–7130	350–800

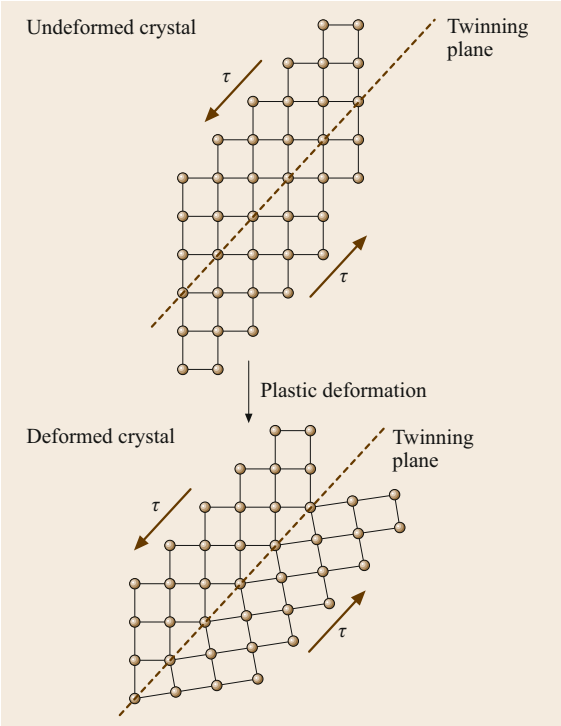

Fig. 11.12 Twinning mechanism for plastic deformation

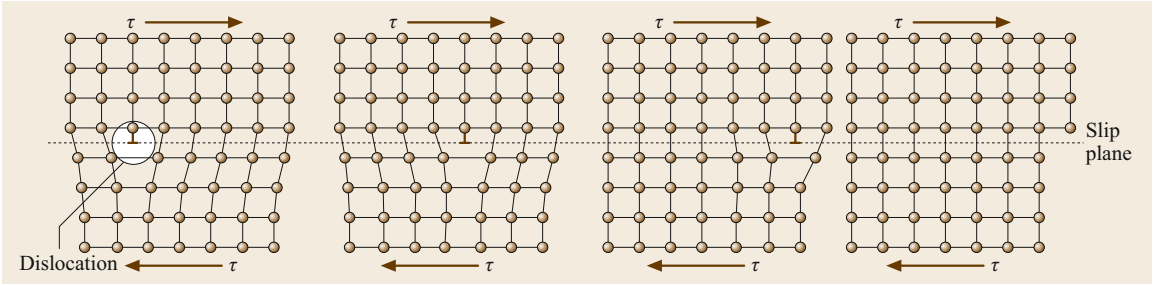

Fig. 11.13 Plastic deformation by dislocation motion

tion. In annealed metals, the length of dislocation lines is $\approx 10^4$–10^8 cm/cm^3 of metal. As plastic deformation proceeds, new dislocations are generated through various mechanisms such as the Frank–Read mechanism. As the number of dislocations increases, they start to hinder each other's motion, so that an increased shear stress is necessary to move them. This increase in yield strength is called strain hardening. In cold-worked metals, the density of dislocations increases to 10^{10}–10^{12} cm/cm^3 of metal. During plastic deformation, about 85–90% of the deformation energy is dissipated as heat. Recent measurements have indicated that this ratio varies with the amount of plastic strain. The rest of the energy is stored in the lattice as strain energy and is directly related to the dislocations.

Other mechanisms that increase the yield strength include solid-solution hardening, particle (dispersion) hardening, and grain-size hardening. These mechanisms can be superposed to obtain an analytical relation for the yield strength as

$$Y = Y_0 + \Delta Y_\mathrm{s} + \Delta Y_\mathrm{d} + \Delta Y_\mathrm{p} \,, \tag{11.2}$$

where Y_0 is the yield stress of the pure single-crystal metal with some dislocations, ΔY_s is the increase in yield strength due to solid-solution hardening, ΔY_d is the increase due to dispersion hardening, and ΔY_p is the increase due to phase boundaries. For ferritic steel, for instance, Y_0 is about 30 MPa, and

$$\Delta Y_\mathrm{s} = \sum_i k_i x_i \,, \tag{11.3}$$

where x_i is the weight percentage of each alloying element and k_i is a weight factor, given in Table 11.2.

Meanwhile, the yield strength increase due to grain refinement is given by the Hall–Petch relationship

$$\Delta Y_\mathrm{p} = \frac{k_y}{\sqrt{d}} \,, \tag{11.4}$$

Table 11.2 Weight factors for solid-solution hardening (after [11.4])

Element	Si	Mn	P	Ni	Mo	Cu	Sn	Al	N
k_i	81	18	590	8	15	40	130	24	2300

where d is the grain size and the constant k_y ranges from 15 to 24 MPa mm$^{1/2}$ for common steels. This relationship reflects the fact that grain boundaries impose geometrical constraints on dislocation motion and hence increase the shear stress that is necessary to move them. The value of ΔY_d depends on the form and morphology of the carbides generated in ferrite.

11.1.2 Reverting Strain Hardening

If a polycrystalline metal is plastically deformed at temperatures below one-third of its melting temperature T_m (in K), the grain shapes change (leading to texturing) and the dislocation density increases (leading to strain hardening). Strain hardening is naturally accompanied by a reduction of the ductility (Fig. 11.14). Although the strain-hardened state of the material is mechanically stable, it is thermodynamically unstable. Hence, at elevated temperatures, this state of the plastically deformed material can be altered.

Recovery

Heating a deformed metal in the range of $0.3T_\mathrm{m}$–$0.5T_\mathrm{m}$ will activate diffusion of atoms. This diffusion of atoms enables the motion of some dislocations, which will cancel each other or restructure themselves. Stored energy is relieved. Residual stresses will be removed, the yield stress will be reduced slightly, while the ductility will increase. Electrical and thermal properties will be recovered as well.

Recrystallization

If a deformed metal is heated at $T > 0.5T_\mathrm{m}$, diffusion processes continue such that similar dislocations start to

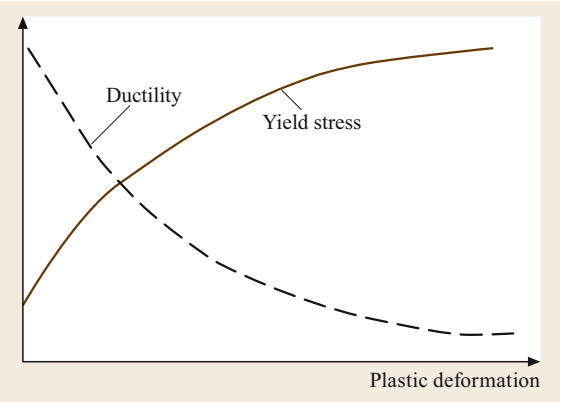

Fig. 11.14 Decrease of ductility and increase of yield stress for $T_m < 0.3$ (in K)

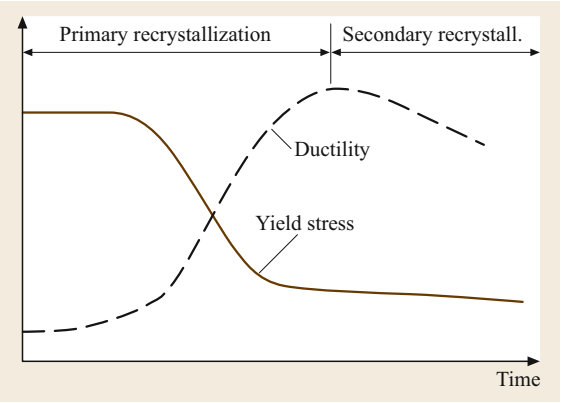

Fig. 11.15 Recrystallization of cold-formed metal ($T > 0.5T_m$)

align in certain regions to form low-angle grain boundaries. If the number of aligned dislocations increases, they can build large-angle grain boundaries via a process called recrystallization. The movable collocated dislocations are the recrystallization nuclei. During recrystallization, a refined grain structure forms and the yield stress of the metal drops to its original value, while the ductility also increases back to its preworked value (Fig. 11.15).

After recrystallization, the new grains show a preferred orientation that is related to both the deformation texture and the character of the grain boundaries. The temperature at which the whole structure is completely recrystallized within 1 h is called the recrystallization temperature of that metal (Table 11.3). Heat treatment that results in recrystallization is called annealing. Recrystallization can only occur after a minimum amount of plastic deformation, since a minimum number of dislocations must be mobilized to form large-angle grain boundaries. The greater the plastic deformation that a metal has experienced, the lower its recrystallization temperature. Time and temperature or prior plastic deformation play interchangeable roles (Fig. 11.16). At high temperatures and following large prior cold plastic deformation, grains can continue to grow after recrystallization has completed, such that larger grains form than before recrystallization. This process is called secondary recrystallization and results in a material with less superior properties than after primary recrystallization (such as lower ductility, or the orange peel effect in deep drawing and bending).

Table 11.3 Recrystallization temperatures for typical metals

Material	T_{rc} (°C)	Material	T_{rc} (°C)
C steel	550	Sn	0–40
Pure Al	290–300	Zn	50–100
Duralumin	360–400	Mo	870
Cu	200	W	900–1000
Pb	−50 to 50	Ni	400–600

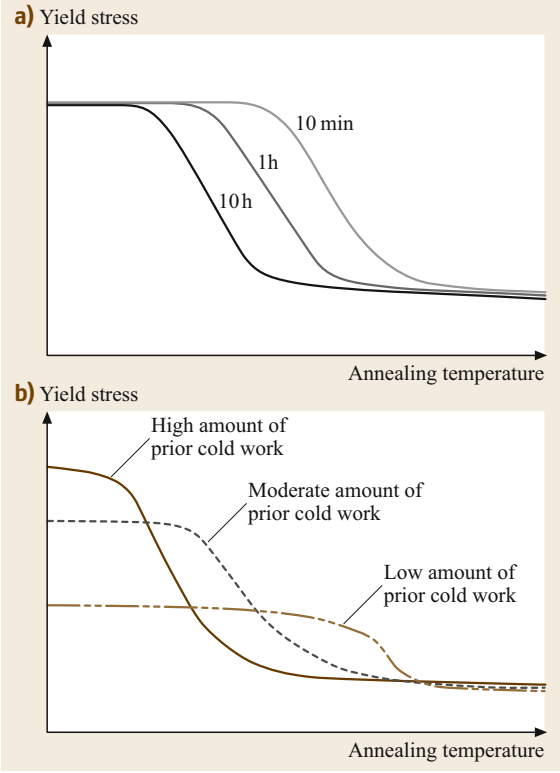

Fig. 11.16a,b Effect of time (**a**) and cold forming (**b**) on recrystallization

11.2 Theoretical Foundations

The theoretical framework for plastic deformation [11.5, 6] is based on four phenomenological foundations: the basic concepts of strain and stress, the flow condition, the flow rule, and the flow curve. Based on these, in conjunction with the equilibrium equations, analytical and numerical methods can be established. Physical simulations also make use of these fundamentals.

11.2.1 Basic Concepts

The Concept of Strain

The intensity of plastic deformation in metal forming is measured by the true strain increment $d\varepsilon$. Considering the uniaxial tension test (Fig. 11.17) in which a uniform rod with current length ℓ and current cross-sectional area A is exposed to an axial force F, the instantaneous strain increment in the axial direction is defined as

$$d\varepsilon = \frac{d\ell}{\ell} \,. \tag{11.5}$$

Assuming uniform straining, the total strain at any point in the rod experienced from the original length ℓ_0 to the final length ℓ_1 is given by

$$\varepsilon = \int_{\ell_0}^{\ell_1} \frac{d\ell}{\ell} = \ln\left(\frac{\ell_1}{\ell_0}\right) . \tag{11.6}$$

Due to the logarithmic nature of this expression, this strain is also called the logarithmic or natural strain. In contrast to the engineering strain, the true strain describes finite deformations correctly, is additive between different straining steps, and supplies the same strain values for the same amount of elongation or compression.

The total strain given in (11.6) is the sum of the elastic (recoverable) and plastic (permanent) strains.

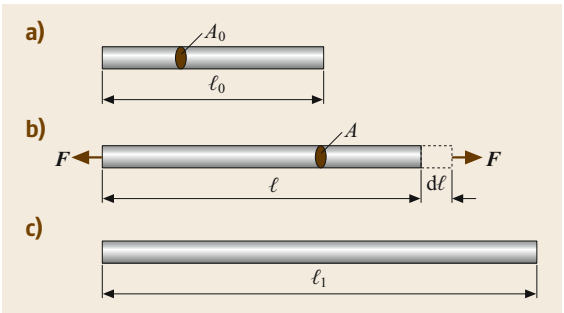

Fig. 11.17a–c Uniaxial tension of a rod: initial **(a)**, intermediate **(b)**, and final configuration **(c)**

However, in metal forming processes, the elastic strains are several orders of magnitude smaller than the plastic strains and can thus be neglected

$$\varepsilon = \varepsilon^{\text{elastic}} + \varepsilon^{\text{plastic}} \approx \varepsilon^{\text{plastic}} \,. \tag{11.7}$$

Therefore, in the forthcoming sections, the superscripts will be omitted.

Strain Rates

If the elongation $d\ell$ takes place in time dt, the strain rate can be defined as

$$\dot{\varepsilon} = \frac{d\varepsilon}{dt} = \frac{d\ell/\ell}{dt} = \frac{d\ell/dt}{d\ell} = \frac{v_{\text{tool}}}{\ell} \,, \tag{11.8}$$

where v_{tool} is the velocity of extension of the rod as imposed by the tool. The concept of strain rate can be extended to three-dimensional general deformations by introducing the velocity field for each particle in three Cartesian directions (v_x, v_y, v_z). The components of the resulting strain rate tensor are then defined by

$$\dot{\varepsilon}_{ij} \equiv \begin{pmatrix} \dot{\varepsilon}_{xx} & \dot{\varepsilon}_{xy} & \dot{\varepsilon}_{xz} \\ \dot{\varepsilon}_{yx} & \dot{\varepsilon}_{yy} & \dot{\varepsilon}_{yz} \\ \dot{\varepsilon}_{zx} & \dot{\varepsilon}_{zy} & \dot{\varepsilon}_{zz} \end{pmatrix}$$

$$= \begin{pmatrix} \dfrac{\partial v_x}{\partial x} & \dfrac{1}{2}\left(\dfrac{\partial v_x}{\partial y} + \dfrac{\partial v_y}{\partial x}\right) & \dfrac{1}{2}\left(\dfrac{\partial v_x}{\partial z} + \dfrac{\partial v_z}{\partial x}\right) \\ & \dfrac{\partial v_y}{\partial y} & \dfrac{1}{2}\left(\dfrac{\partial v_y}{\partial z} + \dfrac{\partial v_z}{\partial y}\right) \\ \text{symm.} & & \dfrac{\partial v_z}{\partial z} \end{pmatrix} . \tag{11.9}$$

Total Strains

For the three-dimensional general deformation state, the strain rates can be integrated over time if and only if all the shear strain rates are zero and the straining path, that is, the ratio of the normal strains, is constant over the respective time increment. In this case, the normal strains are also the principal strains. The total strains can then be determined for the deformation depicted in Fig. 11.18 as

$$\begin{aligned} \varepsilon_1 &= \ln\left(\frac{a_1}{a_0}\right) , \\ \varepsilon_2 &= \ln\left(\frac{b_1}{b_0}\right) , \\ \varepsilon_3 &= \ln\left(\frac{c_1}{c_0}\right) . \end{aligned} \tag{11.10}$$

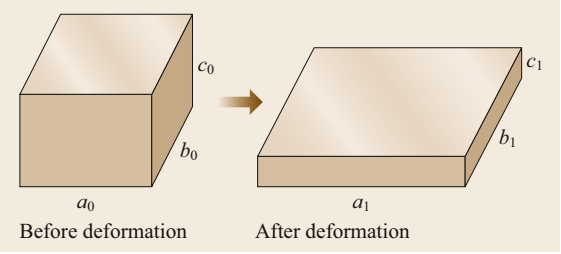

Fig. 11.18 Principal strains

Obviously, total strains can only be used in idealized cases. Here, the Arabic indices denote the principal directions.

Principle of Volume Constancy

Experimental observations have shown that the volume during plastic deformations remains approximately constant. Referring to Fig. 11.18, this means

$$V = \underbrace{a_0 \times b_0 \times c_0}_{\text{initial}} = \underbrace{a_1 \times b_1 \times c_1}_{\text{final}} = \text{const.}\,, \tag{11.11}$$

or in terms of strain rates and strains

$$\begin{aligned} &\dot{\varepsilon}_1 + \dot{\varepsilon}_2 + \dot{\varepsilon}_3 = 0 \quad \text{or} \\ &\varepsilon_1 + \varepsilon_2 + \varepsilon_3 = 0 \quad \text{or} \\ &\varepsilon_x + \varepsilon_y + \varepsilon_z = 0\,. \end{aligned} \tag{11.12}$$

The Concept of Stress

Referring to Fig. 11.17, the true stress (also called the Cauchy stress) in the axial direction is defined by

$$\sigma = \frac{F}{A}\,, \tag{11.13}$$

where A is the current area of the rod. This stress must be carefully distinguished from the engineering stress, which refers to the original cross-sectional area.

The three-dimensional generalization of the internal forces according to (11.13) leads to the stress tensor at a point

$$\boldsymbol{\sigma}_{ij} = \begin{pmatrix} \sigma_{xx} & \tau_{xy} & \tau_{xz} \\ \tau_{yx} & \sigma_{yy} & \tau_{yz} \\ \tau_{zx} & \tau_{zy} & \sigma_{zz} \end{pmatrix}. \tag{11.14}$$

This tensor is also symmetric like the strain rate tensor. Two important special cases of the general stress tensor are the uniaxial stress state (with only the σ_{xx}-component being nonzero) and the plane stress state (in which all components with a z-index are zero).

The three independent stress invariants are defined as

$$\begin{aligned} I_1 &= \sigma_{xx} + \sigma_{yy} + \sigma_{zz} = \sigma_1 + \sigma_2 + \sigma_3\,, \\ I_2 &= \tau_{xy}^2 + \tau_{yz}^2 + \tau_{zx}^2 - \sigma_{xx}\sigma_{yy} - \sigma_{yy}\sigma_{zz} - \sigma_{zz}\sigma_{xx} \\ &= -(\sigma_1\sigma_2 + \sigma_2\sigma_3 + \sigma_3\sigma_1)\,, \\ I_3 &= \sigma_{xx}\sigma_{yy}\sigma_{zz} + 2\tau_{xy}\tau_{yz}\tau_{zx} \\ &\quad - \sigma_{xx}\tau_{yz}^2 - \sigma_{yy}\tau_{zx}^2 - \sigma_{zz}\tau_{xy}^2 \\ &= \sigma_1\sigma_2\sigma_3\,, \end{aligned} \tag{11.15}$$

where σ_1, σ_2, and σ_3 are the principal stresses.

Hydrostatic and Deviatoric Stresses

The hydrostatic stress (a stress invariant) is defined as

$$\sigma_\mathrm{h} = \frac{\sigma_{xx} + \sigma_{yy} + \sigma_{zz}}{3}\,. \tag{11.16}$$

The respective hydrostatic stress tensor is hence

$$\boldsymbol{\sigma}_{ij}^\mathrm{h} = \begin{pmatrix} \sigma_\mathrm{h} & 0 & 0 \\ 0 & \sigma_\mathrm{h} & 0 \\ 0 & 0 & \sigma_\mathrm{h} \end{pmatrix} = \sigma_\mathrm{h} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}. \tag{11.17}$$

It is an experimental observation that hydrostatic stress does not initiate any plastic deformation. However, the ultimate amount of plastic deformation that a metal can withstand increases with increasing compressive hydrostatic stress. Plastic deformation is induced by the deviatoric stress tensor, obtained as

$$\begin{aligned} \boldsymbol{\sigma}'_{ij} &= \boldsymbol{\sigma}_{ij} - \boldsymbol{\sigma}_{ij}^\mathrm{h} \\ &= \begin{pmatrix} (\sigma_{xx} - \sigma_\mathrm{h}) & \tau_{xy} & \tau_{xz} \\ \tau_{yx} & (\sigma_{yy} - \sigma_\mathrm{h}) & \tau_{yz} \\ \tau_{zx} & \tau_{zy} & (\sigma_{zz} - \sigma_\mathrm{h}) \end{pmatrix}. \end{aligned} \tag{11.18}$$

11.2.2 Flow Condition

The flow condition (also called the yield condition) is a hypothesis describing the condition that must be fulfilled for plastic flow to start or continue. Most flow conditions are expressed in terms of components of the stress tensor. Any flow condition must fulfill the trivial case of the uniaxial stress state, for which plastic flow starts if the axial stress is equal to the yield stress. In metal forming, instead of the yield stress, the term "flow stress" is preferred. Referring to Fig. 11.19, the elastic region is terminated by the initial yield stress or the initial flow stress $\sigma_{\mathrm{f}0}$. Increasing the tension force further will also increase the axial stress, but with a much

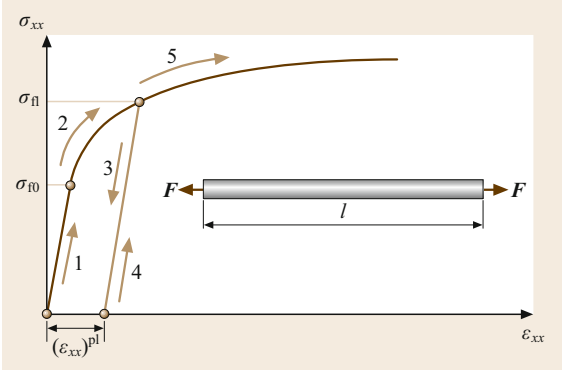

Fig. 11.19 Flow stress in simple tension test (numbers give the sequence)

lower gradient than in the elastic region. If loading is terminated at a flow stress of σ_{fl} and the specimen is unloaded and then reloaded, plastification will this time start at a higher flow stress of σ_{fl}. This phenomenon is called strain or work hardening. Under certain circumstances, the flow stress σ_{fl} may be equal to the initial flow stress σ_{f0}. Such kinds of materials are called nonhardening or perfectly plastic materials. If the flow stress after plastification decreases, the material is strain softening.

The two flow conditions used extensively in metal forming for general three-dimensional stress cases are the Tresca flow condition and the von Mises flow condition.

The Tresca Flow Condition

The Tresca flow condition states that plastic flow will start or continue if the maximum shear stress τ_{max} is equal to a material constant that can be found as $\sigma_f/2$ after tuning this criterion by the simple tension test

$$\tau_{max} = \frac{\sigma_f}{2} , \tag{11.19}$$

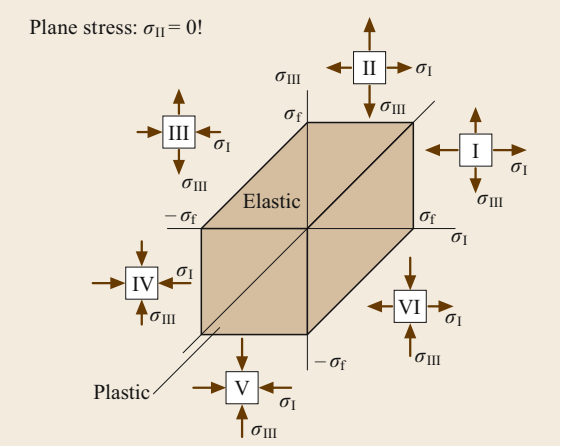
or in terms of principal normal stresses

$$\sigma_{max} - \sigma_{min} = \sigma_f , \tag{11.20}$$

where σ_{max} and σ_{min} are the largest and smallest principal normal stresses. Figure 11.20 shows the flow locus for plane stress states according to Tresca. The table in the figure depicts the various forms that the Tresca flow criterion takes in terms of the spatial plane stress components σ_I and σ_{III}.

The von Mises Flow Condition

In contrast to the Tresca flow condition, the von Mises flow condition considers all the principal shear stresses.



Region		
I	$\sigma_I > \sigma_{III} > 0$	$\sigma_f = \sigma_I$
II	$\sigma_{III} > \sigma_I > 0$	$\sigma_f = \sigma_{III}$
III	$\sigma_{III} > 0 > \sigma_I$	$\sigma_f = \sigma_{III} - \sigma_I$
IV	$0 > \sigma_{III} > \sigma_I$	$\sigma_f = -\sigma_I$
V	$0 > \sigma_I > \sigma_{III}$	$\sigma_f = -\sigma_{III}$
VI	$\sigma_I > 0 > \sigma_{III}$	$\sigma_f = \sigma_I - \sigma_{III}$

Fig. 11.20 Tresca flow hexagon

Accordingly, plastic flow starts or continues if

$$c' = \sqrt{\frac{1}{3}\left[\left(\tau^1_{max}\right)^2 + \left(\tau^2_{max}\right)^2 + \left(\tau^3_{max}\right)^2\right]} , \tag{11.21}$$

where c' is a material constant. Again tuning this equation by the simple tension test gives

$$\sigma_f = \sqrt{\frac{1}{2}\left[\begin{array}{l}(\sigma_{xx} - \sigma_{yy})^2 + (\sigma_{yy} - \sigma_{zz})^2 \\ \quad + (\sigma_{zz} - \sigma_{xx})^2 + 6\left(\tau^2_{xy} + \tau^2_{yz} + \tau^2_{zx}\right)\end{array}\right]} . \tag{11.22}$$

Figure 11.21 shows the flow locus for plane stress states. In this case, (11.22) reduces to

$$\sigma_f = \sqrt{\sigma_I^2 + \sigma_I \sigma_{III} + \sigma_{III}^2} . \tag{11.23}$$

A comparison of the von Mises flow criterion with the Tresca criterion reveals that, for plane stress states, the maximum deviation between the two criteria is 15.5%. Each criterion finds a different shear stress in pure shear for the initiation of plastic flow k

$$k = \begin{cases} \frac{1}{2}\sigma_f & \text{by Tresca} \\ \frac{1}{\sqrt{3}}\sigma_f & \text{by von Mises} . \end{cases} \tag{11.24}$$

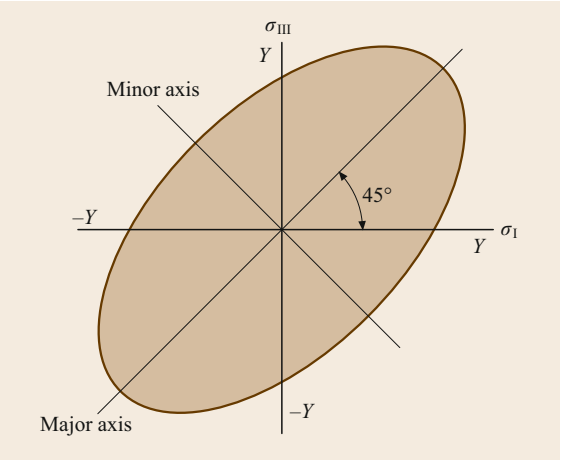


Fig. 11.21 von Mises flow ellipse

Both criteria assume that plastic flow is independent of the hydrostatic stress and of the sense of the stresses. Violation of the latter is also called the Bauschinger effect or kinematic hardening.

11.2.3 The Flow Rule

The relationship between plastic strains and stresses is expressed by the Levy–Mises flow rule. Unlike in Hooke's law for elastic deformations, in plasticity true strain rates are related to deviatoric stresses

$$\dot{\boldsymbol{\varepsilon}}_{ij} = \lambda \boldsymbol{\sigma}'_{ij} \,, \tag{11.25}$$

where λ is a nonnegative real number. By inserting (11.25) into (11.22), the nonnegative parameter can be eliminated, yielding

$$\dot{\boldsymbol{\varepsilon}}_{ij} = \frac{\sqrt{3I_2^{\dot{\varepsilon}_{ij}}}}{\sigma_\mathrm{f}} \boldsymbol{\sigma}'_{ij} \,, \tag{11.26}$$

where $I_2^{\dot{\varepsilon}_{ij}}$ is the second invariant of the strain rate tensor.

11.2.4 Equivalent Plastic Strain and the Flow Curve

The plastic power per unit volume due to the stresses during plastic deformation can be expressed as

$$p = \sum_i^3 \sum_j^3 \sigma_{ij} \dot{\varepsilon}_{ij} = \sum_i^3 \sum_j^3 \sigma'_{ij} \dot{\varepsilon}_{ij} \,. \tag{11.27}$$

Equating this power to the power done by the respective flow stress and a fictitious strain rate leads to the definition of the equivalent plastic strain rate $\dot{\bar{\varepsilon}}$ as

$$p = \sum_i^3 \sum_j^3 \sigma'_{ij} \dot{\varepsilon}_{ij} = \sigma_\mathrm{f} \dot{\bar{\varepsilon}} \,. \tag{11.28}$$

Together with (11.26), this yields

$$\begin{aligned} \dot{\bar{\varepsilon}} &= \sqrt{\frac{4}{3} I_2^{\dot{\varepsilon}_{ij}}} = \sqrt{\frac{2}{3} \left(\sum_i^3 \sum_j^3 \dot{\varepsilon}_{ij} \dot{\varepsilon}_{ij} \right)} \\ &= \sqrt{\frac{2}{3} \left[\left(\dot{\varepsilon}_{xx}^2 + \dot{\varepsilon}_{yy}^2 + \dot{\varepsilon}_{zz}^2 \right) + 2 \left(\dot{\varepsilon}_{xy}^2 + \dot{\varepsilon}_{yz}^2 + \dot{\varepsilon}_{xz}^2 \right) \right]} \,. \end{aligned} \tag{11.29}$$

The total equivalent plastic strain is the time integral of (11.29)

$$\bar{\varepsilon} = \int_t \dot{\bar{\varepsilon}} \, \mathrm{d}t \,, \tag{11.30}$$

or in terms of total strain components

$$\bar{\varepsilon} = \sqrt{\frac{2}{3} \left(\dot{\varepsilon}_1^2 + \dot{\varepsilon}_2^2 + \dot{\varepsilon}_3^2 \right)} \,. \tag{11.31}$$

The equivalent plastic strain is a measure of the increase of the dislocation density and the mutual hindrance of dislocations; i.e., it measures the increase of the flow stress. The change of the flow stress with the equivalent plastic strain is a material property called the flow curve

$$\sigma_\mathrm{f} = \sigma_\mathrm{f}(\bar{\varepsilon}) \,. \tag{11.32}$$

Typical flow curves for various temperatures and strain rates are shown in Fig. 11.22 for the typical cold-forming steel C15. Usually, the flow stress at a given equivalent strain decreases with temperature but increases with strain rate. The flow curve can be determined basically in simple tension, compression, and torsion tests. All theses tests have their limitations regarding the attainable strain values and stress states [11.7].

11.2.5 Temperature Increase During Forming

During plastic deformation, about 85–90% of the plastic work is dissipated as heat. For a homogeneous adiabatic deformation, the average temperature increase can be computed as

$$\Delta T = \frac{(0.85 - 0.95)\, \bar{\sigma}_{\mathrm{f,mean}} \bar{\varepsilon}}{\rho c} \,, \tag{11.33}$$

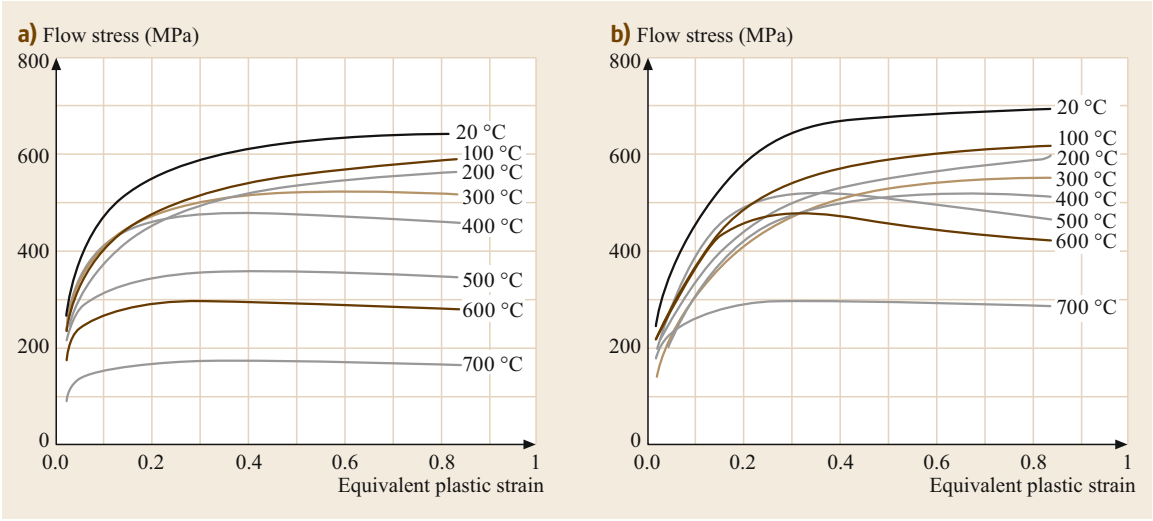

Fig. 11.22a,b Flow curve of a low-carbon steel (C15 steel) at various temperatures and strain rates: **(a)** strain rate: 0.1 s^{-1}, **(b)** strain rate: 10 s^{-1} (after [11.8])

Table 11.4 Average temperature increase during homogeneous metal forming with average plastic strain of unity (after [11.9])

Material	ρ (kg/dm^3)	c (J/(kg K))	$\sigma_{f,mean}$ (N/mm^2)	ΔT (K)
Steel	≈ 7.8	≈ 500	400–1200	100–300
Al alloys	≈ 2.7	≈ 1000	100–300	35–100
Cu alloys	≈ 8.7	≈ 400	200–400	50–100
Ti alloys	≈ 4.5	≈ 600	750–1500	250–500

where $\bar{\sigma}_{f,mean}$ is the mean flow stress during deformation, $\bar{\varepsilon}$ is the mean equivalent plastic strain, c is the specific heat capacity, and ρ is the density of the material. Table 11.4 presents the average temperature increase for a moderate equivalent plastic strain of unity for various materials.

11.2.6 Analytical Methods

All the methods discussed in this section assume rigid plastic behavior and quasistatic loading [11.10–12].

Elementary Plasticity and Friction Models

Here, only equilibrium methods are discussed, being based on the static equilibrium of simple, elementary, standard free bodies (semiinfinitesimal slabs) for which the strain rate state can be easily determined. Basically, three types of elementary free bodies are considered, viz. rectangular (Fig. 11.23a), circular (Fig. 11.23b), and tubular slabs (Fig. 11.23c). The basic assumptions are:

1. The strain rate state in each semiinfinitesimal slab is homogeneous.
2. Plane sections remain plane.
3. The stresses along the characteristic directions of the slabs are principal stresses.
4. Friction at the contact interfaces can be described by either the Coulomb friction model or the constant shear model.

The Coulomb friction model states that the frictional shear stress at a surface element at the interface

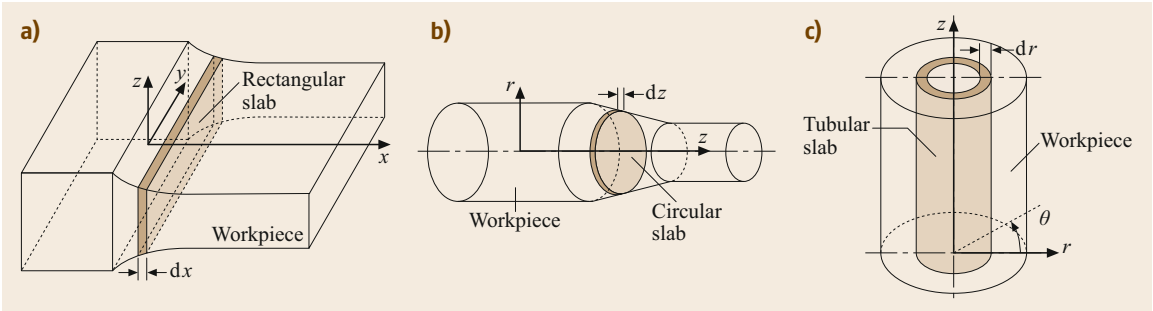

Fig. 11.23a–c Various slab elements: **(a)** rectangular slab, **(b)** circular slab, **(c)** tubular slab

Table 11.5 Typical values of the coefficient of friction and friction factor

Process	Coefficient of friction μ	Friction factor m
Cold forging (steel, stainless steel, Cu alloys, brass)	0.05–0.10 (lower values for phosphated workpieces)	0.05–0.10
Cold forging (Al, Mg alloys)	0.05	0.05–0.10
Wire drawing (steel, stainless steel, Cu alloys, brass)	0.05–0.10	–
Wire drawing (Al, Mg alloys)	0.03–0.10	–
Hot forging	Use not recommended	0.20–0.40
Forging of Ti and Ni alloys	Use not recommended	0.10–0.30 (glass lubrication)
Hot rolling	Use not recommended	0.70–1.00 (no lubrication)
Deep drawing (steel)	0.05–0.10	Use not recommended
Deep drawing (stainless steel)	0.10	Use not recommended
Deep drawing (Cu alloys, brass)	0.05–0.10	Use not recommended
Deep drawing (Al, Mg alloys)	0.05	Use not recommended
Ironing (steel)	0.05–0.10	Use not recommended
Ironing (stainless steel)	0.05	Use not recommended
Ironing (Cu alloys, brass)	0.10	Use not recommended
Ironing (Al and Mg alloys)	0.05	Use not recommended

is proportional to the normal stress

$$\tau_{\text{friction}} = \mu\sigma_{\text{normal}} \,. \tag{11.34}$$

The proportionality factor μ is called the coefficient of friction. In metal forming, the range for μ is given as

$$0 \le \mu \le 0.577 \,. \tag{11.35}$$

The constant shear friction model states that the frictional stress is proportional to the flow stress in shear k

$$\tau_{\text{friction}} = mk \,. \tag{11.36}$$

The proportionality factor m is called the friction factor. The range of m is given by

$$0 \le m \le 1 \,. \tag{11.37}$$

Both models only approximately describe reality. Recent friction models are a combination of both elementary models. Typical values for the coefficient of friction and the friction factor are presented in Table 11.5.

The unknown stresses can be solved using the equilibrium equations and the flow condition. The flow rule is not used. The accuracy of this approach decreases as the friction or the inclination of the free surfaces increases.

Upper- and Lower-Bound Methods

The upper-bound method is based on the first law of thermodynamics. For a kinematically admissible velocity field that satisfies volume constancy and all the velocity boundary conditions for a plastically deforming body, an upper bound for the forming force is given by [11.13]

$$(F_{\text{tool}})^{\text{upper-bound}} = \frac{1}{v_{\text{tool}}}\left(\int_V \sigma_{\text{f}}\dot{\bar{\varepsilon}}\,\mathrm{d}V + \int_{A_{\text{s}}} \text{mk}v_{\text{shear}}\,\mathrm{d}A - \int_{A_{\text{f}}} \boldsymbol{p}\boldsymbol{v}\,\mathrm{d}A\right), \tag{11.38}$$

where v_{tool} is the tool velocity, $\boldsymbol{p}$ is the known pressure vector acting on the workpiece, v_{shear} is the shearing velocity at shear surfaces, v is the velocity vector of points on the workpiece surface, A_{s} is the workpiece area on which friction is specified, and A_{f} is the workpiece area on which forces are specified. To apply the upper-bound method, the plastic region has to be estimated, the constant flow stress has to be estimated in the plastic region, friction stresses must be constant and hence described by the constant shear model, and finally, a kinematically admissible velocity field or appropriate shear planes have to be assumed.

Lower-bound methods lead to forces that are always lower than the actual forces. Here, a statically admissible stress field that fulfills the equilibrium equations and the stress boundary conditions must be guessed. Ideally, for an analysis, the force can be limited between an upper and lower bound. However, the application of the lower-bound method is much more difficult, since the guess of an admissible stress field is not straightforward. Furthermore, in practical applications, an upper bound for the forming forces is sufficient. The *upper-bound* property for the forming force is given if and only if the material's flow stress is correct and the friction stresses are correct. Otherwise, the computed *upper bound* may also be *lower* than the actual physical forces.

The Slip Line Field Solution

The slip line field solution also assumes rigid, perfectly plastic material behavior. Furthermore, the plane strain state is assumed. Moreover, the processes have to be frictionless. If these assumptions are fulfilled, then the theory supplies an exact solution. The slip line field solution is based on the governing equations including the flow condition, the volume constancy equation, the flow rule, and the equilibrium equations for the plane strain state. These equations build up a hyperbolic system of partial differential equations that can be solved by the method of characteristics. If the stresses are expressed in terms of the hydrostatic stress and the orientation of the stress element in the maximum shear stress direction, the two characteristic lines are orthogonal to each other (α and β-slip lines) and correspond to the directions of maximum shear stress; therefore they are called slip lines. The governing equations can be written as ordinary differential equations along each slip line. These equations can be summarized as the Hencky equations for the stresses

$$\begin{aligned}\sigma_\mathrm{h} - 2k\phi &= \text{constant along the } \alpha\text{-slip line}\,,\\ \sigma_\mathrm{h} + 2k\phi &= \text{constant along the } \beta\text{-slip line}\,,\end{aligned} \tag{11.39}$$

and the Geiringer equations in terms of the particle velocities

$$\begin{aligned}\frac{\mathrm{d}v_\alpha}{\mathrm{d}s} &= v_\beta \frac{\mathrm{d}\phi}{\mathrm{d}s} \qquad \text{along } \alpha\text{-slip line}\,,\\ \frac{\mathrm{d}v_\beta}{\mathrm{d}s} &= v_\alpha \frac{\mathrm{d}\phi}{\mathrm{d}s} \qquad \text{along } \beta\text{-slip line}\,,\end{aligned} \tag{11.40}$$

where ϕ is the inclination of the slip line and s is the distance along the slip line. Constructing the slip line field from known boundary conditions, the use of (11.39) and (11.40) supplies the stress and velocity (and hence strain rates) at any point in the deformation zone.

11.2.7 Empirical Methods

The Visioplasticity Method

The visioplasticity method consists of splitting the workpiece before deformation into two parts and marking a grid on one side, then closing these two parts and forming the workpiece. The grids are deformed after forming, then measured in order to determine the particle velocities and displacements. From these data, the strain rates and thus stresses can be computed. Figure 11.41 shows a typical visioplasticity specimen used in forward rod extrusion. The basic assumption is that the initial plane on which the grid is produced remains planar during plastic deformation. The grids can be marked on the specimens by mechanical methods, photomechanical methods, electrochemical methods, or photolithographic methods.

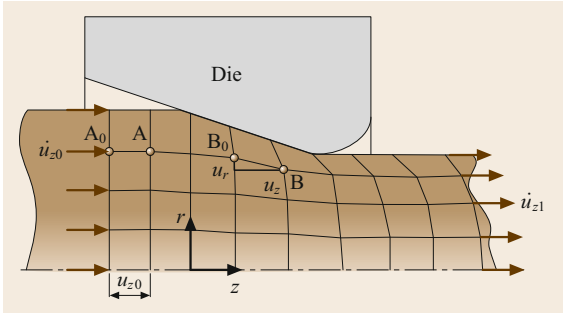

Fig. 11.24 Visioplasticity analysis (after [11.9])

In the case of steady-state processes, the velocities can be determined (Fig. 11.24) by first computing a time increment

$$\Delta t = \frac{u_{z0}}{\dot{u}_{z0}} = \frac{u_z}{\dot{u}_z(\bar{r}_\mathrm{B}, \bar{z}_\mathrm{B})} = \frac{u_r}{\dot{u}_r(\bar{r}_\mathrm{B}, \bar{z}_\mathrm{B})}\,, \tag{11.41}$$

where $\bar{r}_\mathrm{B}$ and $\bar{z}_\mathrm{B}$ are the mean coordinates of point B. Hence, the velocity components of point B can be found as

$$\begin{aligned}\dot{u}_z(\bar{r}_\mathrm{B}, \bar{z}_\mathrm{B}) &= \frac{u_z}{\Delta t} = \frac{u_z}{u_{z0}}\dot{u}_{z0}\,,\\ \dot{u}_r(\bar{r}_\mathrm{B}, \bar{z}_\mathrm{B}) &= \frac{u_r}{\Delta t} = \frac{u_r}{u_{z0}}\dot{u}_{z0}\,.\end{aligned} \tag{11.42}$$

Using these components, the strain rate components can be found. The deviatoric stress components are given by the flow rule in (11.26). The hydrostatic stress found from the stress boundary conditions and the previously found deviatoric stresses are then used to determine the total stress components finally.

Physical Simulation

Using modeling materials such as wax or plastiline, the flow pattern can be visualized and observed through transparent dies, for instance [11.14]. The key idea here is the fact that two materials behave similarly from the viewpoint of plasticity if they have the same strain-hardening exponent n. It is possible to add additives such as kaolin, Indramic, and Filia to wax and plastiline to change the n value and even the strain-rate sensitivity value m. Also, the ductility and strength level can be manipulated by additives. Hence, the basic difference from the forming process of metals is the much lower stress level.

11.2.8 Numerical Methods

The equations governing plasticity cannot be solved in closed form except for a very few simple applications.

An approximate solution of the differential equations can be obtained numerically using various methods. Among these methods, the finite element approach has found the most extended application because of its generality and efficiency.

Rigid–Plastic Finite Element Formulations

The elastic part of the strain is neglected, and the whole body is assumed to deform rigid plastically. The solutions obtained by these formulations cannot describe residual stresses, springback, or similar elastic-strain-dependent variables. Furthermore, since the formulation assumes a pseudoelastic behavior in the rigid parts of the workpiece, friction in these parts may be modeled incorrectly [11.15].

The rigid-plastic formulation is based on Markov's variational principle, which holds only for rigid-plastically deforming bodies

$$\Pi(v) = \int_V \sigma_f \dot{\bar{\varepsilon}}\, \mathrm{d}V + \int_V \frac{S}{2}\dot{\varepsilon}_V^2\, \mathrm{d}V - \int_{A_t} \boldsymbol{t}\boldsymbol{v}\, \mathrm{d}A$$
$$\Rightarrow \text{stationary}\,, \tag{11.43}$$

where Π is the functional, $\boldsymbol{v}$ is the velocity vector of material particles, $\dot{\varepsilon}_V$ is the volumetric strain rate, $\boldsymbol{t}$ is the specified traction acting over the surface A_t of the body, and S is a constant called the penalty factor. The penalty factor term is necessary to impose the volume constancy constraint approximately. Alternatively, the volume constancy constraint can be imposed exactly by using a Lagrange multiplier λ.

It can be shown that the hydrostatic stress is given in both cases by

$$\sigma_H = S\dot{\varepsilon}_V\,,$$
$$\sigma_H = \lambda\,. \tag{11.44}$$

These functionals can be easily discretized by assuming shape functions for the velocities over the element domain.

After the standard discretization procedure, the resulting finite element equations read

$$\left(\mathbf{K}_D^e + \mathbf{K}_H^e\right)\boldsymbol{v}^e = \boldsymbol{f}^e\,, \tag{11.45}$$

where $\boldsymbol{f}^e$ is the nodal force vector of the element compatible with the nodal velocity vector $\boldsymbol{v}^e$. The nonlinear deviatoric stiffness matrix is given by $\mathbf{K}_D^e$, and the linear hydrostatic stiffness matrix by $\mathbf{K}_H^e$. The resulting nonlinear (w.r.t. nodal velocities) equations (11.45) can be solved by using standard numerical methods. The common ones applied are the direct iteration and Newton–Raphson methods. Both methods are iterative and are applied in increments. The time integration is performed explicitly in most commercial software.

Implicit Static Elastoplastic Finite Element Formulations

These formulations usually assume an additive composition of the elastic and plastic strain rate tensors

$$\dot{\boldsymbol{\varepsilon}}_{ij} \approx \dot{\boldsymbol{\varepsilon}}_{ij}^{\mathrm{el}} + \dot{\boldsymbol{\varepsilon}}_{ij}^{\mathrm{pl}}\,. \tag{11.46}$$

This is based on so-called hypoelastic models. Models based on hyperelasticity are also used, leading to a multiplicative split of the elastic and plastic deformations. The generalized Hooke law is used for the elastic strain rates, and the Levy–Mises equations for the plastic strain rates. These then lead to the modified Prandtl–Reuss equations between the objective (frame-invariant) rate of the stress tensor and the strain rates

$$\hat{\boldsymbol{\sigma}}_{ij} = \mathbf{C}_{ijmn}\dot{\boldsymbol{\varepsilon}}_{mn}\,. \tag{11.47}$$

Various types of objective rates can be used, such as the Jaumann rate, the Truesdell rate, or generally any Lie derivative of the true stress tensor. The constitutive fourth-order tensor contains the elastic constants and the plastic properties such as the normal of the flow surface and the slope of the flow curve. For consistent linearization, (11.47) has to be modified slightly.

The elastoplastic field equations are derived from the principle of virtual work, giving (neglecting inertial forces)

$$\int_V \boldsymbol{\sigma}_{ij}\,\delta\left(\frac{\partial u_j}{\partial x_i}\right)\mathrm{d}V - \int_A t_i \delta u_i\,\mathrm{d}A = 0\,. \tag{11.48}$$

Equation (11.48) must be fulfilled in the unknown current configuration. Linearization of this equation about the last known state and space discretization yield the nonlinear finite element equations. Time integration is performed primarily implicitly.

Explicit Dynamic Elastoplastic Finite Element Formulations

The explicit dynamic finite element formulations are based on the virtual work principle, to which an inertia term is added

$$\int_V \boldsymbol{\sigma}_{ij}\,\delta\left(\frac{\partial u_j}{\partial x_i}\right)\mathrm{d}V - \int_A t_i\delta u_i\,\mathrm{d}A + \int_V \rho\ddot{\boldsymbol{u}}_i\delta u_i\,\mathrm{d}V = 0\,, \tag{11.49}$$

where $\ddot{\boldsymbol{u}}_i$ is the acceleration vector and ρ is the density. Discretization of (11.49) leads to

$$\mathbf{M}\ddot{\boldsymbol{u}} = \boldsymbol{F} - \boldsymbol{I}\,, \tag{11.50}$$

where $\mathbf{M}$ is the mass matrix, $\boldsymbol{F}$ is the external force vector, and $\boldsymbol{I}$ is the internal force vector at the current time. Time discretization using a central difference scheme and the addition of a damping term C gives the fundamental equations for the formulation

$$\left[\frac{1}{(\Delta t)^2}\mathbf{M}\right]\boldsymbol{u}^{t+\Delta t} = \boldsymbol{F}^t - \boldsymbol{I}^t + \left(\frac{\mathbf{M}}{2\Delta t} - C\right)\left(\frac{\boldsymbol{u}^t - \boldsymbol{u}^{t-\Delta t}}{\Delta t}\right), \quad (11.51)$$

where Δt is the time increment for the computation, which must satisfy the stability condition

$$\Delta t \leq \frac{L}{c_\mathrm{d}}, \quad (11.52)$$

where c_d is the current dilatational wave speed (the speed of sound) in the material and L is the characteristic element dimension, which can be taken as the minimum distance between any two nodes of an element. The elastic wave speed can be found from

$$c_\mathrm{d} = \sqrt{\frac{2G(1-\nu)}{(1-2\nu)\rho}}. \quad (11.53)$$

11.3 Bulk Forming Processes

This section describes the basic bulk forming processes.

11.3.1 Upsetting

A workpiece with initial diameter d_0 and initial height h_0 is reduced between two flat dies to a specimen with final diameter d_1 and final height h_1 (Fig. 11.25). This process is also called open die forging or free forming.

Due to the friction between the dies and the workpiece, the workpiece bulges. The upsetting process is used as a material characterization process and as a production process in various forms. The basic parameters characterizing the process are the ideal equivalent plastic strain

$$\bar{\varepsilon} = \ln\left(\frac{h_0}{h_1}\right), \quad (11.54)$$

the upsetting ratio

$$s = \frac{h_0}{d_0}, \quad (11.55)$$

the relative height reduction

$$e = \frac{\Delta h}{h_0} = \frac{h_0 - h_1}{h_0}, \quad (11.56)$$

and finally the ideal equivalent plastic strain rate

$$\dot{\bar{\varepsilon}} = \frac{\mathrm{d}\bar{\varepsilon}}{\mathrm{d}t} = \frac{v_\mathrm{tool}}{h}, \quad (11.57)$$

where v_tool is the tool velocity (precisely the velocity difference between the upper and lower dies).

Utilizing elementary plasticity theory (slab method), the axial, radial, and tangential stresses can be found for Coulomb friction as

$$\sigma_z(r) = -\sigma_\mathrm{f} \mathrm{e}^{\frac{2\mu}{h}\left(\frac{D}{2}-r\right)} \approx \underbrace{-\sigma_\mathrm{f}\left[1 + \frac{2\mu}{h}\left(\frac{D}{2}-r\right)\right]}_{\text{after a Taylor's series expansion}},$$

$$\sigma_r(r) = \sigma_\theta(r) = \sigma_z(r) + \sigma_\mathrm{f} \approx \underbrace{-\sigma_\mathrm{f}\left[\frac{2\mu}{h}\left(\frac{D}{2}-r\right)\right]}_{\text{after a Taylor's series expansion}}, \quad (11.58)$$

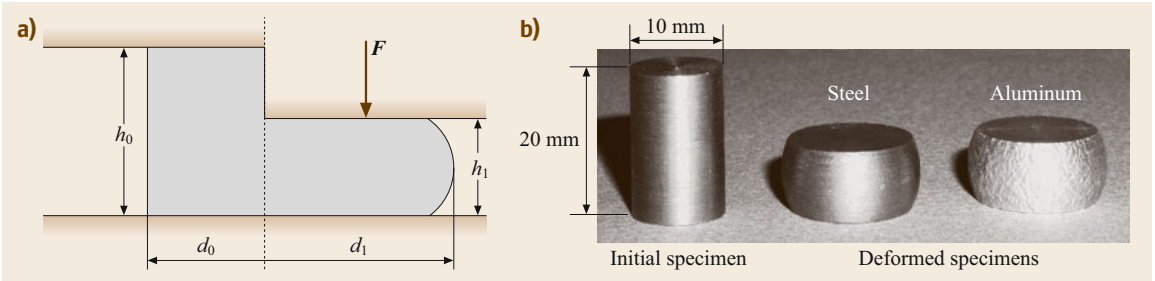

Fig. 11.25 (a) Principle of upsetting process, (b) application examples

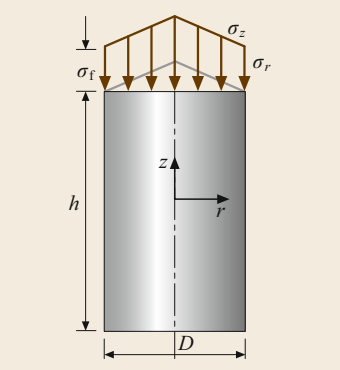

Fig. 11.26 Stresses in upsetting

and for the constant shear friction model

$$\sigma_z(r) = -\sigma_f\left[1 + \frac{m}{\sqrt{3}}\frac{D}{h}\left(1 - \frac{r}{D/2}\right)\right],$$
$$\sigma_r(r) = \sigma_\theta(r) = -\sigma_f\frac{m}{\sqrt{3}}\frac{D}{h}\left(1 - \frac{r}{D/2}\right). \quad (11.59)$$

The stress distribution is shown in Fig. 11.26 for the linearized Coulomb friction model. The upsetting force at a given height is

$$|F_z| = -\int_A \sigma_z \, dA \approx \frac{\pi}{4}D^2\sigma_f\left(1 + \frac{1}{3}\mu\frac{D}{h}\right). \quad (11.60)$$

Figure 11.27 shows a typical force–displacement curve for upsetting. The steep increase of the force towards smaller specimen heights is characteristic of upsetting.

Cold upsetting has the process limits shown in Fig. 11.28. These limits consist of the formability of the workpiece material characterized by a maximum height reduction of 80%, the buckling limit given by the maximum upsetting ratio of 2.3, and finally the tool load limit. The buckling limit can be increased by

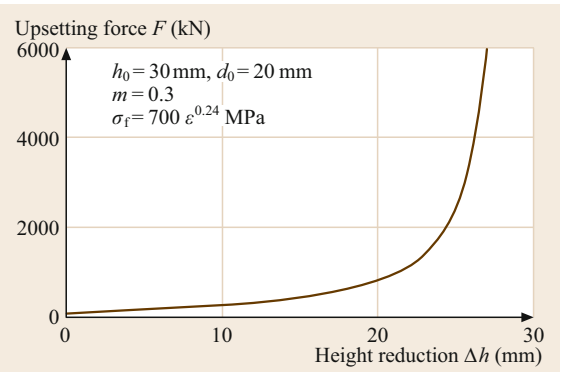

Fig. 11.27 Force–displacement curve in upsetting

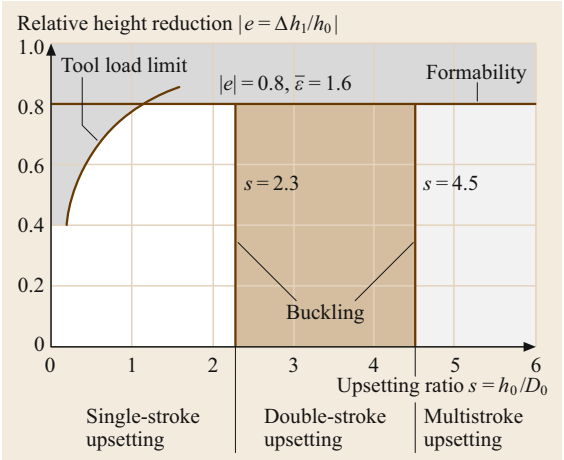

Fig. 11.28 Process limits of cold upsetting (after [11.1, 16])

upsetting in multiple strokes. So, for a two-stroke process, the upsetting ratio can be increased to 4.5, for instance. Formability limits are characterized by two types of cracks: shear cracks in the upset part and longitudinal cracks (basically due to initial faults in the workpiece).

For heading, i.e., the upsetting of one end instead of all of the workpiece, Fig. 11.29 shows the three-step process necessitated by the buckling forming limit. Note that the last step is no longer an open die process.

The design rules for the preforms during head upsetting are given in Fig. 11.30.

The accuracy achieved during cold upsetting depends on the conditions of the forming tools and machines. Wear of the tools is hereby an important issue. Table 11.6 presents some typical accuracy values for a reasonable number of parts formed.

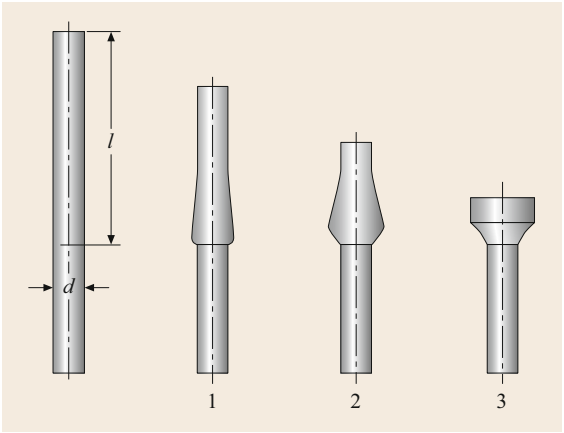

Fig. 11.29 Heading in three steps, upsetting ratio $s = l/d = 7$ (after [11.16])

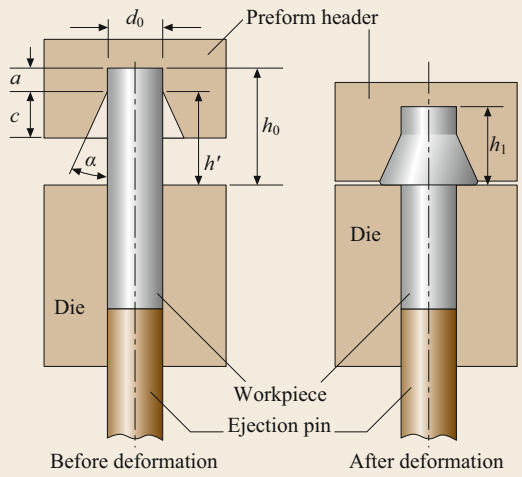

Pre-upsetting design

Upsetting ratio $s = h_0/d_0$	Cone angle 2α (°)	Guide length a (mm)	Conical portion c (mm)
2.5	15	0.6 d_0	1.37 d_0
3.3	15	1.0 d_0	1.56 d_0
3.9	15	1.4 d_0	1.66 d_0
4.3	20	1.7 d_0	1.56 d_0
4.5	25	1.9 d_0	1.45 d_0

Fig. 11.30 Preform design (after [11.17])

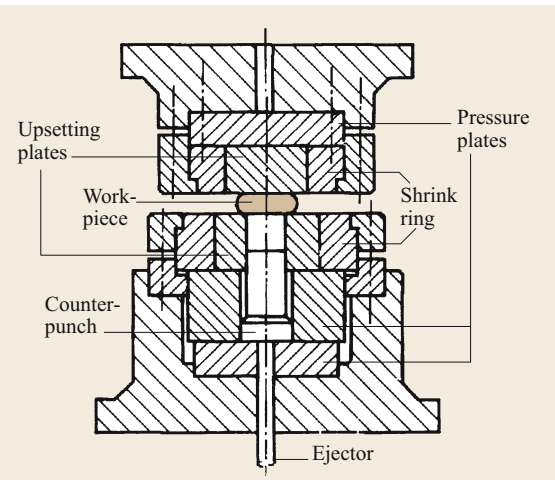

Fig. 11.31 Sketch of a typical upsetting tool (after [11.16])

A typical tool construction is shown in Fig. 11.31. The die is usually supported by a shrink ring to increase its load-carrying capacity. The basic tool materials are presented in Table 11.7, together with their hardness values.

11.3.2 Forging

Forging processes can classified be basically into two groups: open-die forging and closed-die forging (Fig. 11.32). In open-die forging, the dies have simple geometries (usually flat) and the process is conducted hot. This process primarily serves to produce preforms for subsequent forming processes by reducing or increasing the cross-section of the workpiece. Upsetting is a fundamental process of open-die forging.

The basic closed-die forging process is impression forging, in which a flash is produced and must be separated from the workpiece after forging [11.19]. The processes of fullering and gathering are used as preform processes before impression die forging. A typical impression-forged product is shown in Fig. 11.33.

A typical closed die for forging (Fig. 11.34) consists of upper and lower die parts. These parts form the forging cavity and the flash cavity, separated by the parting line. A gutter is placed at the end of the flash land to collect the excess material. The forging cavity consists of webs and ribs. The flash is an important element in forging and controls the filling of the die. Furthermore, it serves as a means to compensate excess material. On the other hand, it is also a source of waste material in forging and should be kept as small as possible.

The force–displacement characteristics during closed-die forging exhibit three regions (Fig. 11.35): Until point P_1, the workpiece in the cavity is upset and then widens. At point P_1, the flash starts to form and hence the resistance to material flow increases, leading to the rising of the material, during which the form of the die cavity is filled. At P_2, the die cavity fills and additional load is applied to close the dies finally. The necessary forming work is the shaded area under the load–displacement curve. This work has to be supplied as the forming energy by the forming machine.

The effect of the flash dimensions is twofold (Fig. 11.36): Increasing the flash–land length-to-thickness ratio (b/s) will increase the braking effect of the flash and hence the stress $\sigma_{z,\max}$ in the die–workpiece contact zone, so that the forging force $\boldsymbol{F}$ will increase. However, at the same time, the excess mass Δm flowing into the die or gutter decreases the required forming energy W. In the given example, for a flash–land ratio of 4.5, there is nearly no change in the excess material, so the minimum forging energy is obtained for a die-to-land ratio of 4–5.

Table 11.6 Typical accuracy during mass production by upsetting (after [11.18])

Nominal dimension (mm)	5	10	20	30	40	50	100
Head height accuracy (mm)	0.18	0.22	0.28	0.33	0.38	0.42	0.50
Head diameter accuracy (mm)	0.12	0.15	0.18	0.20	0.22	0.25	0.30

The stress distribution for axisymmetric forgings given by elementary plasticity theory resembles the stress distribution in upsetting (Fig. 11.37). The maximum stress occurs at the center of the part and is higher for wider flash–land ratios.

The maximum forging force can be estimated, for instance, by the upsetting equations as

$$\boldsymbol{F}^{\max} = -\sigma_{\mathrm{f}} \left(1 + 2\mu \frac{b}{s}\right) A_{\mathrm{p}} \,, \tag{11.61}$$

where σ_{f} is the flow stress (Table 11.8, see also [11.22]), μ is the Coulomb friction coefficient (for steel at 1000–1100 °C, $\mu = 0.12$ for lubricated and $\mu = 0.35$ for unlubricated cases), b/s (Table 11.9) is the flash–land ratio, and A_{p} is the total projected area including the flash. The flow stress can be approximated using the temperature and strain rate at the beginning of the process, although the maximum force occurs towards the end. Hence, the strain rate is found as

$$\dot{\varepsilon} = \frac{v}{h_0} \,, \tag{11.62}$$

where h_0 is the initial height of the billet and v is the striking speed of the tool (11.5). Note that, in Table 11.9, the b/s ratio is given for the three basic types of material flow in forging: upsetting, spreading (with large relative motions along the die surface), and rising (filling of the die cavities).

Typical failures in forged products are as follows:

1. Surface defects: These are surface scratches and cracks that are basically due to defects on the sheared surfaces of the billets or flash formation during preforming, as well as imprints of cracks on the die surfaces.
2. Incomplete filling: Due to insufficient initial workpiece mass, inappropriate preforms, inaccurate workpiece positioning, incorrect flash–land ratios, or too high gas pressures of the lubricant, causing the die cavities to not fill completely.
3. Microstructural failures: The basic failure type is insufficient grain flow.

Some of these failures can be removed by subsequent machining operations on the forged products, so such workpieces need not be scrapped.

Basic die failures in forging are shown in Fig. 11.38. Dies are exposed to high temperatures, pressures, and sliding of workpiece materials along their surfaces. Local pressures can reach as high as 1000 MPa or even higher, and they vary with time. The wear is caused by sliding of workpiece materials with relative speeds of up to 50 m/s. The temperature increases from 100–200 to 700–800 °C in extremely short times, with temperatures gradients of 1000–3000 °C/s. These effects lead to failure of dies through wear, thermal fatigue, mechanical fatigue, and plastic deformation.

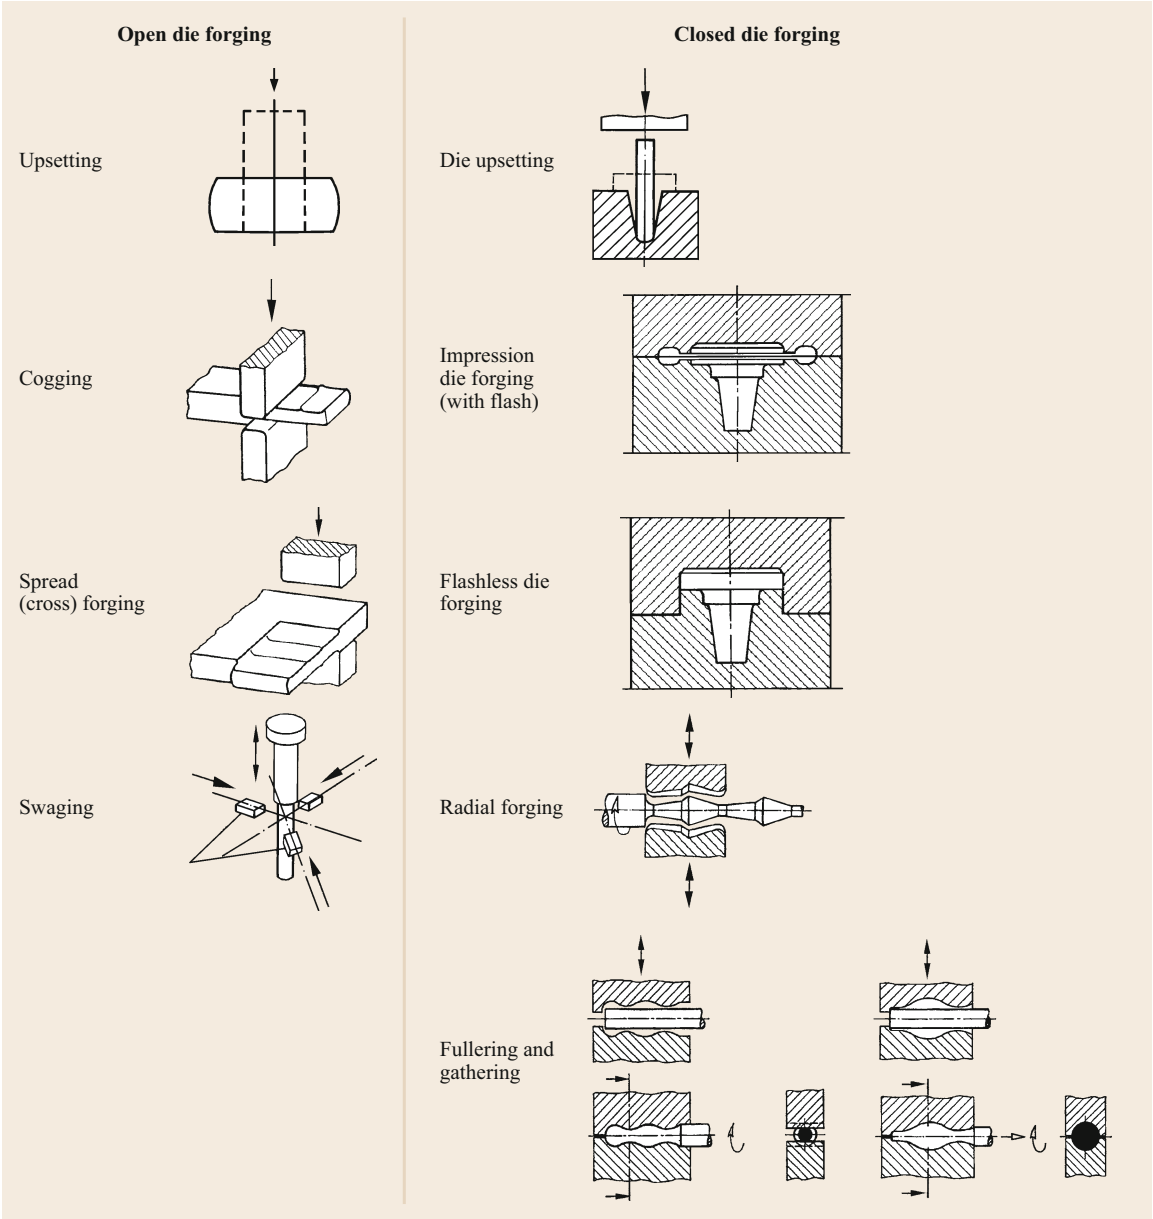

Fig. 11.32 Classification of forging processes

11.3.3 Extrusion

Extrusion processes can be classified according to their technological differences into extrusion, impact extrusion, and reducing (open-die) extrusion. The basic differences between extrusion and impact extrusion are that extrusion aims to produce profiles (semifinished products) whereas impact extrusion aims to produce single parts which are finished products. Furthermore, extrusion is usually performed hot (especially for steel materials almost always), whereas impact extrusion is usually performed cold (therefore also named cold forging). Reducing is extrusion with area reductions less than 25–30%. In this case, there is no deformation of the material in the container. Further classifications can be made according to the workpiece geometry and the relative motion between the tools and workpiece during forming.

Figure 11.39 provides an overview of the principles of various extrusion processes.

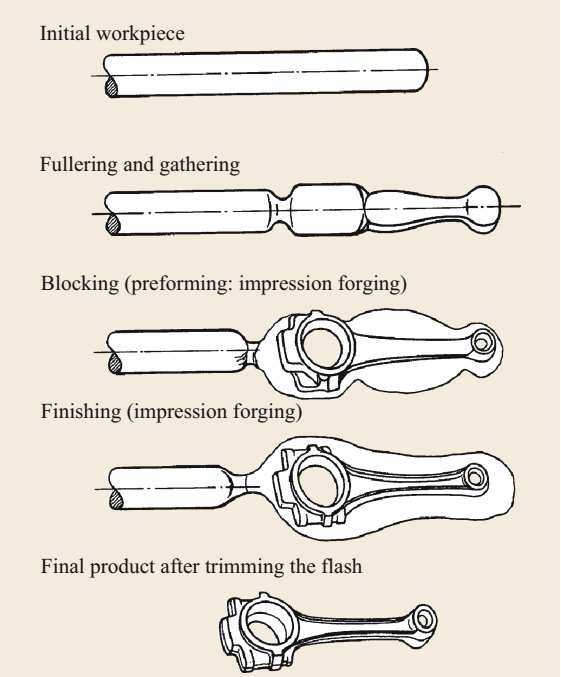

Fig. 11.33 Typical forging sequence (after [11.20])

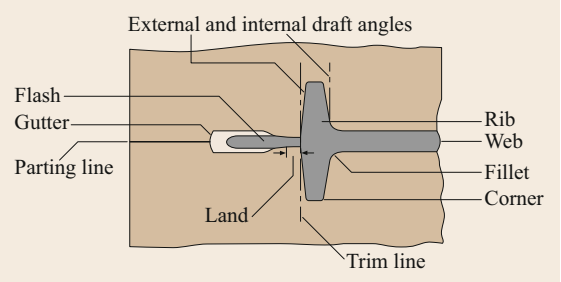

Fig. 11.34 Typical closed forging die (after [11.20]) ◀

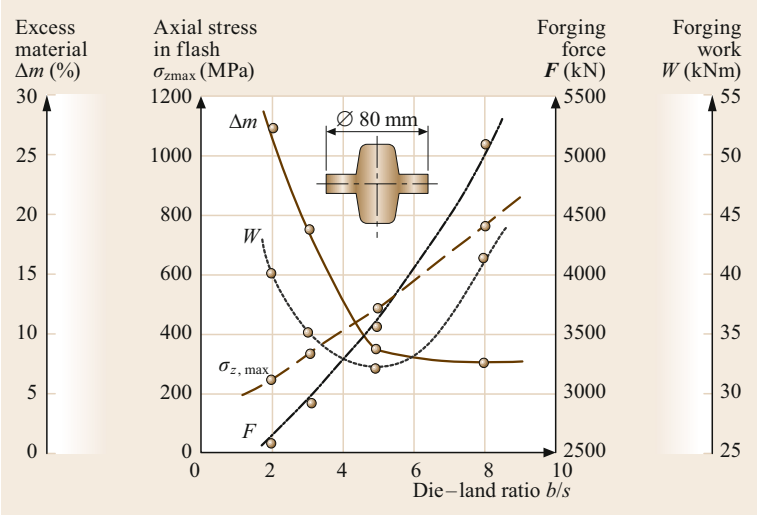

Fig. 11.36 Effect of flash dimensions on forging force and excess material (after [11.16])

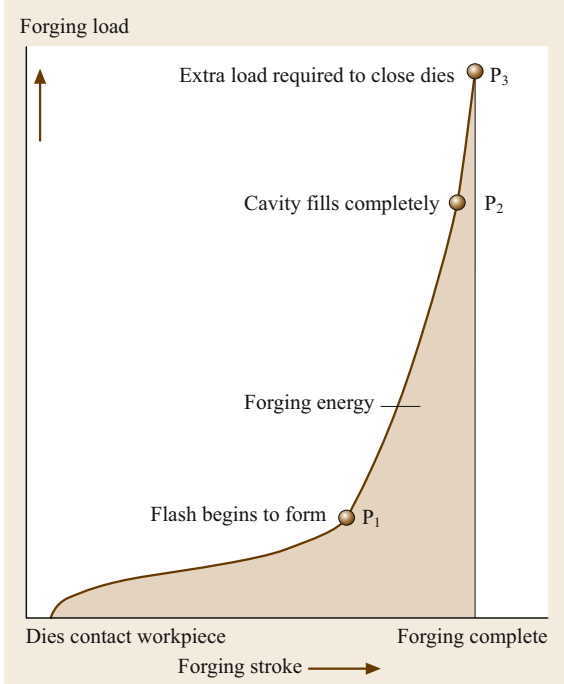

Fig. 11.35 Force–displacement characteristics during impression forging (after [11.21])

In Fig. 11.40, the stress states as estimated by elementary plasticity theory for forward rod extrusion are given. Plastic deformation only occurs in the die-shoulder region, and all stress components are compressive. The workpiece within the container remains basically elastic, as does the extruded rod after exiting the die.

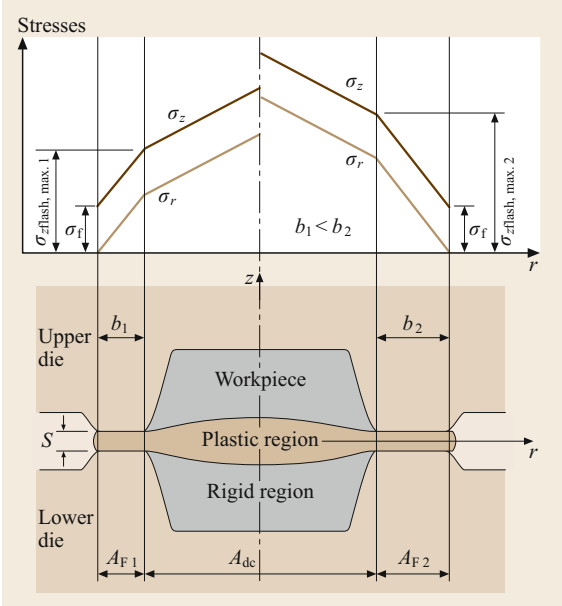

Fig. 11.37 Stress distribution in forging (after [11.16])

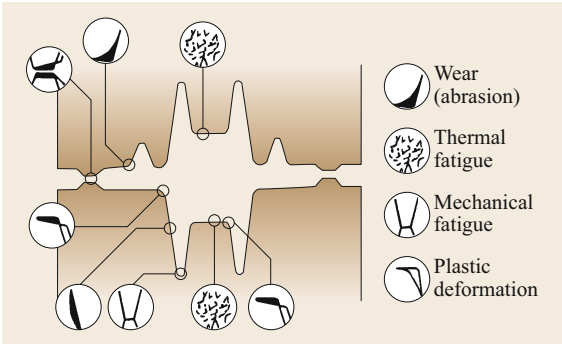

Fig. 11.38 Basic die failures in forging (after [11.16])

The fundamental parameters of the process are defined as the area reduction

$$e = \frac{A_0 - A}{A_0}\,, \tag{11.63}$$

where A_0 and A_1 are the initial and final cross-sectional areas of the workpiece, and the ideal equivalent plastic strain φ

$$\varphi = \ln\left(\frac{A_0}{A} = 2\right) \ln\left(\frac{d_0}{d_1}\right). \tag{11.64}$$

The latter is the plastic equivalent strain at the axis of the extrudate. This strain is the minimum strain across the cross section of the steady-state region of the extruded shaft (Fig. 11.41).

A typical force–displacement curve for the extrusion process is shown in Fig. 11.42. After the process starts at point A, there is a steep increase in force due to the elastic deformation of the billet, followed by its plastification and filling of the die. In many processes, a discontinuity in the curve between A and B can be observed, which is due to the upsetting of the billet in the container (billets are slightly smaller in diameter – by about 0.1–0.2 mm – than the container). The die is filled until point C. There is a local maximum due to the contact between the unlubricated sheared surfaces of the specimens and the die. After point D, the deformation zone in the die shoulder remains steady, so there is only a decrease in the force due to the decrease in the friction forces in the die chamber.

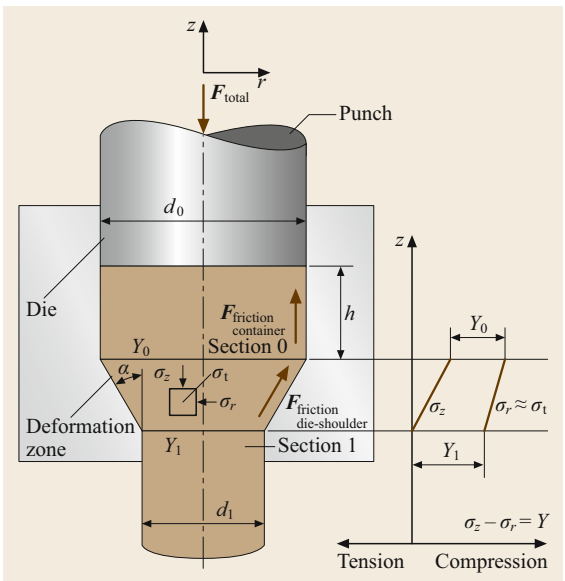

Fig. 11.40 Schematic of forward (impact) extrusion of rods and stress states during extrusion (after [11.16])

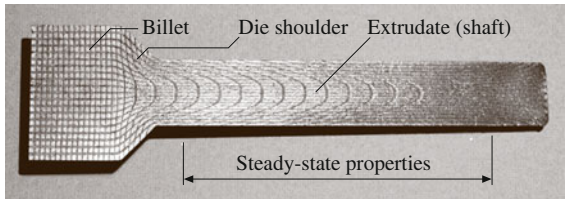

Fig. 11.41 Cross-section of a typical forward rod extrusion product with a deformation grid

The forming forces in extrusion of rods and tubes can be determined by using a model suggested by Siebel. The total extrusion force consists in this case of the following parts

$$F_{total} = F_{ideal} + F_{shear} + F_{friction\ container} + F_{friction\ die\text{-}shoulder} + F_{friction\ mandrel} + F_{friction\ mandrel\text{-}land} \,. \quad (11.65)$$

The force components are described in Table 11.10. Here, σ_{fm} is the mean flow stress in the deformation

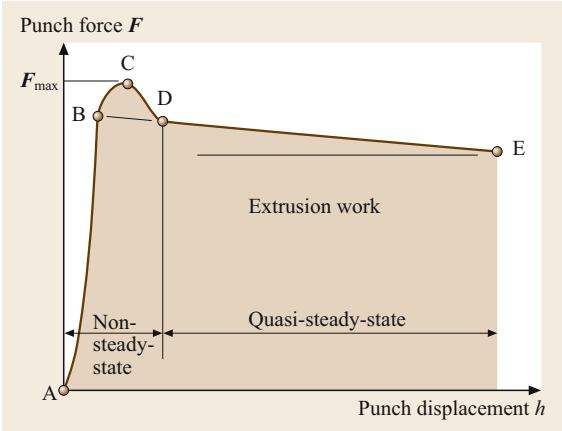

Fig. 11.42 A typical force–displacement curve for forward rod extrusion

zone, given by

$$\sigma_{\mathrm{fm}} = \frac{1}{\varphi_1 - \varphi_0} \int_{\varphi_0}^{\varphi_1} \sigma_{\mathrm{f}}(\varphi)\mathrm{d}\varphi \,. \tag{11.66}$$

μ is the friction coefficient (0.04–0.08 for forward rod extrusion, 0.1–0.125 for tube extrusion), h is the billet length in the container, h_{r} is the length of the die exit land, and p_{r} is the pressure acting between the workpiece and the die (10–12 N/mm^2). For backward extrusion and the open-die container, the friction is zero. For extrusion of profiles, the cone angle 2α is usually 180°. In this case, a dead zone of workpiece material builds up in the die, so that the effective cone angle is $2\alpha = 90°$. This effective angle must be used in all force terms, and the coefficient of Coulomb friction must be taken as 0.5 for the die-shoulder.

The effect of the die cone angle on various force components is shown in Fig. 11.43. The ideal force and the container friction are independent of the cone angle. The shear force increases with the cone angle, whereas the die-shoulder friction is minimum at $2\alpha = 90°$. Hence, the total force assumes a minimum value for the given process parameters at around $2\alpha = 40°$.

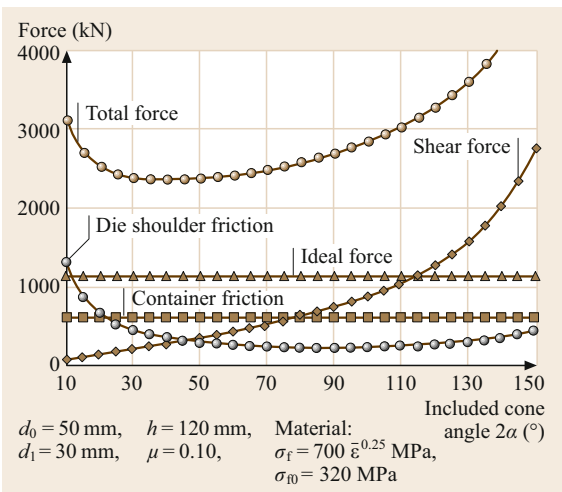

Fig. 11.43 Effect of various parameters on extrusion force

The force for backward can extrusion can be computed using the equation of Dipper (Fig. 11.39)

$$F_{\mathrm{punch}} = A_i\sigma_{\mathrm{f1}}\left(1 + \frac{1}{3}\mu\frac{d_i}{b}\right) + \sigma_{\mathrm{f2}}\left(1 + \frac{\mu + 0.5}{2}\frac{b}{s}\right), \tag{11.67}$$

where A_i is the punch cross-sectional area, μ is the coefficient of friction (0.04–0.08), and the flow stresses

$$\sigma_{\mathrm{f1}} = \sigma_{\mathrm{f}}\left[\varphi = \ln\left(\frac{h_0}{b}\right)\right],$$
$$\sigma_{\mathrm{f2}} = \sigma_{\mathrm{f}}\left[\varphi = \ln\left(\frac{h_0}{b}\right)\left(1 + \frac{d_i}{8s}\right)\right], \tag{11.68}$$

where h_0 is the initial height of the billet.

A simpler but effective equation for the punch load during backward can extrusion was given by Hoogenboom for ideal plastic materials

$$\frac{p}{\sigma_{\mathrm{f}}} = \frac{2+\sqrt{3}}{\sqrt{3}} + \frac{1}{3}\sqrt{\frac{6s + d_i}{s}} \quad \text{early stage},$$
$$\frac{p}{\sigma_{\mathrm{f}}} = \frac{2+\sqrt{3}}{\sqrt{3}} + \frac{1}{2\sqrt{3}}\sqrt{\frac{s}{b} + \frac{b}{s}} \quad \text{late stage}, \tag{11.69}$$

where p is the punch pressure and σ_{f} is the constant flow stress. The early stage is the quasi-steady-state process, whereas the late stage corresponds to the transient de-

Table 11.10 Force computations for rod and tube extrusion (after [11.16])

Process	F_{ideal}	F_{shear}	F_{friction} (container)	F_{friction} (die-shoulder)	F_{friction} (mandrel-die)	F_{friction} (mandrel-land)

formation for a can bottom of

$$\frac{b}{s} < 5.5\frac{A_i}{A_e}\,, \tag{11.70}$$

where A_e is the cross-sectional area of the billet. Other useful equations are given in [11.13].

For workpieces with non-axisymmetric cross sections such as bolts and nuts, the above equations can be applied but replacing the diameters by equivalent diameters corresponding to the cross section of the products.

Typical limits for the various extrusion processes are given in Fig. 11.44. The basic reason for limiting the process is the capacity of the forming presses and the tools. Another limiting factor is the formability of the material.

Typical failures in cold-forged parts are internal and surface ductile cracks as well as galling. Examples of internal cracks are so-called chevron cracks in extrusion (Fig. 11.45). Galling is a type of adhesive wear. Adhesive wear occurs when the tools slide against the workpiece under high pressure after the breakdown of the lubricant. The heat generated due to friction causes microwelds to form between the sliding surfaces. The surface of both the tools and the workpiece may then be damaged.

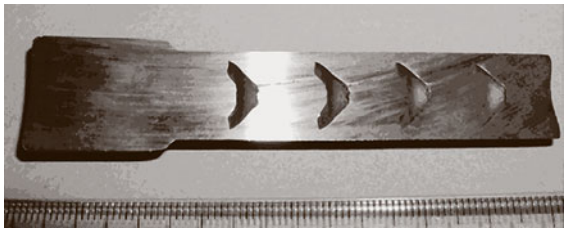

Fig. 11.45 Chevron cracks in cold-extruded rods (material: 100Cr6 (not annealed), $2\alpha = 100°$, $\varphi = 0.25$)

Figure 11.46 shows a typical sequence of processes for cold backward can extrusion. First, a slug is sheared off from a rod. Then, these pieces are phosphated to carry the lubricant under high pressures. The lubricant in this case is soap. An upsetting process is performed to remove the irregular shear surface and act as a centering

Fig. 11.46 Typical process sequences for backward can extrusion

Table 11.11 Typical lubrication procedures (after [11.23])

Process	Deformation	Lubrication
Upsetting	Light	None
		Mi + EP + FA
	Severe	Ph + SP
Ironing and open-die extrusion	Light	Ph + Mi + EP + FA
	Severe	Ph + SP
Extrusion	Light	Ph + Mi + EP + FA
		Ph + SP
		Ph + MoS_2
		Ph + MoS_2 + SP

Mi = mineral oil, SP = soap, EP = extreme pressure additive, Ph = phosphate coating, FA = fatty additives

aid for the main extrusion process. Besides soap, various other lubricants can be possible (Table 11.11). Depending on the degree of deformation, soap or MoS_2 or both with various pressures and fatty additives must be used.

A standard cold-forging tool setup is shown in Fig. 11.47. It consists of reusable parts such as the base plates, pressure plates, intermediate plate, and guides, as well as product-dependent interchangeable parts such as the punch, die insert, and shrink ring. The dies are exposed to radial, tangential, and equivalent stresses, as shown in Fig. 11.48. With no precautions, the maximum internal pressure can be

$$p_i \leq \frac{\text{yield strength of die material}}{2} . \qquad (11.71)$$

By imposing on the die a ring that has a smaller internal diameter than the outer diameter of the inner die, the sustainable internal pressure can be increased to

$$p_i \leq \text{yield strength of die material} . \qquad (11.72)$$

11.3.4 Drawing

Drawing processes can be broadly classified into drawing of solid parts such as rods, wires, or slabs and drawing of hollow parts such as tubes or cans [11.24]. Figure 11.49a,b shows typical wire drawing processes with the associated stress state in the deformation zone.

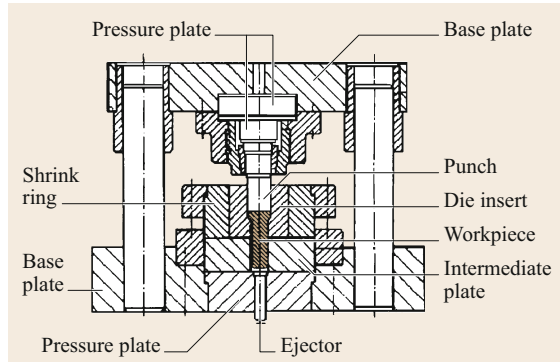

Fig. 11.47 Typical tool setup for cold forward rod extrusion (after [11.23])

Principally, the mechanics of deformation in drawing and extrusion are similar. The only difference is that, in drawing, the external force is applied on the exit side of the die as a tension force, in contrast to extrusion, where this force is applied on the entry side of the die and is compressive. Hence, the axial stresses in drawing processes are basically tensile, in contrast to the compressive ones in extrusion. However, both the radial and circumferential stresses are compressive as in extrusion. In the case of the drawing of tubes, basically two broad categories are recognized: drawing with a mandrel, or drawing without a mandrel. If a mandrel is used, this can be fixed or freely moving, or may have guided movement. One distinct type of tube drawing process is ironing. This is often considered to be a sheet metal forming process, since basically the workpiece is a can obtained by deep drawing. However, in terms of the mechanics of deformation, this process is a typical bulk forming process in which the wall thickness of the can is reduced by drawing it through a die (Fig. 11.49b).

The drawing force can be determined by Siebel's equation

$$F_{\text{total}} = F_{\text{ideal}} + F_{\text{shear}} + F_{\text{friction die-shoulder}} + F_{\text{friction mandrel}} , \qquad (11.73)$$

where the force components are presented in Table 11.12. In the case of ironing, the punch force is

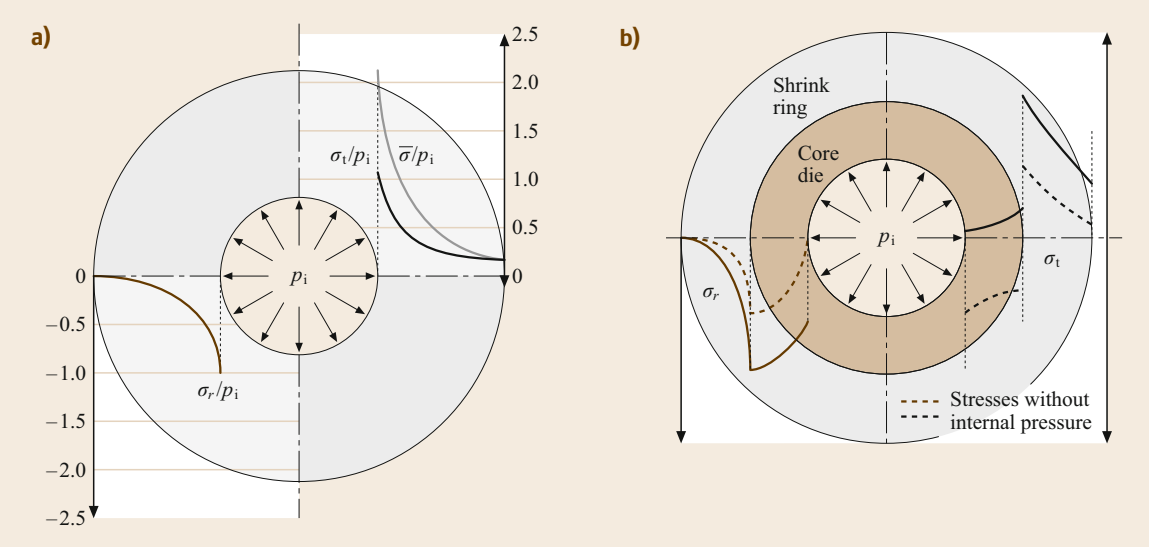

Fig. 11.48a,b Stresses in a die as a function of the internal forming pressure: **(a)** without and **(b)** with a shrink ring

given only by the first three components. However, if the force to be transmitted by the base of the can must be determined, the force due to friction at the mandrel must be taken as negative.

The operating window of the tube drawing process is shown in Fig. 11.50. There are basically three types of failure mode:

1. Rupture of the tube: The basic limitation of the process is that the tensile force must be applied through the formed tube portion. To prevent plastification leading to rupture

$$\sigma_z \leq \sigma_{f1} \,, \tag{11.74}$$

where σ_z is the uniform axial stress at the exit side and σ_{f1} is the mean flow stress at the same side. To ensure the stability of the process, usually the axial stress is taken to be less than 75% of the mean flow stress.
2. Chatter marks: Due to stick–slip effects, the surface of the product shows marks that lower its quality. This defect can be avoided by increasing the stiffness of the workpiece–tool system.
3. Wrinkling: This failure type results from the compressive circumferential stresses in the tubes.

The maximum area reduction for various wire materials during multiple die drawing is presented in Table 11.13.

Wire drawing is basically a cold forming process. Residual stresses in the product are important both for service loading as well as for subsequent processing of the material. Basically, harmful, large tensile resi-

Table 11.12 Force computations for wire and tube drawing (after [11.16])

Process	F_{ideal}	F_{shear}	$F_{friction}$ (die-shoulder)	$F_{friction}$ (mandrel-die)
Wire and bar drawing	$A_1\sigma_{fm}\varphi$	$2/3\tan\alpha\sigma_{fm}A_1$	$2\sigma_{fm}\varphi\mu A_1/\sin 2\alpha$	0
Ironing and tube drawing over fixed mandrel	$A_1\sigma_{fm}\varphi$	$1/2\tan\alpha\sigma_{fm}A_1$	$2\sigma_{fm}\varphi\mu_s A_1/\sin 2\alpha$	$\pm\sigma_{fm}\varphi\mu_M A_1/\tan\alpha$

Table 11.13 Allowable area reduction for wire drawing (after [11.18])

Material	Ultimate strength (MPa)	Initial wire diameter (mm)	Strain φ in each die	Total strain	Number of draws
Steel	400	4–12	0.18–0.22	2.80–4.00	8–21
	1200	4–12	0.18–0.22	3.80–4.00	
	1200	0.5–2.5	0.12–0.15	1.20–1.50	
Cu alloys	Cu (soft)	8–10	0.40–0.50	3.50–4.00	5–13
	250	1–3.5	0.18–0.20	2.00–2.00	
Al alloys	Al (soft)	12–16	0.20–0.25	2.50–3.00	5–13
	80	1–3.5	0.15–0.20	1.50–2.00	

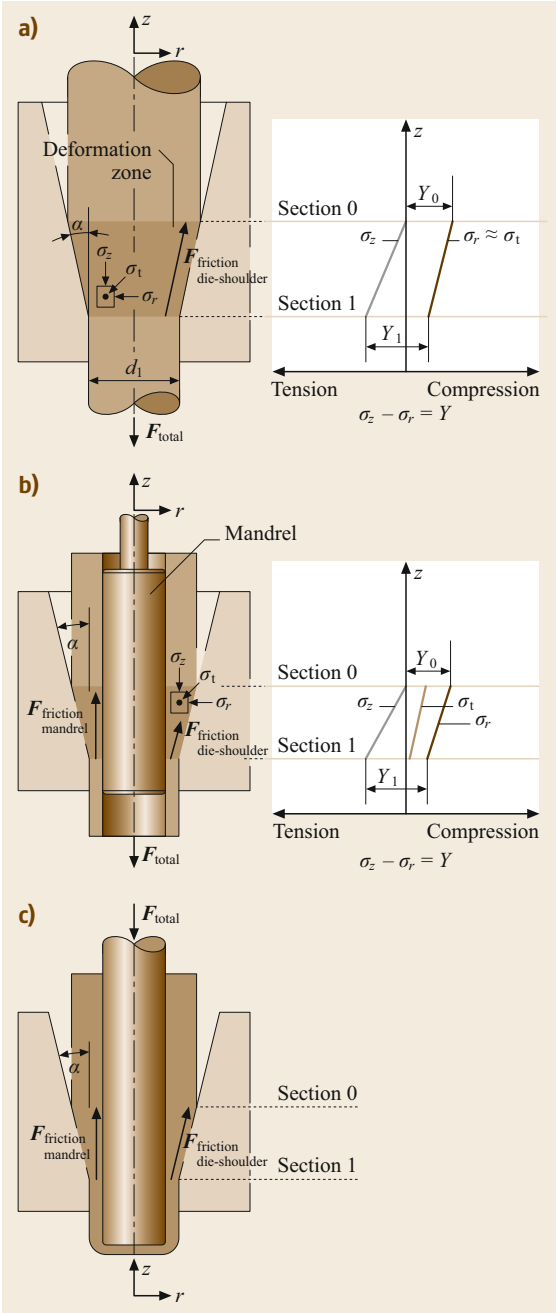

Fig. 11.49a–c Principles of typical drawing processes: **(a)** wire drawing, **(b)** tube drawing, **(c)** ironing

dual stresses are left at the surface of the tube or rod after forming. Therefore, various precautions are suggested to reduce these high tensile residual stresses. One methodology is to use a double-die design in which the second die has a very low area reduction. Figure 11.51 shows the effect of the afterreduction.

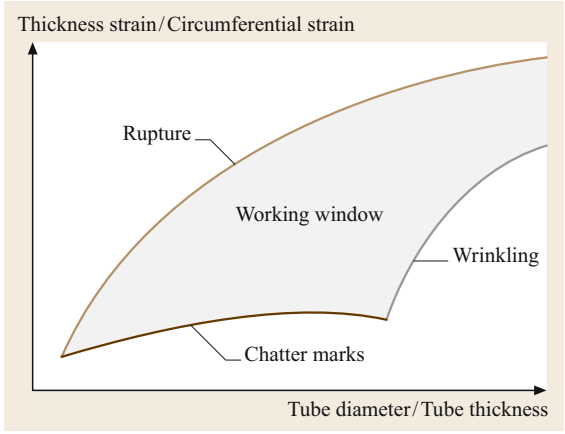

Fig. 11.50 Operating window for tube drawing process (after [11.16])

Through a second low-strain drawing die, the high tensile stresses are reduced from about 550 to 250 MPa.

If the second area reduction is too small, the plastification in the second die will be so low that the residual stress state will not change considerably; if, however, the area reduction is too large, this may cause a high plastic strain that may generate its own residual stress state that may also not be beneficial. Hence, there is an optimum amount of area reduction and also a minimum distance between the two drawing dies.

11.3.5 Rolling

The forming process of passing a workpiece between rotating rolls is called rolling [11.9, 10]. According to the kinematics of the rolls and the workpiece motion, rolling can be classified into three process families (Fig. 11.52). Based on the die geometry, flat rolling (Fig. 11.53a) and profile rolling (Fig. 11.53b) processes can be categorized. The process of reducing the thickness of a slab to produce a thinner and longer but only slightly wider product is referred to as flat rolling, whereas forming by shaped rolls is known as profile rolling. Besides producing continuous products such as slabs, rolling is also used to form discrete parts such as bolts (Fig. 11.54) and rings.

Flat rolling is the basic forming process used to produce plates and sheets. In the initial stages, it is conducted hot. For precision sheets, the final passes are done cold. In both cases, the rolling process generates a typical texture in the products that is the source of anisotropic behavior of sheet products.

The variables of the rolling process are shown in Fig. 11.55. It can be assumed that the width b of the workpiece is large enough such that, during rolling, no widening occurs. At a position s_n, a neutral plane ex-

ists. Before this neutral plane, the workpiece material is slower than the rolls, whereas afterwards, it is faster. To ensure initial grasping of the workpiece by the rolls, the contact angle α must fulfill

$$\alpha \leq \mu \,, \tag{11.75}$$

where μ is the coefficient of Coulomb friction. The mean equivalent strain over the deformation zone is given by

$$\varphi = \ln\left(\frac{h_0}{h_1}\right), \tag{11.76}$$

whereas the mean equivalent strain rate is

$$\dot{\varphi} = \varphi\omega\sqrt{\frac{R}{h_0 - h_1}} \,, \tag{11.77}$$

where ω is the rotational speed of the rolls in rad/s and R is the roll radius.

The vertical component of the pressure on the rolls can be approximated as [11.9]

$$\sigma(x) = \sigma_{\mathrm{fm}}\left(1 + \frac{x^2/R + 2\mu x}{h_1 + x^2/R}\right) \quad \text{for } 0 \leq x \leq s_{\mathrm{n}} \,,$$

$$\sigma(x) = \sigma_{\mathrm{fm}}\left(1 + \frac{2\mu R\,(s-x) - \left(s^2 - x^2\right)}{h_1 R + x^2}\right) \quad \text{for } s_{\mathrm{n}} \leq x \leq s \,. \tag{11.78}$$

The location of the neutral plane is given by

$$s_{\mathrm{n}} = \frac{s}{2}\left(1 - \frac{s}{2\mu R}\right), \tag{11.79}$$

with

$$s = \sqrt{R\,(h_0 - h_1)} \,.$$

The mean flow stress is given in hot rolling for the mean equivalent strain rate and in cold rolling for the mean equivalent strain. The pressure on the rolls assumes a maximum value at the neutral plane (*friction hill*).

The rolling force F is found as

$$F = b\int_0^s \sigma(x)\mathrm{d}x \,. \tag{11.80}$$

The rolling moment M of a single roll is given by

$$M = Fr \,, \tag{11.81}$$

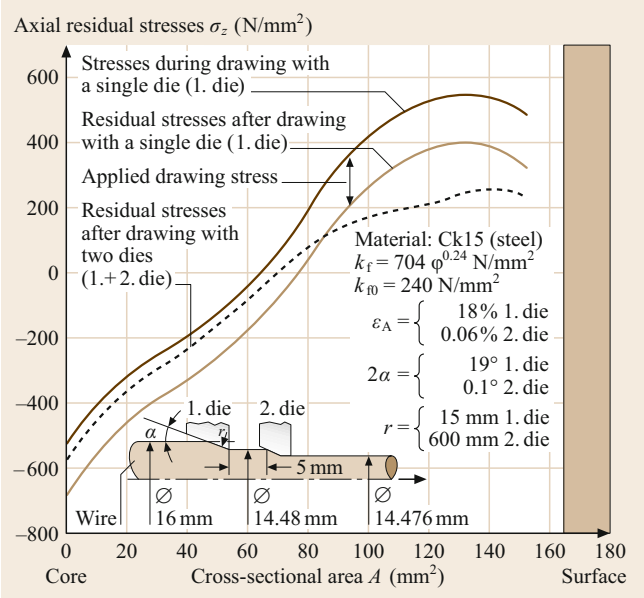

Fig. 11.51 Effect of second drawing die on residual stresses (after [11.25])

where r is the moment arm given by [11.26]

$$r = 0.385s \quad \text{for } \frac{R}{h_1} > 25 \,,$$

$$r = \left[0.78 + 0.017\left(\frac{R}{h_1} - 0.163\sqrt{\frac{R}{h_1}}\right)\right]s \quad \text{for } s \leq 25 \,. \tag{11.82}$$

The power necessary for the rolling process is

$$P = 2M\omega \,. \tag{11.83}$$

The rolls are exposed to a rather uniformly distributed forming load along their axis and hence behave like simply supported beams, bending with a maximum deflection at the center of the roll. To counter this deflection, which may lead to a rolled sheet with varying thickness, rolls are usually cambered, i.e., profiled rather than cylindrical. If the camber is insufficient, the thinner edges elongate plastically more than the center. Hence, in the rolled product, compressive residual stresses are built up at the edges and tensile residual stresses in the center parts (Fig. 11.56). This may also lead to centerline cracking, warping, or edge wrinkling. On the other hand, if the camber is too great, the edge regions are elongated less plastically, leading to tensile residual stresses at the edge region, with edge cracking, centerline wrinkling, and splitting (Fig. 11.57). Roll bending can also be reduced by one or several backup rolls.

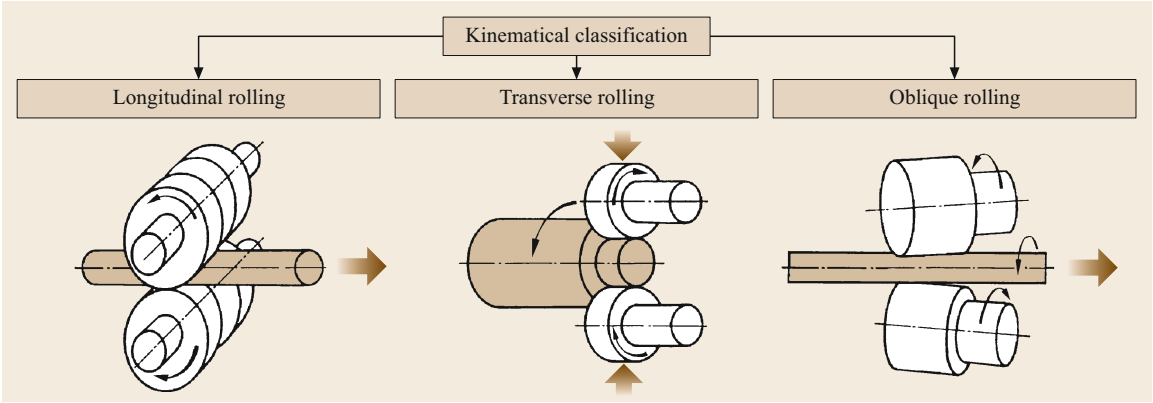

Fig. 11.52 Kinematic classification of rolling processes

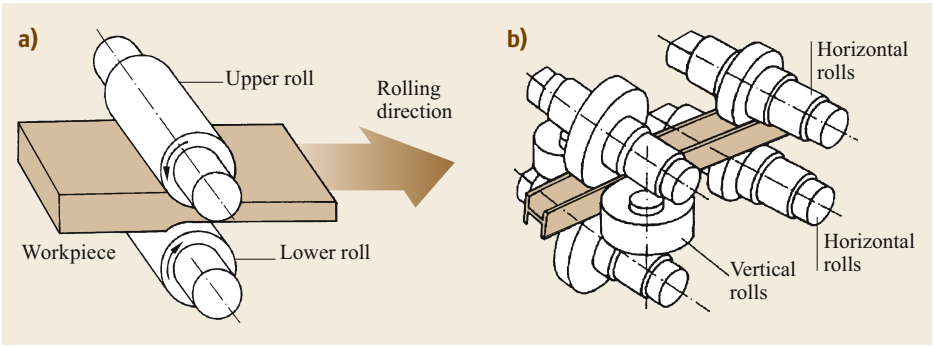

Fig. 11.53a,b Classification of rolling processes by die geometry: **(a)** flat rolling, **(b)** profile rolling

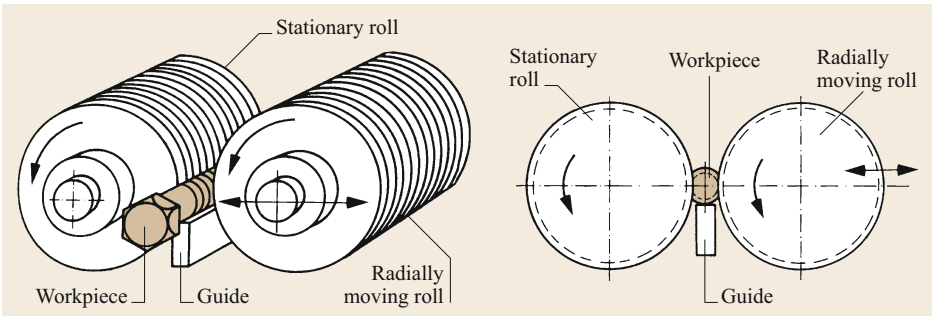

Fig. 11.54 Thread rolling of bolts

Roll flatting is another limiting phenomenon of flat rolling. Due to the elastic deformation of the rolls, there is a minimum thickness of the end product [11.10]

$$(h_1)_{\min} = \frac{C\mu R}{E/(1-\nu^2)}(\sigma_{\mathrm{fm}} - \sigma_{\mathrm{t}}) \,, \qquad (11.84)$$

where C is a factor between 7 and 8, E is the Young's modulus of the roll material, ν is Poisson's ratio, σ_{fm} is the mean flow stress for the deformation zone, and σ_{t} is the front or back tension applied to the rolled sheet. Hence, the minimum thickness that can be rolled can be decreased by decreasing the friction, decreasing the roll diameter, increasing the stiffness of the rolls, decreasing the flow stress, or increasing the back and/or front tension.

Another rolling process is the flow (shear) forming (turning) process (Fig. 11.58). In this process, a flat sheet is formed over a mandrel by means of a shear forming roll that reduces its thickness while keeping its diameter constant. This process should not be mixed with sheet forming process spinning, in which the sheet thickness is more or less constant but the diameter of the initial workpiece is reduced (Fig. 11.10). The final thickness of the workpiece is given by

$$s_1 = s_0 \sin\alpha \,. \qquad (11.85)$$

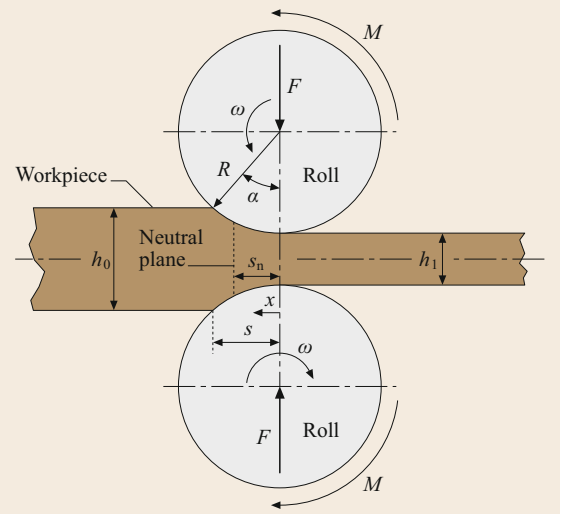

Fig. 11.55 Parameters of flat rolling

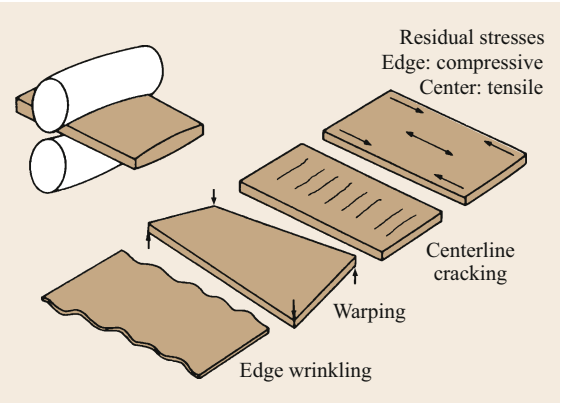

Fig. 11.56 Effects of insufficient camber of rolls (after [11.10])

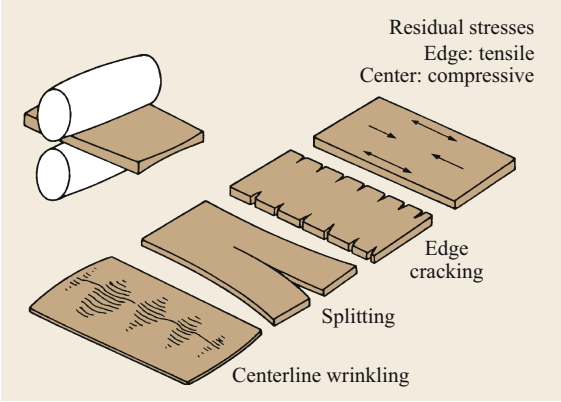

Fig. 11.57 Effects of excessive camber of rolls (after [11.10])

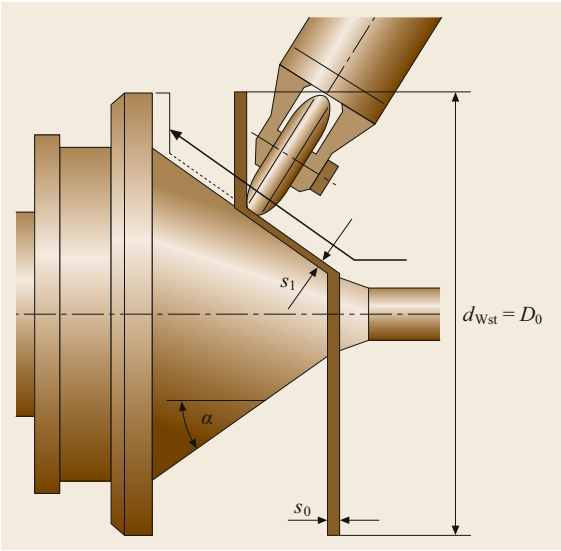

Fig. 11.58 Principle of shear forming

If the final thickness is selected correctly, the plastic deformation is confined only to the roll region, so that the rest of the workpiece remains stress free. The key parameter in this process is the mandrel angle α. This angle must be less than 80° for localized plastic shear deformation and can be at least 12°–18°. Using a second pass, this minimum angle can be reduced to even 8°.

The process of producing cylindrical parts is usually called flow forming, whereas the forming of tapered parts is called shear forming.

11.4 Sheet Forming Processes

11.4.1 Membrane Theory

Approximate analysis of sheet forming processes can be performed using membrane theory [11.27]. Consider an axisymmetrical shell as shown in Fig. 11.59. The principal radii of curvature are in the hoop plane and in the meridian plane.

For thin, plastically deforming shells, the bending moments are negligible, and because of axial symmetry, the hoop (σ_θ) and tangential (σ_ϕ) stresses are principal stresses (Fig. 11.60). The stress normal to the surface can be neglected, so that the resulting stress state is one of plane stress. Friction forces are neglected. Only uniform pressure loads normal to the surface (although

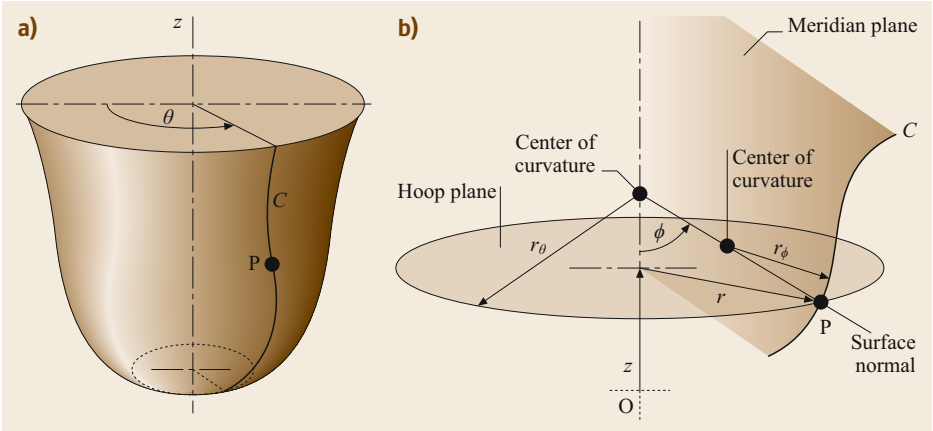

Fig. 11.59 **(a)** Axisymmetrical shell, **(b)** radii of curvature r_θ and r_ϕ

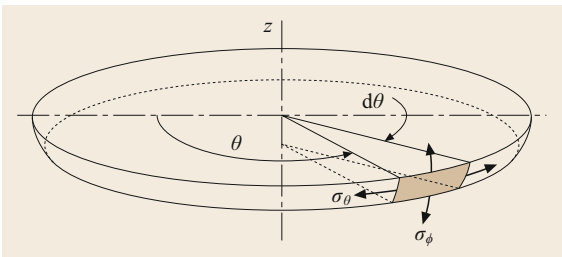

Fig. 11.60 Stress components in a shell

small enough with respect to the flow stress) and uniform edge tensions tangential to the surface are allowed.

It is furthermore assumed that work hardening is compensated by thinning of the sheet, so that the product of flow stress times current thickness is constant

$$\sigma_f t = T_f = \text{const.}\,, \tag{11.86}$$

where T_f is the so-called force resultant.

Finally, the Tresca flow criterion is assumed to be valid, as given in Fig. 11.61.

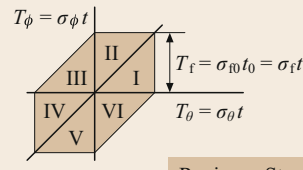
The static equilibrium of forces acting on a typical infinitesimal shell element (Fig. 11.62) supplies in the normal direction to the shell

$$p = \frac{T_\theta}{r_\theta} + \frac{T_\phi}{r_\phi} \tag{11.87}$$

and in the circumferential direction

$$\frac{dT_\phi}{dr} - \frac{T_\theta - T_\phi}{r} = 0\,. \tag{11.88}$$

Equations (11.87) and (11.88) together with the Tresca flow criterion (Fig. 11.61) constitute the framework of the membrane model used to analyze sheet forming processes.



Region	Stress state	Flow condition
I	$T_\theta > T_\phi > 0$	$T_\theta = T_f$
II	$T_\phi > T_\theta > 0$	$T_\phi = T_f$
III	$T_\phi > 0 > T_\theta$	$T_\phi - T_\theta = T_f$
IV	$0 > T_\phi > T_\theta$	$T_\theta = -T_f$
V	$0 > T_\theta > T_\phi$	$T_\phi = -T_f$
VI	$T_\theta > 0 > T_\phi$	$T_\theta - T_\phi = T_f$

Fig. 11.61 Tresca flow criterion in terms of the force resultants

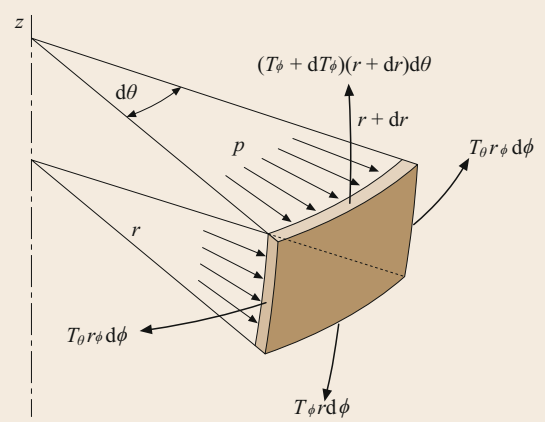


Fig. 11.62 Free body diagram of a typical shell element

11.4.2 Plastic Anisotropy

Characterization of Anisotropy

Grains tend to assume preferred orientations during plastic deformation, since this deformation is achieved by slip or twinning. Such preferred grain orientation will induce a direction-dependent behavior of metals called anisotropy. The most obvious effect of anisotropy is observed in forming of sheets that are produced by rolling. Anisotropy of sheets results in earing at the rim of a deep-drawn product (Fig. 11.84c).

Anisotropy in sheets is characterized by the Lankford parameter or anisotropy coefficient r. It is measured in the simple tension test (Fig. 11.63)

$$r = \frac{\varepsilon_b}{\varepsilon_t} = \frac{\ln(b_1/b_0)}{\ln(t_1/t_0)} , \tag{11.89}$$

where ε_b and ε_t are the true strains in the width and thickness directions. For most metals, the value of r changes with the longitudinal strain, and by convention a longitudinal elongation of 20% is used for comparison purposes.

More importantly, the r-value changes with the orientation of the specimen with respect to the rolling direction. This variation is determined by three r-values obtained from specimens in the rolling direction, transverse to the rolling direction, and at 45° to it. The average r-value, also called the normal anisotropy r_n, is defined as

$$r_n = \frac{r_{0°} + 2r_{45°} + r_{90°}}{4} . \tag{11.90}$$

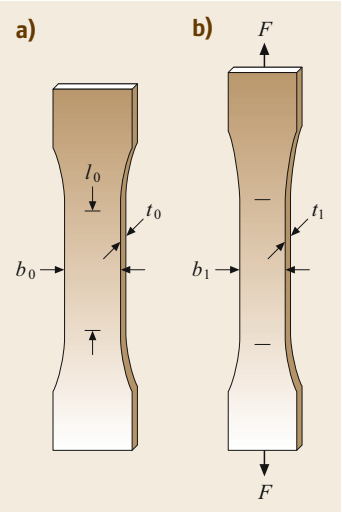

Fig. 11.63a,b Simple tension test of sheet metal: **(a)** undeformed, **(b)** deformed states

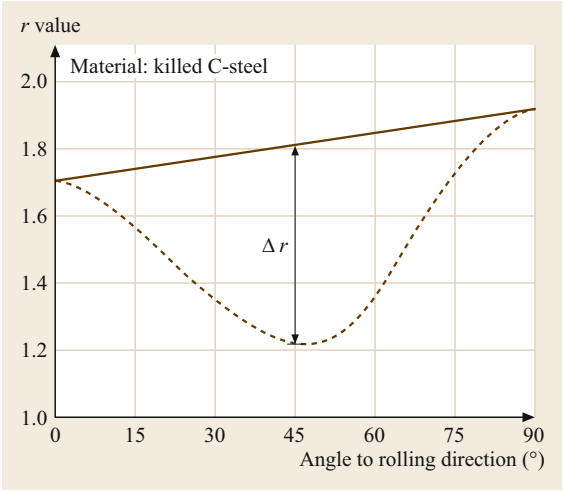

Fig. 11.64 Geometrical interpretation of the planar anisotropy coefficient

Table 11.14 Anisotropy values for various materials

Material	r_n value	Δr
Deep-drawing steels (DC01–DC07; cold rolled)	1.30–2.00	up to 0.70
Stainless steel	0.70–1.10	−0.25 to 0.20
TRIP[a] steels	0.9	about −0.03
Aluminum alloys	0.60–0.80	−0.60 to −0.15
Copper	0.60–0.80	–
Brass	0.80–1.00	–
Zinc alloys	0.20–0.6	–
Titanium alloys	2.00–8.00	up to 4.00

[a] TRIP (transformation induced plasticity) steels

The variation of the r-value over the plane of the sheet is described by Δr, the planar anisotropy coefficient

$$\Delta r = \frac{r_{0°} + r_{90°} - 2r_{45°}}{2} . \tag{11.91}$$

The geometric interpretation of the planar anisotropy coefficient is given in Fig. 11.64.

Typical anisotropy values for various materials are presented in Table 11.14.

The Anisotropic Flow Condition

The first anisotropic flow condition was proposed by *Hill* [11.5]. Neglecting planar anisotropy and assuming plane stress states (which is usually justified for sheet forming processes), the criterion reads in the principal stress configuration as

$$\sigma_1^2 - \frac{2r}{r+1}\sigma_1\sigma_2 + \sigma_2^2 = \sigma_f^2 , \tag{11.92}$$

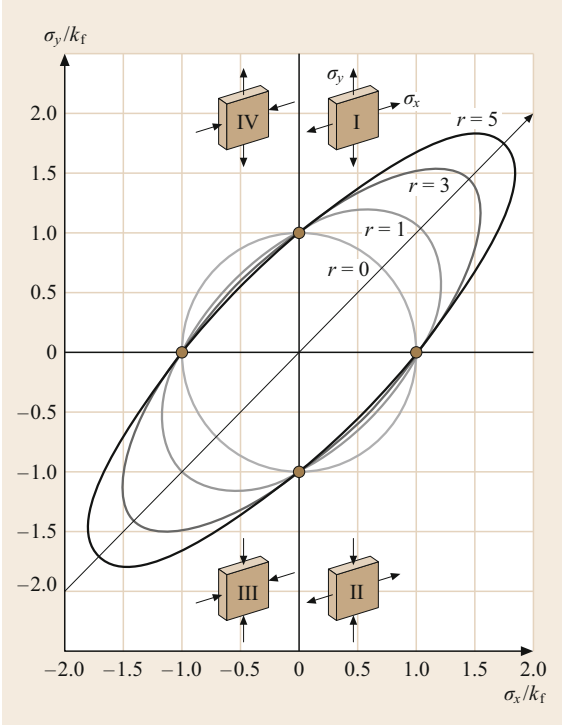

Fig. 11.65 Effect of r value on flow locus

where σ_1 and σ_2 are the in-plane principal stresses and σ_f is the flow stress. The effect of the normal anisotropy value r on the flow locus is shown in Fig. 11.65. For $r = 1$, the standard von Mises ellipse is obtained. For r values larger than 1, the ellipse elongates along the major axis but shrinks along the minor axis. Hence, in the case of biaxial tension or biaxial compression, larger relative stresses are necessary to initiate plastic flow. In the second and fourth quadrants, plastic flow will occur for slightly lower relative stresses than in the isotropic case.

Hill's criterion has proven to be successful for steel, but it fails for aluminum in particular. Also, it can only predict two or four ears in deep drawing, although a different number of ears is also observed for certain materials. Several criteria, also called nonquadratic flow criteria, have been introduced for these reasons. Table 11.15 depicts a few of these. Most of them have been developed basically to model forming of aluminum sheets.

11.4.3 Formability

Basic Failure Modes

Sheet parts can fail under various modes (Fig. 11.66) There are three basic failure types:

1. Wrinkling caused by compressive stresses
2. Rupture/tearing caused by exceeding the capability of the material, usually preceded by necking
3. Surface defects.

Most of the tests used to evaluate the formability of sheet metals in sheet forming operations, and particularly in deep drawing and stretch forming, focus on the fracture failure mode. Fracture usually follows necking, i.e., localized thinning of the metal. Therefore, necking is usually accepted as a failure mode as well.

Necking

Sheets neck under simple tension in two stages: diffuse necking and localized necking (Fig. 11.67); bulk specimens only exhibit diffuse necking. If the material's flow curve is represented by the Ludwik flow curve $\sigma_f = C \times \bar{\varepsilon}^n$, then it can be shown that

$$\text{for diffuse necking:} \quad \varepsilon_1^{\text{necking}} = n\,,$$
$$\text{for localized necking:} \quad \varepsilon_1^{\text{necking}} = 2n\,. \qquad (11.93)$$

Table 11.15 Various nonquadratic anisotropic flow criteria (flow planar isotropy) (after [11.15])

Flow criterion	Equation	Suggested parameter values
Hill 1979	$\lvert\sigma_1+\sigma_2\rvert^m + (2r+1)\lvert\sigma_1-\sigma_2\rvert^m = 2(r+1)\sigma_f^m$	$1.3 \le m \le 2.2$ (for $m = 2$, this criterion reduces to Hill 1948)
Hosford	$\sigma_1^a + r(\sigma_1-\sigma_2)^a + \sigma_2^a = (r+1)\sigma_f^a$	$a = 6$ for fcc metals $a = 8$ for bcc metals
Barlat 1989	$a\lvert k_1+k_2\rvert^M + a\lvert k_1-k_2\rvert^M + (2-a)\lvert 2k_2\rvert^M = 2\sigma_f^M$ $k_1 = \frac{\sigma_x+h\sigma_y}{2},\ k_2 = \left[\left(\frac{\sigma_x-h\sigma_y}{2}\right)^2 + p^2\tau_{xy}^2\right]^{1/2}$	a, h, p, and M are material parameters
Banabic–Barlat 2000	$(m\sigma_1+n\sigma_2)^{2k} + (p\sigma_1+q\sigma_2)^{2k} + (r\sigma_1+s\sigma_2)^{2k} = 2\sigma_f^{2k}$ $m = \frac{-(\sigma_f/\sigma_b)+4}{3},\ n = \frac{(\sigma_f/\sigma_b)-4}{3},\ p = 2\frac{(\sigma_f/\sigma_b)-1}{3},$ $q = \frac{(\sigma_f/\sigma_b)+2}{3},\ r = \frac{-(\sigma_f/\sigma_b)-2}{3},\ s = 2\frac{(\sigma_f/\sigma_b)+1}{3}$	σ_f is the uniaxial flow stress and σ_b is the biaxial flow stress

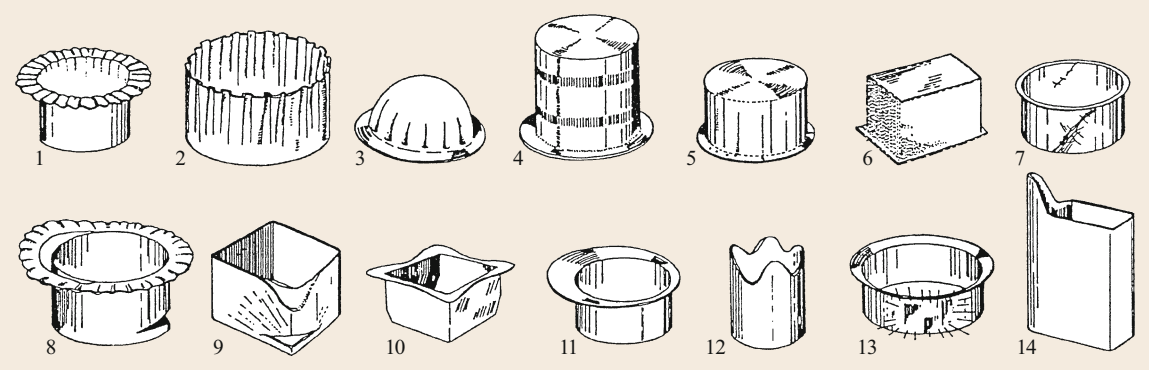

Fig. 11.66 Various failure modes in deep-drawing: 1 – flange wrinkling; 2 – wall wrinkling; 3 – part wrinkling; 4 – ring prints; 5 – traces; 6 – orange skin; 7 – Lüders strips; 8 – bottom fracture; 9 – corner fracture; 10–12 – folding; 13, 14 – corner folding (after [11.15])

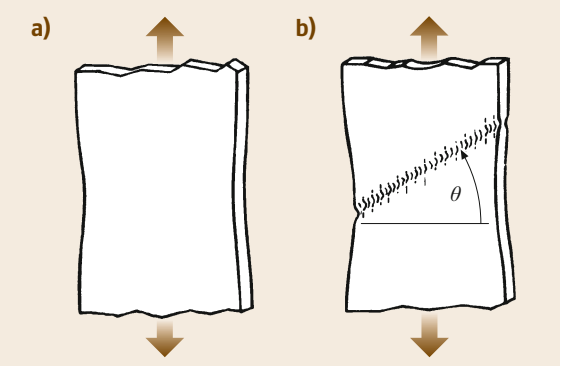

Fig. 11.67a,b Necking of sheet specimens under uniaxial tension: **(a)** diffuse necking, **(b)** localized necking (after [11.10])

If the stress state is not uniaxial, as is the usual case in most sheet forming processes, then the localized necking strain for an isotropic material is given as [11.10, 27]

$$\varepsilon_1^{\text{necking}} = \frac{n}{1 + (\varepsilon_2/\varepsilon_1)} \,. \tag{11.94}$$

The localized necking angle with the tension axis is estimated as

$$\tan\theta = \frac{1}{\sqrt{-(\varepsilon_2/\varepsilon_1)}} \,, \tag{11.95}$$

yielding an angle of 54° for simple tension of an isotropic specimen. For positive ratios of the two principal in-plane strains, no localized necking is possible and only diffuse necking occurs.

Simulative Formability Tests

The Olsen or Erichsen test (Fig. 11.68) was the first test used to evaluate the formability of sheet metals. These

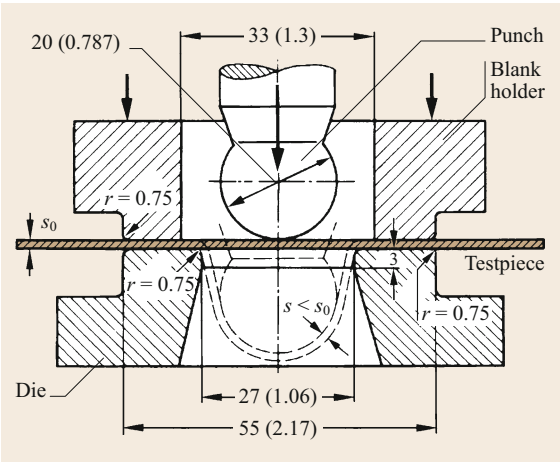

Fig. 11.68 Erichsen test. Dimensions given in mm (inches in parentheses)

two tests only differ slightly in the size of the tools. The principle is to stretch a sheet of metal using a hemispherical punch until fracture is observed. The punch depth in millimeters corresponds to the Erichson index (IE).

Another common test is the limiting dome height test by *Hecker* [11.28] (Fig. 11.69). Hecker's test is an improved Erichson test with larger tools and draw beads to increase the measurement accuracy.

Other tests such as Swift's cup test, the stretch–bend test, the wedge drawing test, the biaxial stretch test, the plane torsion test, hole expansion test etc. have been introduced in practice.

Forming Limit Diagrams

The forming limit diagram (FLD) consists of a curve in the principal in-plane strain space at which either necking starts or fracture is observed. It is basically a material property. Necking is localized in the tension–

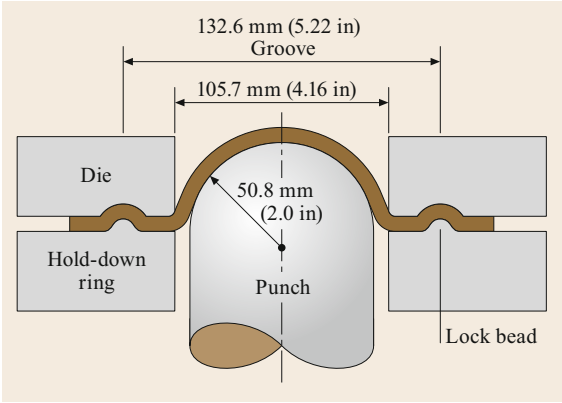

Fig. 11.69 Limiting dome height test by Hecker

compression part and is expected to be diffuse in the tension–tension part (Fig. 11.70). The loading line on the left (dashed line) corresponds to pure shear deformation, the central vertical line to plane strain tension, and the left dashed line to equibiaxial tension. Uniaxial simple tension is seen as a loading line between the left dashed and middle vertical lines.

The FLD provides an efficient and practical method to assess the formability of a sheet product. It is applied in two different manners. *Experimentally*, a circular grid pattern is imposed on the sheet either mechanically, photochemically, or electrochemically. During forming, the circles are deformed into ellipses. The principal strains are assumed to be along the major and minor axes of the ellipses. These minor and major radii of the ellipse are measured either manually or automatically

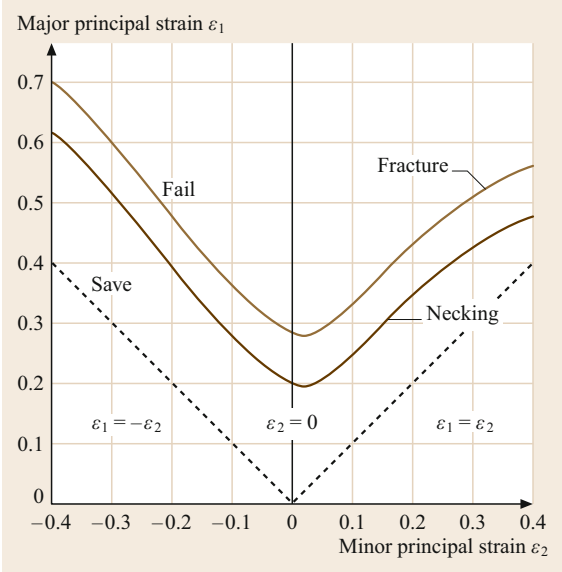

Fig. 11.70 Forming limit diagram for plane stress

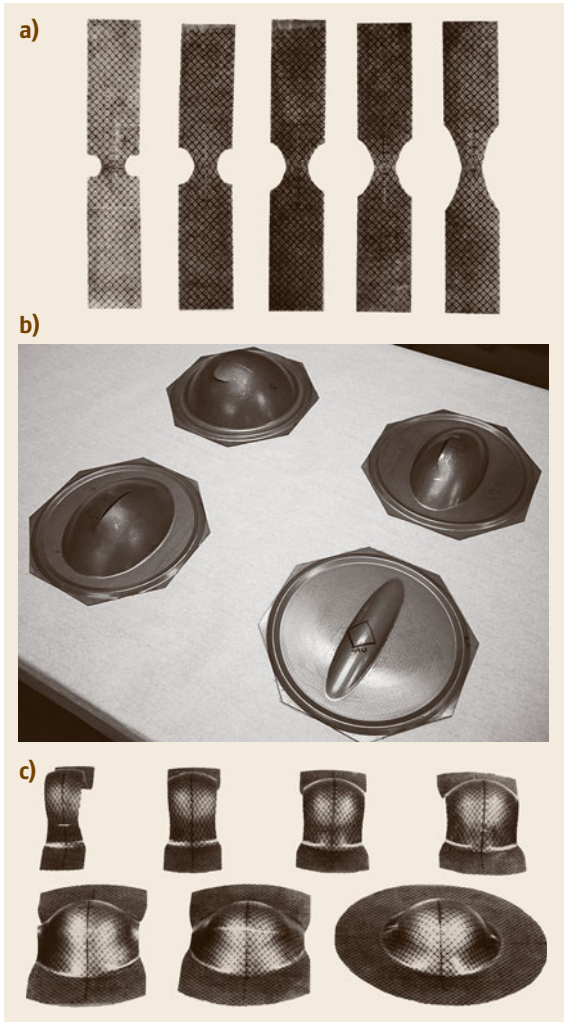

Fig. 11.71a–c Various methods of determining FLD: **(a)** uniaxial tensile test (courtesy V. Hasek), **(b)** hydraulic bulging test (courtesy N. Bay, DTU), **(c)** punch stretching test (courtesy V. Hasek)

by a digital camera. By comparing the measured local strains with the FLD, the range of safety for deep drawing, the critical zones where necking and/or fracture are most likely to occur, the strain level, and the favorable working conditions (blank-holder pressure, lubrication, placement of draw beads, etc.) can be determined, and hence the deep-drawing process can be improved. In this context, a *severity index* ranging from 0 to 10 is introduced, indicating the distance of the measured strain state from the FLD curve. *Numerically*, the analysis of the sheet forming process can be done, for instance, by finite element models before the actual pressing, and the computed strains can be compared with the respective FLD to assess the forming process.

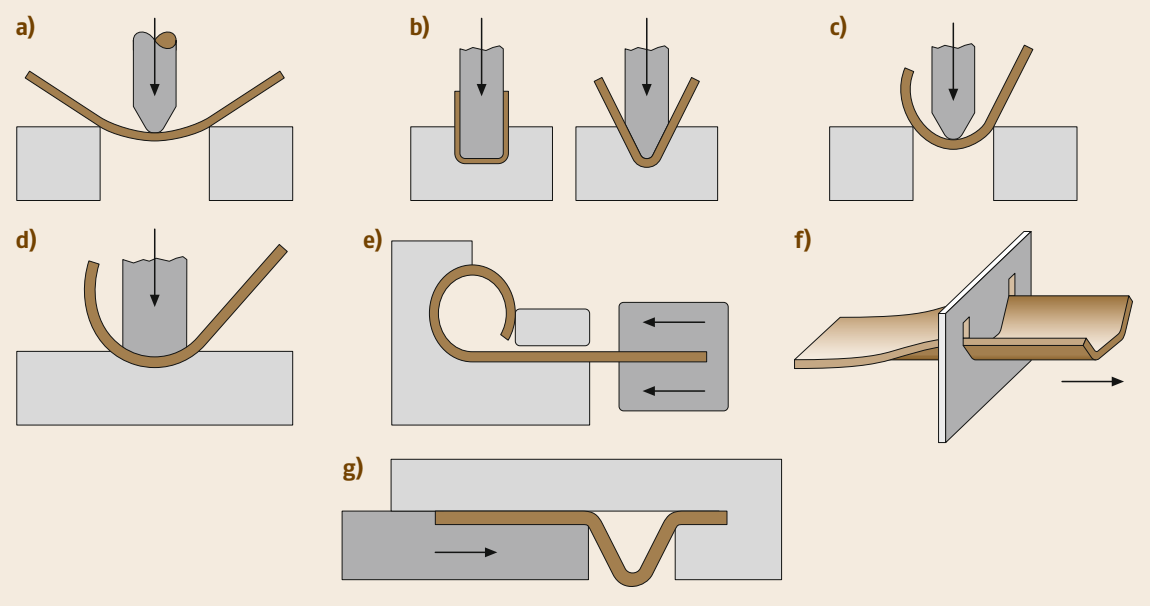

Fig. 11.72a–g Bending with linear tool motion: **(a)** free (air) bending, **(b)** die bending, **(c)** free round bending, **(d)** round bending in a die, **(e)** curling, **(f)** draw bending, and **(g)** bending by buckling

This latter application is basic industrial practice today.

FLDs can be measured using various methods such as the uniaxial tensile test on specimens having various dimensions with and without notches (Fig. 11.71a), the hydraulic bulge test using elliptical dies (Fig. 11.71b), the punch stretching test using strips with various widths (Fig. 11.71c), the Nakazima test (which is similar to the punch stretching test with the difference that the sheet is drawn instead of being stretched), the Hasek test (where circular specimens with various recesses are used), the Marciniak test with hollow punches, etc. Common to all tests is that numerous specimens or die geometries have to be used to simulate various principal strain ratios corresponding to various points on the FLD curve.

Experimentally measured FLDs are not completely material properties; They depend on various other factors. It is known that the FLD curve rises with increasing sheet thickness. Furthermore, it has been noticed experimentally that the failure shows some strain path dependence. Hence, if a tensile load path (meaning a strain path with positive slope in Fig. 11.70) is followed by a compressive load path (negative slope), the failure strain is lower than that predicted by the FLD. On the other hand, if a compressive load path is followed by a tensile one, the failure strain is larger than the FLD strain. Also, the grid size used in the experiments affects the measurements.

11.4.4 Bending

Bending Processes

Basic bending processes can be classified into two broad groups [11.29]: bending by linear tool motion (Fig. 11.72) and bending by rotary tool motion (Fig. 11.73).

In free bending [11.30], there is no contact between the workpiece and the die surface, whereas in die bending the sheet is bent between male and female dies. Free round bending is a continuous free bending process conducted in steps along the bending legs. In curling ,the workpiece is continuously bent by pushing it into a curved die. Bending by buckling is obtained by causing the workpiece to buckle normal to the applied force. The deformation region is limited by either local heating of the workpiece or clamping of the portion of the workpiece not to be deformed. In draw bending, the sheet is shaped by being pulled through a die opening.

Roll bending is achieved by moving the workpiece through the gap created by three adjustable rolls. In roll forming, the sheet is formed into a section between rolls with the form of the section. Folding is bending with a folding wing that folds the workpiece around the bending edge, whereas wiper bending or wiping is bending that creates a full plastic section between a roll and a tool. The section is forced to conform to the roll as the tool is dragged around the roll. In roll straightening, the roll axes can be normal or inclined to the bending

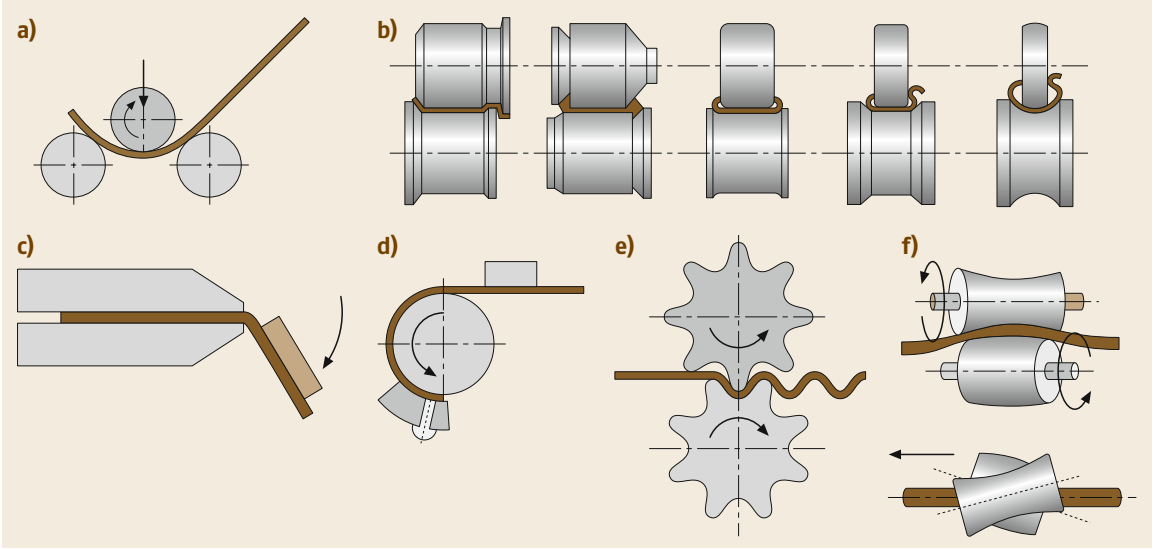

Fig. 11.73a–f Bending with rotary tool motion: **(a)** roll bending (round bending with rolls), **(b)** roll forming, **(c)** folding, **(d)** wiper bending, **(e)** corrugating, and **(f)** roller straightening

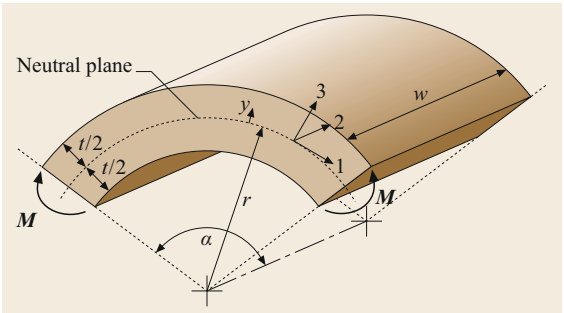

Fig. 11.74 Bending of a strip by pure moments

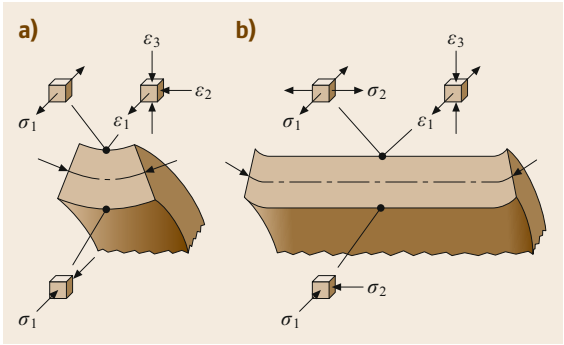

Fig. 11.75a,b Stress and strain states for bending of **(a)** narrow and **(b)** wide strips (after [11.31])

plane. The workpiece is roll bent by corrugated rolls in the corrugating process.

The Mechanics of Bending

If a strip of width w and thickness t is bent by pure moments M at both ends, the strip assumes a curvature with radius r at its neutral axis (Fig. 11.74). The directions 1–3 are assumed as shown in the figure.

The bending strain for any axial fiber is given by

$$\varepsilon_1 = \ln\left(1 + \frac{y}{r}\right), \tag{11.96}$$

where y is the distance of the fiber from the neutral axis having a radius of curvature r. This strain is positive at the upper fibers and negative at the lower fibers.

There are two extreme bending cases [11.31]: If the width of the bent strip w is small compared with its thickness t (Fig. 11.75a), then only bending (axial) stress will develop, hence the stress state will be uniaxial with tensile stresses at the larger-radius side and compressive stresses at the smaller-radius side. The corresponding strain state is therefore

$$\varepsilon_1 = \varepsilon_2 = -\frac{1}{2}\varepsilon_1 . \tag{11.97}$$

Hence, the width of the tension side of the strip will decrease while the width of the compressive side will increase. On the other hand, if the width of the bent strip is much larger than its thickness, then in the middle regions of the strip a plane strain state will develop (Fig. 11.75b) with $\varepsilon_2 = 0$. If furthermore the plane stress state is assumed to have $\sigma_3 = 0$, it can be shown using the flow rule that $\sigma_2 = \sigma_1/2$. For this case of the plastic state, the flow stress and the equivalent strain are related to the axial components by

$$\varepsilon_1 = \sqrt{\frac{3}{2}}\bar{\varepsilon}\,, \quad \sigma_1 = \frac{2}{\sqrt{3}}\sigma_\mathrm{f}\,. \tag{11.98}$$

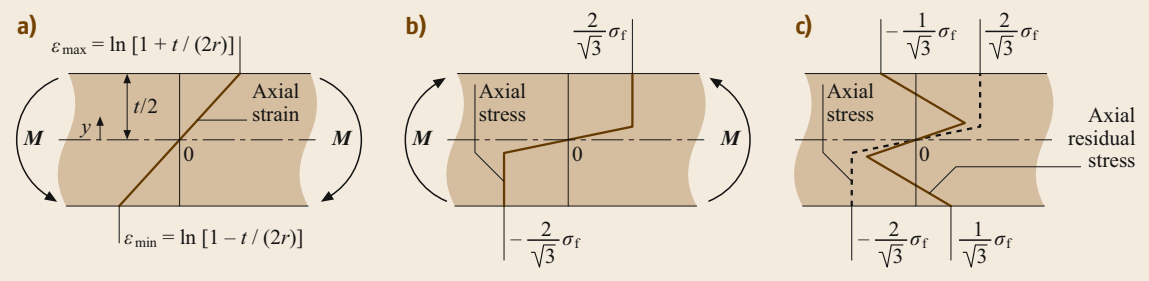

Fig. 11.76 (a) Strains, (b) loading stresses, and (c) residual stresses for a perfectly plastic material during plane strain bending

Even for a wide strip, an uniaxial stress state exists at the ends, leading to a transverse curvature at both ends.

The elastic stress–strain relationship for the plane strain case is given by the generalized Hooke's law as

$$\sigma_1 = \frac{E}{1-\nu^2}\varepsilon_1 \,, \tag{11.99}$$

where E is the Young's modulus and ν is the Poisson's ratio. Introducing the plane strain Young's modulus E', the elastic stress–strain relation becomes

$$\sigma_1 = E'\varepsilon_1 \quad \text{with } E' = \frac{E}{1-\nu^2} \,. \tag{11.100}$$

Figure 11.76a shows the axial strain distribution through the thickness of a strip. The true strain distribution is nearly linear. If the strains are large enough, the material will plastify in the outer regions. Assuming that the material is perfectly plastic and that the strip is wide, in the plastic regions the axial stress will be equal to the flow stress for plane strain as given by (11.98) (Fig. 11.76b). Assuming that the whole cross-section plastifies, the bending moment is given by

$$M = \frac{1}{2\sqrt{3}} W t^2 \sigma_f \,. \tag{11.101}$$

After the moment is removed, the bent part will spring back due to the elastic energy stored during bending (Fig. 11.77). The new radius of curvature will now be

$$r' = \left(\frac{1}{r} - \frac{2\sqrt{3}}{t} \frac{\sigma_f}{E'} \right)^{-1} \,. \tag{11.102}$$

The residual stresses after unloading are given for the plastified region by (Fig. 11.76c)

$$\sigma_1^{\text{residual}} = \frac{2}{\sqrt{3}}\sigma_f \left(1 - \frac{3y}{t}\right) . \tag{11.103}$$

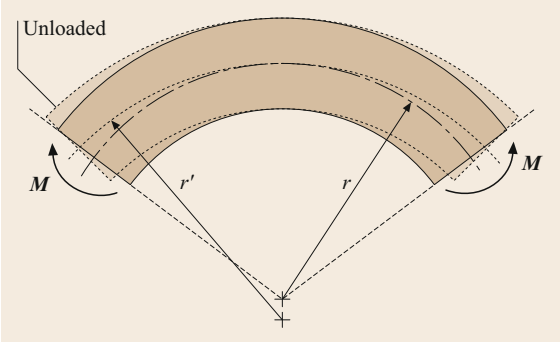

Fig. 11.77 Springback after unloading

The springback factor K_s is defined by

$$\text{springback factor} \equiv \frac{r}{r'} \tag{11.104}$$

and is presented for various materials and two relative bending radii in Table 11.16.

The basic failure mode in bending is fracture at the tensile side of the sheet. The smallest radius to which a sheet can be bent without failure is considered to be

Table 11.16 Springback factor (after [11.32])

Material	Springback factor	
	$r'/t = 1$	$r'/t = 10$

its bendability. The bendability is highest if the bending axis is transverse to the rolling direction.

A typical force–displacement curve for die bending (Fig. 11.72) is shown in Fig. 11.78. The force increases during free bending then starts to drop as the sheet overbends. The steep increase at the end of process occurs when the bent sheet is pressed towards the die by the punch to calibrate the part.

11.4.5 Stretch Forming and Deep Drawing

Industrial sheet forming processes such as the manufacturing of automobile panels involve both stretch forming as well as deep-drawing processes. Stretch forming and deep drawing are similar processes in the sense that they shape a sheet using a rigid punch and a rigid die. On the other hand, they differ fundamentally in the sense that, in stretching, the sheet is fixed at its circumference, and hence the whole in-plane deformation is achieved by thinning of the sheet, whereas in deep drawing the sheet is allowed to be drawn at its circumference so that the shape change of the sheet is achieved under rather unchanged sheet thickness.

Stretch Forming

A circular sheet blank with diameter $2a$ being clamped firmly at its rim is stretched by a spherical punch with radius ρ_p (Fig. 11.79).

Using the membrane equation (11.87), it can be shown that the pressure between the punch and the sheet is

$$p_\mathrm{c} = 2\frac{T_\mathrm{f}}{\rho_\mathrm{p}}\,, \tag{11.105}$$

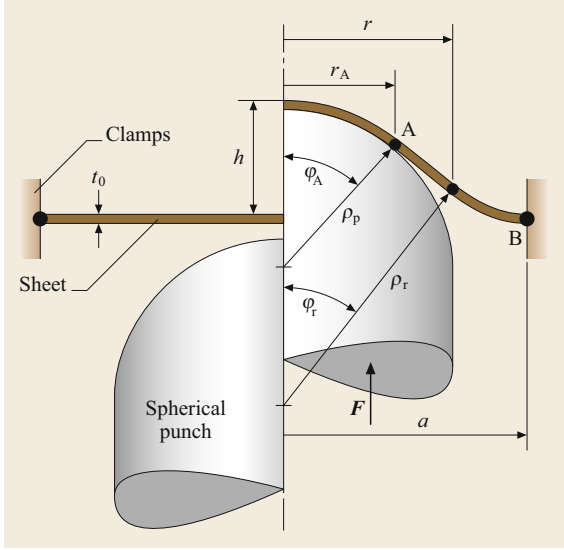

Fig. 11.79 Stretch forming with a spherical punch (after [11.31])

and the punch force for a given contact angle ϕ_A is found as

$$F = T_\mathrm{f}\left(2\pi\rho_\mathrm{p}\right)\sin^2\phi_\mathrm{A}\,. \tag{11.106}$$

Recall that the force resultant T_f is assumed constant and is therefore given as

$$T_\mathrm{f} = \sigma_{\mathrm{f}0}t_0 = \text{const.}\,, \tag{11.107}$$

where t_0 is the initial sheet thickness and $\sigma_{\mathrm{f}0}$ is the initial flow stress.

The shape of the stretched sheet is given by the variable radius of curvature of the unsupported sheet region

$$\rho_\mathrm{r} = \frac{r^2}{r_\mathrm{A}\sin\phi_\mathrm{A}}\,. \tag{11.108}$$

Deep Drawing

In the deep-drawing process, an initially flat sheet (the blank) is formed by a rigid punch into a die cavity (Fig. 11.80). To prevent wrinkling of the blank, a blank holder is usually used. Since the material in the blank is drawn in, the circumferential stresses are compressive here. The strain state at the rim is given by

$$\begin{aligned}
\varepsilon_\theta &= \ln\left(\frac{r_0'}{r_0}\right) \quad \text{(circumferential strain)}\,,\\
\varepsilon_\mathrm{t} &= -\frac{1}{2}\varepsilon_\theta \quad \text{(thickness strain)}\,,\\
\varepsilon_\mathrm{r} &= -\frac{1}{2}\varepsilon_\theta \quad \text{(radial strain)}\,.
\end{aligned} \tag{11.109}$$

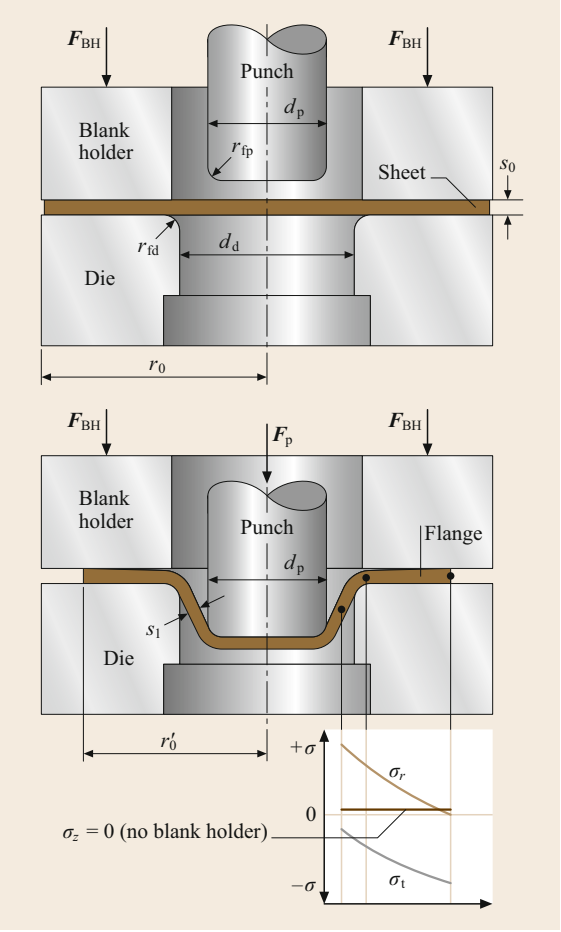

Fig. 11.80 Principle of deep drawing

The wall thicknesses of the drawn cup are given in Fig. 11.81. Assuming that the mean thickness of the cup wall is equal to the initial sheet thickness, the drawn cup height is given as

$$h \approx \frac{r_0^2 - r_m^2}{2r_m} \qquad (11.110)$$

with an error of ±5%.

The limiting drawing ratio β_{max} is an indicator of the drawability of a material and is defined as

$$\beta_{max} = \frac{d_{0,max}}{d_m}\,, \qquad (11.111)$$

where $d_{0,max}$ is the largest blank diameter that can be drawn into a cup with mean diameter of d_m without failure. According to membrane theory, the ideal limiting drawing ratio is

$$\beta_{max} \leq e \approx 2.72\,. \qquad (11.112)$$

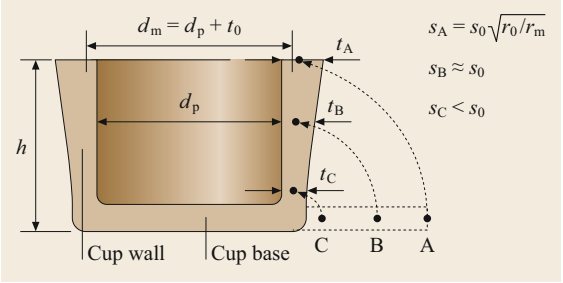

Fig. 11.81 Deep-drawn cup (after [11.29])

In reality, the limiting drawing ratios are 1.8–2.0 for aluminum sheets and 1.9–2.2 for steel sheets (for d_0 =100 mm). This is because various process parameters are not considered in the simplifying membrane theory. One such factor is the dimension of the blank or equivalently the punch. As the relative punch diameter increases, the limiting drawing ratio decreases (Fig. 11.82). Furthermore, as the normal anisotropy r_n increases, the limiting drawing ratio increases; however, as the planar anisotropy Δr increases, β_{max} decreases. Similarly, as the hardening exponent n increases β_{max} increases, but as the friction between the blank and die increases, β_{max} decreases.

To increase the drawing ratio, cups can be drawn successively. This can be achieved by direct redrawing or reverse redrawing (Fig. 11.83). In direct redrawing, the outer surface of the initially drawn cup remains the outer

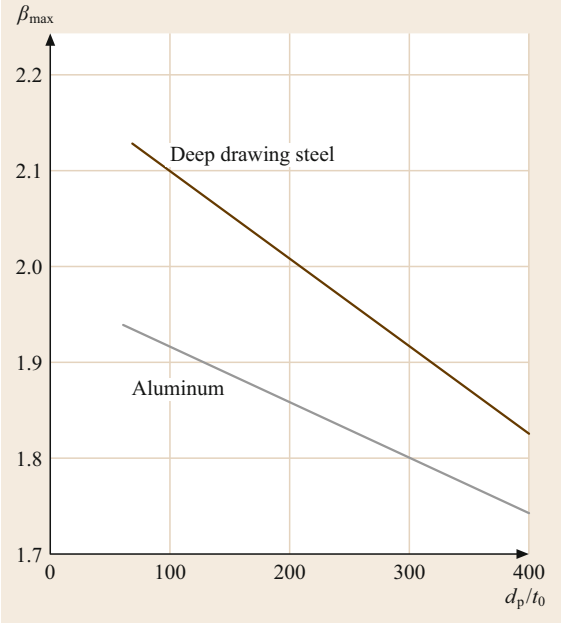

Fig. 11.82 Effect of relative punch diameter on limiting drawing ratio

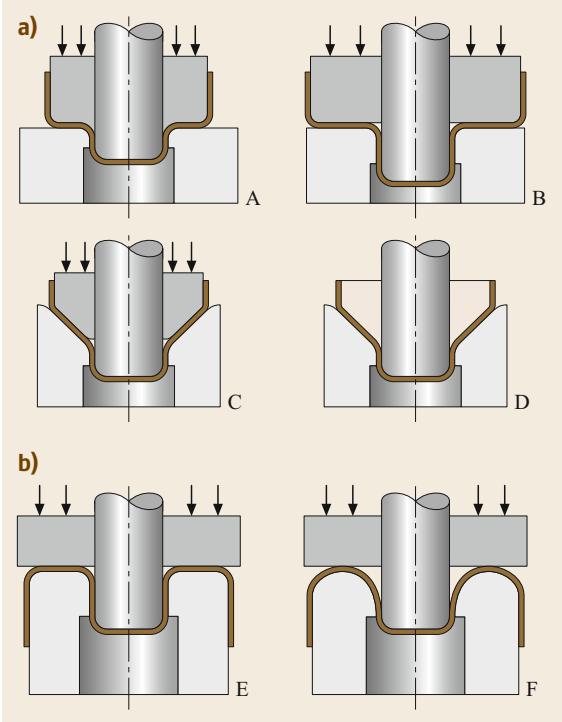

Fig. 11.83a,b Redrawing process to increase the overall drawing ratio: **(a)** direct redrawing, **(b)** inverse redrawing

surface in the redrawn cup, whereas the same surface becomes the inner surface in a reversely redrawn cup. Redrawing can be done either with or without annealing between the draws. Using the redrawing technique, the total drawing ratio achieved without annealing between draws is up to 6.5 for deep-drawing steel. Hereby, the first draw is conducted at a drawing ratio of 2.0 and all the following draws at a drawing ratio of 1.3.

The height of a drawn cup can be increased by reducing the wall thickness of the drawn cup by ironing (Fig. 11.49c). This process is also used to make the wall thickness of the cup uniform. This is virtually a drawing process and must be considered bulk forming.

Typical failure modes in deep drawing are given in Fig. 11.84. Tearing occurs if the drawing force cannot be transmitted by the cup bottom; this is the failure type controlling the limiting drawing ratio. The limiting drawing force is

$$F \leq a\mathrm{UTS}\pi d_\mathrm{p} t_0 \,, \tag{11.113}$$

where a is a correction factor (1.05–1.55 for steel, 0.99–1.22 for aluminum, and 0.92–1.27 for brass) and UTS is the ultimate tensile strength of the sheet material. Wrinkling is caused by compressive stresses that occur in the flange of the workpiece. If the clearance between the punch and die is large, wrinkles can also occur in the cup wall. If the sheet thickness is large enough ($d_0/t_0 <$ 25–40), the sheet has sufficient buckling resistance. For thinner sheets, wrinkles in the flange are prevented by a blank holder. It is suggested to use a blank-holder pressure of 1–2% of the flow stress of the workpiece material.

The working window for the deep-drawing process is sketched in Fig. 11.85. The working window can be enlarged by reducing the flow stress of the workpiece in the flange region, by reducing friction in the flange and at the die radius, by increasing the strength of the material at the cup base–wall transition, and by increasing the friction at the cup base region.

The drawing force during deep drawing (Fig. 11.86) can be estimated as

$$F = 2\pi r_\mathrm{m}\left\{\left[\underbrace{\sigma_{\mathrm{fm,flange}} t_0 \ln\left(\frac{r'_0}{r_\mathrm{m}}\right)}_{\text{ideal force}} + \underbrace{\frac{\mu F_\mathrm{BH}}{\pi r'_0}}_{\text{flange friction}} + \underbrace{\frac{\sigma_{\mathrm{fm,die\text{-}ring}} t_0^2}{2r_\mathrm{fd} + t_0}}_{\text{bending/unbending}}\right] \underbrace{\mathrm{e}^{\mu\phi}}_{\text{die-ring friction}}\right\} \sin\alpha \,. \tag{11.114}$$

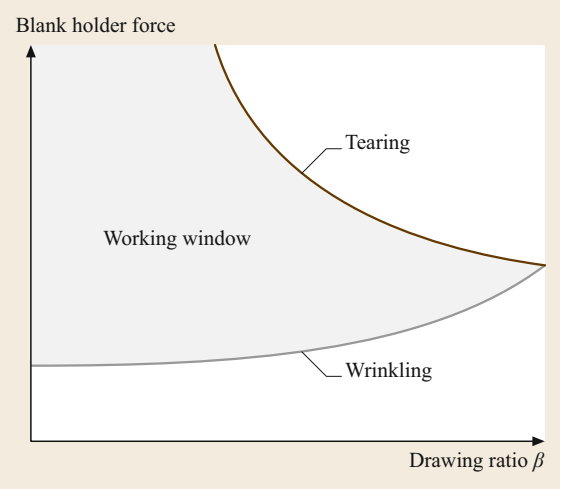

Fig. 11.85 Working window in deep drawing (after [11.31])

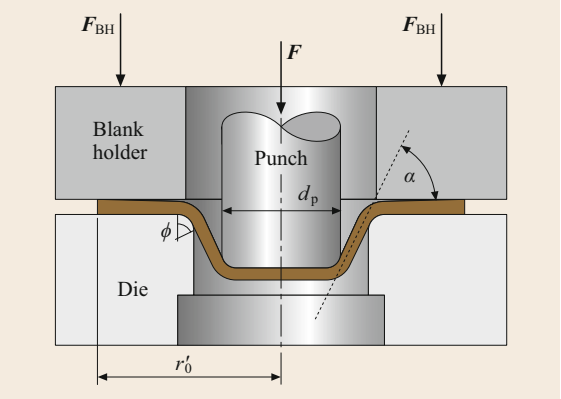

Fig. 11.86 Deep-drawing parameters

The typical force–displacement curve in deep drawing shows a maximum when the blank radius is reduced to around 77% of the initial value (Fig. 11.87). This is the result of the decreasing flange volume and the increasing flow stress in the flange as the punch advances. If the clearance between the punch and the die ring is smaller than the increased sheet thickness towards the rim of the cup, there will be an additional increase in the force due to ironing after the force maximum is reached.

Forming of complex three-dimensional sheets is a combination of stretch forming and deep drawing. The critical issue is to control the material flow within the sheet part during forming. This is achieved basically by four methods:

1. Designing the blank geometry appropriately.
2. Using draw beads or lock beads (Fig. 11.88) that partially or completely prevent the draw-in of the material.

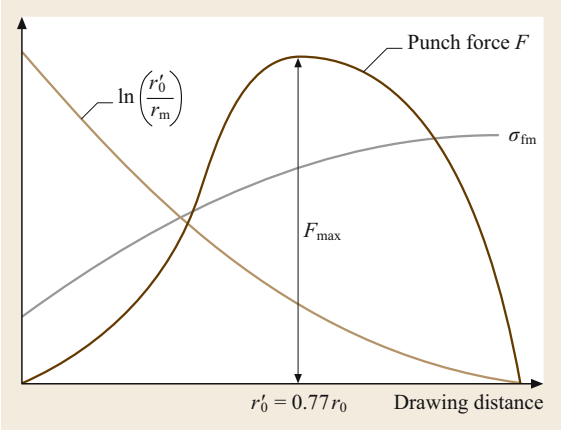

Fig. 11.87 Typical force–displacement curve for deep drawing

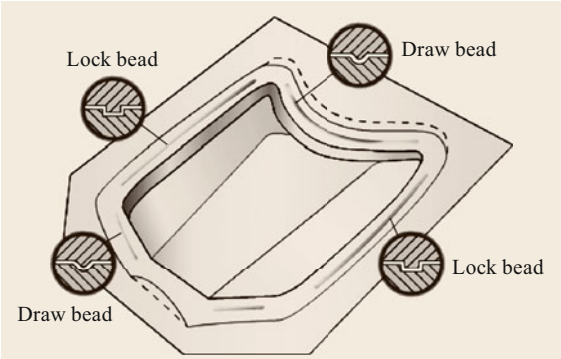

Fig. 11.88 Deep drawing of complex parts using draw beads and lock beads

3. Regulating the blank-holder force. Advanced deep-drawing dies have segmented blank holders to adjust the blank-holder force locally.
4. Regulating the type, amount, and distribution of lubricant during sheet forming.

11.4.6 Hydroforming

Hydroforming is characterized by the replacement of a rigid tool with a pressure medium such as water or oil. There are two broad groups of these processes: Sheet hydroforming and tube hydroforming. Sheet hydroforming processes are basically of two types: processes in which the die is replaced by a pressurized fluid (called hydromechanical deep drawing, the hydromech process, the aquadraw process, hydraulic counterpressure deep drawing, or just hydroform) and processes in which the punch is replaced by a pressurized fluid (called high-pressure sheet forming or just fluid forming).

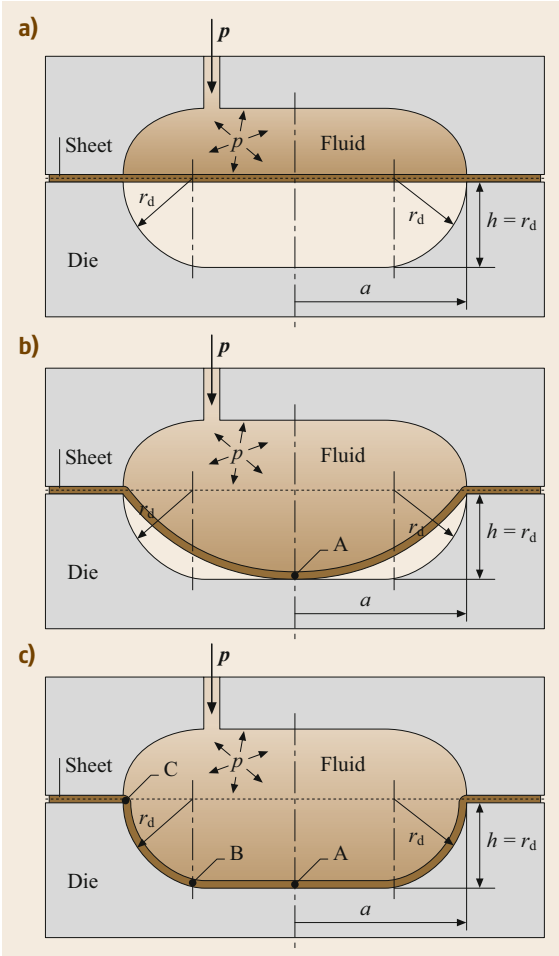

Fig. 11.89a–c Principle of high-pressure sheet forming: **(a)** beginning of process, **(b)** end of free bulging, **(c)** end of cavity filling (after [11.31])

High-Pressure Sheet Forming (Fluid Forming)

The high-pressure sheet forming process consists of two stages (Fig. 11.89): the free bulging stage and the cavity filling stage. Compared with conventionally deep-drawn parts, hydroformed parts have better tolerances and repeatability. Moreover, parts made from blanks of different thickness and materials (tailored blanks) can be produced using the same tools. Another advantage is the low springback and low residual stress levels in the product. On the other hand, due to the free bulging, the depths of the parts are limited. Also, the cycle time is relatively slow, and dies cannot be changed as quickly as conventional dies.

For the typical process shown in Fig. 11.89, the internal pressure at the end of the free bulging state can be estimated using membrane theory as

$$p \approx 4\sigma_{f0} t_0 \frac{r_d}{a^2 + r_d^2} \,. \tag{11.115}$$

The maximum height for the free bulging stage is given by

$$h_{max} = \frac{a}{\sqrt{5}} \approx 0.447a \,. \tag{11.116}$$

The pressure to fill the cavities is approximately

$$p = \sigma_{f0} t_0 \left(\frac{1}{a} + \frac{1}{r_d} \right) . \tag{11.117}$$

The contact pressure at the interface of the sheet and the rigid die between point B and C can be estimated as

$$p_{contact} \approx \frac{\sigma_{f0} t_0}{a} \,. \tag{11.118}$$

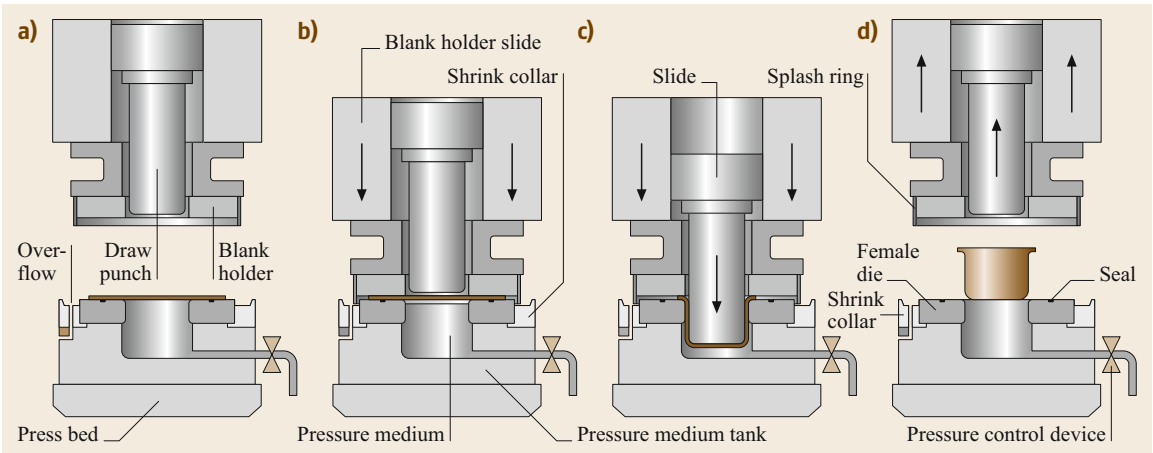

Fig. 11.90a–d Principle of hydromechanical deep drawing. **(a)** Before forming, **(b)** dies closed, **(c)** forming, **(d)** after forming (after [11.32])

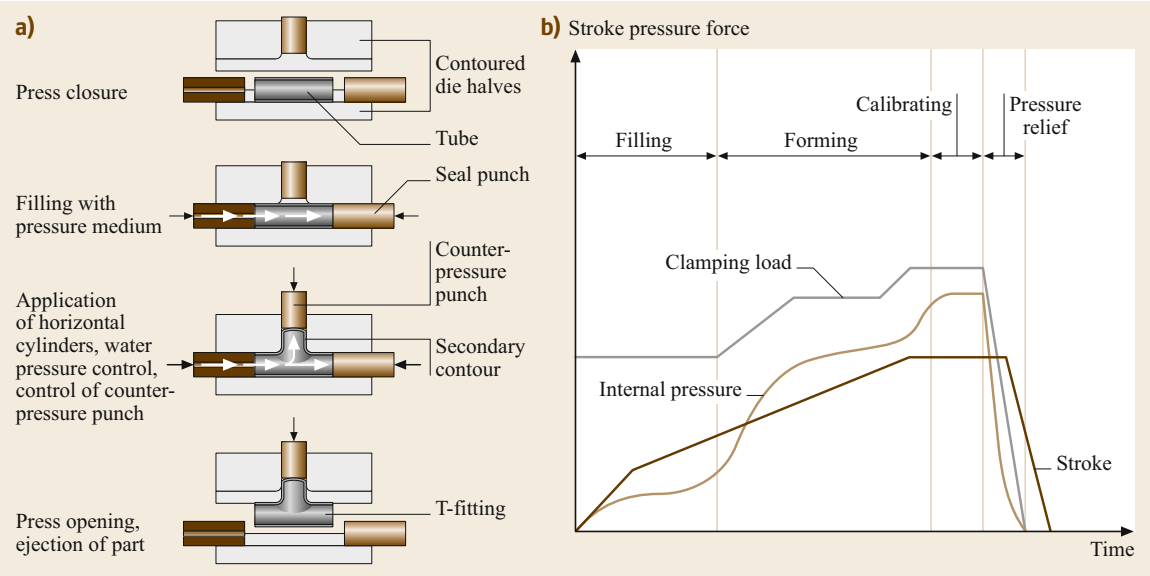

Fig. 11.91 (a) Principle of tube hydroforming and (b) process control (after [11.32])

Hydromechanical Deep Drawing

The working principle of hydromechanical deep drawing is shown in Fig. 11.90 [11.32]. First, the press is opened and the water container is filled in the home position. After the insertion of the blank, the press closes, and the blank holder grips the blank. The blank-holder pressure, set at the press, seals the pressure chamber, and the actual forming process is initiated. The medium pressure builds up as a result of penetration of the draw punch into the water container. During deformation, the sheet metal is pressed against the draw punch. During the forming phase, the control system, which is linked to the pressure chamber, controls the application of the hydraulic pressure as a function of the draw depth.

After reaching the mechanically limited draw depth, the pressure in the chamber is released and the press travels back to its home position.

The advantages of hydromechanical deep drawing are the higher limiting drawing ratio (β_{max} = 2.7) as compared with mechanical deep drawing (β_{max} = 2.0), the better surface quality, and the lower springback of the product. Pressures for various materials during hydromechanical deep drawing are presented in Table 11.17.

Table 11.17 Pressures during hydromechanical deep drawing

Material	Pressure (bar)
Aluminum	50–200
Steel	200–600
Stainless steel	300–1000

Tube Hydroforming

Tube hydroforming is a cold-forming process in which a tube is pressurized internally and simultaneously compressed axially and/or radially [11.32]. The tube is thereby expanded and pressed against a die. The process steps can be illustrated by the manufacturing of a T-fitting (Fig. 11.91a): A special hydraulic press is equipped with a two-part multiple-purpose die. Depending on the workpiece, the dies have two seal punches (horizontal cylinders) positioned axially relative to the tube ends and a counterpressure punch. The tubular preform is placed in the bottom die, and the die is closed. The ends of the tube are sealed by the axial punches, and the tube is filled with pressure medium.

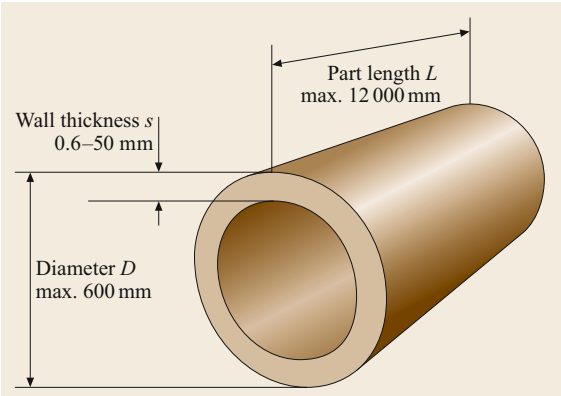

Fig. 11.92 Current limits on workpiece geometry for tube hydroforming (after [11.32])

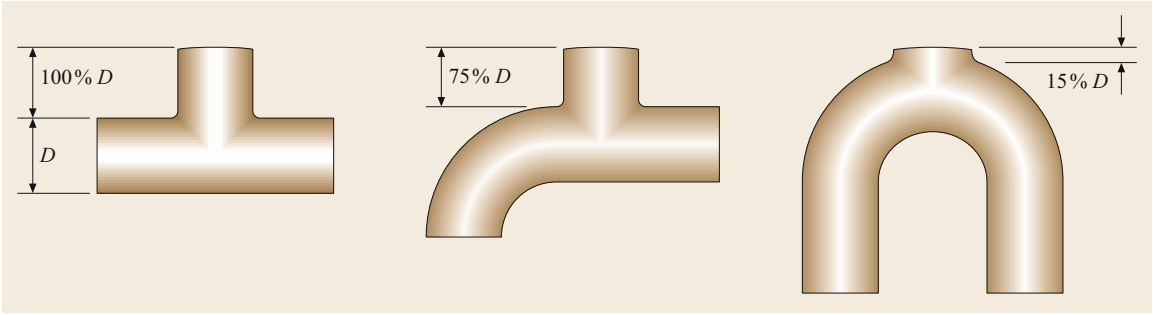

Fig. 11.93 Product geometries producible by tube hydroforming (after [11.32])

In the actual forming process, the punches compress the tube, while the pressure medium is fed to inflate the part until the part wall rests against the die contour. Pressures can reach values up to 4000 bar. The counterpressure punch additionally controls the material flow. The calibration pressure forms the workpiece in such a way that its contour corresponds to that of the die accurately and reproducibly. The die is finally opened, and the formed component is ejected.

Currently, tubes with the maximum dimensions shown in Fig. 11.92 can be formed by tube hydroforming. Typical achievable product dimensions are given in Fig. 11.93.

Tube hydroforming is limited by three failure modes (Fig. 11.94): buckling, wrinkling, and bursting.

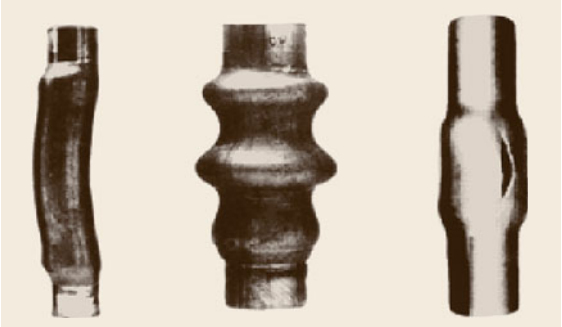

Fig. 11.94 Failure modes in tube hydroforming (after [11.33])

11.5 Forming Machines

Metals are plastically formed by usually at least two tools. These tools have to be moved with certain kinematics and with certain forces. This is achieved by a forming machine. Since various metal forming processes need various load–stroke characteristics, the forming machines used have to be selected accordingly. Besides satisfying the mechanical requirements, forming machines must also provide a long uptime, i.e., the time they are used for forming, and should ensure long tool lives. The latter depends, for instance, on the precision of the guidance of the slides.

The largest group of forming machines is presses. These are machines with linear relative motion between the two tools. Other forming machines include rolling machines, wire or tube drawing machines, and magnetic or explosive forming machines. Here only presses will be discussed.

11.5.1 Parameters of Forming Presses

The various requirements of the forming process such as necessary force, moment, energy, etc. must be matched with the capabilities of the forming press. This can be achieved by comparing characteristic parameters of the forming press with those of the forming process. Basically, four groups of parameters can be identified [11.1, 2]: energy and force parameters, transient parameters, accuracy parameters, and other parameters.

Energy and Force Parameters

For a feasible forming process, the nominal ram force provided by the machine F_{nom} must be larger than or equal to the necessary maximum forming force F_{form} and the available energy of the forming machine E_{nom} must be larger than or equal to the necessary process work W_{proc}. Practically, however, equality makes no sense due to the inherent fluctuations of the forming loads; on the other hand, for economic utilization of the usually expensive forming machines, F_{nom} and E_{nom} should be as close as possible to F_{form} and W_{proc}, respectively. The necessary process work is given by

$$W_{\mathrm{proc}} = W_{\mathrm{form}} + W_{\mathrm{el}} + W_{\mathrm{fr}} + W_{\mathrm{aux}} \,, \qquad (11.119)$$

where W_{form} is the work necessary to plastically deform the metal (including the frictional work at the tool/workpiece interface), W_{el} is the work to elastically deform the press frame and the tools, W_{fr} is the frictional work consumed in the various guides and bearings, and finally W_{aux} is the work consumed by auxiliary equipment such as blank holders, ejectors, etc.

The elastic work absorbed by the press frame and the tools is given by

$$W_{el} = \frac{1}{2}\frac{F_{form}^2}{C}\,, \qquad (11.120)$$

where C is the stiffness of the forming press including the tools. As long as $C > dF_{form}/ds$ (where s is the ram stroke), the elastic energy spent until the maximum forming load is reached can be recovered afterwards. The unrecovered elastic energy leads to vibrations in the drives and in the machine frame. Hence, the higher C is, the higher the chance that the elastic energy can be recovered and the vibrations reduced.

According to the basic physical parameter controlling their action, presses can be classified into stroke-controlled, force-controlled, or energy-controlled presses (Fig. 11.95): *Energy-controlled forming machines* provide a certain amount of energy (E_{nom}) for the process. If this energy is consumed, the press stops. If the energy required for the process is greater than that available, multiple strokes can be executed (Fig. 11.95a). Hence, the basic characteristic parameter of energy-controlled presses is the nominal energy E_{nom}. Hammers and screw presses are two typical representatives of this group. In contrast to hammers, screw presses have drives and frame elements under load, so that for these, in addition to the nominal energy, a nominal force also has to be specified for the design of these machine elements. *Force-controlled presses* provide (independently of the stroke) a given force, obtained as the hydraulic pressure p multiplied by the cylinder cross-sectional area A (Fig. 11.95b). The basic parameter for these presses is therefore the maximum allowable force F_{nom}. The typical representative of this group is the hydraulic press. Finally, *stroke-controlled presses* (Fig. 11.95c) provide a ram force for each ram position depending on the kinematics of the mechanical drive. The characteristic parameters, therefore, are the ram force as a function of the stroke and the maximum ram force F_{nom}. Typical representatives are crank and toggle presses.

Transient Parameters

The basic time-dependent parameters are the effective stroke rate, the contact time of the tools with the workpiece under the forming load, and finally the speed of the

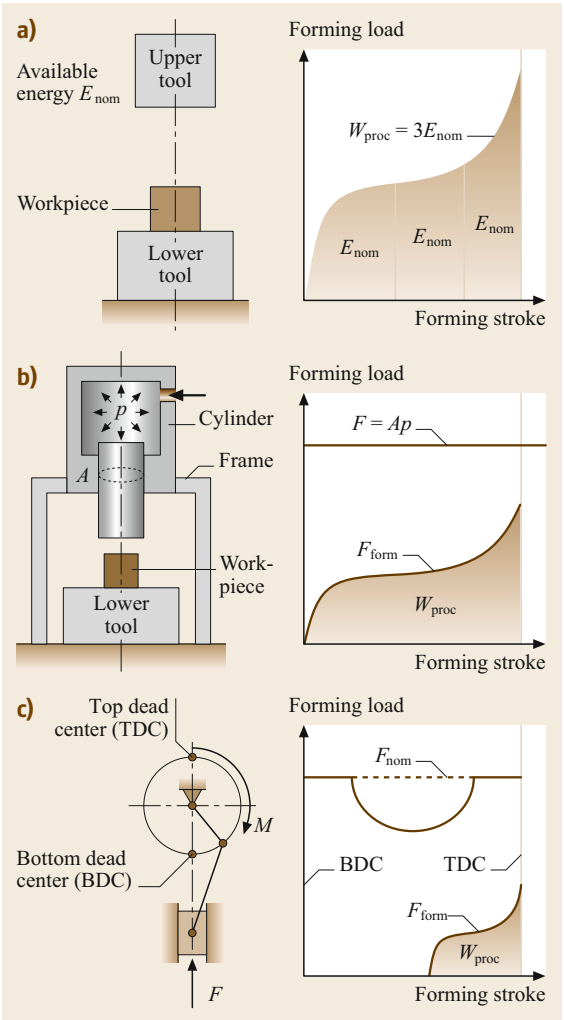

Fig. 11.95a–c Basic types of forming presses: **(a)** energy-controlled forming presses, **(b)** load-controlled forming presses, **(c)** stroke-controlled forming presses

press. The effective stroke rate determines the economic efficiency of the press. This parameter is related to the falling height in case of hammers, to the speed during the load free stroke in case of hydraulic presses, and to the speed and total stroke in case of crank presses. The contact time under pressure is especially important for warm and hot forming processes, since it determines the amount of workpiece cooling required. Typical contact times for various machines are presented in Table 11.18. For stroke-controlled presses, the contact time under pressure is larger the softer the frame and tool system are (i.e., the lower C is). Another important parameter is the speed of the ram of the press. This directly influences the strain rates during forming. Especially in warm and hot forming, the higher the strain rate, the higher

Table 11.18 Order of magnitude of contact times for various press types (after [11.1, 2])

Press type	Contact time under pressure (s)
Hammers	10^{-3}–10^{-2}
Screw presses (with flywheel)	10^{-2}–10^{-1}
Stroke-controlled presses	10^{-1}–5×10^{-1}
Hydraulic presses	10^{-1}–1

the flow stress and hence the higher the forming load. In hammers, the speed is given during the forming process by the power balance, whereas for stroke-driven presses, the ram speed is a function of the ram position. For the latter, note that the true ram speed depends on the stiffness of the frame–tool system.

Accuracy Parameters

The accuracy parameters of presses are related to geometric errors of the workpiece, such as position errors during impact, eccentricity of the product, dimensional errors in product height, the angle of twist of the product, etc. These errors are caused either by inaccuracies of the presses in the idle state, such as excessive clearance of the guides or skewness of the lower die and upper die leading to position errors during impact, or by inaccuracies of the press under load, such as elastic deformations leading to height errors in the tool. The latter errors are strongly dependent on the stiffness of the press, so that this characteristic parameter is the key parameter for the press specification. In presses, generally the frame, the upper tool, the lower tool, and the drive system deflect elastically. In the case of hammers, only the lower tool deflects elastically.

Other Parameters

Finally, parameters such as stroke length, tooling space, space requirements of the press, weight of the press, and necessary power supply can be listed as other characteristic parameters.

11.5.2 Energy-Controlled Presses

Energy-controlled presses provide a certain predetermined amount of energy for the forming process. Force as well as displacement is not controlled directly. There are basically two types of energy-controlled presses: hammers and screw presses.

Hammers

There are basically three types of hammers (Fig. 11.96): Drop hammers provide the energy by a freely falling ram including the upper die. In double-acting hammers, the ram is accelerated by a fluid such as steam, air, or hydraulic oil acting through a cylinder and piston. Finally, in counter-blow hammers, the upper and lower dies are accelerated towards each other. The first two types transmit the forging force to the ground, whereas for the counterblow hammer, the ground remains practically unaffected by the forming load.

The properties of these hammers are presented in Table 11.19. Hammers are basically used in hot forging operations, so that the impact speeds are important for determining the strain rates for the forming process. Furthermore, the contact time of the dies with the workpiece is important to determine the cooling of the workpiece. The contact time for hammers is 10^{-3}–10^{-2} s, being the shortest contact time among all press types. The maximum nominal energy of the hammer cannot be entirely used for forming due to energy losses such as friction at the slides and elastic deformations of the dies. For small loads and large displacements, about 80–90% of the nominal energy can be used, whereas for high loads and small displacements, only 20–50% of the nominal blow energy is available for the forming process.

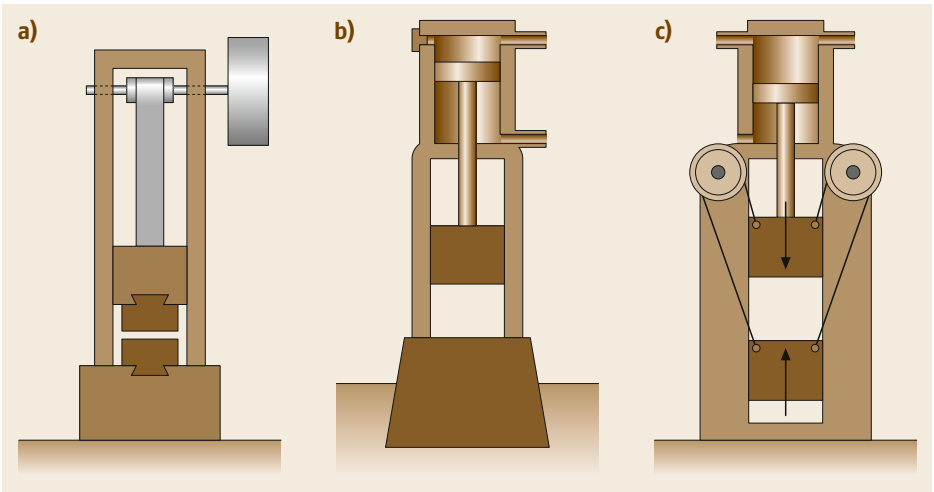

Fig. 11.96a–c Basic types of hammers: **(a)** drop hammer, **(b)** double-acting hammer, **(c)** counterblow hammer

Table 11.19 Properties of various hammers (after [11.18])

Property	Drop hammers	Double-acting hammers	Counterblow hammers
Maximum drop height (m)	1.3–2	about 1.3	–
Acceleration of ram	$< g$	$> g$	$> g$
Impact speed of ram (m/s)	3–5	3–9	5–14
Maximum nominal energy E_N (kN m)	80–160	200	1000
Blow energy equation	mgh	$mgh + pAh$	$\frac{1}{2}(m_1 + m_2)v^2$

Parameters: m: mass of ram, g: gravitational acceleration, h: drop height, p: pressure in cylinder, A: cross-sectional area of cylinder, m_1: mass of upper ram, m_2: mass of lower ram, v: speed of each ram

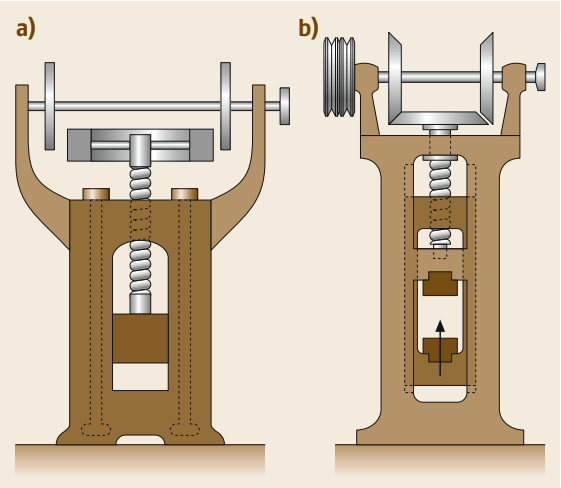

Fig. 11.97a,b Basic types of screw presses: **(a)** friction screw press, **(b)** Vincent friction screw press

Screw Presses

Screw presses are of two basic types (Fig. 11.97): presses with axially moving screw drives and presses with stationary screw drives (also called Vincent presses). The angular kinetic energy of the flywheel is transferred to the screw, which either moves the upper ram (Fig. 11.97a) or the lower die (Fig. 11.97b). In the case of Vincent presses, the frame of the press is not under load during forming. The available energy can be expressed using the rotational speed ω (in rad/s) of the flywheel and its moment of inertia I as

$$E = \frac{1}{2} I\omega^2 \,. \tag{11.121}$$

This energy is used for forming, for overcoming friction in the slides, and for elastically deforming the frame of the press.

The contact time of the dies with the workpiece is longer for screw presses than for hammers and is between 10^{-2} and 10^{-1} s. The impact speed of the dies on the workpiece ranges between 0.7 and 1 m/s. The maximum nominal energy ranges from 800 to 7500 kN m, and the maximum nominal press loads from 20 000 to 140 000 kN, depending on the drive used to accelerate the flywheel (friction, gear, electrical, or hydraulic drives). Impact loads are between 40 000 and 300 000 kN.

Compared with hammers, screw presses have a lower noise level. Because of the lower hitting speed, the strain rates are lower, yet the cooling time of the workpiece under pressure is longer. Also, for the same energy, screw presses have a flywheel mass that is about one-sixth that of the upper die of a hammer. Furthermore, the accuracy of screw presses is higher than that of hammers. A disadvantage of screw presses is, however, that their stroke rate is lower than that of hammers. Screw presses are, therefore, also used in cold calibration operations and coining in addition to hot forging.

11.5.3 Stroke-Controlled Presses

Stroke-controlled presses are also simply called mechanical presses. They all utilize a flywheel to store the necessary forming energy. Figure 11.98 shows a typical eccentric press. A slider crank mechanism is used to transfer the energy of the flywheel through the

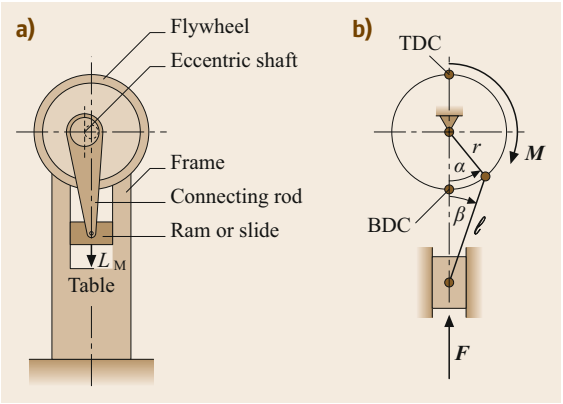

Fig. 11.98a,b A typical eccentric press **(a)** and its mechanism **(b)**

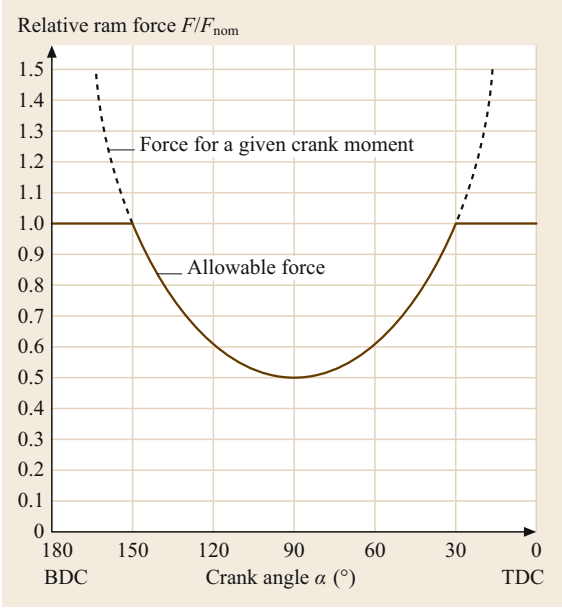

Fig. 11.99 Allowable press force as a function of crank position

crank, the connecting rod, and finally the slide to the workpiece. A slight variation on the eccentric press is the crank press, where a crank link is used instead of an eccentric shaft. These presses are sometimes differentiated by the fact that the total stroke of the crank press cannot be changed whereas the total stroke of the eccentric press is adjustable [11.21].

For crank presses, the ratio of the crank length to coupler length r/ℓ takes values between 1/15 and 1/4, so that the included angle between the coupler link and the press axis β is less than 6°. For this case, the axial ram force acting on the slider is given by

$$F(\alpha) \approx \frac{M}{r \sin \alpha} , \qquad (11.122)$$

where M is the torque supplied by the crank and r is the crank radius. The nominal force of a mechanical press is given for a crank position at 30° to its bottom dead center

$$F_{nom} = F(\alpha = 30°) . \qquad (11.123)$$

This is the highest allowable forming force for the given press. All the mechanical elements of the press are designed for this load. For various crank angles, the current allowable force and the theoretical available force are shown in Fig. 11.99. The crank angle dependence can be converted to the stroke of the press s as measured from bottom dead center using

$$s = r\left[(1 - \cos \alpha) + \frac{1}{2}\left(\frac{r}{\ell}\right) \sin^2 \alpha\right] . \qquad (11.124)$$

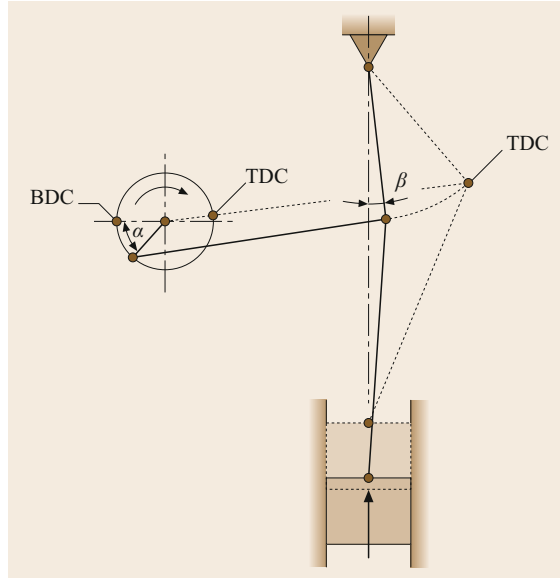

Fig. 11.100 Mechanism of a knuckle-joint press

Table 11.20 Properties of mechanical presses (after [11.18])

Property	Eccentric or crank press	Knuckle-joint press
Stroke (mm)	10–300	3–12
Nominal load (kN)	1000–16 000	1000–16 000
Stroke rate (strokes/min)	10–100	20–200

If the total stroke of the press is denoted by S (= $2r$), then the stroke for which the nominal force is available corresponds to 7.3% of S for r/ℓ = 0.1. Beyond this rather small stroke, the available ram force decreases rapidly.

Another force–stroke characteristic is found for knuckle-joint (toggle) presses (Fig. 11.100). The six-link mechanism employed in this press provides the nominal force over a much smaller stroke than in crank presses, so that they are suitable basically for processes with force maximums toward the end of the stroke, requiring also short strokes. Despite this disadvantage, the velocity characteristic of toggle presses is superior to crank presses, since they are faster over a long stroke but slower towards the dead centers, i.e., in the forming regime, than crank presses (Table 11.20).

A recent development in press technology is the servomotor press [11.21]. One or multiple servomotors are used to drive a crank or toggle mechanism. The obvious advantage of the servomotor press is the almost limitless control of the press. Current limitations are the available motor torques and hence forming forces, since the forming energy must be supplied instantaneously. Despite this disadvantage, 1000-t presses are expected to be available in the near future.

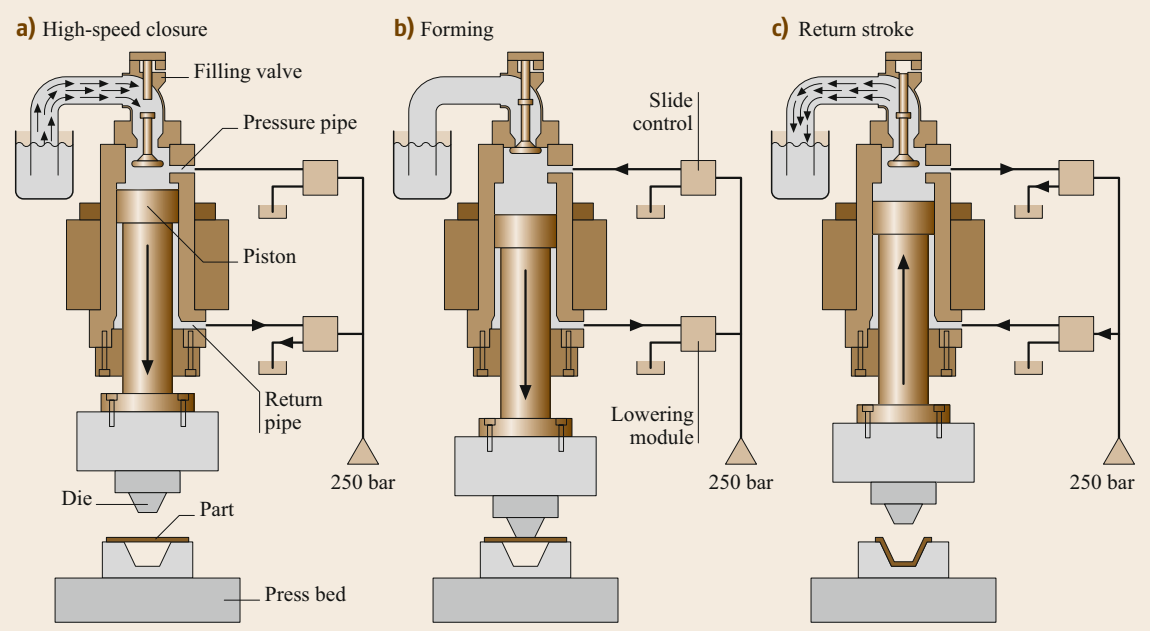

Fig. 11.101a–c Working principle of a hydraulic press: **(a)** high-speed closure, **(b)** forming, **(c)** return stroke (after [11.32])

11.5.4 Force-Controlled Presses

Hydraulic presses supply the nominal forming force independently of the stroke. Figure 11.101 shows the basic working principle of a hydraulic press: A pump converts electrical energy into hydraulic energy, which is finally converted into mechanical energy. A cylinder in the die closure phase is pressurized by hydraulic fluid from a reservoir with high flow rates. This fluid is usually oil. This oil is compressible such that a 0.7–0.8% volume change occurs per 100 bar pressure. After the dies are closed, control of the cylinder is passed to the slide control for the forming action. The cylinder is returned by reversing the fluid flow into the lowering cylinder. Hydraulic presses have the advantage that the whole cycle of die closure/forming/punch reversal can be programmed efficiently and individually. Therefore, these press types are appropriate for many forming processes, such as sheet forming, cold forging, and especially hot forging and hot extrusion.

The basic characteristic parameter of a hydraulic press is the nominal forming force, which can be found from the hydraulic pressure p and the cross-sectional area of the cylinder A as

$$F_{\text{nom}} = pA \,. \tag{11.125}$$

The hydrostatic pressure is up to 320 bar. In contrast to mechanical presses, there is no energy reservoir, so the energy necessary for forming must be supplied instantaneously by the pump. This pump power P is given by

$$P = \frac{1}{\eta_{\text{total}}} p\dot{V} \,, \tag{11.126}$$

where $\dot{V}$ is the volumetric flow rate of the fluid and η_{total} is the total efficiency of the hydraulic system including mechanical and electrical losses. The maximum flow rates are $\approx 185\,\text{L/min}$.

Professor Tekkaya completed his doctoral thesis at the University of Stuttgart in 1985. Until 2005 he was Professor at the METU, Ankara. From 2005 he was the Chairman of the Department of Manufacturing at ATILIM University in Ankara, Turkey. From 2007 he was Director of the Institute of Forming Technology and Lightweight Components at the TU Dortmund University. His current research is on numerical simulation of sheet/bulk metal forming processes and material characterization. He is a fellow of CIRP and member of the International Cold Forging Group (ICFG).

12. Machining Processes

Bernhard Karpuschewski, Gerry Byrne, Berend Denkena, João Oliveira, Anatoly Vereschaka

In this handbook, machining processes are seen in the first place as material removal processes. Any surplus material is removed from a solid object (workpiece) either in the form of small pieces (e.g., chips) or by chipless processes based on e.g., evaporation. To achieve this kind of material removal different tools are mandatory, thus generating surfaces by relative motions between the workpiece and tool provided by the respective machine tool. The following chapter is structured in three major subgroups:

Cutting with geometrically well-defined tool edges
These processes are widely used for material removal in any kind of industrial application. The most prominent processes are turning, drilling, and milling, but also less prominent processes like planning and shaping, broaching, and sawing will be discussed.

Cutting with geometrically undefined tool edges
The tools of this group of processes cannot be described with simple geometrical quantities, because they consist of thousands of small abrasive grains in a bonded structure or as loose grains, but they still generate chips during material removal. The most prominent processes are grinding, honing, lapping, and jet-based applications.

Nonconventional machining (chipless) processes
In chipless machining material, particles are removed from a solid object by nonmechanical means, i.e., by electrical discharges, electrochemical machining, or high-energy beams (laser or electron beams).

In material removal processes, surplus material is removed from a solid object (workpiece) in the form of small pieces (e.g., chips) by means of tools, thus generating surfaces by relative motions between the workpiece and tool provided by the machine tool.

The material removal processes that will be discussed in this section can be divided into three subgroups:

- Cutting with geometrically well-defined tool edges
- Cutting with geometrically undefined tool edges
- Nonconventional machining (chipless) processes.

Cutting is accomplished with the mechanical action of a tool on a workpiece. In chipless machining, material particles are removed from a solid object by nonmechanical means.

K.-H. Grote, H. Hefazi (Eds.), *Springer Handbook of Mechanical Engineering*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-47035-7_12

12.1 Cutting

12.1.1 Fundamentals

During a cutting process particles of material are mechanically removed as chips from a blank or a workpiece by the cutting action of a tool. In machining with geometrically well-defined tool edges, the number of cutting edges, the geometry of the tool, and the position of the cutting edges in relation to the workpiece are known and describable (as opposed to cutting with geometrically undefined tool edges, e.g., grinding).

Figure 12.1 [12.1] illustrates the important processes of this group. The processes differ according to the cutting motion (cutting speed v_c), the feed motion (feed speed v_f), and the resulting effective motion (effective cutting speed v_e). Feed and cutting direction vectors span the working plane. The angle between these two vectors is called the feed motion angle φ, while the angle between the effective direction and the cutting direction is called the effective cutting speed angle η. The following equation applies for all processes

$$\tan\eta = \frac{\sin\varphi}{\frac{v_c}{v_f} + \cos\varphi} \,. \tag{12.1}$$

The mechanical process of separation of material parts from the workpiece, i.e., chip formation, can be described by the example of an orthogonal process (two-dimensional deformation). The wedge is described by the rake angle γ, the clearance angle α, and the edge radius r_B. The wedge penetrates into the working material, which is plastically deformed. Figure 12.2 [12.2] shows the zones of plastic deformation in continuous chip formation. Five effective zones can be distinguished.

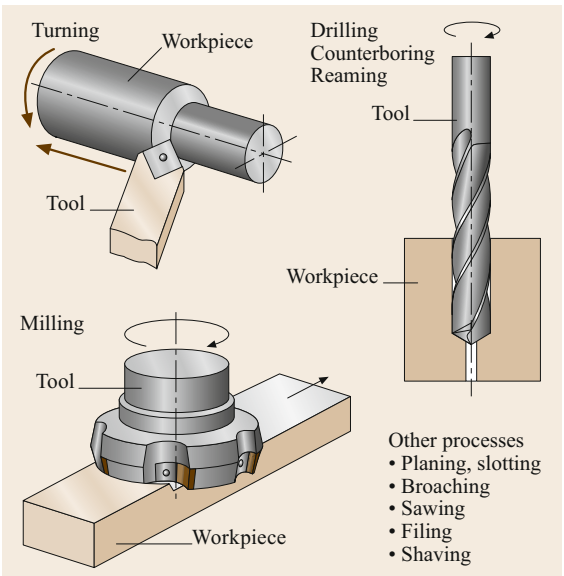

Fig. 12.1 Cutting processes (machining with geometrically well-defined tool edges) [12.1]

The primary shear zone comprises the actual area of chip formation by shearing. In the secondary shear zones in front of the rake and flank face, friction forces act between the tool and the workpiece, causing plastic deformation of these material layers. In the zone in front of the deformation area, chip formation results in stresses that lead to plastic and elastic deformations. In the pressure and cutting zone, the material is deformed and separated under high compressive stresses.

In the course of these processes, the undeformed chip thickness h gives way to the chip thickness h' with the resultant chip compression ratio being $\lambda_h = h'/h$. The shear plane comprises the shear angle ϕ with the cutting speed vector. The deformation angle χ characterizes the shearing of a small part that has passed through the shear plane.

The following chip types can be distinguished: in continuous chip formation the chip slides off over the rake face at a constant speed in a stationary flow. Periodical changes in the intensity of the deformation may occur, mainly at higher cutting speeds. Lamellae are formed in the chip that can reach as far as material separation and the formation of chip segments.

Segmented chip formation is the discontinuous formation of a still continuous chip that, however, shows recognizable differences in the degree of deformation along the direction of flow. Especially negative tool-orthogonal rake angles, but also greater undeformed chip thicknesses, as well as very slow and very fast cutting speeds can result in segmented chip formation. The chip formation is uneven.

Discontinuous chip formation occurs in working materials that possess only a small ability to deform, such as cast iron with graphite lamellae. The parting surface between the chip and the workpiece proceeds irregularly.

Built-up edges can form in ductile, work-hardening materials at low cutting speeds and sufficiently continuous chip formation. Parts of the working material that have been strongly deformed and cold-hardened in the area of the compression zone weld under high pressure at the rounded cutting edge to the chip surface, thus becoming a part of the cutting tip.

The forces acting on the tool in orthogonal cutting can be represented by *Ernst* and *Merchant*'s force cir-

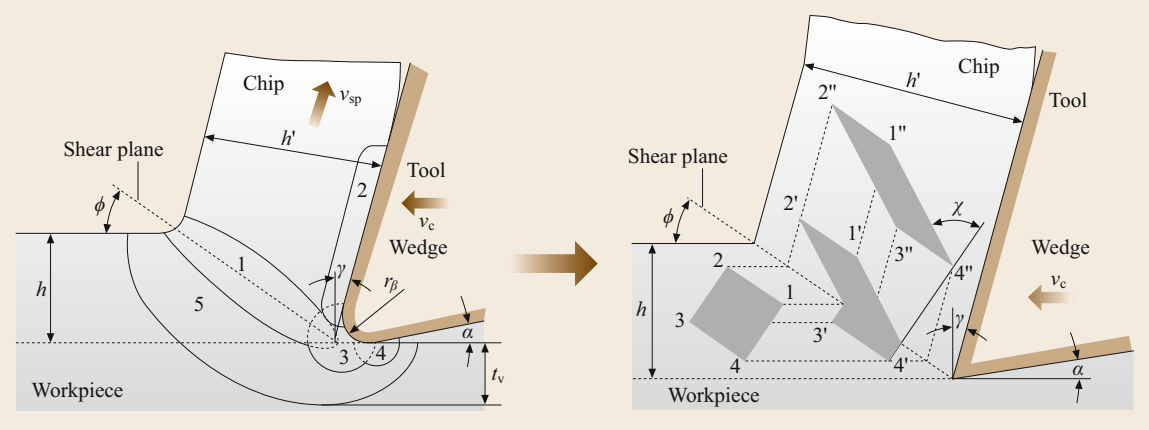

Fig. 12.2 Effective zones in chip formation (*left*) and derived model of deformation (*right*) in the shear plane. 1: Primary shear zone, 2: secondary shear zone at the rake face, 3: secondary shear zone at the cutting edge, 4: secondary shear zone at the flank face, 5: deformation advance zone, χ: deformation angle $\tan\chi = \tan(\phi-\gamma)+1/\tan\phi$, ϕ: shear angle $\tan\phi = \cos\gamma/(\lambda_h - \sin\gamma)\lambda_h = h'/h$, γ: rake angle, α: clearance angle, t_v: deformation depth

cle as shown in Fig. 12.3 [12.3]. The resultant force F_z has two components, F_c and F_p. The cutting force F_c in the direction of the tool path determines the amount of work done in cutting. The thrust force F_p, together with F_c, produces deflections of the tool. The resultant force has two components on the shear plane: $F_{T\varphi}$ is the force required to shear the metal along the shear plane, and $F_{N\varphi}$ is the normal force on this plane. Two other force components on the face of the tool are also represented: the friction force $F_{T\gamma}$ and the normal force $F_{N\gamma}$. From the geometries within the circle, the following relationships can be derived.

The frictional force on the tool rake face

$$F_{T\gamma} = F_p\cos\gamma + F_c\sin\gamma\,. \tag{12.2}$$

The coefficient of friction at the tool–chip interface

$$\mu = \frac{F_p + F_c\tan\gamma}{F_c - F_p\tan\gamma}\,. \tag{12.3}$$

The shear stress in the shear plane, where $A_0 = hw$ is the undeformed chip cross section, and w is the width of the cut

$$\tau = \frac{F_c\sin\varphi\cos\varphi - F_p\sin^2\varphi}{A_0}\,. \tag{12.4}$$

In the chip formation zone, the cutting energy applied, E_c, is completely converted. It can be calculated from

$$E_c = F_c l_c\,, \tag{12.5}$$

where F_c is the cutting force, and l_c is the travel length in the cutting direction.

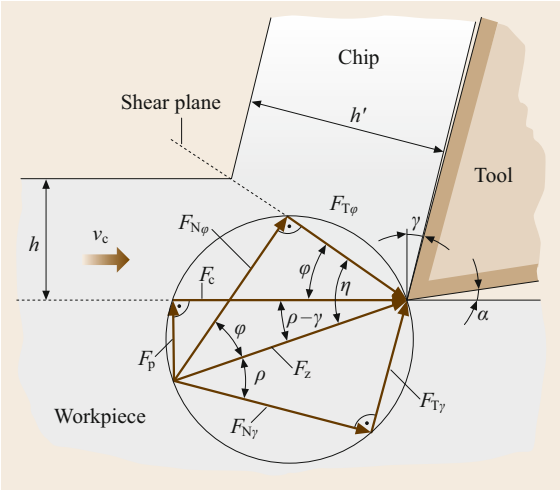

Fig. 12.3 Ernst and Merchant's force circle

The cutting energy is composed of deformation and shear energy E_φ, friction energy at the rake face E_γ, friction energy at the flank face E_α, surface energy for the formation of new surfaces E_τ, and kinetic energy due to chip deflection E_M.

The energy converted during machining one unit of volume is

$$e_c = \frac{E_c}{V_w}\,, \tag{12.6}$$

where e_c is the specific energy, and V_w is the volume of material removed. Like E_c, itself, its individual components can be expressed in relation to V_w.

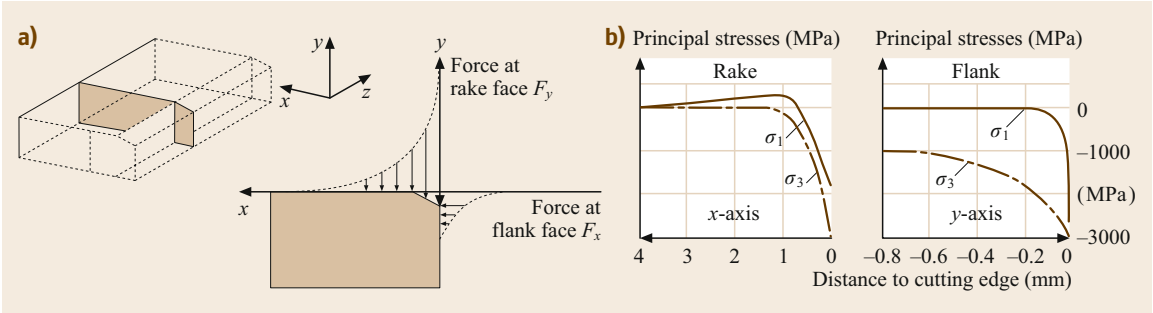

Fig. 12.4a,b Load distribution due to mechanical stress perpendicular to the major cutting edge. **(a)** Surface forces beneath the rake and flank face surfaces; **(b)** principal stresses at rake and flank face

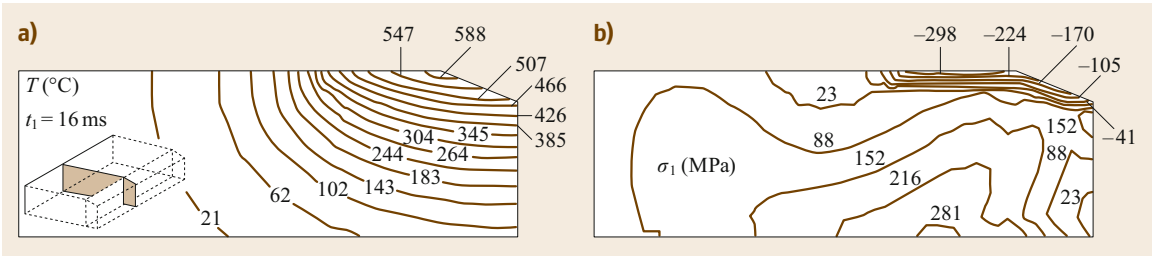

Fig. 12.5a,b Temperature **(a)** and stress distribution **(b)** during constant heat flow to the ceramic cutting tool

From the specific energy e_c the specific cutting force k_c can be derived as a characteristic value for calculating the cutting force

$$k_c = \frac{F_c}{A} = \frac{F_c}{hb}\,, \tag{12.7}$$

where A is the undeformed chip cross section, b is the undeformed chip width, and h is the undeformed chip thickness

$$e_c = \frac{E_c}{V_w} = \frac{P_c}{Q_w} = \frac{F_c v_c}{A v_c} = k_c\,, \tag{12.8}$$

where P_c is the cutting power, Q_w is the material removal rate, and F_c is the cutting force.

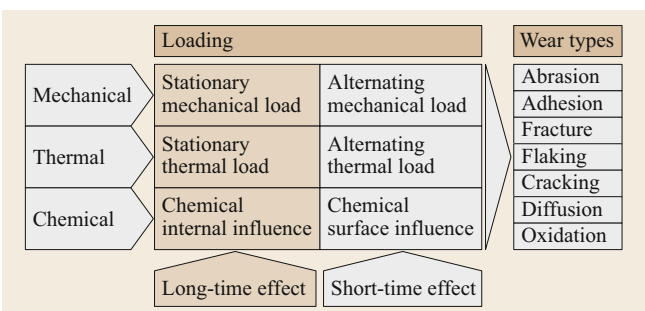

Fig. 12.6 Loading and wear types of cutting tools

Estimation shows that the largest amount of cutting energy is converted into deformation and frictional energy. Thus, the specific cutting force k_c can be seen as an energy-related variable (the application and determination of k_c will be dealt with in more detail in Sect. 12.1.2). The energy introduced into the chip formation zone is almost entirely converted into heat, the minor amount being transformed into residual stress in the chip and in the workpiece (spring energy). Due to this process high temperatures in the cutting edge arise, introducing mechanical and thermal load into this area. Surface forces beneath the rake and flank face surfaces and the principal stresses that can be calculated thereby are shown in Fig. 12.4 [12.2].

Figure 12.5 [12.2] represents the temperature distribution on a highly-loaded ceramic indexable insert and the resulting thermally-induced tensile stresses. These tensile stresses are particularly critical for high-temperature ceramic cutting materials. Mechanical and thermal loads supported by chemical reactions may cause significant wear.

The characteristics of worn cutting tools can be described by different types of wear (Fig. 12.6; [12.2]):

- Fractures and cracks arise in the area of the cutting edge because of mechanical or thermal overload.

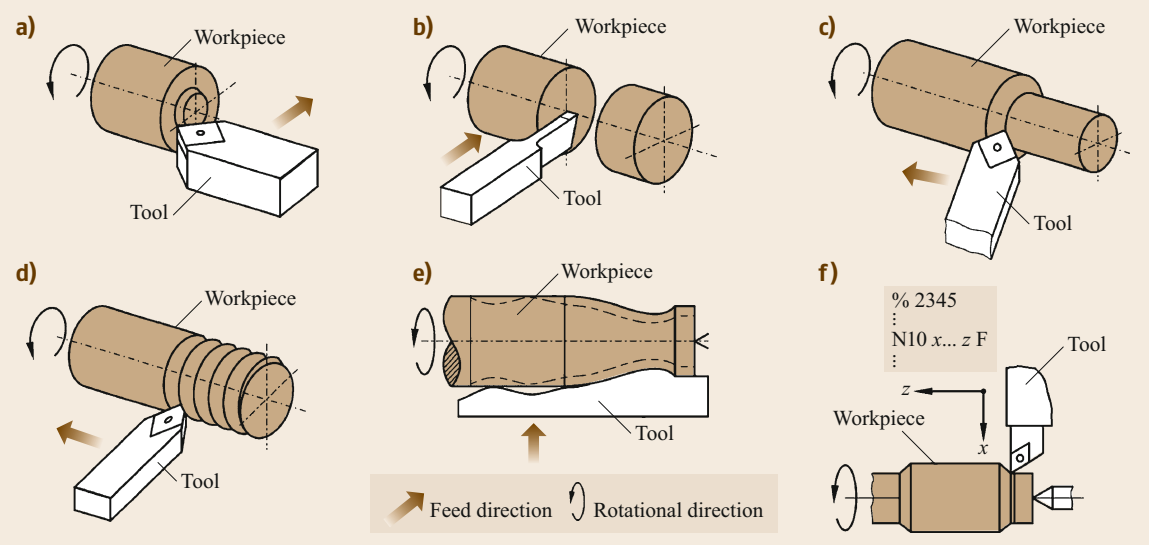

Fig. 12.7a–f Turning processes: **(a)** facing, **(b)** parting-off, **(c)** longitudinal turning, **(d)** thread turning, **(e)** profile turning (tool contour is duplicated in workpiece), **(f)** form turning [12.4]

- Mechanical abrasion (frictional wear) is mainly caused by hard inclusions such as carbides and oxides in the working material.
- Plastic deformation occurs if the cutting material offers inadequate resistance to deformation but provides sufficient toughness.
- Adhesion is the shearing off of pressure-welding areas between the working material and the chip, whereby the point of shearing is located in the cutting material.
- Diffusion occurs at high cutting speeds and mutual solubility of the cutting material and the working material. The cutting material is weakened by chemical reactions, dissolves, and is removed.
- Oxidation also occurs only at high cutting speeds. By contact with oxygen in the air the cutting material oxidizes, and the structure is weakened.

The machinability of a workpiece is determined by the composition of the workpiece material, its structural configuration in the machined area, its previous casting or forging process, and its heat treatment. Machinability is evaluated considering the following criteria:

- Tool wear
- Surface quality of the workpiece
- Machining forces
- Chip form.

For the evaluation of an individual criterion, the machining task must be considered.

12.1.2 Turning

Turning is defined as machining with a continuous (usually circular) cutting motion and any desired feed motion in a plane perpendicular to the cutting direction. The turning axis of the cutting motion keeps its position relative to the workpiece independently of the feed motion. Figure 12.7 [12.4] shows some important turning processes.

In the following, longitudinal cylindrical turning is taken as an example of a turning process. Terminology, names, and designations for geometrical descriptions of the cutting processes can be found in ISO 3002/1 [12.5]. Figure 12.8 [12.2] shows the surfaces and cutting edges defined for the cutting tip.

The angles represented in Fig. 12.9 [12.6] serve to determine the position and shape of the tool in three dimensions. The tool cutting edge angle κ is the angle between the primary cutting edge plane and the working plane. The tool included or edge angle ε is the angle between the primary and secondary cutting edge planes and is given by the cutting edge geometry. The tool cutting edge inclination λ is the angle between the cutting edge and the reference plane and is apparent when looking down onto the primary cutting edge. The clearance angle α, wedge angle β, and rake angle γ can be measured in the tool-orthogonal plane and make up 90° in sum. The values of the relevant tool angles are determined from approximate value tables in relation to the workpiece and cutting materials and the machining process. The tool cutting edge angle κ influences the shape

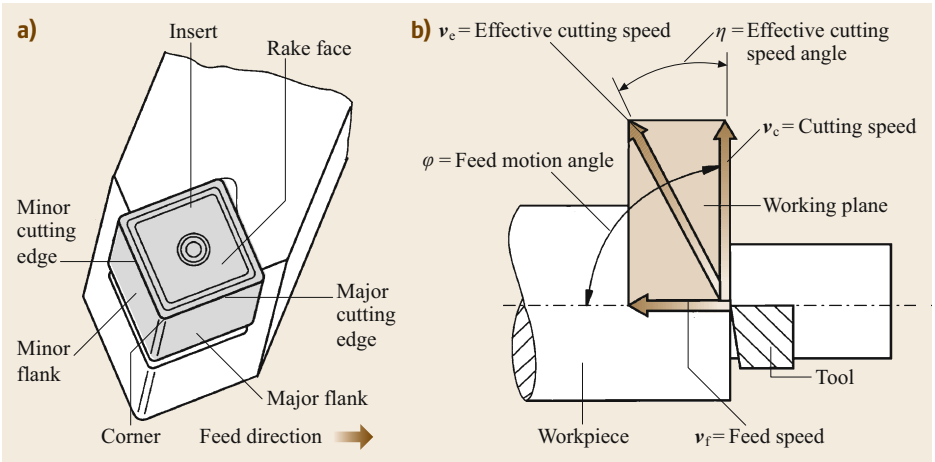

Fig. 12.8a,b Terminology at cutting tip and directions of motion of tool (ISO 3002/1). **(a)** Surfaces; **(b)** motion vectors

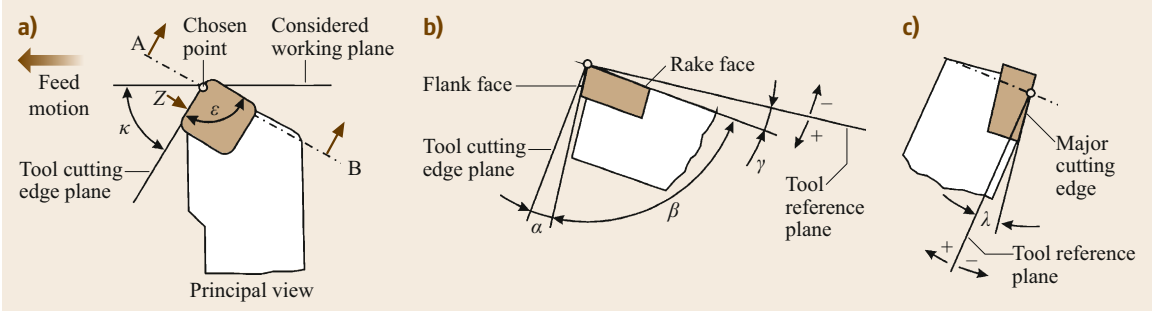

Fig. 12.9a–c Single-point cutting tool angles [12.6]. **(a)** Principal view; **(b)** A–B (tool-orthogonal plane); **(c)** view *Z* (on tool cutting edge plane)

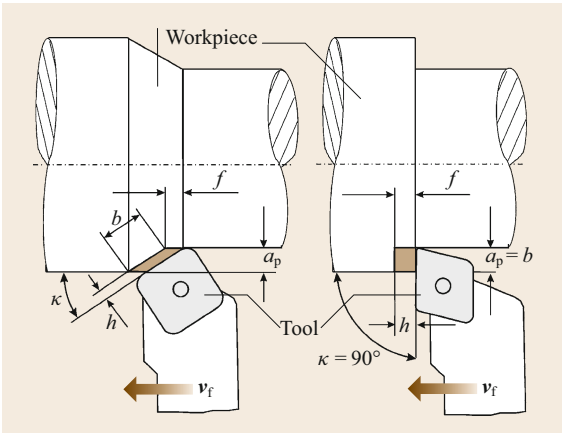

Fig. 12.10 Cut and chip variables in turning; $A = a_p f = bh$, $h = f \sin\kappa$, $b = a_p / \sin\kappa$, $a_e = f$, with A = chip cross section, a_p = depth of cut, f = feed, b = chip width, h = chip thickness, v_f = feed speed, κ = tool cutting edge angle, a_e = width of cut

of the undeformed chip cross section to be removed and, thus, the power required for the machining process (Fig. 12.10; [12.2]).

The bulk volume Q' of the chips flowing over the rake face of the tool varies depending on chip type and form. The characteristic parameter is the chip volume ratio RZ specifying the relationship between the removed chip volume in a given time Q' (bulk chip volume) and the material removal rate Q_w. In this case,

$$RZ = \frac{Q'}{Q_w} , \tag{12.9}$$

$$Q_w = a_p F_c = a_p f D \pi n . \tag{12.10}$$

The chip volume ratio RZ characterizes the *bulkiness* of the chips. It serves to determine the machine tool working spaces, the chip conveying devices, and chip spaces in the cutting tools. The chip volume ratio can amount to very different values according to the chip form (Table 12.1; [12.7]). The more brittle the material,

Table 12.1 Chip shapes, their related chip volume ratio ($RZ = Q'/Q_w$), and rating

Chips	Chip shape	*RZ*	Rating
Ribbon chips		≥ 90	Not positive
Snarled chips		≥ 90	Not positive
Flat helical chips		≥ 50	Not positive
Cylindrical chips		≥ 50	Not positive
Helical chip segments		≥ 25	Good
Spiral chips		≥ 8	Good
Spiral chip segments		≥ 8	Acceptable
Discontinuous chips		≥ 3	Acceptable

the lower this value. Brittleness can be influenced via the composition of the material. For steel, higher sulfur contents (more than 0.04%, free cutting steel with 0.2% S) have a beneficial effect. However, this may impair the toughness of the material in the transverse direction, depending on the form of the dispersed sulfides. Chip breakers ground into the chip surface, sintered in, or attached with the clamping system of inserts cause additional chip deformation, i.e., an additional material load in the chip. The chip is bent by contact with the cut surface of the workpiece or the flank face of the tool and breaks (secondary chip breaking in contrast to segmented or discontinuous chip formation, where the chips leave the chip formation zone as small fragments). Favorable chip forms can also be achieved by selecting the appropriate machine setting data such as feed rate and depth of cut [12.8].

Each material provides resistance towards the penetration of the tool during chip removal. This has to be overcome by means of a force, the resultant force F_z. This force is analyzed by resolving it into its three components (Fig. 12.11; [12.9]). The active force F_a is formed by the cutting force F_c in the direction of the cutting motion together with the feed force F_f. The passive force F_p does not contribute to power conversion, because no motion between the tool and the workpiece takes place in its direction. Thus,

$$F_z = F_a + F_p = F_c + F_f + F_p \,. \tag{12.11}$$

The cutting force related to the area of the undeformed chip is defined as the specific cutting force k_c

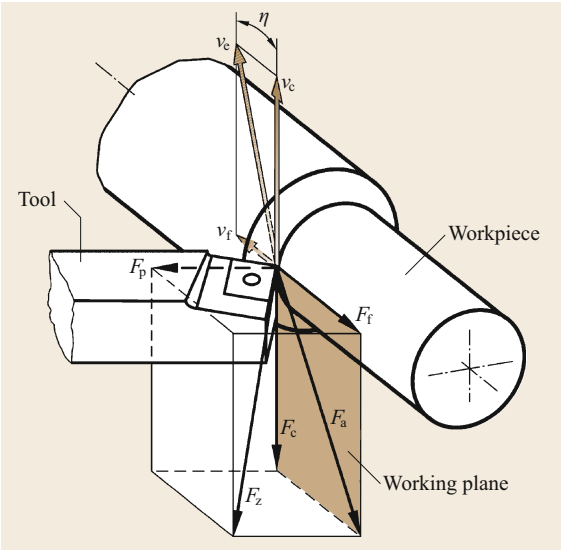

Fig. 12.11 Components of the cutting force (after [12.9])

and depends on a variety of factors

$$k_c = \frac{F_c}{hb} = \frac{F_c}{a_p f} \,. \tag{12.12}$$

It is known from experiments that the specific cutting force k_c is a function of the undeformed chip thickness h. From the logarithmic representation (Fig. 12.12; [12.2]), it can be seen that

$$k_c = k_{c1.1} \left(\frac{h}{h_0} \right)^{-m_c} \,. \tag{12.13}$$

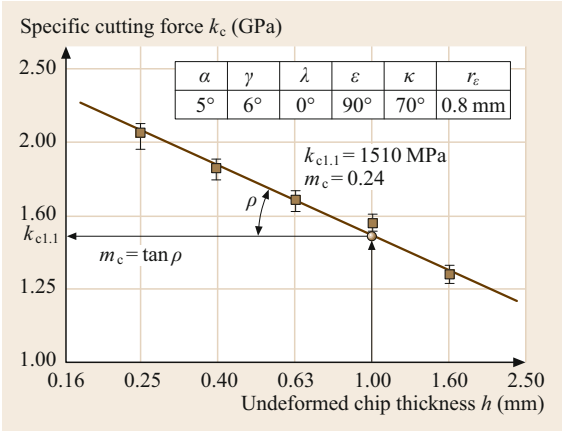

Fig. 12.12 Specific cutting force as a function of undeformed chip thickness. Workpiece material: 20 MnCr5 BG, (1.7147 BG); cutting speed: $v_c = 100\,\mathrm{m/min}$; depth of cut: $\alpha_p = 3\,\mathrm{mm}$; cutting material: HM P10

Here, $k_{c1.1}$ is the unit specific cutting force, i.e., k_c at $h = 1\,\mathrm{mm}$ (indices 1.1 due to $k_{c1.1} = F_c/1.1$ at $b = h = 1\,\mathrm{mm}$). The quantity m_c indicates the increase and is the exponent of the specific cutting force. This equation is named *Kienzle*'s cutting force formula in honor of the initial researcher [12.10] and can also be written as

$$F_c = k_{c1.1} b h^{1-m_c}\,; \tag{12.14}$$

$k_{c1.1}$ and $1 - m_c$ are listed for various ferrous materials in Table 12.2. A direct comparison of the $k_{c1.1}$ values of different materials to indicate the machinability or the energy required for machining is not acceptable, as the exponent m_c can vary significantly. From $m_c < 1$, it follows that at a given cross-sectional area the cutting force and power requirements increase with decreasing undeformed chip thickness. This can be explained physically by the higher share of friction at decreasing undeformed chip thicknesses (Sect.12.1.1).

In addition to the working material and the undeformed chip thickness, k_c depends on further factors as well. Therefore, additional influencing factors will be specified. The correction factors considering the cutting speed K_v, the rake angle K_γ, the cutting material K_{CM}, the tool wear K_{TW}, the cooling lubricant K_{CL}, and the workpiece shape K_{WS} are given in Table 12.3.

The passive force F_p (Fig. 12.11; [12.9]), which is not relevant for the power balance due to its perpendicular orientation, is of importance for the size and form accuracy of the system—machine/workpiece/tool/fixture. Passive force F_p and feed force F_f can be merged to a thrust force F_D. For thin undeformed chip cross sections (bh), the resultant cutting force is perpendicular to the primary cutting edge. From this it follows that

$$\frac{F_f}{F_p} = \tan\kappa\,. \tag{12.15}$$

For normal values of h and b it can be approximated that

$$F_D \approx (0.65 - 0.75) F_c\,, \tag{12.16}$$

wherein F_f and F_p have to be determined.

The exponential functions corresponding to the cutting force formula can be used for a more exact determination. Exponents and the unit-specific cutting force are given in Table 12.2.

The surface finish is determined by the profile of the cutting edge that is creating the workpiece surface and by the feed. From the shaping of the cutting edge corner radius r_ε, the theoretical maximum roughness Rz, th according to EN ISO 4287 [12.11] can be geometrically determined as

$$Rz,\mathrm{th} = \frac{f^2}{8 r_\varepsilon}\,. \tag{12.17}$$

This value should be regarded as a minimum for the surface roughness, which increases due to vibrations, especially at higher rotational and cutting speeds, on the formation of built-up edges (Sect. 12.1.1), and with the progressive wear of the cutting edge.

The tool is subject to mechanical stress due to the machining force, thermal stress due to heating, and chemical attack due to the interaction of the cutting material, the workpiece material, and the surrounding medium. This results in wear on the cutting tool (Sect. 12.1.1). Typical forms of wear are illustrated in Fig. 12.13 [12.12]. In addition, cutting edge wear, rounding of the cutting edge, and scoring may occur on the secondary cutting edge. The type of wear that determines the end of tool life (tool-life criterion) is determined by the respective use. Weakening of the cutting edge by crater wear or an increase in the share of friction in the resultant force due to flank wear are critical in roughing. Cutting edge wear leads to changes in workpiece dimensions, and flank wear or scoring impair surface quality and determine the end of tool life in finishing. Often the lifetime end is set at $V_B = 0.4\,\mathrm{mm}$ or $KT = 0.1\,\mathrm{mm}$. The flank is divided into three zones for more precise identification of the wear.

For a specific cutting material–workpiece-material combination and a given tool-life criterion, the tool life depends mainly on the cutting speed according to an exponential function (Taylor's equation shown on a straight line on a log–log graph) [12.13]

$$\frac{T}{T_0} = \frac{v_c^k}{C}\,. \tag{12.18}$$

Table 12.3 Correction factors for cutting force calculation

Cutting speed correction factor	$K_v = \frac{2.023}{v_c^{0.153}}$ for $v_c < 100$ m/min $K_v = \frac{1.380}{v_c^{0.07}}$ for $v_c > 100$ m/min
Rake angle correction factor	$K_\gamma = 1.09 - 0.015\,\gamma$ (steel) $K_\gamma = 1.03 - 0.015\,\gamma$ (cast iron)
Cutting material correction factor	$K_{CM} = 1.05$ (HSS) $K_{CM} = 1.0$ (cemented carbide) $K_{CM} = 0.9$–0.95 (ceramic)
Tool wear correction factor	$K_{TW} = 1.3$–1.5 $K_{TW} = 1.0$ for sharp cutting edge
Cutting fluid correction factor	$K_{CL} = 1.0$ (dry) $K_{CL} = 0.85$ (nonwater-soluble coolant) $K_{CL} = 0.9$ (emulsion-type coolant)
Workpiece shape correction factor	$K_{WS} = 1.0$ (outer diameter turning) $K_{WS} = 1.2$ (inner diameter turning)

Here, T_0 and v_c are reference values; T_0 is normally set at $T_0 = 1$ min, and C is the cutting speed for an operating period of $T_0 = 1$ min.

The Taylor straight line is plotted on the basis of a wear/tool-life turning test according to [12.12]. With these tests, suitable settings for high-speed steel, hard metals of all machining application categories, and ceramic inserts have been determined. It is usually sufficient to determine the width of the flank wear land VB and/or the crater depth KT, as well as the distance from the crater center to the point of the cutting tip. Table 12.4 shows normal values of the gradient exponent k and the cutting speed C for a tool life of $T = 1$ min and a width of wear land of $VB = 0.4$ mm for various materials.

For metal cutting machines, the optimum cutting speed must be established to meet economical criteria (Fig. 12.14; [12.2]). The optimum cutting speed in relation to time is expressed by

$$v_{c,opt} = C(-k-1)t_{CT}^{1/k}\,. \tag{12.19}$$

Optimization of the cutting speed to minimize unit costs takes into account not only the tool changing time t_{CT} but also the tool costs per cutting edge K_{CT} and the hourly machine tool rate K_M

$$v_{c,opt} = C(-k-1)\left(t_{CT}, +, \frac{K_{CT}}{K_M}\right)^{\frac{1}{k}}\,. \tag{12.20}$$

12.1.3 Drilling and Reaming

Drilling is a metal-cutting process with a rotary cutting motion (primary motion). The tool, i.e., the drill, performs the feed motion in the direction of the rotational axis. Figure 12.15 [12.1] shows common drilling processes. With drilling into solid metal either through holes or blind holes can be produced. The tool is usually a twist drill. Drilled holes are either enlarged with twist drills or with countersinks or counterbores having two or more cutting edges. Step drills produce stepped holes. They usually have multiple cutting edges; for

manufacturing reasons, not every cutting edge has to support all parts of the contour (e.g., one cutting edge may break the edge of a step, while the adjacent one produces a planar surface). Center drills are special profile drills with a thinner spigot and a short, stiff drill section in order to attain a good centering effect. Trepanning cutters produce an annular cut into solid material with the coincidental formation of a solid cylinder or plug. Taps are used to cut internal threads. Reaming is a hole-enlarging process with a small undeformed chip thickness, for producing holes of precise size and shape with a high-quality surface.

For drilling holes with diameters of 1−20 mm and with drilling depths up to five times the diameter, the twist drill is the tool most commonly used (Fig. 12.16; [12.1]). The twist drill consists of the shank and the cutting section. The shank is used to locate and clamp the drill in the machine tool. It is straight or tapered. If a high cutting torque is to be transmitted, tangential flat surfaces transmit the force. The cutting section has a complex geometry, which can be modified to adapt the drill to the respective machining task. Essential parameters are the profile and the web thickness, the flute geometry, and the helix angle, i.e., the pitch of the flutes, the ground drill point, and the drill-point angle. Especially the ground drill point and the drill-point angle can be determined by the user. The profile of the twist drill is designed in such a way that the flutes provide the maximum space for chip removals while ensuring that the drill is capable of adequately

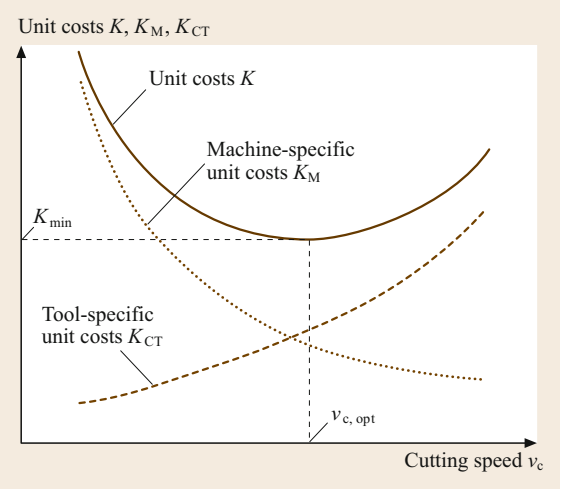

Fig. 12.14 Manufacturing cost as a function of cutting speed v_c

withstanding torsional stresses. These are the two main requirements. A further demand on the drill may be the production of favorable chip forms. This has led to a diversity of special profiles and allows the adaption of the drilling process to particular constraints. Working material also has to be removed from the area in front of the core of the twist drill, with the special boundary condition that the cutting speed v_c in the center is zero. This is achieved by the chisel edge, which connects the major cutting edges.

Along the major and minor cutting edges, the rake angle γ as an important factor influencing the drilling process is not constant but already decreases in front of the major cutting edge from the outside towards the inside. In Fig. 12.17 [12.2], the rake angles at three positions on the major cutting edge and chisel edge, respectively, are shown.

At the outer diameter the rake angle is almost identical to the helix angle δ and decreases in direct proportion to the diameter. Close to the chisel edge, the rake angles on the major cutting edge are already strongly negative. Here, the workpiece material has to be displaced in radial direction. As shown on the left-hand side of Fig. 12.17 all rake angles on the chisel edge are negative. These negative rake angles and the material displacement effect generate high pressures in the area of the chisel edge. To diminish this effect, twist drills are pointed. The center of the drill is tapered by profile grinding in the direction of the flute and towards the drill tip on a conical or similar surface. This way, the rake angle at the chisel edge is increased, and/or the chisel edge is shortened.

The most important type of wear concerning the twist drill is flank wear at the corners. This wear, which is mainly caused by abrasion, generates an increase in the torsional load on the drill, as higher machining forces are present in the corner area. This torsional load may cause the drill to break. Worn twist drills are, therefore, reground until the damaged area of the secondary cutting edge is removed.

Cutting Forces

The forces and moments in drilling are calculated on the basis of *Kienzle*'s approach [12.10, 14]. Figure 12.18 [12.2] illustrates the cutting geometry and the forces implied in drilling processes. The forces arising per cutting edge, which are assumed to act in the middle of the cutting edge, are divided into their components F_c, F_p, and F_f. The cutting forces F_{c1} and F_{c2} generate the cutting moment via the lever arm r_c and the cutting moment M_c

$$M_c = (F_{c1} + F_{c2}) r_c \,, \tag{12.21}$$

$$F_{c1} = F_{c2} = F_{cZ} \,, \tag{12.22}$$

$$M_c = F_{cZ} 2 r_c \,. \tag{12.23}$$

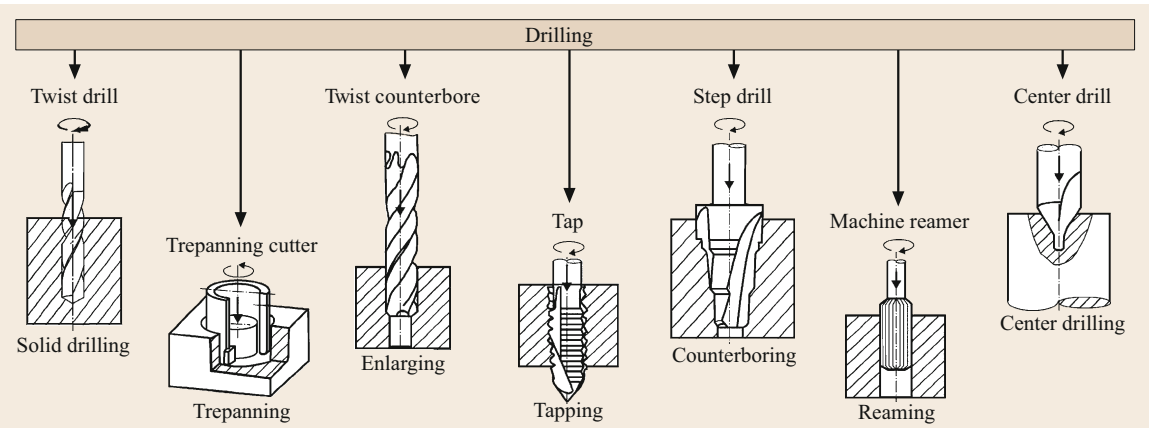

Fig. 12.15 Drilling processes [12.1]

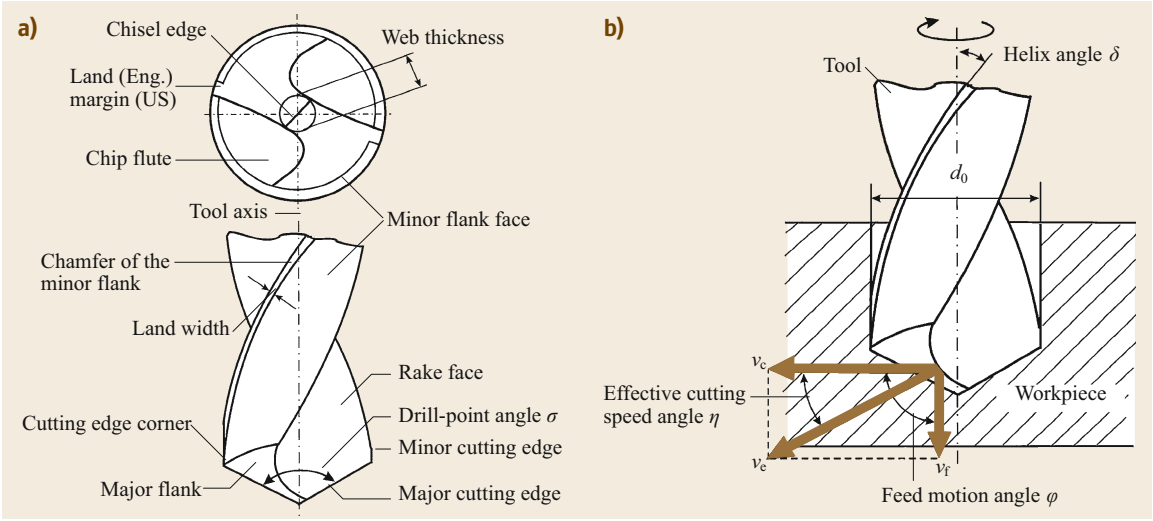

Fig. 12.16a,b Terminology (a) and mode of operation (b) of twist drills [12.1]

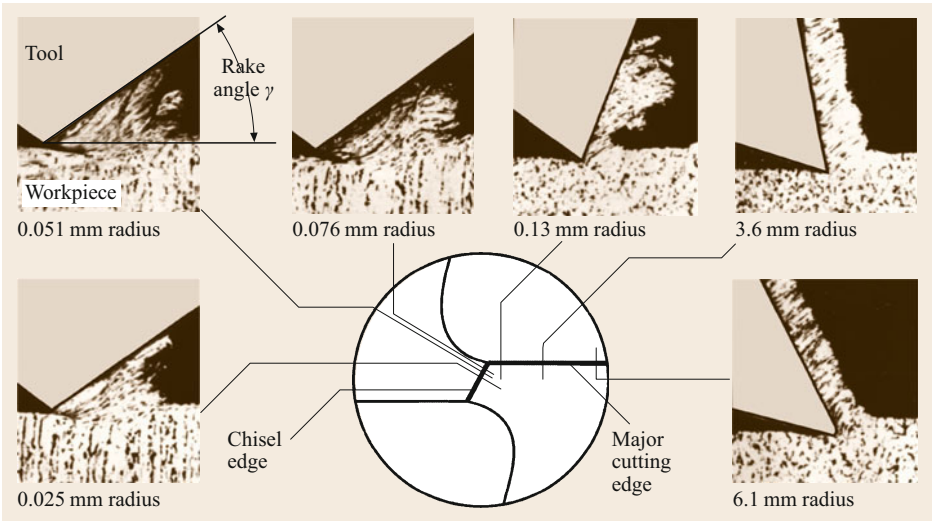

Fig. 12.17 Rake angles at different positions on a drill tip

The sum of the feed forces F_{f1} and F_{f2} is F_f,

$$F_f = F_{f1} + F_{f2} \,, \tag{12.24}$$

$$F_{f1} = F_{f2} = F_{fZ} \,, \tag{12.25}$$

$$F_f = 2F_{fZ} \,. \tag{12.26}$$

In the ideal case, i.e., with a symmetrical drill, the passive forces F_{p1} and F_{p2} cancel each other out. If there are symmetry deviations, F_{p1} and F_{p2} generate interference forces, which impair the quality of the hole. The cutting force per cutting edge results in

$$F_{cZ} = bh^{(1-m_c)}k_{c1.1} \,, \tag{12.27}$$

$$h = F_z \sin\kappa \,, \tag{12.28}$$

$$b = \frac{d_0 - d_i}{2\sin\kappa} \,. \tag{12.29}$$

By analogy, the feed force is

$$F_f = bh^{(1-m_c)}k_{f1.1} \,. \tag{12.30}$$

Values are given in Table 12.5. The feed forces are strongly dependent on the shape of the chisel edge. They can be lowered significantly by web thinning [12.2]. Wear causes them to reach twice their original value or more.

Surface quality in drilling with twist drills corresponds to roughing with $Rz = 10–20\,\mu m$. The surface

roughness can be reduced by reaming with increased dimensional accuracy. The application of solid cemented carbide drills provides another solution. When drilling solid metal, surface qualities, dimensional accuracy, and accuracy of shape like those obtained with reaming are achieved. Most of the drilling tools are further improved by suitable coatings.

Short-Hole Drilling

Short-hole drilling with drilling depths of $L < 2D$ covers a large proportion of bolt-hole drilling, through hole drilling and tapping. For this, short-hole drills with indexable inserts may be used for diameters from 10 to over 120 mm. Their advantage compared to twist drills is the absence of a chisel edge and the increase in cutting speed and feed rate achieved with indexable cemented carbide or ceramic inserts. Due to the asymmetrical machining forces, the use of short-hole drills requires rigid tool spindles similar to those found on common machining centers and milling machines. The higher rigidity of the tool enables pilot drilling of inclined or curved surfaces with an accuracy of IT7.

12.1.4 Milling

Classification of Milling Processes

In milling, the necessary relative motion between the tool and the workpiece is achieved by means of a circular cutting motion of the tool and a feed motion perpendicular to or at an angle to the axis of rotation of the tool. The cutting edge is not continuously in engagement with the workpiece. Therefore, it is subject to alternating thermal and mechanical stresses. The

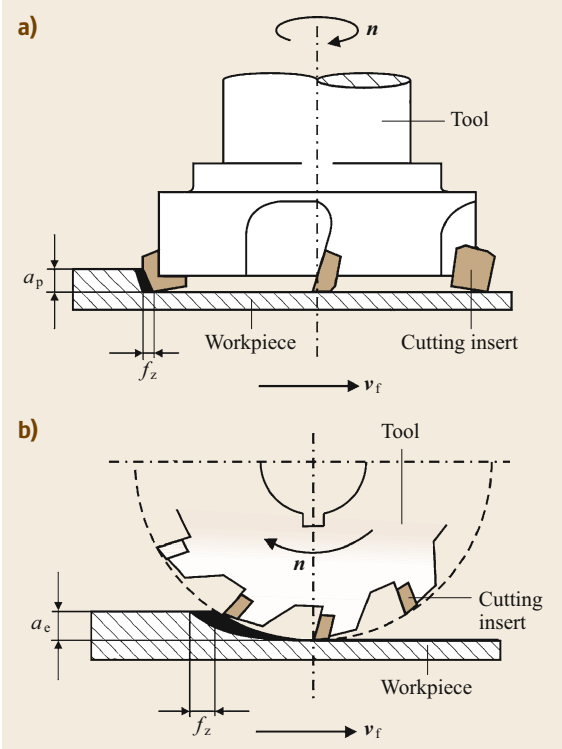

Fig. 12.19a,b Comparison of face milling and peripheral milling. **(a)** Face milling: workpiece surface generated by minor cutting edge. **(b)** Peripheral milling: workpiece surface generated by major cutting edge

complete machine-tool–workpiece-fixture system is dynamically stressed by the interrupted cutting action.

Milling processes are classified according to [12.1] on the basis of the following:

- The nature of the resulting workpiece surface
- The kinematics of the cutting operation
- The profile of the milling cutter.

Milling can be used to produce a practically infinite variety of workpiece surfaces. A distinguishing feature of a process is the cutting edge (major or minor) that produces the workpiece surface (Fig. 12.19): in face milling the minor cutting edge is located at the face of the milling cutter, while in peripheral milling, the major cutting edge is located on the circumference of the milling cutter.

A distinction can be made on the basis of the feed-direction angle φ (Fig. 12.20): in down-milling, the feed direction angle φ is $> 90°$, thus the cutting edge of the milling cutter, enters the workpiece at the maximum undeformed chip thickness, while in up-milling, the feed direction angle φ is $< 90°$; thus the cutting edge enters at the theoretical undeformed chip thickness $h = 0$. This initially results in pinching and rubbing.

A milling operation may include both up-milling and down-milling. The principal milling processes are summarized in Fig. 12.21.

Plain Face Milling with End-Milling Cutters

The kinematics of cutting and the relationship of the cutting forces during milling will be discussed with reference to plain face milling with an end-milling cutter.

Kinematics of Cutting in Milling

To describe the process, it is necessary to distinguish between the tool–workpiece engagement variables and the cutting variables. The engagement variables, which are expressed in relation to the working plane, describe the interaction of the cutting edge and the workpiece. The working plane is described by the cutting speed vector v_c and the feed velocity vector v_f. In milling, the engagement variables are (Fig. 12.22): depth of cut a_p, measured at a right angle to the working plane, cutting engagement a_e, measured in the working plane at right angles to the feed direction, and feed of the cutting edge f_z, measured in the feed direction.

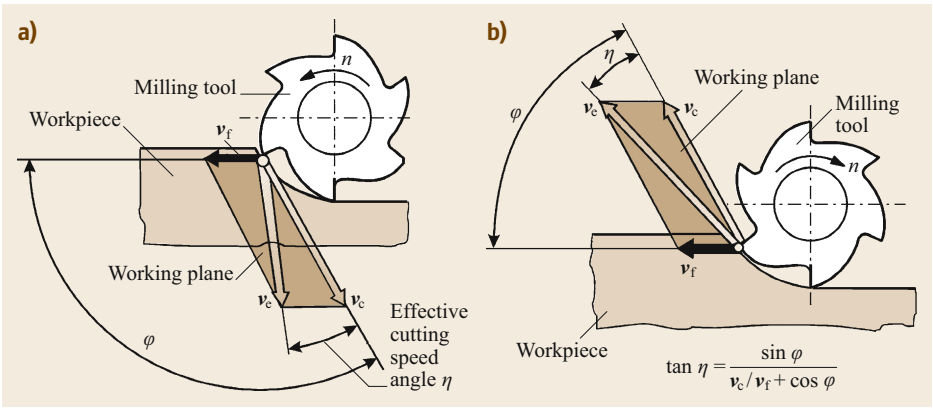

Fig. 12.20a,b Comparison of down and up-milling (DIN 6580) [12.15]. **(a)** Down-milling: feed direction angle $90° \leq \varphi \leq 180°$; **(b)** up-milling: feed direction angle $0° \leq \varphi \leq 90°$

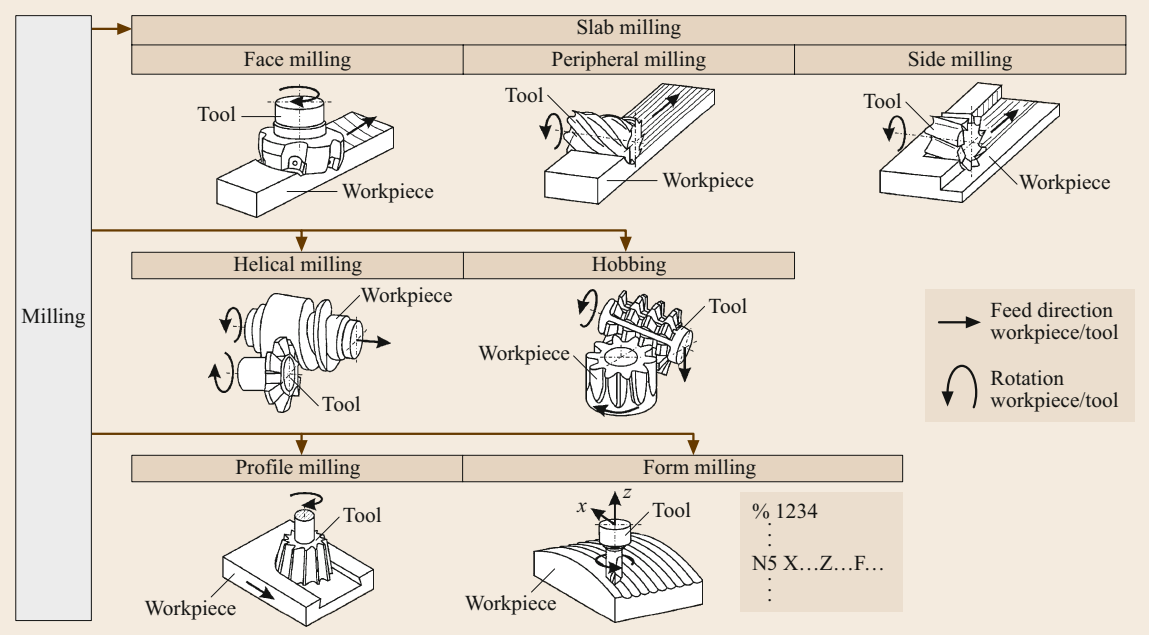

Fig. 12.21 Milling processes [12.1]

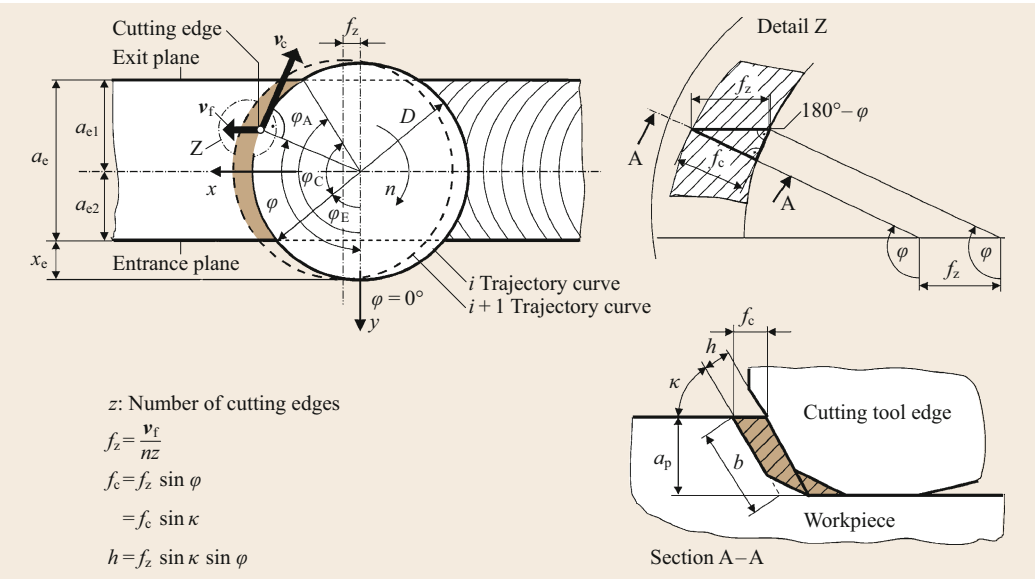

Fig. 12.22 Tool–workpiece engagement variables in plain face milling

For a full description of the kinematics of cutting, the following data are required: milling cutter diameter D, number of teeth z, tool excess x_e, and the cutting edge geometry (side-rake angle γ_f, back-rake angle γ_p, side-clearance angle α_f, back-clearance angle α_p, entry angle κ_r, angle of inclination λ_s, cutting edge radius r, and chamfer).

Due to the interrupted cut, the entry and exit conditions of the cutting edge, and the types of contact, are especially important for milling processes. The types of contact describe the nature of the first and last contacts of the cutting edge with the workpiece. They can be determined from the entry angle φ_E, the exit angle φ_A, and the tool geometry. Generating the first point of contact with the cutting edge tip should be avoided.

From the engagement variables the cutting variables can be derived, which indicate the dimensions of the layer of material to be removed from the workpiece.

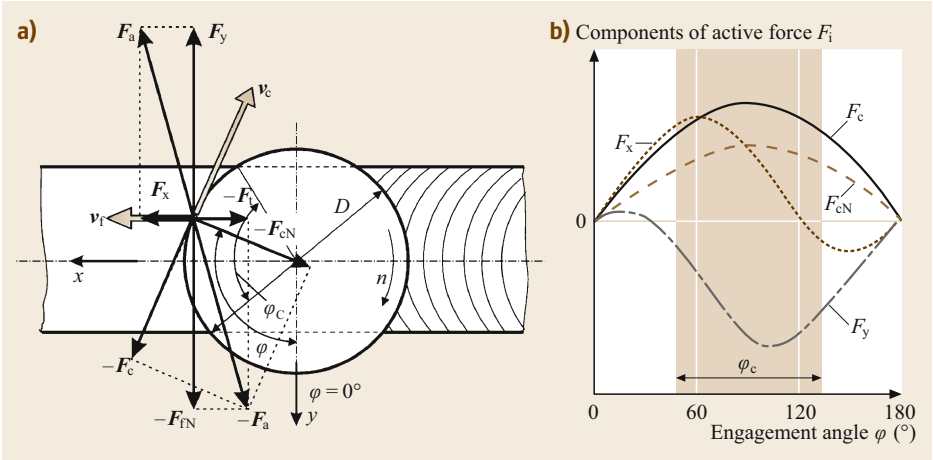

Fig. 12.23a,b Components of cutting force in plain face milling. **(a)** Force vectors in the working plane; **(b)** course of forces versus engagement angle; tool specific forces: F_c, F_{cN}; workpiece-specific forces: F_x, F_y

The cutting variables are not identical to the chip variables, which describe the dimensions of the resulting chips. The cutting edges describe cycloids in relation to the workpiece. As the cutting speed is significantly higher than the feed velocity, they can be approximated by circular paths. Taking this into account, the undeformed chip thickness is (Fig. 12.22)

$$h(\varphi) = f_z \sin\kappa \sin\varphi \,. \tag{12.31}$$

With the undeformed chip width $b = a_p/\sin\kappa$, the undeformed chip cross section is

$$A(\varphi) = bh(\varphi) = a_p f_z \sin\varphi \,. \tag{12.32}$$

The time-related chip volume is $Q = a_c a_p v_f$. The undeformed chip thickness is a function of the entry angle φ and is, thus, not constant as in turning. The evaluation of the milling process is based on the mean undeformed chip thickness

$$\begin{aligned} h_m &= \frac{1}{\varphi_c}\int_{\varphi_E}^{\varphi_A} h(\varphi)\,\mathrm{d}\varphi \\ &= \frac{1}{\varphi_c} f_z \sin\kappa\,(\cos\varphi_E - \cos\varphi_A)\,. \end{aligned} \tag{12.33}$$

Cutting Force Components

The machining force required for chip formation has to be absorbed by the cutting edge and the workpiece. According to [12.9], the machining force F can be resolved into an active force F_a, which lies in the working plane, and a passive force F_p, which is perpendicular to the working plane. The direction of the active force F_a changes with the entry angle φ. The components of the active force can be expressed in relation to the following directions (Fig. 12.23):

- Direction of the cutting speed v_c: the components cutting force F_c and perpendicular cutting force F_{cN} relate to a corotating system of coordinates (tool-specific components of the active force).
- Direction of rate of feed v_f: the components feed force F_f and perpendicular feed force F_{fN} relate to a fixed system of coordinates (workpiece-specific components of the active force).

For converting the active force from the fixed system of coordinates into a corotating system, the following equations apply

$$F_c(\varphi) = F_f(\varphi)\cos\varphi + F_{fN}(\varphi)\sin\varphi \,, \tag{12.34}$$

$$F_{cN}(\varphi) = F_f(\varphi)\cos\varphi + F_{fN}(\varphi)\cos\varphi \,, \tag{12.35}$$

$$F_x(\varphi) = F_f(\varphi) \,, \tag{12.36}$$

$$F_y(\varphi) = F_{fN}(\varphi) \,. \tag{12.37}$$

This transformation is important if, for instance, the cutting force F_c is to be measured with a three-component force-measuring dynamometer that holds the workpiece. Figure 12.23 shows the pattern of the components of the active force in the tool and workpiece-specific systems of coordinates for plain face milling with an end-milling cutter.

Prediction of Cutting-Force Components

Kienzle's machining force equation [12.10] can also be applied to milling. For the machining force components, cutting force F_c, perpendicular cutting force F_{cN}, and passive force F_p, the calculation is

$$F_i = Ak_i \,, \tag{12.38}$$

where $i = c, cN, p$; A is the undeformed chip cross section, and k_i is the specific machining force. Owing to the

Table 12.6 Cutting force components for plain face milling

wide range of undeformed chip thicknesses that is covered by milling (the undeformed chip thickness depends on the engagement angle φ), Kienzle's relationship only applies to certain areas. The undeformed chip thickness range of 0.001 mm < h < 1.0 mm is divided into three sections (Fig. 12.24). For each section, a straight line can be determined, depending on, the unit-specific cutting force k_i and its exponent m_i. For the specific cutting force, the following equations apply

$$k_i = k_{i1.0,01} h^{-m_{i0,01}} \quad \text{for } 0.001\text{ mm} < h < 0.01\text{ mm}\,, \tag{12.39}$$

$$k_i = k_{i1.0,1} h^{-m_{i0,1}} \quad \text{for } 0.01\text{ mm} < h < 0.1\text{ mm}\,, \tag{12.40}$$

$$k_i = k_{i1.1} h^{-m_i} \quad \text{for } 0.1\text{ mm} < h < 1\text{ mm}\,, \tag{12.41}$$

where i = c, cN, p.

Thus, the cutting force for milling with an end-milling cutter is

$$F_i = b k_{i1.1} h^{1-m_i}\,, \tag{12.42}$$

where i = c, cN, p.

The corresponding component of the cutting force can be calculated for milling if the unit-specific cutting force k_i and its exponent m_i for the workpiece/cutting material combination and the cutting conditions are available. The machining indices for axial-plane face milling with a milling head are given in Table 12.6 for a number of workpiece materials and cutting conditions [12.10]. Often, though, to estimate the cutting force during milling, values obtained from turning will have to be used.

The milling machine capacity is designed on the basis of the average machining force

$$F_i = b k_{i1.1} h_m^{1-m_i} K_{pro} K_\gamma K_v K_{TW} K_{CM}\,, \tag{12.43}$$

where i = c, cN, p.

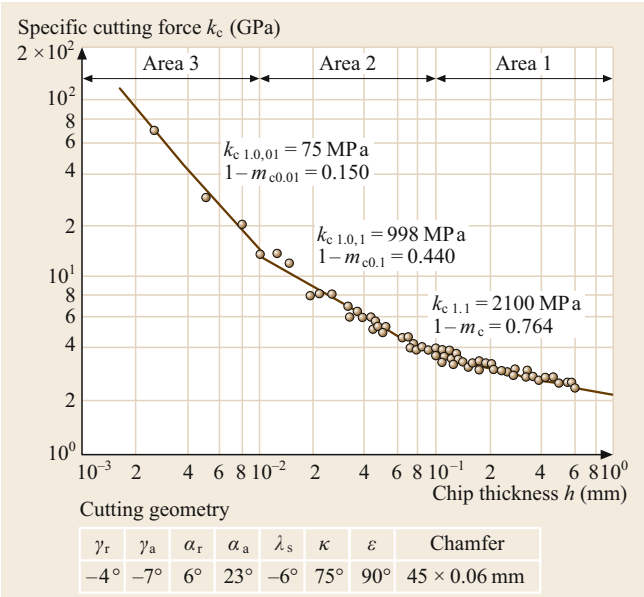

Fig. 12.24 Specific cutting force in plain face milling. Material: Ck45N; material-no.: 1.1191N; cutting tool: HM P 25; cutting conditions: v_c = 190 m/min

In (12.43), h_m is the mean undeformed chip thickness, K_{pro} = 1.2−1.4 is the correction factor for the manufacturing process (the factor takes into account the fact that the machining indices were obtained from turning tests), K_γ is the correction factor for the rake angle (Sect. 12.1.2), K_v is the correction factor for the cutting speed, K_{TW} is the correction factor for tool wear, and K_{CM} is the correction factor for the cutting material. Experimental research on plain face milling has proven that the influence of wear on the machining force components cannot be ignored.

Vibrations

Depending upon the elasticity frequency response of the complete machine-milling cutter–workpiece-fixture

system, the metal cutting forces generate vibrations that may affect surface quality and tool life. According to their origin, these vibrations are divided into separately excited and self-excited vibrations [12.16, 17].

In the case of separate excitation, the complete system vibrates at the frequency of the exciting external forces. Due to the intermittent cutting action of milling, the cutting edges are not constantly in engagement. With a multiple-edged milling cutter, the number of cutting edges in engagement at any time should be taken into account. Depending on the ratio a_c/D, z_{iE} cutting edges are in engagement, the following relationship being valid

$$z_{iE} = \frac{\varphi_c}{2\pi} z, \quad \text{where} \quad \frac{\varphi_c}{2} = \frac{a_c}{D} . \tag{12.44}$$

The mean cutting force acting on the milling cutter and, thus, on the spindle of the milling machine is

$$F_{cm} = z_{iE} F_{cmz} , \tag{12.45}$$

where F_{cmz} is the mean cutting force of a single cutting edge. Superimposed on the mean cutting force is a dynamic-force element. The larger the value of z_{iE}, the smaller the force amplitude; if z_{iE} is an integer, the cutting-force amplitude is at a minimum. The dynamic-force element leads to separately excited vibrations between the workpiece and the milling cutter.

In the case of self-excitation, the complete machining system vibrates at one or more eigenfrequencies, without an external interference force affecting the system. Special importance is attached to self-excited vibrations that arise because of the regenerative effect which are also referred to as *regenerative chatter*. The chatter is caused by variations in cutting force due to changes in undeformed chip thickness [12.16]. Chatter can be influenced by varying the cutting speed, depth of cut, feed rate, and cutting edge geometry.

Tool Wear in Milling

Due to the intermittent cutting action in milling, the cutting material is subject to alternating thermal and mechanical stresses. As a consequence, not only face and flank wear but also cracking in the cutting tip may determine tool life. Figure 12.25 depicts the tool-life travel per tooth based on the flank wear of the primary cutting edge of a ball-nose end-mill cutter for different cutting tool materials [12.2]. As shown especially with the development of cubic boron nitride (CBN), the wear behavior of milling tools could be significantly improved, thus allowing finish-machining of hardened materials by milling [12.18–20]. Suitable data for cutting parameters are accessible via catalogues

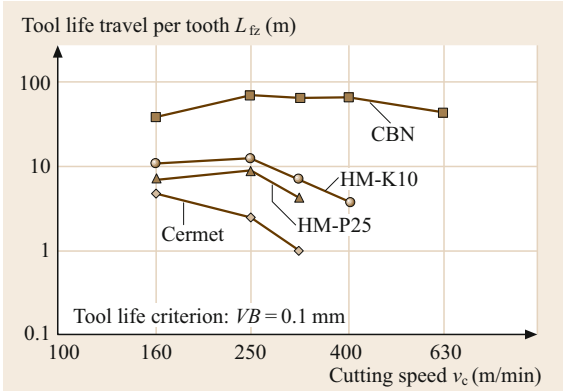

Fig. 12.25 Milling tool wear depending on cutting tool material and speed (after [12.2]). Material: X32CrMoV33; material-no.: 1.2365; $R_m = 1900\,N/mm^2$; ball-nose end mill: $\varnothing = 16$ mm ($z = 2$), $l_w = 37$ mm; cutting conditions: $a_e = 0.8$ mm, $a_p = 0.5$ mm, $f_z = 0.1$ mm, $\beta_f = -40°$

of all major milling tool manufacturers. Depending on the cutting conditions, surface roughness values comparable to those obtained in grinding are achieved. In grinding, the accuracy of shape is achieved by spark-out. As there has to be a minimum undeformed chip thickness in milling, shape defects occur, which can be attributed to the following influencing variables: environment, operating behavior of the milling machine, inhomogeneity in material hardness, heat absorption of the workpiece due to metal cutting, and a change of residual stresses in the edge zone of the workpiece.

Form Milling

Hollow-mold tools such as deep-drawing tools are manufactured by both chip removal and chipless machining processes. Milling plays a dominant role as a controlled material-removal process. The essential characteristic in form milling is the number of actively controlled axes, a distinction accordingly being made between three-axis milling and five-axis milling (Fig. 12.26). In five-axis milling, not only the tip but also the axial direction of the milling cutter is continuously and simultaneously controlled relative to the workpiece coordinate system. The profile of the milled grooves determines the productivity and quality of the process (small final finishing with a small profile depth being desired). It is formed by machining a curved surface in parallel lines and depends on the milling cutter geometry, the workpiece geometry, and the method of work. For a given groove depth t_R, five-axis milling with an end-milling cutter produces significantly larger groove widths b_R than three-axis milling with a convex ball-nose end-mill cutter.

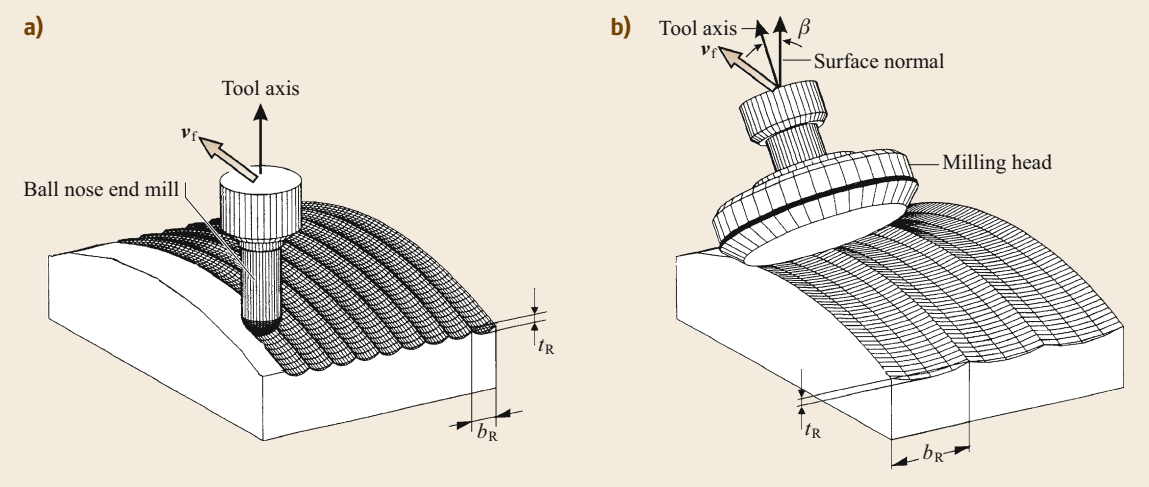

Fig. 12.26a,b Form milling by three-axis milling **(a)** and five-axis milling **(b)**

12.1.5 Other Processes: Planing and Shaping, Broaching, Sawing

Planing and Shaping

According to a German standard, a distinction can be made between planing and shaping. Chip removal is accomplished during the working stroke with a single-point cutting tool. The following return stroke resets the tool to its original position. The feed is performed intermittently, usually at the end of a return stroke.

In planing, the workpiece performs the cutting motion with the cutting speed v_c and the return motion with v_r. Feed f and depth of cut a_p are accomplished by the tool (Fig. 12.27a). In shaping, the tool performs the cutting and return motion, while feed and engagement are accomplished by the workpiece or the tool.

The reciprocating motion of the workpiece (in planing) or the tool (in shaping) produces high inertial forces and limits the cutting speed. As a guideline for the cutting speed, for machining steels, the ranges $v_c = 60–80\,\mathrm{m/min}$ (roughing) and $v_c = 70–100\,\mathrm{m/min}$ (finishing) are well established for cemented carbide tools. Frequently-used special methods are manufacturing by planing or shaping (Fig. 12.27b) to produce involute gears [12.21].

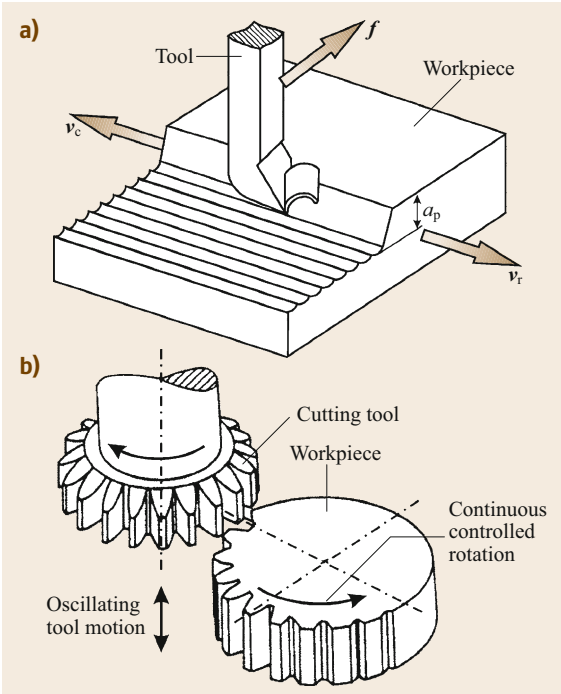

Fig. 12.27 **(a)** Planing and **(b)** gear shaping

Broaching

In broaching, material is removed using a multiple-pointed tool, the teeth of which are one behind the other and are successively stepped by one layer of the material to be removed. Thus, no feed motion is required, as it is *built into* the tool. The cutting motion is usually linear or, under certain circumstances, helical or circular.

The advantages of the process are the high productivity and the possibility of finishing workpieces with a single tool because high-surface finish and dimensional accuracies with tolerances up to IT7 can be achieved. Due to the high cost of the tools, the main areas of use are series and mass production; a new tool is required for each workpiece shape.

A basic distinction is made between internal broaching and external broaching. In internal broaching, the broach is pushed or pulled through a hole, while in external broaching, the tool moves along the surface.

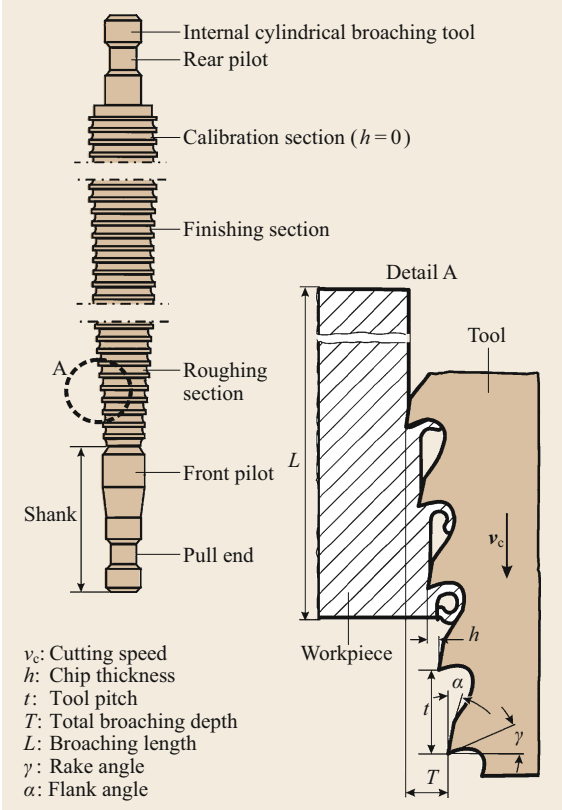

Fig. 12.28 Internal cylindrical broaching tool and process characteristics

Broaches are divided into roughing, finishing, and calibrating teeth sections (Fig. 12.28). Normal undeformed chip thicknesses in flat broaching of steels are $h_z = 0.01–0.15$ mm for roughing and $h_z = 0.003–0.023$ mm for finishing. Broaching of cast materials is carried out up to a thickness of $h_z = 0.02–0.2$ mm in the roughing section and $h_z = 0.01–0.04$ mm in the finishing section.

Cutting speeds are restricted by the hardness of the chosen cutting material at high temperature and by the efficiency of the machine. The cutting material most commonly used, high-speed steel (HSS), permits only low cutting speeds owing to its hot hardness of approximately 600 °C. Cutting speeds of $v_c = 1–30$ m/min are used, with speeds of up to 70 m/min in exceptional cases. The capacity of the process can be increased by using coated HSS or cemented carbide. Due to these developments broaching of case-hardened steel workpieces with cemented carbide tools has also become possible [12.22]. High cutting speeds require high drive-power outputs to accelerate and decelerate the tool and the broach slide, causing a disproportionate increase in equipment costs. Vibration problems might also occur, especially with thin internal broaches.

In broaching, mainly mineral oils are used as cutting fluid for lubricating and cooling in the contact zone, but above all to prevent the formation of built-up edges and to carry away the chips. They usually contain EP (extreme pressure) additives, which are nowadays mostly chlorine free.

Besides the above-mentioned internal and external broaching operations, also special process configurations like gear scraping or turn broaching are used in industry [12.21].

Sawing

Sawing is metal cutting with a multiple-pointed tool with a small width of cut for severing or slitting workpieces. The rotational or linear principal motion is performed by the tool. The teeth of the tool are offset in alternate directions. Thus, the kerf is widened in relation to the saw blade, thus reducing friction between tool and workpiece (Fig. 12.29).

Band sawing is sawing with a continuous, usually straight, cutting motion of a rotating endless band. The motions and cutting parameters are shown in Fig. 12.29a.

The normal cutting speeds for high-speed steels lie within the range of $v_c = 6–45$ m/min, with feed rates per tooth of $F_z = 0.1–0.4$ mm. If bands with inserted cemented carbide teeth are used, the cutting speed can be increased to 200 m/min for steels and up to 2000 m/min for light metals.

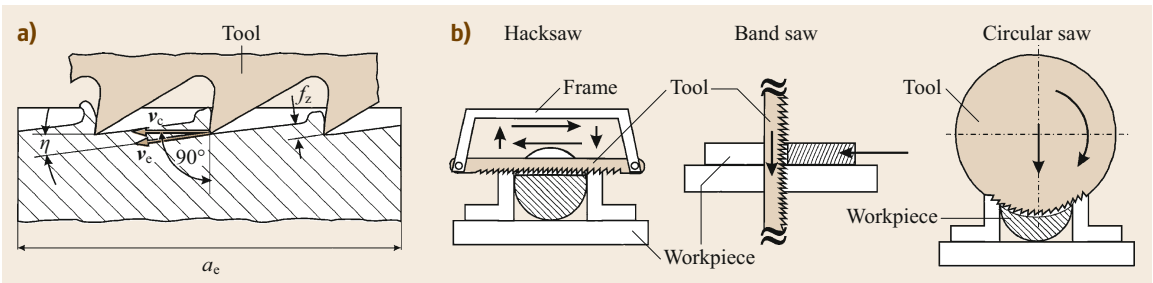

Fig. 12.29a,b Process kinematics of band sawing **(a)** and different sawing variants **(b)**

In reciprocating sawing (hack sawing), a tool of finite length clamped in a holding frame is used. The feed motion is carried out intermittently only as the tool advances or at a constant perpendicular force.

Circular sawing is sawing with a continuous cutting motion using a circular saw blade. In terms of kinematics and metal cutting technique, circular sawing resembles peripheral milling.

12.1.6 Cutting Tool Materials

Cutting tools consist of the cutting tip, the holder, and the shank. Holders and shanks are designed according to constructional and organizational requirements, such as mating dimensions of the machine, the nature and extent of tool storage and tool changing, or the geometry of the workpiece. The cutting tip is responsible for chip removal. It is subject to mechanical and thermal stresses and chemical attack. The tip consequently wears.

A basic dualism applies to all cutting materials. Harder and more wear-resistant materials are typically less tough and stable under periodically changing loads, as well as under unstable cutting conditions and in intermittent cutting. Materials that cope better with variable mechanical or thermal stresses, are often less resistant to wear. The perfect cutting material combining both features is yet to be developed (Fig. 12.30).

To overcome this restricting dualism, various cutting materials are manufactured as composite materials. Coating with hard-wearing carbides or oxides produces a separation of functions; the physically (PVD—physical vapor deposition) or chemically (CVD—chemical vapor deposition) vapor-deposited layers provide wear protection and enhanced tribological performance. The tougher substrate performs the supporting function, even under dynamic load conditions. Examples of these coatings include TiN and TiAlN. The latter is applied in dry-machining applications due to its higher hardness and enhanced thermal stability compared to TiN [12.23]. Multilayer coatings are also increasingly employed due to their superior tribological performance compared to single-layer coatings [12.24].

The primary cutting tool materials include: alloy steels, high-speed steels (HSS), cemented carbides, ceramics, and superhard cutting materials (e.g., diamond and cubic boron nitride).

High-Speed Steels

High-speed steels are usually used for drilling, milling, broaching, sawing, and turning tools. Their hot hardness (up to approximately 600 °C) is far superior to that of tool steels (Fig. 12.31). Their hardness results from their basic martensitic structure and from interspersed carbides: tungsten carbides, tungsten-molybdenum carbides, chromium carbides, and vanadium carbides.

The through-hardenability of tools with large cross sections is increased with molybdenum and/or by alloying with chromium. Tungsten increases the wear resistance and tempered strength, vanadium increases the wear resistance (but is difficult to grind when hard),

and cobalt increases the high-temperature hardness. High-speed steels are traditionally manufactured by casting but can also be manufactured by powder metallurgy (PM). PM steels provide enhanced edge strength and cutting edge durability. They are used for thread-cutting and reaming tools. PM high-speed steels with high vanadium contents are easier to grind than their cast high-speed steel counterparts. Their acceptance is only limited because of their higher cost.

Coated HSS

High-speed steels are usually coated with PVD, which is reactive ion plating performed at low temperatures in order to stay below the tempering temperature during the process. Simple shapes, such as indexable inserts, can be treated by CVD followed by rehardening. Coated tools (drills, taps, hobs, form turning tools) can have a significantly increased tool life compared to uncoated tools.

A coating of single layers or multilayers deposited on the cutting tools improves its performance. The most frequently used coating materials are titanium carbide (TiC), titanium nitride (TiN), titanium-aluminum nitride (TiAlN), and titanium carbonitride (TiCN).

Coated HSS provides increased hot hardness and wear resistance combined with a high ductility and bending strength of the tool. Tool life can be increased up to 2–2.5 times at increased cutting speed by 20–40%. The most important physical-mechanical properties and parameters obtained by PVD processes are shown in Table 12.7.

The application areas of coatings for cutting tools strongly depend on their properties. TiN has high thermodynamic stability; it is chemically passive to ferrous materials. It combines high hardness and sufficient plasticity. TiN-coated HSS tools are mainly used for operations in continuous cutting, e.g., turning, drilling, etc., with the application of cutting fluid.

TiCN provides higher hardness than TiN, and it shows high resistance against oxidation at increased temperatures. TiCN coating is mostly used for milling at increased cutting speeds.

TiAlN has high hardness and increased resistance against oxidation. This material is recommended for high-speed machining combined with flood type application of cutting fluid.

CrN and TiCrN possess high hardness at a rather high level of plasticity. They have high resistance against corrosion and oxidation. HSS tools coated with CrN and TiCrN are recommend for finishing and semifinishing operations at milling with the application of cutting fluid.

Cemented Carbides

Cemented carbides are two-phase or multiphase alloys manufactured by powder metallurgy with a metallic binder. The materials used are tungsten carbide (WC: α-phase), titanium carbide, and tantalum carbide (TiC, TaC: γ-phase). The binder is cobalt (Co; β-phase) with a content of 5–15%. Nickel and molybdenum binders (Ni, Mo) are also used in so-called *cermets* (also cemented carbides). A higher β-phase content increases toughness, while a higher α-phase content increases wear resistance, and a higher γ-phase content enhances wear resistance at high temperatures. Cermets have high edge strength and cutting edge durability. They are suitable for finishing under stable cutting conditions. The manufacturing of cemented carbides by powder metallurgy permits considerable freedom in the choice of constituents (in contrast to casting).

Cemented carbides retain their hardness up to over 1000 °C (Fig. 12.31). They can, therefore, be used at higher speeds (by a factor of 3 or more) than high-speed steels. According to standards (DIN 4990/ISO 513), [12.25, 26] cemented carbides are classified into the metal cutting application groups P (for long-chipping, ductile ferrous materials), K (for short-chipping ferrous materials), M (for ductile cast iron and for ferritic and austenitic steels), N (for nonferrous metals such as aluminum and copper alloys), S (for superalloys and titanium alloys), and H (for hardened materials, such as steels and cast irons). Each group is subdivided due to toughness and wear-resistance grades by adding a num-

Table 12.8 Classification of cemented carbides according to ISO 513:2004-07

Groups of cutting carbide materials			Subgroups of application		Hardness, wear resistance, cutting speed	Toughness, bending strength, feed speed
Designation	Color	Material machined				
P	Dark blue	Steel: all steel, cast steels, except stainless steels	P01 P10 P20 P30 P40 P50	P05 P15 P25 P35	↑	↓
M	Yellow	Stainless steels: austenitic stainless, austenitic-ferritic steels, cast steels	M01 M10 M20 M30 M40	M05 M15 M25 M35	↑	↓
K	Red	Cast irons: cast irons with lamellar graphite, cast irons with spherical graphite	K01 K10 K20 K30 K40	K15 K25 K35	↑	↓
N	Green	Nonferrous metals: aluminum and other nonferrous metals, nonmetal containing materials	N01 N10 N20 N30	N05 N15 N25	↑	↓
S	Brown	Special alloys and titanium: heat resistant special alloys, ferrous – nickel-cobalt, titanium and titanium alloys	S01 S10 S20 S30	S05 S15 S25	↑	↓
H	Gray	Hard materials: tempered steel, high-strength pig iron, chilled cast pig iron	H01 H10 H20 H30	H05 H15 H25	↑	↓

ber. For example, P02 stands for very hard-wearing cemented carbide and P40 stands for tough cemented carbide. The metal cutting application groups do not correspond to grades of cutting tool material, but to the application areas of the finished cutting tools.

Most cemented-carbide cutting tools are coated with titanium carbide (TiC), titanium nitride (TiN), aluminum oxide (Al_2O_3), or chemical or physical combinations of these substances. The coatings are applied by CVD or PVD techniques. They are used to achieve longer tool lives or higher cutting speeds. They broaden the range of use of a grade. Coated cemented carbides should not be used for nonferrous metals, high-nickel ferrous materials, or, because of the edge rounding caused by the coating process, for precision or ultra-precision machining (cermets are better suited for this purpose). Intermittent cutting and milling requires coatings of especially high bonding strength, which can be influenced by process control during coating.

The application areas of carbides fall into six groups, as shown in Table 12.8. The classification is based on the properties of each grade and the machining conditions, type of material being machined, and chip formation.

Ceramics

Ceramic cutting tool materials are single-phase or multiphase sintered, hard materials based on metal oxides, carbides, or nitrides. In contrast to cemented carbides, no metallic binders are needed, and the material provides high hardness even at temperatures above 1200 °C. Ceramic inserts are generally suitable for machining at high cutting speeds, usually exceeding 500 m/min.

The use of aluminum oxide ceramic is restricted by its lower bending strength and fracture toughness compared to cemented carbide. In intermittent cutting with alternating mechanical and thermal stresses,

Table 12.9 Properties of oxide ceramics

Properties	Al_2O_3	Al_2O_3-ZrO_2	Al_2O_3-TiC	Al_2O_3 with SiC whiskers

microcracking, crack growth with microchipping, or total fracture can occur. This effect greatly depends on the nature and composition of the ceramic. The change from single-phase materials (Al_2O_3) to multiphase materials has improved toughness considerably: today, Al_2O_3 containing 10–15% ZrO_2 (transformation toughening), Al_2O_3 with TiC (dispersion strengthening), or Al_2O_3 reinforced with SiC whiskers (high toughness) are used. The main field of application is the turning of flake graphite cast iron at high cutting speeds, though the turning of steel is also feasible. Additions of up to 40% TiC to the Al_2O_3 ceramic (black mixed ceramic) increase toughness and edge strength. These are used for hard machining and the finishing of cast iron.

Silicon nitride (Si_3N_4) exhibits many excellent cutting material qualities (high strength, hardness, oxidation resistance, thermal conductivity, and resistance to thermal shock) owing to strong covalent bonding of the elements. Here, fracture toughness is not a primary limiting factor in selecting application areas. Sintered Si_3N_4 ($\rho = 3.1\,g/cm^3$, $R_m = 650\,MPa$), hot-pressed Si_3N_4 ($\rho = 3.2\,g/cm^3$, $R_m = 700\,MPa$), and the material system Y-Si-Al-O-N are all used as cutting tool materials. The manufacture and use of Si_3N_4 is currently limited by the sintering auxiliaries (e.g., magnesium oxide, yttrium oxide), which determine the glassy phases in the cutting material. When machining steel or ductile cast iron, failure occurs due to severe wear; Si_3N_4 is suitable for turning and milling of gray cast iron, for highly intermittent cutting actions, and for the turning of high-nickel content materials. The properties of some oxide ceramic materials are given in Table 12.9.

Superhard Cutting Tool Materials

Superhard cutting tool materials include polycrystalline diamond (PCD), polycrystalline cubic boron nitride (PCBN), monocrystalline diamond (MCD), and various forms of chemical vapor deposition diamonds (both thin-film coatings and self-supporting thick films). The polycrystalline diamond is typically manufactured as a *backed* 0.5–2.0 mm layer of superhard composite on a cemented carbide substrate. PCD is used to machine nonferrous metals, including metal matrix composites (MMC), wood, composites, stone, and certain cast irons. Due to a well-defined maximum operating temperature of between 700–800 °C, it cannot be used for machining of steels. PCBN is manufactured either as a carbide-backed or solid material. Different grades of PCBN are used for the machining of gray, white, and high-alloy cast irons, and hardened steels. Coatings on PCBN tools are becoming increasingly popular as with cemented carbides. Monocrystalline diamond tools are used for high-precision and ultraprecision machining of aluminum, copper, electroless nickel, glass, plastic, and silicon where, for example; surface finish require-

Table 12.11 Tool clamping devices for advanced applications (after [12.28])

ments of several nm and form errors of less than 0.1 µm are common [12.27]. Because it is a single-crystal material, it is possible to produce an extremely sharp cutting edge, within the range of 10–100 nm. Thick-film CVD diamond is generally considered as lying between monocrystalline and polycrystalline diamond, in terms of properties and behavior in application.

In Table 12.10, conditions of cutting parameters and application areas of PCB and PCD tools are shown.

12.1.7 Tooling

The design of tools has to take all possible impacts into account, which can occur during the specific process, comprising mechanical, thermal and chemical loads, as well as flexibility, changeability, maintenance, and costs. Therefore, solid tools, tools with brazed tips, and tools with indexable inserts are in use.

In turning, the toolholders have to be mounted to the different types of turrets on a lathe, taking into account tool changing time and collision contours. In the case of driven tools, like milling, shank-type cutters have to be clamped in specific toolholders, which are used as an interface between the actual cutting tool and the main spindle of the milling machine (Table 12.11). The stiffness of the cutters and the toolholders is important for the required surface quality and has a strong influence on the probability of chatter in milling.

In the case of high performance or high-speed cutting conditions, significant attention has to be paid to the quality of the machine–tool-interface regarding unbalance, stiffness, and damping [12.28, 29]. The machine facing side of these toolholders is standardized. Most often, short tapers, steep-angle tapers, or hollow shank tapers are used. The toolholders are fixed in the main spindle by mechanical or hydraulic power.

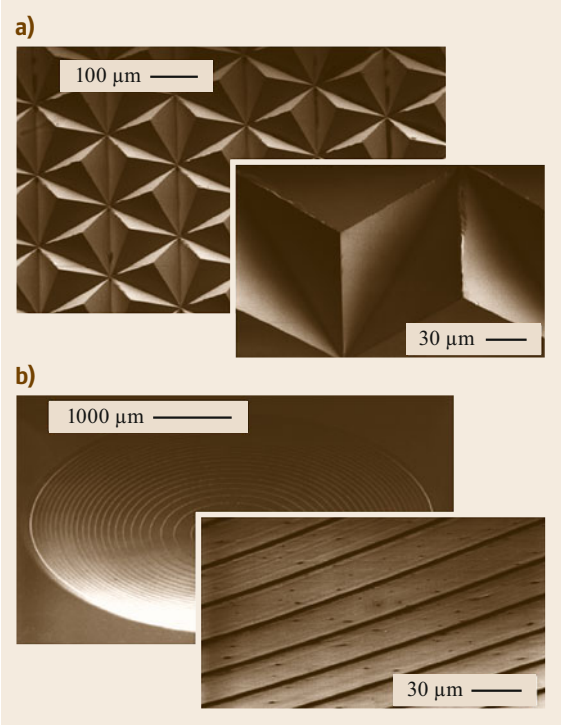

Fig. 12.32a,b Features produced by diamond microcutting (source: LFM, Bremen; after [12.33]). **(a)** Mold for reflection foils with microprisms, material: $AlMg_3$, cutting process: diamond fly cutting; **(b)** injection mold for Fresnel lenses, material: electroless nickel coating on powder metallurgical steel, cutting process: diamond turning

A number of different toolholder systems are available on the market. This system, the machine tool, and the tool changer determine the possible chip-to-chip time in the case of a change of the tool [12.30].

12.1.8 Microcutting

Micromanufacturing is defined as the production of components with feature sizes in the range of 1–500 µm. Microcutting is, therefore, a process used for the production of components of micron dimensions with submicron-form accuracy and surface roughness to within a few tens of nanometers [12.31, 32], achieved by the mechanical removal of material using defined edge tools. Common microcutting operations include microturning, microdrilling, and micromilling. Examples of features produced by microcutting are shown in Fig. 12.32, while microcutting tools are shown in Fig. 12.33.

The scale of the tool cutting edge geometry, often simplified as a single radius of curvature, is generally similar to the scale of the undeformed chip thickness

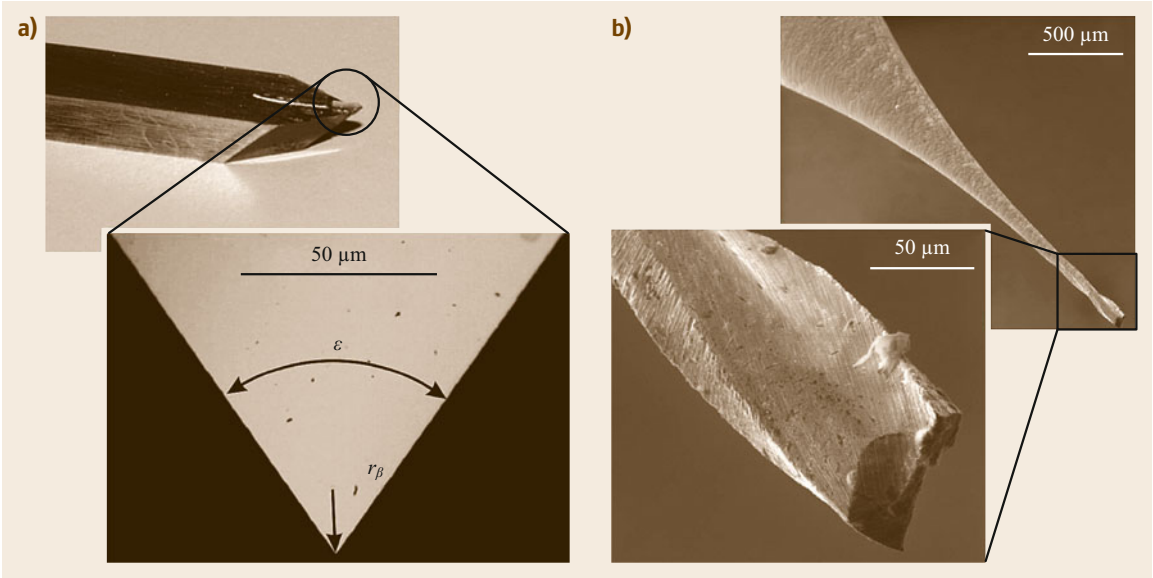

Fig. 12.33a,b Microcutting tools for turning (source: LFM, Bremen) and milling (source: IPK, Berlin; after [12.27, 34]). **(a)** Monocrystalline pointed diamond tool, nose angle ε: 70°30′, cutting edge radius γ_β: < 50 mm; **(b)** micro end mill $D = 0.1$ mm, cemented carbide substrate, coating: TiAlN

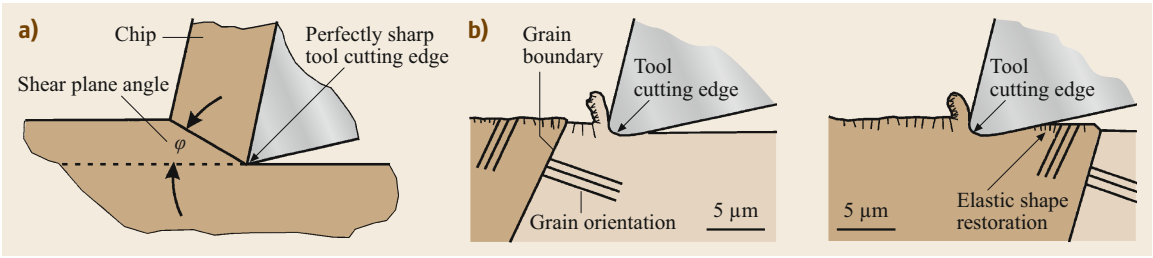

Fig. 12.34 **(a)** Conventional orthogonal cutting and **(b)** microcutting showing finite tool cutting edge geometry and workpiece anisotropy

(as indicated in Fig. 12.34b). The result is a *size effect* due to a more negative *effective rake angle* as the undeformed chip thickness is reduced. There is also an increase in friction, elastic and ploughing energies, relative to the energy expended in material removal, and, therefore, an increase in the specific cutting energy. The increasing negative rake produces hydrostatic stresses in the near surface, enabling ductile mode machining of brittle materials (optical glasses, ceramics, etc.) [12.35]. An isotropic material size effect also pertains, whereby the material strength approaches the theoretical value due to the reduction in dislocation density in the cutting zone as the undeformed chip thickness decreases.

The work material microstructure may also affect the performance of the microcutting process. For example, the grain size and anisotropy of polycrystalline (PC) metals and alloys can affect the surface finish. Figure 12.34b shows a simplified model of this mechanism. The modulus of elasticity E of a PC material varies in different atomic lattice directions. After the cutting tool has passed, as shown, the grains return to equilibrium positions (the *springback effect*) but to different surface levels due to the differences in the crystal orientations and modules of elasticity.

Tool materials for microcutting must be of high hardness. Diamond tools are generally used for cutting nonferrous metals, ceramics, semiconductors, and glasses. Tungsten carbide is used for ferrous-based metals where diamond tools are limited due to their wear conditions (graphitization, oxidation, diffusion, and carbide formation). Single-crystal diamond cutting tools are preferred for microcutting, as they can have cutting edge *radii* in the order of 10 nm. With polycrystalline tools, such as tungsten carbide-based tools, the edge sharpness achievable is limited by the grain size. Ferrous alloys were recently machined with

single-crystal diamond tools using ultrasonic elliptical vibration cutting to lower cutting temperatures [12.36].

The mechanics of tool and machine-tool design must be considered in microcutting. Tools with a small diameter for microdrilling and micromilling require very high spindle speeds. Furthermore, the precision of a machine tool has to be increased in order to maintain a given relative dimensional tolerance. As a component and associated load are reduced in scale, the structural stiffness will decrease, and the natural frequency and internal stresses will increase. Finally, the ratio of the total surface area to the workpiece (feature) volume is increased in microcomponents, making the surface integrity of the component more significant in comparison with bulk properties.

12.1.9 High-Speed Cutting

The development of high-efficiency machine tools and new cutting tool materials facilitated the application of high-speed cutting (HSC) in metal working.

The main objective of HSC application is to the reduce machining time and increase the removal rate. High cutting speeds lead to lower cutting forces, higher machining accuracy, and improved surface quality compared to traditional cutting [12.37].

The high-speed machining (HSM) concept was initially developed for the aerospace industry, especially for machining titanium alloys, but it was soon adapted by other industrial branches using different materials. At present, a range of materials are being machined with HSM, including nickel-based alloys, titanium, steel, cast iron, aluminum, and reinforced plastics. Industries using HSM include the aerospace, automotive, and tool/die industries, just to mention the most important users, primarily for manufacturing parts made from aluminum, titanium, and steel alloys. There are a number of extremely important challenges affecting high-speed machining, namely the need for hard machining, environmentally-friendly hard machining, and the machining of free-form (sculptured) surfaces, high material removal rates, and increased productivity and quality.

In aerospace, the wing spar and stringer components are made from high-grade aerospace aluminum materials. Typically, at least 85% of the aluminum billet is turned into chips, which requires excellent off-line work preparation to eliminate machine tool loading time waste, powerful chip management, and cutting fluid management systems. It is extremely important in the aerospace industry that the HSM technology does not induce residual stresses into the machined component, thus it drastically reduces the problem otherwise caused by fatigue. It is also important that thin walls can be machined easily without deformation.

There are a number of major automotive industries in the world that also use HSM for making their strategic components in combination with hard cutting to replace the very expensive grinding technology.

In the tool/die industry, tools and dies are normally made of difficult-to-machine alloys, which have to be heat treated for high production performance. This represents an extremely great challenge for high-speed machining, including machine tools, cutting tools, and technology alike.

In HSM, the maximum cutting speed depends upon the workpiece material, the type of cutting operation, and the cutting tool used.

Salomon proposed to use high cutting speeds when machining various materials [12.38]. This idea was based on the hypothesis that when the cutting speed increases to a critical value, the cutting temperature decreases. Some research has been carried out with cutting speeds within the range of $v_c = 47\,000–132\,000\,\mathrm{m/min}$. The most general definition of HSM is the economical utilization of resources and functions to remove the greatest amount of material in the shortest time span by mechanical means.

The achievable maximum cutting speed largely depends on the available high-speed spindle technology and tool technology, including the tool diameter. The high-speed range lies between 800 and 10 000 m/min, depending on the cutting material, productivity, and accuracy [12.39].

In principle, the higher the cutting speed, the more energy is required to remove material [12.40]. The heat generated causes a softening of the material, thus the energy requirement is reduced. During high-speed machining, friction and the length of the contact area between the chip and the rake face of the tool reduce contact time. This results in corresponding heat distribution in the cutting system and decreased intensity of heat flow to the tool and workpiece.

The increased productivity of processes using HSC is attributed to the improved material removal rate. Reduction of cutting forces, the thermal emission level at the cutting area, and the thermal-mechanical effect on the machined surface, as well as its elastic form recovery allows considerable improvement of quality and accuracy of machined parts.

HSC has a number of competitive advantages over traditional machining:

- A substantially increased material removal rate.
- An excellent surface finish with superb surface integrity.

Table 12.12 Examples of high-speed cutting technologies

Material	Cutting tool	Machining operation	Cutting speed (m/min)
Al-alloys	Coated carbides, PCD	Milling	1000–7000
Mg-alloys			
High-temperature steel, graphite, copper	Coated carbides, cutting ceramics, PCB	Milling	350–2000
Reinforced plastics, nonferrous metals	Coated cermets	Drilling	100–300

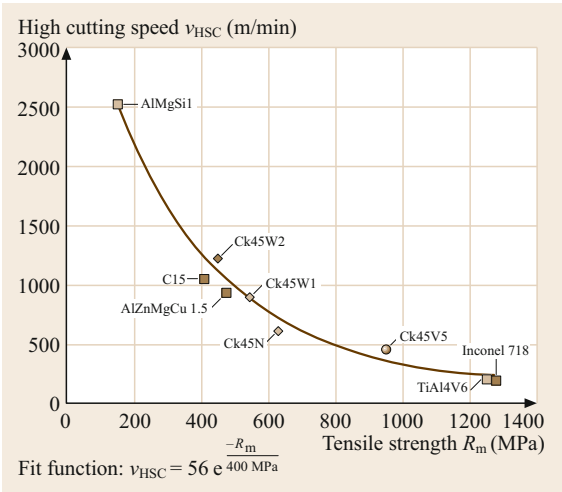

Fig. 12.35 Material dependence definition of HSC (after [12.41])

- Low cutting forces, which allow for the machining of thin-walled sections.
- A high-frequency system that does not cause any vibration during machining. .
- *Cold* machining, whereby the chips take away most of the heat generated in the process.
- An increased accuracy of machining.

Table 12.12 shows some high-speed cutting applications.

The efficiency of high-speed cutting becomes apparent when cutting hardened steels with hardness above 45 HRC. HSC of hardened steels and refractory materials is only possible at a small depth of cut and with small wear land of the cutting tool. Machine tools for high-speed cutting should have high rigidity and be equipped with a high-pressure or minimum-quantity lubrication system.

In any case, the definition of a high cutting speed is material dependent. In Fig. 12.35, an attempt is presented to deduce the area of the high cutting speed v_{HSC} from material properties. Extensive research has led to the conclusion that the tensile strength of the workpiece material is suitable for a definition of v_{HSC} by means of an empirical equation [12.41].

High-Efficiency Machining (HEM)

High-efficiency machining means cutting a part in the least amount of time, which is the real target function in machining. High-efficiency machining can be achieved by a variation in the feed rate. Typically, high-speed machining is accomplished with very small axial cut depths in order to achieve good surface finish and avoid damage to the cutter, workpiece, or spindle. Feed-rate optimization software can be employed to achieve better cutting efficiency with greater axial depths at high feed rates similar to those of HSM and to protect the cutter in those few places where the chip load momentarily increases. Constant chip load tool paths allow optimum use of the cutter's strength and the machine's speed and power. The software detects conditions under which the chip load would be too high and adjusts the feed rate to a more reasonable level. It returns to the higher feed rate when it is suitable [12.42].

Thin-walled components are widely used in the aerospace industry. However, thin-walled components deflect very easily under the cutting forces during the cutting process, which results in compromised machining precision and efficiency. Some solutions have been proposed for the control of machining deflection, such as the NC compensation approach by a tilting tool.

Using this method, the machining deflections are analyzed by FEM. Then, the feed rate is adjusted to the degree of deflection by CNC (computerized numerical control) compensation in order to cut off the excessive material due to the deflection. Thus, the thin-walled component can be machined with high precision and high efficiency on a five-axis CNC machining center.

12.1.10 Hard Machining

Machining of steels of hardness beyond 45 HRC (hardness Rockwell cone) is often required in metal cutting; this is called hard machining. Therefore, hard machining, turning, milling, and drilling, are viable alternatives to grinding.

Hard machining is characterized by a low friction coefficient in the cutting area, the application of a relatively high cutting speed, low feed and depth of cut, which result in reduced chip–tool contact length. Due to the redistribution of the heat generated that causes

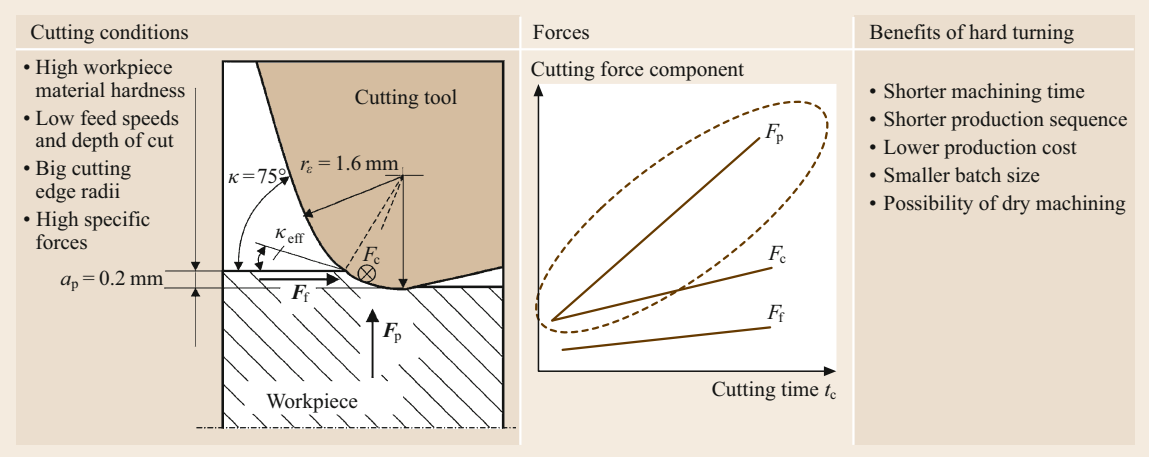

Fig. 12.36 Principle and benefits of hard turning (after [12.43])

a softening of the material and to the high compression load on the workpiece material, machining efficiency increases. The major breakthrough of this technology was connected with the introduction of suitable cutting tool materials such as ceramics and CBN for turning and coated tungsten carbides for milling and drilling. These developments made hard machining a serious competitor for grinding and electro-discharge machining. As an example of successful application of hard machining, the conditions and benefits of hard turning are presented in Fig. 12.36. It is important to mention that this is the fast-rising and dominating passive or back force F_p, which needs an excellent lathe with superior stiffness to compete with grinding. Also the possibility to apply dry machining is a major benefit, allowing all costs and problems related to cutting fluids to be avoided.

12.2 Machining with Geometrically Nondefined Tool Edges

12.2.1 Fundamentals

Machining with geometrically nondefined tool edges is cutting by the mechanical action of cutting edges on the material. The cutting edges are formed by grains of hard material that are randomly shaped and arranged. They are either bonded together into a tool (grinding, honing) or are used loose (lapping, abrasive blasting). The cutting edge geometry is not described with reference to a single grain. The individual cutting edge is geometrically nondefined. The processes are divided into the following subgroups:

- Grinding with rotating tools
- Belt grinding
- Honing
- Lapping
- Free abrasive grinding/abrasive tumbling
- Machining by abrasive blasting.

The common factor in these processes is that the grains of hard material generally form several cutting edges. The important cutting edge angles for chip formation, the clearance angle α, the rake angle γ, and the wedge angle β are only indicated by means of statistical parameters such as mean values or distributions. On average, sharply negative rake angles and large contact and friction zones are formed between the grain and the workpiece. The cutting edges penetrate only a few micrometers into the material. The undeformed chip thickness distribution depends on the positioning of the cutting edges in the mixture of grains (microtopography of the cutting zone) and the geometry of the machined workpiece surface. Not only chip removal but also elastic and plastic deformations without chip removal take place.

High normal forces result between tool and workpiece at the predominantly negative rake angles of the cutting edges. They lead to elastic deformations in the machine (stretching of the frame and deflection of the spindle), the tool, and the workpiece. The amplitude of deformations may be comparable to the normal small feed motions. Therefore, a distinction should be made between the theoretical and the actual feed motion (Fig. 12.37).

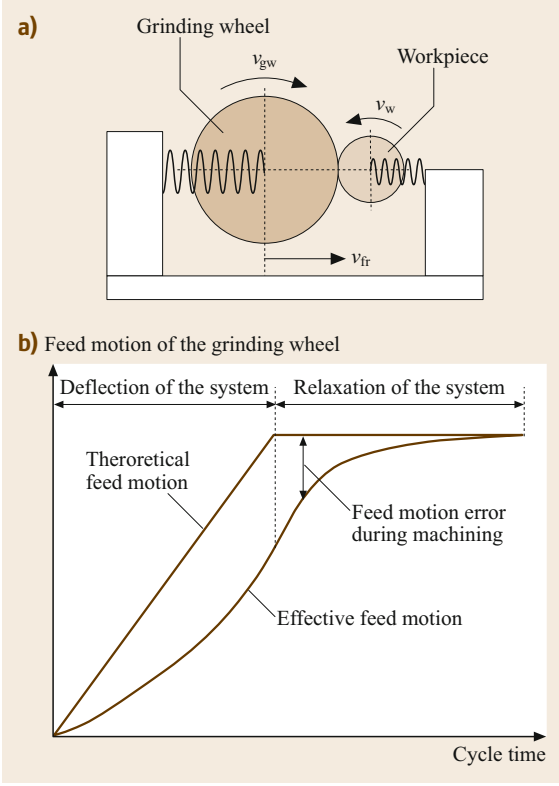

Fig. 12.37a,b Feed motion errors in grinding due to elastic deformations in the machine tool–workpiece system. **(a)** Elastic model of the tool–workpiece system. **(b)** Theoretical versus effective feed motion

Machining processes with geometrically nondefined tool edges are frequently used as final machining processes for workpieces subject to exacting quality requirements. Figure 12.38 shows a comparison of various precision machining processes with regard to operational results and efficiency. It can be seen that the grinding processes achieve high rates of material removal, while honing and lapping are able to produce the best surface qualities.

The chip formation mechanism when using geometrically nondefined tool edges differs from that of machining with geometrically well-defined tool edges (Fig. 12.39). In phase 1, the often sharply negative rake angle of the individual grains causes elastic deformation of the material. In phase 2, plastic deformation occurs, while in phase 3, the actual chip removal takes place. A large amount of friction occurs between the individual grains and the workpiece.

The mechanical energy supplied is almost exclusively converted into heat. Figure 12.40 shows a qualitative distribution of the heat flows around an individual grain. Most of the heat generated flows into the workpiece, while a small part finds its way into the grain, the bond, and the surroundings (cooling lubricant, atmosphere). Temperature increases in the workpiece may harm its surface integrity. This is manifested in thermally-induced residual stresses, structure changes, or cracks, which influence the subsequent behavior of the workpiece in service. The use of abrasive materials (CBN, diamond) and bonds with superior thermal conductivity reduces the proportion of heat that penetrates into the workpiece [12.44, 45].

In machining with geometrically nondefined tool edges, the use of cooling lubricants is important for the end result. The cooling and lubricating effect can reduce tool wear. Furthermore, the temperature of the workpiece is reduced, and the danger of thermal damage to its surface is decreased. The lubricants used are nonwater-miscible (oils) and water-miscible (emulsions, solutions) cooling lubricants, the effect of which can be

	Grinding	Honing	Lapping

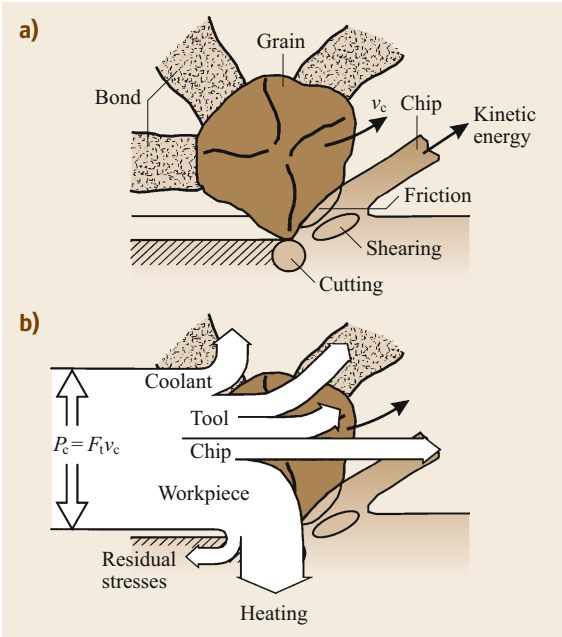

Fig. 12.40a,b Energy conversion: **(a)** effects of energy conversion; **(b)** energy flows

further improved with additives (polar and EP additives to improve the lubricating effect, antifoaming agents, biocides, and rust inhibitors). The cooling effect depends on physical parameters: the specific heat capacity c in kJ/(kg K), the heat transmission coefficient α in W/(m^2 K), the thermal conductivity λ in W/(m K), the heat of evaporation I_d in kJ/kg, and the surface tension σ in N/m. The lubricating effect is described by the tribological parameters of the cooling lubricant.

A comprehensive study on the main effects of coolant type, composition, and application in grinding is presented in [12.46]. The correct selection and use of grinding fluids normally results in enhanced process performance, better workpiece quality, and longer tool life. Lower volumetric wear of the wheel and improved surface finishing are achieved when neat oil is used instead of water-based fluids. On the other hand, water-based fluids can reduce workpiece temperature, pose less risk of fire, and are generally better suited for the working environment and the machine tool operator.

12.2.2 Grinding with Rotating Tools

Processes

Grinding can be performed in a large variety of motions. The six main classifications are related to the shape of the surfaces produced, namely surface, peripheral, thread, gear, profile, and form grinding. Figure 12.41 shows examples of various motion classifications and tool shapes.

Chip Formation

Material is removed by the penetration of abrasive grains into the workpiece material along a defined path. Owing to the generally unfavorable shape of the cutting edge, the actual chip formation is accompanied by friction and displacement processes. The process is evaluated by calculating statistical averages. Figure 12.42 shows, in simplified terms, how a comma-shaped chip is formed by the successive action of two cutting edges. While grain 1 has traveled the path AB, the center of the grinding wheel has moved from P_0 to P_1. The next grain 2 will travel the path CD. In this process, the thickness of an average chip increases from 0 up to h_{max}. A simple relationship for the average undeformed chip thickness $\overline{h}$ is obtained by applying the continuity relationship

$$v_{ft} a_e a_p = v_c C V_{sp} a_p \,, \tag{12.46}$$

$$\overline{h} = \frac{v_{ft}}{v_c} \frac{1}{\overline{b} C} \sqrt{\frac{a_e}{d_{eq}}} \,, \tag{12.47}$$

with $\overline{l} = \sqrt{a_e d_{eq}}$, $V_{sp} = \overline{l}\,\overline{b}\overline{h}$ and $d_{eq} = (d_w d_s)/(d_w \pm d_s)$ (+ external cylindrical grinding, − internal cylindrical grinding) or

$$\overline{h} = \sqrt{\frac{v_{ft}}{v_c} \frac{1}{rC} \sqrt{\frac{a_e}{d_{eq}}}} \quad \text{with} \quad r = \frac{\overline{b}}{\overline{h}} \,. \tag{12.48}$$

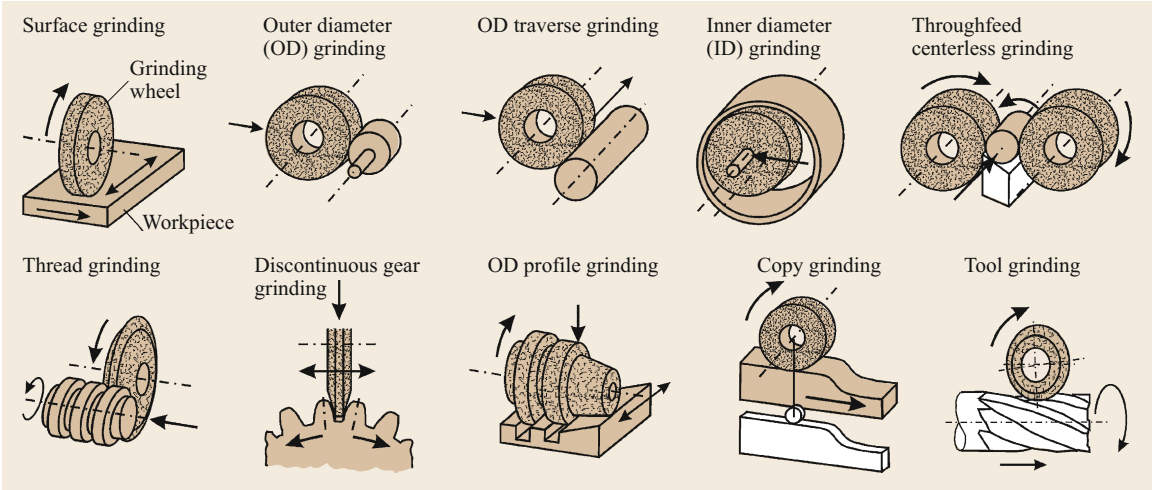

Fig. 12.41 Various grinding processes

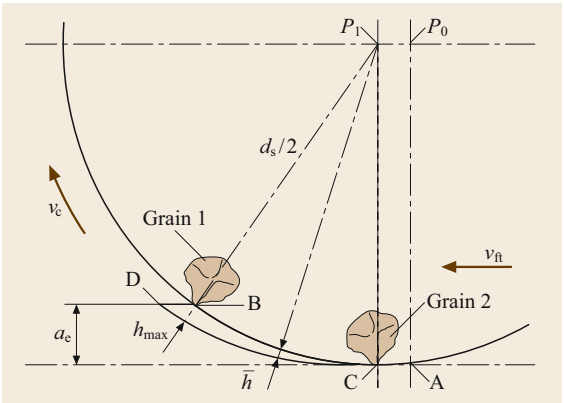

Fig. 12.42 Chip formation in surface grinding

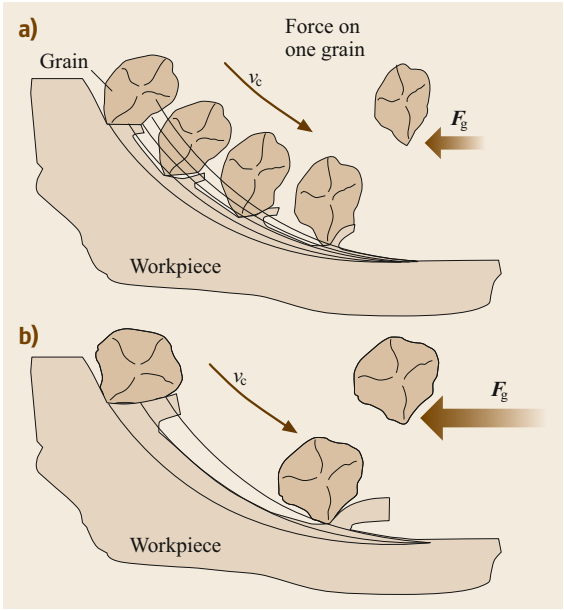

Fig. 12.43a,b Influence of grain concentration on the chip formation mechanism. **(a)** High grain density; **(b)** low grain density

The symbols are as follows: $\overline{h}$ is the average (undeformed) chip thickness, $\overline{l}$ is the average (undeformed) chip length, $\overline{b}$ is the average (undeformed) chip width, v_{ft} is the feed speed of the workpiece, v_c is the cutting speed, a_e is the depth of cut, a_p is the width of engagement (width of grinding), d_{eq} is the equivalent grinding wheel diameter, d_s is the grinding wheel diameter, d_w is the workpiece diameter ($\rightarrow \infty$ in surface grinding), C is the number of active cutting edges per unit of surface area of the grinding wheel, and r is the ratio of the average chip thickness to the average chip width. The maximum chip thickness h_{max} is twice the average chip thickness $\overline{h}$.

The chip thickness is highly dependent on the concentration of abrasives on the grinding wheel surface C (Fig. 12.43). Higher grain density leads to thinner chips and, consequently, lower forces per grain. The grain density decreases with increasing grain size. The correction of these parameters can influence the wear mechanisms on a grinding wheel. Owing to technical difficulties in measuring the number and distribution of grains, the equivalent chip thickness h_{eq} is often used as a parameter for evaluating the grinding process [12.47]. This parameter is directly related to the grinding forces and surface finishing

$$h_{eq} = a_e \left(\frac{v_{ft}}{v_c} \right) . \qquad (12.49)$$

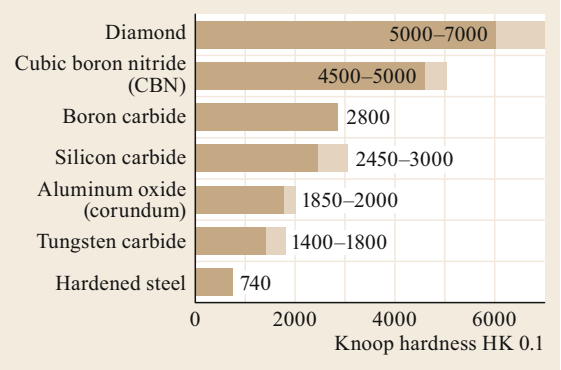

Fig. 12.44 Knoop hardness of various materials

Composition of Grinding Wheels

A grinding wheel consists of grains, bonding material (bond), and pores. The abrasive materials used are hard-brittle ones such as zirconium-corundum (ZrO_2 with Al_2O_3), corundum (Al_2O_3), silicon carbide (SiC), cubic boron nitride (CBN), and diamond (C); their hardness values are presented in Fig. 12.44. However, diamond is unsuitable for machining steel, as there is a high chemical affinity between diamond with its carbon-based cubic lattice structure and iron, which leads to rapid tool wear.

Sorting of the grains according to size is accomplished by screening. The basis of all standards is the mesh of the screens through which the abrasive grains pass. The average grain size is determined by the shape (angularity) of the individual grains. Below a certain grain size, sorting can be carried out by settlement out of a slurried suspension of water and grains. For conventional abrasives (e.g., SiC, Al_2O_3), the grain size is usually given in a mesh number; thus, high numbers represent small grain sizes in the grinding wheel specification. The grain size for superabrasive wheels (only CBN and diamond) follows the FEPA specification related to the grit diameter.

The bonding material (bond) is chosen according to the requirements of the machining process and of the grain material. Inorganic (ceramic, silicate, magnesite), organic (rubber, synthetic resin, glue) and metallic bonds (bronze, steel, cemented carbide) are used; the most popular bonds are those made of ceramic or synthetic resin. In manufacturing a tool, its structure can be influenced to a certain extent by varying the proportions of grains, bond, and pore volume [12.48].

Superabrasive wheels exhibit a particular construction. They consist of a core to which the grinding layer is applied. Usual layer thicknesses are 2–5 mm for resin or vitrified bonds. The core material can be made of metals or fiber-reinforced plastics. Superabrasive

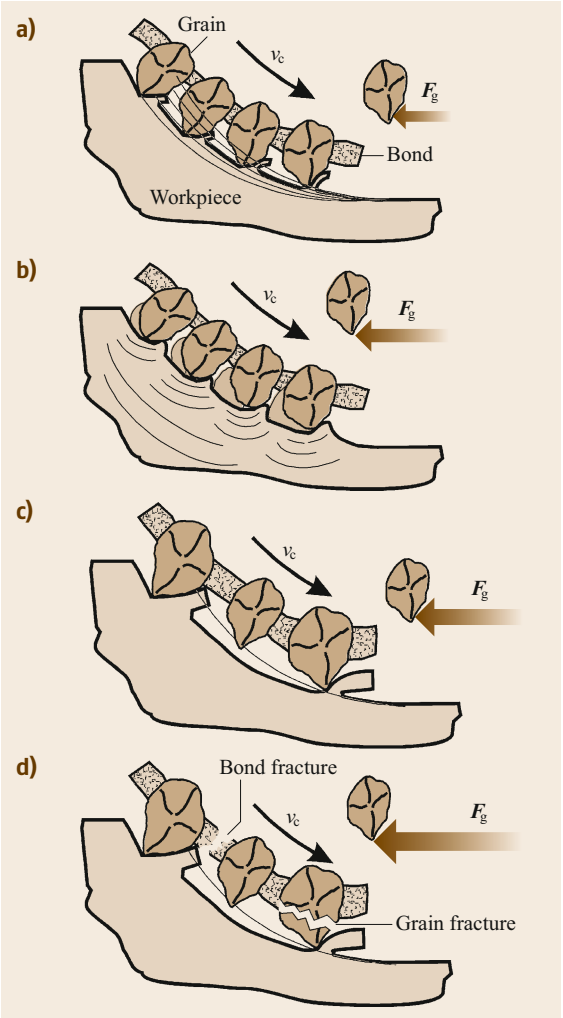

Fig. 12.45a–d Grinding wheel wear mechanisms: **(a)** sharp wheel with low load per grain, **(b)** dulling and loading, **(c)** sharp wheel with high load per grain, **(d)** grain and bond fracture due to very high load

wheels can grind at higher speeds due to the resistance of the core and the higher hardness of the grains. In the grinding wheel specification for superabrasives, the average grain size is usually directly given in µm.

Electroplated bonds are mostly used in superabrasive wheels. They are very thin since they hold only one layer of abrasives. This kind of bond is used for grinding at high speeds due to its high wear and stress resistance. Electroplated wheels are recommended for rough and semifinish grinding. The final surface finish can be obtained with vitrified or resin bonds. The specification of a grinding wheel is standardized in DIN 69100 (for conventional wheels) and ISO 6104 (for CBN and diamond wheels) [12.49, 50].

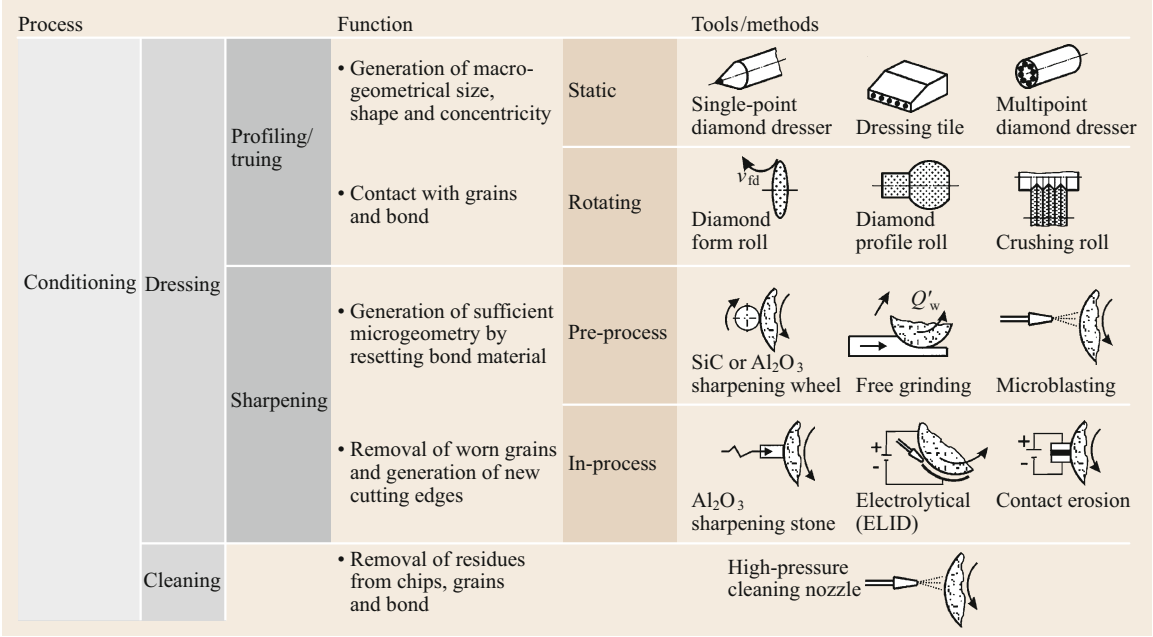

Fig. 12.46 Classification system for grinding wheel conditioning

Tool Wear

Grinding wheel wear may take place in the grains and the bond. The wear phenomena can be related to dulling or grain/bond breakage (Fig. 12.45). In dulling, wear flat areas are formed on the edges. They lead to increasing grinding forces and temperature. This normally happens when the abrasives are submitted to gentle grinding conditions. When the abrasive grains are under higher loads, the grain/bond breakage mechanisms will lead to higher volumetric wear resulting in constant grinding forces and temperature. The quality of the surface finish may deteriorate, and form errors may increase.

Grinding Wheel Conditioning

The purpose of conditioning is to give the grinding wheel the required profile and concentricity (profiling or truing) to produce the necessary grinding wheel topography with sharp grains (sharpening) and to clean the grinding wheel surface [12.51]. The first two operations are summed up under the term dressing and are generally performed simultaneously by passing a dressing tool over the surface of the grinding wheel (Fig. 12.46). In some applications, a separate sharpening step is necessary, which can be performed preprocess or in-process. It is often performed with special equipment with electrolyte supply (ELID = electrolytic in-process dressing) [12.52] or with contact erosion [12.53]. The main components of dressing tools are metallic bonds mixed with diamond particles; however, there are also single-point diamonds, diamond-free steel, and ceramic tools. They reach the end of their life when the diamond layer or the tool geometry is worn out.

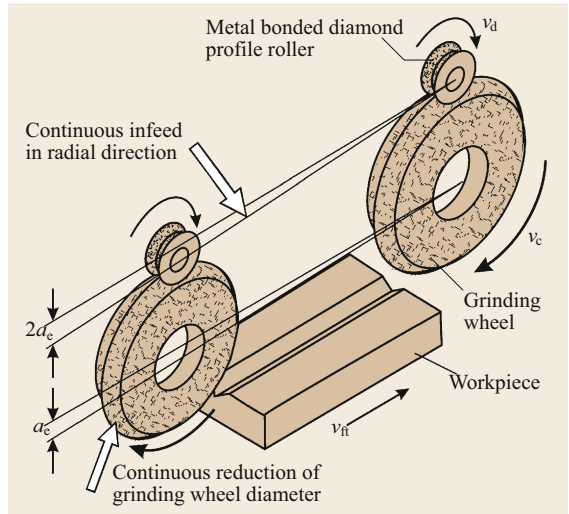

Fig. 12.47 Principle of grinding with continuous dressing (CD grinding)

A special variant of a rotating diamond form roll is called grinding with continuous dressing (CD grinding) (Fig. 12.47). Here, the dressing tool is in engagement during grinding and is continuously advanced radially to the grinding wheel. As a constant grinding wheel

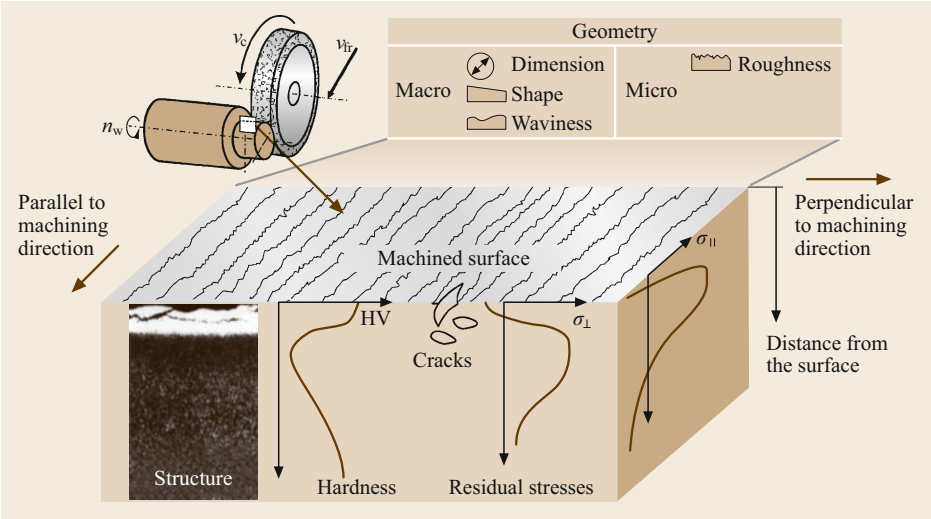

Fig. 12.48
Geometrical and physical quality characteristics after grinding

profile and a uniform grinding wheel topography with sharp cutting edges are permanently ensured, the material removal rate can be increased considerably [12.54]. With the aid of the machine control system, the dressing tool and the grinding wheel have to be advanced in relation to the workpiece in such a way that the decrease in the diameter of the grinding wheel is compensated. This technique is often used for profile grinding of difficult-to-machine materials like the nickel-based alloys used for turbine blades.

Limits of the Grinding Process

Restrictions on the process arise if the original data, e.g., dimensional accuracy, accuracy of shape, surface quality, or condition of the surface integrity of the workpiece do not lie within the required limits. The interaction of the various influencing variables, such as workpiece, machine-setting data, tool, cutting fluid, etc., may be extremely diverse. Mechanical and/or thermal overstressing of the material in the grinding process may adversely affect the characteristics of a ground component [12.55]. Typical grinding defects due to poor process control are visible marks on the surface as a result of regenerative chatter [12.56], hardness and structure changes, tensile residual stresses, and probably even cracks in the workpiece ([12.57], Fig. 12.48). The latter defects can be summarized by the term grinding burn.

Development Trends in Grinding

Grinding has been continuously developed from a traditional precision machining process to improve dimensions, shape, and surface quality into a very versatile and efficient manufacturing process. Creep-feed grinding, high-speed grinding, grinding with continuous dressing (CD grinding), the growing use of superhard abrasives combined with CNC and sensor technologies have been extensively applied in industry [12.58–60]. With the development of advanced open CNC systems, the control of grinding processes nowadays includes intelligent routines. Sensors allow the detection of contact between grinding wheel and workpiece, collisions, and wheel topographic conditions where necessary conditioning/dressing can be automatically activated [12.61]. Gear and other complex profile grinding processes have also been improved with the help of high-performance interpolation routines able to increase productivity and quality with high process flexibility [12.62]. Even the fact that grinding might generate a high amount of heat is turned into a benefit by using this energy for process-integrated hardening while grinding [12.63].

Ultrasonically (US) assisted grinding has reached industrial maturity especially for brittle materials like glass or ceramics. While in the first applications, the US-vibration was generated in a complex spindle system or from the workpiece clamping side, in latest developments the US-excitation is realized with wireless induction transmission in the tool–spindle interface, allowing the tools to be mounted to the actuating tool holder (Fig. 12.49; [12.64]).

12.2.3 Belt Grinding

Belt grinding is grinding with bonded abrasives on a supporting flexible bed. Belt grinding can also be classified according to the surfaces machined, e.g., surface, cylindrical, profile or form-belt grinding. Surface belt grinding predominates in industrial applications (Fig. 12.50). Belt grinding is normally performed at a constant perpendicular force F_n (pressing force).

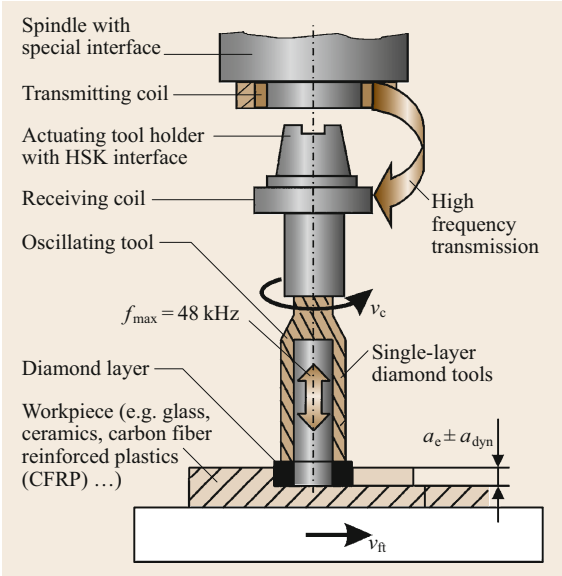

Fig. 12.49 Ultrasonically assisted grinding

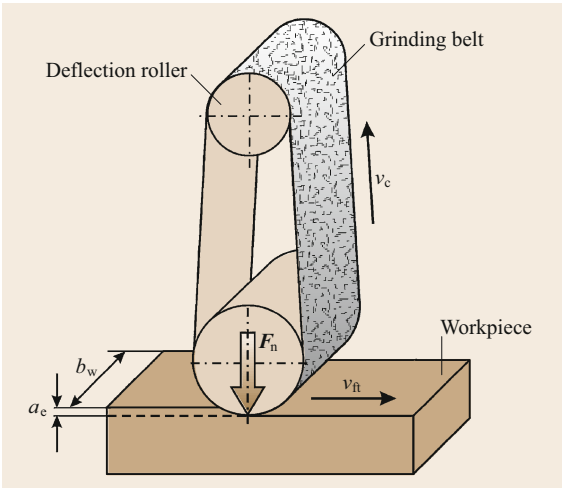

Fig. 12.50 Schematic representation of surface belt grinding

Thus, consistent surface qualities can be produced. The material removal rate is determined by the sharpness of the belt (of the active cutting edges). In belt grinding with constant working engagement a_e, a constant material removal rate is achieved. Surface quality depends on the condition of the cutting edges. This process is especially suitable for removing large volumes of material with high efficiency [12.65].

The adjustment of the process variables during belt grinding derives from the changes of the cutting edges during working. In contrast to grinding wheels, grinding belts generally consist of a single layer of

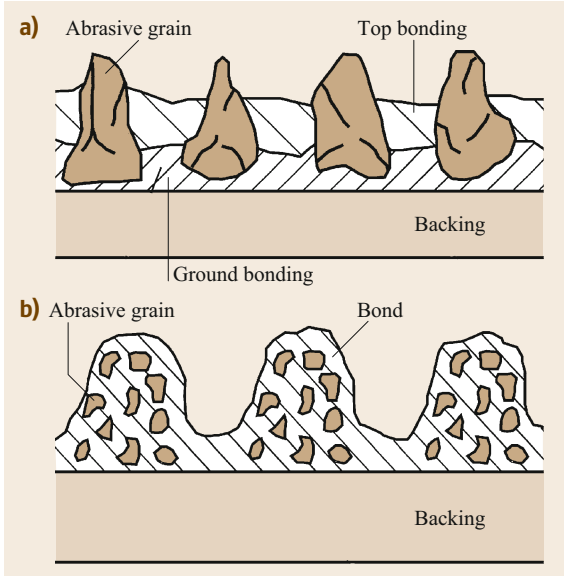

Fig. 12.51a,b Schematic setup of grinding belts. **(a)** Single-layer grinding belt; **(b)** multilayer grinding belt

abrasives. Therefore, the cutting edge zone changes over the period of use, owing to progressive abrasive and bond wear.

Grinding belts consist of four elements: backing (paper, fabric), ground bonding and top bonding materials (phenol resins), and abrasive grains (corundum, zirconium-corundum, silicon carbide). Scattering of the grains on the first coat of bonding material is carried out in an electrostatic field. This ensures that the abrasive grains are aligned perpendicularly (Fig. 12.51). An even grain distribution in belt manufacture compared with conventional gravity scattering can be achieved [12.66].

For higher material-removal rates, multilayer grinding belts are available, where several abrasive grains are held in a bond and mounted to the backing (Fig. 12.51b).

The grinding belt is supported in the working zone by contact elements. A contact disc is used in peripheral grinding, while a contact shoe or beam is used in side grinding. Hard contact rolls made of aluminum or steel are particularly suitable for roughing with coarse grinding belts because they transmit the relatively high grinding forces. Soft, rubber-coated contact rolls are used in finishing with fine grinding belts [12.67]. They absorb the shocks that occur during the process. Conventional applications of belt grinding are grinding of individual sheets and sheet coils, deflashing and deburring, and grinding down of excess metal in welded joints. Heavy-duty belt grinding might even work as a substitute for turning and milling of components made of gray cast iron or aluminum alloys [12.65, 66].

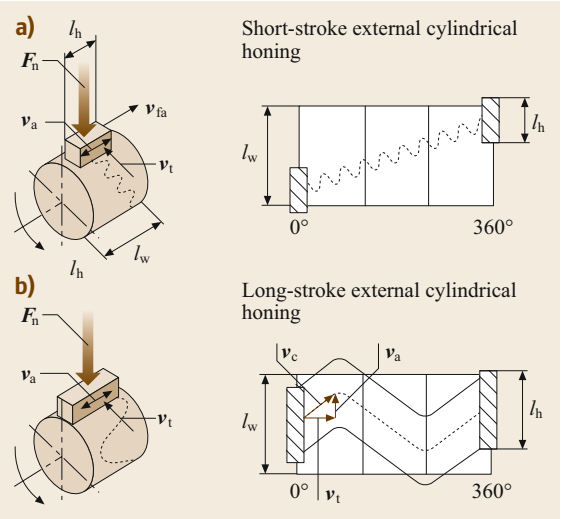

Fig. 12.52a,b Geometry and kinematics in short (**a**) and long-stroke (**b**) superfinishing

12.2.4 Honing, Superfinishing

Honing is performed with a multiple-point cutting tool consisting of bonded abrasive grains using a cutting motion with two components of which at least one is oscillating. The most common honing processes are external cylindrical honing, internal cylindrical honing, and surface honing. The external honing variant is often called superfinishing. According to the oscillation amplitude, a further distinction can be made between two main groups: long-stroke honing and short-stroke honing (Fig. 12.52; [12.68]).

Long-stroke honing employs large oscillation amplitudes at a low frequency; in short-stroke honing, the oscillating motion is performed at low amplitudes and a correspondingly high frequency. The path curves in Fig. 12.52 depict the motion of a honing strip over a developed workpiece surface.

Owing to the superimposed motion during honing, the workpiece surface exhibits intersecting tracks of the cutting grains, the two tracks enclosing an overlap angle α (Fig. 12.53). The magnitude of the overlap angle α is determined by the selection of the ratio of the axial (v_a) and tangential (v_t) cutting speed components. For workpieces without longitudinal and transverse grooves, the angle α is generally 45°. The cutting speed v_c can be calculated by means of the aforementioned speed components according to $v_c = (v_a^2 + v_t^2)^{1/2}$. Usually, the cutting speed does not exceed $v_c = 1.5\,\mathrm{m/s}$ [12.68, 69].

During the cutting motion the honing stones are pressed against the workpiece surface that is to be machined with a perpendicular honing force F_n, which may be generated by means of various feed systems (Fig. 12.54). In force-dependent feeding, a defined hydraulic pressure p_{oil} is set on the machine. The resulting advancing force F_z is transmitted to the honing stones via an advancing pin and cones. In path-dependent feeding, defined feed paths are generated e.g., with a stepping motor, which produces the perpendicular force F_n on the honing stones.

Important variables influencing the result of honing are the type of abrasive, grain size, type of bond, hardness, and impregnation of the honing stones. The types of abrasive can be classified into conventional abrasive materials, such as corundum and silicon carbide, and the superhard abrasive materials diamond and cubic boron nitride (CBN). The grain size influ-

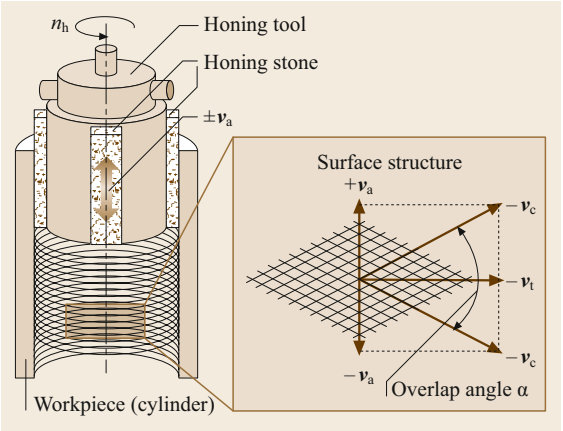

Fig. 12.53 Principle of internal long-stroke honing and the resulting surface structure

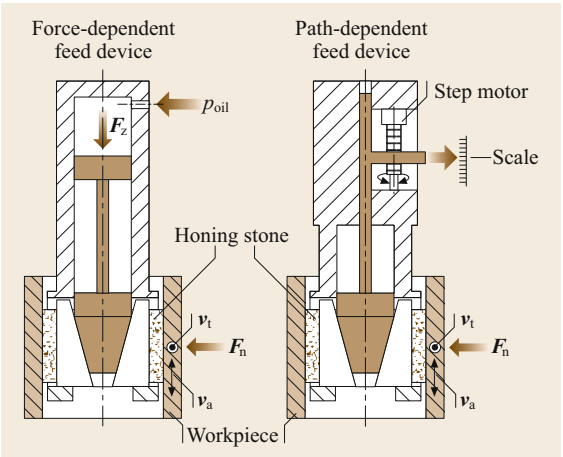

Fig. 12.54 Force and path-dependent feed devices for honing

ences the material removal rate and the surface quality. The achievable surface roughness values are $Rz = 1\,\mu m$ for long-stroke honing and $Rz = 0.1\,\mu m$ for short-stroke honing. Dimensional accuracies and accuracies of shape of the machined workpieces of $1-3\,\mu m$ are achieved [12.70]. Unlike in grinding, the grains bonded in the honing stone are stressed on more than one axis owing to the oscillating motion. Honing tools are, therefore, self-sharpening.

Cutting fluids are used in honing as well as in grinding. Due to the low cutting speed, however, heating is minimal, so the cooling effect plays a minor role. However, the surface contact between the honing stone and the workpiece requires instead a friction-reducing lubrication. For this purpose, pure oil, with additives if required, is generally used.

The applications of honing can also be categorized according to whether long-stroke or short-stroke honing is used. Long-stroke honing is generally used for bores, e.g., cylinders in internal combustion engines. Short-stroke honing is mainly used for machining small cylindrical components, e.g., running surfaces of inner and outer rings and rollers of rolling contact bearings. Furthermore, the application of gear honing should be mentioned. With the coupled motion of a gear-shaped abrasive tool and the workpiece counterpart, a high surface quality for gears can be achieved, thus qualifying honing as an attractive gear finishing technique [12.71].

12.2.5 Other Processes: Inside Diameter Cut-Off Grinding, Lapping, and Abrasive Waterjet Cutting

Inside-Diameter Cut-Off Grinding

Inside-diameter (ID) cut-off grinding is a high-precision finishing-machining process for hard-brittle materials. It is used to cut rod-shaped materials into thin slices (Fig. 12.55). Besides its applications to optical materials (glasses, glass ceramics), magnetic materials (samarium-cobalt, neodymium-iron-boron), and ceramics and crystals for solid-state-type lasers, this process is also used for semiconductor materials. Single-crystal silicon rods are cut into thin slices called wafers.

Compared to conventional abrasive cutting processes, the loss of material in the cutting gap can be reduced by approximately 80% by means of a narrow width of cut. This is a decisive advantage, especially for expensive, high-grade materials.

To achieve the narrow widths of cut that are typical of this process, a comparatively unconventional tool is used for ID cut-off grinding. The basic body of the tool consists of a cold-rolled ring of high-tensile stainless steel with a thickness of $100-170\,\mu m$.

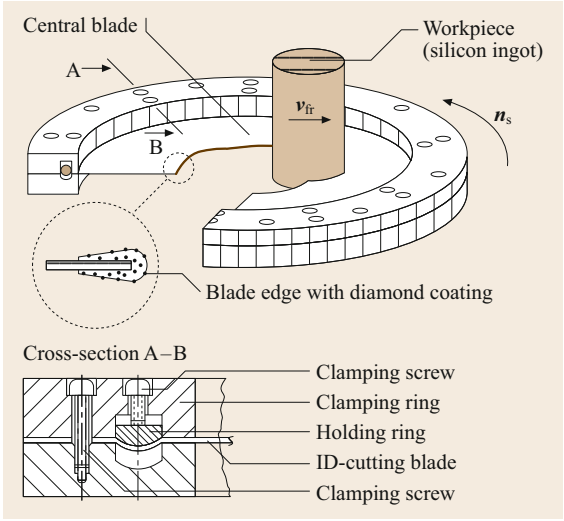

Fig. 12.55 Principle of ID cut-off grinding

The inside edge of the cutting blade is coated by electrodeposition with a diamond layer in a nickel-based bond; this layer forms the droplet-shaped cutting edge. Grain sizes commonly range from 45 to $130\,\mu m$. The width of the cut extends between 0.25 and 0.7 mm. Natural diamond is generally used as the cutting material. CBN may also be used for special applications. Workpieces with a diameter of up to 200 mm can be cut. Due to this diameter limitation, this process has lost its pole position for wafer manufacturing because of the constantly rising diameters of silicon ingots for wafer production in the semiconductor industry.

To achieve the stiffness at the cutting edge that is necessary for cutting, the cutting blade, which can be compared to an eardrum, is clamped at its outside edge with a special clamping device. This widens the ID cutting blade radially until the tangential stresses at the inside edge reach around $1800\,N/mm^2$. In cut-off grinding, the workpiece performs a radial feed motion relative to the rotating tool [12.72, 73].

Lapping

Lapping is defined in a German standard [12.1] as metal cutting with loose grains of abrasive material distributed in a paste or a liquid, the lapping mixture, which is carried on a generally shape-imparting counterpart (lap), and the individual grains following cutting paths, which are random. Lapping processes are divided into surface lapping, cylindrical lapping, hole lapping, and ultrasonically assisted lapping (Fig. 12.56).

Surface lapping or plane-parallel lapping is carried out on single-disc or twin-disc lapping machines. The lapping discs act as the holder for the lapping abrasive. They are frequently made of perlitic cast materials

or hardened steel alloys. The workpieces are usually driven in specific carrier discs, for larger diameter lapping discs often use the planetary gear principle to achieve cycloid motion. A special variant of plane-parallel lapping is based on the use of special slurry as the liquid to carry the abrasives and to improve the material removal process by chemical activation. This process is called chemical-mechanical planarization (CMP) and is widely used in the semiconductor industry to machine wafers made of silicon or other suitable materials [12.74].

The abrasive consists of lapping powder and fluid in a ratio of 1:2−1:6. Particles of silicon carbide, corundum, boron carbide, or diamond are used as the lapping powder. The type of grain for a particular application is determined by the material to be machined. Grain sizes ranging between 5 and 40 µm are generally used. Besides high-viscosity oils or similar fluids, water with suitable additives has been more and more frequently used as a transport medium for the abrasive in recent years. The main purpose of lapping fluids is to cool the workpiece and ensure chip removal from the effective zone.

Lapping is a precision or ultraprecision machining process for the production of functional surfaces of optimum surface quality. Surface roughness values down to $Rt = 0.03\,\mu m$, flatness, and plane parallelisms of $0.2\,\mu m$ are achieved. Besides the semiconductor application, other typical fields of lapping are the machining of precision-cemented carbide tools, calliper gauges, or hydraulic rams.

A special category is ultrasonically (US) assisted lapping, which is particularly suitable for machining hard-brittle materials, e.g., fully-sintered ceramic components [12.75, 76]. The process is carried out by moving a complex-shaped tool called sonotrode downwards into the workpiece while hammering the loose abrasive particles, which are supplied via a liquid to the contact zone, into the workpiece surface for material removal. If rotational symmetric shapes are to be produced, nowadays US-grinding substitutes for this lapping process due to its higher efficiency (Fig. 12.49).

Due to the above-mentioned increase of silicon ingot diameters for wafer production a special variant of lapping has been developed, called multiwire slicing by lapping (Fig. 12.57). In this process, a silicon ingot is glued to a steel support and radially fed downwards to a multiwire field. Comparable to an egg cutter, hundreds of wafers are separated at the same time, because on the specially developed high-strength wire a spray of silicon carbide abrasives in special slurry is applied. This process is capable of significantly increasing the productivity compared to ID cut-off grinding and currently works for diameters up to 300 mm. Parallel research is being done to develop an abrasive coated wire instead of loose lapping grains, thus reintroducing grinding for wafer manufacturing.

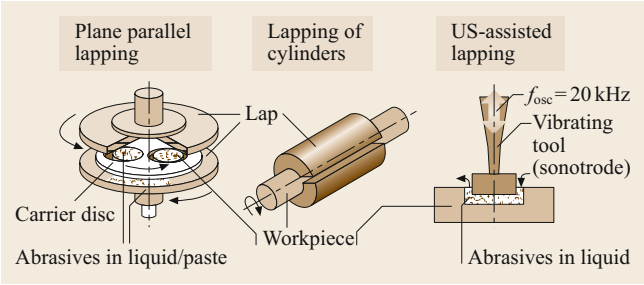

Fig. 12.56 Lapping processes

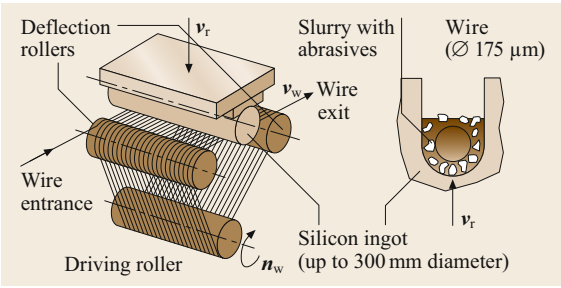

Fig. 12.57 Multiwire slicing

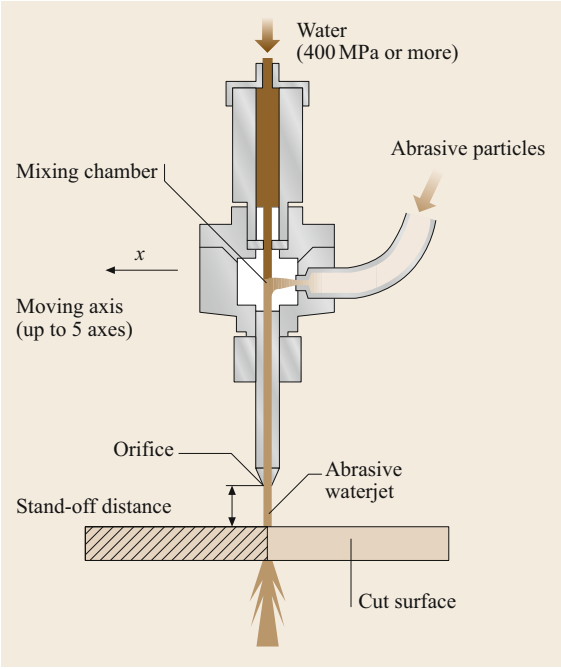

Fig. 12.58 Basic concept of abrasive waterjet cutting

Abrasive Waterjet Machining

Abrasive waterjet (AWJ) machining is a material removal process with a high-velocity slurry jet. The slurry is formed by the injection of abrasive particles into a waterjet by an orifice (Fig. 12.58; [12.77]). The abrasive waterjet head is controlled in two to five axes by a CNC system or by a robot arm. The process is mainly used for cutting a large variety of materials. The main advantages are the versatility regarding complex shapes and the ability to cut both ductile and brittle materials at very low process temperatures.

Abrasive waterjet machining is usually performed at jet pressures up to 400 MPa. The applicability and the advantages of the cutting process beyond 400 MPa pressure have been investigated [12.78]. The success of this process at increased levels of pressure depends on the endurance of the system components subjected to high alternating stresses, the avoidance of solidification of water at ultrahigh pressures, and the good coherence of the jet.

The quality obtained in waterjet cut is higher than that achieved by conventional cutting processes, mainly in the edges. The dimensional and form quality will depend on the CNC system and the coherence of the jet. A cutting thickness of 200 mm and dimensional tolerances of about 0.1 mm can be achieved with this process. The main quality disturbances are related to the jet distortion or turbulence during cutting. Shape distortions occur when cutting corners, thick parts, or at high feed speeds.

The equipment for AWJ can be very simple and relatively inexpensive. A stationary waterjet is usually used in the aerospace industry to trim composites similarly to a band saw. However, abrasive waterjet cutting can also be performed in CNC machines and robots allowing the cutting of complex shapes. In any case, the waterjet has to be caught in a suitable catching system after cutting through the workpiece material to avoid danger to the operator or the environment. Furthermore, noise protection measures are recommended.

12.3 Nonconventional Machining Processes

Nonconventional machining processes can be classified according to the type of energy employed: mechanical, thermoelectric, electrochemical, mechanical, and combinations thereof. The way of material removal varies, and so do the transfer media.

Mechanical energy is used in the abrasive jet and waterjet applications, which were already covered in Sect. 12.2.

Thermoelectric energy is used in electro-discharge machining (EDM) for making cavities, mostly in difficult-to-machine materials. Metal removal is accomplished through the controlled vaporization of the workpiece material by suitably applied electric sparks. A very important variant of EDM applies thin wires to generate small gaps in the workpiece. This is called spark electro-discharge machining (SEDM), spark erosion machining (SEM), or wire-EDM.

The principle of electron beam machining (EBM) is the transformation of the kinetic energy of high-speed electrons into thermal energy as they strike the workpiece. Laser beam machining is based on the transformation of light energy into thermal energy. Plasma arc machining (PAM) and ion beam machining (IBM) utilize ionized plasma for energy transfer. These beam machining processes are used in hole-making and slicing operations and in welding metals and alloys.

Electrochemical energy is harnessed in electrochemical machining (ECM) and in combination with grinding in electrochemical grinding (ECG). Another application is the combination of ECM with EDM, in the form of electrochemical-discharge machining (ECDM). The beam machining group also applies electrical energy in various forms.

Common in all nonconventional electrophysical-chemical machining is the application of high-energy density in the range of 10^3–10^8 W/cm^2. High energy concentration is achieved by space and time localization of the emitted energy [12.79, 80].

12.3.1 Electro-Discharge Machining (EDM)

In the EDM process, material is removed by a series of discrete electrical discharges (sparks) in the machining gap between the electrode and the workpiece, as illustrated in Fig. 12.59. The dielectric fluid creates a path for the discharge as the fluid becomes ionized between the nearest opposing points. The initiation of discharge takes place to cause ionization, and current starts to flow. As conduction continues, the size of the discharge column increases, and so does the current. The discharge temperature is far beyond the melting point of the work materials, including exotic materials.

However, the machinability of metals and alloys depends on their thermal-physical properties and the electric parameters of the process. Material removal is not affected by the mechanical properties of workpiece materials.

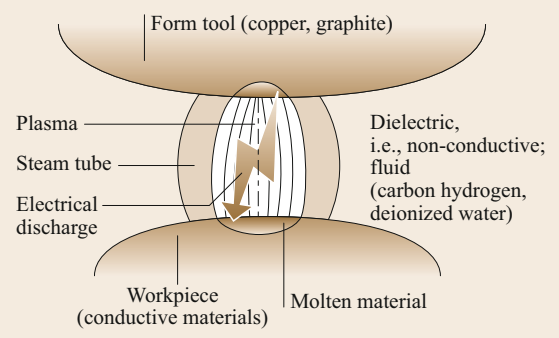

Fig. 12.59 Electro-discharge machining (EDM)

Electric-spark machining is characterized by the use of electric discharge with an on–off time ratio, where the current amplitude to pulse duration is high. The tool electrode is of direct polarity (cathode), applying powers between a few watts and several kilowatts. Application areas include cutting components of complex form by wire electrodes, broaching, and die sinking of precision components from refractory alloys, sintered carbides, and nonferrous metals with surface sizes up to 3–5 cm^2.

In electric pulse machining, the use of electric discharge with a small on–off time ratio with reduced current amplitude to pulses is common. The tool electrode is of reverse polarity (anode). Application areas include the generation of complex surfaces with an area of up to hundreds of thousands mm^2.

The dielectric fluid is an important variable in the EDM process. The methods of its application are shown in Fig. 12.60. It has three main functions: it works as an insulator between tool and workpiece, it acts as coolant, and it acts as a flushing medium to remove chips [12.81]. It also affects electrode wear, material removal rate, and other EDM characteristics. The dielectric fluid normally used is hydrocarbon based, but other fluids like triethylene glycol and tetraethylene glycol are also used to improve the material removal rate. For wire erosion, it is common to use deionized water in constant supply to the working zone.

Tool electrodes are made of graphite and copper, but other materials can also be used. The machined surface shows no direction of marks; on the contrary, the surface is formed from a number of craters and might show areas of molten material with accompanying surface integrity changes, as can be seen in Fig. 12.61 for very progressive parameters [12.82]. This drastic surface modification can be reduced by adapted EDM-process conditions. The application areas of EDM are shown in Fig. 12.62.

Electro-discharge machining provides machining accuracies of up to 0.005–0.02 mm in the case of through holes and up to 0.01–0.1 mm when machining cavities [12.83].

Surface roughness when machining through holes is in the region of $Ra = 0.4–1\ \mu m$ and $Ra = 1–2.5\ \mu m$ for machining cavities.

The material removal rate depends on the volume of material removed by individual sparks and by the dis-

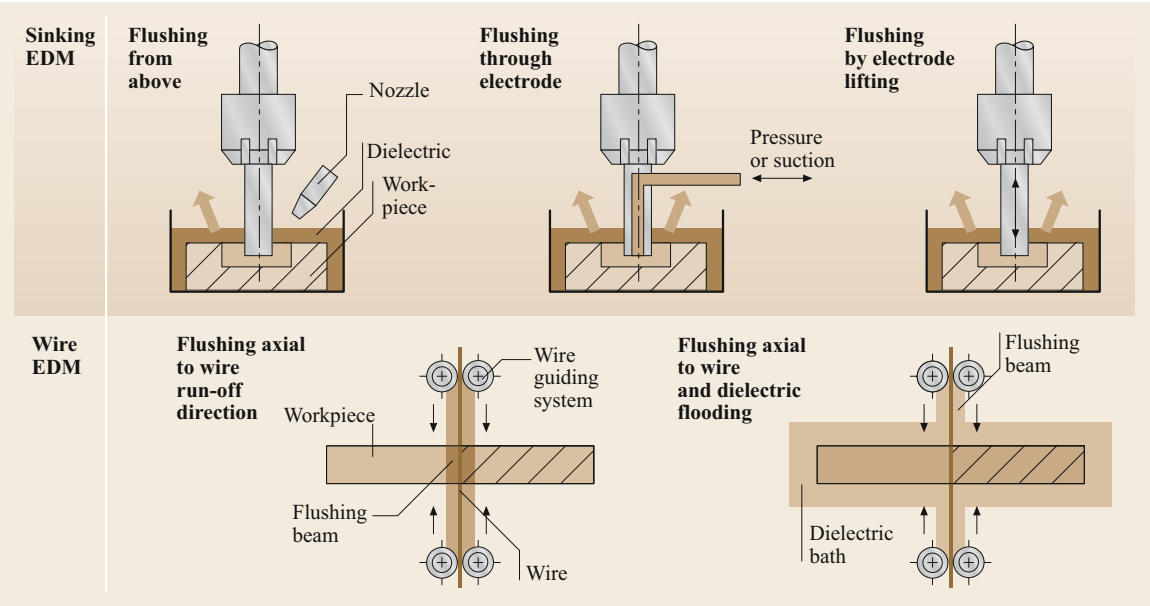

Fig. 12.60 Application of dielectric fluid in EDM (after [12.79])

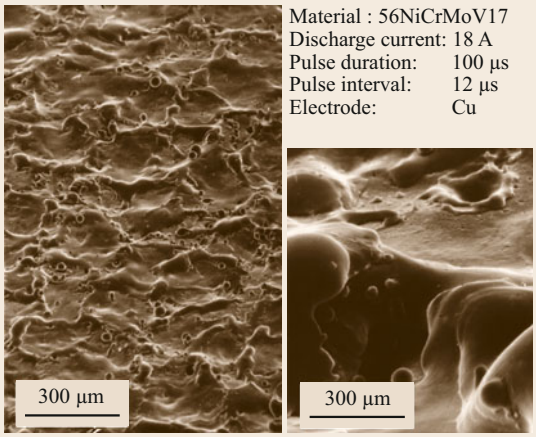

Fig. 12.61 Electro-discharge machined surface

charge frequency. The volume of material is a function of the discharge energy, which increases with the current. The typical removal rate when machining steels lies in the region of $10-12\times10^3\,\mathrm{mm^3/min}$.

Typical output parameters of wire electro-discharge machining (WEDM) are: dimensional accuracy 0.005–0.03 mm, surface roughness $Ra = 0.4-2\,\mu\mathrm{m}$, the surface division rate for steels up to $300\,\mathrm{mm^2/min}$, and for carbides up to $120\,\mathrm{mm^2/min}$.

The given parameters of electro-discharge machining allow these processes to be applied in tool manufacturing and in the production of components made from hard-to-machine materials with complex shapes.

12.3.2 Electrochemical Machining

The operating principles of electrochemical machining (ECM) have been known for a long time. Its two conductive poles are placed in an electrolyte bath and energized by direct current; metal may be removed from the positive pole (anode), the negative pole (cathode) is also metallic.

ECM requires a cathode tool with an appropriate mirror image of the cavity to be made; a workpiece and locating/holding fixture in close proximity to the tool, a suitable electrolyte supply and removal to/from the gap, and a DC (direct current) electrical source with sufficient power to provide high current density between the tool and workpiece [12.84, 85]. The metal is removed rapidly from the workpiece, and, therefore, provision has to be made to feed the tool to maintain the gap at a constant value.

Metal removal is governed by Faraday's and Ohm's laws. The material removal is proportional to the current flow through the gap and the elapsed time, while the current is proportional to the applied voltage and inversely proportional to the gap's electrical resistance.

ECM is carried out as anodic dissolution of metal, and the product is removed from the working zone (gap) by an electrolyte flowing at speeds of about 5–50 m/s. A DC generator supplies the current at a working voltage of 3–24 V governed by the material and technology requirements. A working gap between the two electrodes is maintained accurately by a process-monitoring system between 0.02–0.5 mm. The tool electrodes are typically made of stainless steel, brass, and graphite. A typical ECM arrangement is shown schematically in Fig. 12.63.

Many process parameters affect the output parameters, including tolerances of the product. These can be electrical, chemical, and mechanical parameters, which have to be monitored and controlled all the time.

The applications of ECM include turning, die sinking, hole drilling/multiple-hole drilling, trepanning, broaching, milling, and deburring. In ECM, sinking and broaching the shape of the tool electrode is copied into

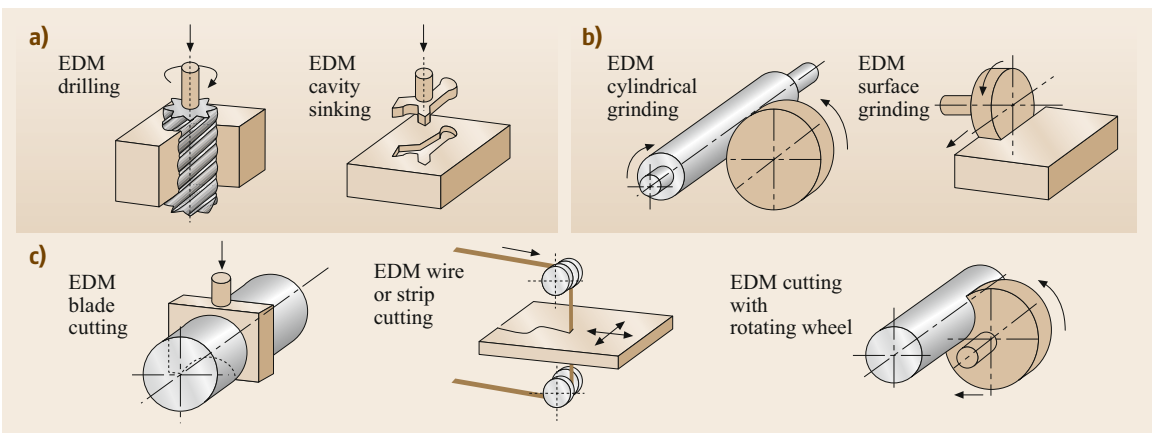

Fig. 12.62a–c Examples of electro-discharge machining. **(a)** EDM shrinking; **(b)** EDM grinding; **(c)** EDM cutting

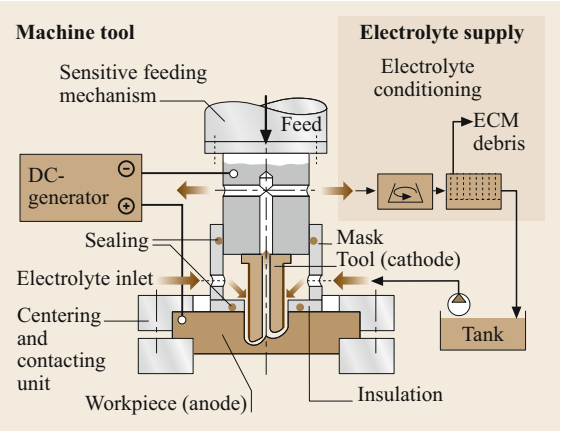

Fig. 12.63 Principle of electrochemical machining (ECM) (after [12.79])

the component. This is used to make cavities for dies, forging stamps, compression molds, casting forms, etc. The roughness of the machined surface is within the range of $Ra = 0.25$ up to $Rz = 20\,\mu\text{m}$. Feed rates of 0.03–0.5 mm/min can be selected.

Electrochemical milling, using rotary cathodes, can be used for the production of profile, flat, and round external surfaces by the cathode wheel at a removal rate of 150–200 mm^3/min in the case of stainless steels and 60–80 mm^3/min when machining carbides. This process can be used to produce thread-cutting dies, various form tools, and thread-rolling dies with a surface roughness of about $Ra = 0.63\,\mu\text{m}$ to $Rz = 20\,\mu\text{m}$. The process can also be used for machining magnetic materials (permanent magnets).

Electrochemical deburring is particularly suited for the deburring of holes, gears, and components of hydraulic equipment, mainly in mass production.

12.3.3 Ultrasonic Machining

Ultrasonic machining (USM) utilizes a tool that oscillates at high frequency beyond the audible limit (hence, the name of the process), i.e., beyond 20 000 Hz. In the case of ultrasonically assisted lapping with loose abrasives, the tool has the same shape as the required cavity in the workpiece (Sect. 12.2.5). The high-speed alternating motion of the tool drives the abrasive grains across a small working gap against the workpiece. The impact energy is responsible for the material removal. Although this process is not restricted to brittle materials, and ductile failure works in machining tough materials as well, it is usually used to machine hard and fragile materials, such as glass, ceramics, silicon, ferrite, ruby, sintered carbide, diamond and the like [12.86]. Besides the oscillation from the tool side, ultrasonic movement of the workpiece is also possible [12.87].

It is accepted that material removal results from the combined effects of hammering (impacting) abrasive particles in the work surface, the impact of free abrasive particles on the surface, cavitations, erosion, and the chemical action of the fluid employed.

The most important process input parameters controlling the material removal rate, surface roughness, and accuracy are the frequency and amplitude of oscillation, abrasive particle size, and, by implication, the impact force. During machining abrasive grains enter the machining zone as abrasive suspension.

Mechanical vibrations of the tool with ultrasonic frequency are achieved by a suitable electromechanical converter. Usually, the converter will consist of magneto-resistive elements with the ability to change their linear size in a variable magnetic field. In some cases, piezoelectric converters are employed in a variable electric field.

Tools for USM are made of structural steels, whilst carbides, CBN, silicon, and diamond are used as grits with grain sizes up to 3–10 µm [12.88].

The abrasive slurry moves into the machining zone either freely or under pressure and is removed by suction through the tool or workpiece, which substantially increases machining productivity. Mass concentration of grits in the abrasive slurry at free feed is in the region of 30–40% and 20–25% when it is supplied under pressure.

When machining sintered carbides, USM can be combined with electrochemical anodic dissolution. Processes of rough and finishing ultrasonic operations can be carried out on one machine tool.

USM can provide a removal speed of up to 5500 m^3/min when machining glass and up to 500 m^3/min when machining carbides; the corresponding surface finish is $Ra = 0.32$–$0.16\,\mu\text{m}$.

In recent ultrasonic developments, the loose abrasive setup is replaced by a tool with bonded abrasives (Sect. 12.2.2). Regarding the kinematics it is an ultrasonically assisted grinding process, but in some cases, it is referred to as ultrasonic milling. Besides milling and drilling also ultrasonically assisted turning has gained attention due to the improved wear behavior of the chosen tools [12.89, 90].

12.3.4 Beam Machining

Thermoelectric processes utilize concentrated thermal energy to remove material and electrical energy, in some ways, to generate thermal energy. The main characteristics of these processes are high temperatures and

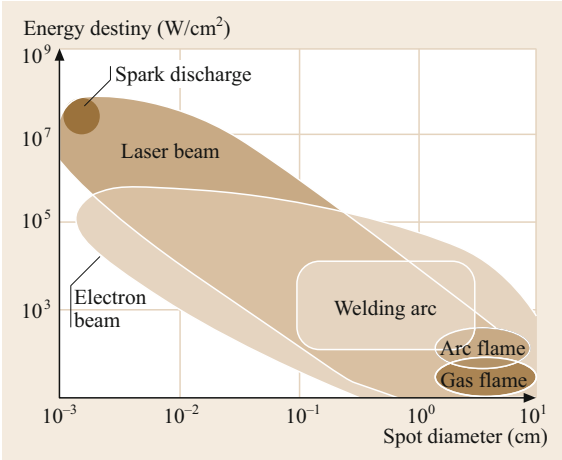

Fig. 12.64 Energy density of various thermal sources (after [12.91])

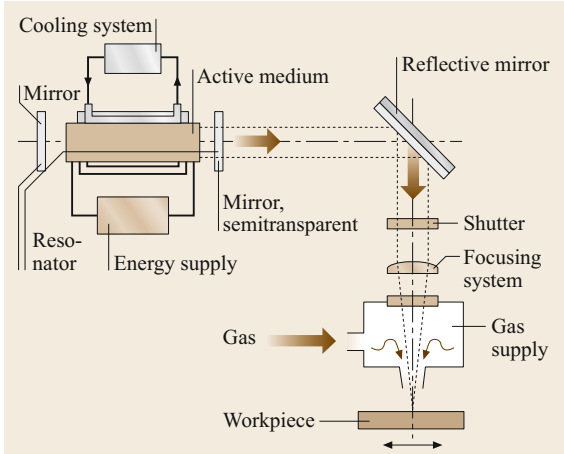

Fig. 12.65 Laser beam cutting

high thermal energy densities that can be achieved for material removal up to 10^9 W/cm^2. The main beam machining processes are: laser beam machining (LBM), electron beam machining (EBM), and plasma beam machining (PBM). Beam machining (BM) can be used for machining both electrically conductive and nonconductive materials.

The energy concentration of beam sources and that of comparative technologies are illustrated in Fig. 12.64. Of the beam-based technologies laser and electron beams provide the greatest intensity of energy in the region of 10^8–10^9 W/cm^2. The main characteristics of high-density beam thermal sources are given in Table 12.13.

Laser Beam Machining

The technical term *laser* is the acronym of light amplification by stimulated emission of radiation. Laser cutting (LC) is based on the use of the monochromatic electromagnetic radiation generated by the laser. The laser beam is formed by means of an optical system and is focused on the machined surface, causing heating, fusion, evaporation, or explosive destruction of the workpiece material (Fig. 12.65).

In the radiation zone, the form and diameter of a light spot changes over a wide range, from several up to hundreds of micrometers. Depending on the temperature and energy concentration on the machined surface, various laser machining processes can be applied, e.g., drilling, cutting, marking, welding, heat treatment, and others. The application of laser beam (LB)-based manufacturing processes is summarized in Fig. 12.66. Meanwhile, the application of laser technology has become state-of-the-art in every area of manufacturing processes.

Laser cutting can be carried out in air, vacuum, or the required gas media. The type of LB-radiation is determined by duration, frequency of following and peak capacity, and also in a kind of continuous or quasicontinuous radiation with the set average capacity modulated with a frequency of 5–50 kHz.

Laser cutting of metallic materials requires intensities of $>10^6$ W/cm, which are achieved by focusing the laser beam with the aid of lenses or mirrors. The ther-

Table 12.13 Characteristics and application of thermal sources (after [12.91, 92])

Thermal source	Limiting concentration of energy (W/cm^2)	Energy source	Application
Gas flame	8×10^2	Jet of the heated gas $T \approx 3500$ K	Cutting off, accompanying heating, maximum thickness up to 3 mm
Arc plasma	6×10^3	Gas and the metal steam ionized by electric discharge	Cutting off up to 3 mm, welding, heat treatment, welding
Electron beam	10^5	Electron beam in vacuum	Cutting off, welding (up to 20 mm/pass), heat treatment, welding
CW-type laser beam	10^9	Beam of photons in a gas	Welding (up to 10 mm/pass), heat treatment, welding on, evaporation of layers
Pulsed laser beam	10^{10}	Beam of photons in a gas	Evaporation of layers, drilling of apertures, surfaces amorphous, shock hardening

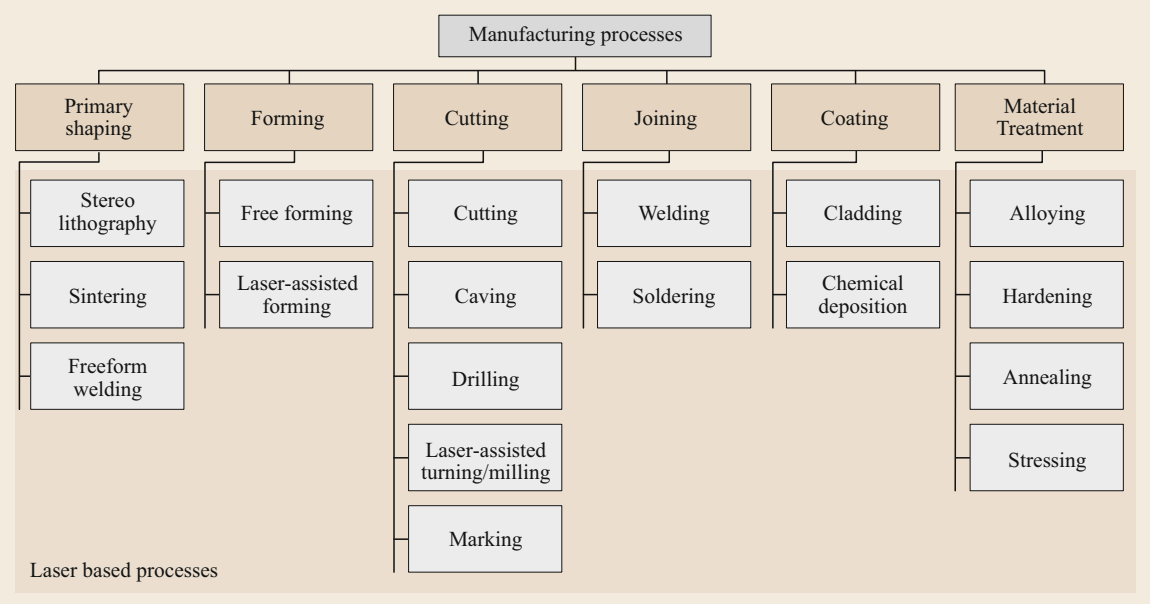

Fig. 12.66 Application of laser beam-based manufacturing processes

mal material removal process, which is directed into the depths of the material, produces a kerf in the material when the feed motion is applied [12.93, 94].

The material is melted (laser fusion cutting), burnt (laser flame cutting), or vaporized (laser sublimation cutting) at the focal point of the laser beam, depending on the intensity and the length of interaction. It is expelled from the kerf by a stream of gas emitted from a nozzle coaxially to the optical axis (Fig. 12.65). The cutting gas also serves to protect the sensitive focusing optics from spattered material.

In laser flame cutting, oxygen or oxygen-rich gas is used as the cutting gas at higher cutting speeds. However, this leads to oxidation of the cut surfaces owing to the introduction of additional exothermic energy. In contrast to the other laser cutting processes mentioned above, inert gases (e.g., argon, nitrogen) are used as cutting gases, which results in a slower cutting speed. However, they produce an oxide-free cut.

The relative motion between the laser beam that produces a continuous kerf and the workpiece is achieved in various ways. For laser cutting of small, easily handled components, the latter are generally moved underneath the stationary laser beam. e.g., with the aid of an X–Y coordinate table. For laser machining of larger workpieces, the laser unit, including the cutting tip, is either moved across the stationary workpiece, or a movable system of mirrors is guided together with the cutting tip (*flying optics*) between the fixed laser unit and the workpiece. For Nd:YAG lasers alone, flexible optical fibers may be used to guide the beam.

The cutting speeds for other metallic and nonmetallic materials for a CO_2 laser with a power of 500 W are summarized in Table 12.14.

High-powered lasers of the type mentioned above generally belong to laser (protection) class 4, which has the highest hazard level (except for laser machining systems with dosed working chambers, which are equipped with additional safety facilities such as interlock systems and radiation-absorbing protective windows). Allocation to this safety class means that even diffusely reflected laser radiation is a hazard to the skin and the human eye.

Technological laser systems mainly use the following types (active media) of laser radiation: excimer lasers (gas); CO_2 lasers (gas); Nd:YAG lasers (solid-state). The special characteristics of each laser system define its optimal field of application. The characteristics of the laser sources are shown in Fig. 12.67, and the main parameters are summarized in Table 12.15.

Basic elements of the equipment for laser machining are the generation source, beam guidance, forming and focusing system, and fixation and control of the workpiece moving system (Fig. 12.68).

The laser equipment based on solid-state lasers is generally used for precision machining in various materials (ceramics, polycrystalline glass, ferrite, ruby) and applications like e.g., apertures for input of a wire electrode, apertures in thin foils and films, apertures in watches, stone billets, diamond marking, atomizers, etc., or precision cutting out and marking.

Table 12.14 Machining parameters for laser cutting of various materials (after [12.95])

Material	Thickness (mm)	Cutting gas/pressure (MPa)	Cutting speed (m/min)
PMMA	4	Air/0.06	3.5
Rubber	3	N_2/0.3	1.8
Asbestos	4	Air/0.3	1.6
Plywood	3	N_2/0.15	5.5
Cement asbestos	4	Air/0.3	0.8
AlTi ceramic	8	N_2/0.5	0.07
Aluminum	1.5	O_2/0.2	0.4
Titanium	3	Air/0.5	2
CrNi steel	2	O_2/0.45	1.9
Electrical sheet	0.35	O_2/0.6	7
Gray cast iron	3	N_2/1	0.9
Laser CO_2/500 W; focal length $f = 127$ mm			

Table 12.15 Parameters and application area for various laser systems (after [12.92])

Parameters and application	CO_2 laser	Nd:YAG laser	Excimer laser
Average power (W)	Up to 10^4	Up to 300 (pulse type)	< 0.3
		Up to1000 (continuous type)	
Wave length (nm)	10 600	1064	193, 248
		532 (double frequency)	308, 351
Pulses duration (s)	10^{-5}–10^{-2}	$(4–20) \times 10^{-8}$	$(3–30) \times 10^{-9}$
Pulse energy (mJ)	–	Up to 18	Up to 15000
Pulse frequency (kHz)	Up to 20	Up to 50	Up to 1
Pumping source	Gas discharge	Lamps/diodes	Gas discharge
Machinable workpiece materials	Glass, Al_2O_3-ceramics	Si_3N_4/AlN-ceramics, various metals	Polymers, plastics, ceramics, glass
Application	Cutting out, welding, heat treatment, drilling	Cutting out, welding, heat treatment, drilling, marking	Heat treatment, marking, surface modification

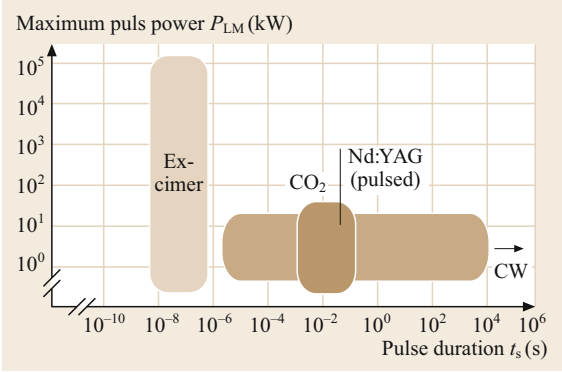

Fig. 12.67 Characteristics of different laser sources (source: LZH)

The fast development of laser sources and the large variety of beam forming systems open a wide field of applications, as shown in Fig. 12.66. Especially in the fields of micromachining and medical applications, laser systems have become an essential driver for innovation and improvement [12.32, 96].

Electron Beam Machining

Electron beam machining (EBM) is based on acceleration and focusing of electrons in a narrow bunch (beam), radiating from the cathode in deep vacuum with the help of a powerful electric field, to hit the machinable workpiece surface (anode). The physical essence of the EBM process is the transformation of electron kinetic energy into thermal energy. The electrons are emitted from a hot cathode and accelerated towards a ring-shaped anode with a round opening (Fig. 12.69). The acceleration voltage is around 25–200 kV. The electrons reach the workpiece surface and release their high kinetic energy. The energy density of an electron beam is up to 10^5–10^7 W/cm^2, which is comparable to laser beams. Due to the fact that electrons, unlike photons, have a mass ($m_e = 9.108 \times 10^{-31}$ kg) and an electric charge ($e = 1.602 \times 10^{-19}$ A s), the energy transfer and effect on the workpiece surface is different compared to laser processes. To prevent electron collisions with gas molecules, the system is highly evacuated. The focusing of the electron beam is done with magnetic fields, which are generated by so-called mag-

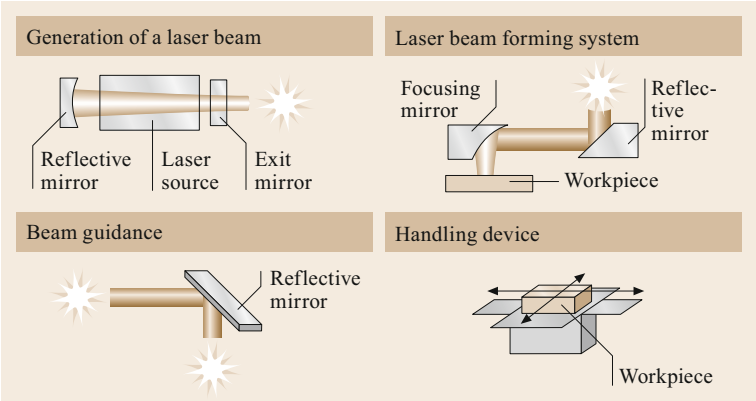

Fig. 12.68 Components of a laser manufacturing system

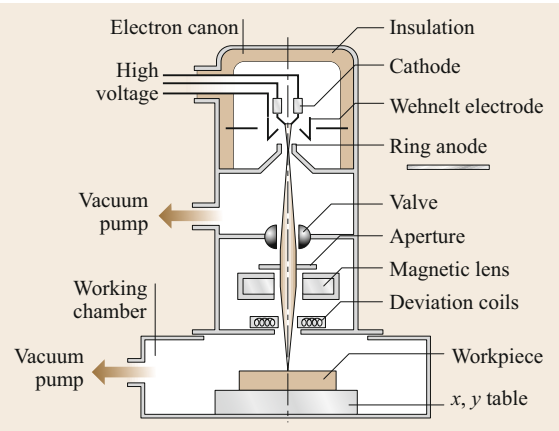

Fig. 12.69 Schematic setup of electron beam machining

netic lenses. The electrons can penetrate much more deeply into the workpiece material than laser beams. They transfer their energy via collisions with enveloping electrons.

EBM systems are more complex compared to regular laser systems. Due to the limitation of the working chamber, this process is dedicated to special applications, where the benefits of a high penetration depth, a high impulse frequency, and fast beam deflection can be used [12.97]. Thus, drilling is a perfect process to elaborate the potential of EBM, e.g., small bores (diameters down to few μm) can be made in thin foils at a rate of up to 10 000 bores/s without moving the target.

Typical application fields are combustion-chambers of aircraft turbines (difficult to machine cobalt-based material, several thousand holes) or spinning heads for glass fiber production (6000 holes of 0.8 mm diameter in 5 mm-thick material [12.98]). A disadvantage of the technology is related to the fact that x-rays are generated above an acceleration voltage of 80 kV, which makes a severe shielding of the system necessary.

Plasma Beam Machining

Plasma beam machining is based on the use of low-temperature open plasma, which is applied to increase the operational properties of machined components, such as wear resistance, corrosion stability, thermal stability, etc. Such an amelioration is carried out in order to attain the formation of functional coatings from corresponding materials, generated by a plasma jet, plasma welding, and plasma depositing. Furthermore, plasma is used in some combined plasma-mechanical processes, in particular in plasma-mechanical machining.

Plasma coating is characterized by a great concentration of the thermal stream and high speed of the plasma jet. For coating, fine-grained powders are used (40–100 μm). The thickness of the deposited layer is around 0.3–0.5 mm and higher; the deposition productivity is 2–4 kg/h.

Plasma cutting is characterized by local removal of metal along a cut line by a plasma jet using quality plasma-forming gases like argon, nitrogen, hydrogen, air, etc. It is applied for cut-off stainless steels with thicknesses up to 60–80 mm and low-carbon and low-alloying steels with thicknesses up to 30–500 mm. After plasma cutting, the surface roughness may reach $Rz = 80–160\,\mu m$.

12.3.5 Combined Methods of Machining

For further development of manufacturing technologies, a combination of energy sources is possible. With a complex joint use of mechanical, thermal, chemical, or electrical energy, an enhanced material removal, better surface quality, or improved tool life can be achieved. Examples of these process combinations are, e.g., electrochemical grinding, electro-discharge grinding, ultrasonic-electrochemical, electro-discharge-chemical, anodic-mechanical, plasma-mechanical, and laser-mechanical processes.

Electrochemical Grinding

Electrochemical grinding (ECG) is carried out by overlapping material removal by microabrasive grains (diamond, CBN) with anodic (electrochemical) dissolution. Anodic dissolution of metallic workpiece materials reduces the microchip thickness and the area of mechanical contact between workpiece and the grinding wheel [12.99]. Furthermore, ECG reduces the material resistance against mechanical penetration by means of reduction of the strength of the superficial microlayer.

ECG processes work at a voltage of up to $U_p = 5-10\,V$ (at machining with an independent electrode $U_p = 24\,V$) and a current density of up to $15-150\,A/cm^2$. Nitrate/nitrite solutions are often used as working media (dielectric fluid). They contain various passivation additives (soda, glycerin, triethylamine, etc.) for reduction of the corrosion activity.

ECG processing is applied on surface ground components of hard, magnetic, heat resisting steels and alloys; surface and cylindrical grinding of thin-walled, nonrigid components; profile grinding; grinding of viscous materials, etc.

Electro-Discharge Grinding

During electro-discharge grinding (EDG), metal removal is carried out by microcutting of bonded abrasive grains, while the grinding wheel working surface is continuously influenced by electroerosion. Electric discharges provide an opening of the grinding wheel topography, allowing new abrasive grains to come into contact, and the removal of adhering chips from the wheel surface to prevent loading. Also just-cut chip segments might be directly evaporated in the zone of contact. Discharges occur between the workpiece and the wheel or between the tool and a specially adapted additional electrode [12.100, 101]. EDG processes can be actively controlled, and their intensity can be adjusted to provide substantial increase and stabilization in the lifetime and cutting ability of the grinding wheel.

For EDG processes, either a standard cutting fluid or 3% water–soda solution is used as the working medium. Current-conducting metal bonded abrasive wheels (or wheels with diamond or CBN grains) are connected to the positive pole, and the workpiece is connected to the negative pole of a pulse voltage source. EDG is applied in tool grinding, surface grinding, and cylindrical internal and external grinding machine tools.

Laser-Assisted Machining

Laser-assisted machining (LAM) has found rising acceptance due to its potential to significantly increase machining efficiency, in particular, in processes of punching and cutting complex-shaped workpieces. Laser radiation is employed for two reasons. Firstly, the laser source is used for heating (thus, annealing or hardness reduction) of the workpiece material surface layer directly in front of the cutting tool. This way, tool life is extended, and the productivity is drastically increased. It even opens the possibility of applying cutting technologies to materials that were not machinable this way before, like laser-assisted turning of ceramics [12.102]. Secondly, the laser can be used for final surface formation (for example, a groove after milling by an end mill). Applied in this combination, LAM processes increase the accuracy and quality of the machined parts.

Bernhard Karpuschewski

Leibniz Institute for Materials Engineering
IWT, Manufacturing Technologies
University of Bremen
Bremen, Germany
karpu@iwt-bremen.de

After receiving his PhD and holding the Chief Engineer position at the University of Hannover, Germany, Bernhard Karpuschewski worked for 1.5 years as Associate Professor at Keio University, Japan, and for 4.5 years as Full Professor for Production Technology at TU Delft, The Netherlands. He has been Full Professor at the University of Bremen and Director of the Leibniz Institute for Materials Engineering IWT Bremen since 2017.

Gerry Byrne

School of Mechanical and Materials Engineering
University College Dublin
Dublin, Ireland
gerald.byrne@ucd.ie

Gerry Byrne FREng is the Professor of Mechanical Engineering and the former Director of the Advanced Manufacturing Science Research Centre at University College Dublin (UCD), Ireland. He has over 30 years of experience with high-precision manufacturing processes, surface engineering, and aspects of surface microstructuring. He is an expert in the field of cutting processes and has published extensively. He is a senior advisor to the President of the Fraunhofer-Gesellschaft.

Berend Denkena

Produktionstechnisches Zentrum Hannover, Institut für Fertigungstechnik und Werkzeugmaschinen
Leibniz Universität Hannover
Garbsen, Germany
denkena@ifw.uni-hannover.de

Professor Berend Denkena is Head of the Institute of Production Engineering and Machine Tools at the Leibniz Universität Hannover. He is Professor of Production Engineering and Machine Tools and Director of the Institute of Production Engineering and Machine Tools at the University of Hannover. His primary areas of research are geometry and functionalizing manufacturing processes, machine tools for cutting and grinding, production planning and control, and simulation of manufacturing processes.

João Oliveira

Scenario Automation Ltda
São Carlos, SP, Brazil
oliveirajfg@gmail.com

Dr Oliveira is Professor of Production Engineering at the University of São Paulo, Brazil. His area of research is abrasive machining processes and their automation. He has published over 220 papers and 6 patents. He is a member of the Brazilian National Science Council Board, Vice President of the Brazilian Academy of Sciences, and a member of the International Academy for Production Engineering.

Anatoly Vereschaka (deceased)

Anatoly Vereschaka received his PhD from Moscow State University (1986). He was Professor of Engineering Technology, Material Cutting Technology, and Surface Engineering Technology in the Department of Mechanical Engineering Technology of Moscow State University of Technology (STANKIN), Russia. His research fields were the physics of metal cutting processes, design theory and methodology of wear resistance, and functional coating for cutting tools. He passed away in 2016.

13. Precision Machinery Using MEMS Technology

Takeshi Hatsuzawa

Some examples of optical microelectromechanical systems MEMS are presented with their fabrication processes. The MEMS-specific driving and display principles and experimental evaluations are also shown. Two types of electrostatic-driven optical MEMS devices: An interferometric display device and an evanescent coupling switching device are shown, in which no liquid crystal or organic electroluminescence materials are required except for a silicon dioxide film with conductive layers.

The interferometric display device consists of a Si reflection mirror at the bottom of an etch pit. On the pit, a SiO_2 film with a metal layer is suspended by two folded leaf springs at both sides, which works as both a half mirror of an interferometer and electrode for positioning. Applying a high voltage between the pit and the half mirror, an electrostatic force acts on two electrodes generating an attractive force to the half mirror. Therefore, the half mirror is drawn to the bottom balancing the repellent force from the leaf springs, which means the distance between the half mirror and the bottom can be controlled by the voltage. Thus, various colors can be generated at the micropit of the interferometer, enabling a microcolor display device. The fabrication process based on the conventional MEMS technology is also described, in which anisotropic etching of the Si is the key technology for forming the flat etch pit of the interferometer.

Another device is based on the evanescent switching between two SiO_2 films. A cantilever, working as a display pixel and an optical pickup from the substrate, is fabricated on an optical waveguide sheet with a separator. The cantilever has a transparent electrode film and it can be attracted and touch down on the substrate when a high voltage is applied between the substrate and the cantilever. Because of the surface roughness of the substrate and cantilever, the two cannot contact perfectly; however, fairly close contact within optical wavelengths can be realized. Therefore, the evanescent light generated by the waveguide sheet can be transferred to the cantilever, resulting in light emission on the cantilever surface as long as it has a high enough roughness for light scattering. The fabrication process using MEMS technology and evaluation of the device are described.

References 467

MEMS (microelectromechanical systems) is one of the new approaches to producing or assembling precision machinery with electronics. Originally, MEMS emerged from the silicon process, which is a combination of techniques such as chemical vapor deposition (CVD), reactive ion etching (RIE), photo or electron beam lithography systems, etc.; it is a concept of creating small mixtures of machines and electronics regardless of the fabrication technology.

K.-H. Grote, H. Hefazi (Eds.), *Springer Handbook of Mechanical Engineering*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-47035-7_13

13.1 Electrostatic-Driven Optical Display Device

Various types of optical switching devices have been proposed and developed. Most of them are intended for switchboard purposes – typically optical-fiber communication [13.1]. For display purposes, the digital micromirror device developed by TI [13.2] is a good example of a commercial application of MEMS. In the micromirror, an application of mechanical action for display purposes is one of the promising potential capabilities of MEMS. In particular, the frequency response of such mechanisms is shown to reach more than hundreds of kilohertz due to their small mass.

Two examples of optical switches are shown: An interferometric display device (IDD) is composed of a small set of interferometers to control contrast and color [13.3, 4]. An evanescent coupling display device (ECDD) is an application of near-field optics for switching light perpendicularly. The basic principle of the device, its manufacturing process, and experimental results are shown.

13.1.1 Principle of the Interferometric Display Device

Figure 13.1 shows the schematic construction of the IDD. An SiO_2 half mirror suspended by leaf springs forms a capacitor to the base plate with a gap of $(n + 1/4)\lambda$ to construct a Fizeau interferometer. When a DC voltage is applied to the capacitor, the half mirror is attracted to the base plate balancing the leaf springs, and the reflection beam from the base plate interferes with the beam reflected from the half mirror. When a monochromatic light source illuminates the device, the contrast is changed periodically according to the displacement of every $\lambda/4$. In the case of a white light source, color variation is realized with a fine half mirror positioning control. Integrating this device like a dot matrix, a reflection-type display can be constructed. The device has the potential to triple the pixel density compared to RGB space separation displays. Also, static driving consumes little energy, and the mirrors have a fast response because of their light mass of tens of micrograms.

13.2 Design of the Device

The displacement of the mirror z is a balance of the leaf spring force and the electrostatic force F. It can be expressed as

$$F = \frac{1}{2}\epsilon S\left(\frac{V}{d-z}\right)^2 = kz\,, \tag{13.1}$$

where ϵ is the dielectric constant, S is the area of the half mirror, V is the applied voltage, d is the gap length without voltage, and k is the spring constant of the leaf spring. The resonant frequency of the mirror f_n is calculated by

$$f_n = \frac{1}{2\pi}\sqrt{\frac{ml^3}{192EI}}\,, \tag{13.2}$$

where m is the mass of the leaf spring, l is the length of the leaf spring, E is the Young modulus of the spring material, and I is the moment of inertia of the leaf spring. This predicts that the relationship between voltage and displacement is nonlinear.

The maximum contrast of the device is obtained when the intensity of the beam reflected by the half mirror and that reflected from the bottom is equal. Suppose the following: half mirror reflectance R_h, transmittance T_h ($\simeq 1 - R_h$), and reflectance of the bottom mirror R_b. The relationship is expressed as

$$R_h = T_h^2 R_b\,. \tag{13.3}$$

This is the optical requirement for the device to obtain the maximum contrast.

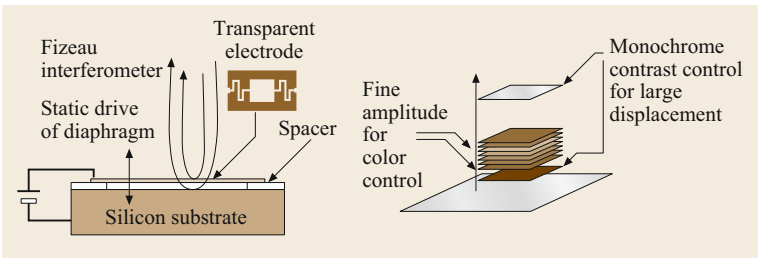

Fig. 13.1 Principle of the interferometric display device

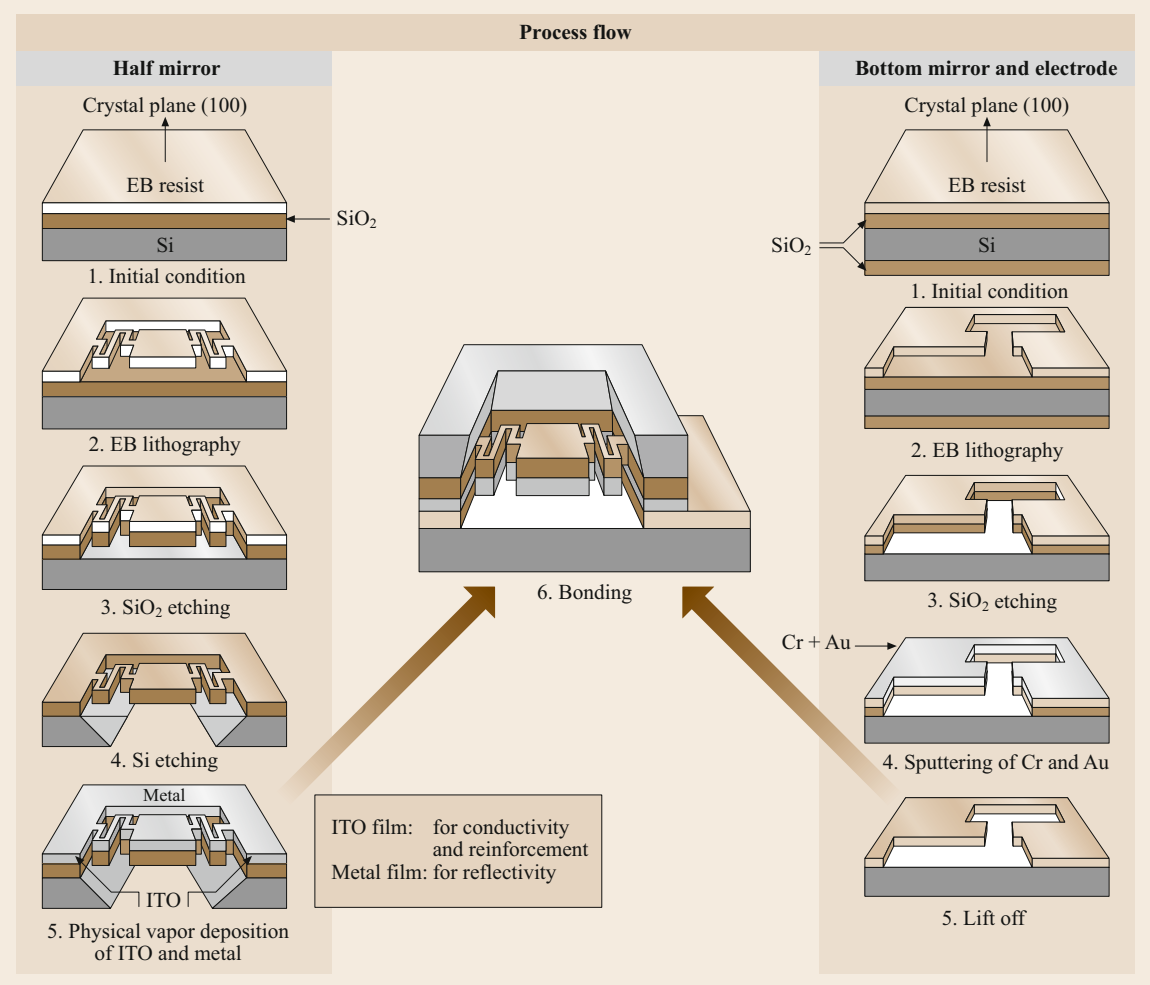

Fig. 13.2 Fabrication process of the IDD

13.2.1 Fabrication of the Device

The half mirror is the key element of this device and it should have a fine parallel movement to the base plate. A double leaf spring suspended mirror is used for this purpose. A 100 μm square mirror is fabricated from a thermally oxidized silicon film of thickness 1 μm, with a spring length of 400 μm, which is folded for a wider pixel aperture. A theoretical resonant frequency of 27 kHz is calculated for the film thickness, a beam width of 5 μm, and an applied voltage of 45 V. Thus, a displacement of the mirror more than a quarter of the wavelength can be obtained by the application of a low driving voltage to the mirror gap.

Figure 13.2 is the process flow for manufacturing the IDD. A wafer bonding technique has been employed to adjust the mirror gap easily. The half mirror and the bottom mirror electrode are fabricated separately. Then the gap is controlled by the film thickness of the SiO_2 as the spacer.

13.2.2 Performance of Prototype IDD

Figure 13.3 is a fabricated example of the IDD. For this prototype, a half mirror dimension of 100 μm, a leaf spring width of 10 μm, and a mirror gap of 5 μm are realized. A driving DC voltage of 15 V and a resonant frequency of 5.3 kHz have been obtained. When the device is illuminated by a halogen lamp, interferometric fringes are observed on the half mirror, instead of uniform contrast change. This originates from the deformation of the half mirror, because of its thin thickness and short leaf spring length compared to the width, and should be improved by increases the film thickness as well as structural modification.

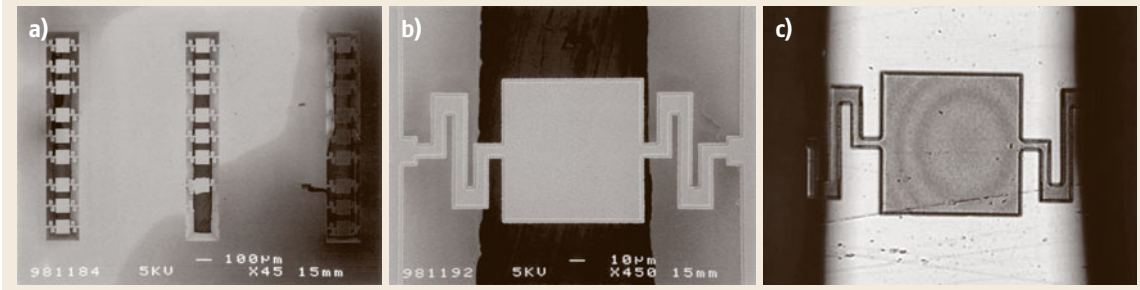

Fig. 13.3a–c Example of the (a) IDD array, (b) IDD pixel and (c) interferometric fringes

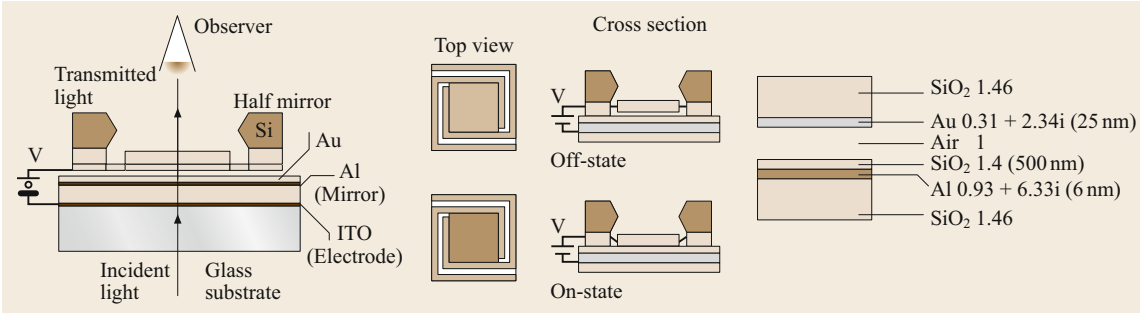

Fig. 13.4 Improved construction of the IDD based on Fabry–Pérot interferometer

13.2.3 Improvement of the IDD

The principle of the device is alternated from the Fizeau interferometer to Fabry–Pérot interferometer, shown in Fig. 13.4, for easier optical adjustment for high contrast and illumination. By experimental optimization, a combination of gold and aluminum film in Fig. 13.4 was found to be the best for satisfying (13.3). Also, to achieve smaller deformation of the half mirror, a spiral structure, shown in Fig. 13.5, is adopted to realize longer leaf spring length so that the deformation may be concentrated only on the leaf spring. With a twofold film thickness of 2 μm surrounding the half mirror, the deformation of the mirror itself was improved to 0.2 μm, which is comparable to a quarter of the wavelength.

By a CCD video capture system, the RGB contrast of the IDD is evaluated. In Fig. 13.6, RGB contrast is obtained for the halogen illumination. Although the pixel image still has a distribution in both color and contrast, no interferometric fringe is observed for this construction thanks to smaller film deformation.

The average contrast of a pixel for each color $C_{R,G,B}$ is calculated as

$$C_{R,G,B} = \frac{I_{max} - I_{min}}{I_{max} + I_{min}} , \qquad (13.4)$$

where I_{max} is the maximum and I_{min} is the minimum intensity of the pixel. The obtained contrasts for Fig. 13.6 were $C_R = 0.18$, $C_G = 0.03$, and $C_B = 0.08$. The con-

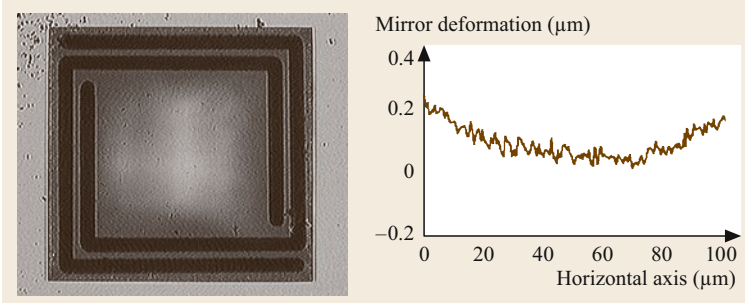

Fig. 13.5 A spiral leaf spring structure and cross sectional deformation

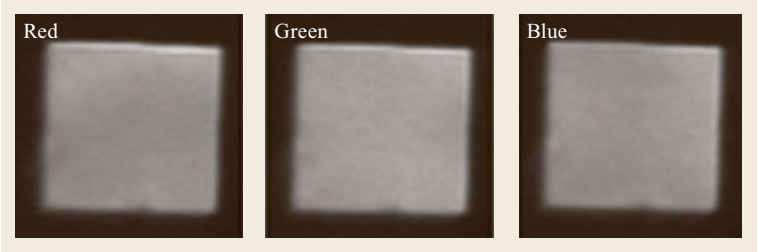

Fig. 13.6 RGB pixel image

trast dependence on color may be attributed to the interferometric layer, which is designed to be fit for only one wavelength.

Frequency response was examined by a function generator and high-voltage power source. Up to 100 Hz, the device follows the input voltage, and for higher driving frequency, it has a phase delay because of the squeeze damping effect of the air. For a driving frequency of 2 Hz and a voltage of 10 V, a maximum contrast of 0.3 was obtained.

13.3 Evanescent Coupling Switching Device

Fabrication for this device is very difficult because of various process problems such as deformation of the half mirror, adhesion of the mirror to the substrate, etc. An alternative is the evanescent coupling display device (ECDD), which uses microfabricated cantilevers for optical switching and is free from mirror deformation [13.5–7]. The principle of the device, its fabrication process, and evaluation are presented in this section.

13.3.1 Principle of the Evanescent Coupling Display Device

The ECDD is fabricated on a glass substrate together with cantilevers as micro-optical switches (Fig. 13.7). The substrate works as a waveguide sheet propagating light horizontally, and the cantilevers are driven electrostatically by DC voltage to engage in or disengage from the switching action. When the cantilevers are attracted to the substrate making mechanical contact, light energy in the waveguide sheet transfers to the optical cantilevers by the evanescent coupling, even if there is a small gap within the wavelength. The transferred light also propagates in the cantilevers horizontally; however, it is scattered from the top surface of the cantilevers because of the rough surface. Then, the cantilevers emit the light perpendicularly, enabling the brightness change of the device. By the on–off switching of the driving voltage, the cantilevers work as a pixel of the optical display.

13.3.2 Fabrication Process of the ECDD

As shown in Fig. 13.8, multicantilevers are fabricated from a silicon substrate with a 2 mm-thick thermal oxide layer. The multicantilevers on the substrate are patterned by photolithography and RIE etching, using a Cr layer as a mask for SiO_2 etching. The silicon substrate under the cantilevers is etched in a solution of 15 wt% tetramethyl ammonium hydroxide (TMAH) solution at 90 °C. Next, the indium tin oxide (ITO) layer as a transparent electrode is sputtered on the cantilevers. A micrograph of the fabricated cantilevers is also shown in Fig. 13.8, nesting eight cantilevers from both sides of the substrate to increase the effective pixel area. The length and width of the cantilevers are 490 and 20 μm, respectively. Due to residual stress of the ITO layer, the fabricated cantilevers are curved toward the silicon substrate with a displacement of 10 μm. Because of the

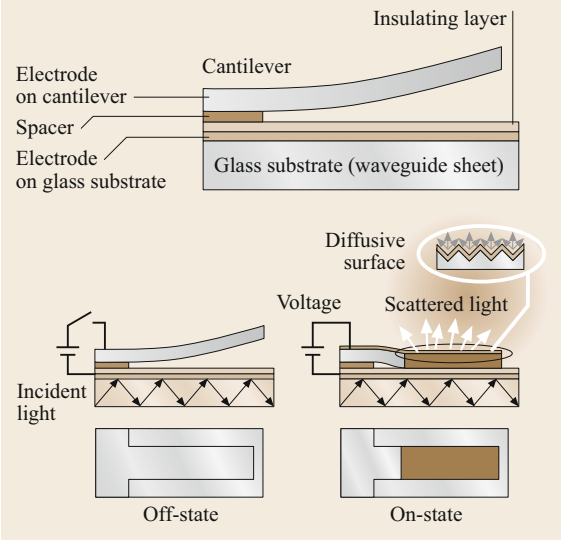

Fig. 13.7 Principle of the evanescent coupling switching device

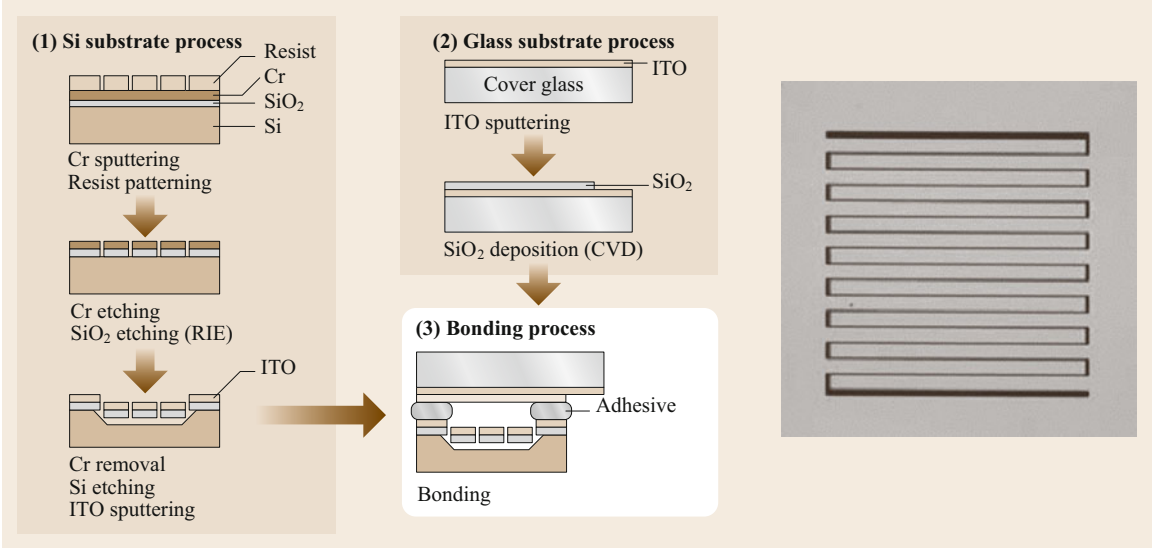

Fig. 13.8 Fabrication process of the ECDD

residual stress, the sticking problem between the cantilevers and the substrate is cleared up even after voltage application.

13.3.3 Evaluation of the ECDD

The characteristics of the ECDD were evaluated by the same system as the IDD. A result of the driving evaluation is shown in Fig. 13.9. Although unnecessary scattering appeared in the off-state, a clear brightness is observed in the on-state of the pixel. A maximum contrast of 0.9, defined by (13.4), was obtained at a driving voltage of 170 V. Hysteresis of the contrast was observed in a slow driving test; however, it does not cause the switching speed to deteriorate.

For frequency response, a square voltage of 170 V and a frequency of 1 kHz can drive the multicantilevers. From this performance, the device has a sufficient response for display application. However, for higher response speed, reduction of the sheet resistance of ITO layers, as well as the size and cantilevers, must be optimized.

A dot matrix-type device, shown in Fig. 13.10, is fabricated to confirm the function as a display. An 8×8 pixel matrix is constructed in $6 \times 6\,\mathrm{mm}^2$ square, with a pixel size of 500 µm. Using an external voltage driver with a laser incident beam to the glass substrate, the device shows the ability of an individual pixel drive as well as row and column driving.

This type of device can display images on transparent media and can be seen from both sides, when every part is made of transparent material.

14. Measuring and Quality Control

Steffen Wengler, Lutz Wisweh, Shuichi Sakamoto, Norge I. Coello Machado

Considering the incessantly increasing requirements on the quality of products and processes, it is necessary to ensure a quality-orientated management in all departments of any type of company and the advantageous application of manufacturing measurement equipment.

In addition to diverse technical requirements, the requirements of national, international, and company-specific norms must also be considered. Companies must not only fulfill the requirements of quality but also those pertaining to safety, the environment, and the economy.

In the following, some aspects of manufacturing measurement technology and quality management and their integration into a manufacturing process will be introduced.

Starting with manufacturing geometrical conditions and statements on drawings (nominal state and geometrical limits) the use of measurement equipment and gages to the evaluation of geometric elements will be described. Basic knowledge of measurement standards, measurement uncertainties as well as calibration and testing of measuring instruments are presented. Based on the physical principles, the equipment and methods for the registration of measurement values, form and position deviations, and surface characteristics will be introduced.

14.1 Quality Management

Nowadays, the quality of products, assemblies, and services not only includes the fulfilment of functional requirements by maintaining tolerances. It also includes the fulfilment of numerous requirements such as shown in part in Fig. 14.1. In this section, some fundamentals of quality management will be described from the multitude of requirements. In Sect. 14.2, some aspects of the requirements of manufacturing measurement technology for the qualification of the geometrical quality of products will be shown.

Among the requirements for organizations involved in quality control, the key concepts of quality management (QM) and total quality management (TQM) include planning, monitoring, and improvement of quality, such as the consideration of representatives and departments relevant to quality, as shown in Fig. 14.2.

14.1.1 Quality Management Methods

To conform to the requirements of modern quality management, nowadays numerous procedures and methods, with many different applications, are available [14.1]. Figure 14.3 presents a selection of relevant methods used in the area of mechanical engineering.

K.-H. Grote, H. Hefazi (Eds.), *Springer Handbook of Mechanical Engineering*, Springer Handbooks,
https://doi.org/10.1007/978-3-030-47035-7_14

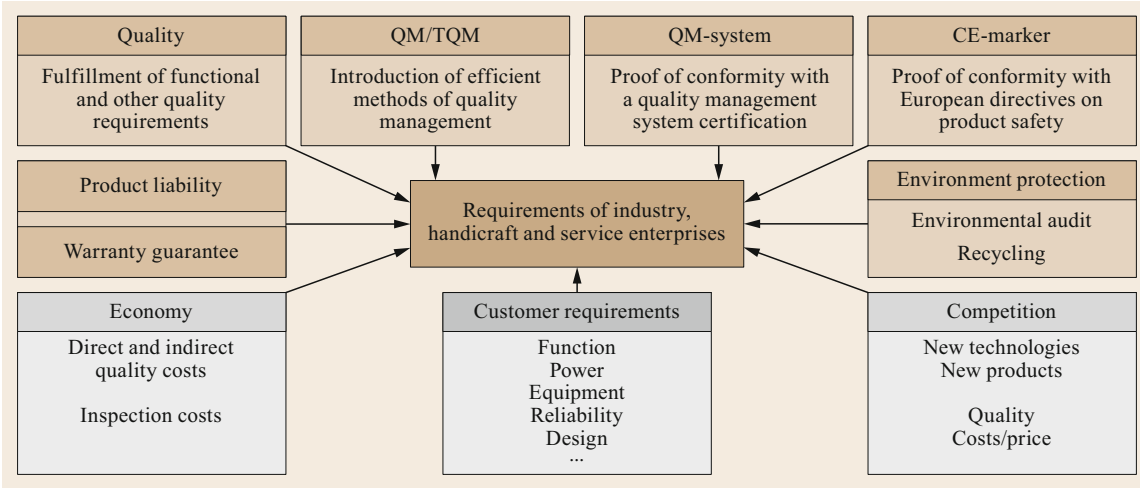

Fig. 14.1 Requirements for industry, craft, and service enterprises

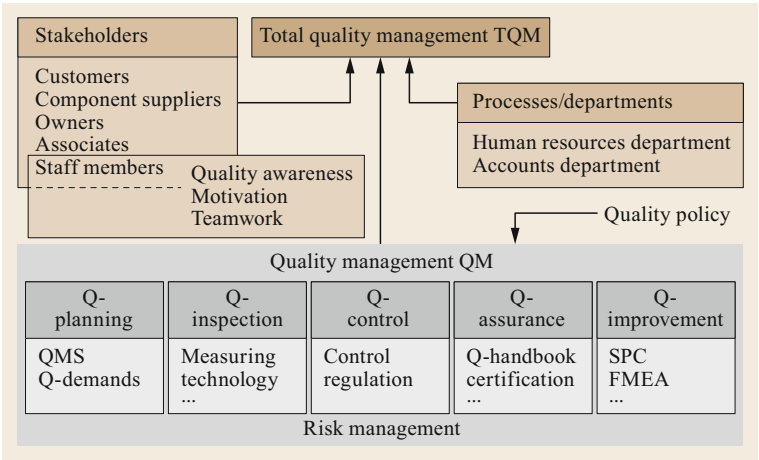

Fig. 14.2 Elements of quality management

The different methods can be associated to two essential groups: *problem-resolving techniques* and *preventive techniques*. The problem-resolving techniques can also be divided into the two other categories: those that find causes of existing quality problems and those that help the engineer develop definite aims in a systematical manner (management methods).

The prime conditions for quality analysis are the collection and preparation of quality data with respect to measured data. *Tally lists* enable a visualization of the accumulation of certain failures or various kinds of mistakes. *Histograms* demonstrate the probability of the occurrence of a certain event within intervals of the measurement range. *Pareto analyses*, also called *ABC analyses*, enable a weighting of the dominant influencing parameters. In combination with the corresponding costs, they are known as Lorenz–Pareto analyses.

Referring to a definite problem, a comprehensive structuring of clustered influences or causes can be presented as a *cause–effect diagram*, also known as a *fishbone diagram* or *Ishikawa diagram*, which can be used to solve possible problems.

The determination of pairs of values in an x–y coordinate system is especially applicable in the experimental causal research of measurement (e.g., quality characteristics). These *scatter diagrams* can be described with the help of statistical calculations, such as regression and correlation analyses, in which the identified regression function describes the kind of functional connection, while the correlation describes the intensity of that connection through the correlation coefficient.

Nowadays, *analysis and evaluation of the quality capability* of procedures and processes takes place

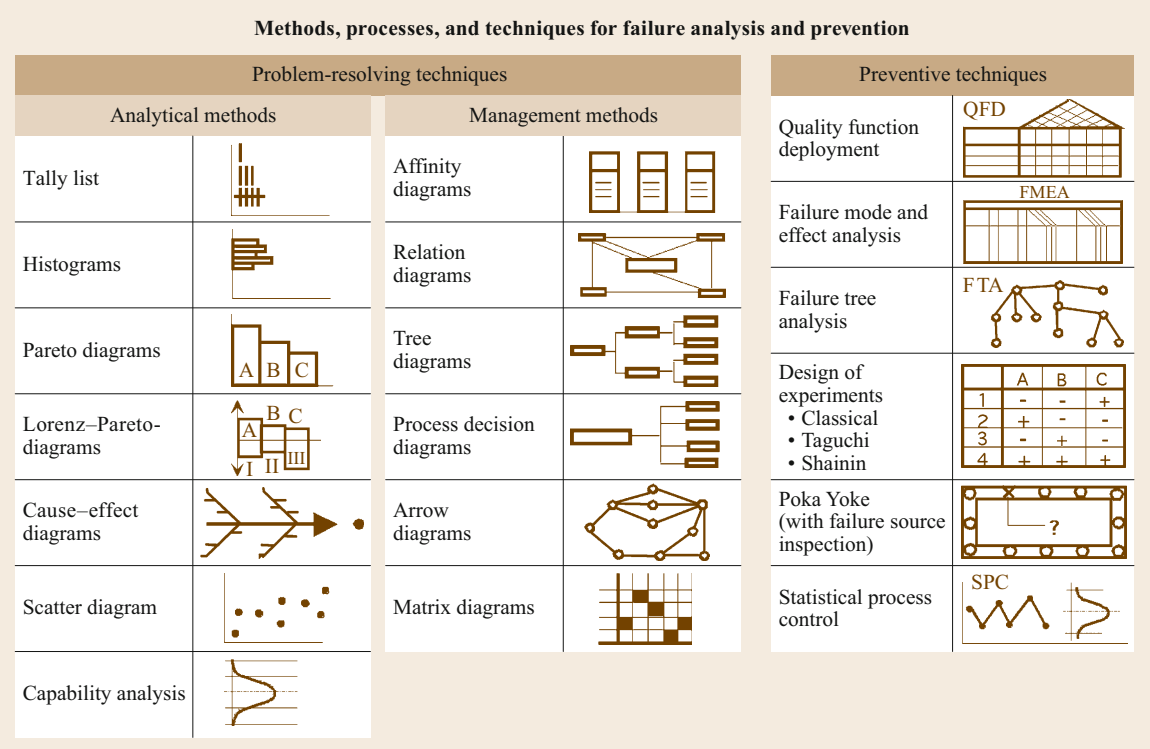

Fig. 14.3 Problem-resolving and preventive techniques

in many areas of mechanical engineering by a comprehensive statistical evaluation in terms of capability coefficients, which express the relation of process spread (6σ) to the tolerance and the position of the arithmetic mean of the tolerance borders. This way, it is possible to compare the quality level of different processes.

Management methods support the solution of problems by a targeted systematic procedure. *Affinity diagrams* allow a structured systematization of ideas in order to point out the correlation between these ideas.

Relation diagrams enable the development of cause–effect relations by visualizing networked structures. *Tree diagrams* specifically subdivide aims until directly realizable activities are practicable.

Firstly, *process–decision diagrams* start by arranging possible problems by

- Urgency
- Probability of occurrence
- Difficulty of prevention.

With the aim of detecting potential problems already in the planning phase and to elaborate corresponding countermeasures.

Arrow diagrams or *net plans* are important resources for project planning for the investigation of *critical paths*, which determine the total permanence of a project. In this method, the determination of a process sequence is made using series and parallel paths to develop a detailed explanation of the working steps required to achieve the project aim, followed by the assignment of the corresponding process durations.

If a lot of information quantities for certain circumstances are available, *matrix diagrams* are suitable for detection of latent structures. By using data evaluation in pairs with the help of matrices for different characteristics, this method enables, for instance, manufacturing and market analysis.

Nowadays, in the field of preventive techniques for failure prevention in technological processes, the schematically compounded methods shown in Fig. 14.3 are mostly applied.

In current quality management, product-related customer wishes are the source of motivation for development from the designing process through the manufacturing process up to the delivery of the products.

With the help of *quality function deployment (QFD)* the *voice of the company* can be developed from the *voice of the customers*. The QFD method systematizes

this process under the application of matrices based on the following four steps:

- Customer wishes in terms of product characteristics
- Product characteristics in terms of part characteristics
- Part characteristics in terms of manufacturing regulations
- Manufacturing regulations in terms of production instructions.

Every phase can be described by matrices in the form of a so-called *house of quality*.

This method offers the possibility of affecting the production aim in the conception phase and at the same time obtaining information about the critical product and process characteristics for the fulfilment of customer expectations. Besides the implementation of marketing information in the product, target conflicts between the individual product characteristics may also become visible.

For the detection of potential failure modes during product development, the introduction of new manufacturing methods and the modification of manufacturing technologies' *failure mode and effect analysis* (FMEA) is used. FMEA is especially used in the case of cost-intensive and risk-products and processes. FMEA has universal application and is not connected with a special field. At the base of a standardized procedure, which can be supported by corresponding blank forms, the main steps of a FMEA can be divided into risk analysis, risk assessment, the determination of measures, and the evaluation of effectiveness. The risk evaluation results from evaluation of the probability of occurrence, its importance (for the customer), and the probability of detection of the corresponding failure before delivery to the customer. The advantages of FMEA are above all a decreased number of failures in the early phases of product manufacturing and in product planning.

The systematic search for imaginable reasons for a failure, called an unwanted event, is possible with the method of *failure-tree analysis*. This method, which originated in the field of safety engineering, enables an evaluation of fixed correlations by the determination of the quantitative probability of the appearance of failures.

For this purpose, the function of single components (devices) is described under different conditions using a so-called *components tree*. A subsequent system analysis aims to holistically describe their organization and the behavior of the technical system. The contribution of the individual components to the protection of the overall function of the system, the evaluation of the consequences of the environmental influences of the overall system, and the description of the reaction of the overall system to failures within the system, of resources and by faulty operations, can be described by a failure-tree analysis and calculated or simulated by various evaluation methods.

The methods of *statistical research planning* have the general aim of adjusting the relevant product and process parameters using a systematically procedure in such a way that the quality-relevant characteristics closely approach the ideal value with as few experiments as possible.

The weighting of the influencing factors and the quantification of their effect can be achieved based on classical statistical research planning using mathematical models (such as factorial research plans); if there are a very large number of influencing factors, this can be solved with the help of the empirical procedures developed by Taguchi or Shainin.

The *Poka Yoke* method (from the Japanese: the avoidance of unintentional errors) is dedicated to preventive avoidance of failures in manual manufacturing and assembling processes through the development of precautions (design measures that eliminate incorrect handling) and facilities for failure avoidance for immediate failure detection in the manufacturing process. This can be realized by a comprehensive implementation of applicable rules for product and process design or by the use of simple ancillary equipment.

The *statistical evaluation and control of the quality of processes* (statistical process control (SPC)) is not only a main goal of modern quality management systems but is also required for cost-efficient production processes.

The aim of the use of statistical methods in quality management also exists in the classical detection of faulty products in the manufacturing process and is increasingly widespread in the qualitative monitoring, control, and improvement of the manufacturing and assembling process.

According to algorithms such as that shown in Fig. 14.4 some basic decisions can be made.

Quality control of processes can be performed using continuous, 100% inspection or on the basis of periodically chosen samples in the form of statistical process control (SPC). Statistical methods can also be used to achieve the aim of monitoring and improving product and process quality. Therefore, it is a direct component

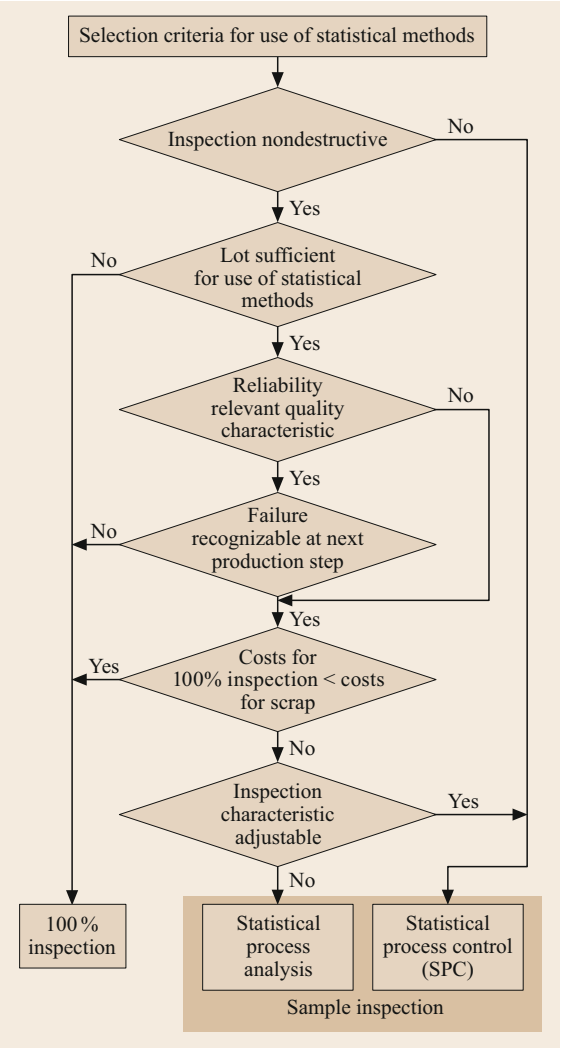

Fig. 14.4 Selection criteria for the use of statistical methods

of the quality control circle. The most important methods in this regard are (Fig. 14.5):

- Measuring controls with statistical control algorithms
- quality control charts
- Capability analyses and evaluations
- Sample inspection by statistical sample plans.

Processes in practice, especially newly-introduced processes, are influenced by numerous systematic and

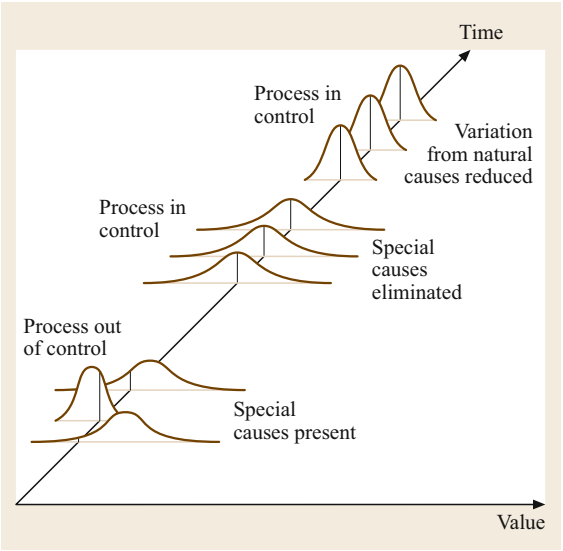

Fig. 14.5 Overview of the use of statistical methods for the evaluation and control of processes

random influences, which make the use of statistical methods difficult.

Many statistical methods require the prerequisite of a normal distribution (e.g., double-sided tolerances or limited quality characteristics) or a logarithmic normal distribution (e.g., one-sided tolerance quality characteristics), which are free of systematical influences.

In such cases, we also speak about the requirement of stable or stationary processes or of so-called *processes in or under statistical control* (Fig. 14.6).

If stable processes are available, they can be further inspected using quality control charts. A quality control chart (QCC) is a graphical representation of a process calculated from the measured results from a small sample or chronological characteristics. The target of quality control charts is to capture quantitative changes in a process that exceed statistically derived control limits (Fig. 14.7).

The recorded results can then be the basis for subsequent statistical evaluations or characterizations in the form of capability coefficients. These coefficients can also be used for the evaluation of machines and processes.

If a product-orientated decision about the acceptance or rejection of a product series or lot takes place, sample plans can be used. The producer (supplier) may also use these in the form of a final inspection, as may the customer in the form of an inspection on receipt.

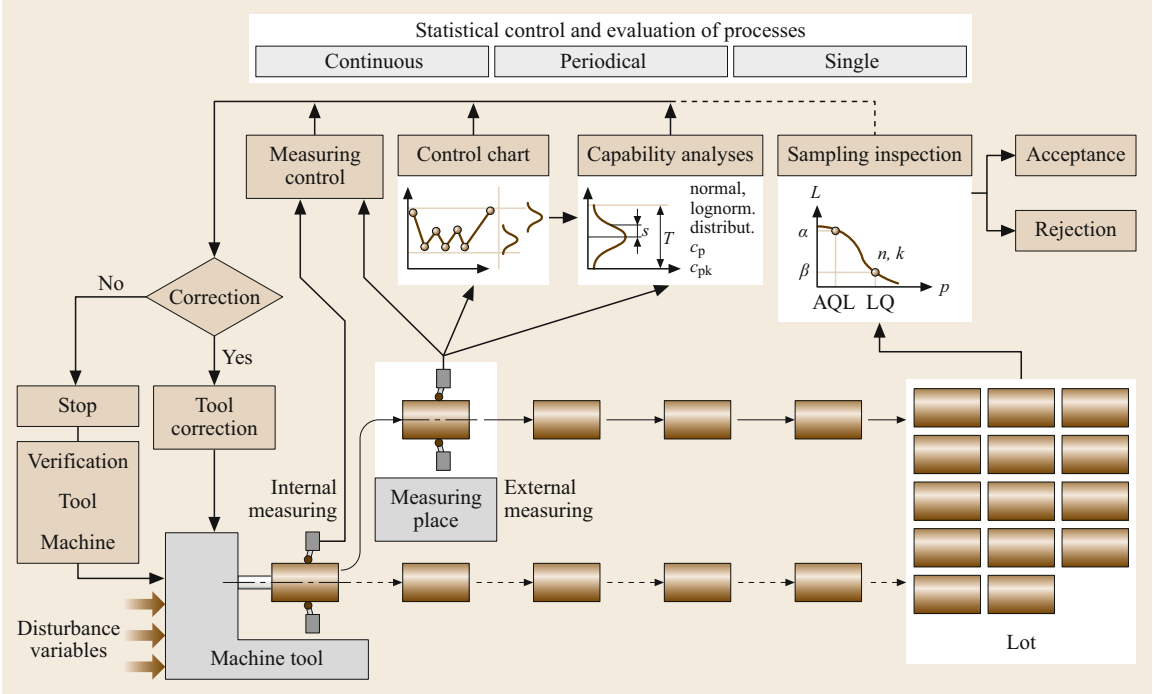

Fig. 14.6 Stabilization of processes through the reduction of systematic and random processes disturbing variables

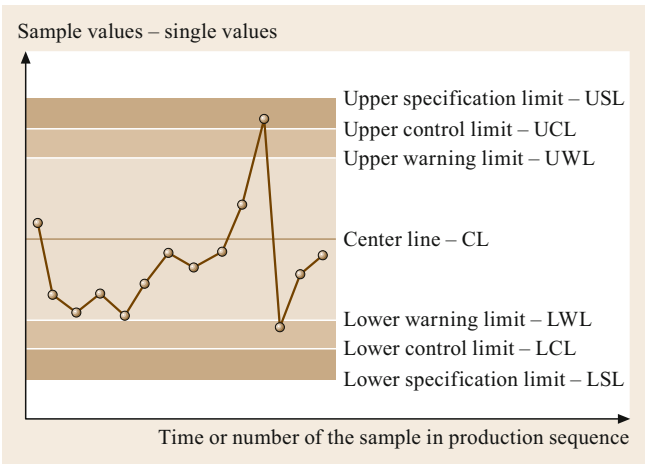

Fig. 14.7 Process monitoring with quality control charts

Statistical analysis results have a wide variety of uses in quality monitoring, evaluation, control, and management, as is shown in Fig. 14.8.

14.1.2 Quality Management Systems

The organizational realization of the concept of quality in all departments of enterprise and in all phases of product realization can be supported by *quality management systems* (QMS), as is shown in Fig. 14.1. In addition to this, the organizational structure and the processes organization of all quality-relevant departments and operations can be evaluated and compared to standardized regulations. The successful introduction and realization of a QMS can be evaluated and validated by an accredited certification body.

As the basis for this, the independent ISO 9000 series of standards can be used [14.2–5]. Based on this, for the worldwide automotive industry, comprehensive additional requirements exist, which are fixed in company-dependent standards. Efforts for the integration of the different requirements of the automotive industry to date are contained in the standard IATF 16949 [14.6].

14.1.3 CE Marking

Within the single market of the European Union, a requirement for the commencement of operation and the placing on the market of products is the fulfilment of harmonized safety requirements. To obtain a conformity certificate for these European Community (EC) requirements, a CE marking is required. This is also valid for products that are produced outside of the European Union if they are also distributed within it.

Examples of EC directives include those for machines, toys, electromagnetic compatibility (EMC), detonating devices, and medical products, etc.

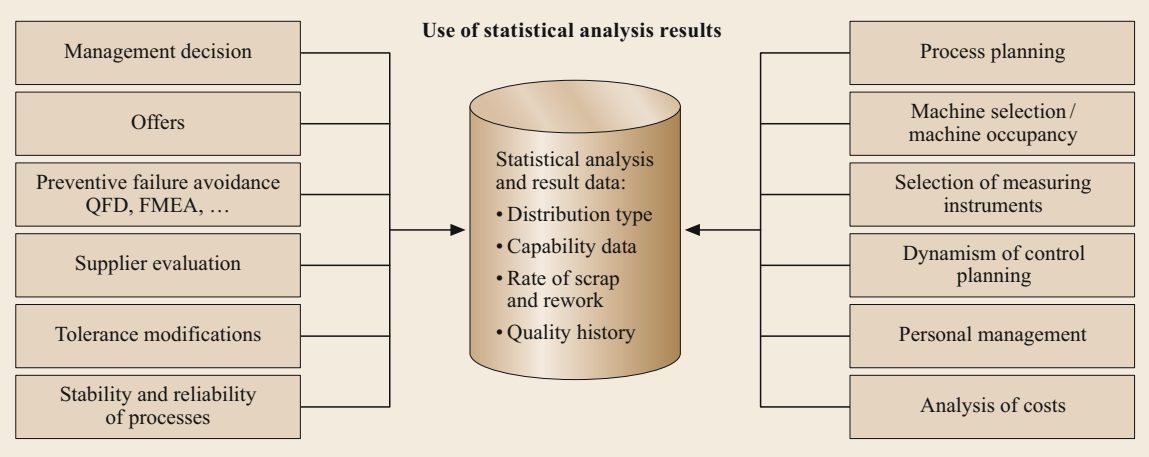

Fig. 14.8 Use of statistical results

14.2 Manufacturing Measurement Technology

Measurement is the determination of the value of a physical quantity (measured quantity) by comparison with a reference value.

Manufacturing measurement technology is part of the field of measurement technology. It deals with the methods, equipment, and strategies for measurement in the realm of mechanical production processes. Manufacturing measurement technology is utilized in various locations, such as rooms with special, controlled environmental conditions, as well as directly integrated into the assembly line. The aims of manufacturing measurement technology are:

- Evaluation of the product
- Evaluation of processes and machines
- Quality-orientated process control.

Here we confine the discussion to the description of the relevant geometrical features and/or technical aspects of obtaining such objects from workpieces. These features include lengths, angles, distances, and surface structures. Most of the principles and definitions described also apply to nongeometrical parameters. The relevant SI unit used to describe these geometrical features is meter. Angles are described in degrees or radians.

The physical measurement that comes from the measuring process is called the measure. The object from which this quantity was measured is called the measuring object. The value of the measure, which actually exists but is currently unknown, is the true value. The aim of the measuring process is to determine this true value. A variable that does not change with time (for example, a diameter) is measured by a static measurement. Dynamic measurement is the measuring of a variable that changes with time (for example, a vibration) or the measurement of a variable, whose variation arises from the time-dependent behavior of another variable (for example, for a roughness measurement, the dependence of the measured value on the scanned measuring length).

In order to determine whether an object fulfils a particular requirement, it is inspected. As subjective inspection should not be considered, one can differentiate objective inspection into measuring and gauging. The inspection means that are employed can be divided into indicating measuring devices, measurement standards, gauges, and additional measuring devices. Figure 14.9 shows a digital dial indicator and a measuring block, as the most important measurement standard of dimensional measuring technology. Measuring blocks are quadrilateral metal or ceramic gauges, whose parallel end faces have a known width and minimal deviation. A gauge and a stand, an example of additional measuring equipment, are represented on the figure too.

14.2.1 Arrangement in the Manufacturing Process

Measuring technology has become an essential ingredient in manufacturing processes. Figure 14.10 shows the multitude of integration possibilities and the corresponding relationships between the production process and measuring technology as well as different possibilities for analyzing the measured data and its feedback into the process.

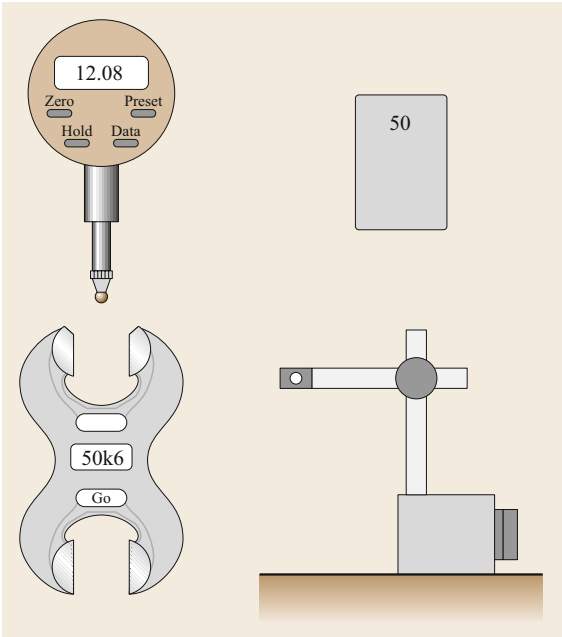

Fig. 14.9 Inspection devices

Inside every tooling machine integrated measuring devices are used to collect parameters (the position of the axes, temperature, force, voltage, current, etc.). These values can be directly used by the machine operator or the machine itself to control future operations. In reference to the collection of data from finished products and in consideration of the drawing specifications, these finished product parameters can be evaluated, classified, and documented. Furthermore, parameters can be derived from the measured values through continued analysis, or more specifically, these parameters that can regulate or control the machining or production of the product. Using an adjustment, the measured value (the controlled variable), which has an instantaneous value, is continuously measured and corrected with a controller with respect to a known value (the set value). It is then possible to eliminate disturbance factors from outside the process. The constant, targeted influencing of a process on the basis of a previously defined model without feedback is what is meant by open-loop control.

Starting from the process analysis, the machining process and/or the processing machines themselves can be evaluated (for example, for machine and process capabilities) and documented. The result of the machine evaluation is, for example, a quality-orientated machine selection. Should the machine not be in a position to produce the desired tolerances, selective inspection and correction of the machine systems may be necessary, or a complete overhaul or a new revision of the machine may even be necessary. Through the additional use of measuring technology for preventive monitoring of a machine, it is possible to implement maintenance procedures or schedules to avoid losses or stops in production.

14.2.2 Specifications on the Drawing

The drawing is the defined input to the manufacturing process based on the required functions outlined by the designer, and is, therefore, the basis for the manufacturing measuring process. The complete, integrated product drawings, as well as single-product element drawings, are used to clarify the permitted allowances and, thereby, the tolerances for manufacturing. The geometrical specifications can be separated into measuring

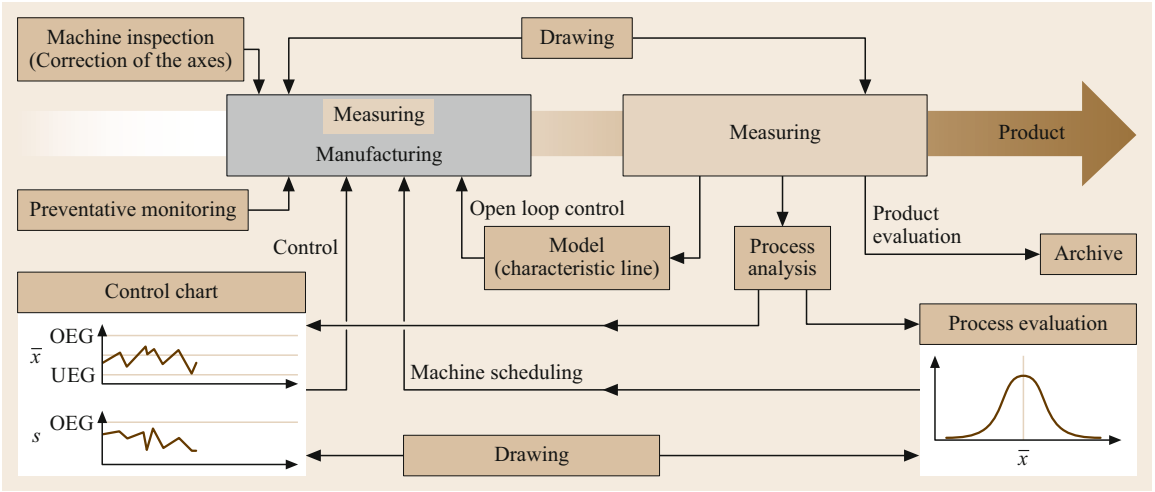

Fig. 14.10 Measuring technology and measuring value analysis in manufacturing processes

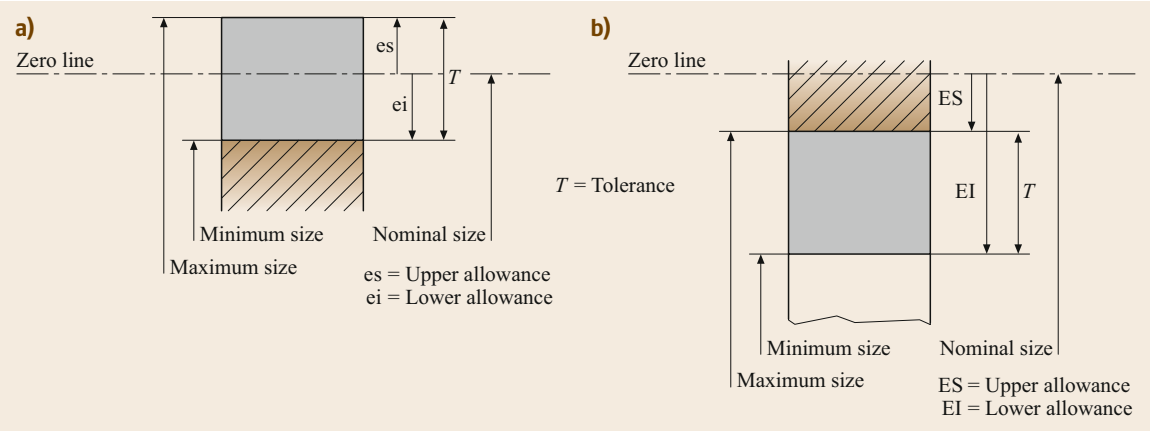

Fig. 14.11a,b Tolerance specifications for lengths: **(a)** shaft, **(b)** hole

tolerances and shape tolerances. Shape tolerances include not only form and position tolerances, but also surface finish tolerances, which can be divided into roughness and waviness.

Tolerance specifications for lengths consist of the nominal size and defined permissible upper and lower allowances (Fig. 14.11). The nominal size plus the upper allowance is the largest acceptable measure, and the nominal size plus the lower allowance is the smallest acceptable measure. The difference between the upper and lower allowances is the tolerance. The definition on the drawing is shown through the specification of a nominal size supplemented either directly by a coded specification of the allowance or through a letter and a number combination (ISO 286 [14.7, 8]). The letter describes the position of the tolerance field with respect to the zero line, and the number represents the magnitude of the tolerance. The specification $36^{-0.025}_{-0.050}$ corresponds to the drawing specification, 36f7, which, in manufacturing terms, means that the largest acceptable measurement is 35.975 mm, and the smallest acceptable measurement is 35.950 mm. Whenever the nominal sizes are the only values displayed on the drawing, free size tolerances according to ISO 2768 can be specified [14.9, 10].

The position of the tolerance with respect to the zero line (which corresponds to the nominal size) and the size of the tolerance determine the function of the proposed piece. The size of the tolerance is, furthermore, decisive for the cost of the manufacturing process.

The form and location tolerances in each case define zones, into which the corresponding element must fit in, when it is within the tolerance. Form tolerances, which are defined in ISO 1101 [14.11], are shown in Table 14.1. Single elements, such as lines, rectangles, circles, cylinders, and profiles are specified as form tolerances. Position tolerances are divided into direction, place, and run tolerances, as summarized in Table 14.2. In each case, position tolerances refer to an individual element of the workpiece. On the drawing, the necessary specifications are represented in a tolerance frame (Fig. 14.12). The tolerance frame contains a symbol that describes the type of tolerance that is being signified and a tolerance value, possibly with a reference length. The indication arrow connects the tolerance frame with the associated element, or rather the associated lines of

measurement or symmetry on the drawing. Whenever the type of tolerance requires it, the reference element is indicated at the end of the tolerance frame through the specification of a letter, which repeats the necessary reference basis. In a few cases, more reference elements are possible.

The tolerance specification for surface finish is shown on the drawing by a basic symbol and supplemented by additional specifications. Whether material cutting machining is *necessary* or *not permissible* is also indicated, as is shown in Fig. 14.13. Additional specifications include tolerances for the roughness value (most of the time, the arithmetic average surface finish (Ra)), and when necessary, amongst others, specifications for the manufacturing process, tolerances for further roughness or waviness parameters, and the grooving direction.

14.2.3 Gauging

Gauges are inspecting devices that represent the dimension and/or form of the workpiece that is to be tested. There are three types of gauges: limit gauges, receiving gauges, and so-called *go and no-go* limit gauges. The procedure is always the same: to try to mate the workpiece elements with the correct gauges. A simple yes or no decision is the result of this process. With limit gauges, one can determine whether the value of a test object is larger or smaller than the value of the gauge (for example, with a pin gauge). With receiving gauges (for example, radius or screw pitch gauges), a comparison is made with the workpiece's form and the form of the gauge, and the best-fitting pieces can then be separated out.

Go and no-go limit gauges are the most important for the inspection of manufacturing tolerance elements. Figure 14.9 shows an example of an external caliper gauge, which is suitable for the inspection of shafts. Limit gauges consist of a *go* side and a *no-go* side, which correspond, respectively, to the largest and smallest measurement possible; the *go* and *no-go* sides are verified one after the other to check for mating. The inspection result is *good* when the workpiece fits comfortably into the *go* side and not into the *no-go* side. The Taylor principle states that, on the *go* side, all the

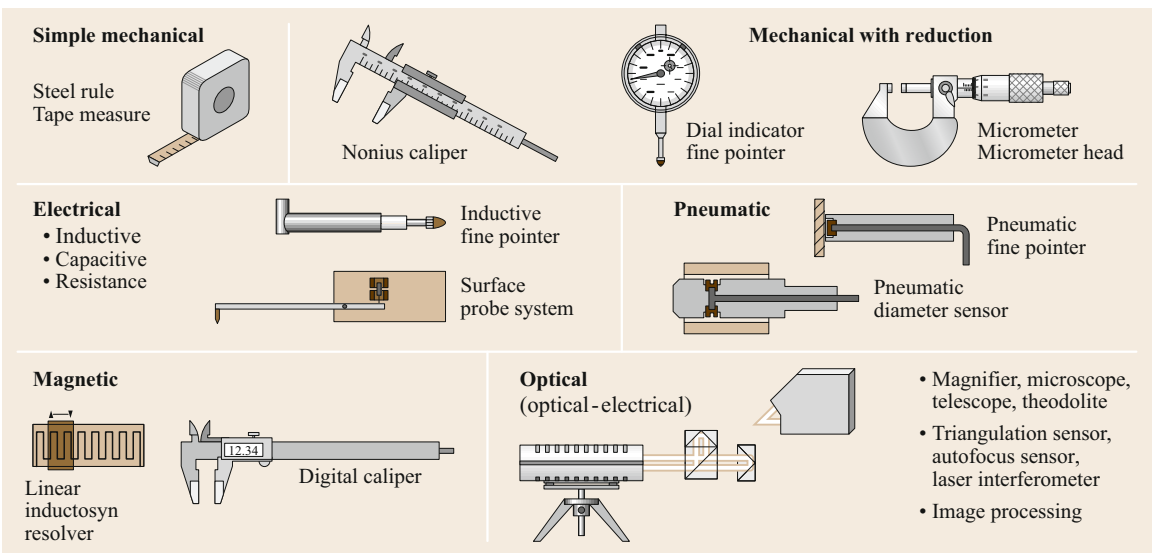

Fig. 14.14 Physical principles of measurement-value collection and example instruments

measurements or control measurements are tested at the same time, but on the *no-go* side, every measurement or control measurement is tested in isolation.

14.2.4 Application of Measuring Devices

Measuring devices work on very different physical principles. Simple mechanical measuring devices include the steel rule or measuring tapes. Measuring devices with mechanical reduction include nonius calipers, dial indicators, and micrometers. Pneumatic systems have long been used because of their noncontact scanning. At present, electrical, magnetic, and optical (more specifically, optical-electrical) principles have emerged in the field of measurements. Their common essential property is that the value measured can be directly transformed into an output signal or onto recording media. A few examples of such equipment are shown in Fig. 14.14.

Essential for a secure measuring value collection is the construction of a measuring chain that is as short as possible and stiff. The measuring chain in Fig. 14.15 is composed of a measuring device, the supports of a stand, a base plate, and the object measured. In the measuring device, starting from the input value (in this case, the displacement of the probe by the measuring object) the output (in this case, the measuring value 8.02 mm) is obtained through the measuring sensor, an amplifier, and an analog-to-digital converter. Depending on which measuring devices are used, their internal parts may be quite different. The output value can then be transferred to a storage device or a processing machine (for example, a personal computer).

The following explains several essential properties of measuring devices. These properties determine the applicability of the equipment. The achievable *information content* of a measurement is an essential distinction criteria. Also, the *accessibility* of the measuring value to the workpiece reduces the possible selection of measuring devices. The *type of probe* (contact and noncontact) is also relevant. Spheres, planes, or cutting edges are the fundamental probe shapes.

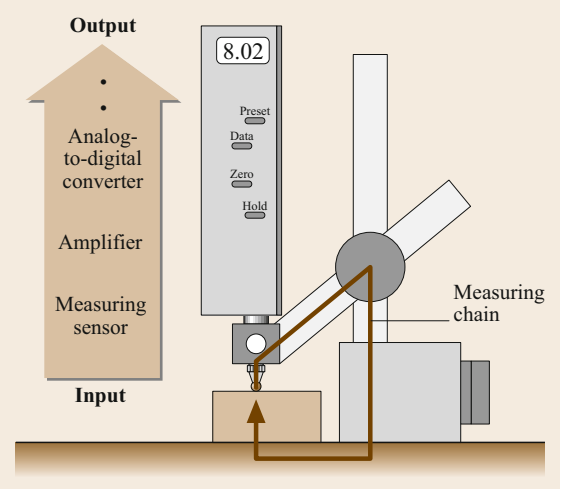

Fig. 14.15 The measuring chain

The *indicating range* of a measuring device is the range of values over which the device can indicate (smallest to largest indicated measuring value). The *measuring range* can deviate from the indicating range and corresponds to the section of the indicating range over which the measuring deviations remain within defined boundaries. The *scale division value* is the change in the measuring value that leads to the movement of the pointer from one to the next dash on a line scale (on digit scales to a digit step). When the measuring devices are clamped (for example, by a support, Fig. 14.15), the range of adjustment of the support and the measuring range of the measuring devices constitute the *range of application*. The relationship between the value of the input and the corresponding output value is the *transfer function*. A linear transfer function is usually aimed for. The *threshold limit* is the smallest possible change in the input that leads to a recognizable change in the output. The effect whereby the same value of the input produces two different results depending on the direction in which the value is approached, is called the *hysteresis*. A slow, time-varying change of the output without a change in the input value is called *drift*. The *response time* is the time between a step change of the input and the time when the output value remains constant within a prescribed range.

Additionally, the *measuring uncertainty* should be highlighted as an essential characteristic of measuring devices. A measuring device is qualified for a designated measuring task only when the uncertainty does not exceed a ratio with the tolerance of $U/T = 0.1$–0.2. Because the exact uncertainty of a chosen measuring device is often not known, one can make do with the *limit of error*. The limit of error is the largest measuring deviation of a measuring device and is usually defined for a group of measuring devices through a standard or by the manufacturer.

The *direct collection of measuring values* (for example, with calipers or micrometers) is the easiest type of measuring implementation. The measuring range of the measuring devices must overlap with the measuring object. In Fig. 14.16, the measurement of a length by means of a micrometer is shown. The range of measurement of the displaced micrometer is shown as being 25 mm. Objects with lengths ranging from 0 to 25 mm can be measured. The measuring uncertainty for such a micrometer can be expected to be in the range of 10–20 µm.

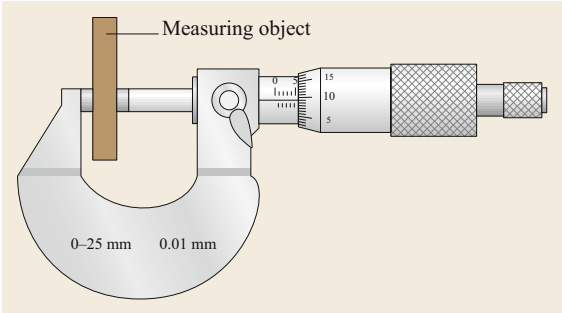

Fig. 14.16 Direct measurement

If the tolerance of the measuring value is so small that the required ratio between the measuring uncertainty and tolerance can no longer be met, one must choose a measuring device with a smaller measuring uncertainty. Smaller measuring uncertainties are often accompanied by smaller measuring ranges. Whenever a measuring device whose range of measurement is smaller than the measuring value must be used, for example because of the requirements of the measuring uncertainty, one can employ *difference measurement* (Fig. 14.17). One chooses a measurement standard, which is shown as a combination of block gauges in Fig. 14.17, whose value differs from the measuring value by no more than the measuring range of the measuring device. The measuring device is used so that the readout both by probing the measurement standard and the measuring object is possible. The length of the measuring object is the sum of the length of the precision gauge block, and the difference between the readout for the measurement standard and the measured object.

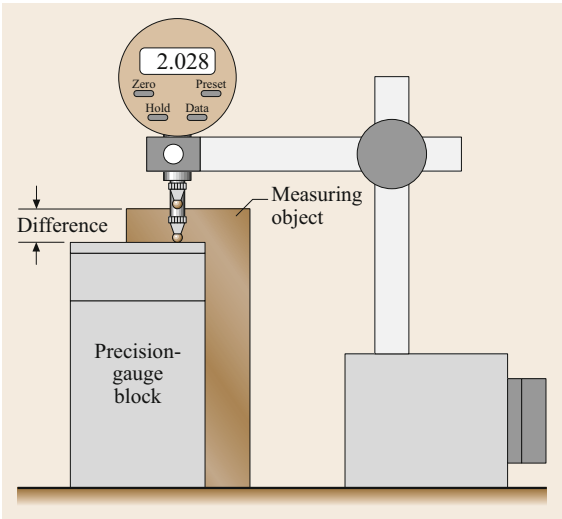

Fig. 14.17 Difference measurement

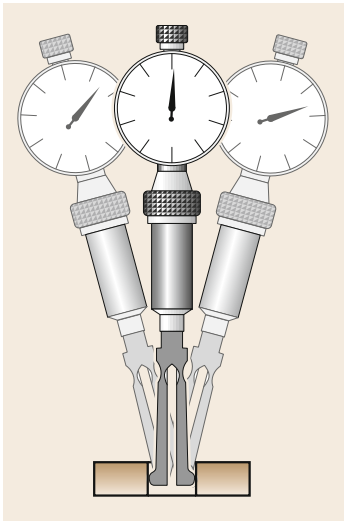

Fig. 14.18 Inversion point

Another important application option is the search for an inversion point. Figure 14.18 shows an example of the measurement of an inside diameter with a two-point measuring instrument (two probing points on the cylinder's interior). Through the measuring force and supported by special structures, the instrument aligns itself so that the cylinder axis intersects the connecting line between the two probe points. The instrument can be pivoted from the left in Fig. 14.18, through the middle, to the right position. One can see that the displayed measuring value becomes smaller at first but, after the middle position, becomes larger. The smallest displayed value, the inversion point of the needle, corresponds to the shortest connection of the probed cylinder surface line and, thus, the diameter.

When measuring workpieces, different influences have a negative impact on the measuring result. For example, inclination between the measuring instrument and measured object, bending, deformation on account of the measuring force, and environmental conditions can lead to deviations of the measurement. Some of these effects can be avoided or notably reduced through the operation of the proper equipment.

Through the adherence to a fundamental measuring technology principle, the Abbe comparator principle, one can reduce the influence of tilting errors. According to this principle, the measured object and the measuring rule are to be aligned flush. Figure 14.19 shows the universal length gauge as one of the essential instruments using this principle. The measured object and the integrated measuring system, which is inside the movable quill, are consecutively aligned flush. Brackets for interior measurement are attached. After removing the brackets the instrument can collect of external measurements. As measuring systems, glass measuring scales

and laser measuring systems are utilized. Such measuring instruments are suitable for the monitoring of gauges and measuring means.

The deflection of workpieces due to their own weight also has a considerable impact on their length. On a bar-type component, one obtains the smallest shortening of the whole length whenever the piece is supported on the so-called Bessel points (Fig. 14.20). These support points are located at a distance $a = 0.220l$ from the ends. Similar effects lead to deformations on account of the measuring force. Deformations of the material are mostly only problematic for soft materials (plastics) and nonmassive workpieces. Here, the workpiece can bend itself whenever the measuring force presses against thin-walled positions. This effect can be reduced using proper fixtures.

Environmental conditions are generally specified by the room where the measurement takes place. Measuring rooms are classified into five classes. Precision measuring rooms (class 1) serve the calibration of reference standards. Fine measuring rooms (class 2) serve for the calibration of the standards used and for acceptance inspection of precision parts. In standard measuring rooms (class 3), measuring tasks for the monitoring of a process, measuring of fixtures and tools, as well as the control of inspection equipment (factory standards) and first prototype inspections are conducted. The production-related measuring room (class 4) serves for monitoring production, machine settings, and instruments. Production-related measuring takes place on the manufacturing measuring site (class 5). The spectrum is supplemented by the special measuring room, for example, for the measuring of semiconductor wafers. Properties whose limit values in every measuring room class are predefined include temperature (basic temperature, time and local temperature variation), vibrations, air quality (fine dust, suspended matter), air humidity, and lighting.

A substantial influential parameter for geometrical data acquisition is temperature. The reference temperature for measurement is 20 °C. The reference temperature is the temperature at which workpieces have their true measurement value and at which the inspection equipment detects it. These specifications apply to all pieces in the measuring chain. Table 14.3 shows the linear expansion coefficients of different materials. For example, for a temperature increase of 1 K, a 1 m-long piece of steel will become about 13 µm longer. The alternative measuring of the existing temperature and consequent correction of the measuring

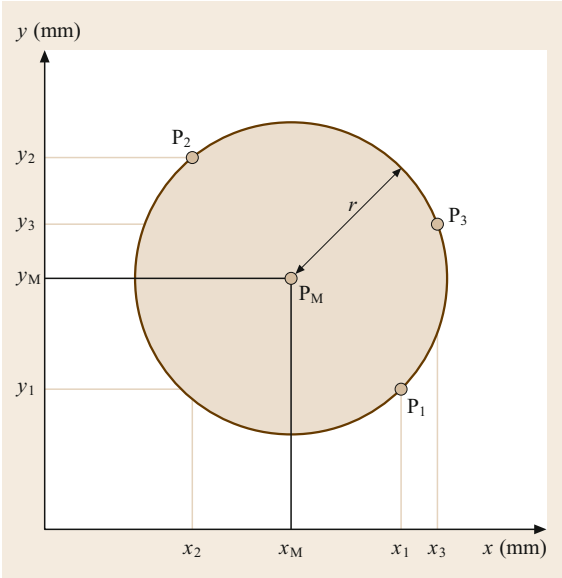

Fig. 14.21 Measuring points on a circle

value is particularly problematic for geometrically and compositionally inhomogeneous inspection equipment or workpieces and with temporally and spatially varying temperatures.

14.2.5 Coordinate Measurements

Coordinate measuring machines are universal, flexibly applicable equipment for the recording of workpiece geometry. As well as measurements of parameter (e.g., diameter and length) position and form (e.g., roundness and concentricity), special (e.g., cylindrical or bevel gears) and free-formed surfaces (castings) can be measured [14.12].

In contrast to conventional measuring techniques, the desired measurements are not measured directly. The principle is the acquisition of single data points from geometrical elements. These elements include circles, planes, cylinders, spheres, and cones. Furthermore, these elements can be combined together to identify distances, angles, or position deviations. The acquired measuring points, which are on the boundary of standard elements, are mostly described by a Cartesian coordinate system (Fig. 14.21, x, y, z). However, it should be noted that cylindrical and spherical coordinate systems are also possible. The described size of these geometrical elements will then be calculated from these measured points. The following example shows the strategy for identifying the radius r and the middle point coordinates x_M, y_M of a circle. For simplification, this example will be confined to a circle in the x–y plane.

The equation for a circle whose center point does not lie at the origin is as follows

$$r^2 = (x - x_M)^2 + (y - y_M)^2 .$$

The variables r, x_M and y_M are unknown. One appoints a measuring point on the circumference of the circle for the variables x and y. Now, because there are three unknowns, and we need a clear description of the circle, we need three equations, which means three data points (the smallest number of data points for determining a circle is three). This yields the following system of equations

$$\begin{aligned}
&\text{For } P_1 \text{ with } [x_1, y_1]\text{: } r^2 = (x_1 - x_M)^2 + (y_1 - y_M)^2 ,\\
&\text{For } P_2 \text{ with } [x_2, y_2]\text{: } r^2 = (x_2 - x_M)^2 + (y_2 - y_M)^2 ,\\
&\text{For } P_3 \text{ with } [x_3, y_3]\text{: } r^2 = (x_3 - x_M)^2 + (y_3 - y_M)^2 .
\end{aligned}$$

Since we are dealing with elements of measured, real-world objects, whose bordering areas deviate from geometrical standards, the collection of a larger number of data points is essential for the determination of the element parameters. An overdetermined (no longer explicitly solvable) system of equations results from a higher number of measured points. This system has the following form

$$\begin{aligned}
&\text{For } P_1 \text{ with } [x_1, y_1]\text{: } f_1 = (x_1 - x_M)^2 + (y_1 - y_M)^2 - r^2 ,\\
&\text{For } P_2 \text{ with } [x_2, y_2]\text{: } f_2 = (x_2 - x_M)^2 + (y_2 - y_M)^2 - r^2 ,\\
&\qquad\vdots\\
&\text{For } P_n \text{ with } [x_n, y_n]\text{: } f_n = (x_n - x_M)^2 + (y_n - y_M)^2 - r^2 ,
\end{aligned}$$

where f_i represents the deviation of the corresponding data point from an ideal circle. One can employ a compensation method to solve this system of equations. A widely used method is the regression equation by Gauss. The sums of the squared deviations are minimized with this method

$$\sum_{i=1}^{n} f_i^2 \rightarrow \min .$$

This least-squares method ensures that all measuring points are included in the calculation. Problems especially arise when one wishes to verify mating. In this case, the inscribed circle gives the description for holes, while the circumscribed circle gives the description for shafts. (The *inscribed circle* is the largest possible circle that has all of the measuring points outside, while the *circumscribed circle* is the smallest possible circle that contains all of the measuring points; Fig. 14.22.) In certain cases, an outlier test may be necessary.

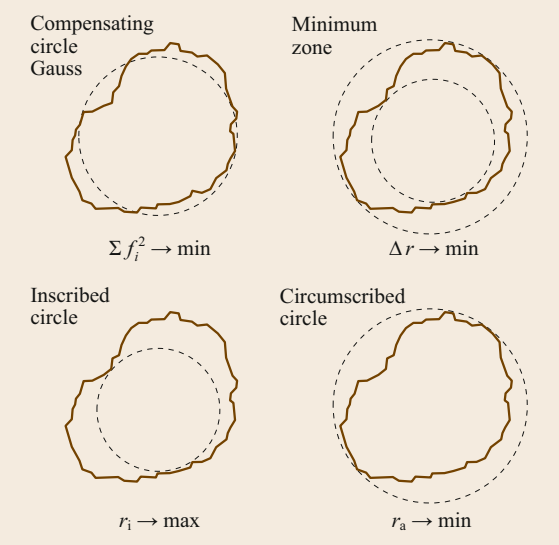

Fig. 14.22 Compensation methods

Equipment, Sensor Technology, and Software

One can subdivide coordinate measuring machines on the basis of their construction into portal, bridge, and standing measuring machines. In Fig. 14.23, the basic configuration of a portal measuring machine is represented. The mechanically embodied axes (in the example shown, portal and quill) are arranged on the measuring table at right angles to each other. Additionally, the axes of rotation can be integrated for the realization of rotary movement. The instantaneous positions of the axes are logged through the measuring system and forwarded to the connected computer. Glass measuring scales are mostly used in measuring systems.

The probe system is attached to the quill. In addition to the frequently utilized mechanical probe systems, there are contactless options such as edge recognition, optical methods, and/or laser probes. One speaks of a multisensor coordinate measuring machine when various probing systems are arranged inside (Fig. 14.24).

Figures 14.25 and 14.26 illustrate various mechanic probing systems. One can distinguish between measuring and switching mechanical probing systems. In both cases, the workpiece is touched with the probe element, which is fixed onto the probing system. The probe element consists mostly of a shaft and an almost ideally round, wear-resistant sphere (in most cases, made of ruby). In a switching measuring system (Fig. 14.25), the contact between the probe sphere and workpiece releases an impulse. At the moment of this signal, the x, y, and z-coordinates of the current position from the table, portal, and pinhole are transferred to the computer and stored there for further processing as required.

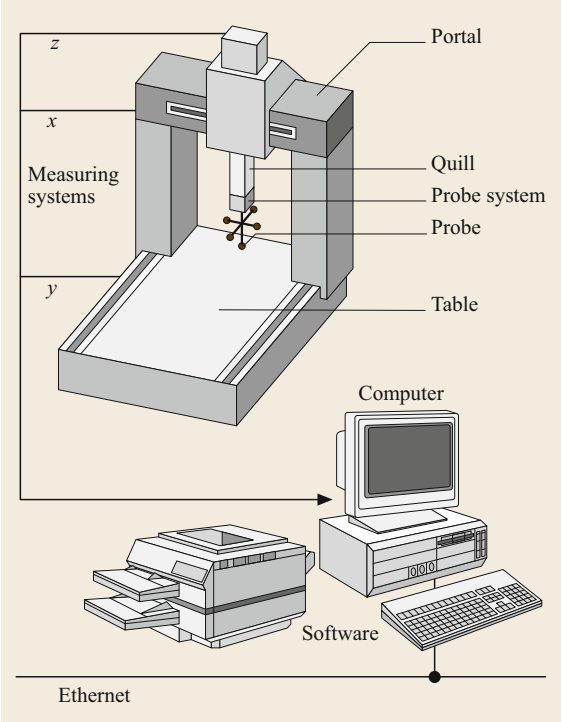

Fig. 14.23 Basic configuration

Contact between the probe and workpiece leads to deflections of the probe head in all three coordinates in a measuring probe system (in Fig. 14.26, the deflection is only represented in one direction). These deflections are measured and combined with the associated coordinates of the inherent positions of the table, portal, and quill. The measuring point coordinates obtained in this way are passed to the computer. However, care must be taken to note that the measuring point coordinates acquired always refer to the middle point of the probe sphere of the reference probe, not to the contact point between actual probe and workpiece.

Very flat outlines or color transitions are not mechanically probable. In these cases, optical acquisition is an option. For this purpose, the measuring object is illuminated, according to the target measurement (using through light, light-field, or dark-field illumination) and imaged through optics. The optics used may work with changed or zoom objectives in order to obtain different magnifications between the measured object and the image. In the simplest case, only the contours to be measured are scanned, using an edge finder. In the next most sophisticated system, based on image processing, the measured object is displayed on a charge-coupled device (CCD) matrix. As with a mechanical measuring probe system, the measuring point coordinates results

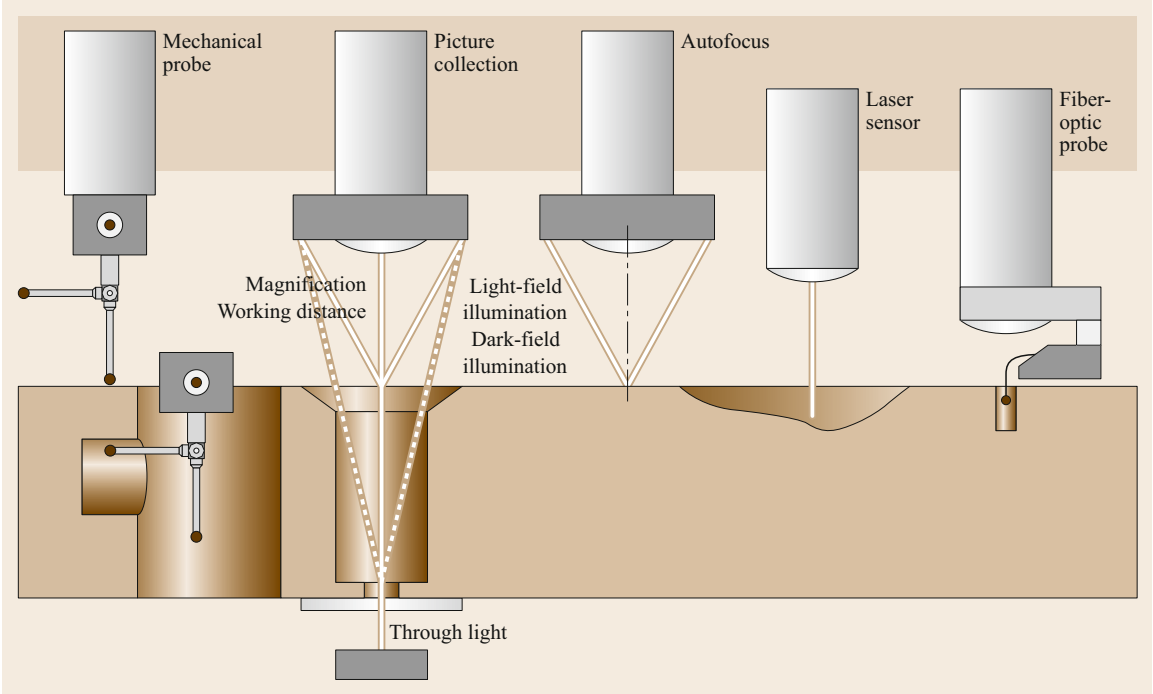

Fig. 14.24 Multisensor technology

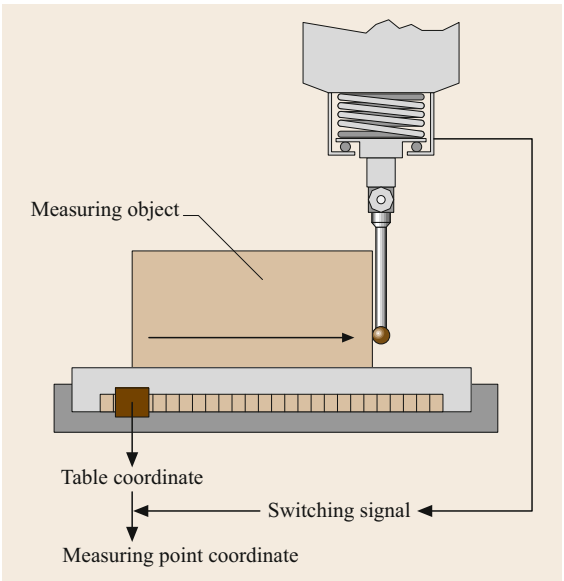

Fig. 14.25 Switching probe system

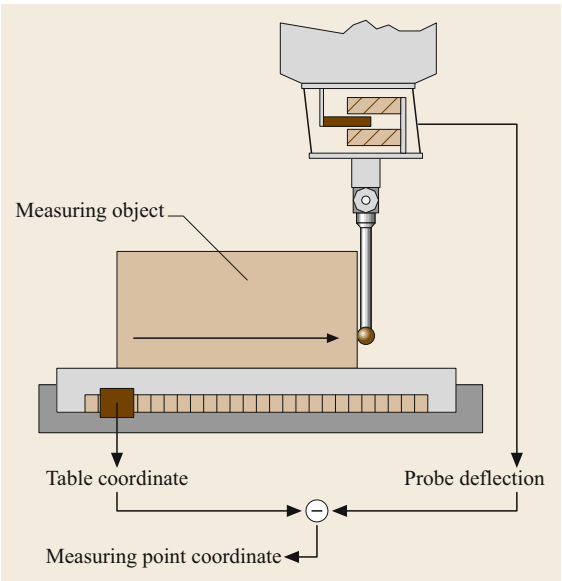

Fig. 14.26 Measuring probe system

as a combination of the pixel coordinates and the inherent positions of the table, portal, and quill.

While the optical variants described so far operate in the x–y plane, the focusing of an optical system can also capture the z-coordinate. The focusing can be automated by means of a laser or contrast evaluation in the image-processing system. The sensor controls the shift of the quill in the z-direction. The respective z-value supplements the x–y coordinates of the associated position to actual measured three-dimensional (3-D) values. Instead of autofocusing options, one can also use a direct laser measuring system for the addition of

the third coordinate, for example, a triangulation sensor. This method forms a laser point on the surface of the workpiece. Using observational optics arranged at a defined angle with respect to the sensor, a difference in the height of the surface of the workpiece is recorded directly. When the measuring range of the triangulation sensor is not sufficient, one can extend its application range by shifting with the quill. The measured z-value can then be calculated from the z-axis of the measuring system and the measured value from the triangulation sensor.

One very new and interesting sensor variation is the fiber-optic sensor patented by Werth Messtechnik (Fig. 14.24). It consists of an extremely small glass sphere, which is suspended by a glass fiber. Over this light pipe, the sphere can be directly illuminated. To capture the measuring points, the glass sphere is placed on the workpiece to be measured. The image-capturing system (CCD matrix) can detect this probe either in transmitted light or through its self-lighting. The center of the sphere describes the coordinate of the measuring point, just as for normal mechanical probes.

The *software* in the attached computer essentially has the following tasks:

- Capture of the measuring points
- Corrections, for example, perpendicularity and guideway deviations of the measuring machine components, probe radius and middle point, probe bending, temperature influences
- Coordinate transformations, for example turntable and workpiece coordinate systems
- The calculation of ideally geometric substitution elements from the measuring points
- The combination of single elements
- Conversions, projections, etc.
- Evaluation (nominal-actual comparison), protocol, statistics.

Device control (point or path-control, scanning) comes with the computer numerical controlled (CNC) coordinate measuring machines.

For the archiving of results or for further processing, data transfer by means of a network is possible.

Proceeding with the Measurement

The completion of a measuring task by means of coordinate measuring machines is explained in the following. Three phases will be differentiated.

Phase 1: Planning. The planning phase can be done remotely from the measuring machine, but requires knowledge of the technical possibilities, the available probes and clamping elements as well as extensive experience. Especially this phase is decisive for a metrologically safe and economically justifiable execution of the measuring task. The test task, which is generally fixed on the drawing, forms the basis for the planning of the measurement. Differences in the path arise, whenever the aims of the measurement (evaluation of the part), quality-orientated production control, or check for assembling possibility are changing. In this case, knowledge about the production of the piece (for example, the machining base) or its later application (subsequent machining and assembly) is useful. The test task is divided into its single elements and combinations. A sequence from easiest to most complicated is then sought.

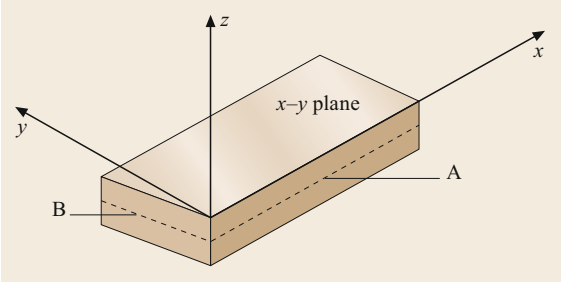

Fig. 14.27 The workpiece coordinate system

It is advantageous to specify a coordinate system on the workpiece not only for the measurement, but also for the evaluation of the results. This workpiece coordinate system must be clearly described mathematically. To do this, the following steps are required:

1. Space adjustment: description of a coordinate axis (mainly z) as the main direction of important form elements (for example, the direction normal to a surface, the axle of a cylinder). The z-axis is described in the example picture (Fig. 14.27) by the normal to the upper workpiece plane.
2. Plane adjustment: hindering the rotation of a coordinate system around these under point 1 defined axes (for example, by fixing to an edge or the straight line connecting the middle of two holes). The direction of the x-axis in the example picture (Fig. 14.27) is defined in the x–y plane by the corresponding direction of the long rectangular surface (dashed line A). This fixes also the direction of the y-axis, which must be orientated at a right angle to the x-axis.
3. Point adjustment: definition of the origin for x, y, and z. The origin of the z-axis through the measured x–y plane and the origin for the x- and y-axes through the intersection of lines A and B are described in Fig. 14.27.

The probe element must be chosen so that all of the elements to be measured are reachable. For this reason, more probing elements may be necessary, as shown

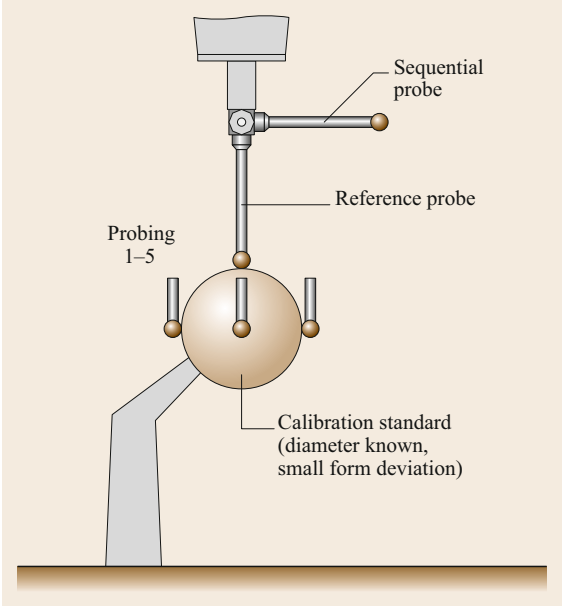

Fig. 14.28 Probe setup and calibration

in Fig. 14.28. One calls the connection of more than one probe element a probe combination or a probe tree. It can also occur that different sensors are needed for a particular measuring task. In the preparation for the calibration, a probe element is specified as a reference probe element. With multiple probe combinations or sensors, there is only one reference probe. Whenever more probe combinations are necessary, the work is implified by an automatic probe-changing mechanism.

The workpiece is set or clamped onto the measuring machine table, so that it lies as firmly and clearly as possible. Easy clamping elements, clamping element component systems, or special clamping devices are available. All of the form elements to be measured must be reachable with the chosen probe configuration. It is not allowed to come into contact with gripping or clamping elements.

The specification of the sequence of probing essentially occurs from an economical point of view (shortest routes between the elements). The type of probing (for example, mechanical or optical, point-to-point or scanning, auto-centering) is substantially limited by the technical capabilities of the measuring machine. Remark: scanning is the independent tracing of a workpiece contour by the measuring machine. One must give a starting point, an end point, the direction, and a scanning plane. The path results from the cut of the scanning plane with the workpiece surface. The scanning speed and point density must be provided by the operator. The minimum measuring point count follows from the type of geometrical elements. The aim of measurement (parameter or form deviation) forms the basis for the definition of the real measuring point count used. With increasing numbers of measuring points, the determination of the individual form elements becomes more certain. In any case, more measuring points than the minimum should be utilized. Around two to three times the minimum point count for the recording of a measurement and its deviation is sound from a measuring technology and economic viewpoint. For form deviation, one needs substantially more points. Here, the number depends on the size of the smallest geometric portions to be recorded. The measuring points should, if possible, be evenly distributed on the measured element and, in addition, must be able to represent these form elements with the desired deviations.

Phase 2: Preparation and Measuring. The probe combination is assembled as defined and then calibrated. Figure 14.28 shows the calibration of one probe of a two-probe combination. Through measurement of a calibration standard (a sphere with a known diameter and a very small spherical deviation) with both probes, the actual diameter of the probe tips and the distance of the middle of the sequential probe sphere to the middle of the reference probe sphere in the x, y, and z-directions are determined. After clamping the workpiece the machine parameters (e.g., velocity, measuring force) are defined.

The degree of automation of the measuring machine is of deciding importance for the probing of the measuring points. For manually controlled machines, the entire course (measuring point probing and manoeuvres in space between the machine elements and gripping devices) at every single point is realized by the operator. CNC-controlled machines allow the programming of a course of motion and have an automatic drive to adopt the required positions. One distinguishes between three possible programming methods:

- By teach-in, the machine learns the course of the measuring directly from the handling of the operator, i.e., his motion. He executes the course to the points to be measured as on a manually controlled machine. This way, all of the measuring point coordinates and all necessary points for collision-free manoeuvring between the machine parts and gripping mechanisms can be recorded. Afterwards, the control system can reproduce this course independently.
- The generation of the target coordinates can take place far from the machine. In this method, all measuring coordinates and position coordinates are derived from the figures or drawing data. This procedure requires great spatial imagination from the programmer. This approach is used mostly in conjunction with teach-in portions.

- Computer-aided design (CAD) systems that have a measuring module at their disposal can directly provide measuring machine programs (compare with the next section).

Phase 3: Evaluation. The description parameters for the associated geometric elements are determined from the measuring points through compensating calculations (for example: Gauss, inscribed circle, circumscribed circle). Take note that either the measuring points or the description parameters are to correct by the calibration data (probe sphere diameter, distance to the reference probe). On the foundations of the description parameters, elements can be mathematically linked or joined with each other. So, new characteristics that describe the geometry of the entire workpiece can be developed. The parameters of the individual elements (diameter, length) and the resulting parameters from the links (distance, angle) can be compared with the nominal and tolerance data. Afterwards, the results can be represented graphically or numerically.

Integration into CAD and CAM

Coordinate measuring machines (CMM) are suitable for integration into CAD/CAM environments (Fig. 14.29). This integration is possible under two criteria.

In CAD systems, the geometric data for a new workpiece is created. With that, outstanding conditions exist for the derivation of the measuring program on the basis of this data. In addition to the data describing the workpiece, a measuring module implemented in the CAD system needs data for the possible elements of the probe combination and the gripping system. *The complete measuring program can be produced in a simulated measuring run*. It is important for later functions that the coordinate system for the description in the CAD system agrees with that for the measured workpiece on the measuring machine. The measuring program can be written in a specialized programming language for the measuring equipment manufacturer or in the manufacturer-independent universal language dimensional measuring interface specification (DMIS), depending on the measuring modules available. For integration into the measuring machine program, a special interpreter is then necessary. After successful measuring, the possibility exists for the acquired deviations to be transferred back to the CAD system, to be processed or represented. Of course, an external process through best-fit and distance determination of the CAD data is possible.

The second possibility for the integration of a coordinate measuring machine is the *digitalization of an unknown workpiece geometry*. Here, a manufactured sample forms the basis (prototype). This sample is touched in a previously-defined grid. The measuring point coordinates acquired are handed over to the CAD system. There, a surface feedback or reproduction of the data model takes place. This can then be transferred to a manufacturing machine that makes a copy of the prototype.

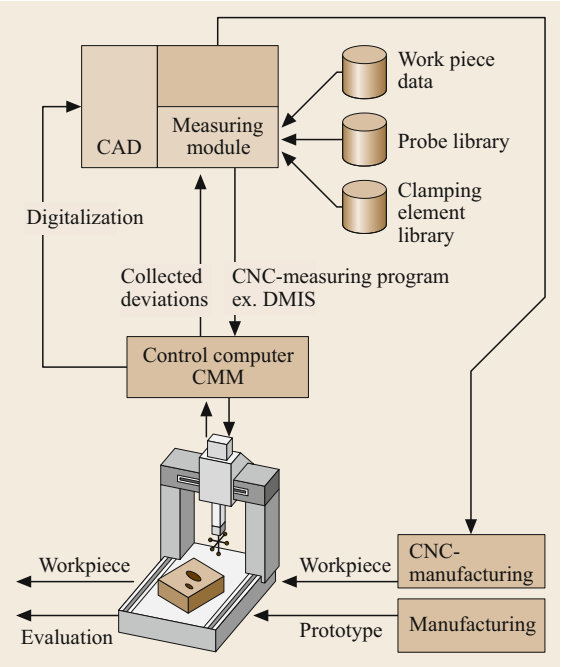

Fig. 14.29 Connection CMM–CAD

14.2.6 Surface Metrology

Instrument Technology

The surfaces of geometric objects continuously provide an informative testing object. Considerations include appearance, evaluation of the expected functional behavior, and manufacturing and wear conditions. The application of modern measuring devices in conjunction with sophisticated computer technology facilitates detailed evaluations and conclusions, which were unthinkable only a few years ago. With the equipment available and the demands of the user, these approaches are being widely applied.

Small, independent, portable instruments with skid pick-up systems are easily implemented to directly monitor tooling processes. In addition, stationary laboratory instruments with free probing systems, with correspondingly large measuring ranges and higher resolutions, have become established. Figure 14.30 shows the basic construction of a stationary surface metrology instrument. It consists of a base and pillar. The

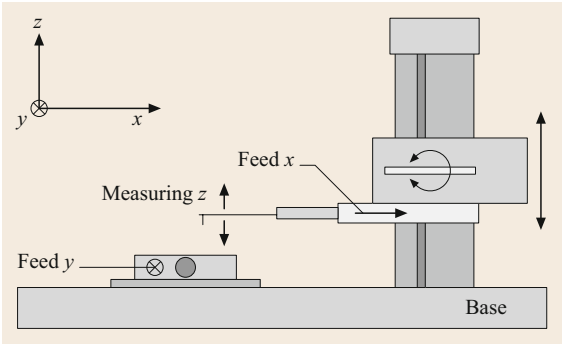

Fig. 14.30 Stationary surface metrology instrument

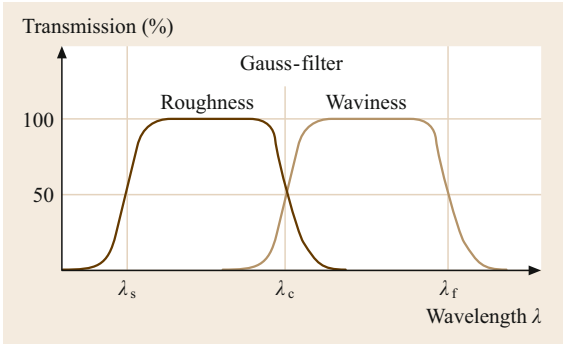

Fig. 14.31 Roughness and waviness profiles

feed unit, attached to the pillar, can be positioned aloft and be pivoted opposite the base. The probing system is positioned with high precision on the feed unit. This positioning constitutes the measuring basis for the probing of a measuring object. If required, the system can be supplemented with an additional y-table. This y-table facilitates the step-by-step movement of the workpiece perpendicular to the feeder movement, enabling three-dimensional scanning.

Instruments constructed as component systems allow a surface probing system to be used as a contour probing system (larger measuring range, many different types of possible probes) and, therefore, to expand the application range of the instrument considerably. It is also possible to implement, instead of a mechanical probing system, a noncontact probing system if the surfaces are sensitive to mechanical probing. One option is to use autofocusing laser sensors (Sect. 14.2.8).

Developments in electronics over the last few years have made it possible to digitize large quantities of data with a higher decimal precision (a higher number of levels) with sufficient speed. This has enabled the collection of many measuring points (with a smaller distance between measuring points at an acceptable collection speed) over larger measuring ranges with greater resolution (small Δz). The accessories for roughness measuring instruments range from stylus stop attachments to a large selection of speciality probing elements and various skids. The instrument can be tailored to the measuring task with these specialized accessories. As well as instrument equipment, the environmental conditions are also an important aspect to consider. The implementation in the laboratory setting, in contrast to the factory floor, brings with it a significant improvement in environmental conditions. This facilitates tasks with greater demands for precision.

ISO Standards and Consequent Requirements

The relevant ISO standards give not only the definition of characteristics but also requirements on the measuring instruments (e.g., the probe-tip radius, the distance between measuring points) and software (e.g., a phase-correction Gauss filter). The profile, which is obtained by means of the section probing method, is called, after the application of the filter for short wavelengths λ_s, the primary profile (P-profile). The roughness profile (R-profile) is obtained through the deletion of the long-wavelength profile features (threshold wavelength λ_c) from the primary profile. The waviness profile (W-profile) is made by filtering the primary profile by means of λ_c and λ_f, as is depicted in Fig. 14.31.

The cut-off wavelengths λ_c and λ_s required for this filtering can be seen in Fig. 14.32 according to the profile classification between periodic and aperiodic. Currently, no concrete definition exists for the threshold wavelength λ_f, only the recommendation of $\lambda_f = 10(5)\lambda_c$. Besides the threshold wavelengths for the separation of profile elements, definitions of the maximum probe element radii and the distances between measuring points are being established. However, there are severe restrictions for the use of instruments in this way.

Characteristics can be calculated from all profile types (P, R, W). Figure 14.33 shows the arrangement of surface characteristics based on the example of the roughness profile. Fundamentally, horizontal, vertical, and hybrid characteristics can be differentiated. These are supplemented by characteristic curves from which parameters can be derived.

Because the explanation of the single characteristic definitions would be too lengthy, the corresponding standards (ISO 4287 [14.15]) is referred to instead.

Analysis of a Surface

Whereas the previously explained, easy-to-handle instruments with skid pick-up systems can only collect and evaluate roughness, instruments with reference-surface probing systems produce data that, with proper software, can measure not only roughness and waviness characteristics but also size, form, and positional deviations. Also, a description of surface alterations by

abrasion and coating, amongst other effects, is possible with these systems.

The difference in the information content of the data is immediately recognizable in Fig. 14.34. Whereas the skid pick-up system only captures the roughness portion approximately, a slant and curvature can be recognized in the data collected from the reference-surface probe system. The skid pick-up system manages with essentially small measuring ranges and poor guidance, which makes these instruments much more affordable. However, one should pay attention to the fact that the mechanical filtering of the signal, by means of the skid, cannot be removed during the follow-up evaluation.

The larger information content collected with a reference-surface probe system is accompanied by substantial disadvantages related to the instrument technology. The disadvantages are the relatively large measuring range of the probing system, which is required

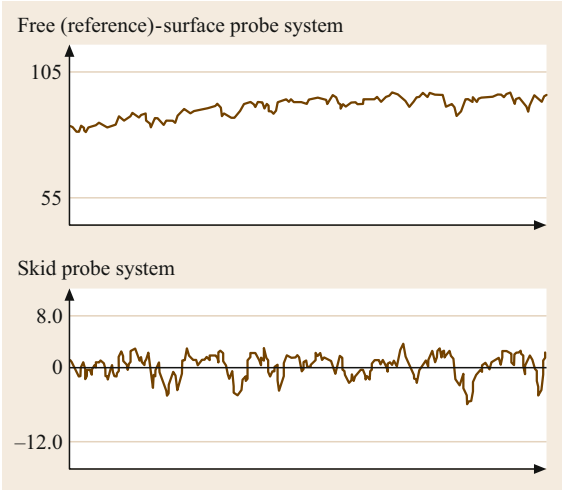

Fig. 14.34 Primary profile

in order to obtain the primary signal within a justifiable adjustment effort, and the fact that the straightness of the feed unit movement must be very good, as it contributes to the measuring signal. Both effects lead to relatively high instrument costs.

Figure 14.35 shows the example of the implementation of surface metrology equipment with a reference-surface probing system. At the top, data collected from a partially coated workpiece is shown. The implementation of a probe element with a comparatively large radius ($r = 500\,\mu m$) leads to the low-pass mechanical filtering. For the compensating calculation, only data that represents the uncoated material is used. After this calculation, the course of the layer thickness between the measured profile and the extended compensation profile is clearly recognizable in the coated section. Similar approaches are also suitable for wear measurement whenever unworn workpiece sections are still available. On the lower part of Fig. 14.35, production progress is shown by a double profile. The basic result is a turning surface profile, which is then smoothed in a second processing step. Clearly, the varying manufacturing results achieved by changing the machining parameters (low or optimal pressing force on the tool) can be noted.

The additional assembly of a *y*-shift table perpendicular to the actual feed direction (Fig. 14.30) allows the collection of data from flat, three-dimensional structures. With the use of an appropriate software package, one can derive three-dimensional surface characteristics from this data, or rather a visual impression of the surface for the benefit of the user. This allows conclusions on properties of the surface, which one cannot easily derive from a single profile. Figure 14.36 shows the three-dimensional measured structure of a workpiece

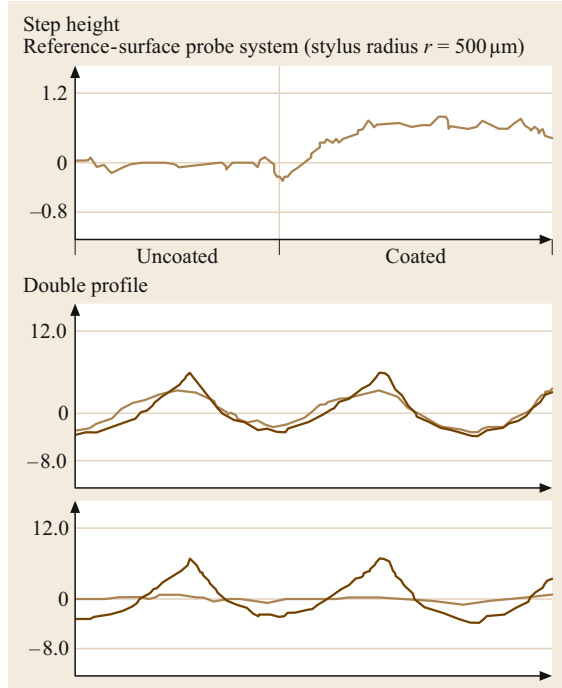

Fig. 14.35 Application for the manufacturing measurement technology

that was milled with a spherical-headed milling tool. In the left-hand side of the figure, a detail from the actual surface is shown. The differences in altitude are represented by different brightness. There is also the choice of an isoline representation (connected lines of equal height). The curvature left behind by the spherical cutter is clearly recognizable. Under this relatively strong curvature, the detailed structure remains hidden.

The right-hand side of Fig. 14.36 shows the same section. In order to make the details clearer, the dominating curvature in the left part of Fig. 14.36 is removed with the use of a compensating calculation (a three-dimensional, second-order polynomial fit). Now the milling feed is clearly recognizable. The unclear structure in the middle of the illustration emerges because there are no definite cutting properties in the domain of the center of the cutting tool.

14.2.7 Form and Position Measuring

Instrument Technology

Form inspection equipment in most cases consists of a base and a column. A turntable is integrated into the base. An arm that carries the measuring system is located on the column. Even after construction of the instrument, the turntable, the column, and/or the arm can be arranged as a measuring base. In most cases,

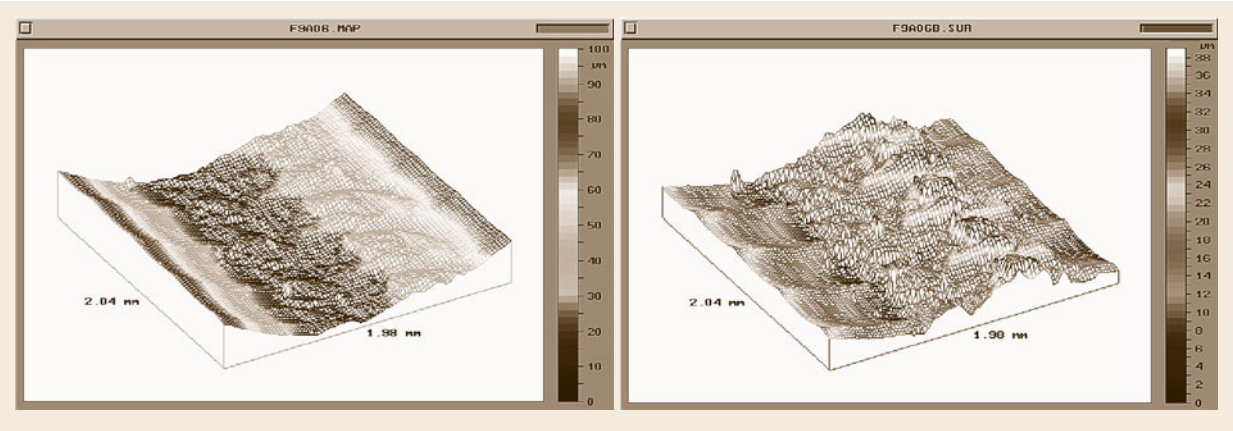

Fig. 14.36 3-D surface structure

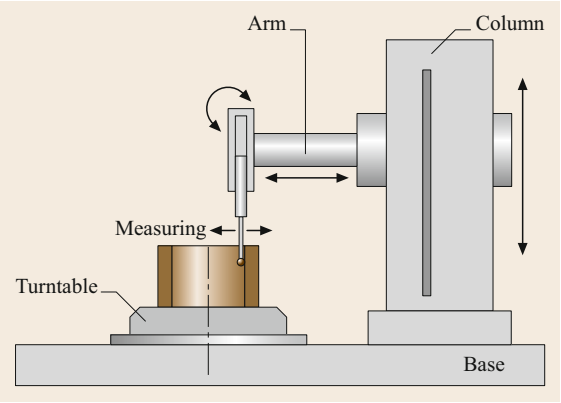

Fig. 14.37 Form inspection instrument

the measuring system is inductive. Probing is carried out with a spherical probe element. In order to keep abrasion to a minimum, ruby probing elements, as used in coordinate measuring machines, are utilized. The measuring system is inclinable so that the direction of the measuring force can be reversed. Therefore, almost all necessary measuring points can be reached. Figure 14.37 shows a vertically arranged probe system, by which the measuring force from the workpiece acts radially outwards. Subject to the measuring task, one or more feed axes can be implemented.

Measuring Execution

Figure 14.38 shows, in the upper left-hand corner, a roundness inspection. After positioning the piece on the turntable, the piece is orientated to the rotating axis so that the measuring system remains in the measuring range during the course of inspection. With a large measuring range, visual judgement suffices for orientation. The large measuring range leads to a bad resolution. A more accurate orientation of the piece is demanded

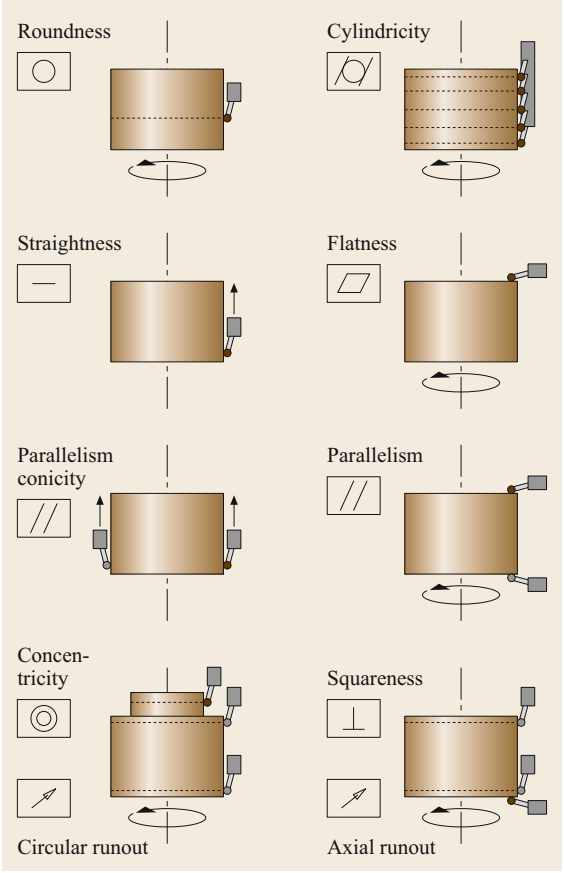

Fig. 14.38 Measuring execution

for a smaller measuring range, which directly leads to a better resolution.

After the probe is brought into contact with the desired position on the object, the measuring object is rotated 360° by the turntable, and, while the object is

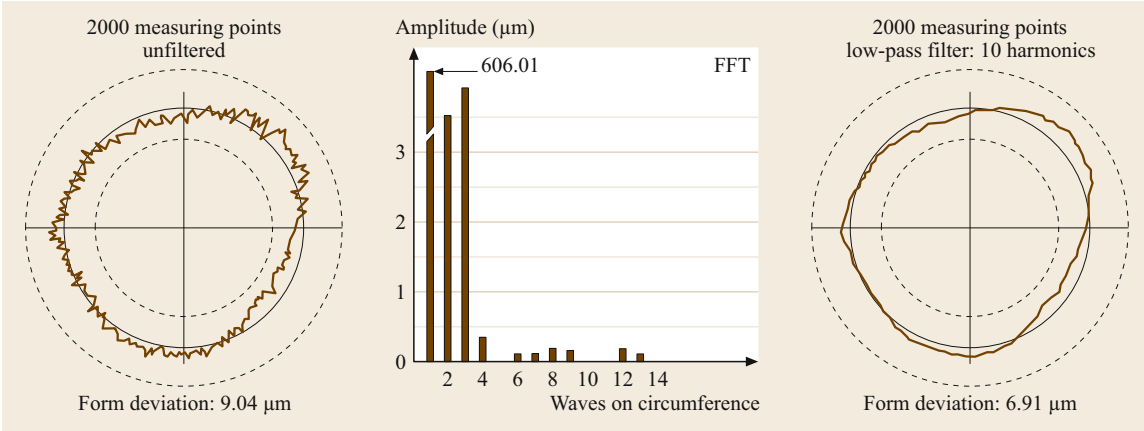

Fig. 14.39 Roundness deviation

turning, the measuring points are scanned. An ideal circle is calculated from the measuring points. For this, depending on the aims of the inspection, compensating methods (e.g., Gauss, circumscribed circle, inscribed circle, see Sect. 14.2.5) can be chosen. In reference to the compensating circle, the range between the lowest point and the highest point is the roundness deviation. For the investigation of causes of deviations, one can filter the desired frequency domains or use a frequency analysis, e.g., a fast Fourier transform (FFT) (Fig. 14.39).

On the left-hand side of Fig. 14.39, the unfiltered circular form deviation is depicted for evaluation of the workpiece. The frequency analysis in the graph next to it shows that waves, especially with a period of two and three harmonics, dominate the result. The right-hand side of Fig. 14.39 shows the measuring result after running the data through a low-pass filter (limit wavelength of 10 harmonics). Here, it is easier to recognize causes of deviations and to implement corresponding quality-orientated corrective action into the manufacturing process.

Figure 14.40 shows the collection of cylinder form deviation. Here, in addition to a high-precision rotating axis, a column axis with a correspondingly small straightness deviation is used in order to facilitate vertical movement. When positioning, movement of the arm should be avoided. All of the measuring points collected, located on circles, are put through a compensating calculation together. From the distances between the single measuring points and the compensating cylinder, the cylinder form-deviation is derived.

Just as the number of points on a circle is important for the determination of the circular form deviation, the number of measured circles for the cylinder-form deviation is not to be neglected. In Fig. 14.40, a picture that used three circles is shown on the left, and a picture that

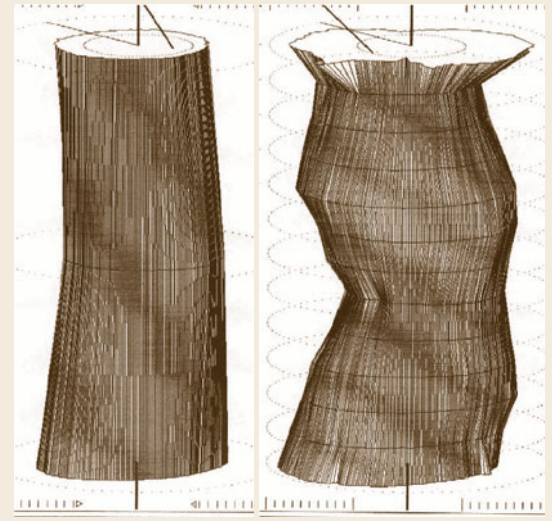

Fig. 14.40 Cylinder form deviation

used 13 circles to calculate the cylinder form deviation is shown on the right-hand side. Clearly, there is a noticeable difference in information content between the two.

To detect referenced elements, like for example, the concentricity depicted in Fig. 14.38, one uses methods already known from coordinate measuring technology. First, both of the circles on the lower cylinder are probed. The circles should have the largest possible distance from each other in order to reduce the measuring uncertainty. Compensating circles are calculated from the corresponding measuring points. The line that connects both midpoints of the circles serves as the reference axis. After the inspection of the circle on the smaller cylinder and the corresponding determina-

tion of the parameters of the compensating circle, the eccentricity is calculated as the distance between the midpoint of the circle and the reference axis. The tolerance zone for the concentricity describes a circle around the reference axis.

14.2.8 Laser Measuring Technology

Due to its properties, laser measuring technology has gained a strong position in the field of integrated measuring technology inside the manufacturing processes. In this section, a few examples are explained and the advantages and disadvantages highlighted. The application profiles of laser measuring systems are as different as their parameters and range from simple dimensional completeness checks to high-precision measuring systems that determine surface roughness or even the acceleration of tooling machine components. From the many possible implementation variations, only a few are considered, those that use the various properties of light. After the time-of-flight method, which is not commonly implemented in mechanical engineering applications, come uses of such properties include linear propagation, reflection, or interference. The selection of the best sensor for the specific application and the arrangement of the sensor to the measuring object is based on criteria such as:

- Operating distance
- Measuring range
- Resolution (scale value)
- Measurement uncertainty
- Measuring spot diameter
- Light color and intensity.

Of course, the price of the complete system which consists of sensor, evaluation electronics and possibly components for moving the measuring object, is also relevant.

In addition to the technical and scientific considerations, protection against accidents is also an issue that should not be ignored. Because most laser measuring systems are equipped with low-power lasers (hazard category 1–3), skin burns are rather improbable. However, the eyes must be well protected. Reflected radiation from metallic surfaces is also problematic. The mandatory guidelines, for instance in Germany, demand labeling for hazard category 3B and above, the application of opaque enclosures, laser protection eyewear, and special warning and emergency facilities.

Laser Applications in Measuring Technology

The *linear propagation* of a laser beam is used by a whole range of measuring devices. To clarify this application, two examples are presented. The first is a laser scanner (Fig. 14.41), which amongst other applications is used here for the quick scanning of the diameter of shafts.

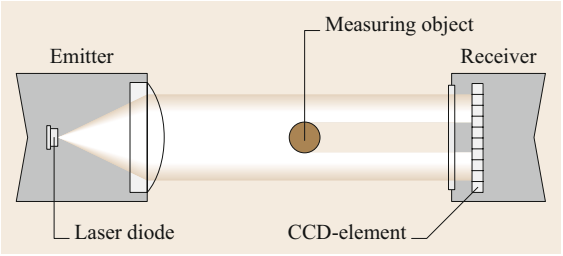

Fig. 14.41 Laser scanner

The laser beam, created by a diode, is expanded into a fan shape and aligned so that the beam is parallel. As shown in Fig. 14.41, this alignment is done by optical components. There are also laser scanners in which the beam expansion occurs by means of a spinning polygonal mirror. The laser beam is directed toward the measuring object. Behind the measuring object, a receiver is arranged where the laser beam strikes a light-sensitive CCD line array. Because the laser beam is broken by the measuring object, in this case the shaft, the size of the shadow on the receiver can determine the diameter of the object. The emitter and receiver can be adjusted axially to the shaft very quickly, so that in a short time, the diameters of various shaft sections can be determined.

A second application of linear laser expansion is shown in Fig. 14.42. The emitter, which emits a laser beam with a narrow diameter, is arranged on the fixed part of a tooling machine base. The receiver is assembled on the sliding bed and consists of a CCD matrix sensor field (in the middle of the figure). Different manufacturers also use four quadrant diodes at this location as a receiver.

Now, the sliding bed of the tooling machine is steered to its home position. The point at which the laser beam strikes the sensor field is registered (y_1, z_1 at $x_1 = 0\,\text{mm}$). On the way to the end position, it is stopped at defined points, and for each stop, the laser point is registered on the sensor field (y_2, z_2 at x_2, and so on). From the points obtained, the straightness deviation of the sliding bed movement is shown divided into the x–y and x–z planes.

A laser beam reflected by the measuring object is generally used by laser distance sensors. These are employed for the contactless measurement of deformable, very rough, sensitive, hot, or moving surfaces. A laser autofocusing sensor and a laser triangulation sensor are given as application examples. Figure 14.43 shows schematically the construction of an autofocus sensor

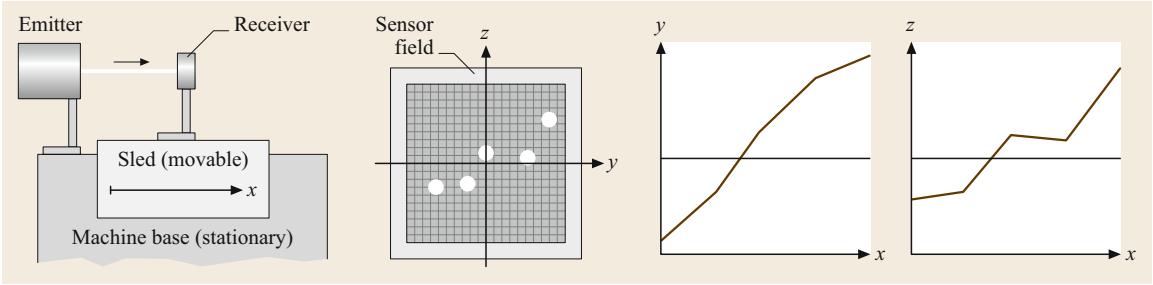

Fig. 14.42 Alignment measuring system

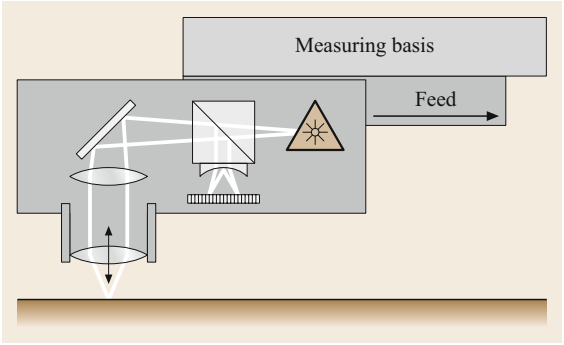

Fig. 14.43 Autofocus sensor

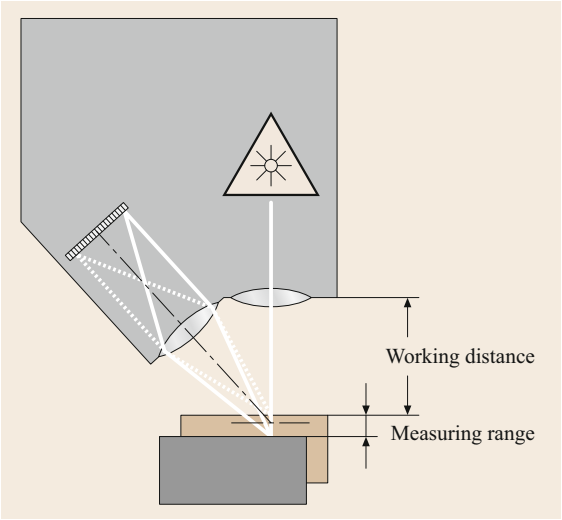

Fig. 14.44 Triangulation sensor

(Mikrofokus from UBM). The laser beam is projected onto the surface of the measuring object, and the laser beam is reflected from this surface. Specialized electronics monitor the focusing and, when necessary, readjust the lens system. The displacement of the lenses is recorded as the measuring value. The previously-mentioned sensor example has a working distance of about 5 mm and a measuring range of 1 mm. The laser spot focused on the surface of the measuring object has a diameter of 1–5 µm, while the beam has an angular aperture of 30°. The electronics used in the example allow the measuring signal to be broken up into steps of 16 nm. With these parameters, the sensor is well suited for contactless surface inspection. The advantages of noncontact probing are also accompanied with disadvantages. Problems especially arise due to locally strong reflective materials (for example, single grains on grinding wheels) and also by nonreflective materials, as well as by steeply inclined surfaces (over 30°). In these cases, the reflected beam cannot be collected for evaluation. The reaction of the system to such problems is variable (measuring value setting, holding or searching) and must be taken into consideration by evaluation of the signal.

Triangulation sensors (Fig. 14.44) likewise project a light point onto the surface of the object measured. This light point is observed from a defined angle. By changing the distance between the sensor and measuring object, the reflected point wanders across a CCD row. This way, the change of the distance is collected directly. In addition, some sensors project one or many laser lines onto the surface inspected. These lines can then be evaluated in terms of the contour of the measuring object by means of a CCD matrix.

The example sensor chosen has an average working distance of 105 mm, a measuring range of ±25 mm, a projected laser spot diameter of 0.1 mm, and a triangulation angle of 18°. With these parameters, these sensors can be applied, for example, to:

- Size or form inspection
- The collection of runout and position deviation
- The collection of thickness
- The collection of deformations
- Completeness or integrity control.

As Fig. 14.45 shows, single or combined sensors are necessary for these applications. The measuring signal collects the surface of the measuring object in the range of the entire measuring spot diameter. So, a low-pass

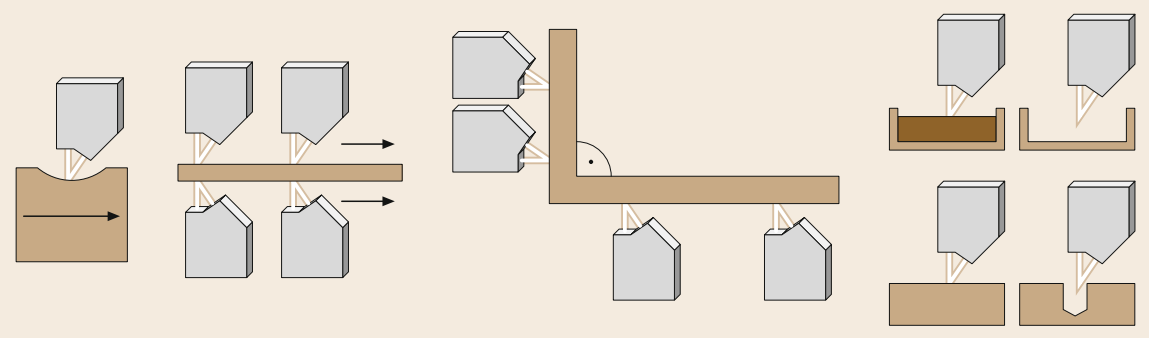

Fig. 14.45 Examples of applications using triangulation sensors

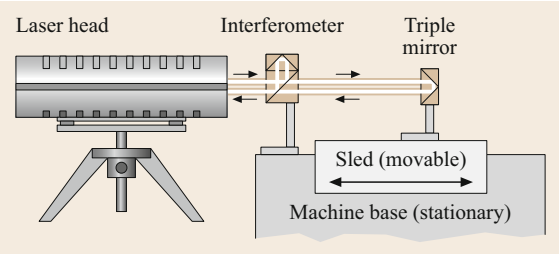

Fig. 14.46 Interferometer for the determination of position

filter processes and determines the mean distance in this area. The plane in which the beam is sent and reflected is arranged parallel to the surface structure to guarantee a reflection.

In laser interferometers, the laser beam is separated into two beams (reference and measuring beam) by means of a semireflecting mirror. While the reference beam always follows the same path inside the interferometer, the measuring beam is reflected off a triple mirror on the object to be measured, as shown in Fig. 14.46. When the two beams come together, interference occurs (Fig. 14.47). When the peaks of the waves meet (phase shift 0°), the light is amplified. When the peak of one wave meets the valley of the other (phase shift 180°), the waves cancel. The distance between the interferometer and the triple mirror changes when the sled moves. The phase between the reference and measuring beam shifts. This resulting change in the interference is interpreted as the measuring value.

This type of measuring system is used for applications with large lengths (10–20 m) and with a high resolution (5 nm). In each case, it only collects the changes from an initial state. A disadvantage is that the optical components must be mounted on the object that is to be measured and that the frequency of the light, and therefore the measuring result, is strongly influenced by environmental conditions such as air temperature, humidity, and pressure. Corrections can be made by collecting these environmental conditions and carrying out a subsequent adjustment of the data, or more specifically, through the application of a refractometer (an instrument in which the effects of the environmental conditions can be directly compared with the light properties in a vacuum).

Figure 14.46 shows an example combination that determines the position of a machine component with

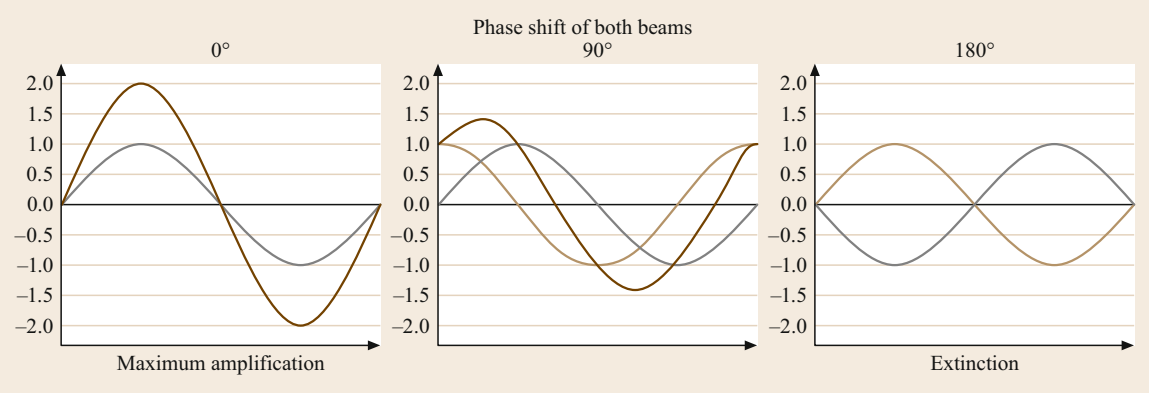

Fig. 14.47 Phase shift and interference

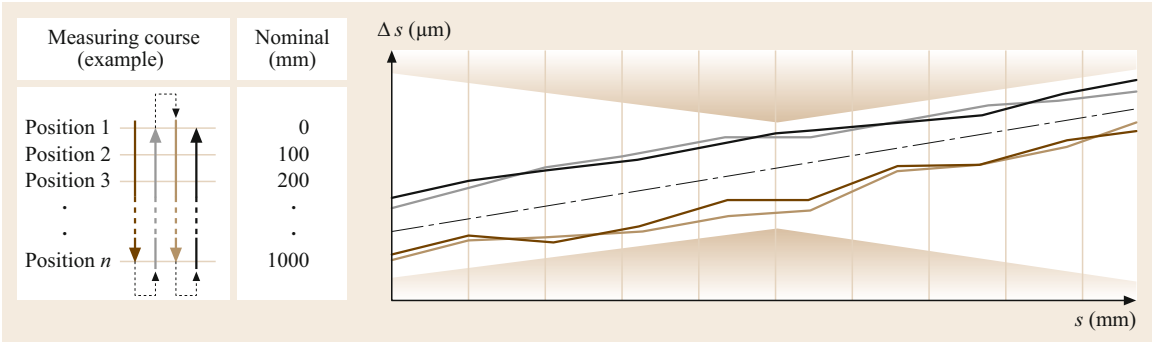

Fig. 14.48 Position deviation, measuring course, and results

respect to another, or rather to a chosen fixed point. This setup is used as an independent measuring system (for example, with coordinate measuring machines) but also as a measuring system for the collection of position deviations. Figure 14.48 shows the procedure for the collection of position deviations of a tooling machine. While the machine, controlled by its measuring system, follows the defined positions labeled 1 to n, the position deviations are determined by means of a laser interferometer. The measuring course, which is executed step by step over the entire range of the positions to be measured, is completed multiply in both directions (increasing and decreasing values). The deviances collected in this way are shown on the right-hand side of Fig. 14.48. From the depicted course of measuring values, a linear trend and span superimposed with random sections can be read. The limits shown in the diagram depict usual tolerance ranges for tooling machine position deviations. The systematic parts are compensated for, when necessary, through mechanical aligning of machine components, or afterwards by means of a correction table or correction function.

Similar arrangements allow the collection of tilt and rotation angles, as well as the determination of straightness deviations. When the measuring value transmission frequency can be chosen to be sufficiently large, a dynamic series (for example, the reaching of a desired position) can be collected with the layout shown.

14.2.9 Measuring Uncertainty and Traceability

The result of measuring is the measurement value. This measurement includes the true value and also systematic and random deviations of the measurement (Fig. 14.49). It is possible to estimate the expected value of the measurement by calculating the arithmetic mean of several independent measurements. The more single values that are processed, the more the random parts of the measuring deviation are reduced.

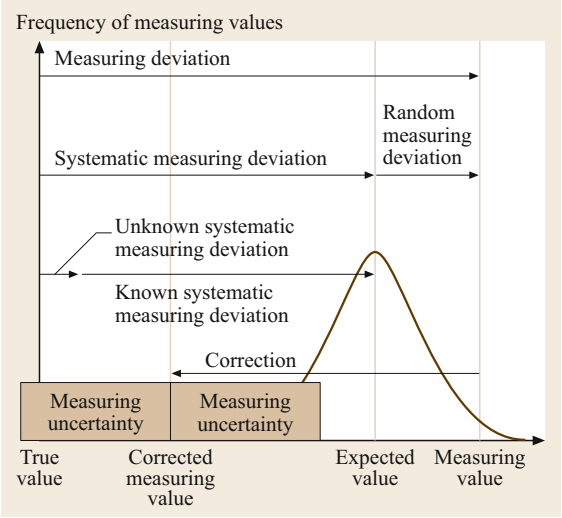

Fig. 14.49 Summary of measuring values

The systematic part of the measuring deviation can be determined by measuring an object with a known value. Such objects, measurement standards, are measuring blocks for lengths. Angles can be represented with angle gauges, precision polygons, or with sine bars used in conjunction with measuring blocks. The known value of the measurement standard (whose small deviation from the true value is negligible for the purpose of comparison), is called the correct value. The systematic measurement deviations can be calculated from the difference between the measured value of the measurement standard and its correct value. Afterwards, one can correct all measuring values by use of the known systematic deviation. The nonmeasurable or not measured (for instance, because it is too expensive) elements of the systematic measuring deviation are combined with random measuring deviations to constitute the measuring uncertainty. So, the measuring uncertainty is a parameter obtained from the measurement. It describes the region around the cor-

rected measuring value where the true value must be found. The complete result of measuring is given as the corrected measuring value plus/minus the measuring uncertainty [14.16].

In order to guarantee the correctness of measuring results, measuring devices must be affiliated to the national standard of the respective measurement. In Germany for instance, this is the National Physical Technical Institute (PTB), located in Braunschweig, which is responsible for the representation and propagation of physical units. Through the PTB, calibrating laboratories are accredited, so that their measuring devices and measuring standards coincide with the national standards (the units), according to the defined and accepted techniques. These are the laboratories of Germany's national accreditation body (DAkkS), former German Calibration Service (DKD).

All in-company measuring devices, or rather standards, should be consistently traceable back to the national standard of the PTB (Fig. 14.50). In order to verify this, the instruments are calibrated by a DAkkS laboratory or the PTB themselves. *Calibration* is defined as the inspection of measuring devices and measurement standards with reference to the accepted national standard. Successful calibration is generally documented through a protocol, the calibration certificate. On the calibration certificate, all of the calibration results, the reference standards, and additional measuring equipment (used during the calibration), the environmental conditions, and the calculated measuring uncertainty are documented.

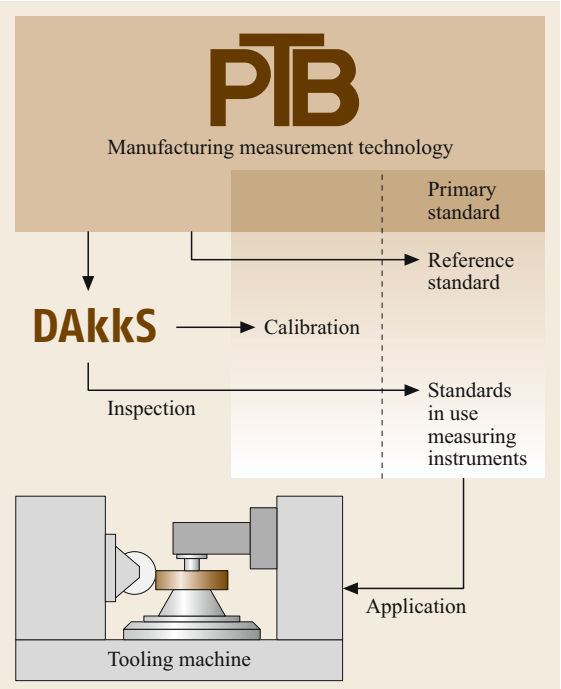

Fig. 14.50 Traceability

One should use certified instruments, standards, and methods in order to achieve cost-effective, in-company control of inspection instruments. Otherwise, a traceability certificate is not possible.

The setting-up and balancing of a measuring instrument, by which known systematic deviations of the measuring result are eliminated, is called *adjusting*.

14.2.10 Inspection Planning

Inspection planning means the planning of quality inspection in the entire production process, from the arrival of raw products to the delivery of the final product. For this, inspection tasks and procedures are specified with inspection feature, inspection location (close to production, measuring room), frequency of inspection, point of time within the production process, inspection methods, inspection equipment, and operators. One should consider both technical and economic aspects. The inspection planner must consider knowledge of the function and application of the piece or the components, safety hazards, the production process, technical documentation (drawings, standards, stipulations), and the inspection equipment. It should be consistently checked that the data is complete, current, and inspected (approved by the operating department).

For the selection of the test methods a systematic search in the drawing(s), in the work plan, in the documentation, in delivery instructions and in contractual agreements, is required. When searching in drawings it is possible to search according to the type of parameter (dimension, shape and positional tolerance, surface tolerance, etc.), according to the drawing view and/or according to grid squares (e.g. starting at the top left, clockwise).

The definition of the inspection frequency (number of samples, sample size) occurs on the basis of mathematical statistical facts. The time point in the production process allows company organizational and economical considerations. The late recognition of inadmissible errors can bring about several disadvantages.

The definition of inspection methods and inspection equipment are related, and, thus, should each be chosen with the other in mind. The choice of measuring device begins with a consideration of the required information content of the measuring result. This way, the aim of the inspection (evaluation of workpiece or process, manufacturing control) and the impact of the measuring instrument itself can be taken into account. Geometrical

limitations, such as the accessibility of the piece, the geometry of the probing element, the range of measurement (direct measurement, difference measurement) of the instrument, and especially for soft materials, the measuring force, have been previously decided upon. Finalized statements for the usability of a measuring instrument can be made after inspection of the scale division value and the measuring uncertainty. The measuring uncertainty must adhere to the ratio of the inspected tolerance by the relation $U/T = 0.1–0.2$. Alternatively, it is possible to obtain measuring capability coefficients and check the adherence of these characteristics to previously defined limits [14.17]. Supplemental criteria are, for example, the surfaces available for the measurement and transfer for processing, protocol, and archiving.

The required measuring time (capability of the measurement to be automated) in conjunction with the number of pieces to be tested is the essential criterion for the cost effectiveness of the application of a measuring device. Included in the inspection costs are also the equipment costs, equipment observation, calibration, and personnel costs (work time, education).

To guarantee the comparability of the measuring result and low uncertainty of the acquired characteristics the following conditions should be taken into account when specifying measurement methods:

- Explicit guidelines for the measuring procedure, including the parameters required for an appropriate measurement. Specification of the reference basis for the measuring procedure, the accuracy of the applied measuring instruments and measurement standards, gripping elements employed, and additional measuring equipment.
- Details of the measuring strategy, for example, the definition of the measurement location on the piece, or the number and arrangement of single measurements as a basis for a good average value.
- Details of the measuring value collection method for selective inspection and of the further steps of measured value processing, or guidelines for the application of analyzing software (for example, the selection of a compensating method).
- Legal warranty of adequate qualification of the personnel conducting the measurement.

The result of inspection planning is the inspection plan.

15. Machine Elements

Frank Engelmann, Karl-Heinrich Grote, Thomas Guthmann

Machine elements are components with the same or similar form that are very frequently found in machines, plants, and apparatus. They can be simple elements, such as washers or keys, or more complex components such as shafts, rolling bearings, or gears. The essential functional properties of the elements are mostly defined in corresponding standards. In general, guidelines and calculation regulations are available for the design and dimensioning of machine elements.

The machine elements most frequently used in practice, such as fasteners, connectors, axles/shafts, shaft-hub joints, bearings, seals and gaskets, sprockets, springs, and pipes are introduced and discussed in this chapter. It focuses on choosing suitable elements for a specific problem and proper design/dimensioning of these elements. The chapter is aimed both at engineers in practice and students in training.

15.1 Basic Dimensioning Principles

Components must be dimensioned so that they can absorb the forces acting on them with sufficient safety and without becoming unacceptably damaged. Possible damage/failure modes include:

- Unacceptable deformation
- Fracture (fast/forced or creep rupture/fatigue fracture)
- Kinking or buckling
- Unacceptable wear
- Unacceptable heating

If several failure modes can occur, each individual mode must be assessed. The most unfavorable (worst case) conditions are decisive.

The mechanical stresses that occur in the cross section must be smaller than allowable stresses.

The level of the allowable stresses is influenced by:

- The strength of the material
- The type of load/effect (e.g., stress)
- The geometrical shape of the component
- Other influences (temperature, internal or residual stresses in the component, material defects, etc.)

15.1.1 Types of Load and Effects

Load and Effect

The terms load and strain are often inadequately differentiated in practice. In this text, the terms are used as follows.

If external forces and moments act on a component, the component is loaded by a load and this results in component strain.

Strain is subdivided into intentional and unintentional strain:

- Intentional strain: results from the function of the component and its ability to absorb and/or transfer loads; mostly known or can be recorded reliably
- Unintentional strain: results from unwanted effects that are mostly difficult to record, for example, from impacts or shocks, vibrations, and thermal stresses

The internal force effects caused by the strain produce mechanical stresses depending on the component cross section.

Even without the effect of external loads, production, deformation, jointing, and heat-treatment processes can cause stresses to occur in the components in the form of so-called residual stresses. These are often difficult to record. They can be mitigated or minimized through stress relieving.

Loading Modes

Possible loading modes are shown in Fig. 15.1.

The moments of inertia necessary to calculate the bending or torsional stress are listed in Table 15.1.

Special Forms of Compressive Loading. Possible special forms resulting from compressive loading (compression) are:

- Surface pressure
- Hertzian contact pressure
- Buckling (instability)

Surface Pressure. Surface pressure p acts on the contact surface A of two parts pressed together by an external force F. In this case, the average surface pressure equals the specific surface pressure $\overline{p}$ (Fig. 15.2a) and is determined from

$$\overline{p} = \frac{F}{A} = \frac{F}{ab} \,. \tag{15.1}$$

If the contact surfaces are curved, surface pressure only occurs if both surfaces have exactly the same curvature, e.g., in pairs of round objects with zero clearance according to Fig. 15.2b,c.

The pressure in zero clearance pairs of round objects is then uniformly distributed if the bore (housing, eye) is pliable, i.e., yielding.

Then, according to Fig. 15.2b,

$$\overline{p} = \frac{F}{A} = \frac{F}{db} \,. \tag{15.2}$$

Hertzian Contact Pressure. If the bodies have different curvatures, very small contact surfaces result in the

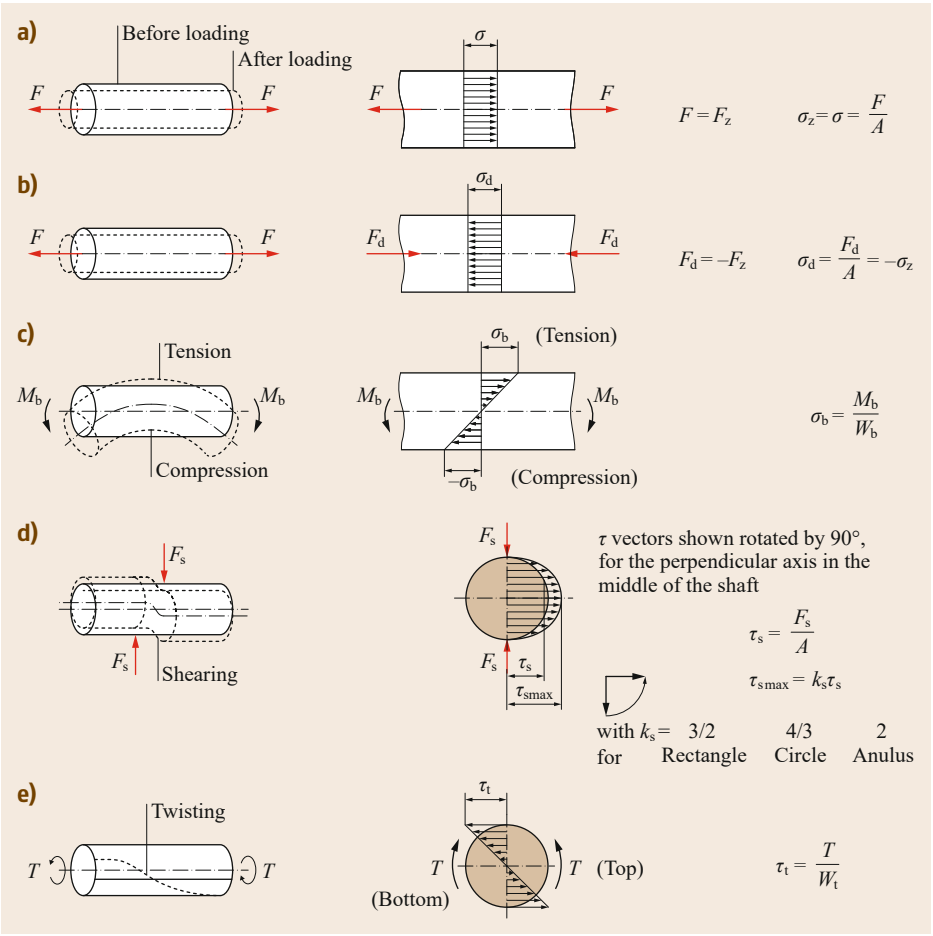

Fig. 15.1a–e Overview of types of loading. Direct stresses **(a,b)** with bending **(c)**; tangential stresses: shear **(d)** and torsion **(e)**

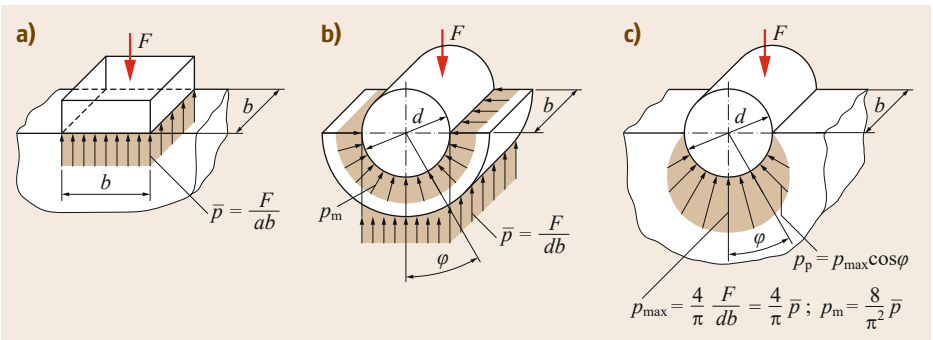

Fig. 15.2a–c Surface pressure on flat **(a)** and curved surfaces in which the bore is yielding **(b)** or stiff **(c)**

contact zone as a result of deformation. In the case of punctiform contact, these are (theoretically) circular or ellipsoidal, and in the case of linear contact they are rectangular.

The normal forces F acting on the objects cause compressive stresses/pressures called Hertzian contact pressures in the small contact surfaces.

Buckling. If slender components (e.g., bars, rods, pipes, columns, spindles) are loaded by a compressive force in the longitudinal direction, their straight condition is stable only up to a certain critical load. Above this load, buckling is expected.

Exceeding of the critical compressive load on thin, flat components leads to outward bulging.

15.1.2 Complex Stress

In a loaded component, in general a normal (perpendicular) stress and two tangential stresses can act in each of the six bounding surfaces of an (imaginary) cubic solid element (Fig. 15.3).

If all surfaces of the cube are stressed, this is called a (spatial) triaxial stress state.

If all stresses on two opposite surfaces of the cube equal zero, as is frequently assumed for flat components, this is called a (plane/2-D) biaxial stress state. In such a case, only the stresses σ_x, σ_y, and $\tau_{xy} = \tau_{yx}$ (due to the moment equilibrium about the z-axis) exist, and all other stresses on the element are zero.

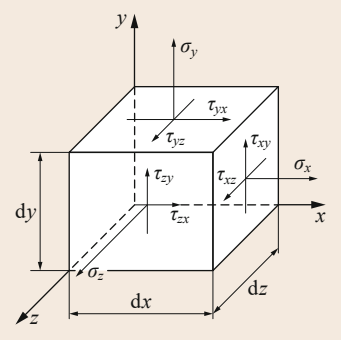

Fig. 15.3 Spatial (3-D) stress state

If only one direct stress (also known as normal stress) acts on the cubic element, that is to say all other stresses equal zero, this is called a uniaxial stress state.

Strength values of materials are (usually) determined in a tensile test, in which only direct stresses occur (uniaxial stress state).

However, in real components, normal and tangential stresses frequently occur simultaneously in different directions. In such a case, the equivalent stress must be formed from the individual stresses [15.1, 2]. The equivalent stress σ_v represents a (notional) direct stress, which brings about the same effect in the component as the direct stresses and tangential stresses that exist.

Various strength hypotheses are used to calculate this equivalent stress, depending on the strength properties of the material (Table 15.2).

The Von Mises distortion energy theory (DET) criterion is used for tough (ductile) materials (e.g., structural steel, quenched, and tempered steel with $\sigma_{lim} \approx \sqrt{3}\tau_{lim}$). In this hypothesis it is assumed that the component fails if the maximum shear strain energy exceeds a (material dependent) limit value.

The maximum principal stress (MPS) criterion (Rankine's maximum principal stress fracture criterion) is used for brittle materials (e.g., gray cast iron and tempered steel with $\sigma_{limit} \approx \tau_{limit}$). Here it is assumed that the component fails as a result of the largest direct stress on exceeding the fracture strength (R_m, σ_B) without prior plastic deformation.

The maximum shear theory, or Tresca maximum shear stress (MSS) criterion, is used for particularly tough materials (tough steel with $\sigma_{limit} \approx 2\tau_{limit}$) with a distinct yield point and Hertzian contacts. The cause of the failure is the largest difference in the principal stresses $\sigma_{max} - \sigma_{min}$.

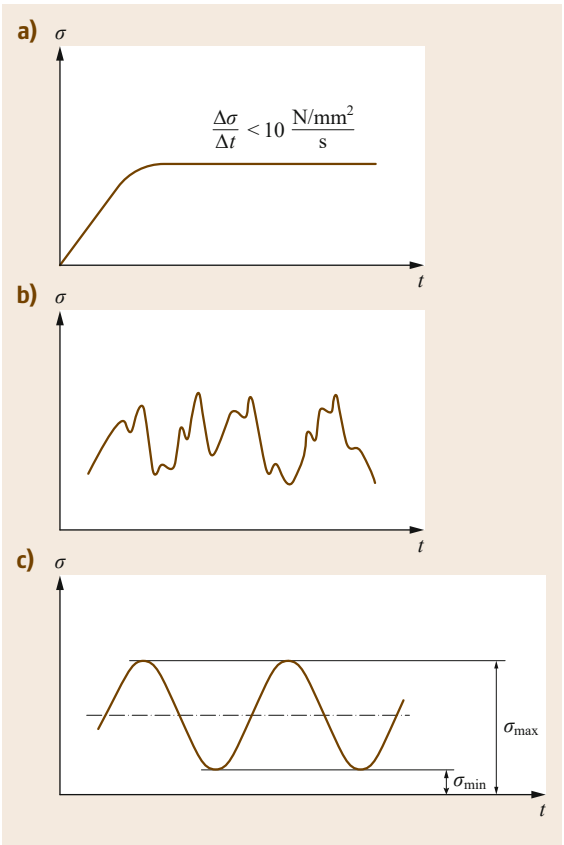

Fig. 15.4a–c Stress–time curves: **(a)** static, **(b)** dynamic (general arbitrarily oscillating), and **(c)** dynamic (idealized, uniformly oscillating)

If the stresses that occur are of the same type, they can be added together to form a resultant stress

$$\sigma_{res} = \sigma_{z;d} + \sigma_b\,; \quad \tau_{res} = \tau_s + \tau_t\,. \tag{15.3}$$

15.1.3 Static and Dynamic Effects

The loads (actions) acting on a component are frequently not constant over time. For this reason, not only is the maximum load significant for the dimensioning of components, but also the load change over time (load–time profile).

Therefore, for the calculation, a differentiation must be made between static and dynamic effects of loading (stress states):

Table 15.2 Equivalent stresses of established failure theories for the plane stress state

DET	MPS	MSS
$\sigma_V = \sqrt{\sigma_x^2 + \sigma_y^2 - \sigma_x\sigma_y + 3\tau_{xy}^2}$	$\sigma_V = \frac{\sigma_x+\sigma_y}{2} + \sqrt{\left(\frac{\sigma_x+\sigma_y}{2}\right)^2 + \tau_{xy}^2}$	$\sigma_V = \sqrt{(\sigma_x - \sigma_y)^2 + 4\tau_{xy}^2}$

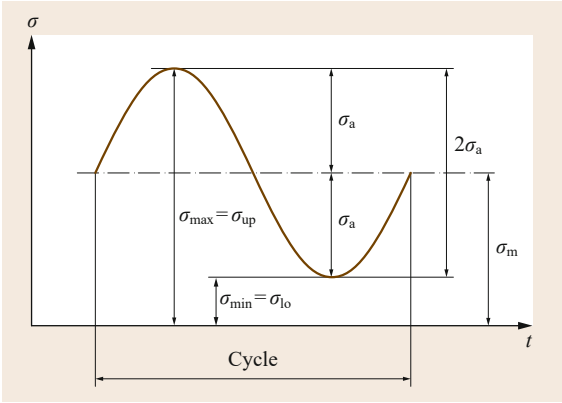

Fig. 15.5 Characteristics of a stress cycle

- Static stresses are constant over time (Fig. 15.4a).
- Dynamic stresses are (arbitrarily) changeable over time (Fig. 15.4b). Periodic oscillation is a frequently occurring special case (Fig. 15.4c).

In practice, the real change over time of an arbitrary dynamic load can frequently be idealized by a simply applied mathematical function (e.g., sine function) (Fig. 15.4c).

The characteristics of a cycle are used to describe stress–time profiles (Fig. 15.5).

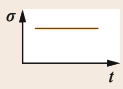
Distinctive characteristics are:

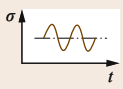
- The mean stress σ_m
- The stress amplitude σ_a
- The upper stress σ_{up} (= maximum stress σ_{max})
- The lower stress σ_{lo} (= minimum stress σ_{min})
- The (limit) stress ratio $\kappa = \sigma_{lo}/\sigma_{up}$

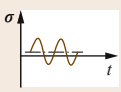
The position of the mean stress σ_m relative to the zero stress line ($\sigma = 0$) is also important for the loading, or rather stress, of a component (Table 15.3). A differentiation is made between:

- The static stress (as a special case of stress in general)
- The repeated stress (cyclic stress, pulsating stress), which only change in the positive (compression) or in the negative (tension) area

Table 15.3 Stress cases and their representation

Stress types		
Static Load case I	Dynamic, cyclic Load case II	Dynamic, alternating Load case III
		






- The alternating stress (alternating cyclic stress, reversing stress), in which the stress profiles intersect the zero line (constant change between tensile and compressive stress)

If different types of load act on a component simultaneously, the load cases can differ. For rough calculations, the correction factor α_0 can be used to convert the shear stress to the respective direct stress load case and can then be used in the modified equation for the equivalent stresses ((15.4)–(15.6)). Rough values for the correction factor are given in Table 15.4.

Maximum principal stress criterion:

$$\sigma_V = 0.5\left[\sigma_b + \sqrt{\sigma_b^2 + 4\,(\alpha_0\tau_t)^2}\right] \qquad (15.4)$$

Maximum shear stress criterion:

$$\sigma_V = \sqrt{\sigma_b^2 + 4\,(\alpha_0\tau_t)^2} \qquad (15.5)$$

Maximum shear strain energy criterion:

$$\sigma_V = \sqrt{\sigma_b^2 + 3\,(\alpha_0\tau_t)^2} \qquad (15.6)$$

Load peaks can occur while dynamically loaded components are in service that exceed the nominal force (nominal load) or the nominal torque (rated torque) significantly. As these are very difficult to record by measurement in practice, they are taken into account in calculations by the application and service factor K_A (15.7). Values for the application and service factor can be found in Table 15.5.

$$F = K_A F_{nom} \quad \text{and} \quad T = K_A T_{nom} \qquad (15.7)$$

15.1.4 Strength Characteristics

In principle, a distinction is made between static and dynamic strength.

Static Strength

The static strength is generally determined by tensile testing and is represented in the stress–strain diagram (Fig. 15.6).

Depending on the failure criterion, the dimensioning of the components is based on the elastic limit R_e or

Table 15.4 Rough correction factors for steel (after *Decker* [15.3])

	Load cases with τ stress			
Load cases with σ stress	α_0	τ_I	τ_{II}	τ_{III}

	σ_{II}	0.7	1	1.35
	σ_{III}	0.5	0.75	1

Table 15.5 Application and service factors K_A (based on ISO 6336-1 [15.4])

Working characteristics of the driving machine	Working characteristics of the driven machine			
	Uniform	Light shocks	Moderate shocks	Heavy shocks
Uniform	1.00	1.25	1.5	1.75
Light shocks	1.10	1.35	1.60	1.85
Moderate shocks	1.25	1.50	1.75	2.00
Heavy shocks	1.50	1.75	2.00	≥ 2.25

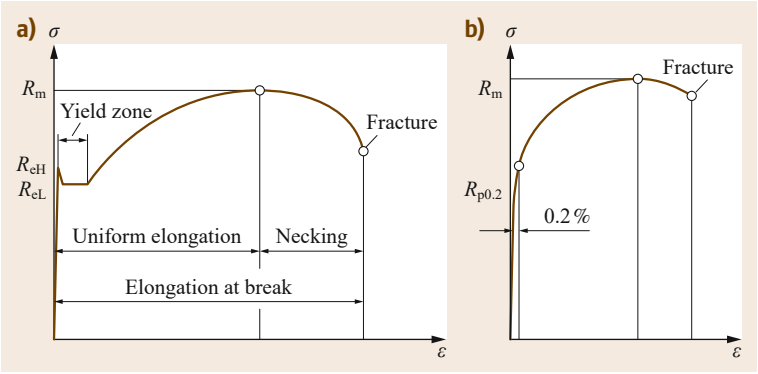

Fig. 15.6a,b Stress–strain diagram for steel (schematic) **(a)** with and **(b)** without a distinct yield point

the ultimate strength R_m (fracture limit). Instead of R_e, the 0.2% proof strength $R_{p0.2}$ (yield strength) is used for brittle materials without a distinct yield point.

Depending on the loading mode (type of stress), the underlying material strengths result in the strength characteristics for steel materials at room temperature according to Table 15.6.

Dynamic Strength

The stress fluctuations that occur due to dynamic loading can intensify at outer (geometric) and/or inner (metallurgical) notches and lead to damage to the material. Local exceeding of the ultimate strength can cause microcracks to form, which gradually grow into the component and ultimately lead to fatigue fracture.

A fatigue fracture is mostly characterized by smooth, bright fracture surfaces with arrest lines (also known as a clamshell pattern or beach marks) and a fast fracture (forced fracture) in the remaining cross section (fracture zone) (Fig. 15.7).

The sustainable load intensity depends on the number of load changes (cycles). If a test piece is loaded by a defined repeated load (alternating or cyclic) just under R_m, it can withstand N_D cycles before failure occurs. Different numbers of sustainable load cycles result depending on the level of the repeated load.

If the repeated load is sufficiently small, the test piece does not fail. The value of the load equals the fatigue strength and the corresponding number of cycles is the fatigue life N_{FS}. The fatigue strength of steel exists if the sustainable number of load cycles is $N_{FS} > 10^7$. The graphic representation of the maximum possible repeated load above the corresponding number of cycles produces the so-called Wöhler curve (also known as a stress-cycle (S–N) curve) (Fig. 15.8).

A component can be designed for a finite life or for infinite life. A component has a finite life if the stresses that occur exceed the value of the fatigue strength σ_{FS} (Fig. 15.9a). If the stresses that occur are smaller than σ_{FS}, the component is considered to have an infinite life (Fig. 15.9b).

Table 15.6 Loading and corresponding static material characteristics for steel at room temperature (based on [15.2, 5])

Loading	Failure criterion	Underlying strength value	Symbol
Tension	Deformation	$= R_e$; $R_{p0.2}$	σ_{zF}
	Fracture	$= R_m$	σ_{zB}
Compression	Deformation	$= R_e$; $R_{p0.2}$	σ_{dF}
	Fracture	$= R_m$	σ_{dB}
Bending[a]	Deformation	$\approx R_e$	σ_{bF}
	Fracture	$\approx R_m$	σ_{bB}
Torsion[a]	Deformation	$\approx 0.58 R_e$	τ_{tF}
	Fracture	$\approx R_m$	τ_{tB}
Shearing	Deformation	$\approx 0.58 R_e$	τ_{sF}
	Fracture	$\approx 0.58 R_m$	τ_{sB}

[a] The strength characteristics in bending and torsion are dependent on the stress gradient. The supporting effect of partial plasticization results in higher strength characteristics

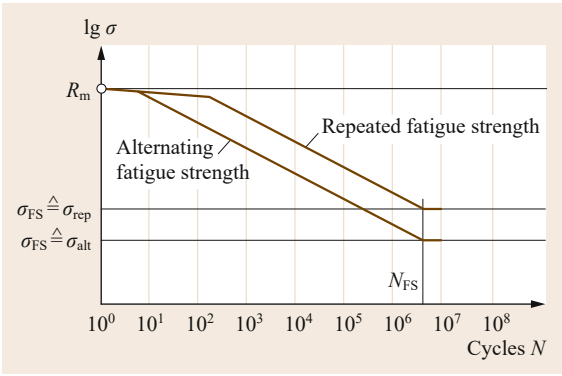

Fig. 15.8 Wöhler curve for steel (schematic)

15.1.5 Strength-Reducing Effects

Strictly speaking, the strength characteristics described in the literature apply only to the standardized test piece with which they were determined. As the real components differ substantially from the test bars with regard to their size, shape, and surface properties, the material strengths determined by testing must be converted into the corresponding component strengths or component design strengths τ_G; σ_G. To do this, all strength-changing influencing factors (e.g., notch effect) must be taken into consideration.

Notch Effect

In a component without cross-sectional change, the force lines and nominal stresses are undisturbed. If the force line pattern or path is disturbed by cross-sectional changes (e.g., notches), force line compression (stress concentration) can occur in this area. This leads to nonuniform stress distribution with local stress peaks (Fig. 15.10a,b), which reduces the load-bearing capacity of the component.

The level of the stress peaks depends on the geometry of the discontinuity, also known as the stress raiser (notch). The more sharp-edged or acute-angled the notches are, the larger the stress peaks that occur at them (Fig. 15.10c). The ratio of the stress peak σ_{max} and the calculated nominal stress $\sigma_N = F/A$ is called the theoretical stress concentration factor $\alpha_{ki} \geq 1$:

$$\alpha_{k\sigma} = \frac{\sigma_{max}}{\sigma_N} \quad \text{and} \quad \alpha_{k\tau} = \frac{\tau_{max}}{\tau_N} \,. \tag{15.8}$$

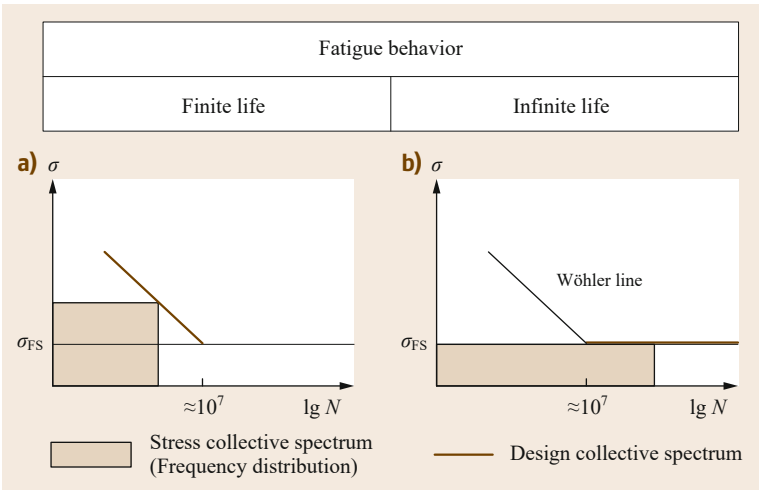

Fig. 15.9a,b Types of repeated stress and fatigue strength: (**a**) high cycle fatigue and (**b**) very high cycle fatigue

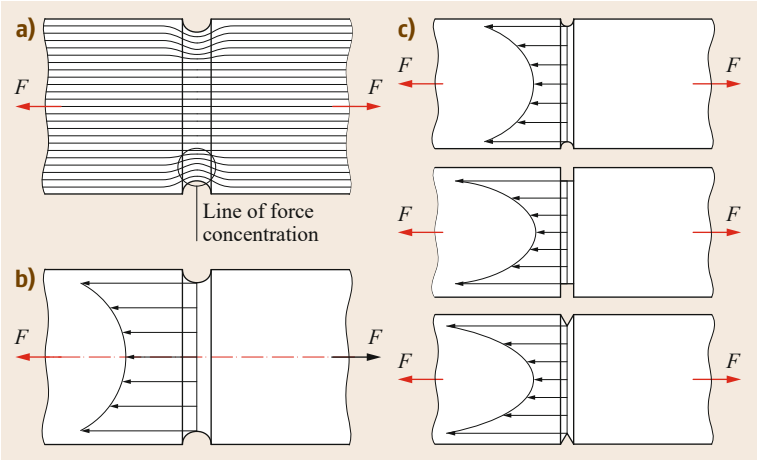

Fig. 15.10a–c Stress distribution in notched components with the same stress cross sections: **(a)** force line profile in a tension bar, **(b)** stress distribution in the tension bar, and **(c)** influence of the notch shape on the stress peaks

When the local stress peak σ_{max} is below the material yield point R_e, the value of the theoretical stress concentration factor α_{ki} of the notch depends only on the notch geometry and the loading mode. If the local stress peak lies above the material yield point, the effect of the notch increases with increasing material brittleness.

Ductile materials can partly minimize stress peaks that occur through locally limited yield. As a result, areas originally subjected to low stress become more highly loaded. The area immediately surrounding the notch is relieved, so that the notch effect is reduced compared to brittle materials with the same notch geometry. In this way, the areas further away from the notch have a support function for the near-notch areas.

The fatigue strength of a component is also changed by notches:

- The static strength (yield point) increases as a result of the support function from R_e to R_{ek}.
- The dynamic strength (alternating fatigue strength or amplitude fatigue strength) drops from σ_W and σ_A to σ_{GW} and σ_{GA}, respectively.

The ratio of the alternating fatigue strength of the smooth test bar σ_W and the alternating fatigue strength of the notched test bar σ_{GW} under the same conditions is defined as the fatigue notch factor β_k (for dynamic loading, by analogy for tangential stress):

$$\beta_k = \frac{\sigma_W}{\sigma_{GW}} = \frac{\sigma_A}{\sigma_{GA}} , \qquad (15.9)$$

where $1 \le \beta_k \le \alpha_k$. For (brittle) materials completely sensitive to notches, β_k takes the value of the theoretical stress concentration factor of the notch α_k.

Values for the fatigue notch factor can be determined experimentally or can be taken from the appropriate literature (for example, [15.6–8]).

Relief notches can reduce the notch effect at design-related main notches through a more uniform stress profile (Fig. 15.11).

Other Influences

In addition to notches, the following factors also affect component strength:

- The surface roughness. Roughnesses act like small notches.
- The size effect. The higher strength of the boundary zone (e.g., through quenching and tempering) or geometrical size dependency of the stress gradients reduce the component strength with increasing component cross section, especially in bending and torsion.
- Surface hardening. Residual compressive stresses due to production-related surface hardening can increase the fatigue strength.
- The shape of the loaded cross section (rectangle, circle, etc.). This is taken into consideration in the stress concentration factor.
- The temperature. Higher temperatures reduce the strength, while lower temperatures increase the risk of brittle failure.
- The load frequency. Very high and very low frequencies reduce the alternating fatigue strength.
- The ambient medium. Aggressive media (e.g., saltwater) reduce the alternating fatigue strength.
- The support effect (i.e., higher strength values) is more favorable in terms of tension than in compression in gray cast iron.

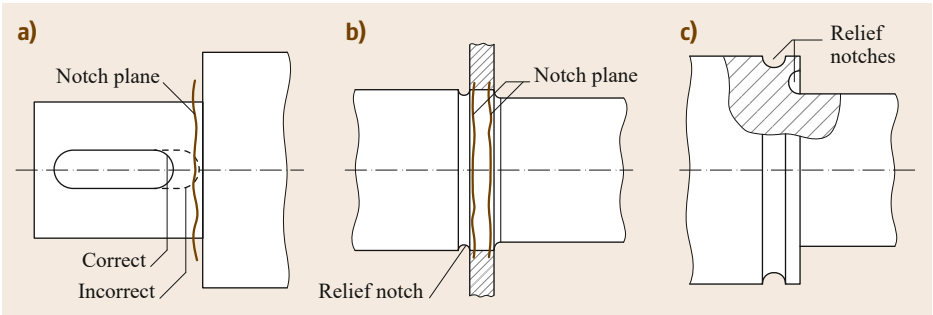

Fig. 15.11a–c Notch form and notch effect: **(a)** superimposition of notch planes, **(b)** relief notch in seized hub, and **(c)** relief notch on shaft shoulder

The effect of the individual influences on the component strength is taken into consideration by corresponding influence factors, which are given in the relevant literature [15.2–10].

15.1.6 Practical Strength Calculation

The objective of component dimensioning is to specify the component dimensions, taking into consideration defined boundary conditions. These boundary conditions result from:

- Allowable stresses
- Allowable deformations
- Allowable heating
- Allowable speeds
- Allowable noise emissions
- Necessary life

This requires all influence factors acting on the component (e.g., forces, climatic conditions, and vibrations) to be known or identifiable.

Components that are mainly loaded mechanically are dimensioned on the basis of the allowable stresses, with consideration of the required safety factors. The strength values necessary for this are generally only available from static tensile tests. For rough estimate calculations, they can be used to approximately deduce the sustainable stresses for other static loads and stresses according to Table 15.7.

The following relationship exists between the sustainable stresses and the allowable stresses:

$$\text{allowable stress} = \frac{\text{sustainable stress}}{\text{factor of safety}} .$$

The durability of a component is considered to be assured, if

$$\text{sustainable stress} \leq \text{allowable stress} .$$

For statically or mainly statically loaded components made of tough materials, the yield strength (yield point) R_e is decisive (or rather σ_{bF} or τ_{tF}) and for brittle materials the fracture strength R_m is decisive, from which

$$\sigma \leq \sigma_{all} = \frac{R_e}{S_Y} , \tag{15.10}$$

or rather

$$\sigma \leq \sigma_{all} = \frac{R_m}{S_F} , \tag{15.11}$$

where S_Y is the factor of safety against yielding in tough materials and S_F is the factor of safety against fracture in brittle materials.

For dynamically loaded components, for which the notch effect, size, and surface properties are initially unknown, the relevant fatigue strength is assumed initially

$$\sigma \leq \sigma_{all} = \frac{\sigma_D}{S_D} \quad \text{or} \quad \tau \leq \tau_{all} = \frac{\tau_D}{S_D} , \tag{15.12}$$

Table 15.7 Standard static strength characteristics for rough estimate calculations (approximate values, after [15.2])

	Material					
	Ductile (tough)			**Brittle**		
Loading mode	Steel, Cast steel, Cu alloy	Al wrought alloy	Al cast alloy	Ductile iron	Malleable cast iron	Gray iron
Tension	R_e ($R_{p0.2}$)			R_m		
Compression	R_e	R_e	$1.5R_e$	$1.3R_m$	$1.5R_m$	$2.5R_m$
Bending	$1.1R_e$	R_e	R_e	R_m	R_m	R_m
Torsion	$0.65R_e$	$0.6R_e$	–	–	–	–
Shear	$0.6R_e$	$0.6R_e$	$0.75R_e$	$0.65R_m$	$0.75R_m$	$0.85R_m$

Table 15.8 Standard safety values [15.2]

			Rolled and forged steel		Ductile cast iron materials			
			Consequences of damage		Untested consequences of damage		Nondestructive tested consequences of damage	
			High	Low	High	Low	High	Low
S_Y (S_F)	Likelihood of occurrence of the largest stresses or the most unfavorable stress combination	High	1.5 (2.0)	1.3 (1.75)	2.1 (2.8)	1.8 (2.45)	1.9 (2.5)	1.65 (2.2)
		Low	1.35 (1.8)	1.2 (1.6)	1.9 (2.55)	1.65 (2.2)	1.7 (2.25)	1.5 (2.0)
S_D	Regular inspection	No	1.5	1.3	2.1	1.8	1.9	1.65
		Yes	1.35	1.2	1.9	1.7	1.7	1.5

where S_D is a factor of safety against fatigue fracture. The allowable stresses (σ_{all}, τ_{all}) relate to the cross sections weakened by notches and/or grooves or the smaller cross sections in places with cross-sectional change.

The safety factors reduce the sustainable material strengths in calculation terms, as a result of which they allow for uncertainties and inaccuracies in the calculation operation (e.g., calculation with average values and simplifications in the calculation approach), the load assumption (e.g., load fluctuations that are difficult to record), and the material properties (e.g., scatter in the determination of strength values):

- The value of the safety factors to be used is essentially based on experience and is only partly defined in standards and guidelines.

The following aspects play a role when specifying the values:

- Smaller safety if the external loads can be reliably identified and recorded and failure does not have any disastrous consequences
- Larger safety if the external forces cannot be precisely identified or recorded and if failure can have disastrous consequences (e.g., risk to life and serious operational disruptions)

The effects must be carefully analyzed. A safety factor that is too high can also be fatal (apart from the economic viability or unviability). For example, in the case of components that heat up in service, it must be noted that the thermal stresses increase with increasing wall thickness and that the force effects induced by thermal expansion between fixed points become larger the stronger or sturdier the design. Table 15.8 gives an overview of standard, commonly used safety values.

The (actual) available component safety can only be determined for components that have already been designed, as only then can all influences (size, notch effect, surface quality) be approximately recorded.

For a component subjected to static and dynamic loading, after it has been designed (dimensioning and form), the appropriate strength verifications (stress analyses) can be used to ensure that it satisfies the planned static and dynamic loading.

The general algorithm for performing strength verifications is illustrated graphically in Fig. 15.12.

Notes on Component Dimensioning and Design

The following steps must be worked through systematically when dimensioning and designing a component:

- Definition/determination of the external forces and moments (loads) acting on the component
- Rough calculation (and choice) of the dimensions based on allowable stresses, design, and functional requirements
- Design (including the details) of the component
- Calculation of the stresses occurring at the relevant parts of the component (stresses)
- Calculation of the static and dynamic component strengths (design strengths) for the relevant places on the component
- Determination of the existing safety and comparison with the required safety (static and dynamic strength verification (stress analysis))

If the existing safety is inadequate, the component must be modified (e.g., changing its dimensions, detailed design, and material as well as possibly its load and application points) so that the required safety is achieved. Repeated calculations are frequently necessary.

If an existing safety is disproportionately high, it is necessary to examine how improved utilization of the strength can be achieved. It may be possible to

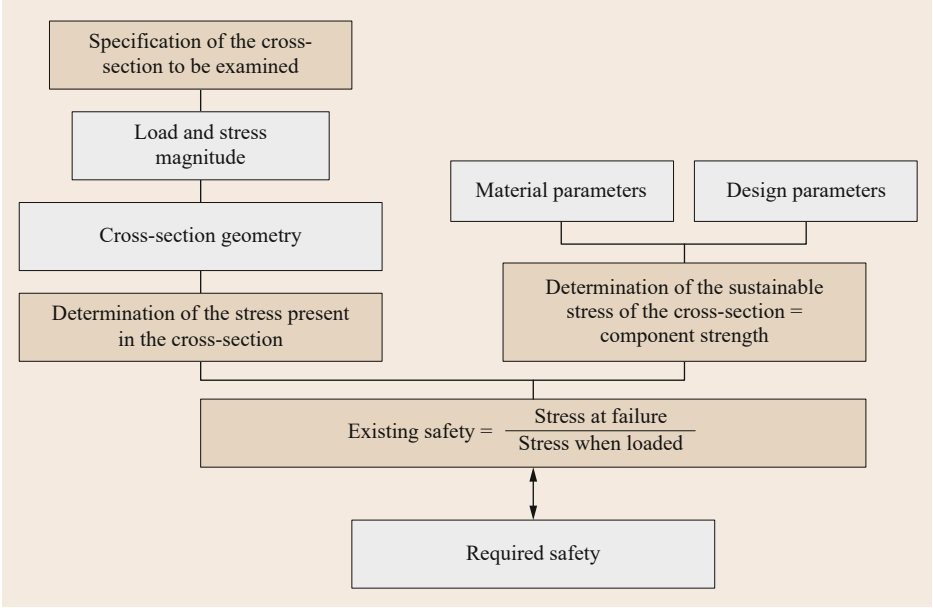

Fig. 15.12 General algorithm for strength verification

build smaller and more lightweight or to use more cost-effective materials with a lower strength. This frequently leads to solutions that are more favorable economically.

It should be noted that the required safety must be achieved at the critical places of the component, while for design reasons, other places can be overdimensioned with regard to strength (even with disproportionately high safety).

Other dimensioning criteria (deformation, heating, and wear) may also have to be considered in the assessment accordingly.

The specified allowable strength values must never be exceeded.

If use of a component requires compliance with several dimensioning criteria, all these criteria must be examined. The design must then be performed according to the failure criterion (failure limit) to be achieved first. Compliance with the remaining required criteria must be demonstrated.

15.1.7 Further Reading

Hibbeler [15.1], *Young* et al. [15.11] and *Issler* et al. [15.12] provide deeper insight into the mechanics of materials and the strength of materials.

Further information on service strength is provided by *Lee* et al. [15.13], *Haibach* [15.14], *Bannantine* et al. [15.15] and *Manson* and *Halford* [15.16]. In their book, *Fatigue Assessment of Welded Joints by Local Approaches* [15.17], *Radaj* et al. discuss in particular the service strength of welded joints.

Guidelines for the calculated verification of component strength are given in the FKM Guidelines [15.5].

15.2 Fasteners

Fasteners (connecting elements) are used to joint components and/or to define their position relative to each other. They are used to transfer forces. The mode of action of the connection (joint) can be based on form closure (also known as positive locking), force closure (also known as force locking), or material bonding (Table 15.9).

15.2.1 Modes of Action

In several jointing methods (e.g., riveted joints, keyed connections, and fitting bolts), several modes of action apply simultaneously so that clear separation between the modes of action is not possible.

Table 15.9 Modes of action of the fasteners and connectors

Modes of action	Form closure	Force closure	Material bonding
Joint	Through engagement or interlocking of the components or through drivers or fasteners/connectors engaging with the components	(Including friction), achieved by pressing together the adjoining faces (contact surfaces) of components	Achieved by means of an additional material that permanently bonds with the components
Example	Bolts, pins, keys, etc. 	In screw and press-fit connections or joints, friction couplings, stopping breaks, etc. 	Welding, soldering, adhesive bonding 
15.2.2 Form-Closure Joints

General Information

Form-closure fasteners, such as bolts, pins, keys, woodruff keys, wedges, profiled shafts, and rivets, are all standardized and are available as standard components. They are characterized by the fact that, unlike force closure and material bonding, the components permanently or immovably connect together or continue to be able to move, e.g., the possibility for bolts to turn or sliding keys to be pushed. In addition, form-closure joints can normally be nondestructively undone, whereby the rivet constitutes an exception.

Form-closure fasteners are generally mainly subjected to surface pressure, shearing, and possibly bending and must be dimensioned according to these loading modes.

The calculation approaches listed in the following give an overview of the dimensioning of the individual fasteners. Here it must be noted that the calculation principles may need to be adapted to the specific calculation case.

Pinned Joints

Pinned joints are used:

- To form a fixed connection between wheel and lever hubs and axles or shafts
- To secure the position/centering machine parts
- As pins for fixing tabs, link plates, springs, etc.
- As overload protection (shear pins)

Application examples are shown in Fig. 15.13.

Depending on their shape, a differentiation is made between parallel pins, tapered pins, grooved pins, and spring-type straight pins (Fig. 15.14).

Parallel pins are primarily used for the fixed (tolerance grade m6) or loose (tolerance grade h8 or h11) connection of components. The holes in the components to be connected must be reamed to the required size limit according to the requirements, which results in high production costs.

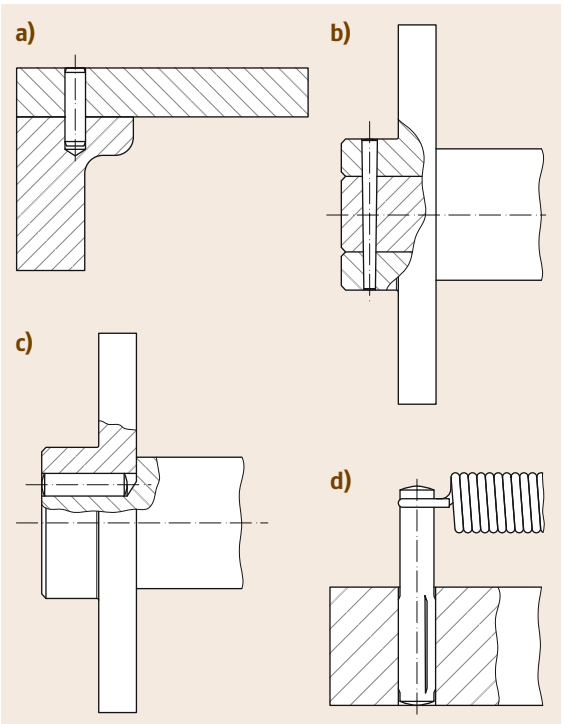

Fig. 15.13a–d Pinned joints (examples): **(a)** position fixing using parallel pins, **(b)** transverse pin jointing using tapered pin, **(c)** longitudinal pin with cylindrical grooved pin, and **(d)** cylindrical grooved pins (with neck) as pins

Tapered pins are used in a similar way to parallel pins. Due to the tapered hole (expensive) the contact surfaces only briefly rub together on removing the pin, which results in low wear. Above all, they are suitable for precise positioning of components/devices that must be frequently undone or detached.

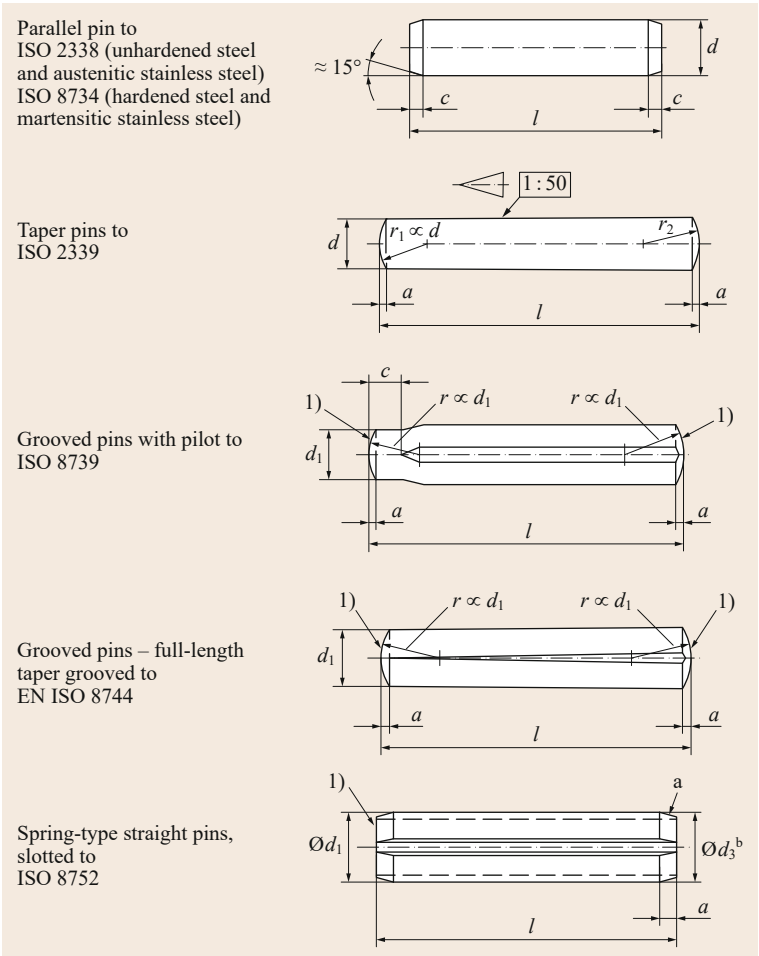

Fig. 15.14 Standardized pin types (selection) (after [15.18–22])

Grooved pins have several swaged grooves on their circumference with a raised portion on the side of each groove; these raised portions are deformed when knocked into the hole and produce a tight, interference fit on the hole. Due to the raised portions, tight hole tolerances are not necessary.

Axially slotted spring-type straight pins are an alternative to grooved pins. They are made of spring steel and have a large oversize (interference) of 0.2–0.5 mm. Due to their directional transverse load elasticity compared to parallel, tapered, and grooved pins, they tend to displace the pinned parts.

As a result of the applied forces and moments, pins are subjected to surface pressure and shear; shear pins are also subjected to bending (Fig. 15.15).

Transverse Pinned Joints. Transverse pin joints, which are for transferring a nominal torque T_{nom}, as in a lever hub (Fig. 15.15a), must be checked for surface pressure and shearing in the case of larger forces.

With the symbols from Fig. 15.15 and the application and service factor K_A according to Table 15.5:

- The mean surface pressure p_N in the hub is

$$p_N = K_A \frac{F_{\text{nom}}}{ds} = K_A \frac{T_{\text{nom}}}{ds(d_W + s)} \leq p_{\text{all}} , \quad (15.13)$$

where:
d pin diameter
D external diameter of the hub
d_W shaft diameter
s pin width in the hub; $s = D - d_w/2$

- The maximum value of the mean surface pressure p_W in the shaft is

$$p_W = 4K_A \frac{F_{W\,\text{nom}}}{dd_w} = 2K_A \frac{3T_{\text{nom}}}{2d_W dd_W/2}$$
$$= K_A \frac{6T_{\text{nom}}}{dd_W^2} \leq p_{\text{all}} . \quad (15.14)$$

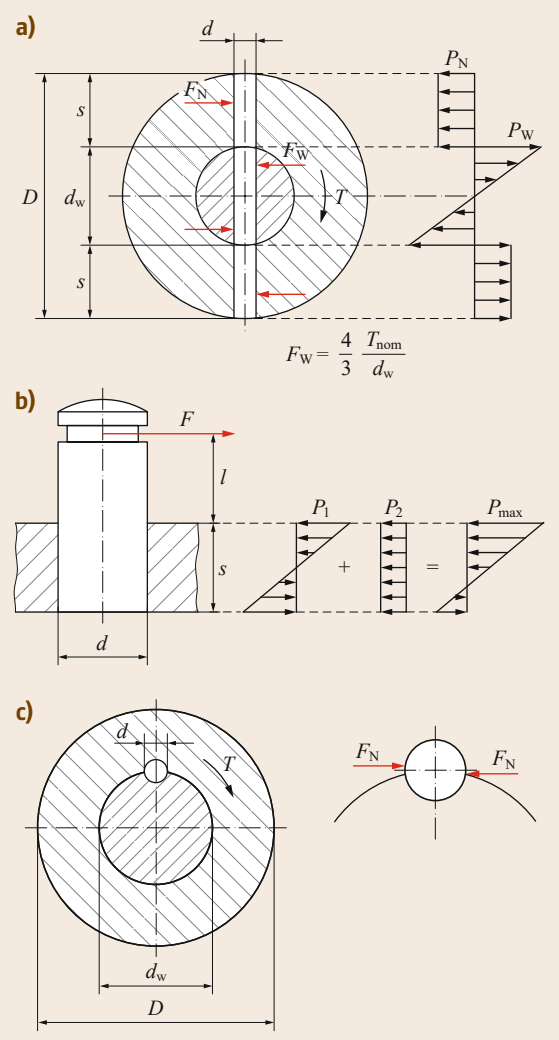

Fig. 15.15a–c Forces on pinned joints: **(a)** transverse pin, **(b)** push-fit pin, and **(c)** longitudinal pin

- For the mean shear stress τ_S in the pin

$$\tau_S = K_A \frac{F_{W\,nom}}{A_S} = K_A \frac{4T_{nom}}{d_W \pi d^2} \le \tau_{s\,all}\,, \qquad (15.15)$$

where:

p_{all} see Table 15.10 (multiply values by 0.7 for slotted straight pins)

$\tau_{s\,all}$ see Table 15.10 (multiply values by 0.8 for slotted straight pins)

From experience, for the design a pin diameter $d = (0.2–0.3)d_W$ and hub wall thicknesses $s = (0.25–0.5)d_W$ are chosen for steel hubs and $s = 0.75d_W$ for gray cast iron hubs.

Longitudinal Pinned Joints. Under the force F_N on the longitudinal pin (also round key) (Fig. 15.15c), the mean surface pressure p is twice the magnitude of the shear stress τ_s.

Therefore, it is not necessary to calculate the shear stress in solid pins. The relevant mean surface pressure in both parts (shaft and hub) is calculated from

$$p = K_A \frac{F_{nom}}{A} = K_A \frac{4T_{nom}}{d_W dl} \le p_{all}\,, \qquad (15.16)$$

where Table 15.10 lists p_{all} values (multiply values by 0.7 for slotted straight pins.)

From experience, pin diameters $d = (0.15–0.2)d_W$ and load-bearing pin lengths $l = (1–1.5)d_W$ are chosen.

In the case of large torques, several pins can be arranged on the circumference.

Clevis Pin Joints. Clevis pins (Fig. 15.15b) must be calculated for bending and for surface pressure. The transverse force (shear) can be ignored.

The bending stress σ_b must be verified with bending moment $M_b = Fl$:

$$\sigma_b = K_A \frac{M_b}{W_b} \approx K_A \frac{M_b}{0.1d^3} \le \sigma_{b\,all}\,, \qquad (15.17)$$

where:

$\sigma_{b\,all}$ see Table 15.10 (multiply values by 0.7 for slotted straight pins)

W_b see Table 15.1

The surface pressure is made up of the component changeable along the hole $p_1 = F(l + s/2)/(ds^2/6)$ (corresponds to $p_1 = M_b/W_b$, where $M_b = F(l + s/2)$ and $W_b = d^2/6$ due to the bending stress profile as in a slab or plate) resulting from the overturning effect on the pin and the component constant along the hole $p_2 = F/(ds)$ resulting from the shearing effect of F.

The maximum mean surface pressure is then

$$p_{max} = p_1 + p_2 = K_A \frac{F_{nom}}{ds^2}(6l + 4s) \le p_{all}\,, \qquad (15.18)$$

where Table 15.10 lists p_{all} values (multiply values by 0.7 for slotted straight pins).

Bolted Joints

Bolts are used to make preferably free-to-rotate joints (Fig. 15.16).

Taking into account their type of use, bolted joints are adapted according to the required fit tolerances and properties of the mating material. Thus, diameter

Table 15.10 Guide values for allowable stresses for bolted and pinned joints under approximately static load [15.23, 24]

Material	Type of bolt, pin, component	Allowable stress (N/mm²)			
		p_{all}	$\sigma_{b\,all}$	$\tau_{s\,all}$ Static	Sliding
S235JR...E295	Tapers, parallel pins, bolts, shafts	160	140	90	15
E335; E360	Bolts, grooved pins, shafts	240	200	140	
Cast steel	Hubs	120	–	–	8
Cast iron	Hubs	90	–	–	5

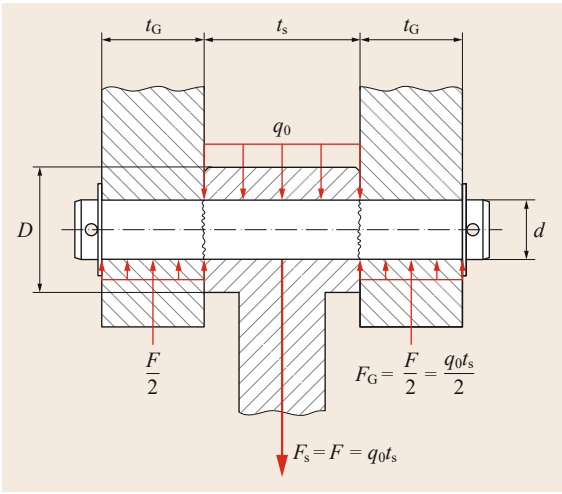

Fig. 15.16 Basic design and loading of a bolted joint with related dimensions

tolerances h11 or h8 with appropriate choice of hole tolerance enable clearance or interference fit for different use cases. Movable bolted joints are subjected to wear at the contact points that slide on each other. This can be reduced by lubrication, suitable selection of the material combination or by using bearing bushes. The force transfer within the bolted joints loads the fasteners with bending, shear, and surface pressure, whereby in general for joints at rest, the bending load is decisive and for moving joints the surface pressure is decisive. Standard bolt forms for different applications are shown in Fig. 15.17.

Depending on the type of fit between the bolt and bar or between the bolt and fork, three different installation cases are possible, which lead to different types of bending moment profiles and thus to different stresses in the bolt. The possible installation cases and equations required for the calculation are shown in Table 15.11.

Guide values for the allowable stresses are shown in Table 15.10.

If sliding movement occurs in the bolted joint, this must be taken into account in the material selection. If necessary, the sliding surfaces must be lubricated and a significantly lower allowable surface pressure must be used.

In highly loaded hinged joints, in addition to the bolt and bar cross section, the strength of the cross sections at the bar head and the fork most at risk must also be checked.

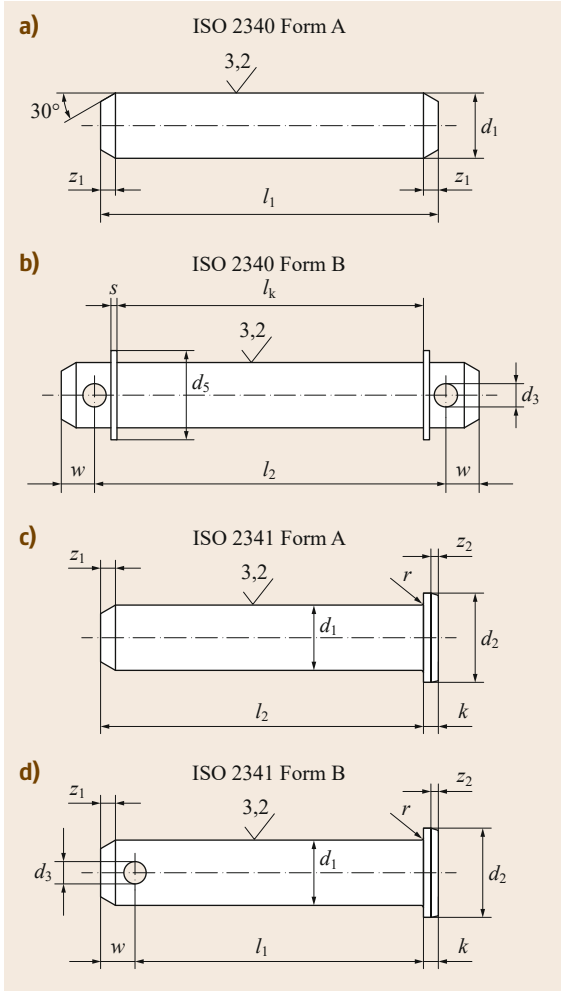

Fig. 15.17a–d Bolt forms: **(a)** without head, **(b)** without head with split pin holes and washers, **(c)** with head, and **(d)** with head and split pin hole (after [15.25, 26])

Table 15.11 Possible installation cases with the corresponding calculation equations

	Installation case 1	Installation case 2	Installation case 3
Fork fit	Clearance fit	Interference fit	Clearance fit
Rod fit	Clearance fit	Clearance fit	Interference fit
Moment profiles (bending moment diagrams)			Maximum bending stress	$\sigma_{b\,max} = \frac{8F(t_G + t_S)}{\pi d^3}$	$\sigma_{b\,max} = \frac{8Ft_S}{3\pi d^3}$	$\sigma_{b\,max} = \frac{8Ft_G}{\pi d^3}$
Shear stress	$\tau_S = \frac{2F}{\pi d^2}$		
Fork surface pressure	$p = \frac{F}{2dt_S}$		
Rod surface pressure	$p = \frac{F}{dt_G}$		

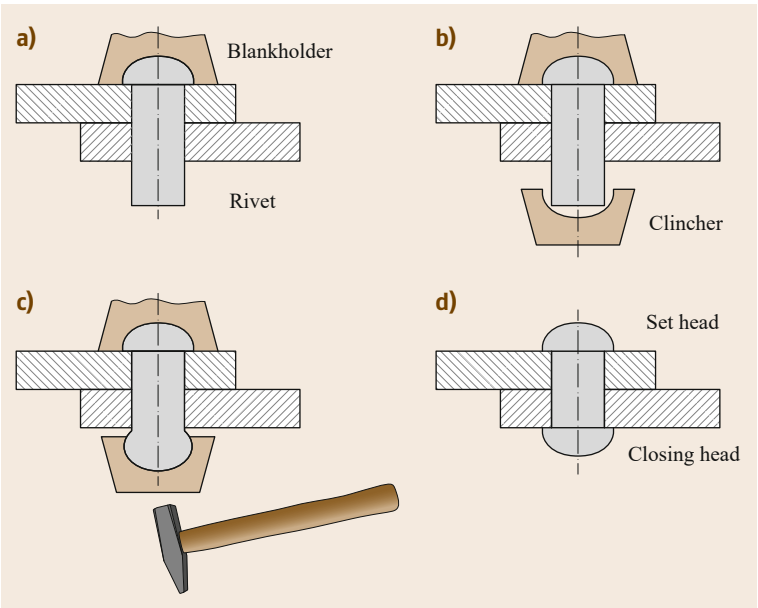

Fig. 15.18a–d Classic riveting. **(a)** Position of the rivet and blankholder, **(b)** position of the clincher, **(c)** plastic forming of the head, **(d)** finished riveted joint

Other Form-Closure Joints

Riveted Joints. Rivets are primarily used to join two or more overlapping components. Unlike welding procedures, dissimilar materials can be joined when cold, so that effects such as distortion, hardening, or (micro) structural changes are avoided. To make the classic rivet joint, a rivet is placed in an existing hole or hole to be made (exception: punch riveting with a semitubular rivet), fixed and is then plastically deformed from the opposite side, so that a rivet head forms (Fig. 15.18). Here a differentiation is made between hot and cold riveting.

Hot riveting is primarily used for steel rivets with diameters of 10 mm and larger. The rivet, inserted when heated (approximately 1000 °C), contracts due to cooling, resulting in the overlapping components being pressed together (force-closure joint).

With cold riveting, the radial widening of the rivet forms a primarily form-closure joint.

If the rear of the joint is not accessible, blind rivets (pop rivets) can be used (Fig. 15.19). These are an economically favorable solution for many fastening tasks. Compared to conventional riveted joints, they can be made by one person.

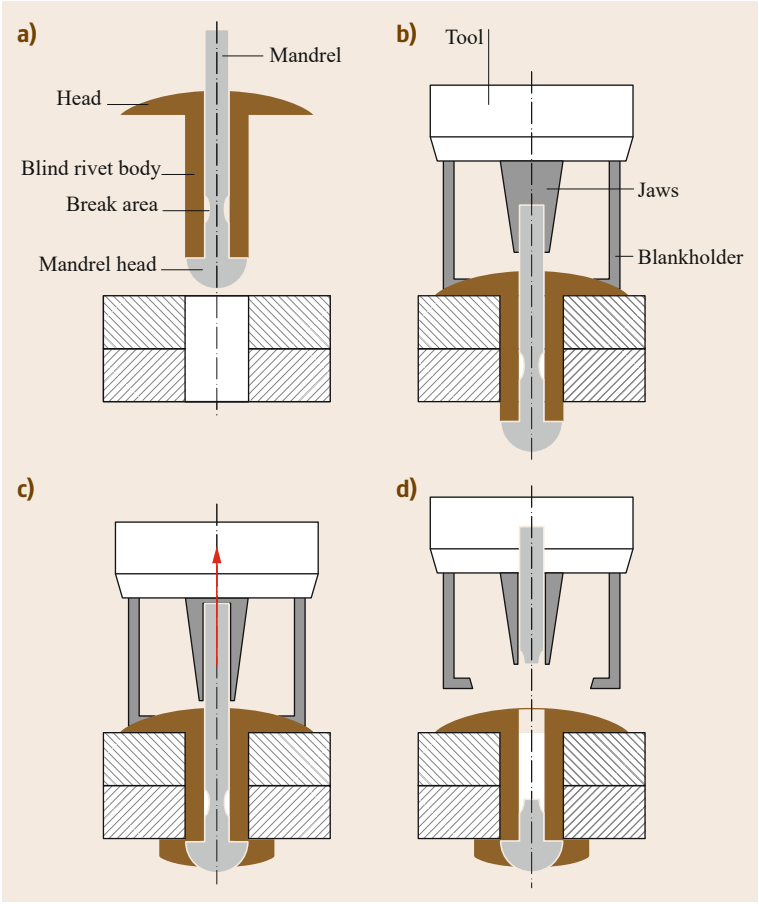

Fig. 15.19a–d Blind riveting process

With punch riveting, unlike the classic riveting process, making the hole before the actual riveting is omitted. With self-piercing riveting with solid rivets, the actual rivet simultaneously functions as a cutting punch and perforates the parts to be joined. The bottom sheet is then pressed by an appropriately shaped die into an all-round groove of the rivet (plastically deformed), which results in a form-closure joint (Fig. 15.20a). With self-piercing riveting with semitubular rivets, the rivet also acts as a cutting punch; however, it does not completely penetrate the components to be jointed, and as a result a gas- and liquid-tight joint is formed (Fig. 15.20b).

Riveted joints are generally not nondestructively separable. They can only be undone by removing the rivet (or rather drilling out or cutting off the rivet head).

Other standard riveting processes are listed in Table 15.12.

The advantages and disadvantages of riveting methods are shown in Table 15.13.

Reference is made to the relevant literature for the calculation of riveted joints (design and strength verification), for example [15.2, 24].

Form-Closure Retaining Elements. Form-closure retaining elements, for example, retaining rings, cotter pins (split pins), setting rings, and axle holders (axle stays) are frequently used for axial fixing and locating (keeping in position) shafts and bearings.

Figure 15.21 shows different retaining rings for various application cases for installation in corresponding annular grooves in round bodies (e.g., axles, shafts, bolts, and pins) or in holes.

When axial forces act on retaining rings they cause surface pressure on the load-bearing shoulders between the ring and groove, which must not exceed allowable values. In cases of doubt, these should be checked by calculation.

Axially mounted retaining rings according to DIN 471 [15.29] for metric round bodies (Fig. 15.21a) and according to DIN 472 [15.30] for metric bores (Fig. 15.21b) are most frequently used. Retaining rings for inch-measure round bodies and holes are also available. The dimensions for the retaining rings and corresponding groove are given in the manufacturers' catalogs.

Table 15.12 Riveting processes according to DIN 8593-5 [15.27]

Process	Figure	Description
Riveting		Setting (squeezing) a bolt-shaped rivet
Semitubular riveting		Turning over of protruding parts of a hollow rivet (bifurcated rivets)
Peg riveting		Setting a peg-shaped end on one of the two parts to be joined
Tubular peg riveting		Turning over of protruding parts of the tubular peg-shaped end on one of the two parts to be joined
Intermediate peg riveting		Setting an intermediate peg on one of the two parts to be joined

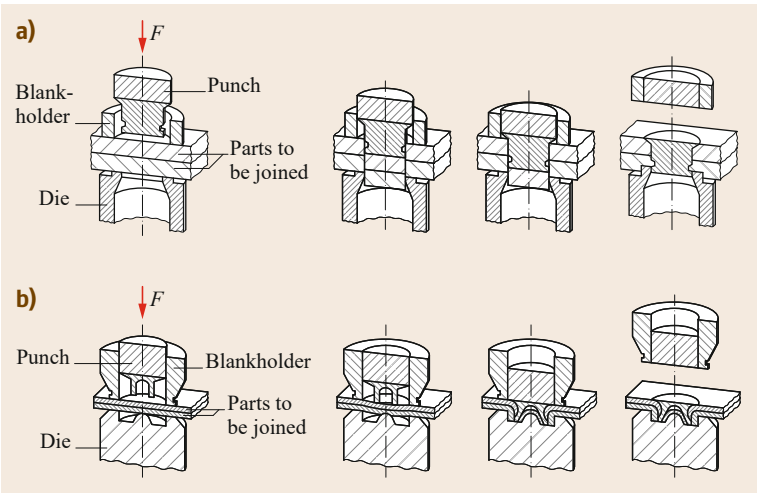

Fig. 15.20a,b Punch (self-piercing) rivets: **(a)** solid rivet process and **(b)** semitubular rivet process (after [15.27])

If the load-bearing surfaces are too small due to large chamfers or rounding on the annular grooves, or if axial clearances have to be levelled out, additional shim washers or supporting rings according to DIN 988 [15.31] are used in conjunction with the retaining rings according to DIN 471 and DIN 472 (Fig. 15.21c).

The locating surfaces can also be enlarged using rings according to DIN 983 [15.32] and DIN 984 [15.33] (Fig. 15.21d,e).

Radial mountable retaining washers according to DIN 6799 [15.34] (Fig. 15.21f) (E-clips) are used for small shaft diameters. They surround the groove bottom, are radially resilient with segments, and form a relatively high shoulder.

Round wire snap rings according to DIN 9925 [15.35] and DIN 9926 [15.36] (Fig. 15.21g) (external snap rings) for bores and shafts are used for axial position fixing for secondary purposes with small axial forces. They are often difficult to remove from holes.

Table 15.13 Advantages and disadvantages of rivet joints

Advantages	Disadvantages
Unlike materials can be joined together	Butt joints not possible
No distortion of the components	Components are weakened by rivet holes
No material change (hardening, transformations), unlike welding	No smooth walls due to necessary overlapping (lap joints) or cover plates
On construction sites, frequently more cost effective than other joints	Unfavorable force flow
They do not fail suddenly, because they can absorb high deformation energy	More cost intensive than welded joints
Easier to check (visual inspection, impact control)	

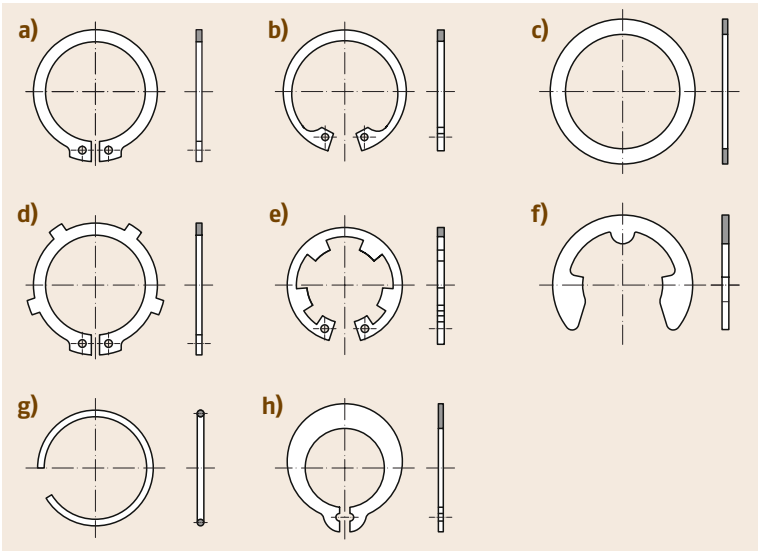

Fig. 15.21a–h Types of retaining rings (selection). **(a)** Circlips for axles or shafts, **(b)** circlips for bores, **(c)** shim washer, **(d)** circlips for axles or shafts with enlarged locating surface, **(e)** circlips for bores with enlarged locating surface, **(f)** E-clips, **(g)** round wire snap ring, and **(h)** grip rings

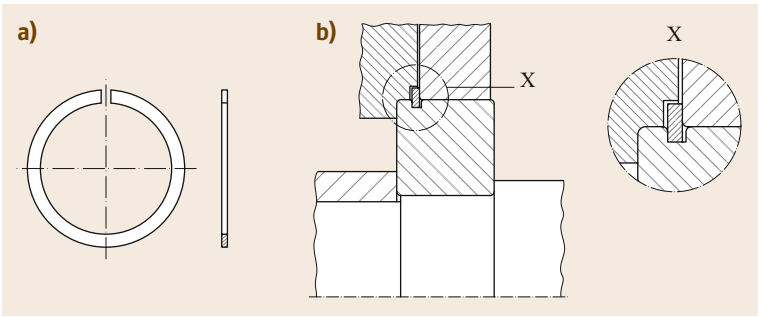

Fig. 15.22a,b Snap ring: **(a)** according to DIN 5417 and **(b)** installation example (after [15.28])

Self-locking grip rings for shafts without a groove (Fig. 15.21h) have a force-closure effect. They can be used to adjust axial clearances under small axial forces.

Snap rings for rolling bearings according to DIN 5417 [15.28] (Fig. 15.22) can be used to fasten radial bearings with an annular groove according to DIN 616 [15.37].

Laminar rings (Fig. 15.23) are an alternative to retaining rings according to DIN 471 and DIN 472. They can be mounted without special pliers and require less installation space due to their lack of eyes.

The fact that in many cases, depending on the existing requirements, the use of retaining rings can achieve substantial design simplifications and thus save costs, is shown by the rolling bearing design in Fig. 15.24. Figure 15.24b requires fewer parts, less production work (smooth continuous housing hole, no thread), and is also more compact.

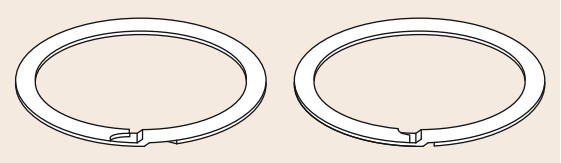

Fig. 15.23 Spiral rings for holes (*left*) and shafts (*right*)

Split pins (Fig. 15.25a) are mainly used for loose, articulated pin joints and for bolted joints (castellated nuts). In general, they may only be used once and cannot be used for force transfer.

Spring cotters are used for bolted joints, which have to be undone often. Spring cotters are frequently captively connected to the assembly to be secured, for example, by a chain (Fig. 15.25b).

15.2.3 Force-Closure Joints

Force-closure joints transfer forces from one component to another by friction between the components.

Modes of Action

The contact forces necessary in a force-closure joint can be generated by special clamping elements (e.g., screws, wedges, and clamping collars) or as contact forces, which arise between the components due to jointing with interference fit.

If additional clamping elements are used, the contact forces are produced by tensioning these elements with the components to be joined.

Threaded Fasteners

Screws and bolts are the elements used most to connect components. They are all standardized and can be nondestructively undone and reused.

Apart from fastening and connecting, screws and bolts are also used to set and adjust, to measure, to tension, and as leadscrews for translating rotational movements into longitudinal movements.

The advantages of bolted assemblies are shown in Table 15.14.

Mode of Action, Variants, and Descriptive Sizes. The screw or bolt thread can be thought of as being a cylinder with a helix-shaped notch. The notch usually runs rising clockwise (Fig. 15.26). The mating thread (nut or threaded hole) corresponds to the negative image of the screw or bolt thread.

The thread pitch P is the relative axial displacement between the screw (external thread) and nut (internal thread) in one screw turn. The pitch angle φ follows from the thread pitch P and the (mean) pitch diameter d_2 and is calculated as

$$\tan\phi = \frac{P}{\pi d_2}\,; \quad \phi = \arctan\frac{P}{\pi d_2}\,. \tag{15.19}$$

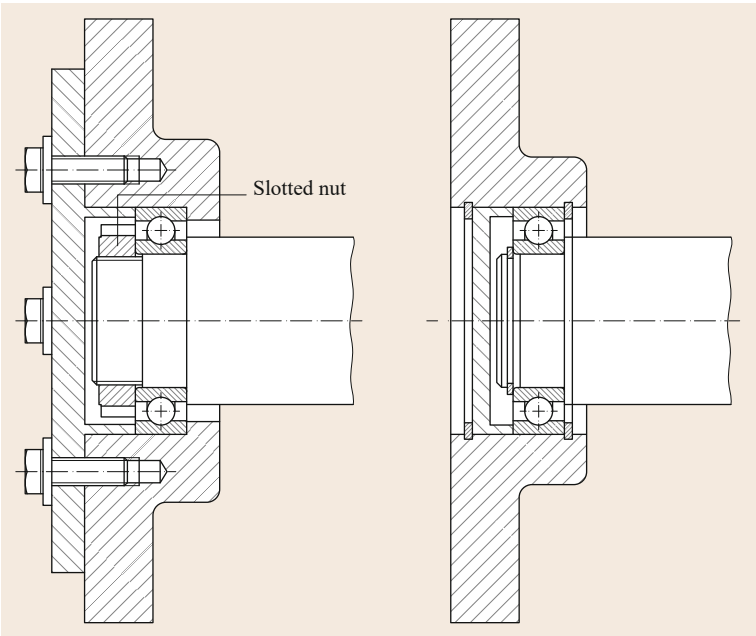

Fig. 15.24 Installation options for a rolling bearing as fixed bearing

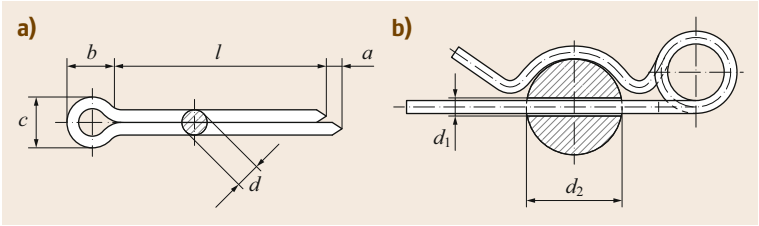

Fig. 15.25a,b Split pins according to ISO 1234 [15.38] **(a)** and spring cotters according to DIN 11024 [15.39] **(b)** in their mounted condition

Table 15.14 Advantages and disadvantages of screwed joints

Advantages	Disadvantages
Easy assembly and dismantling	Necessary holes disturb force path
Can be nondestructively undone	High costs compared to riveted, adhesive bonding and welded joints
Generally reusable	Susceptible to crevice corrosion
Different materials can be joined	
Good temperature resistance	

Depending on the intended use and underlying standard, the dimensions vary in detail within the thread form, so that in general there is no exchangeability between the individual thread types. Table 15.15 shows standard international thread forms with their corresponding designation.

Coarse thread (for example metric ISO thread according to DIN 13-1 or UNC thread to ANSI B1.1) is used for fixing screws and bolts (and corresponding nuts) of all kinds.

The fine pitch thread (for example according to DIN 13-2, DIN 13-11, or UNF according to ANSI B1.1) is used for large dimensions, loads, and stresses, in thin-walled parts and for micrometers and adjustment screws.

Trapezoidal thread (for example according to DIN 103 or ANSI B1.5) is preferably used as a translation or power transmission thread on spindles, for example, in machine tools, presses, valves, and vices.

Buttress threads (for example, according to DIN 513 or ANSI B1.9) have a higher load capability compared to the trapezoidal thread due to the larger rounded thread roots and due to the larger thread engagement depth and their radial *jump-out effect* in the nut thread remains lower than in other thread forms. Buttress threads are used as single or multistart translation or power transmission threads for high one-sided loads, for example, in jackscrews and pressing spindles.

Round threads (for example, according to DIN 405) display almost no notch effect, however have only a small thread engagement depth. Due to their large root and thread clearance they are suitable as translation or power transmission threads in severe soiling conditions, for example, as coupling rods in railway carriage couplings.

In addition to the above-mentioned thread forms or thread types, there are other variants for special applications, some of which are standardized.

The thread and screw/bolt dimensions required for the calculation of threaded fasteners (fixing screws and bolts) are shown for metric ISO thread (coarse thread) in Table 15.16 and for inch-measure UNC threads in Table 15.17. Reference is made to relevant books of tables and standards for other thread forms.

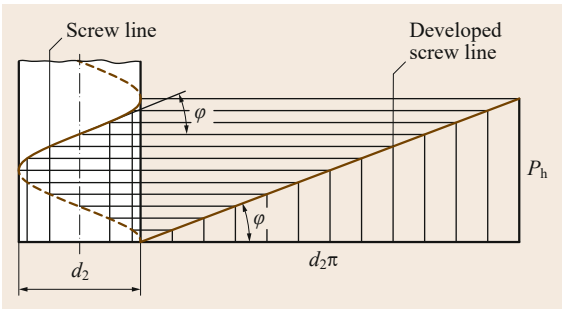

Fig. 15.26 Creation of the screw line

Calculation of Bolted Joints. The calculation method presented in the following for fixing screws and bolts is mainly based on the VDI Guideline 2230 *Systematic calculation of highly stressed bolted joints–Joints with one cylindrical bolt* [15.40, 41].

Bolted joints are generally loaded by:

- Transverse forces F_Q at right angles to the bolt axis (Fig. 15.28) and/or
- By tensile forces (bolt loads or forces) F_S along the bolt axis,

whereby the joint must be designed so that bending moments and shear forces in the bolt or screw are avoided as much as possible and it is loaded under tension only.

Table 15.15 Overview of the most common types of thread

Shape	Use	Designation	Abbreviation	Standard		Abbreviation
V-thread						
Metric ISO thread						
	General	Coarse thread (single and multiple start)	M	ISO 1502	DIN 14 0.3–0.9 mm DIN 13 1–68 mm	M 0.8 M 12

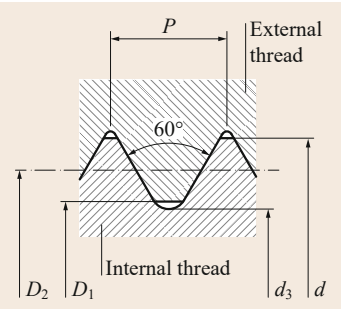

Fig. 15.27 Thread sizes

This does not include preloaded fit bolts, which are calculated like bolts for shear and surface pressure (hole friction).

If transverse forces F_Q occur, the bolts must be preloaded so that the friction force $F_R > F_Q$ necessary for the required force closure is generated, i.e.,

$$F_R = F_{V\,min}\,\mu n i_R \geq F_Q S_H \quad \text{or}$$

$$F_{V\,min} \geq \frac{F_Q S_H}{\mu n i_R}\,, \tag{15.20}$$

where:

F_Q transverse force on the bolted joint
$F_{V\,min}$ minimum preload in the bolt
μ coefficient of friction in the interface (separating joint) between the components to be connected (e.g., $\mu = 0.1$–0.15 for dry steel–steel pairings)

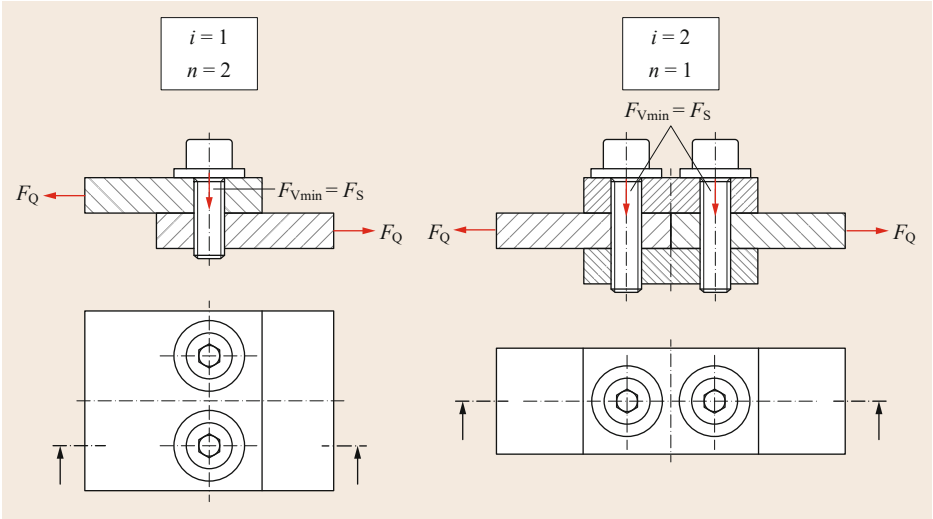

Fig. 15.28 Diagram showing the relevant number of bolts n and the friction pairings i_R in transversely loaded bolted joints

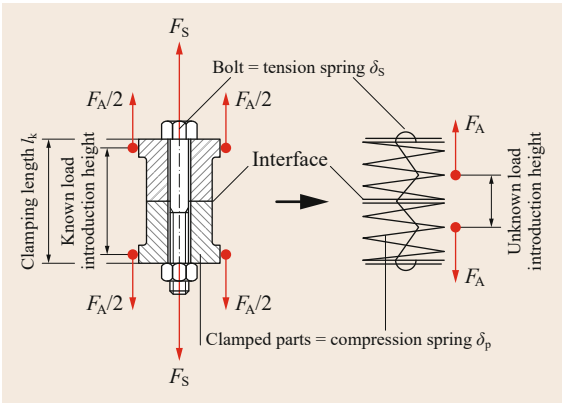

Fig. 15.29 Centrically clamped bolted joint and corresponding spring model according to VDI 2230 (after [15.40])

n relevant number of bolts in the joint (Fig. 15.28)
i_R number of effective friction couples (friction pairing) (Fig. 15.28)
S_H adhesion safety factor: $S_H \approx 1.3$ under static and $S_H \approx 1.5$ under dynamic loading

Due to the elasticity of the bolt and the clamped parts, the bolted joint behaves like springs connected in parallel (Fig. 15.29), where the bolt acts as a tensile spring and the clamped parts act as compression springs.

The elongation of the bolt f_S is more or less proportional to the acting force F_S and can be calculated using (15.21):

$$f_S = c_S F_S = \frac{1}{\delta_S} F_S \,, \tag{15.21}$$

where c_S is the spring stiffness of the bolt and δ_S is the resilience of the bolt.

The compression of the clamped parts f_P is calculated from

$$f_P = c_P F_P = \frac{1}{\delta_P} F_P \,, \tag{15.22}$$

where c_P is the clamped length and δ_P is the modulus of elasticity of the clamped parts.

According to (15.23), the total resilience δ_S of the bolt is made up of the resiliences of the partial areas:

$$\delta_S = \delta_{SK} + \delta_{Gew} + \delta_{GM} + \sum_1^n \delta_i \,, \tag{15.23}$$

where:

δ_{SK} resilience of the bolt head
δ_{Gew} resilience of the exposed (protruding) thread
δ_{GM} resilience of the screwed-in thread
δ_i resilience of the cylindrical shank section i

The resilience of the bolt head of hexagon and hexagon socket head bolts can be calculated using

$$\delta_{SK} = \frac{4 l_{SK}}{E_S \pi d} \,. \tag{15.24}$$

where:

l_{SK} height of the bolt head (Fig. 15.30); for hexagon head bolts $l_{SK} = 0.5d$ and for hexagon socket head cap screws (bolts), $l_{SK} = 0.4d$

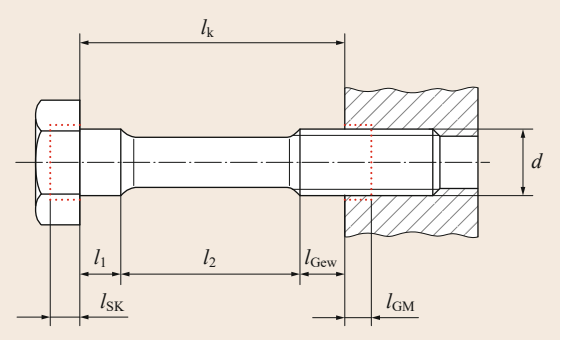

Fig. 15.30 Individual deformation areas of the bolt (after [15.40])

E_S modulus of elasticity of the bolt material
d nominal diameter of the thread (Fig. 15.30)

The resilience of the protruding thread, not screwed in, is calculated from

$$\delta_{Gew} = \frac{4 l_{Gew}}{E_S \pi d_3} , \tag{15.25}$$

where:

l_{Gew} length of the protruding thread (Fig. 15.30)
d_3 core diameter of the thread (Fig. 15.30).

In the area of the screwed-in thread, the total resilience is made up of the resilience of the nut δ_M and of the thread δ_G as given by

$$\delta_{GM} = \delta_G + \delta_M , \tag{15.26}$$

where

$$\delta_G = \frac{4 l_G}{E_S \pi d_3} , \tag{15.27}$$

and

$$\delta_M = \frac{4 l_M}{E_M \pi d} , \tag{15.28}$$

where:

l_G length of thread engagement; as a rule $l_G = 0.5d$
l_M height of the nut; for screw-in thread $l_M = 0.33d$ and for through-bolted joints $l_M = 0.4d$
E_M modulus of elasticity of the nut

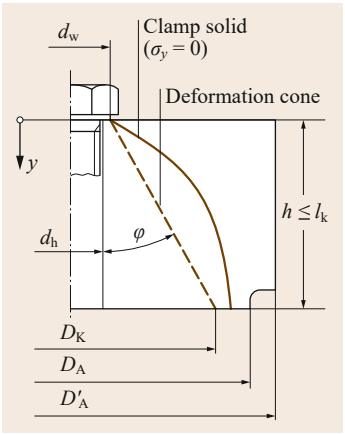

Fig. 15.31 Clamped body and derived deformation cone (after [15.40])

The resiliences of the individual shank areas can be calculated using (15.29):

$$\delta_i = \frac{4 l_i}{E_S \pi d_i} , \tag{15.29}$$

where l_i is the shank length i and d_i is the shank diameter i.

Calculating the resilience of the clamped parts is significantly more difficult due to the more complex stress curve. Below the bolt head, a rotational paraboloid clamped body (solid) forms, at whose boundaries $\sigma_y = 0$ (Fig. 15.31). The spring stiffness or rather the resilience in this area is defined by:

$$\delta_P = \int_{y=0}^{l_K} \frac{dy}{E(y)\, A(y)} . \tag{15.30}$$

In practical calculations, this deformation body is approximated by a deformation cone.

The complete distribution of an equivalent deformation cone in a cylindrical screw-in joint is shown in Fig. 15.32a. If the deformation cone cannot form radially in full due to the limited component width, the cone is replaced by a sleeve in the relevant area (Fig. 15.32b). In the special case in which the bolt head or nut bearing surface is larger than the external diameter of the clamped parts, only a deformation sleeve exists and not a deformation cone.

Complete formation of the deformation cone exists if

$$D_A \ge D_{A,Gr} = d_W + w l_K \tan\varphi , \tag{15.31}$$

where:

D_A external diameter of the clamped parts
$D_{A,Gr}$ limiting diameter of the deformation cone

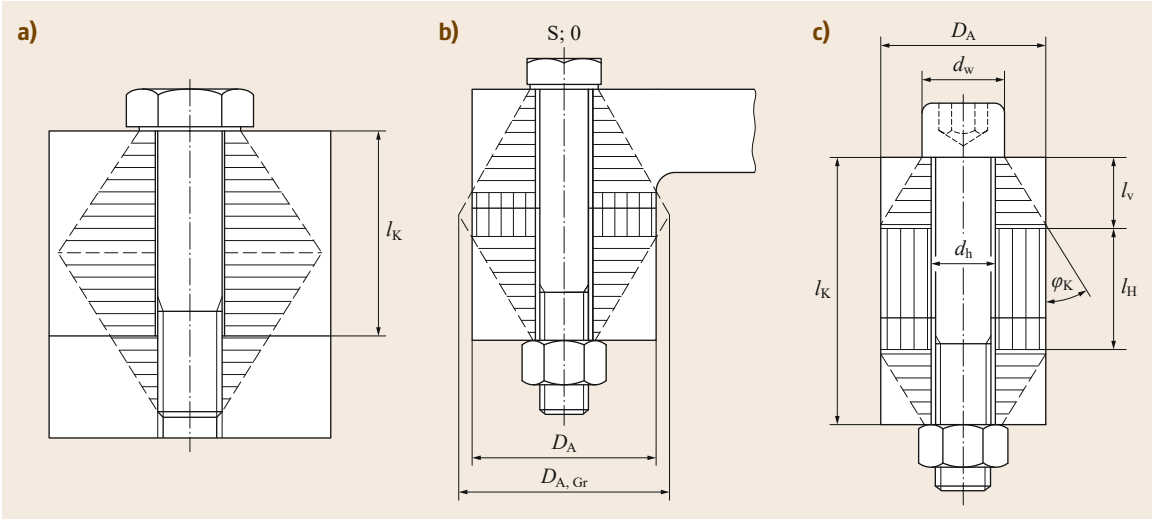

Fig. 15.32a–c Completely formed equivalent deformation cone of a screw-in joint **(a)** and through-bolted joint with deformation cone and sleeve **(b,c)** according to VDI 2230 (after [15.40])

d_w bearing diameter of the bolt head; the nut
w joint coefficient:
$w = 2$ for screw-in joints
$w = 1$ for through-bolted joints
l_K clamped length (Fig. 15.32a)
φ_K cone taper angle of the joint (15.32)

If (15.31) is not fulfilled, a deformation sleeve must be considered in addition to the deformation cone.

The angle of the deformation cone is calculated for screw-in joints as

$$\tan\varphi_{KE} = 0.348 + 0.013\ln\beta_L + 0.193\ln y$$

and for through-bolted joints as

$$\tan\varphi_{KD} = 0.362 + 0.032\ln\left(\frac{\beta_L}{2}\right) + 0.153\ln y\,, \tag{15.32}$$

where: $\beta_L = l_K/d_w$

$$y = \frac{D'_A}{d_w}$$

D'_A equivalent external diameter of the basic solid (Fig. 15.31)

The resilience of the individual deformation cone can be calculated using

$$\delta_P^V = \frac{\ln\left(\frac{(d_w+d_h)(d_w+2l_V\tan\varphi_K-d_h)}{(d_w-d_h)(d_w+2l_V\tan\varphi_K+d_h)}\right)}{E_P d_h \pi\tan\varphi_K}\,, \tag{15.33}$$

where d_h is hole diameter (Fig. 15.31) and the height of the deformation cone is

$$l_V = \frac{D_A - d_w}{2\tan\varphi_K} \le \frac{w l_K}{2}\,. \tag{15.34}$$

The resilience of the sleeve is calculated from

$$\delta_P^H = \frac{4l_H}{E_P\pi\left(D_A^2 - d_h^2\right)}\,, \tag{15.35}$$

where the height of the sleeve is

$$l_H = l_K - \frac{2l_V}{w}\,. \tag{15.36}$$

From these equations, the total resilience is

$$\delta_P = \frac{2}{w}\delta_P^V + \delta_P^H\,. \tag{15.37}$$

If several components with different moduli of elasticity are bolted together, the deformation bodies (cone and sleeve) must be broken down into corresponding partial areas $j; m$ with the same modulus of elasticity and the resilience calculated bit by bit.

In the area of the deformation cone, instead of the bolt head bearing diameter d_w, the end diameter of the adjacent cone $d_{w,i}$ is used in (15.33), where

$$d_{w,i} = d_w + 2\tan\varphi\sum_{i=1}^{j} l_{i-1}\,. \tag{15.38}$$

Furthermore, in (15.33) and (15.35) the height of the deformation body, l_V or rather l_H, is replaced by the height

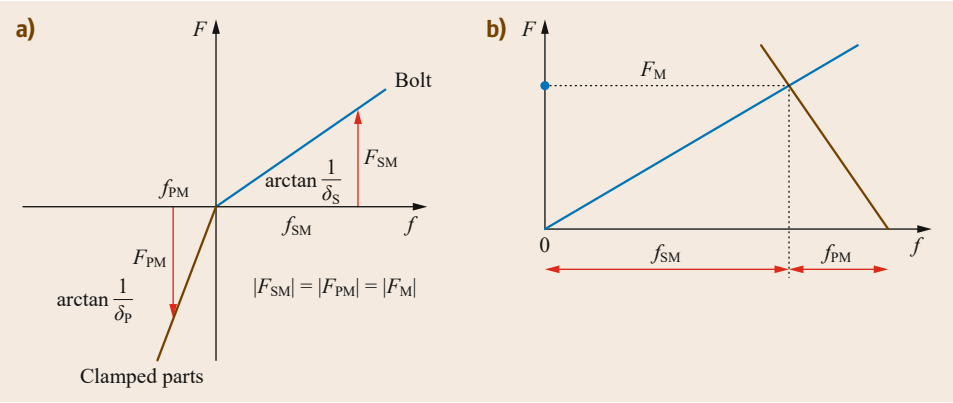

Fig. 15.33a,b Deformation characteristics of the bolt and the clamped parts (**a**) and the resulting joint diagram (**b**)

l_i of the subsegment and the modulus of elasticity E_P is replaced by E_{Pi}.

The total resilience of the clamped parts is thus

$$\delta_P = \sum_{i=1}^{j} \delta_{Pi}^{V} + \sum_{i=j+1}^{m} \delta_{Pi}^{H} . \qquad (15.39)$$

Strictly speaking, the equations given only apply to cylindrical components with centrally inserted bolts. Rectangular flanges or multiple bolt joints are assumed to be approximately cylindrical, whereby the external diameter corresponds to twice the average edge distance in the interface.

For details of how to calculate eccentric bolted joints or multiple bolt joints, reference is made to the relevant literature, for example, VDI 2230-2 [15.41].

The resilience of the bolt and of the clamped parts can be used to construct the joint diagram of the joint. First the deformations of the parts are drawn on a diagram with the correct sign (+/–) (Fig. 15.33a).

The deformation characteristic of the clamped parts is then mirrored about the abscissa (x-axis) and is moved to the right in the first quadrant, until $|F_{PM}| = |F_{SM}| = |F_M|$. The result is the joint diagram shown in Fig. 15.33b with the assembly force F_M and the resulting deformation of the bolt f_{SM}, or rather the clamped parts f_{PM}.

The relatively small bearing surfaces in the threads, underneath the bolt head, or rather of the nut in conjunction with the surface roughness in the contact zones of the joint partners leads to high surface pressures in these areas, as a result of which creep and thus relaxation of the joint occurs. The amount of relaxation is called the embedding (set) f_Z and the resulting loss of force is called the loss of preload F_Z, where

$$F_Z = \frac{f_Z}{(\delta_S + \delta_P)} . \qquad (15.40)$$

Guide values for the embedding are given in Table 15.18.

As a result of the loss of preload, the assembly force $F_{M\,min}$ of the bolt must be larger than the minimum preload required according to (15.20), so that

$$F_{M\,min} = F_{V\,min} + F_Z . \qquad (15.41)$$

The maximum assembly force $F_{M\,max}$ allows for fluctuations in the assembly force due to imprecise tightening methods or errors in the determination of the coefficients of friction. It is obtained from

$$F_{M\,max} = \alpha_A F_{M\,min} . \qquad (15.42)$$

Values for the tightening factor α_A are given in Table 15.19.

Table 15.18 Guide values for embedments of uncoated steel bolts and compact clamped parts made of steel depending on surface roughness [15.40]

Mean roughness depth R_z (µm) according to ISO 4287	Load	Guide values for embedments (µm)		
		In the thread	Per head or nut bearing	Per internal interface
< 10	Tension/compression	3	2.5	1.5
	Shear	3	3	2
10–40	Tension/compression	3	3	2
	Shear	3	4.5	2.5
40–160	Tension/compression	3	4	3
	Shear	3	6.5	3.5

Table 15.19 Guide values for tightening factor α_A

α_A	Use
1.1–1.2	With the most precise tightening method (e.g., checking the change in bolt length)
1.25–1.8	Tightening with torque wrench
1.8–2	Tightening with controlled impact wrench
2.5–4	Tightening by hand or with impact wrench

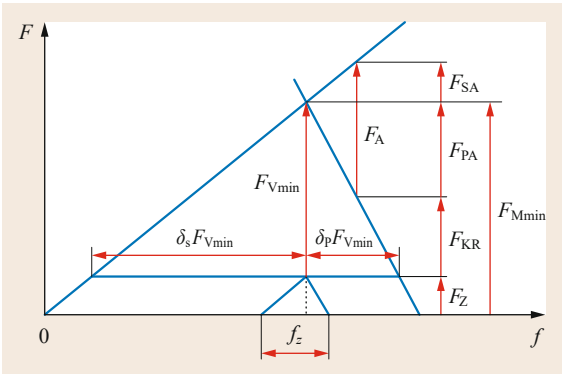

Fig. 15.34 Joint diagram showing the main dimensional variables acting

If a preloaded bolted joint is additionally loaded by an axial working load F_A directly underneath the bolt head, or rather the nut is tensioned, the bolt extends further by the amount f_{SA}, which causes the upsetting (compressive strain) of the clamped components to reduce by the same amount f_{PA} (Fig. 15.34).

The increase in axial bolt force due to the working load is called the additional bolt load F_{SA}:

$$F_{SA} = \frac{\delta_P}{\delta_S + \delta_P} F_A = \Phi F_A \,, \tag{15.43}$$

where the term Φ is the simplified dimensionless force ratio and

$$\Phi = \frac{\delta_P}{\delta_S + \delta_P} \,. \tag{15.44}$$

While the bolt is subjected to additional loading due to the working load, the clamped parts are relieved by F_{PA}:

$$F_{PA} = F_A - F_{SA} = (1 - \Phi)\, F_A \,. \tag{15.45}$$

As a result of the relieving of the clamped parts, the clamping force between them also reduces. The remaining residual clamp load is given by

$$F_{KR} = F_V - F_{PA} = F_V - (1 - \Phi)\, F_A \,. \tag{15.46}$$

The maximum bolt load (before embedding) is given by

$$\begin{aligned} F_{S\,max} &= \alpha_A\,(F_V + F_Z) + F_{SA} \\ &= F_{M\,max} + F_{SA} \,. \end{aligned} \tag{15.47}$$

In practice, the working load does not generally act directly underneath the bolt head or rather the nut, as shown in Fig. 15.35a. In most cases the load application point is in the area of the clamped parts, so that these are only partly relieved, while the compressive load increases in the remaining part (Fig. 15.35b,c). As a result of the load application point shifted from the ideal point, the resilience of the bolt appears to be larger, while the resilience of the clamped parts is smaller.

The type of load introduction is taken into account in the calculation by the dimensionless load introduction factor n, such that

$$\Phi = n\Phi_K \,, \tag{15.48}$$

where Φ_K is the simplified force ratio (15.44).

For the special case of load introduction directly underneath the bolt head, $n = 1$, so $\Phi = \Phi_K$. The force introduction factors for clamping cases deviating from this are given in Table 15.20, whereby the following points apply:

- The plates must have the same modulus of elasticity.
- The joint must be able to be classified as a joint type in Fig. 15.36 with regard to the position of the interface and load introduction point.

For rough bolt dimensioning of transversely loaded bolts, $n = 1$ can be assumed, as the resulting bolt load is highest in this case.

The assembly force required for the joint is generated by tightening the bolt with an appropriate *tightening torque* (wrench torque) M_A.

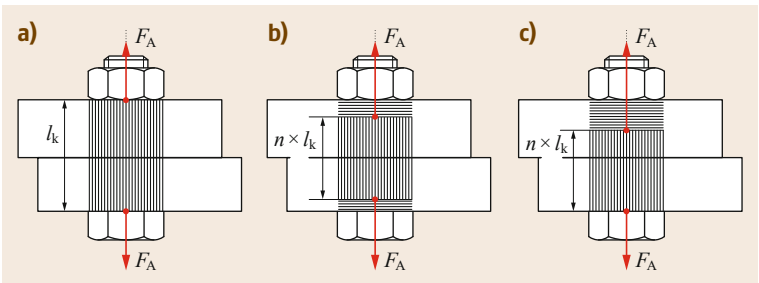

Fig. 15.35a–c Load introduction in the clamped parts: **(a)** simplified case, **(b,c)** general cases

Table 15.20 Guide values for load introduction factor n depending on the joint type SV and the dimensions of the bolted joint according to VDI 2230 [15.40]. For an explanation, see Fig. 15.36

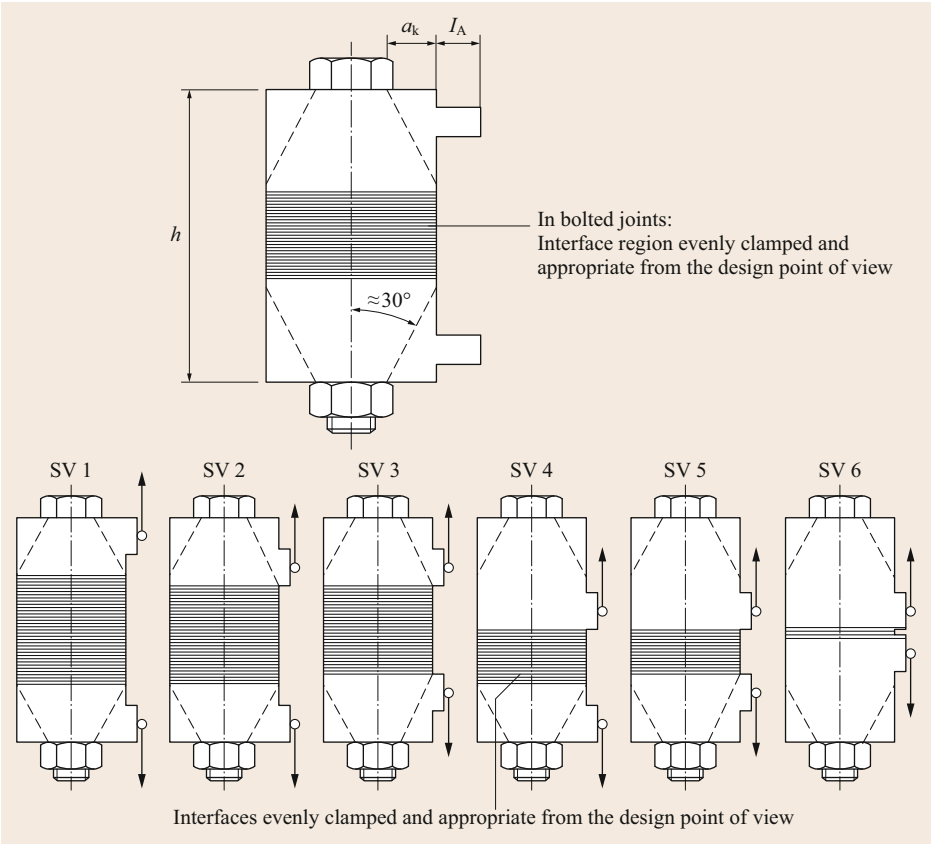

Fig. 15.36 Joint type and parameters for determining the load introduction factor according to VDI 2230 (after [15.40])

The tightening torque M_A is made up of

$$M_A = M_G M_K \,, \tag{15.49}$$

where:

M_G friction moment (friction torque) in the screwed-in thread
M_K bearing friction moment (torque) in the contact area between the bolt head, or rather the nut, and the parts to be bolted

The friction torque in the thread is given by

$$M_G = F_{M\max} \frac{d_2}{2} \tan\left(\phi \pm \rho'\right) , \tag{15.50}$$

where:

d_2 pitch diameter of the thread
φ pitch angle (helix angle) of the thread (15.19)
ρ' friction angle of the thread

The plus sign in (15.50) applies to the tightening and the minus sign to the undoing of the bolt.

Table 15.21 Thread coefficients of friction μ_G after *Schlecht* [15.42]

Thread					External (bolt)								
Thread	Material				Steel								
	Material	Surface			Black tempered or phosphated				Electrolytically galvanized		Electrolytically cadmium plated		Adhesive
		Surface	Production		Rolled			Cut	Rolled and cut				
			Production	Lubrication	Dry	Oiled	MoS_2	Oiled	Dry	Oiled	Dry	Oiled	Dry

		Electrolytically galvanized			0.10 – 0.16	–	–	–	0.12 – 0.20	0.10 – 0.18	–	–	0.14 – 0.25
		Electrolytically cadmium plated			0.08 – 0.14	–	–	–	–	–	0.12 – 0.16	0.12 – 0.14	–
	Grey-/-malleable iron	Blank			–	0.10 – 0.18	–	0.10 – 0.18	–	0.10 – 0.16	–	0.08 – 0.16	–
	Al/Mg	Blank			–	0.08 – 0.20	–	–	–	–	–	–	–

The friction angle of the thread is a notional variable and results from the coefficient of friction in the thread μ_G (Table 15.21) and the flank angle of the thread α.

$$\tan \rho' = \mu'_G = \frac{\mu_G}{\cos\left(\frac{\alpha}{2}\right)} \tag{15.51}$$

Threaded fasteners must be self-locking so that they do not undo themselves. The thread is self-locking if the pitch angle φ of the thread is smaller than the thread friction angle ρ', i.e., $\varphi < \rho'$.

For a metric ISO thread with flank angle 60°, $\mu'_G \approx 1.155\mu_G$. Thus (15.50) can be rearranged to

$$M_G = F_{M\,max}\,(0.16P + 0.58 d_2 \mu_{G\,min})\,, \tag{15.52}$$

where P is the thread pitch (15.19) and $\mu_{G\,min}$ is the smallest coefficient of friction in the thread.

The bearing friction torque M_K is calculated from the assembly force $F_{M\,max}$ on tightening the bolt:

$$M_K = F_{M\,max}\frac{(d_W + D_{Ki})}{4} = F_{M\,max}\frac{D_{Km}}{2}\mu_K\,, \tag{15.53}$$

where

d_W external diameter of the bolt head or nut bearing ($d_W \approx 1.4d$)
D_{Ki} internal diameter of the flat (planar) head bearing
D_{Km} mean bearing diameter at the nut or at the bolt head ($D_{Km} \approx 1.3d$ for metric hexagon head and head cap bolts and screws)

μ_K coefficient of friction ($\mu_K \approx 0.12$ for the normal case or similar to μ_G according to Table 15.21)

The thread torque M_G and the bearing friction torque M_K can be used to calculate the tightening torque (bolt torque):

$$M_A = M_G + M_K \tag{15.54}$$
$$= F_{M\,max}\left(\frac{d_2}{2}\right)\tan\left(\phi \pm \rho'\right) + F_{M\,max}\,\mu_K\frac{D_{Km}}{2},$$

$$M_A = F_{M\,max}\left(0.16P + 0.58d_2\,\mu_{G\,min} + \frac{D_{Km}}{2}\mu_K\right). \tag{15.55}$$

Due to the scatter of the coefficients of friction (Table 15.21), when calculating tightening torques or when tightening screws and bolts, it should be borne in mind that with low coefficients of friction the same tightening torques can produce substantially larger preloads (bolt stresses) and with high coefficients of friction small preloads can result.

The assembly preload $F_{M\,max}$ causes a tensile stress $\sigma_M = F_{M\,max}/A_0$ in the loaded stress cross section (or shank cross section) $A_0 = A_{min}$.

As a result of the thread torque M_G according to (15.55), a torsional stress $\tau_t = M_G/W_t$, where $W_t \approx \pi d_{min}^3/16$ is introduced into the bolt cross section.

According to the maximum shear strain energy hypothesis, this leads to an equivalent stress $\sigma_V = \sigma_{red}$:

$$\sigma_v = \sigma_{red} = \sqrt{\sigma_M^2 + 3\tau_t^2}\,. \tag{15.56}$$

In general, on tightening the bolted joint the maximum strength of the bolt is not utilized and this prevents exceeding the yield point in the service case. Usually, 90% of the yield point is used as the limit value, so that

$$\sigma_{red} \le 0.9R_{p0.2}\,, \tag{15.57}$$

where $R_{p0.2}$ is the elasticity limit of the bolt material (Tables 15.24 and 15.25).

Furthermore, it must also be checked that the increase in bolt load as a result of the working load does not lead to plastic deformation:

$$F_{AS} = n\Phi_K F_A \le 0.1R_{p0.2}A_0\,. \tag{15.58}$$

In addition to the allowable stresses in the bolt, the surface pressure on the bearing surfaces of the bolt head, or rather the nut, and the clamped parts must also be checked. In the assembled state this is done by calculating

$$p_{M\,max} = \frac{F_{M\,max}}{A_{p\,min}} \le p_G\,. \tag{15.59}$$

Table 15.22 Allowable limit surface pressures (interface pressures) (after *Wittel* et al. [15.2])

And in the service state

$$p_{B\,max} = \frac{(F_{V\,max} + F_{SA\,max})}{A_{p\,min}} \le p_G\,, \tag{15.60}$$

where $p_{M\,max}$ is the maximum surface pressure immediately after installation of the bolt, $p_{B\,max}$ is the maximum surface pressure under service load, $A_{p\,min}$ is the minimum contact area, p_G is the allowable surface pressure on the boundary surfaces (interfaces) (VDI = limit surface pressure) (Table 15.22), $F_{V\,max}$ is the maximum preload of the joint, and $F_{SA\,max}$ is the maximum additional bolt load.

The nominal diameter of bolts and screws depending on the strength class is estimated according to Table 15.23, in conjunction with the Fig. 15.37.

First, using the axial and/or transverse forces (loads) acting on the bolt $F_{A,Q}$, the next highest load is looked for in the first column of Table 15.23. Depending on the load case and assembly method, the choice must then be shifted a certain number of rows down. The sum of the

Table 15.23 Preselection of screws and bolts according to VDI 2230-1 (after [15.40])

1 Force $F_{A,Q}$ (N)	2 Nominal diameter (mm) Strength class 12.9	3 10.9	4 8.8
250			
400

250 000	24	27	30
400 000	30	36	
630 000	36		

rows to be moved down can be determined using the flow chart in Fig. 15.37. The necessary bolt diameter, depending on the bolt's strength class, is found in the corresponding row, in columns 2–4.

Example 15.1

A bolted joint tightened with a torque wrench must withstand an eccentric, static axial load of 10 000 N and an additional transverse force of 5000 N. The screw has strength class 10.9.

Solution 15.1

According to Table 15.23, the next highest load is 10 000 N (row 9).

$$\frac{F_{Q\max}}{\mu} = \frac{5000\,\mathrm{N}}{0.15} = 3333.3\,\mathrm{N} < F_A = 10\,000\,\mathrm{N}$$

From the flow chart, for this load case (static and eccentrically acting axial load), one row must be skipped.

In addition, due to the assembly using a torque wrench, the row selection must be moved downwards by an additional row.

Thus, the selection (row 9) must be moved downwards by an additional two rows, which gives row 11.

Thus, the necessary bolt diameter for the selected strength class (10.9) is 10 mm.

Bolts, screws, and nuts made of steel are classified in strength classes depending on the material strength. The strength classes for bolts and screws made of steel and alloyed steel with metric thread according to ISO 68-1 [15.44] are defined in EN ISO 898-1 [15.43] (Table 15.24).

The strength class of hexagon head screws and bolts and hexagon socket head cap screws and bolts is marked by two numbers separated by a dot on the top of the screw or bolt head. The first number indicates one hundredth of the minimum tensile strength R_m in N/mm^2. The second number stands for 10 times the ratio R_e/R_m, or rather $R_{p0.2}/R_m$.

Table 15.24 Strength classes, materials, and mechanical properties of screws, bolts, and studs according to EN ISO 898-1 (excerpt) [15.43]

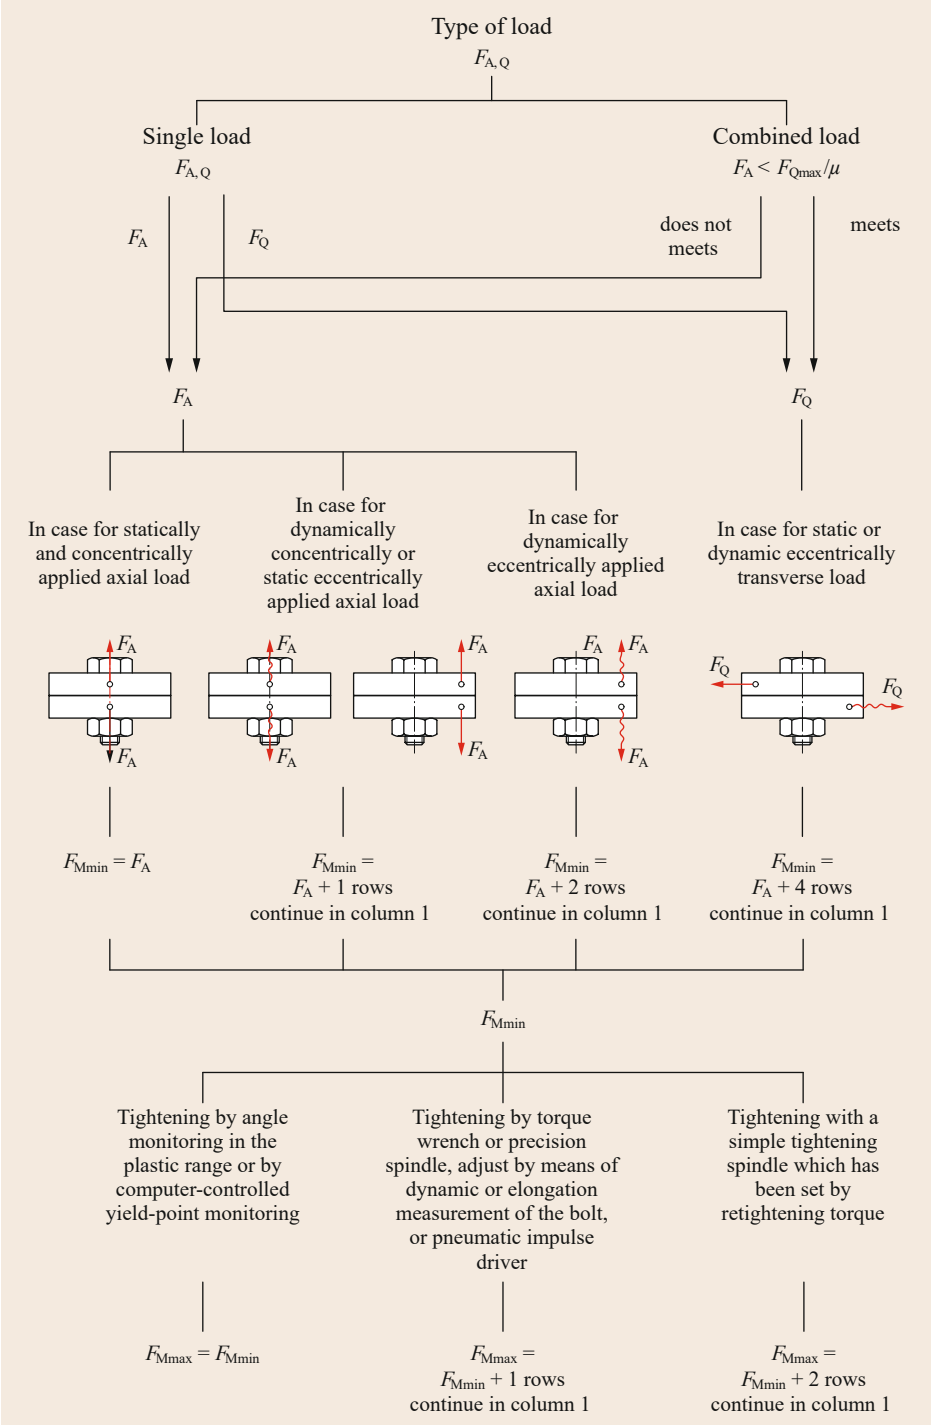

Fig. 15.37 Flow chart for rough screw/bolt selection according to VDI 2230-1 (after [15.40])

Example 15.2

An example of the strength class

Strength class 5.6:

$$R_m = 5 \times 100 = 500\,\mathrm{N/mm^2}$$

$$R_{e;p0.2} = 0.6R_m = 0.6 \times 500\,\frac{\mathrm{N}}{\mathrm{mm^2}} = 300\,\frac{\mathrm{N}}{\mathrm{mm^2}}\,.$$

Several different specifications, some of which are similar, exist in parallel for imperial and inch-measure screws and bolts. The individual strength classes are marked on the screw or bolt head by a marking system, whereby the corresponding strength values are given in the relevant tables (Table 15.25).

Design Guidelines for Bolted Joints. A small selection of examples of unfavorable and favorable designs of bolted joints is shown in Table 15.26.

Screw-/Bolt-Locking and Accessories. Dynamically loaded bolted joints must be locked to prevent them from loosening themselves. This can be done by using form closure, force closure or material-bonding screw or bolt locking.

Force-closure locking elements are spring-loaded components, whose spring load provides additional axial clamping force in the bolted joint and as a result increases the force closure (e.g., split washers, spring lock washers, and lock nuts) (Fig. 15.38a–c). Force-closure bolt locking is also achieved by *locking* (clamping against each other) two nuts.

Form-closure locking elements immobilize the nut or bolt head through their shape or deformation (Fig. 15.38d,e).

Material-bonding locking is achieved by adhesive bonding of the bolt thread with the help of special adhesives (threadlockers) or by coating the bolt with special plastics in the factory.

These coloaded elements are partly standardized as accessory components for bolted joints.

If the material of the bolted parts is very soft, the pressure on the bearing surfaces of the components can be reduced by using (plain) *washers*.

15.2.4 Material-Bonded Joints

Material-bonded joints include, for example, adhesive bonding, welding and, soldering joining methods. What they have in common is that the parts to be joined (components) are permanently bonded together, either directly or by means of an additional substance. In general, undoing such joints involves damaging or destroying the components or rather the additional material.

Table 15.25 Strength classes for inch-measure screws and bolts according to SAE [15.45] and ASTM [15.46] (excerpt)

Grade identification marking/head marking										
									307A	307B

Table 15.26 Design examples for bolted joints

No.	Unfavorable	Favorable	Comments
1	a)  	b)  c)  d) 	In the case of blind-hole threaded fasteners, the highest stress concentration for the nut thread is at the end of the threaded bolt. There is thus a risk of fatigue failure of the nut thread under dynamic loading. The stress peaks in the nut thread can be dissipated by various measures: b) Protruding bolt thread, overhang $\geq 2P$ c) Rounded cylindrical counterbore and protruding bolt thread d) Reboring/drilling out of the threaded bolt
2	a)  b)  	c)  d) 	The nuts and bolt heads should have a bearing surface perpendicular to the bolt axis, as otherwise additional bending stresses occur in the bolt shank: $\sigma_b = adE/(2l)$ If a skewed head bearing is unavoidable, e.g., due to component deformation (b), flexible bolts (d small, l large) are favorable. The flange inclination of sections can be levelled out by square washers, e.g., by using tapered washers for U-sections according to DIN 434 or tapered washers for I-sections according to DIN 435 (c). In the case of cast parts, counterbores according to DIN 974 or machine cut eyes are to be provided (d).
3	a)  	b)  	In the case of high stresses the fatigue life can be improved by the following measures: – Greater elastic resilience of the bolt (δ_s large) – Moving the working load application point towards the interface (n small)

Table 15.26 (continued)

No.	Unfavorable	Favorable	Comments
4	a)  	b)  c)  	If clamped with metal screws or bolts, plastic components creep under gradual loss of the preload or the bolt or screw cracks as a result of the large thermal elongation of the plastic. The following measures can be taken: b) By using coloaded spring lock washers or conical spring washers the preload is largely maintained, even after creep has occurred and in changing temperatures. c) Metallic support sleeves transfer the preload.
5	a) 	b)  	Due to the overlapping of the pressure cone that forms in the component under prestress, a continuous force flow results in the interface. This leads to low additional bolt loads, good sealing, and prevention of fretting corrosion (frictional corrosion). The bolt spacing should roughly equal the component height: $\approx d_W + h_{min}$

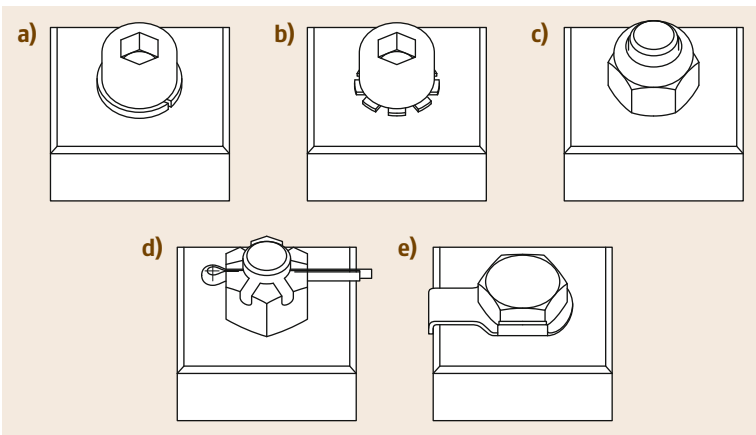

Fig. 15.38a–e Locking elements: **(a)** bolt with split washer, **(b)** bolt with toothed lock washer, **(c)** nut with clamping part, **(d)** castellated nut with split pin, and **(e)** tab washer with long tab

Table 15.27 Advantages and disadvantages of adhesive joints

Advantages	Disadvantages
Different materials can be joined	Joint not nondestructively separable
Faces of very thin components can be joined	Low thermal endurance
Joining of heat-sensitive components is possible	Low peeling strength
High stiffness due to continuous, uniformly distributed load transfer via joined surfaces	The surface often requires pretreating before bonding
Joint has vibration damping effect	Only limited resistance to environmental effects and chemicals
If executed properly, no internal (residual) stresses in the joined components	Volume reduction when liquid adhesives set or harden
Uniform stress distribution when loaded (Fig. 15.39)	Adhesives or rather their solvents can be harmful
Joint is gas- and/or liquid-tight	
Very good gap bridgeability (rough tolerancing possible)	
Depending on the adhesive selection, the joint can be electrically insulating or conductive	
In general, cost effective and easily automatable	

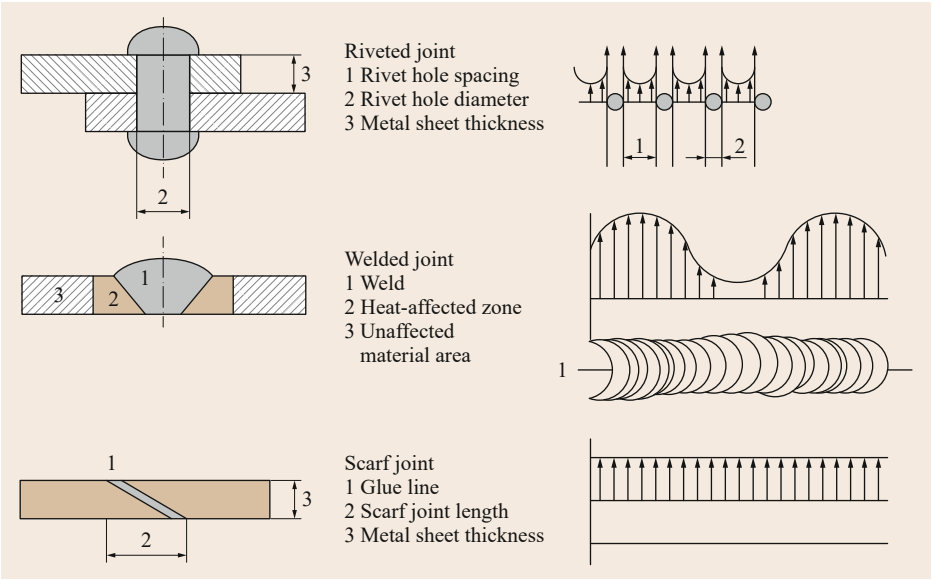

Fig. 15.39 Comparison of the stress distribution in riveting, welding, and adhesive bonding

Adhesive Bonding

In the case of adhesive bonding, components (mostly flat) are joined with the help of an adhesive, with the objective of transferring forces (loads) and/or achieving a sealing effect.

According to EN 923 [15.47], an adhesive is a "non-metallic substance capable of joining materials by surface bonding (adhesion), and the bond possessing adequate internal strength (cohesion)."

Adhesive bonding is one of the oldest jointing methods. Even in the Stone Age, people used natural adhesives such as tree gum or pitch to join together materials. The advantages (Table 15.27) of adhesive bonding, particularly the possibility of quickly and reliably bonding together different materials (composite construction), the easy automatability, and the development of special high-strength and aging-resistant adhesives mean that adhesive joints are still a modern jointing method and are used industrially to an ever-increasing extent.

Adhesive joints are now used on a large scale, among other things, to produce packaging in the consumer goods industry, in the wood-processing industry, and also to an increasing extent in vehicle manufacturing.

The adhesives used industrially nowadays are generally made of synthetically produced polymers. They can be divided into physically setting adhesives and chemically reacting adhesives, depending on their type of solidification mechanism.

Table 15.28 Areas of application of standard adhesives (excerpt)

Adhesive type	Hardening/curing	Use/special features	Chemical resistance	Service temperature (°C)	Tensile shear strength (N/mm^2)
Anaerobic adhesive	Hardens in absence of air (oxygen) in the presence of metal irons	Adhesive bonding of metallic components (e.g., shaft–hub connection, threadlocker) An activator may have to be used for passive metal surfaces (chrome or stainless steel) or plastics	Good	−55…200	Up to 30
Cyanoacrylate (superglue)	Hardens due to humidity or surface moisture Very fast hardening	Frequently used instant adhesive Metals, plastics (e.g., PMMA, POM, ABS, H-PVC, PS, NBR, EPDM) Conditionally suitable for bonding glass Adhesive joint is very brittle and can only withstand low mechanical load	Poor	−30…100	Up to 20
Silicone adhesive	Interlinking due to humidity or through the addition of hardener	Above all as sealants and as adhesive for glass Very good gap bridging Permanently elastic		−55…180	< 1
Epoxy resin (1-component)	Hardening takes place by application of heat	For bonding load-bearing structures made of metal, plastic or ceramic	Very good	−50…200	Up to 29
Epoxy resin (2-component)	Curing achieved by adding a curing agent (hardener)	Good bridging of gaps	Good	−50…130	Up to 40
Polyurethane adhesive (2-component)	Curing achieved by adding a curing agent (hardener)	Suitable for adhesive bonding of metal, wood, and plastic Good gap bridgeability Suitable for large area bonding	Medium	−40…100	Up to 25
Radiation curing plastics	By UV radiation	Suitable for metals, plastics, ceramics, and glass	Good	−40…100	Up to 25

Physically setting adhesives solidify by:

- Volatilization of solvent/dispersant (solvent-borne adhesive/dispersion adhesive)
- Melting and subsequent solidifying of the polymer (hot-melt adhesive)
- Gelling of a mixture of powdered thermoplastic polymers and liquid plasticizers through the addition of heat (plastisols)

Chemically reacting adhesives solidify due to a reaction of mostly one- or two-component systems at room temperature or at increased temperatures.

The technical properties and thus the possible uses of modern adhesives are vary widely. They are often especially adapted to the application case. A rough overview of industrially used adhesives is given in Table 15.28, whereby it should be noted that depending on the composition, the properties can vary within a wide framework. For this reason, refer to the corresponding data sheets of the manufacturers for precise information.

The strength of the adhesive joint decisively depends on the adhesive forces between the adhesive and the components to be joined. Although adhesives are now available that can be applied directly onto oily metal sheets, in general the surfaces must be cleaned and pretreated before joining. The adhesive forces can be increased, for example, by roughening or pickling the bond planes.

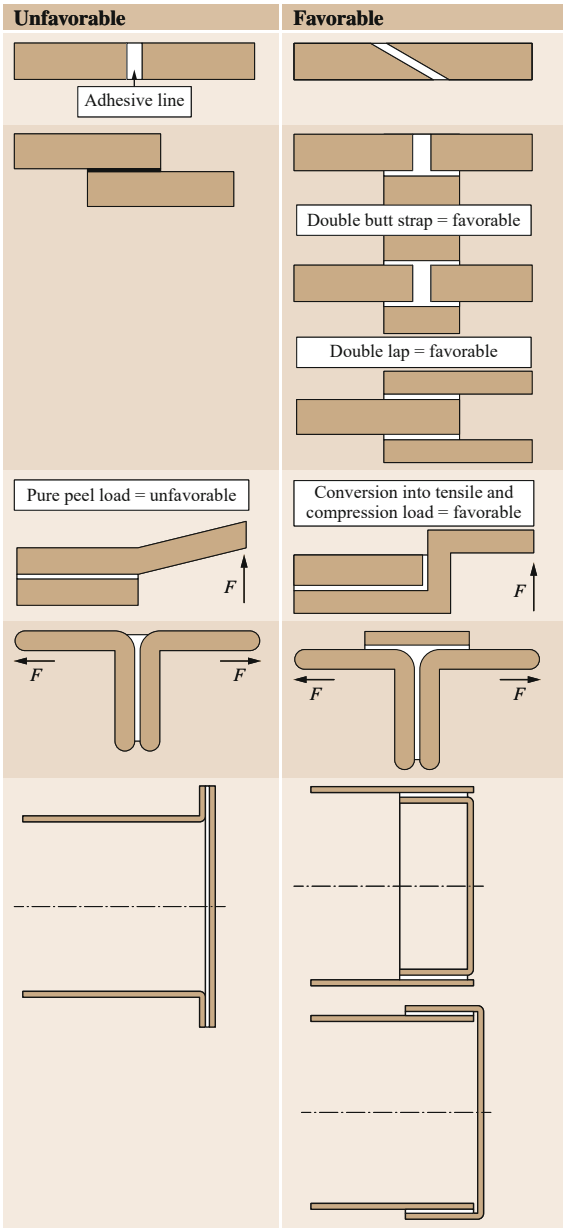
The wettability of plastic surfaces can be problematic due to their low surface energy. The wettability of plastics can be improved by treating them with reactive gases (for example ozone or fluorine), plasmas, or by flame treatment.

The special properties of adhesive bonds must be taken into consideration in their design. For example, adhesive bonds respond very sensitively to peel loading. Table 15.29 shows examples of appropriate, process-compatible designs of the adhesive joints.

Welding

In welding, the parts to be joined and the optional filler material made of similar materials are melted. They form a joint melt and solidify together during subsequent cooling, as a result of which a permanent bond is formed. The welding process can be assisted by using

Table 15.29 Design examples for adhesive joints



welding auxiliaries (e.g., powder, pastes, or gases). The energy (heat) required for melting the materials can be provided directly by using gas flames, arcs, or radiation or indirectly by, for example, electrical current or friction heat.

Both metallic and nonmetallic materials (e.g., plastics and glass) can be bonded together.

Soldering

Soldering is a process characterized by the fact that a metallic filler material (solder) with a melting point significantly lower than that of the materials to be joined is used to join metallic components and the joint can form by adhesion and diffusion mechanisms.

Soldered joints can be undone under certain circumstances by melting the filler metal.

Apart from the different soldering methods, soldering is also divided into hard soldering and soft soldering.

In *hard soldering (brazing)* (at operating temperatures up to 1100 °C) joints must be achieved that satisfy certain strength requirements.

In *soft soldering* (at operating temperatures below 450 °C) the focus is on the sealing and/or electric conducting properties of the soldered joint. The strength requirements of the joint are secondary. It can be undone by melting the solder.

15.2.5 Further Reading

Further details on the calculation of fasteners and jointing compounds are given, for example, by *Spotts* et al. [15.48], *Wittel* et al. [15.2], *Niemann* et al. [15.24] and *Schlecht* [15.42]. VDI guidelines 2230-1 [15.40] and 2230-2 [15.41] are the standard works for the calculation of fixing screws and bolts.

Information on individual welding procedures is given in *Matthes* and *Schneider* [15.49]. Details of the design of welded joints in structural steelwork are given in the Eurocode EN 1993-1-8 [15.50].

The adhesive bonding manual by *Rasche* [15.51] describes further literature on the topic.

15.3 Axles and Shafts

The primary task of axles and shafts is the storage of rotating machine elements such as rollers, wheels, or joints.

15.3.1 Standard Types

Axles

Axles are used to hold and support stationary, rotating, and swinging machine parts, for example, wheels or pulleys. By definition, they do not transfer torque. They are mainly loaded by transverse forces and bending moments. Longitudinal forces rarely occur.

A differentiation is made between fixed and rotating axles. In the case of fixed axles, mounted components rotate loosely on the fixed axle. Therefore, the loading and stresses are generally only caused at rest or repeated (cyclic, pulsating) by shear from the transverse forces and by bending. Rotating axles are defined by the fixed components, which turn with the bearing-mounted axle. The loading and stresses result from alternating and rotating bending. As a result of this, rotating axles with the same shape and material have less load-bearing capacity than a fixed axle.

Shafts

Shafts are rotating components used to transfer torque. The loads are caused by torsion, transverse forces, and bending moments. Additional longitudinal forces can occur in certain transmission elements, such as bevel gears or helical spur gears.

Journals

A journal is the name given to stepped axle and shaft ends, which are used for support and bearing. These elements can be cylindrical, conical, and spherical.

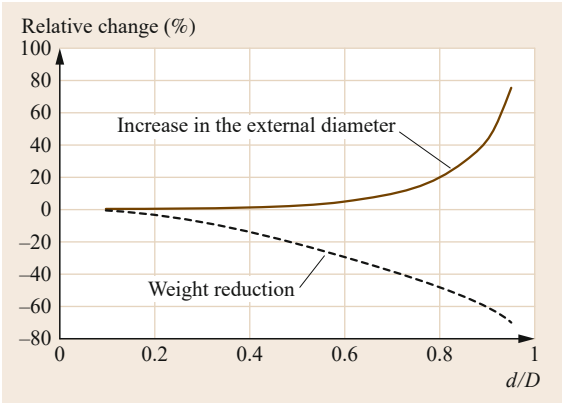


Fig. 15.40 Comparison of solid shaft and hollow shaft

15.3.2 Special Types

Hollow Shafts and Axles

Axles and shafts with a through-hole are called hollow axles or hollow shafts, respectively.

The load-bearing capability of shafts under bending and torsion increases with the cube of the diameter. Due to the nonuniform distribution of the bending and torsion stress, the internal area of the shaft volume of a solid shaft is hardly used for the load-bearing capacity, however it increases the component weight noticeably. From this it follows that hollow shafts with the same load-bearing capacity have a lower weight than solid shafts. In this special type, if the strength remains constant, as the ratio d/D increases the increase in the external diameter is far smaller than the reduction in weight (Fig. 15.40). For example, for the ratio $d/D = 0.6$; the weight G of the hollow shaft is 30% less than the solid shaft. However, the diameter D increases by only approximately 5%. One disadvantage

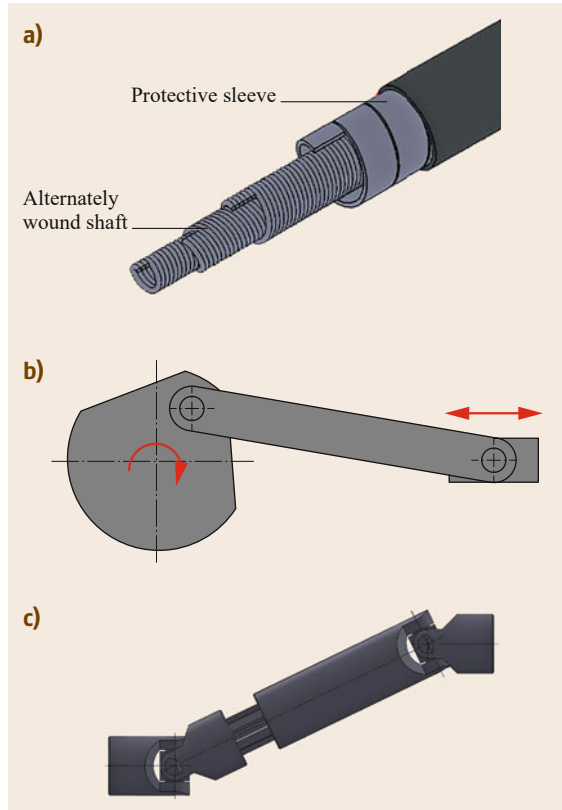

Fig. 15.41a–c Special types of shafts: **(a)** flexible shaft, **(b)** crankshaft, and **(c)** cardan shafts

of the hollow shaft compared to the solid version is the amount of production work, cost, and disadvantageous stress distribution in force-closure shaft–hub connections.

Other Special Types of Shafts

Flexible shafts are used to drive movable tools with fixed drives and low torques. Crankshafts are used to convert translational movement into rotational movement. Cardan shafts are used to transfer torques at nonaligned shaft ends. The different special types of shafts are shown in Fig. 15.41.

15.3.3 Materials for Axles and Shafts

In addition to strength, the choice of material is influenced by other factors such as wear and corrosion resistance as well as high-temperature strength. Table 15.30 shows the standard materials used in practice for different application cases.

15.3.4 Design Calculation

The main load on axles occurs as a result of bending. The rotational bending must be considered for rotating

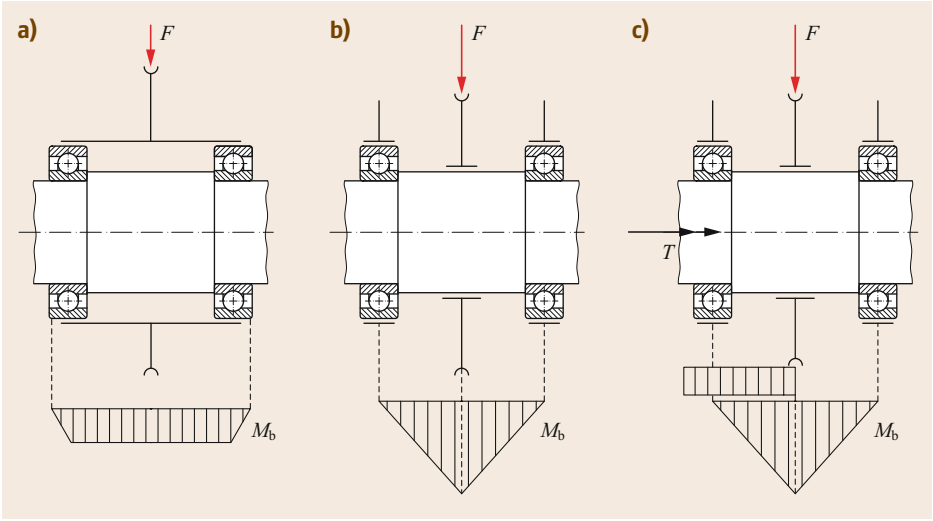

Fig. 15.42a–c Different loading of axles and shafts. **(a)** Rope pulley with stationary axle (static bending), **(b)** rope pulley with rotating axle (rotating bending), and **(c)** belt pulley with drive shaft (torsion and bending)

axles. Shear can be the priority loading of very short axles. In general, the main loading of shafts is caused by torsion (Fig. 15.42).

Careful analysis of the loading conditions is generally indispensable, as the application of torsional moments and transverse forces can vary greatly.

Frequent causes of loading:

- Driving power (torque)
- Vibrations:
  - Inertia forces
  - Imbalances
- Preloading and circumferential forces of belts and chains (radial forces)
- Service factors:
  - Acceleration and braking
  - Drive and load characteristics
- Foundation vibrations
- Temperature effect

A differentiation is made between two cases for the calculation of the given torque:

a) If the installation space for the shaft is predefined by the overall design, the bearing spacing is known and thus the bending moment can be determined.
b) If the installation space is unknown, the bearing spacing is determined by the shaft to be designed and the bending forces are initially unknown.

In case b) the diameter can thus only be determined temporarily in a rough calculation. The precise calculation is performed after the details have been defined (e.g., bearing spacing).

Determination of the Torques and Bending Moments

The nominal torque of a shaft to be transferred is formed as the quotient of the power to be transferred P and the angular velocity $\omega = 2\pi n$:

$$T_{\text{nom}} = \frac{P}{\omega} \,. \tag{15.61}$$

Equation (15.61) can be expressed as a numerical value equation with T_{nom} in Nm, P in kW, and n in min^{-1} as follows:

$$T_{\text{nom}} \approx 9550 \frac{P}{n} \,. \tag{15.62}$$

The action forces (belt and tooth forces) must be determined based on the maximum torsional moment. The reaction forces (bearing forces) must be determined for all cases. The following simplifications are to be taken into consideration:

- External forces are applied as point loads.
- In the case of long hubs, the load is assumed to be uniformly distributed.

In Fig. 15.43 the forces and moment diagrams of a shaft with straight-cut spur gears are shown highly simplified (all forces lie within one plane and only tangential forces act on the teeth).

If the action forces do not lie within one plane they must be resolved vectorially. If additional axial forces act (e.g., on helical gears), as a result of the *tilting effect*, these produce an additional radial tilting moment with a corresponding radial bearing force, which must also be considered.

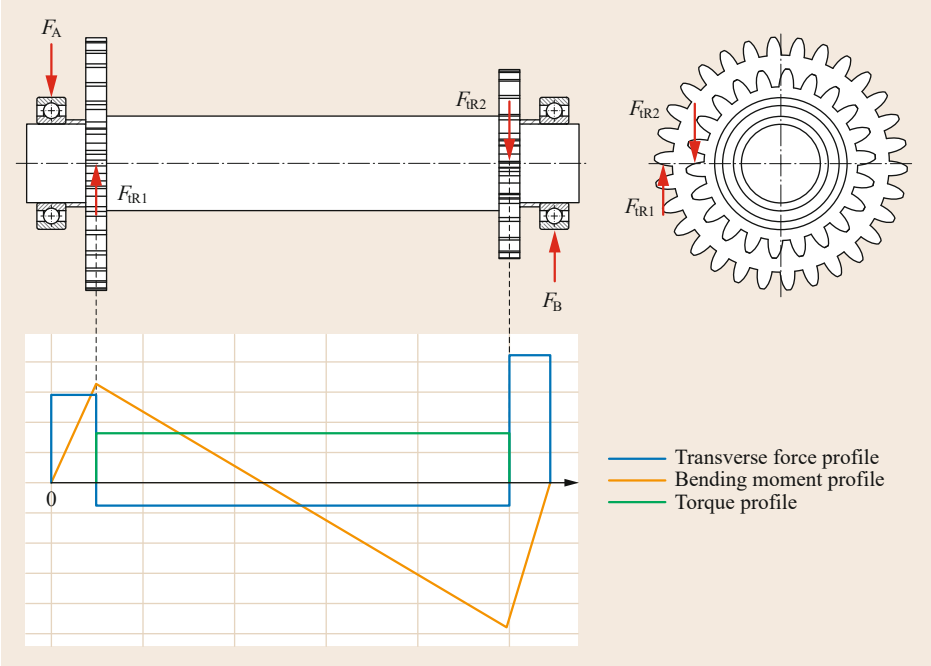

Fig. 15.43 Forces and moment diagrams of a shaft with straight-cut spur gears (simplified representation)

Determination of the Diameter

The allowable and actual loads and stresses are decisive for the dimensioning of the diameter of axles and shafts. However, under certain circumstances the deformations (twist angle or deflections) or the speeds (Sect. 15.3.5, *Critical Speed*) can be decisive for the definition of the diameter and require an adjustment. These aspects must be considered especially if higher requirements are set for the running accuracy and for longer shafts.

Determination of the Diameter from Bending (Axles). The maximum bending stress in cylindrical axles is calculated from the maximum bending moment $M_{b\,max}$ and the section modulus W_b under pure bending (mostly assumed, as longitudinal forces generally have only a small influence):

$$\sigma_{b\,max} = \frac{M_{b\,max}}{W_b} \le \sigma_{b\,all} \,. \tag{15.63}$$

The minimum diameter d required for the cylindrical axle is calculated with the help of the axial section modulus $W_b = \pi d^3/32$ from

$$d \ge \sqrt[3]{\frac{32M_b}{\pi\sigma_{b\,all}}} \approx 2.17\sqrt[3]{\frac{M_b}{\sigma_{b\,all}}} \,. \tag{15.64}$$

The allowable bending stress $\sigma_{b\,all}$ is determined as a rough estimate depending on the type of loading and the existing influencing variables (e.g., notch effects).

Table 15.31 Indicative values for allowable bending stress (after *Niemann* et al. [15.24])

Stationary axles	$\sigma_{b\,all} = \sigma_W/(1.2\ldots2)^a$
Rotating axles	$\sigma_{b\,all} = \sigma_W/(1.8\ldots4)^a$

[a] Smaller values apply to light service; larger values apply to heavy-duty service

Indicative values for the allowable bending stress are shown in Table 15.31.

To save material and weight for heavy-duty axles and shafts that are mainly subjected to bending, in accordance with (15.65), they can also be executed as a beam with the same strength.

$$d \ge \sqrt[3]{\frac{32M_{bx}}{\pi\sigma_{b\,all}}} \approx 2.17\sqrt[3]{\frac{F_A x}{\sigma_{b\,all}}} \tag{15.65}$$

If (15.65) is applied throughout, a body of revolution results, which is bound by a cubic parabola (Fig. 15.44).

The surface pressure in the bearing points must be handled in the same way as in a bolted joint (Sect. 15.2.2).

Determination of the Diameter from the Torsional Load (Shafts). Pure torsional loading of shafts is rare, as additional bending is often present. The maximum torsional stress in solid cylindrical shafts is calculated from the torsional moment T and the polar section mod-

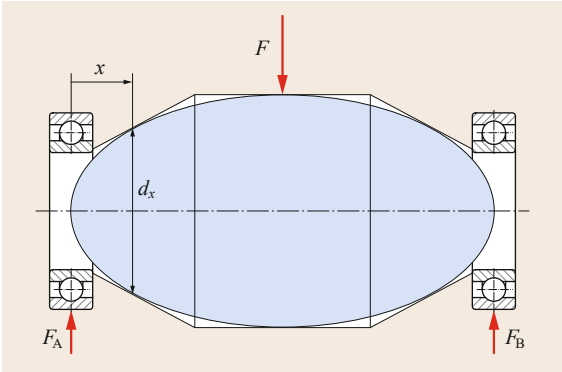

Fig. 15.44 Beam with the same strength

ulus W_p:

$$\tau_{t\,max} = \frac{T}{W_p} \le \tau_{t\,all} \,. \tag{15.66}$$

If $W_p = \pi d^3/16$, the requirement minimum diameter of the shaft is

$$d \ge \sqrt[3]{\frac{6T}{\pi \tau_{t\,all}}} \approx 1.72 \sqrt[3]{\frac{T}{\tau_{t\,all}}} \,. \tag{15.67}$$

The allowable torsional stress $\tau_{t\,all}$ is determined as an estimate value depending on the type of load and the influencing variables that exist (e.g., notch effects). Indicative values for the allowable torsional stress result after *Niemann* et al. [15.24] from

$$\tau_{t\,all} = \frac{\sigma_W}{(3 \ldots 6)} . \tag{15.68}$$

When using (15.68), it must be taken into account that smaller safety values are used for light service and larger safety values for heavy-duty service.

Determination of the Diameter from Torsion and Bending. In practice, a combination of torsion and bending usually occurs in shafts, which produces a multiaxial stress state. An equivalent stress hypothesis can be used to transform the individual superimposed bending and torsional stresses into a single-axis stress state corresponding to pure tension or pure bending, which allows an equivalent stress to be calculated. In most cases, the equivalent stress for the calculation of shafts subjected to torsion and bending is formed on the basis of the Von Mises criterion (Sect. 15.1.2 or rather Sect. 15.1.3):

$$\sigma_V = \sqrt{\sigma_b^2 + 3\,(\alpha_0 \tau_t)^2} \le \sigma_{all} = \sigma_{b\,all} \,. \tag{15.69}$$

The equivalent moment M_V (equivalent bending moment with the same effect as the bending and torsional moment together) with $\sigma_b = M_b/W_b$ and $\tau_t = T/\left(W_p\right) = T/\left(2W_b\right)$ is calculated from

$$M_v = \sqrt{M_b^2 + 0.75\,(\alpha_0 T)^2} \,. \tag{15.70}$$

With the condition $\sigma_V = M_V/W_b \le \sigma_{b\,all}$, the required shaft diameter is

$$d \ge \sqrt[3]{\frac{32 M_v b'}{\pi \sigma_{b\,all}}} \approx 2.17 \sqrt[3]{\frac{M_v b'}{\sigma_{b\,all}}} \,. \tag{15.71}$$

The factor b' for a solid or hollow shaft is:

$$\text{Solid shaft:} \quad b' = 1 \tag{15.72}$$

$$\text{Hollow shaft:} \quad b' = \frac{1}{1 - (d_i/d)^4} \tag{15.73}$$

Depending on the type of load and the existing influencing variables (e.g., not effects), the allowable bending stress $\sigma_{b\,all}$ is initially determined as an estimate value (Table 15.31).

For the initial design, the minimum shaft diameters determined above form the basic size and stand for the calculated required cross section. For the final definition, however, grooves, holes and other features must be considered. However, the executed core diameter d_c should not be less than the determined diameter d' (Fig. 15.45).

15.3.5 Check Calculations

Following the design of the axle or shaft, taking into account the determined minimum diameter, the strength of the component must be verified. In particular, this verification should be performed for areas in which cross-sectional weaknesses exist, such as thread undercuts, grooves, or shaft shoulders.

Strength Verification

The strength verification basically includes three calculation steps. In the first calculation step, the equivalent stress σ_V produced in the component by all applied forces and moments is calculated. The procedure for this is explained in Sect. 15.1.2. The fatigue strength σ_G of the component is determined in the second calculation step. This results from the material strength, taking into consideration all strength-reducing effects (Sects. 15.1.4 and 15.1.5). The strength verification is performed in the third step. It demonstrates

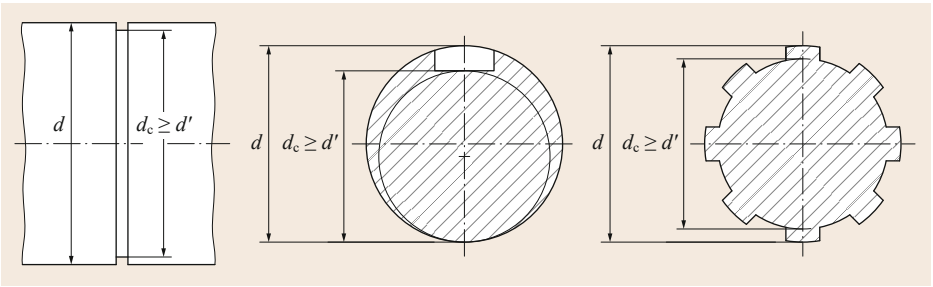

Fig. 15.45 Estimated and final shaft diameter

Table 15.32 Indicative values for allowable deflection (after *Niemann* et al. [15.24])

General shafts	$f_{all}/l^a = 0.3 \times 10^{-3}$
Shafts without guide functions	$f_{all}/l = 0.5 \times 10^{-3}$
Shafts in machine tools	$f_{all}/l = 0.2 \times 10^{-3}$
Shafts in electric motors	$f_{all} = (0.2 \ldots 0.5) \times$ air gap

[a] l = distance between the bearings

Table 15.33 Indicative values for allowable inclination angle (after *Niemann* et al. [15.24])

Roller bearings	$\beta_{all} = 0.3 \times 10^{-4}$
Deep-groove ball bearings	$\beta_{all} = (0.6 \ldots 3) \times 10^{-3}$
Plain bearings with movement shells	$\beta_{all} = 3 \times 10^{-4}$
Plain bearings with adjustable shells	$\beta_{all} = 1 \times 10^{-3}$
Gear train	$\beta_{all} = (4 \ldots 15) \times 10^{-4}$

that the safety S is greater or equal to the agreed safety S_{agr}

$$S = \frac{\sigma_G}{\sigma_V} \leq S_{agr} \,. \tag{15.74}$$

The safety required depends on the application case and potential damage. For rough calculations, from practical experience: $S_{agr} = 1.2 \ldots 2.0$.

A detailed strength verification procedure is described in the DIN 743 [15.9] standard and in the FKM guidelines [15.5].

Deformation Due to Bending Forces

For deformation due to bending forces, the deflection f of the axle or shaft and the inclination angle β of the elastic curve must be checked. These are decisively influenced by the acting forces and the elasticity of the material used. Increased deflection and inclination, especially in shafts with gears, leads to meshing faults on the teeth, which in turn results in noise generation and premature wear. In bearing positions, excessive inclination also results in increased bearing wear.

The deflection and inclination angle of the bending line can be determined both graphically using Mohr's method and analytically via the elastic bending line or Castigliano's theorem. In complex axle/shaft geometries or load conditions the deformation can be calculated with the help of numerical methods such as the finite element method.

Guide values for the allowable deflection are given in Table 15.32 and for the inclination angle in Table 15.33.

Deformation Due to Torsional Moments

For the dimensioning of longer shafts, for example, slewing gear shafts of slewing cranes or power take-off drive shafts in utility vehicles, the twist is decisive due to torques (Fig. 15.46). Together with torque fluctuations, these deformations can lead to vibrations. Furthermore, low torsional stiffness requires a large twist angle and consequently gives rise to a low critical speed.

As a result of the described effects, the actual twist angle φ must be below the allowable twist angle φ_{all} ($\varphi \leq \varphi_{all}$). Equation (15.75) can be used as indicative values for the allowable twist angle:

$$\varphi_{all} = (0.25 \ldots 0.5) \, \frac{^\circ}{m} \, l \,. \tag{15.75}$$

Critical Speed

Vibration and Resonance. If a body is deformed elastically by a force F or rather by a torque T, it can be made

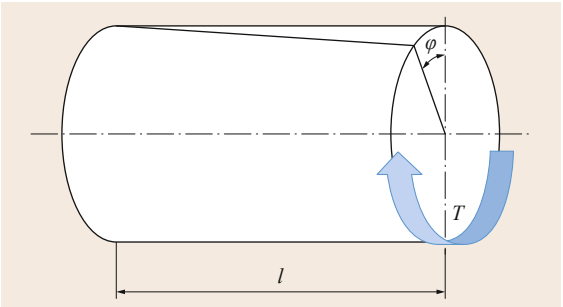

Fig. 15.46 Elastic deformation under torsion

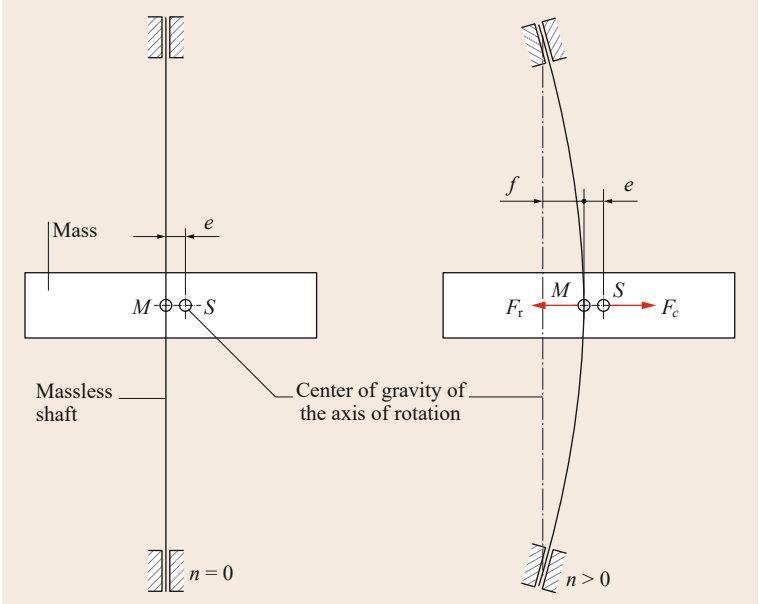

Fig. 15.47 Deformation of the shaft by centrifugal force

to vibrate flexurally (bending) or torsionally (rotation) by the restoring force acting in the opposite direction after sudden withdrawal of the force (unloading).

With increasing stiffness (spring constant) and decreasing mass of the component, the vibration frequency increases. This is independent of the size of the exciting force, which only determines the vibrational amplitude. Consequently, all bodies have a certain constant natural frequency. Multibody systems with $i = 1 \ldots n$ masses and $i = 1 \ldots n$ springs, have $n = 1 \ldots n$ natural frequencies.

If a body is made to vibrate by an excitation frequency that equals the natural frequency (or an integral multiple of it), the excitation frequency superimposes the natural frequency and resonance occurs. The vibration amplitude increases as a result, which can cause the axle or shaft to fracture.

Together with the coupled machine parts, rotating shafts and axles form vibratory systems. In general it must be considered that flexural and torsional vibrations are also caused by rotational frequencies induced as excitation and periodically varying forces and moments.

Critical Bending Speed. Due to nonrotationally symmetrical design elements (for example, parallel key connections) or production inaccuracies, the center of gravity of shafts and axles does not generally coincide with the center of rotation (Fig. 15.47).

If the shaft or axle rotates with angular velocity ω, the unbalance produces the centrifugal force F_C:

$$F_C = mr\omega^2 = m\,(f + e)\,\omega^2\,. \tag{15.76}$$

At the same time, a restoring force F_r dependent on the spring bending stiffness of c_b counteracts the centrifugal force:

$$F_r = c_b f\,. \tag{15.77}$$

In force equilibrium,

$$\begin{aligned} 0 &= F_r - F_C \\ &= m\,(f + e)\,\omega^2 - c_b f\,. \end{aligned} \tag{15.78}$$

Rearranging to obtain the deflection f we get

$$y = \frac{e}{\left(\frac{c_b}{m\omega^2} - 1\right)}\,. \tag{15.79}$$

From (15.79) it can be seen that in the case where $\omega^2 = c_b/m$, deflection tends to infinity, so that the critical angular velocity ω_C is

$$\omega_C = \sqrt{\frac{c_b}{m}}\,. \tag{15.80}$$

Accordingly, the critical bending speed is

$$n_k = \frac{30}{\pi}\sqrt{\frac{c_b}{m}} \quad \text{in} \quad \frac{1}{\text{min}}\,. \tag{15.81}$$

Multisupport shafts with n masses also have n critical speeds, whereby in most cases the lowest critical speed is significant in practice. Due to the complexity of such a multimass system, the critical speed is mostly determined approximately using special calculation programs or is determined experimentally.

Torsional Critical Speed. A system of shafts with components fixed on it can also be characterized as a torsion rod. Torque impulses, for example, due to a pulsating drive torque in combustion engines, a critical torsional vibration can be caused with the natural frequency of the shaft system. Torsional vibration resonances occur, which can damage the shaft.

The torsional critical speed n_C of a single degree of freedom system (SDOF) (e.g., torsion pendulum) is calculated from

$$n_C = \frac{30}{\pi}\sqrt{\frac{R_t}{I_m}}\,, \tag{15.82}$$

where:

R_t torsion spring rate of the shaft in Nm
I_m moment of inertia in kg m^2

For a shaft with two masses,

$$I_m = \frac{I_{m1} I_{m2}}{I_{m1} + I_{m2}}\,. \tag{15.83}$$

Conclusions for the Design of Shafts and Axles. Determining the deformation in multiple shouldered shafts and calculating the moments of inertia are difficult. For this reason, an exact calculated determination of the critical speeds with a reasonable calculation time is often only possible with very large effort. Furthermore, the influence of the environment and the shaft length on the system cannot be ignored. As a result of this, the natural frequency is often determined experimentally. For safe operation of the shaft, the excitation frequency (mostly the speed) should be at least 20% above or below the natural frequency.

When dimensioning, the following design measures must be considered to prevent resonance phenomena:

- The bearings must be positioned as closely as possible to the rotating discs. This achieves smaller deflection.
- Through careful balancing of shafts with rotating parts, smaller centrifugal forces occur.
- On the material side, the critical speeds can only be influenced by the modulus of elasticity or the shear modulus.

15.3.6 Further Reading

A deeper insight into the dimensioning of axles and shafts is given, among others, by *Wittel* et al. [15.2] and the DIN 743 Part 1–4 series of standards [15.7, 9, 10].

In their book *Maschinendynamik* [15.54] (machine dynamics), *Dresig* and *Holzweißig* provide a standard reference on vibration analysis of machine parts.

15.4 Shaft–Hub Connections

Shaft–hub connections are standardized connections for fastening components, such as wheels, gears, pulleys, levers, etc., on shafts, axles, and journals. They are primarily used to transfer torques and rotary movements. In certain applications, however, bending moments (e.g., in the case of inclined shaft positions) or axial forces (e.g., in the case of helical gears) must also be transferred.

Depending on the type of force transfer, shaft–hub connections are divided into:

- Form-closure shaft–hub connections: The connection is made by a specific shape design (e.g., by spline profiles, serrations, or polygonal splines) or through additional elements (e.g., by parallel keys, Woodruff keys, or transverse pins/cross pins).
- Frictional shaft–hub connections: The connection is achieved by frictional clamping or pressing of the hub onto the shaft or axle (e.g., via interference fit assemblies/press fit, taper seats, or clamping elements).
- Preloaded form-closure shaft–hub connections: Combination of frictional and form-closure connections (primarily achieved through different types of wedges and compression connections secured by parallel keys).
- Material-bonding shaft–hub connections: The connection is made by material bonding (e.g., by adhesive bonding, soldering, or welding). In many cases the connection can only be undone by destroying it.

A selection aid for specifying a suitable shaft–hub connection is given in Table 15.34.

15.4.1 Form-Closure Shaft–Hub Connections

Form-closure shaft–hub connections are simple and inexpensive in their structure and assembly. The form closure is achieved by appropriate shaping of the shaft and/or hub (e.g., serrated or polygonal connection) or by using additional components (e.g., parallel keys and pins). The torques to be transferred are resolved

Table 15.34 Notes on the selection of shaft–hub connections (after *Niemann* et al. [15.24])

Suitable for	Form closure	Friction	Preloaded form-closure	Material bonding
Smaller torques	Transverse pin, Woodruff key	Force fit (clamped seat), hollow key (saddle key), tolerance ring	–	Adhesive bonded sliding seat, soldered joint
Mean one-sided torques	Transverse pin, parallel key	Press fit, force fit (clamped seat)	–	Shrink-adhesive bonded fit
Mean alternating torques	Parallel key (with limitations)	Hollow key (saddle key), tolerance ring	–	
Large alternating or pulsating, intermittent torques, e.g., flywheel fixing	–	Transverse press fit (shrink fit seat, compressed oil connection)	Multispline and polygonal spline with press fit, tangential key	Welded joint
Short hub with large torque	Multispline, serrated and polygonal spline	Shrink fits with carborundum powder	–	Welded joint (direct connection of the wheel discs with the shaft), shrink-adhesive bonded fit
Sliding hub and shaft	Sliding key, multiple spline	–	–	–
Easily separable hub	Parallel key, multispline, serrated and polygonal spline	Force fit (clamped seat), taper seat, taper bush, pressurized oil assembly, Ringfeder clamping element, clamp rings	Gib head taper key, thread with longitudinal positioning of the hub on the shaft shoulder and tapered thread for one rotational direction	Adhesive bonded, sliding and shrink fit seat (heating)
Hub to be subsequently attached to smooth shaft	–	Hollow key (saddle key), force fit (clamped seat), taper bush, Ringfeder clamping element	–	–
Hub adjustable in rotational direction	Serrated profile	Hollow key (saddle key), force fit (clamped seat), taper seat, taper bush, clamp rings	–	–
Thin-walled hub	Serrated profile	Clamp rings	Thread with longitudinal positioning of the hub on the shaft seat with one-sided torque	Adhesive bonded, sliding and shrink fit seat

into tangential forces or surface pressure at the contact points of the parts to be joined. Axial forces can generally only be transferred in conjunction with additional axial fixing (for example, stops or shaft retaining rings).

Parallel Key Connection

Parallel key connections are the most frequently used form-closure shaft–hub connection for a torque acting on one side, for example, for belt pulleys, gears, and couplings.

They can be easily mounted, dismantled, and reused.

Frequently used forms according to DIN 6885-1 [15.55] (Fig. 15.48) are:

- Form A: high form with round end faces
- Form B: high form with straight end faces

For hubs that move longitudinally, for example, sliding gears in gear units, the parallel key with corresponding tolerances becomes a sliding key.

In conjunction with force fit (clamped seat) or taper seats, they are used as a so-called preloaded form-closure connection for position fixing.

The circumferential force F_u resulting from the torque is transferred via the side faces (flanks) of the parallel key. This results in loading of the side faces with surface pressure and shear in the interface between the shaft and hub. With standard parallel keys the surface pressure on the side faces is exceeded before the allowable shear stress is exceeded. For this reason, parallel keys must be dimensioned for surface pressure.

Surface pressure in the hub:

$$p = \frac{F_u}{(h - t_1)\, l_t i \varphi} = \frac{2T}{d\,(h - t_1)\, l_t i \varphi} \leq p_{all} \qquad (15.84)$$

Surface pressure in the shaft:

$$p = \frac{F_u}{t_1 l_t i \varphi} = \frac{2T}{d t_1 l_t i \varphi} \leq p_{all} \qquad (15.85)$$

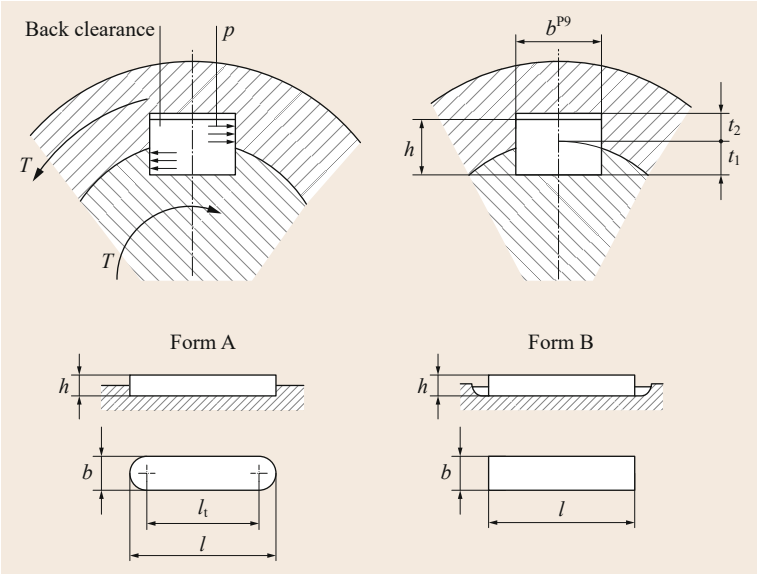

Fig. 15.48 Parallel key connection. Mode of action and forms (selection) according to DIN 6885-1 [15.55]

Table 15.35 Allowable pressures for parallel keys made of steel in N/mm^2

	For light shocks		For strong shocks	
	One-sided	Alternating	One-sided	Alternating
Cast iron hubs	65	45	40	20
Cast steel or steel hubs	120	80	80	35

where

F_u circumferential force $F_u = 2T/d$
h parallel key height (Fig. 15.48)
t_1 shaft groove depth (Fig. 15.48)
l_t effective length of the parallel key
T torsional moment
d shaft diameter
i number of parallel keys
φ bearing factor $\varphi = 1$ if $i = 1$; $\varphi = 0.75$ if $i > 1$
p_{all} allowable pressures (Table 15.35)

For parallel keys with round end faces (feather keys) (Fig. 15.48), the load-bearing length (effective length) l_t is determined by deducing the width of the parallel key b from the total length l ($l_t = l - b$).

If more than one parallel key is used, the bearing factor φ allows for nonuniform load bearing of the individual parallel keys.

Dimensions and tolerances of the parallel keys for a given shaft diameter are given in the relevant standards/reference tables (DIN 6885-1 [15.55] for metric parallel keys and ANSI B17.1 [15.56] for inch-measure parallel keys).

Table 15.36 Empirical values for hub lengths l_N and hub external diameters d_N depending on the shaft diameter d

	Cast iron	Steel/cast steel
Hub diameter d_N	$1.8 \ldots 2.0d$	$1.6 \ldots 1.8d$
Hub length l_N	$1.8 \ldots 2.0d$	$1.6 \ldots 1.8d$

Indicative values for allowable surface pressures p_{all} are given in Table 15.35. The dimensions of the hub depends on the joining diameter (Table 15.36).

Woodruff Key Joint

Woodruff keys are frequently used in small machine tools and in vehicle construction to transfer smaller torques (Fig. 15.49). Compared to a normal parallel key connection, it is easier to produce and thus less expensive. However, at the same time, due to the deeper shaft groove, it leads to greater weakening of the shaft.

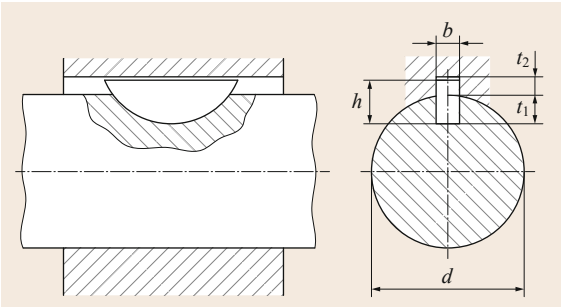

Fig. 15.49 Woodruff keys according to ISO 3912/ANSI B17.2

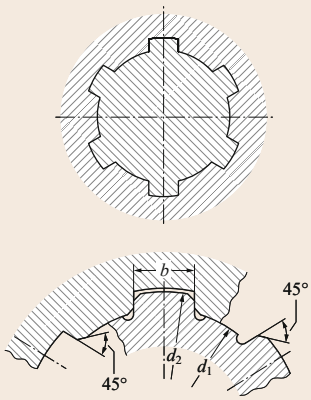
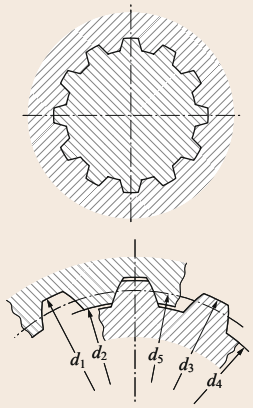
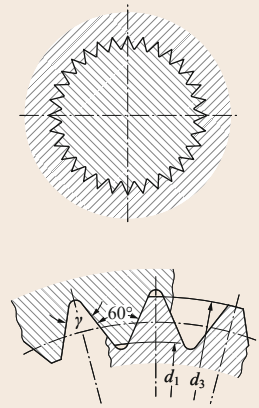
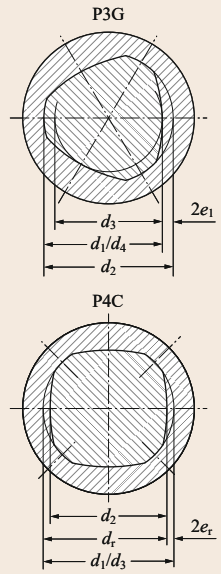
Table 15.37 Standard profile shaft connections

Straight-sided spline connections	Splined-shaft connections		Polygonal connections
	Involute spline profile	Serrated spline profile	
Transfer surfaces are parallel with each other	Transfer surfaces are involute surfaces	Transfer surfaces are triangular	Transfer surfaces are out-of-round (not circular) (generally triangular and rectangular profiles)
Light- and medium-duty series according to DIN ISO 14 Heavy-duty series according to DIN 5464	According to ISO 4156 (metric); ANSI B92.1 (inch)	According to DIN 5481, NF E22-151	Triangle (P3G) according to DIN 32711 Rectangle (P4C) according to DIN 32712
			








The dimensions of woodruff keys are defined in the ISO 3912 standard [15.57] and in the American code ANSI B17.2 [15.58].

The calculation is performed similarly to that for a parallel key connection, whereby in most cases the surface pressure in the hub groove is the limiting factor.

Profile Shaft Connections

Profile shaft connections transfer the torques (in the form of tangential forces) via several effective areas. They are suitable for higher, intermittent (shock-like) torques (including alternate torques). They have a very good centering effect, which results in low unbalance and uniform distribution of the circumferential load. They can also be designed as sliding hubs by choosing an appropriate fit.

Standard profile shaft connections are shown in Table 15.37.

Straight-Sided Spline Connections

The even number of *male splines* arranged on the circumference act like parallel keys. They are relatively inexpensive to produce and are used, for example, in gear units in combination with sliding hubs (gear wheel or clutch sleeve). A differentiation is made, depending on the type of centering effect, between:

- Internal centering: very precise centering; used in machine tools
- Flank centering: difficult to produce; advantageous for shock and alternate loading

Splined-Shaft Connections

Due to their large number of teeth, splined-shaft connections can absorb particularly large and intermittent (shock-like) forces. At the same time, the large number of teeth enables fine adjustment from tooth to tooth, as a result of which the angular position of actuating elements can be easily varied. The small tooth height leads to narrow hubs. Their cost-effective production and good adjustability makes them especially suitable for actuating elements. A differentiation is made between involute and serrated spline connections, depending on the shape of the teeth.

Polygonal Connections

These are used as separable connections in sliding or press-fit seats for the transfer of shock-like, intermittent torques. However, due to micromovements between the parts to be joined there is a risk of vibration fretting.

Tight or interference fit is possible, depending on the clearance chosen. Clearance fits are to be avoided due to the associated micromovements.

Triangular and rectangular profiles P3G and P4C (Table 15.37) are primarily used.

Compared to the P3G profile, the P4C profile is particularly suitable for connections that are intended to be longitudinally slidable under load (torque).

The profile geometries are usually turned on a profile lathe (shaft) or are broached using a broaching machine (hub).

Calculation of Profile Shaft Connections

Profile shaft connections are designed for surface pressure on the respective effective surfaces. For straight-sided spline and splined-shaft connections

$$p = \frac{2T}{d_m h l_t i \varphi} \leq p_{all} \,, \tag{15.86}$$

where:

T torsional moment
d_m average profile diameter
h load-bearing tooth height
l_t effective length of the connection
i number of teeth
φ bearing factor:
splined shaft with internal centering: $\varphi = 0.75$
splined shaft with external centering: $\varphi = 0.9$
splined shaft with serrated toothing: $\varphi = 0.5$
splined shaft with involute toothing: $\varphi = 0.75$
p_{all} see Table 15.35

For P3G polygonal connections, the surface pressure must be checked using

$$p \approx \frac{T}{l_t \left(0.75 \pi e_1 d_1 + 0.05 d_1^2\right)} \leq p_{all} \,, \tag{15.87}$$

where e_1; d_1 is the geometrical profile size (Table 15.37).

For the P4C profile, the surface pressure is approximately

$$p \approx \frac{T}{l_t \left(\pi e_r d_r + 0.05 d_r^2\right)} \leq p_{all} \,, \tag{15.88}$$

where e_r; d_r is the geometrical profile size (Table 15.37)

The allowable surface pressures are given in Table 15.35.

15.4.2 Frictional Shaft–Hub Connection

Frictional connections generate the forces necessary for force and moment transfer solely through friction at the interfaces between the shaft and hub.

According to Coulomb's friction law,

$$F_\mu = \mu_i F_n \,. \tag{15.89}$$

The friction coefficient μ_i used to calculate the friction forces is either the sliding coefficient of friction μ or the static coefficient of friction μ_0, depending of the form of friction present.

In frictional connections, the frictional force must always be larger than the forces to be transferred, so that for slip-free transfer of axial forces F_a and torques $T = F_u D_F / 2$:

Axial force:

$$F_a \leq F_{\mu a} = \frac{\mu_0 F_n}{S_r} = \frac{\mu_0 \pi D_F l_F p_F}{S_r} \tag{15.90}$$

Torque:

$$T \leq T_\mu = \mu_0 F_n \frac{D_F}{2 S_r} = \frac{\mu_0 \pi D_F^2 l_F p_F}{2 S_r} \,, \tag{15.91}$$

where:

μ_0 static coefficient of friction (Table 15.38)
D_F nominal diameter of the joint
p_F surface pressure in the joint gap (joint compression, interference of the joint)
l_F specified factor of safety against plastic elongation (1–1.3)
S_r factor of safety against slipping (1.5–2)

Table 15.38 Guide values for coefficients of friction of longitudinal press-fit connections with quick loading according to DIN 7190-1 [15.59]

Material pairing (shaft/hub)	Friction values Dry		Lubricated	
	μ_0	μ	μ_0	μ
Steel/cast steel	0.10–0.11	0.08–0.09	0.07–0.08	0.06–0.07
Steel/cast iron	0.10–0.12	0.09–0.11	0.06	0.05
Steel/aluminum	0.07	0.06	0.05	0.04

Table 15.39 Coefficients of friction of transverse press-fit assemblies in longitudinal and circumferential direction on slipping according to DIN 7190-1 [15.59]

Material pairing, lubrication, joining	Friction values μ
Steel-steel pairing	
Pressurized oil assemblies normally joined with mineral oil	0.12
Pressurized oil assemblies with degreased pressure contact surfaces joined together with glycerine	0.18
Shrink-fit assembly, normal, after heating the external part up to 300 °C in the electric furnace	0.14
Shrink-fit assembly with degreased pressure contact surfaces after heating in the electric furnace up to 300 °C	0.20
Steel-cast iron pairing	
Pressurized oil assemblies normally joined with mineral oil	0.10
Pressurized oil assemblies with degreased pressure contact surfaces	0.16
Steel-MgAl pairing, dry	0.10–0.15
Steel-CuZn pairing, dry	0.17–0.25

The ability of a connection or joint to transfer forces and moments essentially depends on the coefficient of friction and the normal (perpendicular) force F_n.

While the coefficient of friction is highly dependent on the type of paired materials, the surface finish, the lubricated condition, and relative speed of the paired components (guide values in Tables 15.38 and 15.39), F_n is limited by the allowable surface pressure $p_{F\,all}$.

Table 15.40 Advantages and disadvantages of frictional shaft–hub connections

Advantages	Disadvantages
Simple structure	Assembly and dismantling difficult at times (press-fit connection)
Low unbalances (high speeds possible)	A minimum preload is required for force transfer
Withstands high dynamic loads	Risk of fretting in the case of alternating (cyclic) stress or loading
No cross-sectional weakening of the shaft	
Simultaneous transfer of axial and tangential forces	
Very suitable for alternating (cyclical) loads	

Frictional connections can basically be divided into (Fig. 15.50):

- Connections with and without intermediate parts
- Connections with cylindrical and tapered fit joints

When selecting friction connections, in addition to the force closure, other properties such as self-centering, setting and adjustability, production and assembly costs, the necessary production tolerances, and the separability or reusability must also be considered.

Advantages and disadvantages of frictional shaft–hub connections are given in Table 15.40; execution examples are given in Fig. 15.51.

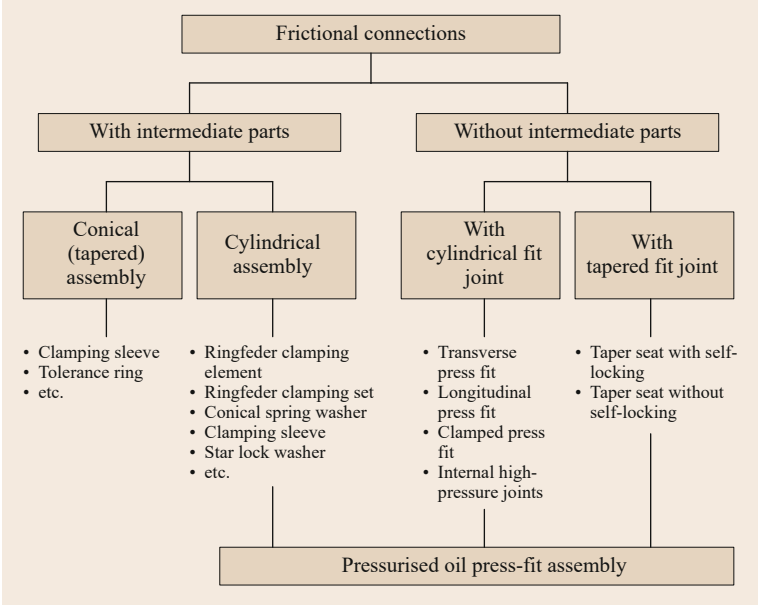


Fig. 15.50 Classification of frictional shaft–hub connections

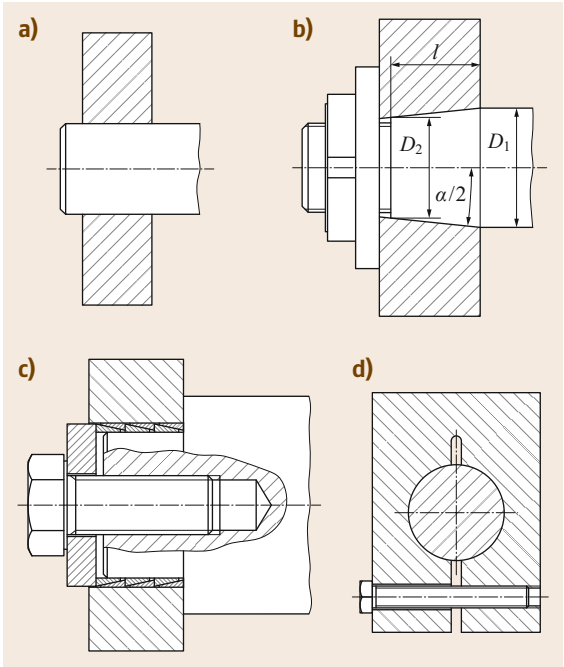

Fig. 15.51a–d Examples of frictional connections. **(a)** Cylindrical press-fit assembly, **(b)** conical press-fit assembly, **(c)** press-fit connection with intermediate parts (tapered clamping elements), and **(d)** compression connection

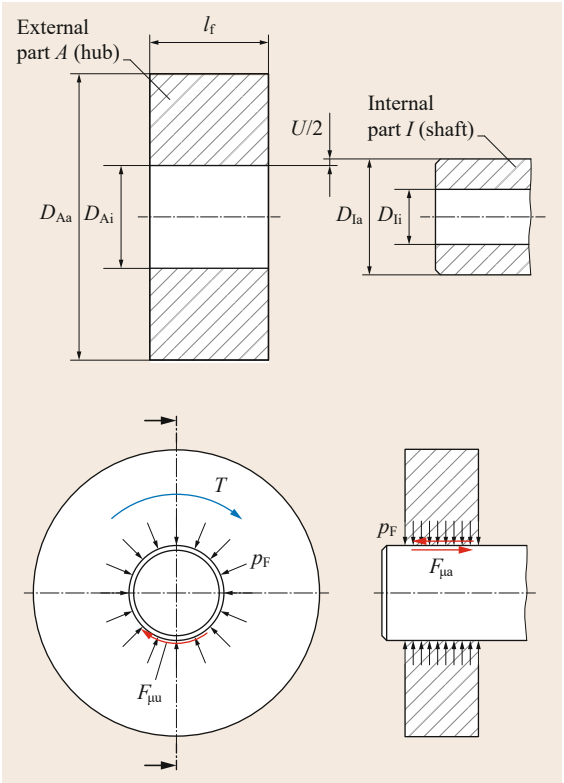

Fig. 15.52 Mode of action of a press-fit connection and force (load) distribution. Index i = internal; index a = external

Cylindrical Compression (Press-Fit) Connections

The internal diameter of the external part D_{Ai} and the external diameter of the internal part D_{Ia} are chosen so that an oversize (interference) U results (Fig. 15.52). If the external part is joined with the internal part, the oversize causes surface pressure p_F, also called joint compression, in the joint gap. Combined with the existing coefficient of friction in the joint gap, a friction force results that enables the frictional transfer of axial or rather circumferential forces.

Due to the elasticity of the clamped parts, they are permanently joined together, which makes correction of the hub position very difficult.

Cylindrical press-fit connections are mainly used for permanent connections, such as flywheels, belt pulleys, gears, plain bearing bushes in housings, and rolling bearing rings.

After the type of joining has been chosen, a differentiation is made between longitudinal press-fit connections, transverse press-fit connections, and press-fit connections to be mounted or dismantled with pressurized oil methods (Fig. 15.53).

Longitudinal press-fit connections are mostly joined at room temperature by pressing the shaft into the hub. A slight taper at the end of the shaft makes it easier to insert the shaft. The longitudinal displacement causes smoothing of the surface, as a result of which the adhesive force is less than in a transverse force joint. Lubricants reduce the sliding coefficient of friction and thus make it easier to press in the shaft. After joining, they are slowly displaced from the joint gap so that the full adhesive force is not reached until after a longer adhesion time (approximately 48 h).

In the case of transverse press-fit connections the oversize necessary for the force transfer is cancelled out by heating the hub and/or cooling the shaft, so that a clearance fit results. In this condition, the components can be joined without force. After the temperature has equalized, the press fit required for the force transfer results.

Similar to transverse press-fit connections, oil injection press-fit connections can be joined almost force-free. In this case, during assembly or dismantling, oil is

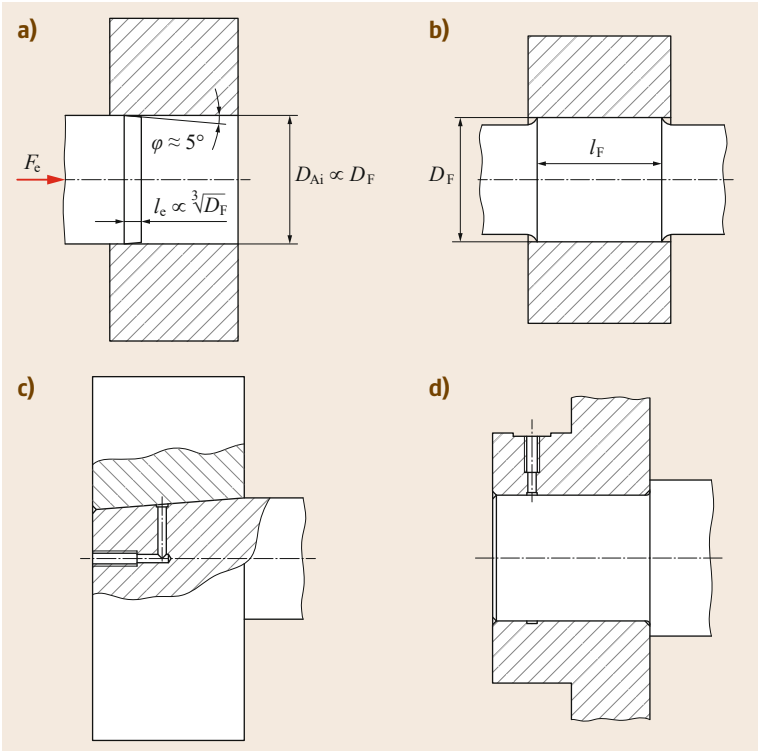

Fig. 15.53a–d Press-fit connections. **(a)** Longitudinal press-fit connection, **(b)** transverse press-fit connection, **(c)** conical press-fit connection joined with pressurized oil method, and **(d)** cylindrical press-fit connection to be dismantled with pressurized oil method

injected from the outside under high pressure through a slightly tapered fitting joint, which causes the hub to widen slightly and a thin film of oil results between the shaft and hub, which separates the contact surfaces from each other. Thus, when the parts are pushed together only fluid friction acts. Cylindrically shaped press-fit connections cannot be joined by this method; however, it can be used to undo them. After joining, a waiting time of approximately 2 h is required before loading the joint. The advantages and disadvantages of cylindrical press-fit connections are listed in Table 15.41.

Practical Calculation of Cylindrical Press-Fit Connections. The press-fit connection is calculated based on the standard DIN 7190-1 [15.59], whereby the calculation sequence has been modified. In calculation terms, the smallest required oversize U_{min} and the largest allowable oversize U_{max} must be determined based on the minimum surface pressure required in the joint gap $p_{F\,min}$ and the maximum allowable surface pressure in the joint gap p_{Fall}.

Calculation of the required and allowable oversizes requires knowledge of all other geometrical variables of the press-fit connection.

According to Table 15.42, the hub dimensions can be roughly defined depending on the joint diameter.

Table 15.41 Advantages and disadvantages of cylindrical press-fit connections

Advantages	Disadvantages
Transfer of large, alternating, and/or intermittent, shock-like axial forces and torques	Tight tolerancing required
Precise centering of the hub on the shaft	Difficult or rather permanent (except oil injection press-fit connections)
Minor unbalances	Correction of the hub position not possible
No weakening of the shaft due to grooves (keys)	
Simple, inexpensive production	

Table 15.42 Rough, estimated values for hub dimensions of press-fit connections

	Cast iron	Steel/cast steel
Hub diameter D_{Aa}	$2.2 \ldots 2.6 D_F$	$2.0 \ldots 2.5 D_F$
Hub length l	$1.2 \ldots 1.5 D_F$	$0.8 \ldots 1.0 D_F$

The stated calculation requires pure elastic deformation of the internal and external parts; in practice, certain proportions of plastic deformation are allowed. The DIN 7190-1 standard gives a simple calculation

method for elastic-plastic loaded press-fit assemblies (interference fits) for limited application, which is not discussed any further here.

Smallest Required and Largest Allowable Joint Compression. For a given torsional moment T, or rather a given axial force F_a, (15.90) and (15.91) can be rearranged to determine the minimum joint compression $p_{F\min}$ necessary for safe and reliable transfer:

Pure torque:

$$p_{F\min} = \frac{2TS_r}{\mu_0 \pi D_F^2 l_F} \tag{15.92}$$

Pure axial force:

$$p_{F\min} = \frac{F_a S_r}{\mu_0 \pi D_F l_F} \tag{15.93}$$

Simultaneous axial force and torque:

$$p_{F\min} = \frac{\sqrt{{F_a}^2 + \left(\frac{2T}{D_F}\right)^2}\, S_r}{\mu_0 \pi D_F l_F} \tag{15.94}$$

The maximum allowable joint compression $p_{F\max}$ is limited by the allowable material strength in the hub, or rather in the shaft.

External part:

$$p_{F\max A} = \frac{1 - Q_A^2}{\sqrt{3} S_{PA}} R_{elA} \tag{15.95}$$

Internal part (hollow shaft):

$$p_{F\max I} = \frac{1 - Q_i^2}{\sqrt{3} S_{PI}} R_{elI} \tag{15.96}$$

Internal part (solid shaft):

$$p_{F\max I} = \frac{2R_{elI}}{\sqrt{3} S_{PI}} \tag{15.97}$$

where:

Q_A; Q_I diameter ratios $Q_A = D_F/D_{Aa}$; $Q_I = D_{Ii}/D_F$ (Fig. 15.53a)
S_{PA}; S_{PI} specified factor of safety of the hub, or rather the shaft against plasticization (1−1.3)
R_{elA}; R_{elI} lower elasticity limit of the hub, or rather the shaft

For further calculation, the smallest value of the minimum allowable surface pressure according to (15.95)–(15.97) must be used.

Smallest Required and Largest Allowable Oversize. From the smallest required and largest allowable joint compression $p_{F\min}$ and $p_{F\max}$, with joint diameter D_F and the auxiliary variable K according to (15.99), the smallest required and largest allowable adhesion $Z_{\min}$ and $Z_{\max}$ can be calculated as follows:

Smallest required adhesion:

$$Z_{\min} = \frac{p_{F\min} D_F}{E_A}$$

Largest allowable adhesion:

$$Z_{\max} = \frac{p_{F\max} D_F}{E_A} \tag{15.98}$$

with

$$K = \frac{E_A}{E_I}\left(\frac{1 + Q_I^2}{1 - Q_I^2} - \upsilon_I\right) + \frac{1 + Q_A^2}{1 - Q_A^2} + \upsilon_A\,, \tag{15.99}$$

where:

E_A; E_I modulus of elasticity of the hub, or rather of the shaft, respectively
υ_A, υ_I Poisson's ratio of the hub, or rather of the shaft, respectively

On joining the components, smoothing (plastic deformation) of the surface roughnesses causes a loss in oversize ΔU (Fig. 15.54). With smoothing amounts of the surfaces $G_{Ai} \approx 0.2R_{zAi}$ and $G_{Ia} \approx 0.2R_{zIa}$, the total loss in oversize is:

$$\Delta U = 2G_{Ai} + 2G_{Ia} = 0.4\,(R_{zAi} + R_{zIa})\,. \tag{15.100}$$

The smallest required or largest allowable oversizes to be set in before joining are made up of the adhesions

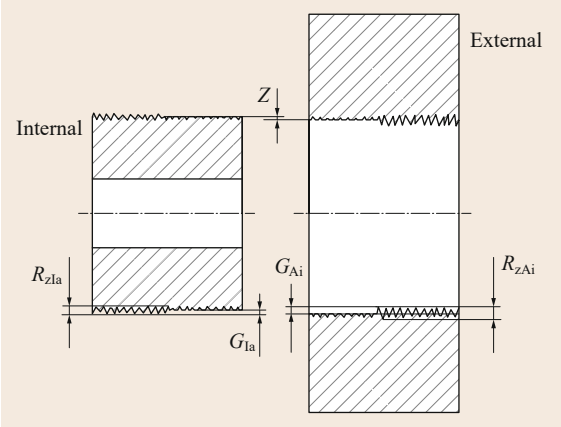

Fig. 15.54 Surface smoothing in the longitudinal joints of the components

according to (15.98) and the loss of oversize according to (15.100) as follows:

$$\begin{aligned} &\text{Smallest required oversize:} \quad U_{\min} = Z_{\min} + \Delta U \\ &\text{Largest allowable oversize:} \quad U_{\max} = Z_{\max} + \Delta U \end{aligned} \tag{15.101}$$

The maximum allowable dimensional fluctuation of the components, the fit tolerance P_T, is defined by the oversizes $U_{\min}$ and $U_{\max}$:

$$P_T = U_{\max} - U_{\min} \,. \tag{15.102}$$

The fit tolerance P_T must be divided between the tolerance zones of the hole T_A and the shaft T_I:

$$P_T = T_A + T_I \,. \tag{15.103}$$

Notes:

- In the case of very fast rotating press-fit connections, the centrifugal forces that occur can reduce the fitting joint pressure. For this reason, the effect of the speed on fast rotating connections must be checked (DIN 7190-1 [15.59]).
- If the press-fit assembly is loaded dynamically, the fatigue strength of the shaft must be verified using a suitable method (FKM guidelines [15.5] or DIN 743 [15.9]).

Joining Temperatures for Transverse Press Fits. The clearance fit S_e required for unforced joining must be established by heating the hub and/or cooling the shaft. For the necessary clearance, depending on the joint diameter D_F or the maximum oversize $U'_{\max}$ measured at ambient temperature, the following conditions apply: $S_e/D_F \approx 10^{-3}$, or rather $S_e/U'_{\max} \approx 0.5$.

The joining temperature of the external part ϑ_A at known joining temperature of the internal part ϑ_I with ambient temperature ϑ, the coefficients of thermal expansion of the external and internal part α_A and α_I (Table 15.43) and the joint diameter D_F is approximately calculated as

$$\vartheta_A \approx \vartheta + \frac{U'_{\max} + S_e}{\alpha_A D_F} + \frac{\alpha_I}{\alpha_A} (\vartheta_I - \vartheta) \,. \tag{15.104}$$

The maximum possible heating of the hub is limited by its temperature resistance. Above this temperature limit, material strength losses are to be expected due to structural changes in the material. Guide values for the maximum joining temperature are given in Table 15.44.

Table 15.43 Coefficients of thermal expansion according to DIN 7190-1 [15.59]

Material	α_A (heating) (1/K)	α_I (undercooling) (1/K)
Steel and cast steel	11×10^{-6}	-8.5×10^{-6}
Cast iron	10×10^{-6}	-8×10^{-6}
Lightweight metal alloys (Al alloys)	23×10^{-6}	-18×10^{-6}
Copper alloys		
Red brass	17×10^{-6}	-15×10^{-6}
Brass	18×10^{-6}	-16×10^{-6}

Table 15.44 Maximum joining temperatures [15.59]

Hub material	Maximum joining temperature (°C)
Low-strength structural steel Cast steel Nodular cast iron	350
Steel or cast steel, quenched and tempered	300
Steel, boundary-hardened	250
Steel, case-hardened or high-strength quenched and tempered structural steel	200

Pressing-In and Pressing-Out Forces in Longitudinal Press-Fit Connections. The jointing force necessary to join the longitudinal press-fit connection is calculated from

$$F_{in} = \pi D_F l_F p'_{F\max} \mu \,, \tag{15.105}$$

where:

D_F joint diameter
l_F hub length
$p'_{F\max}$ largest joint compression ((15.106))
μ coefficient of friction on pressing in (Table 15.38)

The largest joint compression $p'_{F\max}$ present describes the joint compression that sets in under the stated largest oversize $U'_{\max}$:

$$p'_{F\max} = \frac{(U'_{\max} - \Delta U)\, p_{F\max}}{Z_{\max}} \,, \tag{15.106}$$

where:

$U'_{\max}$ available interference
ΔU interference loss (−100)
$z_{\max}$ largest allowable adhesion (15.98)
$p_{F\max}$ maximum allowable joint compression ((15.95)–(15.97))

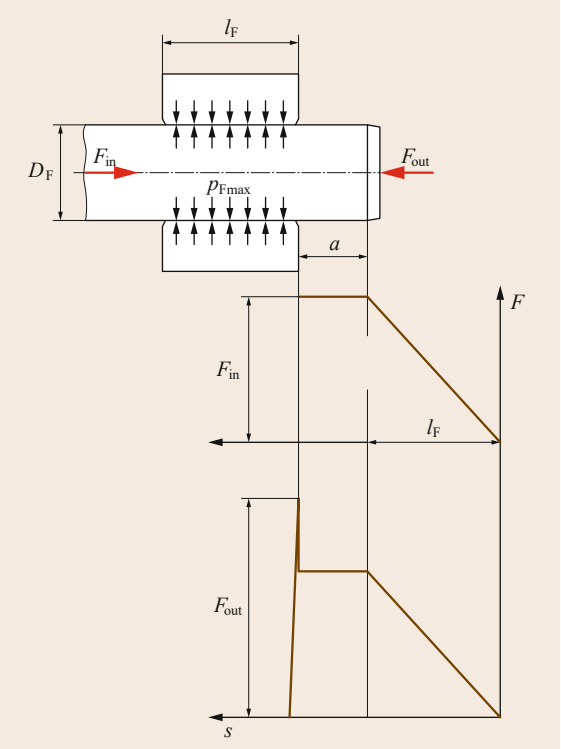

Fig. 15.55 Pressing-in and pressing-out forces in longitudinal press-fit connection

Due to the static friction, a larger force is required for the pressing out, so that: $F_{out} > F_{in}$ (Fig. 15.55). By inserting the static coefficient of friction μ_0 (Table 15.38) for μ in (15.105), the pressing-in force is specified on the safe side.

The empirical value $F_{in}/D_F = 4–7\,\text{kN/mm}$ is used for orientation.

15.4.3 Press-Fit Connection Through Hydrojoining

Unlike the classic longitudinal or rather transverse press-fit connection, with this type of connection a joint clearance exists between the hub and the hollow shaft before the joining. To produce the necessary joint compression for the force transfer, a pressure (joining pressure) is applied to the hollow shaft underneath the hub, which causes it to widen (Fig. 15.56). The parts to be joined and the process parameters (joint gap, joining pressure) are matched with each other so that the shaft undergoes plastic deformation and the hub undergoes elastic deformation. As a result, even after the joining pressure is removed, a permanent surface pressure occurs between the parts to be joined, which enables frictional force transfer.

Table 15.45 Advantages and disadvantages of hydrojoined press-fit connections

Advantages	Disadvantages
Generous tolerancing of the joint gap possible	Connection cannot be separated nondestructively
No additional unbalances	Shaft must be hollow underneath the hub
Less susceptible to fretting corrosion due to the favorable surface pressure curve	Joining probe requires an appropriate surface quality on the inside of the shaft due to the attached seal
Hub can be very easily positioned on the shaft	Calculation very difficult/time consuming

The advantages and disadvantages of hydrojoined press-fit connections are shown in Table 15.45.

Conical Press-Fit Connections

In conical (tapered) press-fit connections the conical hub is pressed axially onto a (mainly attached to the end of the shaft) rotationally symmetrical cone (Fig. 15.51b). They are used to transfer dynamic forces and moments, for example, in wheel, disc and clutch hubs or in machine tools for holding the tools. Their advantages and disadvantages are clearly shown in Table 15.46.

The internal and external part have the same cone taper angle or inclination angle $\alpha/2$:

$$\tan\left(\frac{\alpha}{2}\right) = \frac{D_1 - D_2}{2l}\,. \tag{15.107}$$

The cone inclination can also be given by the rate of taper:

$$C = \frac{D_1 - D_2}{l}\,. \tag{15.108}$$

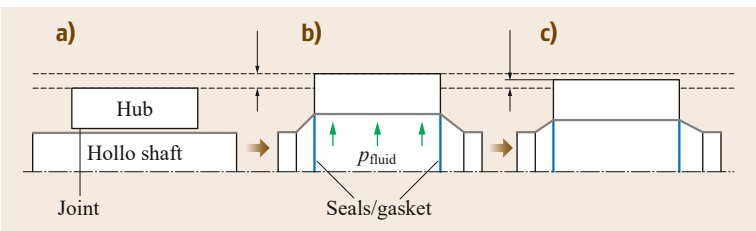

Fig. 15.56a–c Production process for hydrojoining. **(a)** Clearance fit before joining, **(b)** maximum widening during the joining process, and **(c)** permanent widening after joining process

Table 15.46 Advantages and disadvantages of conical press-fit connections

Advantages	Disadvantages
Easy assembly and dismantling	More expensive production than cylindrical press-fit connections
No weakening of the shaft and hub due to grooves (keys)	In the case of large alternating, intermittent loads, small relative movements can occur, which in turn can cause fretting (vibration wear)
Low unbalances due to a rotationally symmetrical contact surface	
High running accuracy and smooth and quiet running due to the very good centering effect	
Backlash-free joining possible	
Axial force is adjustable	

The following rates of taper are suggested in DIN 254 [15.60]:

Easily separable connection: $C = 1:5$
Difficult to separate connection: $C = 1:10$
Toolholders: $C = 1:20$, $C = 1:30$, $C = 1:50$
Morse taper: $C = 1:19.002$ to $1:20.047$

Self-locking exists in the conical press-fit connection if the angle of friction $\rho = \arctan(\mu_0)$ is larger than the taper angle $\alpha/2$.

The conical press-fit connection can be calculated as described in the DIN 7190-2 [15.61] standard.

Clamping-Element Connections

In this type of connection, the load is transferred via an additional component, the clamping element. Clamping-element connections are a special type of conical connections. Axial clamping causes conical clamping elements to be elongated elastically in the tangential direction (external part) and compressed (internal part), which produces a surface pressure between the shaft surface and the clamping element, or rather between the clamping element and the hub hole. The advantages and disadvantages are shown in Table 15.47.

Tapered Clamping Elements. The mode of action of tapered clamping elements is similar to that of conical press-fit connections. They mostly consist of two rings pushed inside each other (clamping set), which are conical on their joint contact surface (Fig. 15.57). The clamping set is cylindrical on the inside and outside, and is dimensioned so that it can be pushed into the hub or onto the shaft with clearance.

Table 15.47 Advantages and disadvantages of clamping-element connections

Advantages	Disadvantages
Easy assembly and dismantling	Clamping element is an additional component
Fixing of hubs, wheels, etc. onto smooth shafts	In most cases, separate centering of the hub on the shaft is required
Axially and tangentially freely settable and adjustable	Increased space requirement compared to press fit
Generally reusable	
Clearance-/backlash-free connection	
Suitable for transferring intermittent, shock-like or alternating torsional moments (torques)	

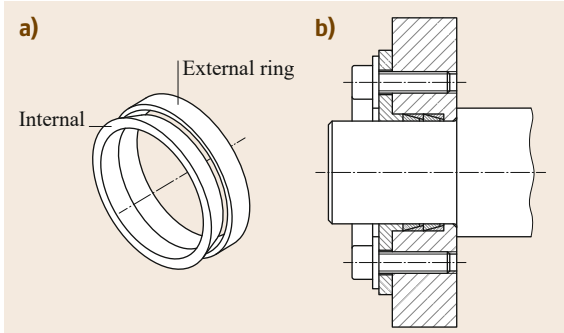

Fig. 15.57a,b Tapered clamping elements, individually **(a)** and assembled **(b)**

If the two rings are pushed inside each other by an axial force (mostly generated by screws or bolts) (Fig. 15.57), the external ring widens elastically, while the internal ring is compressed elastically. This radial deformation causes friction forces between the hub and clamping set and the shaft and clamping set, and these enable force transfer.

Several tapered clamping elements can be connected successively to transfer higher forces/torques. In this case, it must be noted that due to friction losses, the axial force acting on the individual elements reduces from element to element (Fig. 15.58).

Refer to the manufacturers' information for notes on dimensioning and calculation. The advantages and disadvantages of tapered clamping element are listed in Table 15.48.

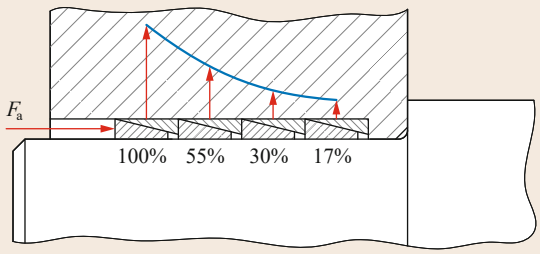

Fig. 15.58 Force distribution of the contact forces in several successive tapered clamping elements

Table 15.48 Advantages and disadvantages of tapered clamping elements

Advantages	Disadvantages
Easy assembly and dismantling	Force transfer less than with normal press-fit connection
Larger production tolerances possible for shaft and hub	Additional centering of the hub on the shaft required
Clamping set is available as a finished, ready-to-use component	Increased space requirement due to clamping elements
No additional axial fixing necessary	

Ringfeder Clamping Sets. The mode of action of Ringfeder (brand name) clamping elements is the same as that of tapered clamping elements. They differ in that the elements for clamping (bolts) are already integrated in the clamping set (Fig. 15.59).

The advantages and disadvantages of Ringfeder clamping sets are described in Table 15.49.

In addition to Ringfeder clamping sets, other special clamping sets are available with the same mode of action. They differ in their number of conical friction surfaces and the way in which the contact force is produced (Fig. 15.60).

Table 15.49 Advantages and disadvantages of Ringfeder clamping sets

Advantages	Disadvantages
Easy assembly and dismantling	Large hub dimensions due to large space requirement
Suitable for heavy-duty designs for transferring high static and/or dynamic moments	
No threaded holes	
No additional axial fixing necessary	

Table 15.50 Advantages and disadvantages of Taper Lock® connections

Advantages	Disadvantages
Easy assembly and dismantling	Large installation space
No additional axial fixing necessary	High production cost due to conical (tapered) hub hole and threaded hole for studs
Standardized hub geometries can be adapted to different shaft sizes with the help of various taper bushes	

Taper Lock® Connection. Taper Lock® connections are an alternative to the fixing of standardized belt pulleys and sprockets with classic parallel key connection. In these connections, an external conical taper bush is pressed, with the help of studs, into a hub with a corresponding mating shape (Fig. 15.61). They have a parallel keyway for additional security against twisting. Due to its longitudinal slot, the taper bush has very high elasticity. The press-fit connection can be undone with the help of specially threaded dismantling holes.

The advantages and disadvantages of Taper Lock® connections are shown in Table 15.50.

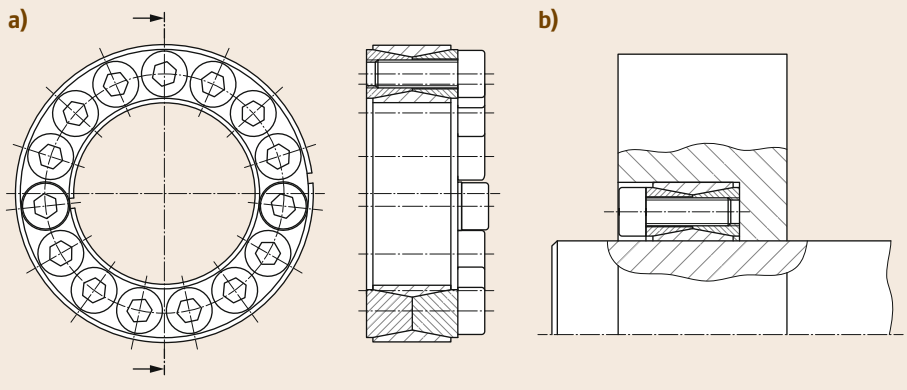

Fig. 15.59a,b Ringfeder clamping set **(a)** and assembled clamping set **(b)**

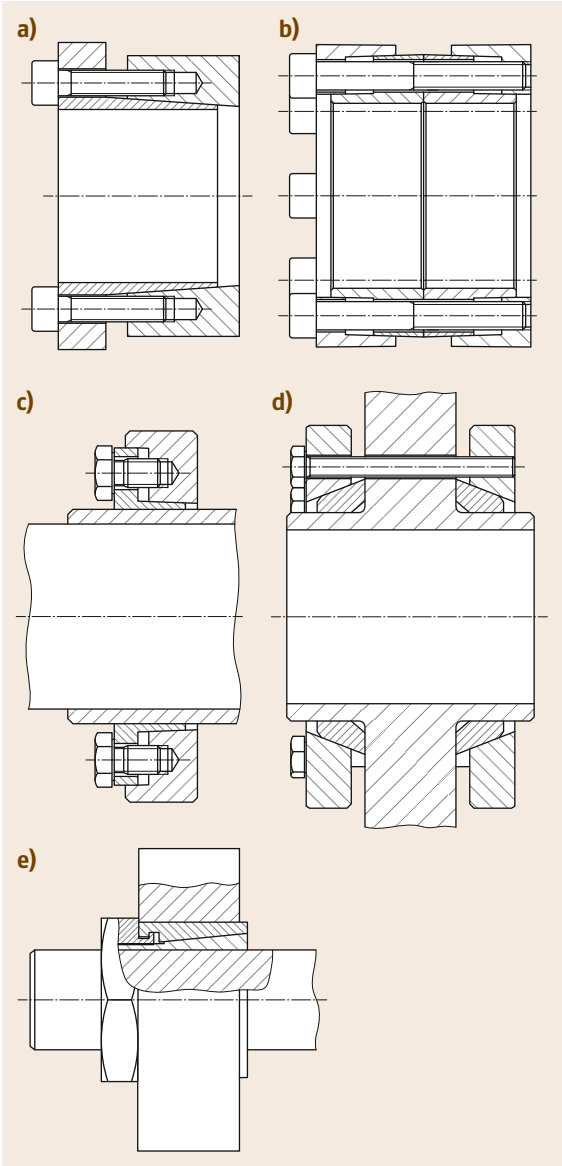

Fig. 15.60a–e Other clamping sets (selection): **(a)** self-centering internal clamping set (make: Klempex), **(b)** internal clamping set for transferring large torques (make: Stüwe), **(c)** clamp ring (make: Stüwe), **(d)** two-piece clamp ring (make: Stüwe), and **(e)** clamping set with hexagon nut

Compression Connections

Compression connections are mainly used to fix belt pulleys and levers. The clamping forces necessary for the force transfer are applied by screws/bolts or tilting forces. Parallel keys or tangential keys are also frequently installed for position fixing in the case of larger loads.

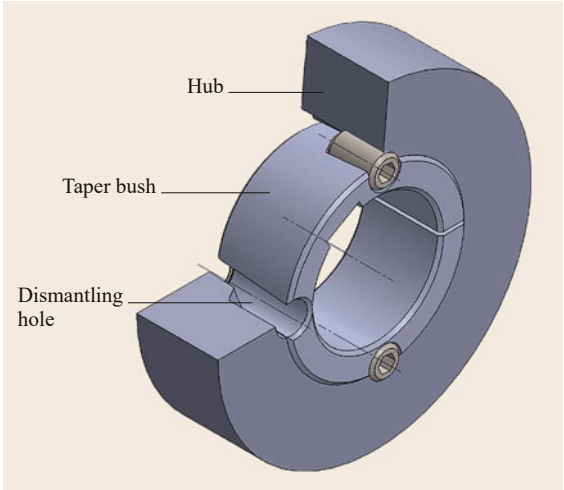

Fig. 15.61 Connection with taper bush

Materials	Cast iron	Steel/cast steel
Hub diameter	$(2.0 \ldots 2.2)d$	$(1.8 \ldots 2.0)d$
Hub length	$(1.6 \ldots 2.0)d$	$(1.2 \ldots 1.5)d$

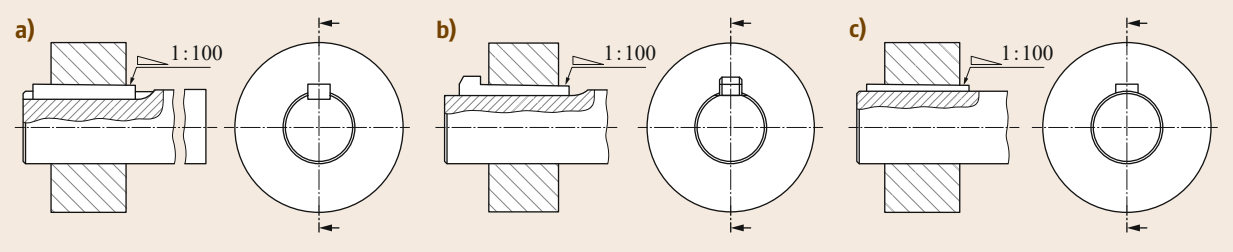

Fig. 15.63a–c Longitudinal key connection with keyway **(a)**, flat gib-head key **(b)**, and hollow (saddle) key connection **(c)**

Guide values for the selection of the hub dimensions depend on the shaft diameter d according to Table 15.51.

Depending on the direction of the clamping forces, the connections can be divided into axial and radial compression connections. In the case of axial compression connections, the hub or the flange is pressed onto the shaft by one or several bolts, which produces a force-closure connection (Fig. 15.62a,b). Radial compression connections can be achieved by hubs that are clamped with the help of bolts and that are slotted on one side or divided (Fig. 15.62c,d).

Keyed Joints

Keyed joints are preferably used for rough service and alternating, intermittent shock-like torques and low precision requirements, for example, for the fixed connection of heavy-duty discs, wheels, or clutches in large machines, excavators, cranes, agricultural machines, or heavy-duty machine tools.

Driving-in forces produce surface pressures and thus friction forces on the keys, which results in the superimposition of frictional and form-closure connections.

A differentiation is made between longitudinal key connections, which produce a frictional connection in normal service and cottered connections with a preloaded form-closure connection. The advantages and disadvantages of keyed connections are shown in Table 15.52.

Table 15.52 Advantages and disadvantages of keyed connections

Advantages	Disadvantages
Secure and fixed fit of the hub without additional axial securing	Difficult dismantling (especially gib-head keys)
Insensitive to dirt	Excessive force applied for driving in can cause the hub to crack or tear (especially gray cast iron hubs)
	One-sided driving in of the key can cause canting and off-center fit of the hub
	High speeds not possible

Longitudinal Key Connections. In normal service, the force transfer is by means of force closure (clamping of the shaft and hub by means of longitudinally inserted key) (Fig. 15.63). If the forces/moments to be transferred exceed the friction forces present, form-closure force transfer also occurs (except for hollow saddle key connections).

Longitudinal key connections are frequently used due to the ease with which they can be tightened and reclamped, and due to their reusability.

Cottered Joints. Cottered joints are used to connect parts that are mainly loaded in the longitudinal direction or as fixing and adjusting keys, for example, to secure tool tapers and as a clamping element in jig construction.

The disadvantages of this connection are the relatively high production costs, the unfavorable stress distribution, and the difficulty in controlling the driving-in force. A bolted connection can be a useful alternative.

The basic structure of a cottered connection is shown in Fig. 15.64.

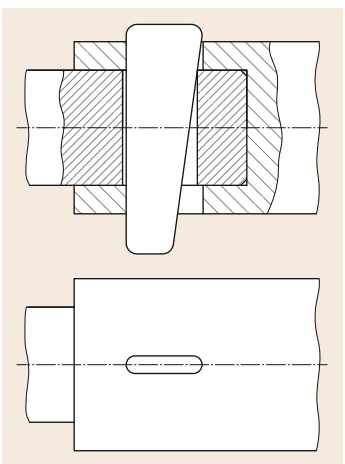

Fig. 15.64 Cottered joints

To be on the safe side, keyed connections are frequently dimensioned in the same way as parallel key connections, as the size of the driving-in force and thus the friction force are often difficult to determine.

15.4.4 Further Reading

More information on shaft–hub connections is provided in the reference book of the same name by *Kollmann* [15.62].

15.5 Rolling Bearings

The main tasks of bearings are to guide components that move relative to each other as well as absorb and transfer the acting forces or loads. They should enable movements (rotation and translation) in the required degrees of freedom and inhibit them in unwanted degrees of freedom.

They can basically be divided into rolling bearings and plain bearings. The movement or force transfer in rolling bearings takes place via rolling elements, which are arranged between rings or discs. Rolling friction dominates, so energy losses are low. In the case of plain bearings (sometimes called sliding bearings), the surfaces moving relative to each other rub each other directly (Fig. 15.65).

Rolling bearings, as maintenance-free or low-maintenance bearings, are preferably used under normal requirements, for example, in gear units, machine tools, conveyor systems, or all kinds of vehicles. They are also used in spindle guides and cradles/turrets, as they operate with low friction from a standstill and at low speeds and withstand large loads. Their advantages and disadvantages are given in Table 15.53.

Table 15.53 Advantages and disadvantages of rolling bearings

Advantages	Disadvantages
Cost effective in mass production and can be produced with high degree of accuracy	More expensive than simple plain bearings
Replaceability possible within wide limits due to international standardization	Noisy running
Less frictional losses than comparable plain bearings at low speeds	Speed limited due to centrifugal force effect on rolling elements
No distinct running-in characteristic	Sensitive to dirt (sealing required)
Low maintenance cost and lubricant requirement	Sensitive to large temperature differences
	Sensitive to vibrations and shocks (especially when at a standstill and at low speeds)
	Lubrication required (except for special plastic bearings)
	Higher wear than hydrodynamic plain bearings

15.5.1 Structure and Properties

Structure

A differentiation is made between *radial rolling bearings* (Fig. 15.66a) and *thrust rolling bearings* (Fig. 15.66b) depending on the type of position fixing.

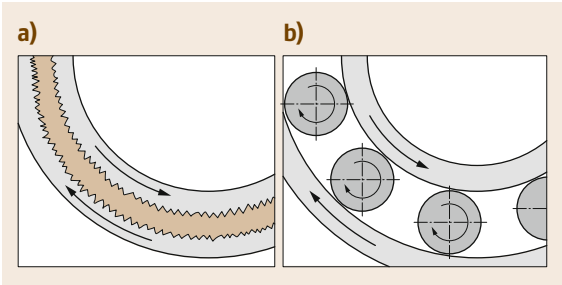

Fig. 15.65a,b Plain (a) and rolling (b) bearings

Depending on their type, radial rolling bearings can absorb axial forces in addition to radial forces, while rolling thrust bearings are generally only suitable for axial loads.

Rolling bearings are further subdivided depending on their rolling element geometry (Fig. 15.66c) into:

- Ball bearings
- Cylindrical roller bearings
- Needle roller bearings
- Tapered roller bearings
- Barrel roller bearings

The basic structure of rolling bearings is shown in Fig. 15.67:

- Radial bearings: outer ring, inner ring, rolling element, cage
- Thrust bearings: shaft washer, housing washer, rolling element, cage

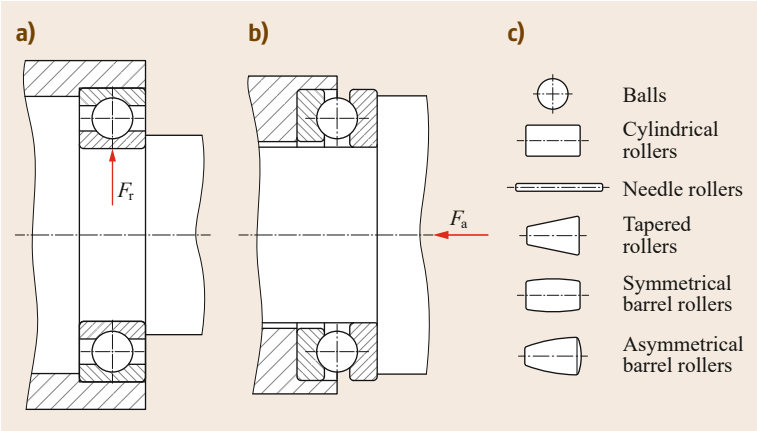

Fig. 15.66a–c Radial and thrust bearings (selection with installation examples). **(a)** Radial deep-groove ball bearings; **(b)** deep-groove thrust ball bearings, and **(c)** rolling element shapes

The inner and outer ring, or rather shaft and housing washer, of the roller bearings, via corresponding tolerances, are in direct contact with the surroundings of the bearing position.

During service, with the help of the lubricant, an elastohydrodynamic lubricant film (EHD contact) builds up between the rolling elements and the raceways of the bearing rings or washers. A ring-shaped cage secures the position of the rolling elements (Fig. 15.67).

Bearing Dimensions and Designation

The external dimensions for metric bearings (inside and outside diameter, width, height, chamfer dimensions) are internationally standardized in ISO 15 [15.63] (radial bearings), ISO 355 [15.64], DIN 720 [15.65] (tapered roller bearings), and ISO 104 [15.66] (thrust bearings). Rolling bearings with inch-size or imperial dimensions are available (for example, ANSI/ABMA 12.2 [15.67], ANSI/ABMA 19.2 [15.68]), but should no longer be used for new designs.

Bearing designation based on the DIN 623-1 [15.69] standard is widely used internationally. Here, the bearing designation is made up of a prefix, a basic designation, a suffix, and additional designations (characters or numbers).

Prefixes. Prefixes are used if applicable to identify certain individual rolling bearing parts or special bearing materials, for example:

K: Cage with rolling elements
L: Free ring of a separable bearing
R: Bearing ring with roller and cage or needle roller and cage assembly
S: Stainless steel

Basic Designation. The basic designation contains the bearing type in a coded form, the dimension series (width series for bearing width B and diameter series for the outer diameter D), and the bore diameter (bore ID number for the bore diameter d) (Fig. 15.68).

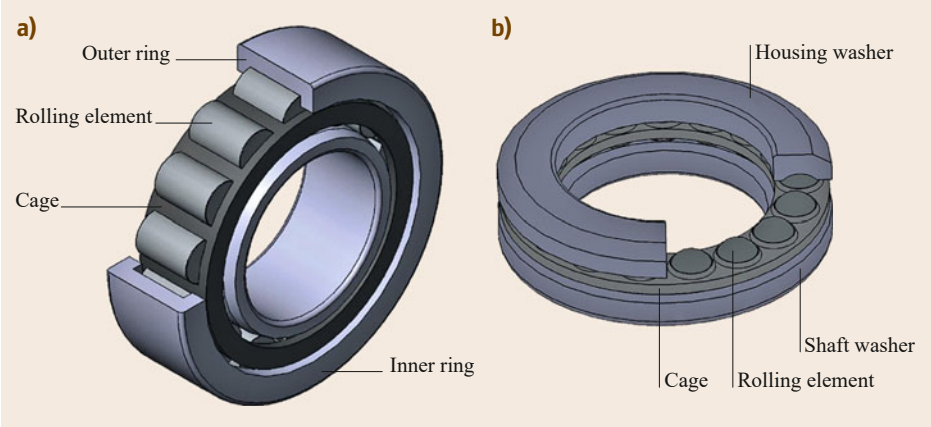

Fig. 15.67a,b Basic structure of a rolling bearing according to ISO 5593. **(a)** Radial bearing and **(b)** thrust bearing

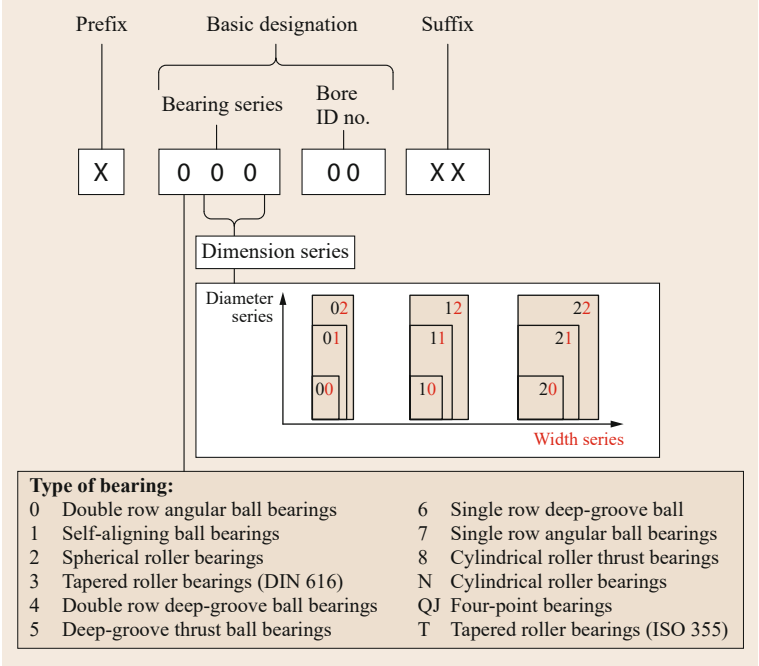

Fig. 15.68 Bearing designation according to DIN 623-1 (after [15.69])

Suffixes. Deviations from the standard version are to be given by suffixes.

As there are a large number of different suffixes, reference is made here to the bearing catalogs of the bearing manufacturers.

Additional Designation. Can contain additional information from the manufacturer.

15.5.2 Types, Properties, and Use

Table 15.54 gives an overview of the most commonly used types of rolling bearings.

Depending on the axial loadability and the installation situation, the following application cases result for radial bearings:

- As guide or fixed bearings (axial forces possible in both directions)
- As support bearings (axial forces possible in one direction)
- As a loose bearing (no absorption of axial forces)

Rolling bearings in which the external force is always divided into an axial and radial component, regardless of the load angle, are called angular contact bearings.

Standard Types

Many different types of rolling bearings are available. Table 15.55 gives a brief overview of the most commonly used types of rolling bearings.

Bearing Selection. For frequently occurring service cases and certain requirements, the bearing can be selected using Fig. 15.69. As deep-groove ball bearings are suitable for radial and for axial loads, have high running accuracy, have a small installation space, and are also readily available, their usability should be checked first.

15.5.3 Load Capacity and Life of the Rolling Bearings

Static Load Capacity According to ISO 76

In relation to rolling bearings, static loading is assumed if the bearing is loaded when it is at a standstill, at very low speeds ($n < 10\,\mathrm{min}^{-1}$), or during slow oscillatory movements. The forces acting on the bearing can be changeable over time (dynamic).

The static load capability is limited by the occurrence of plastic deformations in the contact point between the rolling elements and their raceway.

A rolling bearing is deemed to be statically operable if, at the contact point subject to the highest loading, the

Table 15.54 Overview of types of rolling bearings

Rolling bearings			Ball bearings	Roller bearings	
	Rotational movements	Mainly radial loading	Deep-groove ball bearings	Cylindrical roller bearings with cage	
			Aligning deep-groove ball bearings	Cylindrical roller bearings, full complement	
			Self-aligning ball bearings	Spherical roller bearings	
			Magneto ball bearings	Barrel roller bearings	
			Angular roller bearings	Needle roller bearings	
			Angular ball bearings, single row	Needle roller and cage assemblies	
			Angular ball bearings, double-row	Drawn cups with one closed end	
		Combined radial and axial loading	Magneto ball bearings (in pairs)	Tapered roller bearings (in pairs)	
			Angular ball bearings, single row	Cylindrical roller bearings (with ribs)	
			Angular ball bearings, double-row	Crossed roller bearings	
			Four-point bearings	Roller slewing ring bearings	
			Ball slewing ring bearings		
		Mainly axial loading	Deep-groove thrust ball bearings	Cylindrical roller thrust bearings	
			Angular roller thrust bearings	Spherical-roller thrust bearings	
				Needle roller thrust bearings	
	Linear movements		Flat ball cages	Flat roller cages	Linear guide systems
			Recirculating ball shoe bearings	Flat cage guides	
			Linear ball bearings	Recirculating roller shoe bearings	
			Recirculating ball guides	Recirculating roller units	
			Track rollers	Track rollers	

size of the total permanent deformation of the rolling element and raceway does not exceed 0.01% of the rolling element diameter.

The safety of a rolling bearing compared to the static loading is calculated from the ratio of the static load rating C_0 to the equivalent static load P_0 and is given in the form of the static safety factor S_0 as follows:

$$\text{For radial bearings:} \quad S_0 = \frac{C_{0r}}{P_{0r}}$$

$$\text{For thrust bearings:} \quad S_0 = \frac{C_{0a}}{P_{0a}} \qquad (15.109)$$

Guide values for the static safety factor are given in Table 15.56.

The static load rating C_0 of a rolling bearing equals the load at which a calculated stress of 4000–4600 MPa (depending on the bearing type) occurs at the contact points between the rolling elements and the raceways.

Values for C_0 are given in the corresponding catalogs of the relevant manufacturers or must be calculated with the help of the equations given in ISO 76 [15.70].

As the static load rating corresponds to pure radial loading for radial bearings and pure axial loading for thrust bearings, simultaneously occurring radial and axial forces F_r and F_a with radial and axial factors X_0 and Y_0 are to be summarized as an equivalent static load P_0.

Table 15.55 Overview of the most commonly used standard rolling bearings

Bearing type	Loadability		Features
	Radial	Axial	
Deep-groove ball bearings 	High	Medium	– Balls run between the inner and outer ring – Diverse uses – Very common and particularly economical – Suitable for high speeds – Design is not separable, i.e., is not easily separable – Only small shaft displacement tolerable – Bearings also available sealed
Single-row angular roller bearings 	High	One-sided depending on the contact angle	– Bearing rings each with a low and a high shoulder – Intended for pair-wise installation in face-to-face, back-to-back, or tandem arrangement – Design is not separable – Only small shaft displacement tolerable – Sealed bearings available
Self-aligning ball bearings 	High	Low	– Double row type with spherical raceway in outer ring – Design is not separable – For levelling out shaft displacement and shaft deflection (up to 4°) – Sealed bearings available
Cylindrical roller bearings 	Very high	Not loadable	– In the standard version, two fixed ribs on one ring (inside or outside ring) and no rib on the other ring – Maximum speed lower compared to ball bearings – Enable very stiff and precise shaft bearing – Standard version is separable
Spherical roller bearings 	Very high	Low	– Double-row type with spherical raceway in the outer ring – Rolling element barrel-shaped – Enable levelling out of shaft displacement and shaft deflection up to 4°
Tapered roller bearings 	High	High on one side	– Tapered raceways, whose extended generatrices intersect at a point – Removable outer ring makes assembly easier – Internal clearance settable by axial displacement of the bearing rings – Installation often in pairs with face-to-face, back-to-back, or tandem arrangement (Sect. 15.5.4, *Bearing Arrangements*)
Needle roller bearings 	Very high	Not loadable	– Special type of the cylindrical roller bearing – Combines the smallest installation dimensions with large radial stiffness – Insensitive to shocks – Separable – Version with or without inside and outside ring

Table 15.55 (Continued)

Bearing type	Loadability		Features
	Radial	Axial	
Deep-groove thrust ball bearings 	Not loadable	High on one side	– Thrust bearing acting on one side – Ball and cage assembly runs between two housing washers – Bearing is separable
Spherical-roller thrust bearings 	Low	High on one side	– Thrust bearing acting on one side – Rolling elements are asymmetrical barrel rollers – For levelling out shaft displacement up to 3°

Rolling bearing types and their usability	Requirement

Fig. 15.69 Selection of rolling bearings

Table 15.56 Guide values for the required static safety factor according to ISO 76 [15.70] (excerpt)

Type of service	S_0 min. for ball bearings	S_0 min. for roller bearings
Application cases with low-noise running: Smooth, quiet running, vibration free, high rotational accuracy	2	3
Application cases with normal running: Smooth, quiet running, vibration free, normal rotational accuracy	1	1.5
Application cases with shock, intermittent loading: Distinct shock loading	1.5	3

For spherical roller thrust bearings, a minimum value of 4 is recommended for S_0 in all operating modes, and a minimum value of 3 for case-hardened cups with one closed end or both ends open

Table 15.57 Values for the factors X_0 and Y_0 according to ISO 76 (excerpt)

Type of bearing		Single row bearings[a]		Double row bearings	
		X_0	Y_0	X_0	Y_0
Radial ball bearings		0.6	0.5	0.6	0.5
Angular ball bearings, $\alpha =$	5°	0.5	0.52	1	1.04
	15°	0.5	0.46	1	0.92
	25°	0.5	0.38	1	0.76
	35°	0.5	0.29	1	0.58
	45°	0.5	0.22	1	0.44
Self-aligning ball bearings, $\alpha \neq 0°$		0.5	$0.22 \cot \alpha$	1	$0.44 \cot \alpha$
Radial roller bearings, $\alpha \neq 0°$		0.5	$0.22 \cot \alpha$	1	$0.44 \cot \alpha$

[a] The allowable maximum value of F_a/C_{0r} depends on the bearing design
α is the nominal contact angle in degrees

The equation for the static equivalent radial load is

$$P_{0r} = X_0 F_r + Y_0 F_a$$
$$\text{if } F_a = 0 \quad \text{then } P_{0r} = F_r \,. \tag{15.110}$$

Values for X_0 and Y_0 are given in Table 15.57 and the relevant information of the bearing manufacturers.

The static equivalent axial load can be calculated using

$$\text{If } \alpha \neq 90° \quad \text{then: } P_{0a} = 2.3 F_r \tan \alpha + F_a \,;$$
$$\text{if } \alpha = 90° \quad \text{then: } P_{0a} = F_a \,. \tag{15.111}$$

Equation (15.111) applies to double-direction bearings for all ratios of radial to axial loads.

It applies to single-direction bearings under the following condition: $F_r/F_a \leq 0.44 \cot \alpha$.

For spherical-roller thrust bearings simultaneously subjected to radial and axial loads:

$$P_0 = F_a + 2.5 \ldots 2.9 F_r \,. \tag{15.112}$$

Dynamic Load Capability

During their service, rolling bearings are subject to wear, which limits their life. According to ISO 281, the life of a rolling bearing is defined as the number of revolutions completed by a bearing ring (or a bearing washer) in relation to the other bearing ring (other bearing washer), before the first indication of material fatigue becomes visible on one of the two rings (or washers) or on rolling elements [15.71].

Statements on the life of rolling bearings are of a statistical character, which means that the given/calculated values are subject to a certain scatter.

When calculating the life, a differentiation is made between the basic and the modified rating life.

Basic Rating Life. According to ISO 281, the basic rating life L_{10} is the rating life associated with 90% reliability for bearings manufactured with commonly used high-quality material, of good manufacturing quality, and operating under conventional operating conditions [15.71]. From a statistical point of view, 10% of the bearings used can thus fail before reaching the basic rating life.

Table 15.58 Values for radial factors X and axial factors Y for selected types of bearings according to ISO 281 [15.71] (excerpt)

Type of bearing		X	Y
Radial deep-groove ball bearings	$\frac{F_A}{F_R} \le e^a$	1	0
	$\frac{F_A}{F_R} > e^a$	0.56	See Fig. 15.70
Single direction radial deep-groove ball bearings, separable (magneto ball bearings)	$\frac{F_A}{F_R} \le 0.2$	1	0
	$\frac{F_A}{F_R} > 0.2$	0.5	2.5

[a] For values of e see Fig. 15.70.

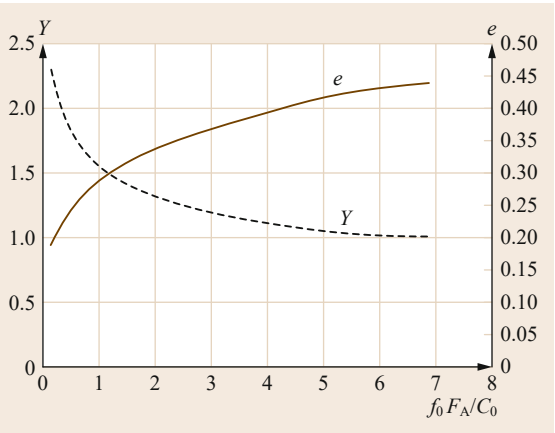

Fig. 15.70 Axial factor Y and limit value for applicability e. Indicative values for f_0 (after *Niemann* et al. [15.24]): deep-groove and angular ball bearings $f_0 \approx 14$, roller bearings $f_0 \approx 35$, and self-aligning and magneto ball bearings $f_0 \approx 2.5$; for precise values, see ISO 76 (after [15.70])

The basic rating of a bearing can be determined with the help of

For radial bearings

$$L_{10} = \left(\frac{C_r}{P_r}\right)^p 10^6 \; revolutions \; ;$$

for thrust bearings

$$L_{10} = \left(\frac{C_a}{P_{r,a}}\right)^p 10^6 \; revolutions \; , \qquad (15.113)$$

where:

$C_{r,a}$ dynamic load rating of the radial/thrust bearing
$P_{r,a}$ equivalent bearing load of the radial/thrust bearing (15.114)
p life exponent for ball bearings: $p = 3$; for roller bearings $p = 10/3$

The dynamic load rating C is the bearing load at which the bearing can statistically complete 10^6 revolutions with a failure probability of 10%. It is given in the respective information of the rolling bearing manufacturers.

The life calculation using (15.113) applies to pure radial and axial loads. If radial and axial loads occur simultaneously, they must be converted into a dynamic equivalent load $P_{r;a}$, which has the same effect on the bearing as the pure radial or axial load such that,

$$P_{r;a} = XF_r + YF_a \; , \qquad (15.114)$$

where:

F_r actual radial load
F_a actual axial load
X radial factor
Y axial factor

The radial and axial factors for several selected bearing types are shown in Table 15.58.

For spherical roller thrust ball bearings simultaneously subjected to radial and axial load, under the condition $F_r \le 0.55F_a$,

$$P_{r;a} = F_a + 1.2F_r \; . \qquad (15.115)$$

The life of a bearing is usually given in operating hours. With the given speed n in 1/min, (15.113) thus becomes

for radial bearings:

$$L_{10h} = \left(\frac{C_r}{P_r}\right)^p \frac{10^6}{60n} \quad \text{in h} \; ,$$

and for thrust bearings:

$$L_{10h} = \left(\frac{C_a}{P_a}\right)^p \frac{10^6}{60n} \quad \text{in h} \; . \qquad (15.116)$$

A selection of guide values for the required basic rating lives in operating hours is given in Table 15.59.

Table 15.59 Guide values for the required basic rating lives L_{10h} of ball bearings and roller bearings (selection) (according to *Schaeffler* [15.72])

Machine type	L_{10h} in operating hours	
	Ball bearings	Roller bearings
Car drives	500–1100	500–1200
Heavy trucks	4000–8800	5000–12 000
Gear boxes/transmissions of rail vehicles	14 000–46 000	20 000–75 000
Agricultural machines	500–4000	500–5000
Electric motors for household appliances	1700–4000	–
Electric motors for industrial applications	21 000–32 000	35 000–50 000
Lathe and milling-cutter spindles of machine tools	14 000–46 000	20 000–75 000

Modified Life. The basic rating life calculated with the help of the equations above applies to normal material qualities under standard operating conditions.

The actual life of the rolling bearings, however, is highly influenced by other criteria:

- Lubrication of the bearing (type and viscosity of the lubricant, contained additives)
- Material properties (purity, hardness, fatigue limit, surface quality, temperature resistance)
- Internal stresses (due to production or assembly)
- Ambient conditions (dirt, moisture)

With the help of the modified rating life, compared to the basic rating life, more precise values can be determined for the durability of the bearings under the specific use conditions.

Detailed calculation steps are given in the ISO 281 standard [15.71] or the calculation regulations of the individual manufacturers.

Minimum Bearing Load

A minimum force (axial or radial, depending on the bearing type) is required to ensure correct rolling of the rolling elements on the contact surfaces.

As a rough guide value, the bearing load for ball bearings and for roller bearings should not fall below 1 and 2%, respectively, of the dynamic load capability.

When in doubt, follow the regulations of the individual bearing manufacturers.

15.5.4 Design

In addition to suitable bearing selection, the design of the bearings must also consider the bearing arrangement, the installation tolerances, and the lubricant supply with the corresponding seals.

Bearing Arrangements

Bearings must basically be arranged so that the components can be guided both axially and radially. Depending on the amount and direction of the actual loads, running accuracy requirements, and assembly and dismantling options, a suitable arrangement must be chosen for the rolling bearings. A differentiation is made between fixed-loose bearings, spring-loaded or preloaded bearings, and floating bearings (support bearings). The features and examples for the individual bearings are shown in Table 15.60.

Installation Guidelines

The design of the bearing seat on the shaft or in the housing essentially depends on the task (fixed or loose bearings) and the type of load (point or circumferential load).

The bearings must be fixed onto the shaft or in the housing in both the radial and in the axial direction (except loose bearings). The radial fixing is achieved via appropriately designed fits. Oversize fit is necessary if a circumferential load acts on the bearing ring (inner or outer ring). If the load direction relative to the bearing ring does not change (point load), a transition fit or slight clearance fit is allowed.

In the axial direction, the fixing is mostly achieved by one-sided ridge and steps/shoulders, whereby moving in the opposite direction is prevented by retaining rings, threaded fasteners, or the housing cover (Figs. 15.71 and 15.72).

15.5.5 Lubrication of the Rolling Bearings

The life of rolling bearings depends to a decisive degree on their lubrication. During the rolling operation, a thin film of lubricant should form between the parts moving relative to each other in the bearing (rolling element, raceways, and cage); this film separates the contact surfaces from each other and thus reduces wear significantly. In addition, the lubricant should protect the bearing against corrosion, remove any friction heat that occurs, dampen vibrations, remove abraded material (circulating oil lubrication), or bind abraded material (permanent lubrication). To a limited extent, bearings with a grease fill also have a sealing effect.

Table 15.60 Features and examples of different bearings

Fixed-loose bearings	Spring-loaded bearing	Floating bearings
• Combination of fixed bearing and loose bearing • Fixed bearing absorbs radial and axial forces • Loose bearings can only absorb radial forces and have axial clearance; for levelling out production tolerances and thermal expansion • Standard bearing combination for multi-support shafts	• Tapered roller bearings or angular ball bearings are clamped with a mirror image • Depending on the pressure line curve, a differentiation is made between a face-to-face and back-to-back arrangement • Heating of a face-to-face arrangement leads to an increase in the bearing preload, it is reduced in a back-to-back arrangement • Face-to-face arrangement for load application between bearings • Back-to-back arrangement for load application outside of the bearing	• Combination of two bearings with axial clearance for levelling out production tolerances and thermal expansion • Shaft can move axially within the range of the axial clearance • Only possible with nonseparable bearings • Simple and cost-effective variant if axial forces only act in one direction and axial clearance is allowed
	Face-to-face arrangement  Back-to-back arrangement 	

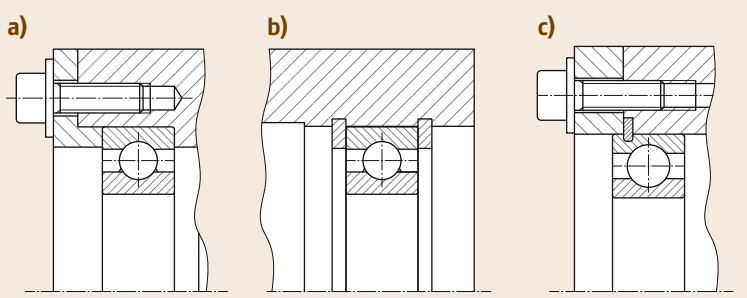

Fig. 15.71a–c Axial fixing of rolling bearings in the housing: **(a)** through cover and rib, **(b)** through retaining rings, and **(c)** through bearing with groove and snap ring

Selection of the Lubrication Method

Choice of the correct lubrication method and the corresponding lubricant should take place at the beginning of the bearing design. The choice of suitable lubrication method depends, among other things, on:

- The size and type of bearing
- The operating conditions
- The running quietness/smooth running requirements
- The connection design

Depending on the lubricant used, a differentiation is basically made between grease, oil, and solid lubrication, although solid lubrication is only seldom used.

The advantages and disadvantages of grease and oil lubrication are listed in Table 15.61.

In practice, approximately 90% of all rolling bearings are lubricated with grease. As the lubricants age due to thermal and mechanical loading and also become contaminated due to abraded material and dirt input, their life is limited. If replacement of the lubricant (relubrication) is not possible, as for example with two-sided sealed bearings, the service life of the lubricant can, under certain circumstances, constitute the limiting factor in the bearing life consideration.

Table 15.61 Advantages and disadvantages of grease and oil lubrication

	Grease lubrication	Oil lubrication
Advantages	• Low design cost (time and effort) • Additional sealing effect • Low maintenance cost (lifetime lubrication under certain circumstances) • Low friction moment	• Good lubricant distribution • Heat removal possible (important especially for high speeds) • Wear particles and dirt are flushed out • Precise metering possible (drip, oil-mist lubrication)
Disadvantages	• No heat removal by lubricant • No transporting away of wear particles and dirt or contamination	• More expensive/complicated design (supply and sealing) • Very low friction losses with minimum lubrication

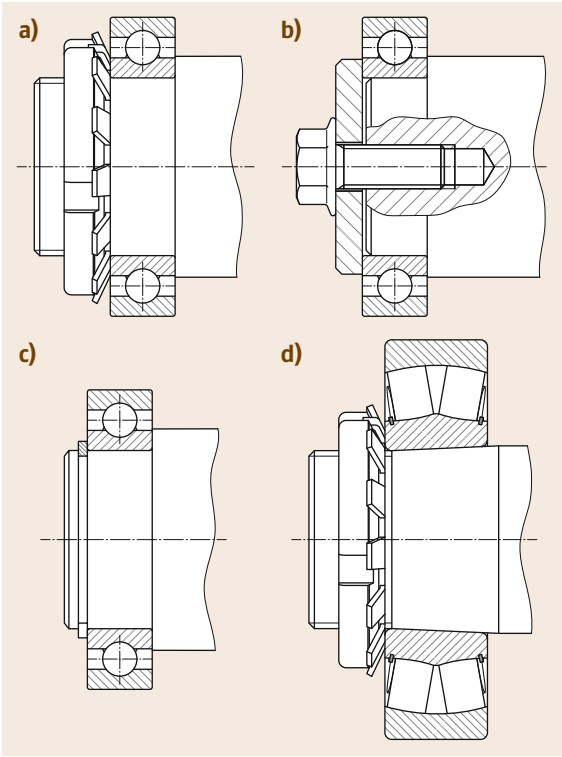

Fig. 15.72a–d Axial fixing of rolling bearings on the shaft: **(a)** with slotted nut, **(b)** with end washer, **(c)** with retaining ring, and **(d)** taper seat with slotted nut

15.5.6 Sealing of Rolling Bearings

The sealing of rolling bearings should essentially fulfill two functions:

1. Sealing the bearing against gaseous, liquid, and/or solid substances/contamination
2. Prevent the escape of lubricant

To achieve this, the bearings themselves can have a seal (for example RS bearings or Z bearings) or the surroundings of the bearing must be sealed accordingly. More detailed information on the possible sealing systems is given in Sect. 15.7.

15.5.7 Rolling Bearing Damage

If installed correctly and operated as intended, rolling bearings are very reliable and are generally largely maintenance free.

Statistically, only 0.335% of all rolling bearings fail prematurely as a result of production or material errors [15.73].

Premature failure of a bearing significantly before the rated life L_{10h}, is generally viewed as being bearing damage.

The most frequent causes of bearing damage are shown graphically in Fig. 15.73.

The bearing damage that occurs can be divided into six different categories according to ISO 15243 [15.76] (Fig. 15.74).

Bearing Damage Due to Fatigue

Fatigue is the term used to describe the flaking or spalling of surface layers as a result of cyclical loading of the contact surfaces.

Depending on the origin of the damage, a differentiation is also made between subsurface-initiated fatigue (fatigue beginning under the surface) and surface-initiated fatigue (fatigue beginning on the surface).

Subsurface-initiated fatigue in the form of microcracks under the surface is caused by continuous rolling over the contact surfaces with high loads. These microcracks propagate up to the surface where they cause flaking/spalling, pitting, and peeling.

Surface-initiated fatigue is caused, among other things, by surface fatigue wear as a result of microcracks on roughness peaks, microchips/spalling on roughness peaks, and zones with microchips.

Indentations due to dirt particles or incorrect handling/assembly can also result in fatigue phenomena on the surface.

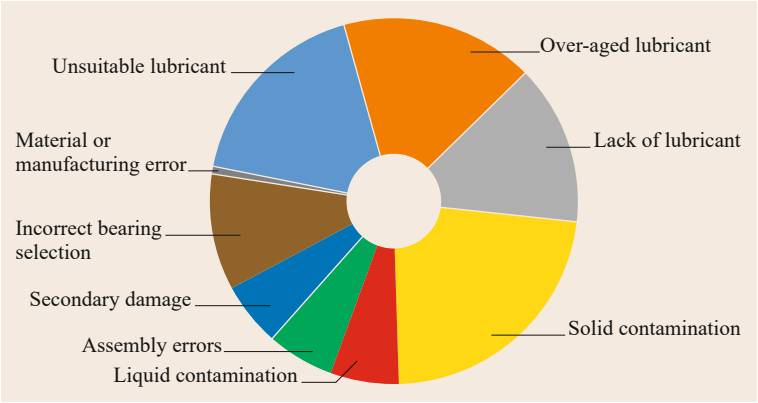

Fig. 15.73 Causes of bearing damage (after [15.74, 75])

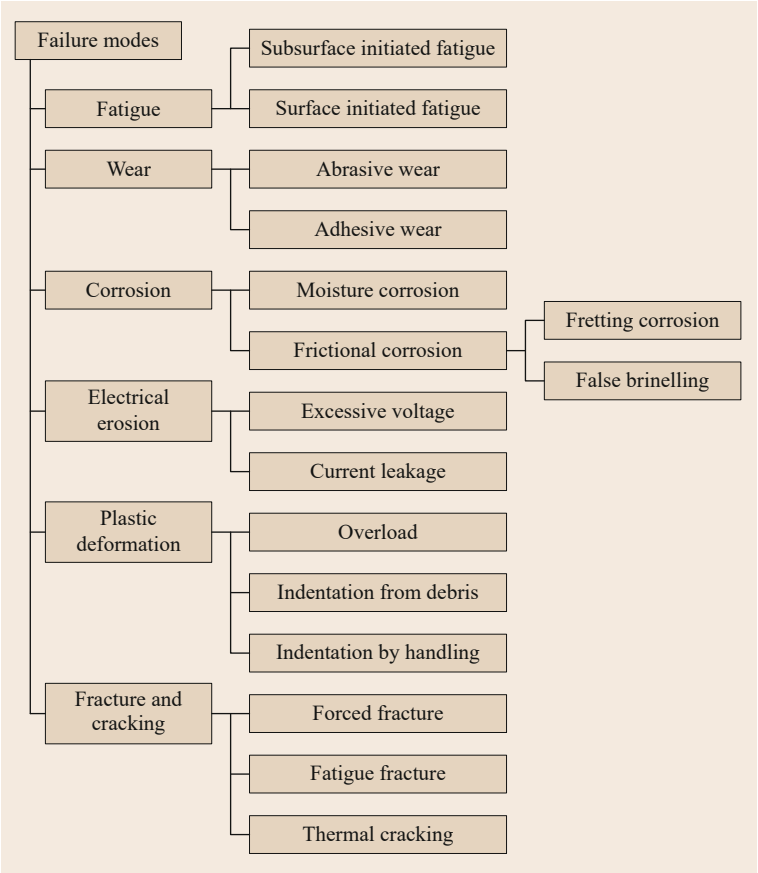

Fig. 15.74 Types of damage to rolling bearings according to ISO 15243 (after [15.76])

Bearing Damage Due to Wear

The removal of material at the contact surface between the rolling elements and the contact surfaces is called wear. While rolling bearings are always subject to normal wear, increased wear leads to premature failure of the bearing.

Abrasive wear is caused by the abrasive effect of very small particles between the contact surfaces. These particles form marks (indentations) in the contact surfaces or the rolling elements when rolled over and this in turn causes damage to the surfaces and elements. The abrasion produced accelerates the wear so that a chain reaction occurs, which reduces the life of the bearing severely.

Unwanted sliding movements between the rolling elements and the contact surfaces can, among other

things, initiate material transfer from one contact partner to the other which causes adhesive wear. This is mostly caused by inadequate lubrication or excessive speeds.

Bearing Damage Due to Corrosion

Moisture corrosion is initiated by the effect of water or aggressive liquids on the bearing and can irreparably damage the bearing within a very short time.

Microsliding movements between the two loaded surfaces can cause the formation of fretting corrosion. The bearing seats in the housing or on the shaft are mainly affected by this type of corrosion. Due to the increase in volume caused by the formation of iron oxide in the joint gab, considerable stresses are produced in the bearing rings, which can ultimately lead to fracture.

Microsliding movements between the rolling elements and the contact surfaces can also initiate a type of friction corrosion (fretting). This is called *false brinelling*. This mainly applies to bearings at a standstill, which are primarily exposed to vibrations.

Bearing Damage Due to Electrical Erosion

If the flow of electrical current through the bearing is too large due to excessive voltage, microscopic light arcs can be triggered in the contact area between the rolling elements. These light arcs generate very high temperatures locally, which extend up to the melting range of the bearing material. The high temperatures also lead to thermal decomposition of the bearing lubricant, which causes it to lose its lubricity.

Compared to excessive voltage, leakage currents generate lower temperatures in the contact area, which primarily lead to a loss of hardness in the contact zone. Electrical installations with frequency converters are particularly susceptible to this type of electrical erosion.

Bearing Damage Due to Plastic Deformation

Caused if the bearing material is loaded above its yield strength.

Overloading of the allowable surface pressures cause indentations of the rolling elements on the contact surfaces, which reduce the life as well as the smooth and quiet operation severely.

Foreign bodies (debris) in the bearings can leave behind plastic deformation (indentations) on the contact partner rolling over it.

Indentations due to improper handling are caused by incorrect assembly (pressure on the wrong bearing ring) or handling errors (dropping the bearings).

Fracture and Cracking

Fractures or cracks occur in the bearing components (the bearing rings of the bearing cage) if the tensile strength of the respective bearing material is exceeded.

Large shocks, impacts with a hardened chisel, or excessive pressure on the bearing seat can cause forced fracture during assembly or startup of the bearing.

Exceeding the fatigue strength under cyclical loading causes a fatigue fracture. Small cracks are formed, which increasingly propagate. If the tensile strength is exceeded in the remaining cross section, a forced fracture also occurs.

High dynamic (sliding) friction between the contact partners can result in thermal cracking caused by the friction heat.

Table 15.62 shows the relationship between the bearing damage that occurs and its cause in the form of a matrix.

It is advisable to comply with the following points to avoid bearing damage:

- Ensure precise analysis of the bearing loads that occur (forces, speeds, temperatures).
- Use and design the bearing according to the manufacturer's information.
- Pay attention to tolerancing of the connection dimensions (fit tolerances, shaft offset/deflection).
- Prevent the flow of electrical current through the bearing.
- Ensure adequate protection of the bearing from moisture/dirt.
- Select a lubricant suitable for the operating situation.
- Lubricate the bearing adequately.
- Use suitable tools/jigs for the assembly and installation.
- Ensure cleanliness during assembly.

15.5.8 Further Reading

In addition to the standard machine element references, principles for the selection and design of rolling bearings are also provided, for example, in [15.77].

Details on bearing calculations are given in the ISO 76 [15.70] and ISO 281 [15.71] standards.

Information on the bearing construction, its dimensions, load capabilities, and examples of the connection geometry design are provided in the manufacturers' catalogs, for example, [15.78, 79].

Typical rolling bearing damage and its causes are described in [15.73, 80].

15.6 Plain Bearings

Plain bearings are used to store the components. In this type of bearing, the parts moving relative to each other slide off each other, whereby the sliding surfaces can touch or can be separated by an intermediate medium (mostly oil or grease). The advantages and disadvantages of plain bearings are listed in Table 15.63.

Depending on the bearing type and lubrication condition, dry friction, surface layer friction, mixed friction, and liquid friction occur [15.73].

Dry friction (Fig. 15.75a) is technologically of hardly any significance, as under atmospheric conditions, surface reaction layers form on all technical surfaces, or rather gas or liquid modules adhere, which generally reduce the frictional resistance.

Surface layer friction occurs on unlubricated technical surfaces under atmospheric conditions (Fig. 15.75b). The sliding process here is favored by the constant shearing off and reformation of the surface layers with low shear strength.

Dry lubrication exists if the friction process is helped by applying solid lubricants such as graphite, molybdenum(IV)-sulfide, very fine ceramic particles, or plastics (PTFE, PA, POM). Solid lubricants act in two different ways. The contact surfaces are separated by the solid particles and can slide/roll off of them. At the same time, they fill uneven irregularities, which improves the load-bearing behavior of the surfaces.

In the case of fluid or pasty lubricants, the type of friction depends on the friction speed (relative speed between mating parts) (Fig. 15.76).

At low friction speeds, the touching of the contact surfaces causes solid friction, also called boundary friction. The lubricant is displaced from the contact point by the very high local surface pressures. With increasing relative speed, the lubricant begins to separate the contact partners, so that mixed friction exists, whereby the coefficient of friction reduces with increasing speed. With complete separation of the contact surfaces the mixed friction becomes liquid friction.

The relationships between the prevailing form of friction and the friction speed in lubricated plain bearings are shown graphically in the so-called Stribeck curve (Fig. 15.76).

According to ISO 4378-1 [15.81], among other things, plain bearings can be subdivided according to the type of load (static or dynamic), the load direction (radial or thrust bearings), and the type of lubrication (for example, hydrostatic, hydrodynamic, and maintenance-free plain bearings).

Table 15.63 General advantages and disadvantages of plain bearings

Advantages	Disadvantages
Low noise	Increased wear in start-stop operation
Insensitive to impacts/shocks	Increased friction moment on starting up
Low unit volume	Increased thermal load compared to rolling bearings
High load-bearing capacity	Rolling bearings, as a standardized component in mass production, are mostly less expensive
Very large speed range	Sensitive to canting
Very easy assembly and installation due to separate half-bearings	Risk of seizure
Long life	
Separable bearings easy to implement	

15.6.1 Hydrostatic Plain Bearings

In the case of hydrostatic plain bearings, liquid or gaseous lubricant is pressed into the bearing gap under high pressure with the help of an external pressure

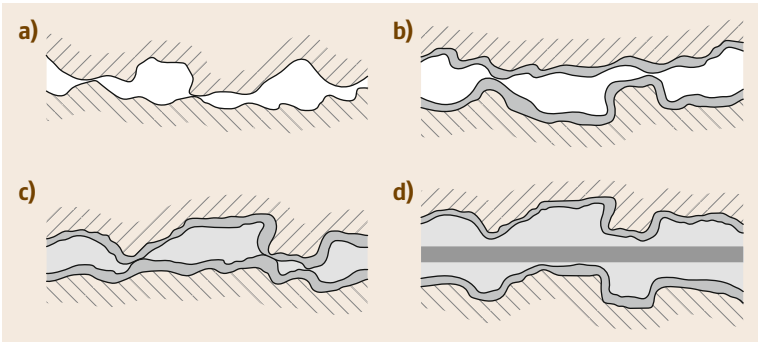

Fig. 15.75a–d Friction states between the contact surfaces: (a) dry friction, (b) surface layer friction, (c) mixed friction, and (d) liquid (viscous) friction

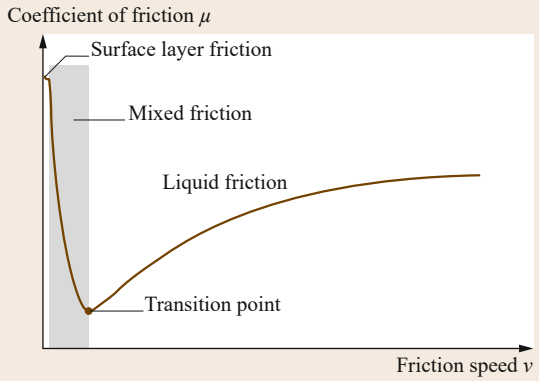

Fig. 15.76 Stribeck curve (schematic)

Table 15.64 Advantages and disadvantages of hydrostatic plain bearings

Advantages	Disadvantages
No minimum speed required	External pressure supply is required
No stick-slip effect on starting up (high accuracy)	Large space requirement
Movement is seemingly wear-free	
Very good damping properties	

source; this causes the contact surfaces to be separated, so that liquid friction exists even if the contact surfaces are at a standstill. As a result, these bearings operate as if wear-free. The advantages and disadvantages of this type of bearing are listed in Table 15.64.

15.6.2 Hydrodynamic Plain Bearings

Unlike hydrostatic plain bearings, in hydrodynamic plain bearings the contact surfaces are separated by the dynamic build-up of pressure in the bearing itself. This requires the contact surfaces to move relative to each other with an appropriately high speed (Fig. 15.76), a viscous lubricant, and a constricting lubrication gap. The lubricant is pressed into the constricting gap by adhesive forces, which causes a pressure to form that separates the contact surfaces.

The constricting lubrication gap in radial bearings is formed by the eccentricity e of the shaft in the bearing and in thrust bearings, for example, by key beds (wedge-shaped surfaces) (Fig. 15.77).

The eccentricity e and the attitude angle β in plain radial bearings depend on the bearing force, the bearing geometry, the viscosity, and the speed ratios such that the integral of the pressure distribution over the bearing surface is in equilibrium with the external bearing force.

Table 15.65 Advantages and disadvantages of hydrodynamic plain bearings compared to hydrostatic plain bearings

Advantages	Disadvantages
Compact design	Increased friction and wear on starting
Simple structure	Requires a minimum speed for complete separation of the contact surfaces
Easier lubricant supply	Radial displacement of the shaft
	Susceptible to vibration at high speeds

Table 15.65 lists the advantages and disadvantages of hydrodynamic plain bearings.

15.6.3 Hydrostatic Starting Aids

If frequent starting under high starting load, idling with low speeds, or very long run-down times occur in hydrodynamic plain bearings, using hydrostatic starting aids (boosters) can be advisable.

To do this, one or two oil pockets in the bottom half-bearing are introduced in the contact area with the shaft, which are supplied with a pressurized lubricant by an external pump with a pump pressure of max. 200 bar on lifting and of approximately 100 bar for holding the shaft.

15.6.4 Maintenance-Free Plain Bearings

Plain bearings without a separate lubricant supply are called maintenance-free plain bearings. With these bearings, increased wear at the start of use is accepted, whereby the softer bearing material and/or integrated solid lubricants (for example, PTFE, molybdenum(IV) sulfide, or graphite) are rubbed off and fill up the roughness valleys on the mating surface. In the ideal case, the roughness valleys are completely clogged with the abraded material (acts as solid lubricant), which results in favorable load-bearing behavior. Compared to hydrodynamic plain bearings, maintenance-free plain bearings have a significantly higher load-bearing capacity at lower friction speeds.

15.6.5 Bearing Materials

The material of the plain bearing must be matched with the material of the shaft/axle. In general, a softer material is chosen for the bearing than for the shaft, so that wear occurs in the bearing first (because it is easier and less expensive to replace).

In addition to adequate strength, the bearing material should have good corrosion resistance and be

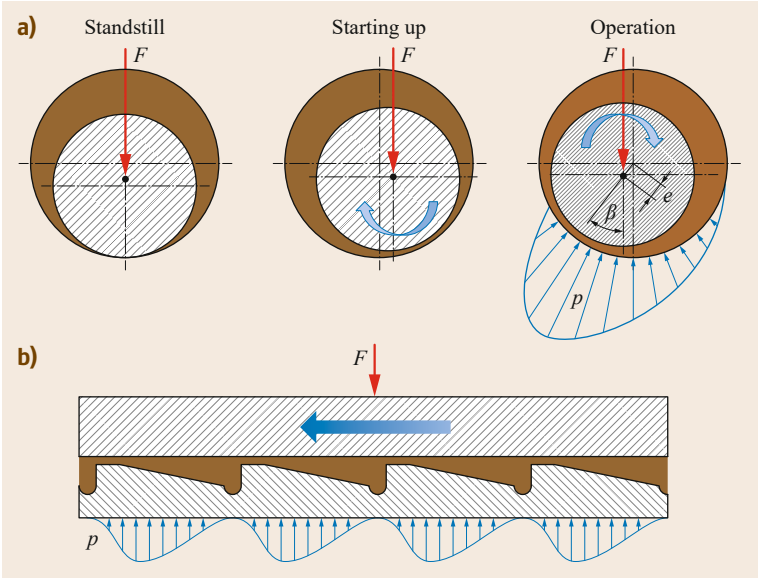

Fig. 15.77a,b Schematic diagram of the function of a hydrodynamic radial bearing **(a)** and a thrust bearing **(b)**

insensitive to the lubricants used, or rather the additives they contain.

Due to the good wetting ability of the sliding surfaces, the lubricant can also penetrate narrow gaps and separate the contact surfaces from each other.

This is significant, especially in the mixed friction area on starting up and running out the bearing, if there is only little lubricant in the contact zone.

Bearings with good emergency running properties (resistance to galling) handle short-term failure of the lubrication without major damage. The emergency running properties are primarily determined by the bearing materials. Metals with a low hardness, low melting temperature, and that do not tend to bond with the contact partner due to adhesive forces are particularly suitable.

Plain bearing materials with good running-in characteristics, adapt to the geometry of the shaft/axle through local wear and deformation, without noticeably impairing the function of the bearing.

The introduction of hard foreign bodies (dirt and/or wear particles) into the sliding surface of the bearing is called embedment. This should largely cancel the harmful effect of the foreign bodies. However, even in bearings with good embedment properties, attention must be paid to the cleanliness of the lubricant used.

High wear resistance ensures a long bearing life. In practice, plain bearings are only subjected to noteworthy wear if they are operated within the area of boundary or mixed friction. In the case of hydrodynamic plain bearings, this is the case above all during starting up and runout.
